and Ag22, which is at the center of the cluster, has a trigonal-bipyramidal coordination sphere (Ag–S: 2.692–2.937(5) Å).

The space-filling model of **1** in Figure 2a shows that the Ag-S-core, which has a maximum diameter of 1.7–2.0 nm, is completely shielded by the *t*Bu groups of the S*t*Bu ligands in the oblate-spheroidal cluster. Further cluster growth is thus not possible. The maximum diameter of the molecule including the *t*Bu groups is 2.0–2.5 nm.

Surprisingly, the use of another silver salt ($AgPhCO_2$ or Ag*S*t*Bu instead of $AgCH_3CO_2$) leads to the formation of the metal-rich cluster **2**. Crystal-structure analysis[5] shows that **2** crystallizes in the space group *C*2/*c* with four molecules per unit cell. The cluster molecules form a quasi cubic close packing in the lattice, with the 12 disordered toluene molecules per formula unit situated in the holes.

In Figure 2b a space-filling diagram of **2** is shown. As in **1**, the cluster surface is covered exclusively by *t*Bu groups. The maximum total diameter of the molecule is 3.7 nm. The molecular shape is similar to am ellipsoid, which has a minor diameter of 2.6 nm (see Figure 4b). The dimensions of the Ag–S core are 3.2 and 2.2 nm. A precise description of the formula of **2** is, however, not possible from the structural analysis alone. The molecules are clearly not well ordered in the lattice. This is apparent since when using $Mo_{K\alpha}$ radiation there are almost no reflections above $2\theta = 36°$ with significant intensity.

Disorder in the cluster renders a full discussion of the molecular structure impossible. We have measured 20 data sets from different crystals at different temperatures. None of these led to an improved interpretation of the structure. It is of note, however, that the outermost cluster layer of 96 Ag*S*t*Bu groups is ordered. The nearer the Ag and S atoms lie to the center of the cluster, the higher the degree of disorder. This situation is revealed in the higher temperature factors of the inner Ag and S layers. In this sense **2** is comparable with the structure of $[Ag_{262}S_{100}(StBu)_{62}]$, although the degree of disorder is clearly higher in **2**. In both cases an there is an ordered layer surrounding a solid solution of Ag_2S. Assuming that nonbonding Ag–Ag distances are greater than 2.80 Å, and bonding Ag–S interactions are in the range 2.40–2.90 Å, the formula $[Ag_{344}S_{124}(StBu)_{96}]$ can be obtained. The elemental analysis of **2** is in excellent agreement with this formula.[6] The experimental density of the crystal is also consistent with the density calculated from the X-ray crystal structure. The MALDI-TOF mass spectrum of **2**[7] shows broad mass distribution with maxima at *m*/*z* 49446, 93104, 135586, 176572, and 216487 (Figure 3). At higher resolution, molecular ions with *m*/*z* 258028 and 298149 can be assigned. The molecular weight of **2** (49.645 kDa) is, allowing for the errors in the determination of the peak maxima, in good agreement with the signal at *m*/*z* 49446. Note, however, that the fragmentation of the molecule is such that it leads to a very broad size distribution. Between the individual maxima a difference of approximately 41.5 kDa is found. This mass could be assigned to $[Ag_{344}S_{124}]^+$ (41.046 kDa), the molecule fragment of **2** from which all the S*t*Bu groups have been lost. The higher masses are likely to result from aggregates with unknown composition, which are formed from these molecular ions under the conditions of the MALDI-TOF experiment.[7]

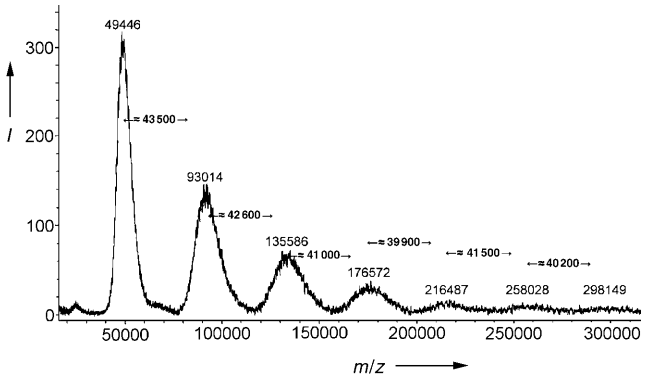

Figure 3. MALDI-TOF spectrum of **2**.

MALDI-TOF mass spectrometry has only recently been shown to be a significant technique for the characterization of ZnS nanoparticles. It is clear that it offers the possibility to characterize related materials.[8]

Additional evidence for the proposed formula of **2** is obtained through transmission electron microscopy (TEM) investigations of the reaction solutions from the synthesis of **2**. Such TEM images,[9] shows particles with a monodisperse size distribution and a diameter of approximately 3 nm (Figure 4).

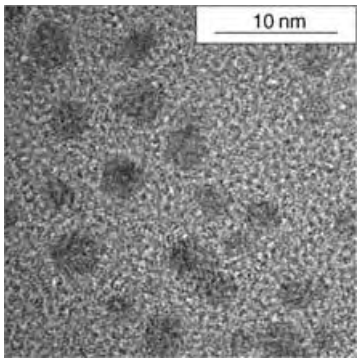

Figure 4. Electron microscope image of cluster **2**.

This diameter corresponds to the size of the Ag-S-core in **2**. Further elucidation of the structure of the cluster is however not possible, since upon irradiation of the cluster for a long time the Ag–S cluster is converted into silver. This change is to be expected since Ag_2S decomposes at temperatures above 200 °C. Further discussion of the structure of **2** is therefore not realistic. Figure 5 illustrates the molecular structure from two directions, with the disorder omitted for clarity. The sulfur atoms of the S*t*Bu groups act as μ_2- and μ_3-bridging ligands. The Ag–S distances are similar to those found in **1**.

It is possible that the observed disorder is an intrinsic problem of nanoscopic Ag–S clusters. The surface tension of these particles gives rise to a Laplace pressure which in turn leads to a pressure within the particles, which is dependent upon particle radius.[13] This pressure can result in disorder or a phase change. The transition of crystalline *a*-Ag_2S into the tetragonal high-pressure phase has been reported.[12] Another explanation is that interactions between defects in the cluster

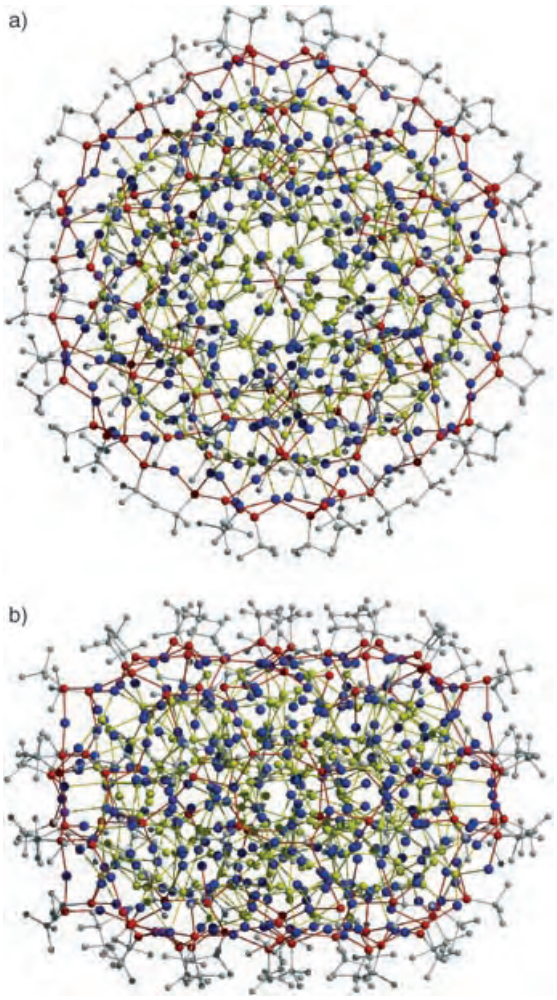

Figure 5. a) and b) Molecular structure of **2** viewed from two directions. For clarity, the disorder is omitted. Image (b) is rotated by 90° relative to image (a). Color code as for Figure 2.

can lead to a rise in the concentration of defects. This defect concentration is temperature dependent.[10] To test this idea we have collected X-ray data sets over the temperature range 100–200 K. Measurement at higher temperatures is not possible because the crystals lose solvent of crystallization and become amorphous. Over this temperature range, however, no increase in the disorder could be determined.

In conclusion, **1** and **2** can be described as core–shell particles. In **1** the core is $\{(Ag_2S)_{35}Ag_3\}^-$, and in **2** $\{(AgS)_{124}\}$, the core in **1** is surrounded by a shell of 50 S*t*Bu units and in **2** by 96 S*t*Bu units. We believe that clusters that are metal-richer and have larger particle diameters can be synthesized. These may, as a consequence of the lower Laplace pressure, have an ordered $\{(Ag_2S)_n\}$ core.

It is emphasized that the syntheses of **1** and **2** are reproducible under the described conditions. Small changes, such as the choice of solvent or the ratio of the amounts of starting materials, however lead to the formation of cubic or needle-like crystals, the structures of which we have not yet determined. The unit cell volumes of these crystals are however significantly larger than those of **1** and **2**. It is likely that current analytical techniques will reach the limits of their

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

ability to characterize these compounds, and precise formulations and crystal-structure determinations may at present not be possible.

Experimental Section

All processes were carried out with the exclusion of water and oxygen in an atmosphere of purified N_2.

1: $AgCH_3CO_2$ (0.167 g, 1 mmol) and dppxy (0.119 g, 0.25 mmol) were suspended in toluene (20 mL), and S(*t*Bu)SSiMe$_3$ (0.16 mL, 0.9 mmol) was added at room temperature. The solution became yellow, then orange. After the mixture had been stirred for 5 min, $S(SiMe_3)_2$ (0.08 mL, 0.5 mmol) was added at room temperature. After a few hours the solution became deep red, and undissolved starting material was slowly consumed. The solution was stirred for a further 2 h and then allowed to rest. After four to six weeks dark brown rhombic crystals of **1** formed with a yield of 40 %.

2: $AgPhCO_2$ (0.23 g, 1 mmol) and dppxy (0.119 g, 0.25 mmol) were suspended in toluene (25 mL), and S(*t*Bu)SiMe$_3$ (0.18 mL, 1 mmol) was added at room temperature. The mixture became orange-red and contained residual starting material. After the mixture had been stirred for 5 min, $S(SiMe_3)_2$ (0.08 mL, 0.5 mmol) was added and after a further 30 min the mixture was heated to reflux. The solution became clear and deep red. After the solution was allowed to cool to room temperature, red crystals formed and then dissolved, and after 3–5 weeks black crystals of **2** were formed in 60 % yield.

In the alternative synthesis of **2** a suspension of AgS*t*Bu (0.1 g, 0.5 mmol) with dppxy (0.06 g, 0.125 mmol) in toluene (25 mL) was mixed with $S(SiMe_3)_2$ (0.04 mL, 0.25 mmol). The solution, cloudy from undissolved starting material, initially turned red. Brief heating to reflux yielded a clear deep red solution, which then rapidly became dark brown. After the solution was allowed to cool to room temperature, black crystals of **2** formed in 30–50 % yield over several weeks.

Cooperative Binding of p53 to DNA: Regulation by Protein–Protein Interactions through a Double Salt Bridge**

*Alexander Dehner, Christian Klein, Silke Hansen, Lin Müller, Johannes Buchner, Manfred Schwaiger, and Horst Kessler**

The p53 protein is a transcription factor that regulates many cellular processes and acts as major tumor suppressor.[1–5] It is mutated to a loss of function in 50% of all human tumors, and the majority of these mutations occur in the DNA-binding domain (DBD).[6,7] So far, two main functional classes of p53 mutations have been identified: 1) mutations that affect direct contact with DNA and 2) mutations that destabilize the structural integrity of p53 (R249S, G245S, R175H, C242S, V143A).[8,9] They cause the Li–Fraumeni syndrome (LFS), which is based in germ-line mutations in the p53 gene. LFS is a familial, dominantly inherited cancer characterized by a wide range of neoplasms occurring in children and young adults.[10] Some Li–Fraumeni syndrome mutations such as E180X, localized in the proposed dimerization interface of the H1 helix region, do not fall into either of the above classes, and the reasons behind the observed cancer illness phenotypes were previously unknown.[11] Herein, we present a mutational study of solvent-exposed residues within the H1 helix region of p53. The results provide evidence for the presence of two intermolecular salt bridges, which are essential for cooperative DNA binding. Moreover, the absence of cooperativity observed[12] in the p53 family members[13] p63DBD and p73DBD can now be understood on a structural basis.

The complete p53 molecule contains 393 amino acids. It recognizes and binds a consensus sequence of promoter DNA in tetrameric, octameric, and higher oligomeric forms. There is currently no structural information about full-length p53 and its tetrameric organization bound to DNA, yet several reports discuss modeling of the interdomain contacts in p53[8,14–18] based on individual structures of p53DBD[14,17] and the tetramerization domain.[19–21] We have shown previously[22,23] that the DBD binds cooperatively to small (2×16 nucleotide) DNA sequences as dimers. Titrations of this oligonucleotide into ^{15}N-labeled p53DBD (monitored by NMR spectroscopy) allowed us to identify the protein–protein contact interface, and to postulate an essential role for the short H1 helix (P177–C182) in mediating intermolecular p53DBD dimerization. Furthermore, symmetry considerations led us to propose a model in which two antiparallel DNA strands bind p53 in its tetrameric state, whereby the tetramerization domain in the C-terminal fragment of p53 is in the center of this model complex.[22] However, no direct experimental proof has been presented for the participation of the H1 helix in protein–protein interactions upon p53 binding to DNA.

Herein, we report investigations of the possible role of H1 helix residues through site-directed mutagenesis and analysis of the ability of p53DBD mutants to bind to p53 consensus DNA by using electrophoretic mobility shift assays (EMSAs), NMR spectroscopic diffusion measurements, and fluorescence anisotropy measurements. The following dimerization mutations were introduced by site-directed mutagenesis: H178A, R181A, C182A, E180R, R181E, and one double-site mutation: E180R/R181E. Additionally, three alanine mutations H178A, R181A, and C182A and the R181E mutation were introduced into a GST fusion plasmid (GST = glutathione S transferase) yielding GST–mutant p53DBD fusion proteins. As the GST domain acts as an artificial dimerization domain, such constructs are expected to enhance the cooperative DNA binding affinity, as previously observed for p63DBD.[12]

Besides the structurally important residues that coordinate the zinc atom such as H179,[14] even the solvent-exposed residues of the H1 helix are highly conserved and mostly identical across various species, as illustrated by the sequence alignment of this region (Figure 1). An overlay of the ^{15}N HSQC spectra of all six mutants and the wild-type p53DBD is shown in Figure 2. Major differences in chemical shifts are only observed for signals of residues within the H1 helix or near the specifically mutated residues. Residues further away are only slightly affected by these mutations or not affected at all, which affords the conclusion that all dimerization mutants are folded in the native conformation. Addition of 0.5 equivalent of a decamer consensus DNA oligonucleotide (CON2x5; 5′-CCTAGACATGCCTAAT-3′, elongated by three nucleotides on each side) to the U-^{15}N-labeled p53DBD dimerization mutants resulted in changes in chemical shift and a strong line-broadening in the ^{15}N,^{1}H correlation spectrum of the protein. This is the result of a slow exchange process in the micro- to millisecond range, as has been observed for the wild-type p53DBD–DNA complex.[22,23] Addition of DNase II to the DNA–p53DBD dimerization mutant complexes restored the original spectrum of the respective p53DBD mutant, excluding protein degradation.

The translational diffusion coefficient of a molecule is proportional to its effective molecular weight and shape[24]

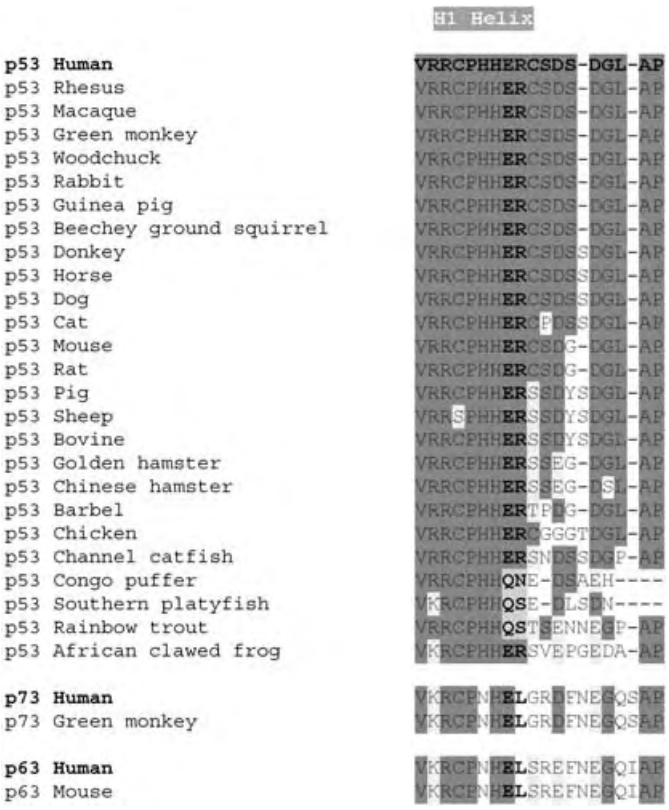

Figure 1. Primary structure alignment of the H1 helix regions of p53DBD and the homologous p63- and p73DBDs. Residues identical or similar to human p53 are shown in gray.

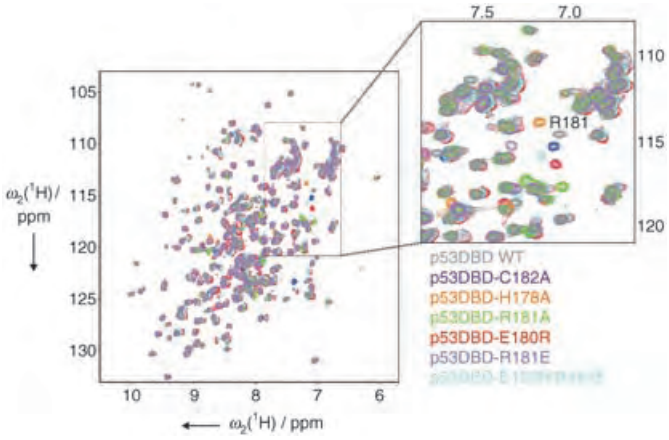

Figure 2. Superposition of the ^{15}N HSQC spectra of wild-type p53DBD (gray) and the six mutated p53DBD forms. The enlarged section shows residue R181 within the H1 helix.

and is therefore a sensitive gauge of changes in the overall molecule. Thus, measuring the diffusion rate is an independent way to study intermolecular interactions.[25–28] We analyzed the hydrodynamic properties of p53DBD dimerization mutants and their DNA binding by pulsed field gradient diffusion experiments.[29] The addition of the consensus oligonucleotide to wild-type p53DBD causes the diffusion coefficient of p53DBD to decrease by 27.1% (Figure 3). This

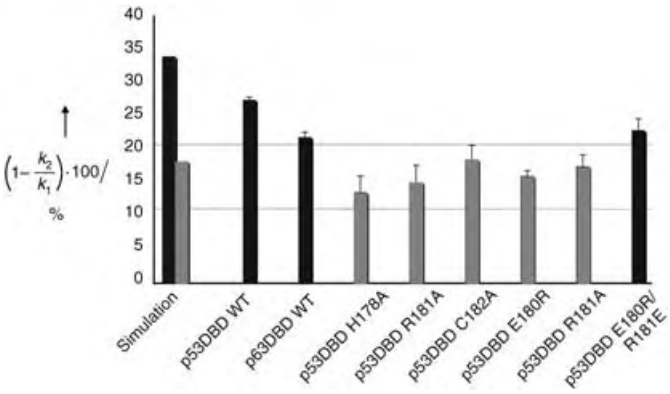

Figure 3. Decrease in the diffusion coefficients of p53DBD, p63DBD and the p53DBD dimerization mutants upon complex formation (k_2) with consensus DNA (CON2x5) as measured by pulsed field gradient NMR spectroscopy; black: cooperative DNA binding, gray: nonspecific DNA binding. A hydrodynamic simulation with a cooperative model complex with p53DBD/DNA = 2:1 yields a theoretical decrease of 33%, whereas a single-site binding of DNA (PDB code 1TSR, chain B, including DNA) results in a decrease of 18%.

is due to the cooperative binding of two p53DBDs to one decamer half-site consensus oligonucleotide. The measured value is in good agreement with hydrodynamic calculations performed with the shell model of HYDRONMR[30] and a dimeric p53DBD–DNA model complex as described by Klein et al.[22] This results in a theoretical decrease in the diffusion coefficient of about 33%. The monomeric p53DBD–DNA complex (PDB code 1TSR; chain B including the DNA) was also used for hydrodynamic calculations, and gave a decrease of 18% upon binding DNA relative to the coefficient of free p53DBD. These two theoretical values represent the expected range for an equilibrium between monomeric and fully cooperative DNA-bound forms. Deviations from theoretical and experimental data reflect an averaging of higher and lower oligomeric states.

Figure 3 illustrates the decrease in diffusion coefficient upon addition of 0.6 equivalent CON2x5 half-site oligonucleotide to obtain a stoichiometric DNA/p53DBD ratio of 1:2 for the wild-type DBD forms of p53 and p63 and the p53DBD dimerization mutants. As already indicated by ^{15}N HSQC titration experiments, all mutants bind to DNA, resulting in a decrease in diffusion rate of at least 13%. NMR spectroscopic experiments were performed in the absence of nonspecific competitor DNA; therefore, it cannot be concluded whether this overall decrease results from nonspecific or specific cooperative DNA binding. However, with experimental errors taken into consideration, two classes of p53 can be distinguished: p53DBD wild-type and the p53DBD E180R/R181E double-site mutant have a significantly higher population of oligomeric states upon DNA binding than all other p53DBD dimerization mutants (Figure 3). Therefore, p53DBD wild-type and the E180R/R181E double-site mutant share a similar tendency to bind DNA cooperatively, whereas this tendency is less pronounced in the single-site mutants p53DBD-H178A, p53DBD-R181A, p53DBD-C 182A, p53DBD-E180R, and p53DBD-R181E.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

EMSAs were performed to clarify whether the dimerization mutants bind DNA specifically or nonspecifically. After incubation with fluorescently labeled double-stranded consensus oligonucleotide (CON4x5; 5′-CCTAGACATGCCTAGACATGCCTAAT-3′) in the presence of nonspecific and unlabeled competitor DNA, p53DBD wild-type dimerizes and binds specifically to labeled consensus DNA (Figure 4a, lane 1). As a negative control, we analyzed the p53DBD mutant R248W. Arg248 interacts directly with bound DNA; mutations of this residue result in p53 forms that belong to the class of mutants with impaired DNA binding;[9] indeed, this is reflected in lane 2 of Figure 4a. p63DBD was unable to bind labeled consensus DNA significantly (Figure 4a, lane 3), whereas an artificial dimerization of p63DBD through the GST–p63DBD fusion protein restores a DNA binding affinity similar to that of p53DBD (Figure 4c, lane 2).[12] Lanes 4–6 of Figure 4a show that p53 alanine mutations of solvent-exposed residues H178A, R181A, and C182A have decreased specific DNA-binding affinity relative to that of wild-type p53DBD.

The single-site mutants p53DBD-E180R and p53DBD-R181E, in which two consecutive Arg and two consecutive Glu residues are respectively present, do not bind DNA (Figure 4a, lanes 7 and 8). However, an exchange of the wild-type position of these two residues reflected in the double-site mutant p53DBD-E180R/R181E restores DNA binding affinity to nearly that of wild-type p53DBD (Figure 4a, lane 9). As a cross-check to determine whether two identically charged sequential residues in mutants p53DBD-E180R and p53DBD-R181E have an impact on the structural integrity of the H1 helix (which would preclude DNA binding), we co-incubated both mutants with consensus DNA and competitor DNA, which restored DNA-binding affinity through heterodimerization of each mutant (Figure 4b). Thus these EMSAs corroborate the pulsed field gradient diffusion measurements in which both the p53DBD wild-type and the p53DBD-E 180R/R181E mutant bind specifically and cooperatively to fluorescently labeled consensus DNA in the presence of competitor DNA. In contrast, the single-site mutants p53DBD-E180R and p53DBD-R181E, which both display two identically charged sequential residues within the designated dimerization interface, do not show any specific binding of consensus DNA (Figure 4a, lanes 7 and 8).

Additional EMSAs were performed under the same conditions, but with a selection of mutant p53DBD–GST fusion proteins: the three alanine mutants p53DBD-H178A,

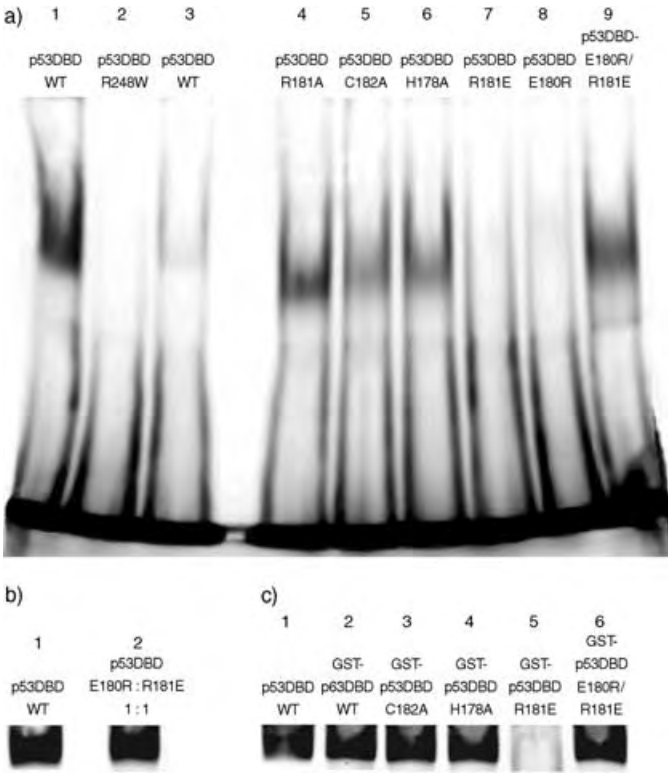

Figure 4. a) EMSAs of wild-type p53DBD, p53DBD-R248W, wild-type p63DBD, and p53DBD dimerization mutants in the presence of nonspecific unlabeled pBluescriptII SK$^+$ competitor DNA. b) A 1:1 mixture of p53DBD-R181E and p53DBD-E180R. c) EMSAs for wild-type p53DBD and the GST fusion proteins.

p53DBD-R181A, p53DBD-C182A, as well as p53DBD-R 181E, which contains two consecutive, negatively charged (Glu) residues at positions 180 and 181. The GST portion of these mutants serves as an artificial dimerization domain in an analogous manner to the tetramerization domain of full-length wild-type p53; it enhances cooperativity and therefore specific DNA binding. As a positive control, lanes 1 and 2 in Figure 4c contain p53DBD and p63DBD–GST, respectively, which bind consensus DNA with similar affinity, whereas free p63DBD without the GST domain lacks this cooperativity (Figure 4a, lane 2).[12] Analogous to p63DBD, the three alanine mutations of p53DBD exhibit enhanced cooperativity in DNA binding with the dimeric GST fusion domain and show an affinity similar to that of wild-type p53DBD. Therefore, the alanine mutations p53DBD-H178A, p53DBD-R181A, and p53DBD-C182A do not actively prevent possible dimerization upon binding of DNA, as demonstrated by 1) residual DNA binding and 2) such DNA binding can be enhanced by GST-mediated dimerization. The p53DBD-R181E–GST mutant, however, does not exhibit specific DNA binding; the induced cooperative effect of GST-mediated dimerization is not strong enough to overcome the repulsive charge–charge interactions which would occur at the dimerization interface. From this we can conclude that there is no other dimerization interface within p53DBD that could substitute for the E180–R181 intermolecular salt bridges.

The GST-mediated enhancement of cooperative DNA binding was already observed for p63DBD.[12] It was deduced that conformational differences within the H1 helix might be responsible for the different dimerization behavior. However, from our results it is clear that the aliphatic leucine group present at the homologous p53DBD codon position 180 (Figure 1) is not able to form an intermolecular salt bridge, which explains the previously observed absence of selective and cooperative DNA binding with free p63DBD (Figure 6a).[12]

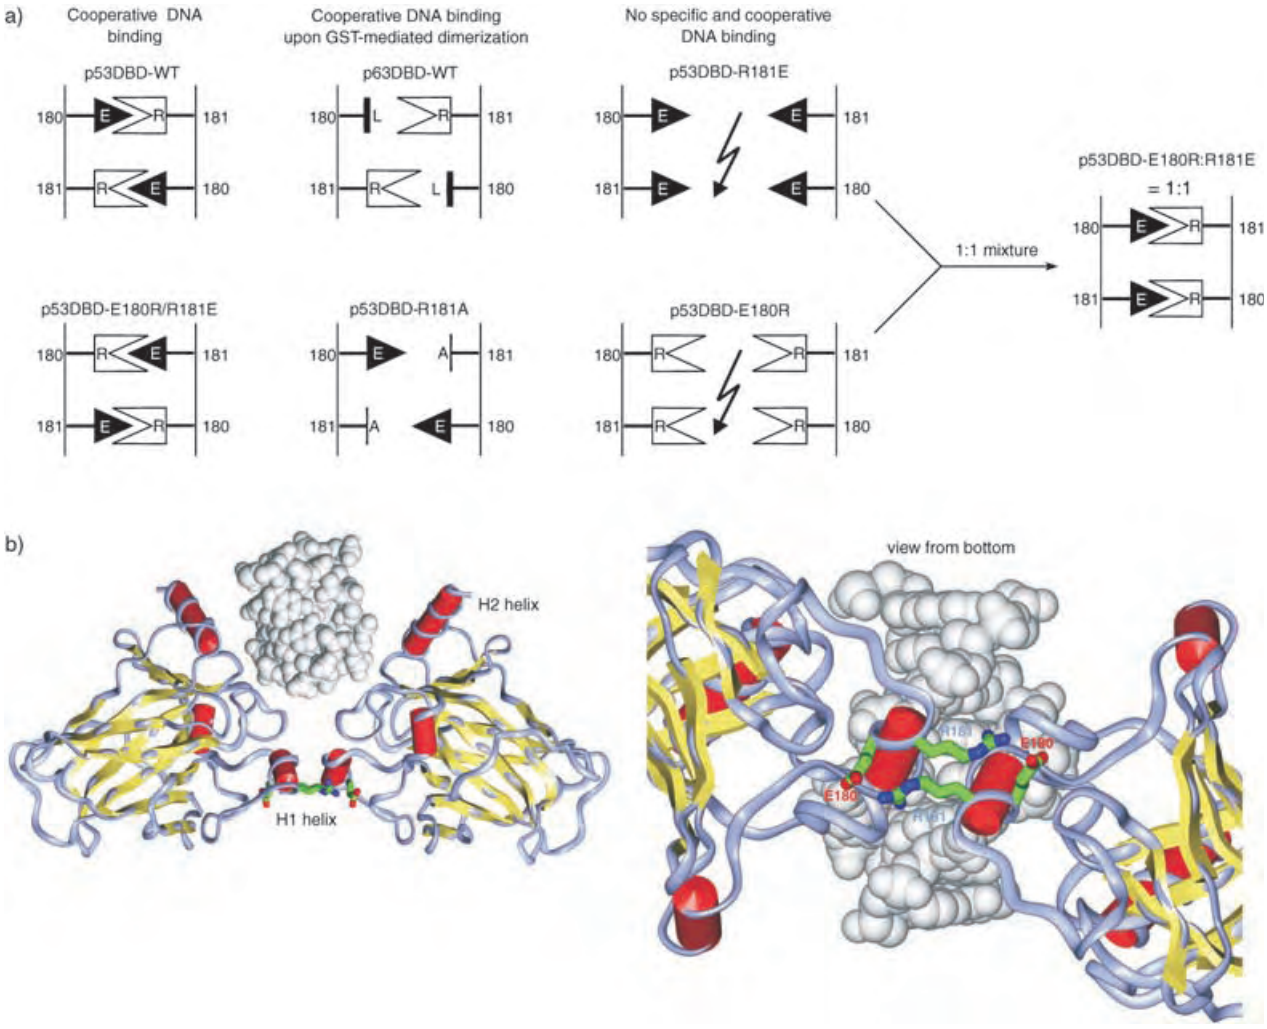

Figure 6. a) Schematic representation of dimerization patterns. Cooperative DNA binding is observed with wild-type p53DBD, the double-site mutant p53DBD-E180R/R181E, and a 1:1 mixture of p53DBD-E180R and p53DBD-R181E. Cooperative DNA binding by wild-type p63DBD and the alanine dimerization mutants of p53DBD can be enhanced by GST-mediated dimerization. Repulsive charge–charge interactions prevent cooperative DNA binding for the p53DBD-E180R and p53DBD-R181E mutants. b) C_2-symmetric model complex for the identified dimerization interface of p53DBD upon cooperative DNA binding. The dimerization interface is stabilized by a double intermolecular salt bridge between residues E180 and R181 of each monomer.

These results were further corroborated by fluorescence anisotropy measurements.[31] Figure 5a shows the specific affinity of wild-type p53DBD and the dimerization mutants toward consensus DNA. Increasing concentrations of wild-type p53DBD and mutant forms were added to fluorescently labeled CON4x5 oligonucleotide (25 nM) in potassium phosphate (50 mM), KCl (50 mM), and dithiothreitol (DTT, 5 mM). For a low concentration of p53DBD or the mutants, a single cooperative binding to CON4x5 can be assumed (Figure 5a). The details of curve fitting are described in the Supporting Information. Wild-type p53DBD gives a dissociation constant of 82 ± 8 nM, whereas the binding affinities of the p53DBD mutants are about threefold less (p53DBD-E180R: 245 ± 38 nM; p53DBD-R181E: 238 ± 43 nM). The value for the alanine mutant p53DBD-R181A ($K_d = 182 \pm 34$ nM) lies halfway between those of the wild-type and the p53DBD-E180R and p53DBD-R181E mutants, which may explain the slightly higher binding affinity observed in the EMSAs (Figure 4a, lane 4). The double mutant p53DBD-E180R/R181E ($K_d = 124 \pm 15$ nM) has a dissociation constant similar to that of wild-type p53DBD (Figure 5b).

Taken together, our results prove that the proposed additional p53DBD dimerization interface, which stabilizes cooperative and selective DNA binding events, consists mainly of two intermolecular Glu180–Arg181 salt bridges from each monomer to the other (Figure 6a). These salt bridges are in agreement with a C_2-symmetric model complex (Figure 6b) as proposed by Lebrun, Klein, and co-workers.[15,22] The formation of salt bridges also rationalizes the difference in DNA-binding behavior between p53DBD and p63DBD. Moreover, the results provide new insight into the oncogenic mutations E180X and R181X in Li–Fraumeni syndrome, as they decrease the cooperativity in DNA binding.

Membrane-Mimetic Nanocarriers Formed by a Dipalmitoylated Cell-Penetrating Peptide**

Sandro Keller, Ines Sauer, Holger Strauss, Klaus Gast, Margitta Dathe, and Michael Bienert*

Molecular and supramolecular drug-delivery systems have attracted great attention as pharmaceutical formulations for the administration of otherwise only poorly soluble, rapidly degradable, or even toxic molecules.[1] Within the multitude of colloidal vehicles developed to date, micelles belong to the most useful tools for the delivery of hydrophobic compounds.[2] However, some serious disadvantages of micellar carriers remain, among which the problem that some normally membrane-located biomolecular devices like vector peptides lose their native conformation and are severely compromised in their activity when removed from the lipid bilayer.[3,4] Here we introduce a dipalmitoylated cell-penetrating peptide that is superior to previously described biofunctional colloids in its ability to incorporate large amounts of lipid in mixed micelles. Hence this peptide constitutes a potent lead for the intracellular delivery of hydrophobic drugs using bilayer-mimetic nanocarriers.

Ideally, such vehicles would meet a number of criteria. First, a customizable peptide sequence designed to trigger a specific response upon interaction with biological targets has to be exposed on the micellar surface.[5] Second, the nanocarriers should contain an excess of lipid and thus offer a bilayer-like environment in order to preserve the functionality of the surface-bound peptide. Third, as such a compound will unavoidably be a strong detergent, its aggregational state must be easily controllable, and the kinetics of membrane solubilization should be slow.

In our search for a peptidic vector promoting internalization into a broad range of different cells, we chose a 20-residue tandem dimer [A2, $(LRKLRKRLLR)_2$] comprising binding sites for the low-density lipoprotein receptor and for cell-surface heparan sulfate proteoglycans, two ubiquitous mammalian membrane constituents able to mediate uptake of their ligands.[6] A2 has recently been demonstrated to induce internalization of liposomes into primary rat brain capillary endothelial cells when covalently linked to the vesicle surface,[7] and the presence of lipids is known to be crucial for receptor binding by its parent apolipoprotein E.[3] As fatty acid modified peptides have turned out to be extraordinarily powerful detergents for suspending membrane proteins in mixed micelles providing a bilayer-mimetic environment,[8,9] we opted for dipalmitoylation (P2) of two neighboring amino acids in a 3-residue sequence linked to the N terminus of A2 as a means of hydrophobization. The lipopeptide P2A2 was prepared with high yields and in quantities of several hundred milligrams in a simple and effective procedure. A standard solid-phase protocol based on N^{α}-9-fluorenylmethoxycarbonyl(Fmoc)-protected amino acids was used to synthesize A2 extended N-terminally with the sequence Fmoc-WK(Dde)G containing an N^{ε}-1-(4,4-dimethyl-2,6-dioxocyclohex-1-ylidene)ethyl(Dde)-protected lysine residue. After hydrazine cleavage of the Dde and the amino-terminal Fmoc moieties, the two amino groups in the lysine side chain and at the N terminus were acylated simultaneously with palmitic acid.[10]

The resulting chimera P2A2 (Figure 1) with a molar mass of 3.53 kg mol^{-1} has an amphipathic structure in which the two acyl chains form a very hydrophobic tail attached to the charged peptide, but it is nevertheless well-soluble (> 5 mM)

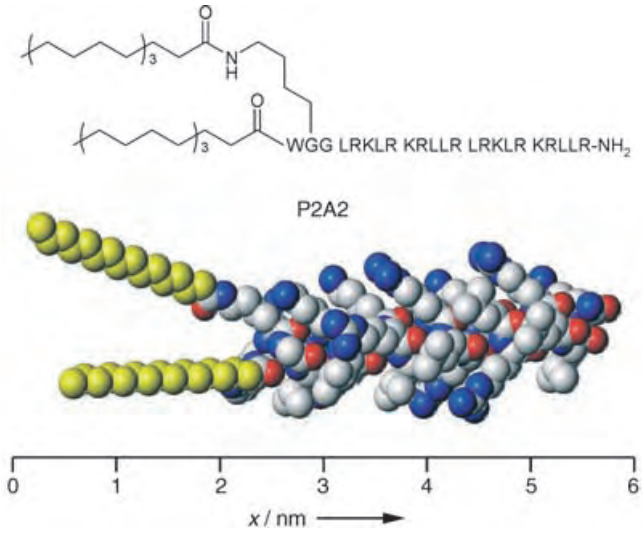

Figure 1. Structure of P2A2. The two palmitoyl chains are linked through amide groups to the N-terminal tryptophan and to the side chain of the neighboring lysine (one-letter amino acid code, formal valence $z = 12$ at pH 7.4). The hydrophobic methylene and methyl groups of the palmitoyl residues are highlighted in yellow in the space-filling model.[11]

in aqueous solution (10 mM 2-amino-2-(hydroxymethyl)propane-1,3-diol (Tris), 154 mM NaCl, 0.1 mM ethylenediaminetetraacetate (EDTA), pH 7.4).[12] Unlike double-chained phospholipids possessing relatively small headgroups, the bulky peptide of P2A2 does not appear to allow self-association into bilayers but rather implies detergent-like micellization.

Analytical ultracentrifugation revealed indeed that P2A2 assembles into well-defined aggregates with a molar mass of $M = 68\ \mathrm{kg\,mol^{-1}}$ corresponding to 19 monomers (Figure 2a).

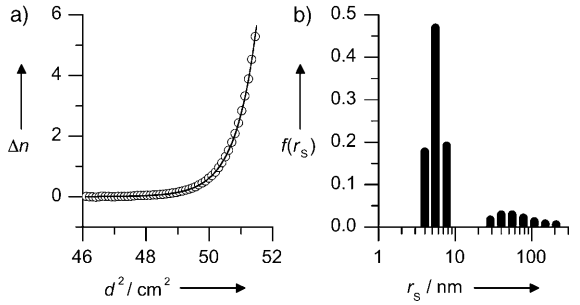

Figure 2. Mass and size characterization of P2A2 micelles. a) Analytical ultracentrifugation at $c_{P2A2} = 96\ \mu M$ and 20 krpm gave the local refractive index difference, Δn, (open circles) as a function of the squared distance from the rotor axis, d^2, at sedimentation equilibrium. The best single-species fit (solid line) was obtained for a molar mass of $M = (67.7 \pm 0.3)\ \mathrm{kg\,mol^{-1}}$. b) Dynamic light scattering at $c_{P2A2} = 244\ \mu M$ yielded the distribution function, $f(r_S)$, of the Stokes radius, r_S. The stronger peaks at small radii observed at four different concentrations were used to extrapolate $r_S^{expt} = (5.25 \pm 0.30)$ nm.[10]

Static light scattering (LS) confirmed this result;[10] however, dynamic LS yielded a Stokes radius of $r_S^{expt} = 5.3$ nm (Figure 2b), which is distinctly larger than the value of $r_S^{calcd} = 3.4$ nm calculated for a spherical particle of this mass.[10] This discrepancy and the small aggregation number most likely arise from a nonspherical micellar geometry as invoked for other lipopeptides[8] and are also reminiscent of bile salts.[13]

However, as a practical advantage over bile salts, the critical micellar concentration (CMC) of P2A2 is expected to be considerably lower owing to the pronounced hydrophobicity conferred by the two palmitoyl chains, which should thus preserve the colloidal state also upon extreme dilution. In fact, the subnanomolar CMC of the lipopeptide is below the ranges experimentally accessible by fluorescence spectroscopy (nanomolar) and calorimetry (micromolar),[12,14] suggesting that the concentration of monomeric P2A2 is always negligible.

The efficacy of P2A2 in forming lipid-rich micelles was monitored on the basis of the light scattering intensity, I, of its mixtures with the zwitterionic phospholipid 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC). To this end, dry lipid films were suspended in buffer containing various concentrations of P2A2, and standard procedures for preparing unilamellar vesicles were then applied.[10] For a series of samples with identical lipid concentration, the I values rose only slightly with the P2A2 concentration up to a saturating detergent/lipid mole ratio, $R_e^{sat.}$, at which membrane solubilization began (Figure 3a). A further increase in c_{P2A2} led to a drastic drop in I until solubilization was completed at $R_e^{sol.}$. This was in excellent agreement with a second type of

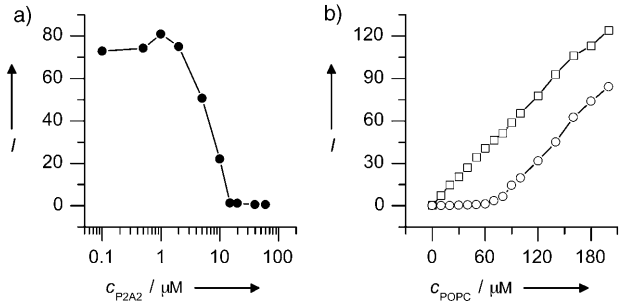

Figure 3. Detergent activity of P2A2 on 100-nm POPC vesicles as monitored by right-angle light scattering. a) Scattering intensity, I, obtained from 100 μM POPC extruded along with increasing P2A2 concentrations, c_{P2A2}. b) I values for various lipid concentrations, c_{POPC}, prepared in the presence (circles) or absence (squares) of 10 μM P2A2.

scattering experiment employing a constant lipopeptide concentration but different amounts of lipid (Figure 3b).

Plotting the characteristic P2A2 concentrations at the break points in the curves obtained with LS and calorimetry[10,15] versus the lipid concentration yields a simple phase diagram (Figure 4).[16,17] The two straight lines with slopes of

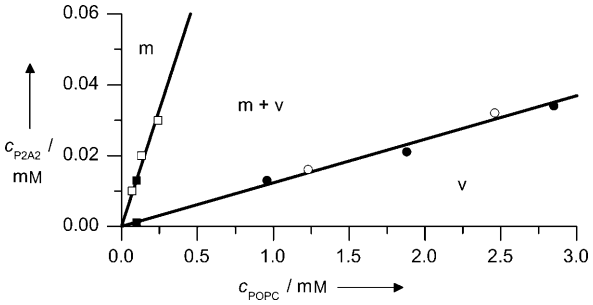

Figure 4. Phase diagram of dilute aqueous P2A2/POPC mixtures. Data are taken from solubilization (filled symbols) and reconstitution (open symbols) experiments conducted with light scattering (squares) and titration calorimetry (circles), [10] respectively. The linear regression lines separate the micellar (m) and the vesicular (v) areas from the transition range (m + v).[17]

$R_e^{sat.} = 0.012$ and $R_e^{sol.} = 0.13$ delimit three areas ascribed to the micellar, the transitional, and the vesicular range, respectively.[18] Thus, to our knowledge P2A2 is by far the most efficient detergent in that it can solubilize about seven lipid molecules per lipopeptide, that is, 50 times more than other peptides with two fatty acyl chains.[8] The partition coefficient of P2A2 from vesicles (v) to micelles (m) amounts to $P_{P2A2}^{m/v} = 10$ and reflects the preference of the lipopeptide for the micellar state. In contrast, POPC reveals only a slight penchant for membranes with $P_{POPC}^{m/v} = 0.9$, indicating that

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the lipid can be accommodated in the micelle almost as well as in the liposome and underpinning the suitability of P2A2 for micellar vehicles offering a bilayer-mimetic environment.

Most importantly, the clearcut boundaries in the phase diagram (Figure 4) permit direct control of the aggregational state of P2A2/POPC mixtures by adjusting the concentrations of the components. Hence, in addition to micellar also liposomal structures are available as supramolecular carriers, and vesicles doped with P2A2 reveal superior properties in terms of high lipid affinity, stable bilayer anchorage, and low membrane permeabilization when compared with the properties of other hydrophobized A2 derivatives.[19] Preliminary studies with confocal laser scanning microscopy revealed the efficient internalization of micelles composed of a fluorescently labeled P2A2 derivative (P2fA2) into mouse brain capillary endothelial cells (Figure 5). Moreover, the slow kinetics of solubilization[10] even suggests application of nonequilibrium formulations in which P2A2-oversaturated vesicles gradually rearrange into mixed micelles. This is particularly intriguing in light of the increasing importance of delayed and sustained release of drugs from delivery systems.[20]

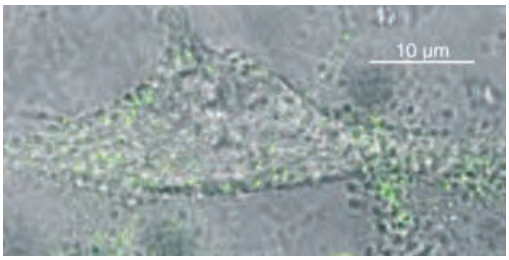

Figure 5. Internalization of a carboxyfluorescein-labeled P2A2 derivative (P2fA2) into immortalized b.End3 mouse brain capillary endothelial cells as visualized by confocal laser scanning microscopy. After exposure to 1 µM P2fA2 for 30 min at 37 °C, this representative cell displayed a punctuate intracellular fluorescence pattern pointing to a predominantly endocytotic mode of uptake. Membrane integrity and cell viability were confirmed by staining with trypan blue.[12]

We have shown that a novel lipopeptide composed of a target-specific peptidic vector and two adjacent fatty acyl chains is a highly promising candidate for solubilizing hydrophobic drugs in lipid-rich, membrane-mimetic nanocarriers. Owing to their small size, these supramolecular vehicles share many advantages with other micelles,[2] while the bioactivity of the peptide moiety is maintained thanks to the bilayer-like environment offered by the palmitoyl tails. These unique properties and the sound physicochemical characterization make the colloidal state of P2A2/lipid systems readily manageable and provide versatile formulations for in vitro experiments, which have indeed demonstrated rapid cellular internalization. The straightforward synthesis and good solubility should render P2A2 amenable to a more detailed structure elucidation and might also prove useful for other fields, such as membrane protein reconstitution.[8,9] Finally, the peptide sequence need not be restricted to the cell-penetrating A2 but may be adaptable to a broad spectrum of ligands destined to diverse biological targets. We are conducting further studies to shed light on the mechanism of uptake and to extend the approach presented in this work to similar chimerical lipopeptides.

[17] Vesicle–micelle coexistence is the simplest but not the only model providing a consistent interpretation, and other scenarios might be envisaged, for example, a transition from vesicles to disk-shaped bilayers or bicelles at $R_e^{sat.}$ followed by a gradual shrinking caused by a further increase in c_{P2A2}. Rather than a thermodynamically meaningful parameter, $R_e^{sol.}$ would then be an arbitrarily defined threshold at which the bilayer disks become hardly distinguishable in size from pure P2A2 micelles as judged from the *I* values.

Antiaromatic Species

DOI: 10.1002/anie.200500831

3,5,7,9-Tetraphenylhexaazaacridine: A Highly Stable, Weakly Antiaromatic Species with 16 π Electrons**

Peter Langer, Anja Bodtke, Nehad N. R. Saleh, Helmar Görls, and Peter R. Schreiner**

The efficiency of electrical, magnetic, and optical devices based on organic materials is closely related to their HOMO–LUMO energy gap.[1] The structure of tetraphenylhexaazaanthracene (TPH-anthracene, **1**), first prepared in 1908 as a

1a (TPH-anthracene) **1b**

stable, highly fluorescent compound,[2] was recently studied by Wudl and Houk et al.; **1** exists as a zwitterionic cyanine (resonance structure **1a**) that undergoes photoinduced intramolecular electron transfer to give a radical pair.[3,4] Wudl and

Houk et al. concluded that the apparent antiaromaticity of **1** is overwhelmed by the dominance of cyanine ion stabilization. However, the aromatic properties, which can be assessed in a straightforward manner by, for instance, nucleus-independent chemical shifts (NICS),[5] were not analyzed further.

Herein, we report the synthesis of what is, to the best of our knowledge, the first example of a hexaazaacridine, namely 3,5,7,9-tetraphenylhexaazaacridine (TPH-acridine, **2**). By means of a combination of experimental and computational results, we show that **1** and **2** can be viewed as stable, 16-π-electron, weakly antiaromatic highly zwitterionic structures with very low lying triplet states. As neutral molecules are usually less polarized than their excited states, **2**, along with its carbon analogue **1**, is the exception where the state polarity is reversed so that photoexcitation leads to a less polarized excited state. As a consequence, normally much higher lying triplet and singlet states are much closer in energy. It is conceivable that appropriately substituted acridines can have open-shell ground states and would be excellent candidates for organic magnets and data storage.[1]

The synthesis of TPH-acridine (**2**) essentially follows the strategy reported for the synthesis of **1** (Scheme 1).[2,3]

Scheme 1. Synthesis of TPH-acridine (**2a**): a) PhCOCl (2 equiv), NEt_3 (2 equiv), CH_2Cl_2, 14 h, 0–20 °C, 48%; b) PCl_5 (2.9 equiv), toluene, 1.5 h, 20 °C, then 2 h, reflux, 88%; c) $PhNHNH_2$ (2.7 equiv), *n*-hexane, 14 h, 0–20 °C, 90%; d) air, DBU (2.8 equiv), MeOH, 4 d, 20 °C, 10%. DBU = diazabicyclo[5.4.0]undec-7-ene.

However, the oxidative cyclization of **6** as the key step proved to be very sluggish and afforded **2** in only 3% yield. After much experimentation, we found that **2** can be obtained reproducibly in 10% yield. Both the workup of the final product and the quality of **6** proved to be important parameters. In this context, the preparation of (rather unstable) bis(imidoyl) dichloride **5** in high purity was crucial and required careful handling.

The deep purple hexaazaacridine **2** is air stable, thermally stable up to 400 °C, and poorly soluble in most organic solvents. Particularly noteworthy is its strong solvatochromic character (Table 1): a solution of **2** in DMF is orange colored ($\lambda_{max} = 547$ nm) and, despite the low solubility of **2**, highly fluorescent at $F(\lambda_{max}) = 585$ nm. In TFA (CF_3CO_2H), however, the solubility of **2** is higher owing to protonation to give

Table 1: Solvatochromic properties of **2**.

Solvent	λ_{max} [nm] ($\log\varepsilon$)	Color of solution
DMF	547 (4.51)	orange, strongly fluorescent, poorly soluble
CH_3CO_2H	535 (4.57)	orange, fluorescent, poorly soluble
conc. HNO_3	–	red, very poorly soluble
conc. H_3PO_4	540 (4.29)	bluish purple, poorly soluble
conc. $HClO_4$	–	green, very poorly soluble
CF_3CO_2H	–	deep purple, reasonably soluble
conc. H_2SO_4	662 (4.34)	deep green, highly soluble

cationic **2**-H^+ (deep purple solution). Therefore, most NMR spectra were recorded in [D_1]TFA. Compound **2** is somewhat soluble in glacial acetic acid, concentrated nitric acid, phosphoric acid, and perchloric acid to give orange, red, bluish purple, and green solutions, respectively. Excellent solubility and strong bathochromism were observed in concentrated sulfuric acid ($\lambda_{max} = 662$ nm, deep green solution). Successive dilution of this solution with water or acetone changes the color from green to blue and purple and finally to pink and orange (see Supporting Information for quantitative measurements); this process is reversible. In addition to the acidity and concentration, the counterion also affects the absorption of the solution, which suggests the formation of aggregates.

The structure of TPH-acridine (**2**) was independently confirmed through a crystal structure analysis of the cation **2**-H^+, which was prepared by protonation of **2** with hydrochloric and glacial acetic acids (Figures 1 and 2). Protonated TPH-

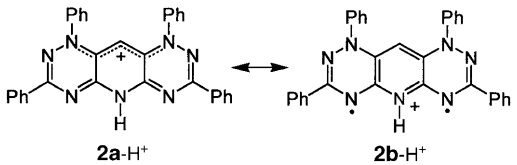

Figure 1. Resonance structures of protonated TPH-acridine, **2**-H^+.

acridine is a symmetric molecule that is protonated at the central nitrogen atom. Analysis of the bond lengths of THP-acridine indicates that the ionic resonance structure **2a**-H^+ is more important than the diradical contributor **2b**-H^+; this compares well with **1**.

For a better understanding of the electronic nature of **2**, we also computed its properties and compared those to **1**. As Wudl and Houk et al. successfully employed density functional theory (DFT) to examine the structures and energies of **1**, we adopted the same approach (B3LYP)[6] but expanded the basis set from 6-31G* to 6-311 + G** for the energies on the B3LYP/6-31G*-optimized geometries because we noted a marked basis set dependence of the singlet–triplet energy separation (ΔE_{ST}); this is not unexpected for species with

These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

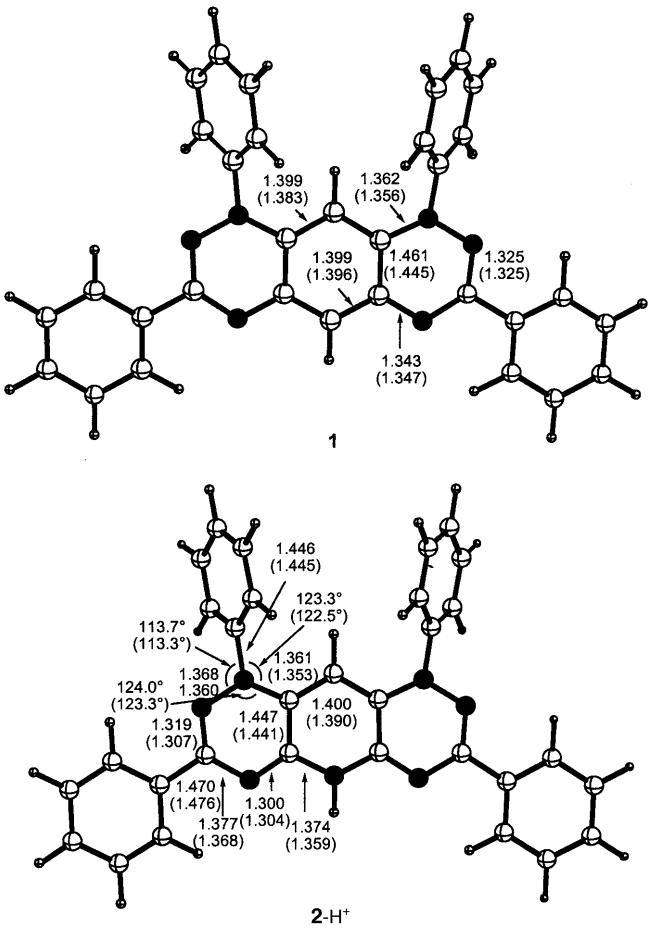

Figure 3. TPH-anthracene (**1**) and protonated TPH-acridine, **2**-H$^+$: comparison of selected bond lengths [Å] of the computed structure (B3LYP/6-31G*) and the crystal structure (in parentheses).

highly polarized ground and close-lying excited states. Our final level is therefore B3LYP/6-311+G**//B3LYP/6-31G*; zero-point vibrational energy (ZPVE) differences are marginal and are therefore not applied (the ZPVEs are reported in the Supporting Information). For the computation of UV spectra, we utilized time-dependent DFT (TD-B3LYP/6-311+G**), which is capable of describing vertical excited states more reliably than, for example, configuration interaction with single excitations (CIS).[7]

Since the crystal structure of TPH-anthracene (**1**) is known and the structure of the complete molecule had not been computed (the phenyl groups had been replaced by hydrogen atoms in the original publication),[3] we first optimized the structure of **1** to establish whether our computational approach would reproduce the structural details within acceptable errors. We computed **1** in C_s and C_2 symmetry (rotation of one of the *N*-phenyl groups relates these two structures) and found the C_s form to be very slightly preferred (0.3 kcal mol^{-1}); the X-ray crystal structure is asymmetric (C_1) as a result of packing effects. The key structural parameters agree quite well (Figure 3), and we expect our approach also to give good structural data for TPH-acridine (**2**). The phenyl groups in **1** lower ΔE_{ST} by 2.4 kcal mol^{-1} (at B3LYP/6-31G*), but this separation (16.3 kcal mol^{-1} for the preferred C_s structure) increases to 17.1 kcal mol^{-1} when we employ a more polarizable and diffuse basis set at our reference level. For proper comparison, we also computed protonated TPH-acridine, **2**-H$^+$, at B3LYP/6-31G*; the key structural parameters are in excellent agreement with the crystal structure data (Figure 3).

A comparison of the measured and computed ^{13}C NMR data of protonated **2** (the spectrum was recorded in [D$_1$]TFA) also is favorable (Table 2); the average deviation of the computed data to lower fields is only about 5 ppm and can be explained by neglect of solvent effects.

The UV/Vis spectrum is also well reproduced computationally with a maximum absorption at 506 nm (experimentally at 535 nm in AcOH), which is assigned to an excited state that corresponds qualitatively to the lowest triplet state (as in **1**).[3] By analogy to **1**, the fluorescence spectrum is not a mirror image of the UV/Vis absorption spectrum; the Stoke's

shift of **2** is about 26000 cm^{-1}, even larger than that of **1** (15000 cm^{-1}) and hence about 5 to 40 times the typical Stoke's shift of typical laser dyes.[8]

Azaacridine **2** also has a C_s singlet ground state with a ΔE_{ST} of 15.1 kcal mol^{-1}; note that this gap is significantly larger at B3LYP/6-31G* (21.1 kcal mol^{-1}). The C_2 singlet state lies 7.9 kcal mol^{-1} higher in energy and displays an even larger basis set effect on the ΔE_{ST} (20.8 at B3LYP/6-31G* and only 6.2 kcal mol^{-1} at our reference level). Stability tests showed no instabilities in the wavefunctions of the singlet states; in other words, the small ΔE_{ST} can be interpreted on the basis of aromaticity/antiaromaticity (see below). Like anthracene **1**, acridine **2** is highly polar (dipole moment: 8.2 D) and displays pronounced charge separation. The nitrogen atom in the central ring is the most negatively polarized (−0.53 according to a natural bond orbital (NBO) analysis) and is also the preferred site of protonation (in either the C_s or C_2 form); protonation at N3 and N2 is 3.8 and 18.4 kcal mol^{-1} less favorable, respectively. This is nicely confirmed by the crystal structure of **2**-H^+.

The computed NICS values in the ring centers (Table 3) reveal that all three rings of acridine **2** are antiaromatic. The same is true for **1** although the degree of antiaromaticity varies more strongly. As NICS values in the ring centers often are affected by the σ electrons of neighboring bonds, we also computed the NICS values above the ring centers and compare these with the extreme case of an antiaromatic species, namely D_{4h} cyclobutadiene.[9] This analysis shows that the outer rings of **1**, **2**, and **2**-H^+ at 0.5 Å above the ring of the plane are, with the exception of the inner ring of **1**, weakly antiaromatic. NICS points that are further away from the ring centers demonstrate that the antiaromatic character decreases rapidly, in particular for the inner rings; these NICS values are typical for nonaromatic structures. The decrease in antiaromaticity, which is much more pronounced than for cyclobutadiene, can be rationalized by differences in the ring size and the high polarity of the heterocycles in **1** and **2**.

Table 3: NICS values (B3LYP/6-311+G**//B3LYP/6-31G*) of **1**, **2**, and **2**-H^+.

NICS value relative to ring center	**1**		**2**		**2**-H^+		Cyclobutadiene (D_{4h})
	inner	outer	inner	outer	inner	outer	
0.0	+0.6	+7.9	+3.5	+6.3	+3.1	+4.1	+27.1
0.5	−1.1	+5.6	+0.9	+4.0	+1.5	+1.9	+27.9
1.0	−2.0	+2.6	−1.1	+1.4	+0.3	−0.1	+19.0
2.0	−0.2	+0.7	−0.5	+0.1	+0.2	−0.3	+4.5
3.0	+0.2	+0.2	−0.2	−0.1	0.0	−0.2	+1.2
4.0	+0.2	+0.1	−0.2	−0.2	−0.1	−0.2	+0.4

Hence, **1** and **2** must be considered to be stable, weakly antiaromatic molecules with highly polar singlet ground states. Our conclusions are further supported by visual inspection of the HOMO of **2** (C_s; Figure 4), which is symmetrically π-antibonding. This is in analogy to the simplest neutral antiaromatic singlet, the highly unstable D_{4h}-symmetric cyclobutadiene (it is common knowledge that it has a triplet ground state). Remarkably, the ΔE_{ST} for cyclobutadiene is in the same range (5.9 kcal mol^{-1} at B3LYP/6-311+G** and 11.5 kcal mol^{-1} at CCSD(T)/cc-pVDZ//B3LYP/6-311+G**)[10] as that of **1** and **2**, which lends further support to the proposal that these polycyclic structures are indeed stable antiaromatic entities. Although this formally contradicts the conclusions of Wudl und Houk et al.[3] for TPH-anthracene that double cyanine ion stabilization of zwitterion **1a** is preferred over the formal 16-π antiaromaticity (**1b**),[11] we remark that the earlier study computationally examined a smaller model system with a smaller basis set, which has a large effect on the energies (see above). However, the two conclusions are not necessarily mutually exclusive because the systems under consideration are only weakly antiaromatic and partially avoid this unfavorable situation through strong polarization.

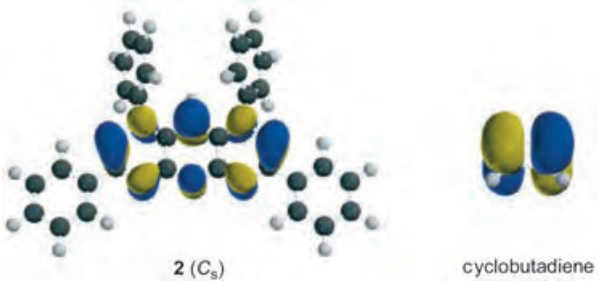

Figure 4. HOMOs of **2** and cyclobutadiene (only one of the two degenerate HOMOs is shown).

In conclusion, TPH-acridine, which we have synthesized and characterized, represents the first hexaazaacridine. The structure and spectroscopic properties of TPH-acridine and TPH-anthracene were studied by DFT computations and NICS analysis. TPH-acridine and TPH-anthracene represent highly zwitterionic structures with very low-lying triplet states. Both polycyclic structures can be considered to be stable 16-π-electron, weakly antiaromatic entities. TPH-acridine and TPH-anthracene are of great theoretical and structural interest and exhibit exciting physical properties that may be utilized in organomagnetic applications.

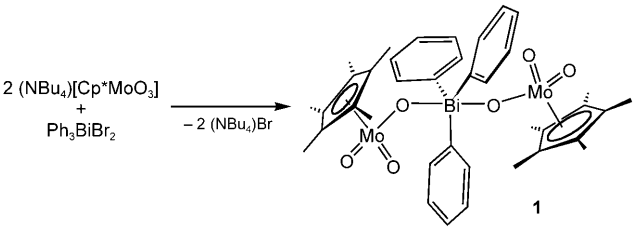
Molecular Compounds with Mo-O-Bi Moieties**

Stefan Roggan, Christian Limberg, and Burkhard Ziemer*



Dedicated to Professor Manfred Meisel on the occasion of his 65th birthday

The unique property of $n MoO_3/Bi_2O_3$ phases to act as catalysts for the allylic oxidation of propene (SOHIO process) remains a subject of intense discussion.[1] It might be related inter alia to the presence of surface species containing Mo-O-Bi linkages, assuming that these possess favorable hydrogen-atom abstraction or radical trapping properties. At present, there are no structurally characterized molecular complexes known that contain Mo-O-Bi moieties,[2] and the hypothesis that such units might play key roles in heterogeneous catalysis[1] stimulates attempts to create them at the molecular level.

We initially pursued the synthesis of Mo-O-Bi compounds by salt metathesis by employing seemingly suitable starting materials. However, these reactions all led only to insoluble, intractable solids, so we turned our attention to Mo-Bi-alkoxide chemistry. Alkoxidic systems are often related to oxides but exhibit certain advantages in practical terms, and it was hoped that the access to Mo/Bi alkoxides would lead to an understanding of principal problems and to new strategies for the development of oxidic structures. By employing starting materials in which part of the coordination sphere at the Mo centers was shielded by tightly bound organic ligands, we finally achieved the synthesis of the first Mo/Bi alkoxides.[3] These proved to be suitable single-source precursors for the creation of novel types of molybdenumoxo/bismuthoxo composites on inert supports.[4] However, as all attempts to prepare Mo-O-Bi complexes starting from these compounds failed, we decided to follow an alternative strategy: new complexes containing Mo–Bi metal bonds were prepared, which appeared to be appropriate to be treated with oxygenating reagents;[5] the latter were envisioned to insert oxo atoms into the metal–metal bonds. Even though this approach led to an interesting C–H activation chemistry,[6] Mo-O-Bi compounds still remained elusive.

In 1980 Klemperer and Liu communicated[7] that the reaction between Ph_3BiBr_2 and water-containing $(NBu_4)_2[MoO_4]$ leads to a white solid that analyses as $(NBu_4)_2[BiPh_3(MoO_4)_2]\cdot 3H_2O$. A structure with a Bi^V ion surrounded by three phenyl substituents and two molybdate units was suggested, and the water molecules were proposed to act only as solvate molecules. However, X-ray quality crystals could not be obtained; these would have allowed the confirmation of that idea and the clarification of whether the interaction between the Bi center and the molybdate anions has a covalent or more ionic character.

Having experienced that Mo/Bi alkoxides became accessible when organomolybdenum starting materials were employed,[3] we performed the reaction reported by Klemperer by replacing the molybdate $[MoO_4]^{2-}$ by an organomolybdenum(VI)oxo anion, namely $[Cp^*MoO_3]^-$ ($Cp^* = \eta^5$-C_5Me_5). Treatment of Ph_3BiBr_2[8] with two equivalents of $(NBu_4)[Cp^*MoO_3]$[9] in dichloromethane leads to a yellow solution containing $[(Cp^*MoO_3)_2BiPh_3]$ (**1**; Scheme 1). Workup and recrystallization from diethyl ether yielded single crystals, which were examined by X-ray diffraction. The structure analysis revealed, to our knowledge, the first structurally authenticated Mo-O-Bi linkages in a molecular compound (Figure 1).[10]

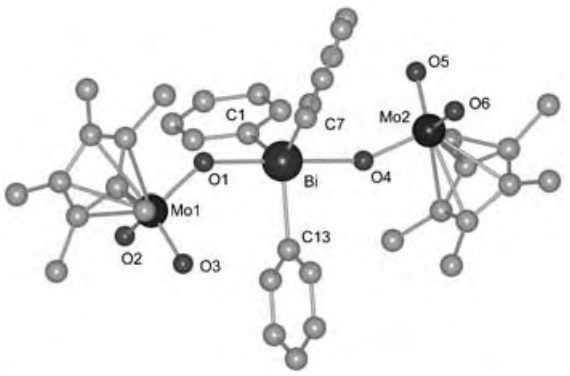

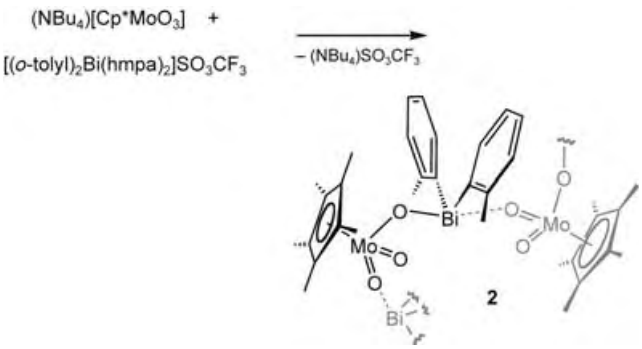

Figure 1. Molecular structure of **1**; all hydrogen atoms as well as a co-crystallized molecule of diethyl ether were omitted for clarity. Selected bond lengths [Å] and angles [°]: Bi-O1 2.198(6), Bi-O4 2.204(6), Bi-C1 2.187(9), Bi-C7 2.211(7), Bi-C13 2.195(7), Mo1-O1 1.835(5), Mo1-O2 1.725(6), Mo1-O3 1.706(6), Mo2-O4 1.822(5), Mo2-O5 1.728(6), Mo2-O6 1.718(6); O1-Bi-O4 176.7(2), C1-Bi-C13 114.3(3), C1-Bi-C7 122.0(3), C13-Bi-C7 123.7(3), C1-Bi-O1 92.9(3), C13-Bi-O1 91.0(3), C7-Bi-O1 88.0(3), C1-Bi-O4 90.3(3), C7-Bi-O4 89.6(3), C13-Bi-O4 88.4(3), Mo1-O1-Bi 139.5(3), Mo2-O4-Bi 152.8(3), O3-Mo1-O2 105.9(3), O3-Mo1-O1 106.9(3), O2-Mo1-O1 106.3(3), O6-Mo2-O5 106.1(3), O6-Mo2-O4 107.4(3), O5-Mo2-O4 105.4(3).

The Bi atom is located at the center of a slightly distorted trigonal bipyramid, in which the oxygen atoms occur at the apical sites. The phenyl rings occupy the equatorial positions in a typical manner for Ph_3BiX_2 structures.[11a] The Mo-O-Bi moieties are bent (Mo1-O1-Bi 139.5(3)°, Mo2-O4-Bi 152.8(3)°) and the Bi–O distances of 2.198(6) (Bi–O1) and 2.204(6) (Bi–O4) Å are somewhat longer than those reported for the known μ-oxo-bridged dinuclear organobismuth(V) compounds of the type $[(Ar_3BiY)_2O]$ ($Y = ClO_4^-$, $CF_3SO_3^-$, $Ar = Ph$; $Y = Cl^-$, $Ar = 4\text{-}(Me_2N)C_6H_4$), which cover a range from 2.02 to 2.12 Å.[11b–d] This is probably due to the fact that the two oxo ligands in **1** are located *trans* to each other and compete as strong π acceptors for the same orbitals (thereby mutually weakening their bonds), whereas in the other compounds mentioned the oxo ligands are positioned *trans* to weakly coordinating ligands; they can thus form stronger bonds. The Mo–O single-bond lengths of 1.835(5) (Mo1–O1) and 1.822(5) Å (Mo2–O4) in **1** appear quite short compared to those in the polymorphs of $[(Cp^*MoO_2)_2O]$ (1.855(6)–1.894(4) Å).[12] The latter exhibit a wide range of distances for the Mo=O double bonds (1.667(8)–1.721(5) Å),[12] and those in **1** (1.706(6)–1.728(6) Å) are more similar to the longer ones.

As the strategy of combining a hard {(O_2Mo)-O-Bi} metal-oxo core with soft ligands proved appropriate for the preparation of a Mo^{VI}-O-Bi^{V} compound, it should now be applied to the next synthetic target: Although some authors have assigned an active role[13] to Bi^V ions during the SOHIO process, Bi^{III} species are thought to be more relevant by the majority.[1] We thus pursued the synthesis of Mo^{VI}-O-Bi^{III} complexes in the next step, and the route to success seemed to be straightforward: the reaction of Ph_2BiBr[8] with $(NBu_4)[Cp^*MoO_3]$. However, Bi^{III} compounds such as Ph_2BiBr are Lewis acidic and show a strong tendency to accept an additional anionic ligand to form a hypervalent compound. Hence, many attempts to react the above-mentioned compounds ultimately led to the isolation of the well-crystallizing $(NBu_4)[Ph_2BiBr_2]$.[14] This finding certainly indicates that the intended metathesis under elimination of $[NBu_4]Br$ must have proceeded at least to some extent, but trapping of the $[NBu_4]Br$ by unconsumed starting material led to a non-uniform course of the reaction, which prohibited the isolation of the second bismuth-containing product. We therefore decided to employ $[(o\text{-tolyl})_2Bi(hmpa)_2]SO_3CF_3$ (o-tolyl = 2-$(Me)C_6H_4$; hmpa = hexamethylphosphoric acid triamide)[15] instead of Ph_2BiBr as the starting material, as it seemed to offer several advantages with respect to the above-mentioned problems: The *o*-tolyl groups are sterically somewhat more demanding than phenyl groups are, the hmpa ligands can occupy vacant coordination sites where necessary, and moreover, in contrast to halide ions, triflate anions are very weak ligands.

The reaction of $[(o\text{-tolyl})_2Bi(hmpa)_2]SO_3CF_3$ with $(NBu_4)[Cp^*MoO_3]$ proceeds smoothly in THF and yields a yellow solid that can be recrystallized from a mixture of diethyl ether and dichloromethane. A single-crystal X-ray structure analysis[10] confirmed the successful synthesis of the first Mo^{VI}-O-Bi^{III} complex, namely $[(Cp^*MoO_2)$-μ-O-{$Bi(o\text{-tolyl})_2$}$]_n$ (**2**; Scheme 2, Figure 2).

Scheme 2. The synthesis of **2**.

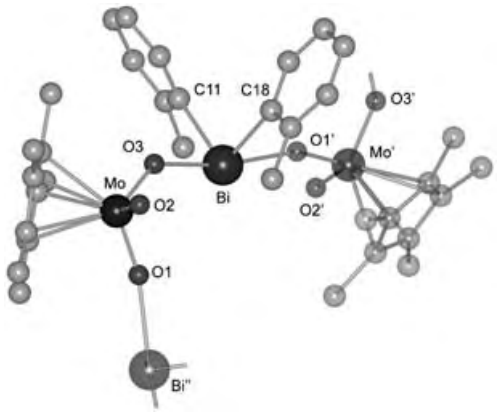

Figure 2. Molecular structure of **2**; all hydrogen atoms as well as the cocrystallized molecules of dichloromethane were omitted for clarity. Selected bond lengths [Å] and angles [°]: Bi-O3 2.310(2), Bi-O1′ 2.385(2), Bi-C18 2.237(3), Bi-C11 2.240(3), Mo-O1 1.768(2), Mo-O2 1.720(2), Mo-O3 1.786(2); O3-Bi-O1′ 170.46(9), O2-Mo-O1 105.5(2), O2-Mo-O3 105.9(2), O1-Mo-O3 105.4(2), Mo-O1-Bi′′ 160.6(2), Mo-O3-Bi 138.0(2), C18-Bi-C11 94.6(2), C18-Bi-O3 89.7(2), C11-Bi-O3 86.6(2), C18-Bi-O1′ 82.1(2), C11-Bi-O1′ 89.12(2).

In **2** a $[Cp^*MoO_3]^-$ moiety is covalently bonded through an oxygen atom to a $[(o\text{-tolyl})_2Bi]^+$ ion. The resulting hypothetical molecule $[(Cp^*MoO_2)\text{-}(\mu\text{-}O)\text{-}\{Bi(o\text{-tolyl})_2\}]$ features a still Lewis acidic Bi^{III} center on one side and basic Mo=O oxygen atoms on the other side. Consequently, Lewis acid/base Mo=O···Bi interactions occur leading to a chainlike coordination polymer with pseudo-trigonal bipyramidal or seesaw ligand geometries around the Bi atoms: the C atoms of the *o*-tolyl ligands occupy equatorial positions, the oxygen atoms the apical sites. The angle between the oxygen atoms (O1′-Bi-O3 170.46(9)°) is close to the ideal value of 180°. In contrast, the angle between the *ipso*-carbon atoms (C11-Bi-C18) of only 94.6(2)° is much smaller than expected for a trigonal bipyramid (120°). Such acute angles are not uncommon in the structural chemistry of heavy main group elements and can be explained in two ways: if the ligand sphere is described as pseudo-trigonal bipyramidal, a strong stereochemical effect of the bismuth lone pair on the C-Bi-C angle is implied. Alternatively, a bonding model based on unhybridized 6p orbitals with the lone pair of electrons at the bismuth center in a 6s orbital appears equally appropriate.[11a,e,f,g]

The Mo-O-Bi moieties are bent with angles (Mo-O1-Bi″ 160.6(2)°, Mo-O3-Bi 138.0(2)°) similar to those in **1**. Surprisingly, the Bi–O1′ bond in the Bi···O=Mo moiety (2.385(2) Å) is only slightly longer than the Bi–O bond in the covalent Mo-O-Bi unit (Bi–O3 2.310(2) Å). This might be understood if the Mo=O···Bi interaction is accomplished with a strong involvement of the Bi–O3 σ* orbital. A strong coordinative O···Bi interaction would then weaken the covalent Bi–O bond, and indeed the Bi···O=Mo interaction has to be considered as strong: the situation is comparable to the one in the complex $[\{Cl_3Bi\cdots O{=}V(OC_2H_4OCH_3)_3\}_2]$[16] in which, however, the distance between the Bi center and the vanadyl O atom is 2.703(!) Å. Naturally, both Bi–O bonds in **2** are significantly longer than those in **1**, but they are comparable to the bonds in the $\{Bi_3(\mu_3\text{-}O)\}$ units (2.037(8)–2.665(8) Å) of the recently communicated bismuth-oxo cluster cation $[Bi_{22}O_{26}]^{14+}$.[17] The Bi–O bond lengths found for Mo-O-Bi units in β-bismuth molybdate, $Bi_2Mo_2O_9$,[18] lie between 2.34(3) and 2.79(3) Å, and are thus longer than those in **2**. The Mo–O3 distance in the Mo-O-Bi unit in **2** is 1.786(2) Å and is thus significantly shorter than the Mo–O bond lengths in $[\{Cp^*MoO_2\}_2O]$[12] (1.855(6)–1.894(4) Å). At the same time it is at the upper end of the corresponding range determined for Mo–O bonds in the $Bi_2Mo_2O_9$ phase (1.71(3)–1.78(3) Å).[18] The two Mo=O distances in **2** differ significantly from each other. Whereas the Mo=O2 bond length (1.720(2) Å) is comparable to those found for the $[\{Cp^*MoO_2\}_2O]$ system (1.667(8)–1.721(5) Å), the Mo=O1 double bond (1.768(2) Å) is only slightly shorter than the Mo–O3 single bond. This significant elongation must be the consequence of the strong coordination of O1 to the Lewis acidic bismuth center.

In conclusion we have managed to access to Mo-O-Bi complexes—a previously unknown and long-sought class of compounds. Currently we are investigating their chemical properties, that is, their behavior in the presence of hydrocarbons such as olefins, substrates with weak C–H bonds, and as organic radicals, to establish their potential as functional models for Mo-O-Bi units on bismuth molybdate surfaces.

Experimental Section

All manipulations were carried out in an argon atmosphere using dried solvents.

1: A solution of Ph_3BiBr_2 (0.115 g, 0.19 mmol)[8] in CH_2Cl_2 (10 mL) was added slowly at −78 °C to a stirred solution of $(Bu_4N)[Cp^*MoO_3]$ (0.200 g, 0.38 mmol)[9] in CH_2Cl_2 (10 mL). The reaction mixture slowly turned yellow, and after stirring at −78 °C for 1 h and for a further 4 h at room temperature, the solvent was evaporated under reduced pressure. The resulting yellow residue was extracted with toluene leading to a yellow solution which was separated from undissolved $(NBu_4)Br$ by filtration. Evaporation of the solvent yielded crude **1** (160 mg; 83 %), which according to ^{1}H NMR spectroscopy was still contaminated by some ammonium salt as well as by the known compound $[(Cp^*MoO_2)_2O]$.[19] Repeated recrystallization from diethyl ether finally yielded pure **1** (30 mg; 16 %). C,H analysis calcd (%) for $C_{38}H_{45}BiMo_2O_6$: C 45.70, H 4.54; found: C 45.47, H 4.87; ^{1}H NMR (400.1 MHz, CD_2Cl_2): $\delta = 8.04$ (d, 6H, $^3J_{H,H} = 8.19$ Hz; *o*-phenyl), 7.71 (m, 6H; *m*-phenyl), 7.57 (m, 3H; *p*-phenyl), 1.69 ppm (s, 30H; Me_{Cp^*}); ^{13}C NMR (100.6 MHz, CD_2Cl_2): $\delta = 10.3$ ($Cp^*\text{-}CH_3$), 118.0 ($Me\text{-}C_{Cp^*}$), 131.3 (*m*-phenyl), 131.8 (*p*-phenyl), 134.5 (*o*-phenyl); signals for the *ipso*-carbon atoms were not detected; IR (KBr): $\tilde{\nu} = 3050$w, 2964w, 2916w, 2857w, 1637b, 1561w, 1469w, 1437m, 1377w, 1262w, 1162w, 1096w, 1024w, 1013w, 989m, 897s, 865s, 817m, 805m, 800m, 736s, 697vs, 621m, 447m, 423w cm^{-1}.

2: A colorless solution of $(Bu_4N)[Cp^*MoO_3]$ (0.200 g, 0.38 mmol) in THF (10 mL) was added over 10 min to a stirred light yellow solution of $[(o\text{-tolyl})_2Bi(hmpa)_2]SO_3CF_3$ (0.345 g, 0.38 mmol)[16] in THF (10 mL) held at −78 °C. The solution turned yellow immediately. After the addition was complete, the solution was stirred for a further 45 min at −78 °C and then for 2 h at room temperature. The solution was then reduced to a volume of 10 mL and cooled to −30 °C. A yellow solid precipitated overnight which was still contaminated by small amounts of $(NBu_4)SO_3CF_3$ and hmpa. An analytically pure sample (170 mg; 67 % yield) was obtained by washing the precipitate repeatedly with cold CH_2Cl_2. Single crystals suitable for X-ray analysis were grown by overlaying a solution of **2** in CH_2Cl_2 with diethyl ether. C, H analysis calcd (%) for $C_{24}H_{29}BiMoO_3$: C 43.00, H 4.36; found: C 43.02, H 4.68. ^{1}H NMR (400.1 MHz, CD_2Cl_2): $\delta = 8.25$ (dd, 2H, $^3J_{H,H} = 7.63$ Hz, $^4J_{H,H} = 1.55$ Hz; *o*-tolyl), 7.51 (m, 4H; *m*-tolyl), 7.32 (m, 2H; *p*-tolyl), 2.45 (s, 6H; CH_3), 1.72 ppm (s, 15H; Me_{Cp^*}); ^{13}C NMR (100.6 MHz, CD_2Cl_2): $\delta = 144.5/137.4/132.2/129.6/128.5$ (aryl C), 118.9 ($Me\text{-}C_{Cp^*}$), 24.0 ($tolyl\text{-}CH_3$), 10.31 ppm ($Cp^*\text{-}CH_3$); the signals for the *ipso*-carbon atoms were not detected; IR (KBr): $\tilde{\nu} = 3048$w, 2995w, 2961w, 2913m, 2857w, 1448m, 1379w, 1272w, 1203w, 1157w, 1116w, 1069w, 1031w, 1019w, 988w, 8921s, 863w, 819s, 802s, 783s, 744vs, 719vs, 703s, 621m, 472m cm^{-1}.

nanobiotechnology.[1,2] For example, for drug-delivery applications the separated incompatible compartments of the hydrophobic core could enable the selective entrapment and release of various hydrophobic drugs, while the hydrophilic shell stabilizes these nanostructures in physiological media. Thus, several strategies for preparing multicompartment micelles have been proposed recently.[1,3–8] However, so far, the number of morphological studies concerning such micelles is rather low and therefore little is known about their exact internal structure.[2]

The most straightforward pathway for preparing multicompartment micelles is the direct aqueous self-assembly of synthetic polymeric amphiphiles possessing one hydrophilic segment and two incompatible hydrophobic segments. Copolymers made of different segments covalently bonded together such as block, graft, star-block, and miktoarm star copolymers can often spontaneously self-assemble into various organized superstructures.[9] Such self-assembly processes are driven by diverse repulsion forces between the segments. In a bulk material, the thermodynamic incompatibility between various connected results in ordered segregated nanophases.[10] In liquid media, the differences in affinity of the various segments for the solvent lead to dispersed organized objects. Either in bulk or in solution, the morphology of the self-assembled structures depends on the molecular shape of the polymeric building blocks (number of segments, segment lengths, block sequence, architecture, and composition).[9] Naturally, the more complex the starting copolymers, the more complicated and difficult to analyze the resulting superstructures are. The latter is particularly true in solution because of the dynamic behavior of most self-assemblies.

For copolymers composed of only two different segments (AB), the factors governing self-assembly in solution are now well-understood, and the main morphologies such as spherical micelles,[11] wormlike micelles,[12] and vesicles[13] have been described. However, for more complex macromolecules such as ABC triblock copolymers, the possibilities of self-assembly in solution remain quite unexplored, although some morphologies have been characterized in either aqueous or organic media. In the simplest case, two of the three ABC segments are soluble in the solvent, resulting in micelles with an insoluble inner core and a mixed-arm soluble shell.[14–16] But, if two of the three ABC segments are insoluble in the solvent, the precise morphology of the self-assemblies is usually more difficult to describe. Concerning the general shape of the superstructure: spherical micelles[15–23] and vesicles[19,24] have been prepared from ABC copolymers having two insoluble segments. However, the morphology of the inner core is usually hard to elucidate.

If the two blocks composing the core are large enough and thermodynamically incompatible, they should most likely segregate into different phases, forming two or more separated compartments in the core of the micelle. Nevertheless, depending on the molecular structure of the segments, diverse morphologies can be expected for the multicompartment core, for example, "spheres in spheres" (core–shell model, onionlike) or "spheres on spheres" (raspberrylike). Up to now, the core structures were often presumed (in most cases, core–shell construction was proposed) but were not characterized or observed by microscopy. Most recently, Lodge et al. reported a first convincing visualization by cryo-transmission electron microscopy (cryo-TEM) of multicompartment micelles prepared in aqueous medium by self-assembly of miktoarm star copolymers;[25] they described the coexistence of segregated domains in the hydrophobic core of the formed nanostructures. However, the precise morphology of this inner core was not assessed.

In the present work, the aqueous self-assembly of an ABC linear triblock copolymer, poly(4-methyl-4-(4-vinylbenzyl)morpholin-4-ium chloride)-*block*-polystyrene-*block*-poly(pentafluorophenyl 4-vinylbenzyl ether) (PVBM-*b*-PS-*b*-PVBFP) was studied (Scheme 1). The copolymer

Scheme 1. Molecular structure of the triblock copolymer PVBM-*b*-PS-*b*-PVBFP and possible morphology of the multicompartment micelles observed in aqueous medium. Light gray: hydrophilic block with morpholinium units; dark gray: hydrophobic hydrocarbon block; black: hydrophobic fluorocarbon-rich block.

building blocks consist of a long cationic hydrophilic block, PVBM, and two short consecutive hydrophobic blocks: a hydrocarbon one (PS) and a mixed hydrocarbon/fluorocarbon one (PVBFP). Hydrocarbon and fluorocarbon blocks were selected since such segments tend to be strongly incompatible and should thus favor the segregation into distinct domains.[1] Moreover, such a choice should lead to compartments of markedly differing properties,[1,3,5,6] as desirable, for example, for drug-delivery applications.

The copolymer PVBM-*b*-PS-*b*-PVBFP was obtained by quaternization of a poly(vinylbenzyl chloride)-*b*-PS-*b*-PVBFP precursor with *N*-methylmorpholine. The triblock precursor was prepared by a three-step reversible addition fragmentation transfer (RAFT) polymerization process using

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

benzyl dithiobenzoate as a chain-transfer agent. To prepare the multicompartment micelles, the triblock PVBM-*b*-PS-*b*-PVBFP was initially dispersed in a dioxane/water mixture and subsequently dialyzed stepwise against pure water. Indeed, the choice of the organic solvent and of the mode of its removal is crucial for the outcome of the self-assembly.[26]

Figure 1 shows typical cryo-TEM images of the aqueous solution obtained. The images reveal uniformly dispersed dark gray spherical objects with an average diameter of 12–15 nm. These correspond to the formed micelles' hydrophobic core, which is composed of segregated domains: inside the sphere of the micellar core, dark spheres with an average diameter of about 3.4 ± 0.2 nm can be distinguished. The strong contrast in the images can be attributed to the presence of electron-rich fluorine atoms.[25] In average, four to ten segregated dark domains are observed for each micellar core. The hydrosoluble PVBM corona of the micelles is not directly observable but can be estimated from the objects interdistance to be around 20–30 nm in diameter.

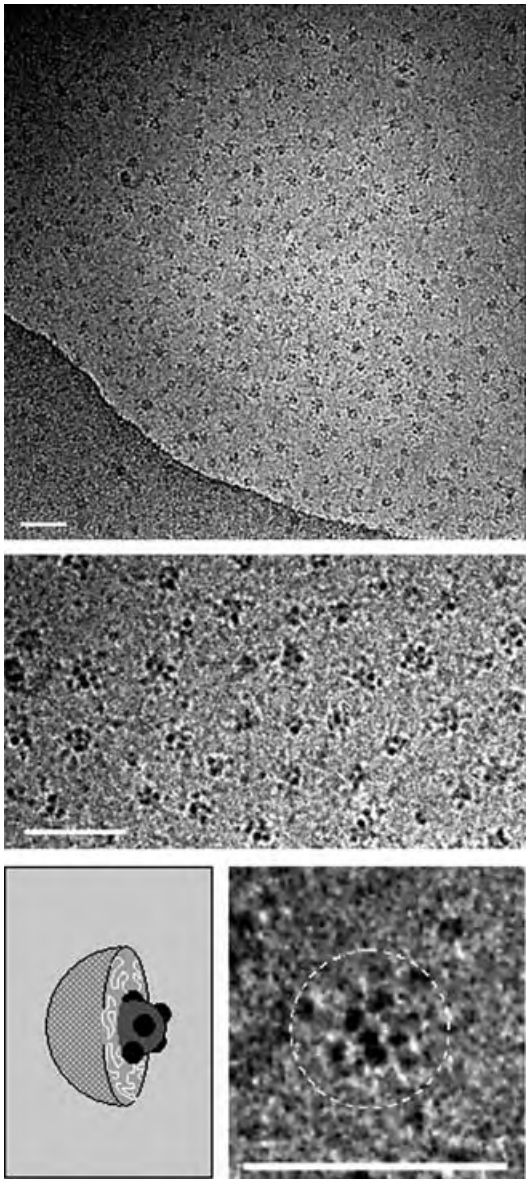

Figure 1. Cryo-TEM images and a schematic representation of the structure of multicompartment micelles obtained by self-assembly of the triblock copolymer PVBM-*b*-PS-*b*-PVBFP in aqueous medium. The corona of the micelles is not visible. The scale bars correspond to 50 nm.

The observed core morphology resembles a raspberrylike morphology, as first described by Stadler et al. for the bulk self-assembly of polystyrene-*b*-polybutadiene-*b*-poly(methyl methacrylate) (SBM) triblock copolymers.[27] Pascault et al. demonstrated that the raspberrylike morphology can also be observed in a micellar structure.[28,29] In their study, micelles of SBM were initially dispersed in a reactive epoxy–amine mixture, which was subsequently polymerized. Their work indicated that the initial micelle morphology was fixed in the polymer matrix by polymerization and therefore could be studied by TEM. Figure 1 shows a first example of a similar morphology for micelles prepared in aqueous medium. However, the cryo-TEM images cannot distinguish whether the dark fluorocarbon domains are covering the surface of a central hydrocarbon core (spheres-on-spheres, raspberrylike morphology) as shown in Scheme 1 and as described by Stadler et al.,[27] or whether the dark domains are embedded in the hydrocarbon core (spheres-in-spheres morphology). The latter structure might be expected intuitively since the fluorinated block is the C block of the ABC sequence.

Another question arises concerning the observed morphology: are the segregated dark domains made of the complete PVBFP blocks or only of the fluorocarbon moieties of PVBFP? Only if the latter scenario is true can the size measured by cryo-TEM be correlated to the molecular volumes of the copolymers (see the Supporting Information). For this scenario, the calculations give a global theoretical diameter of 20.5 nm for the whole micelle (swelling of the corona with water is not taken into account), and a diameter of 13.8 nm for the whole hydrophobic core, values in good agreement with the numbers obtained from the cryo-TEM images. In contrast, when we assume that the dark regions are due to the whole PVBFP blocks (hydrocarbon and fluorocarbon parts), the calculated diameters for the whole micelle and for the hydrophobic core are too small. Therefore, we conclude that the dark spheres comprise only the fluorocarbon moieties of PVBFP, whereas the dark gray region contains both the hydrocarbon domains of PS and PVBFP.

The overall dimension of the micelle was also confirmed by static light scattering (see the Supporting Information). The scattering curve corresponds to the scattering of spherical particles with a radius of gyration R_g of 14.5 nm. This number is in good agreement with theoretical calculations and size estimated from cryo-TEM. Also in agreement with the micrographs, the scattering curve indicates that the size distribution of these objects is relatively broad, as may be expected from the polydispersity of the polymers ($M_w/M_n = 1.7$).

In conclusion, multicompartment micelles having a diameter of 20–30 nm were prepared by the self-assembly in aqueous medium of the amphiphilic triblock copolymer PVBM-*b*-PS-*b*-PVBFP. As evidenced by cryo-TEM, the core is segregated into nanometer-sized compartments in which many small, fluorocarbon-rich domains coexist with a

continuous hydrocarbon-rich region. These novel nanostructured colloids may serve as models as well as mimics for biological structures such as globular proteins, and may open up interesting opportunities for nanotechnology applications.

Enantioselective Total Synthesis and Determination of the Absolute Configuration of the 4,6,8,10,16,18-Hexamethyldocosane from *Antitrogus parvulus***

*Christian Herber and Bernhard Breit**

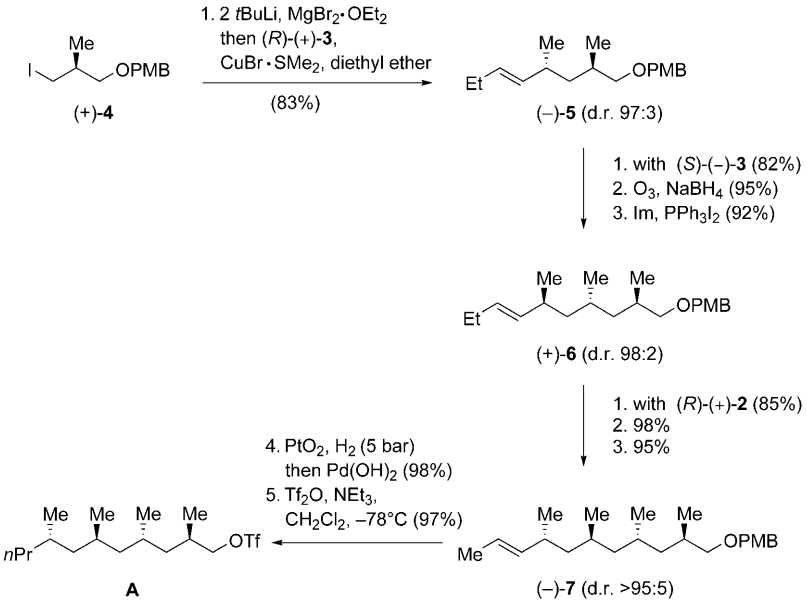
The larvae of the cane beetle *Antitrogus parvulus* (known as cane grubs) are a source of major damage in sugar-cane crops in Australia.[1] On searching for an environmentally benign plant-protection strategy, recent research has focused on the identification of sex pheromones of the cane beetle. As a result hydrocarbons, such as 4,6,8,10,16-penta- and 4,6,8,10,16,18-hexamethyldocosanes (**1**), that feature an unprecedented *anti-anti-anti* stereochemistry in the 4,6,8,10-methyl tetrad have been discovered.[2] However, the small amount of material isolated from the natural source has not yet allowed the determination of their biological role. Combined spectroscopic and synthetic efforts have elucidated the relative *anti* configuration of the four methyl-bearing stereocenters in the tetrad unit of **1** and the relative *syn* configuration within the methyl diad region. However, so far the stereochemical relation between the all-*anti* tetrad and the *syn* diad remains unknown (**1a** or **1b**), as does the absolute configuration (Scheme 1).[2]

We herein report on the total synthesis of both diastereomers **1a** and **1b** in enantiomerically pure form, thus enabling the determination of the relative and absolute configurations of the natural product. The synthesis relies heavily on our recently developed copper-mediated and *ortho*-diphenylphosphanylbenzoyl (*o*-DPPB)-directed *syn*-allylic substitution with Grignard reagents for iterative deoxypropionate synthesis.[3] Additionally, we demonstrate the power of copper-catalyzed sp^3–sp^3 cross coupling by employing it for building-block construction and as the fragment-coupling step in a convergent total synthesis.

Scheme 1. Retrosynthesis for **1a** and **1b**. PG = protecting group, LG = leaving group, M = metal.

Our synthetic plan is outlined in Scheme 1. Fragment coupling of the methyl tetrad and the methyl diad by employing a catalytic sp^3–sp^3 cross-coupling reaction[4] was envisioned as an attractive final step of the synthesis to allow the flexible construction of both diastereomers **1a** and **1b**.

The corresponding tetradeoxypropionate building block should be assembled by our iterative deoxypropionate synthetic strategy employing enantiomerically pure allylic *o*-DPPB building blocks **2** and **3** as propionate acetate and propionate units, respectively.[3] The two optical antipodes of the methyl diad building block should be readily accessible by similar chemistry.



The synthesis began with construction of the tetrad building block **A** (Scheme 2). Thus, iodide (+)-**4** (available

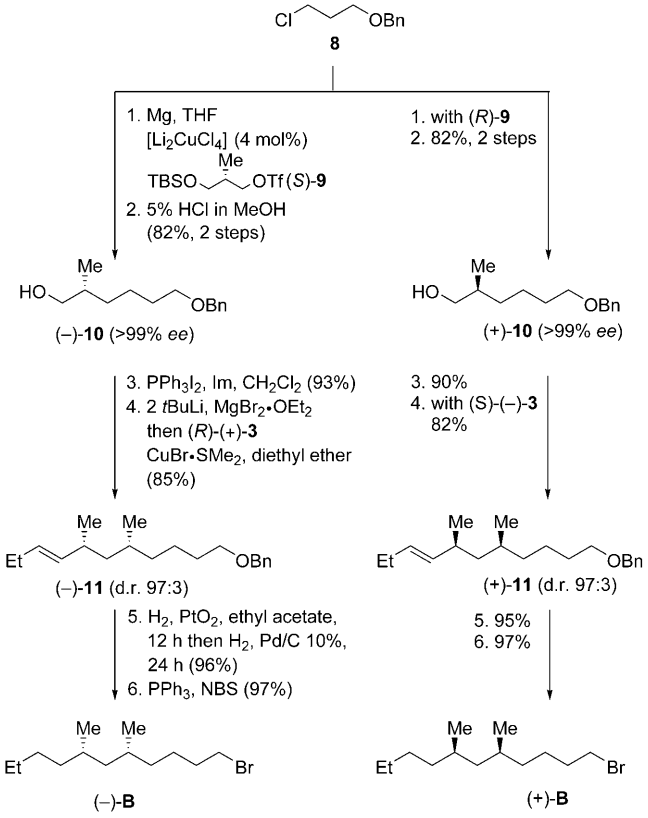
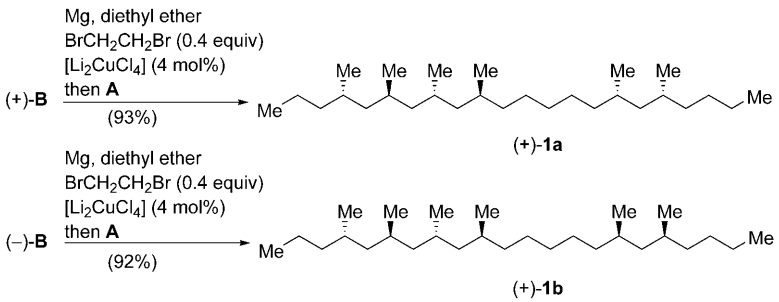


Scheme 2. Synthesis of tetradeoxypropionate building block **A**. Im = imidazole, Tf = trifluoromethanesulfonyl.

in three steps from the Roche ester)[5] was transformed into a Grignard reagent and subjected to *o*-DPPB-directed *syn*-allylic substitution with allylic *o*-DPPB ester (*R*)-(+)-**3** in the presence of 0.5 equivalents of copper bromide·dimethyl sulfide to give the dideoxypropionate (−)-**5** with a complete 1,3-chirality transfer.[3] Two separate iterations consisting of three steps (alkene ozonolysis with a reductive workup ($NaBH_4$), transformation to the iodide, and directed *syn*-allylic substitution with (*S*)-(−)-**3** and (*R*)-(+)-**2**, respectively) furnished the tetradeoxypropionate (−)-**7** with all the carbon atoms and stereocenters in place. Alkene hydrogenation and reductive cleavage of the *para*-methoxybenzyl (PMB) ether group occurred upon heterogenous catalytic hydrogenation. The thus-derived building block **A** was stored as the alcohol and activated prior to fragment coupling as the corresponding triflate.



Synthesis of the dideoxypropionate building blocks **B** commenced from chloride **8** (Scheme 3).[6] For the expansion of the carbon skeleton, we chose a copper-catalyzed sp^3–sp^3 cross-coupling reaction with a three-carbon electrophile of type **9** derived from the Roche ester.[7] Orientating experiments with the corresponding bromide and iodide derivatives, however, showed that significant chemoselectivity problems occurred because of elimination and reduction processes. These problems could be circumvented by employing the triflates (+)-**9** and (−)-**9** at −20 °C. In these cases, clean cross coupling in the presence of 4 mol % of $[Li_2CuCl_4]$ was observed. Exposure of the crude coupling product to methanolic hydrogen chloride gave the primary alcohols (−)-**10** and (+)-**10** in 82 % yield (two steps). The Mukaiyama redox condensation furnished the corresponding iodides, which were subjected to the above protocol for the directed *syn*-allylic substitution with (*R*)-(+)-**3** and (*S*)-(−)-**3**, respectively, to furnish the dideoxypropionates (−)-**11** and (+)-**11** in excellent yield and complete diastereoselectivity. Minimal, standard functional-group manipulation led to building blocks (−)-**B** and (+)-**B**.

The final fragment-coupling step (Scheme 4) employing a copper-catalyzed sp^3–sp^3 cross coupling of the Grignard reagent derived from (−)/(+)-**B** with triflate **A** required some optimization because of problems that arose from the small scale of the reaction (0.1 mmol). It was found that generation of a Grignard reagent on this small scale was successful in the presence of an excess of dibromoethane. However, the thus-formed excess of magnesium bromide also reacted with the triflate electrophile to yield the corresponding bromide as a by-product (which unfortunately did not undergo further cross coupling). This problem could be circumvented by the addition of an ethereal solution of triflate **A** together with 4 mol % of the catalyst $[Li_2CuCl_4]$ to an ethereal solution of the Grignard-reagent-derived form of **B**. Excellent yields of both diastereomers **1a** and **1b** were obtained under these conditions. Purification of the final product was achieved through kugelrohr distillation, which, as an additional benefit, allowed the boiling points of **1a** and **1b** (210 °C/20 mbar) to be determined.

Scheme 3. Synthesis of the enantiomeric dideoxypropionate building blocks (−)-**B**/(+)-**B**. Bn = benzyl, TBS = *tert*-butyldimethylsilyl, NBS = *N*-bromosuccinimide.

Scheme 4. Fragment coupling through Cu-catalyzed sp^3–sp^3 cross coupling. Synthesis of (+)-**1a** and (+)-**1b**.

To prove the identity of the natural and synthetic material ^{13}C NMR spectra of **1a** and **1b** were recorded in the presence of an internal glass-capillary tube containing a solution of the natural product in $CDCl_3$.[8] Comparison of these spectra showed a perfect match for diastereomer **1b**. Finally, comparison of the optical-rotation studies of the natural material ($[\alpha]_D^{20}$ +10.7 ($c = 0.44$, $CHCl_3$)) and the synthetic product **1b** ($[\alpha]_D^{20}$ +8.5 ($c = 1.21$, $CHCl_3$)) determined the absolute configuration of the natural product as that depicted in Scheme 4.

In conclusion, the enantioselective total synthesis of the (4*S*,6*R*,8*R*,10*S*,16*R*,18*S*)-hexamethyldocosane from *Antitrogus parvulus* has been accomplished, thus enabling the relative and the absolute configuration of the natural product to be determined. The successful enantioselective synthesis of **1b** (and its diastereomer **1a**) highlights the synthetic power of our recent methodology for deoxypropionate construction, which relies on an *o*-DPPB-directed and copper-mediated allylic substitution by Grignard reagents. Furthermore, the synthetic utility of copper-catalyzed sp^3–sp^3 cross-coupling for fragment coupling in a total synthesis has been demonstrated.

Pd^{II} Complexes Possessing a Seven-Membered N-Heterocyclic Carbene Ligand**

*Christopher C. Scarborough, Michael J. W. Grady, Ilia A. Guzei, Bhavesh A. Gandhi, Emilio E. Bunel, and Shannon S. Stahl**

Since the discovery of stable N-heterocyclic carbenes (NHCs),[1] these complexes have found widespread use in catalysis, in which they serve both as nucleophilic catalysts[2] and as ligands in metal-mediated reactions.[3] Carbenes derived from five-membered heterocycles represent the most common class of these molecules (**1**–**3**, Scheme 1);[1–3] however, four-[4] and six-membered[5] analogues have also been reported (**4** and **5**). Most of these structures possess a

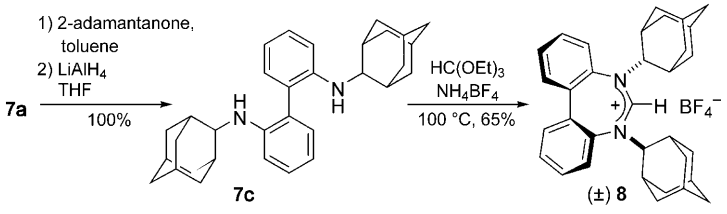
nearly planar heterocyclic framework, and this feature places constraints on the spatial arrangement of the NHC substituents. To relax this constraint, we targeted a new class of NHCs with a seven-membered heterocyclic framework **6** that would undergo a torsional twist to alleviate ring strain. Structures of this type have been analyzed previously by computational methods,[6] but synthetic examples have not been prepared. We describe herein the facile synthesis of two Pd^{II} complexes that possess the first member of this new class of carbene ligands, in which R = 2-adamantyl (2-ad).



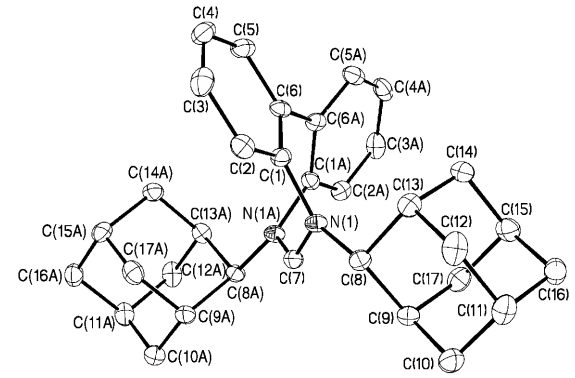
6

Our initial synthetic efforts targeted analogues of **6** with bulky aryl substituents (e.g., R = mesityl, 2,6-diisopropylphenyl), which are commonly found in stable NHCs. 2,2′-Diaminobiphenyl (**7a**) was obtained in quantitative yield by reduction of 2,2′-dinitrobiphenyl, and mesitylation of **7a** proceeded effectively under previously reported conditions (Scheme 2).[7] Subsequent condensation to afford the amidinium salt, however, was unsuccessful when a variety of known protocols was used. The origin of this failure is not certain, but we reasoned that it may result from the weak basicity of the diaryl amines, and therefore *N*-alkylated derivatives might be more successful.

Scheme 2. Attempted synthesis of an arylated seven-membered NHC. Mes = mesitylene, binap = 1,1′-binaphthalene-2,2′-diylbis(diphenylphosphine).

Preparation of *N*-substituted derivatives of **7a** with sterically encumbered primary and secondary alkyl groups proceeds smoothly (R = neopentyl, 2-adamantyl; Scheme 3).[8] For example, condensation of **7a** with 2-adamantanone followed by reduction of the imine with lithium aluminum hydride produces **7c** in quantitative yield.[9] Heating **7c** in neat triethylorthoformate with NH_4BF_4[10] produces the C_2-symmetric amidinium tetrafluoroborate salt **8**, which was characterized by single-crystal X-ray diffraction analysis (Figure 1).[11]

Scheme 3. Synthesis of a seven-membered biphenyl amidinium salt.



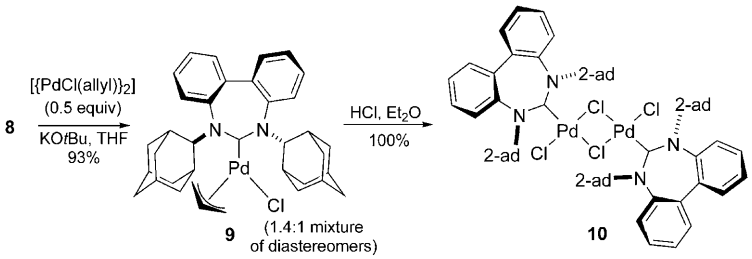


Figure 1. Molecular structure of the amidinium salt **8**. Hydrogen atoms and the BF_4^- counterion are omitted for clarity. Thermal ellipsoids are shown at 50% probability. Selected bond lengths [Å] and angles [°]: C(7)-N(1) 1.319(2), N(1)-C(1) 1.456(3), C(1)–C(6) 1.393(3), C(6)-C(6A) 1.472(4), C(1)-C(2) 1.388(3), C(2)-C(3) 1.385(3), C(3)-C(4) 1.384(3), C(4)-C(5) 1.401(3), C(55)-C(6) 1.401(3); N(1)-C(7)-N(1A) 124.2(3), C(7)-N(1)-C(8) 118.52(19), C(7)-N(1)-C(1) 117.21(18), C(1)-N(1)-C(8) 120.89(16).

The amidinium salt **8** represents an attractive NHC precursor, and our initial studies focused on the preparation of NHC-coordinated Pd^{II} complexes. Deprotonation of **8** with potassium *tert*-butoxide in a THF solution of [{PdCl(allyl)}$_2$][12–14] generated the NHC–PdCl(allyl) complex **9** in high yield (Scheme 4). This complex is air stable and can be purified by flash column chromatography on silica gel under ambient conditions. The ^{1}H NMR spectrum of **9** reveals the presence of two diastereomeric allyl rotamers in solution in a 1.4:1 ratio.[15] Single-crystal X-ray diffraction studies[11] confirmed the identity of **9** (Figure 2); a mixture of diastereomers is also present in the solid state, with the allyl group disordered over two positions in a 2.7:1 ratio.

Scheme 4. Synthesis of NHC-coordinated Pd^{II} complexes.

Protonolysis of the allyl ligand[12] of **9** with HCl produces [{$PdCl_2$(NHC)}$_2$] (**10**) in quantitative yield (Scheme 4). Only one isomer of this dimeric compound is detected in solution by ^{1}H NMR spectroscopic analysis. Single-crystal X-ray diffraction studies reveal the presence of a heterochiral dimer (Figure 3).[11]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

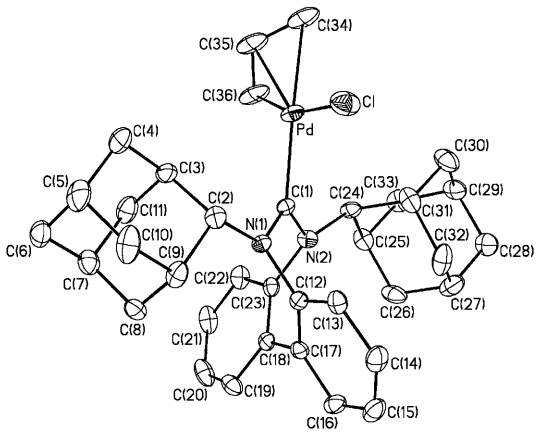

Figure 2. Solid-state molecular structure of **9**. Only the preferred orientation of the allyl group is shown. Hydrogen atoms and the solvent are omitted for clarity. Thermal ellipsoids are shown at 30% probability.

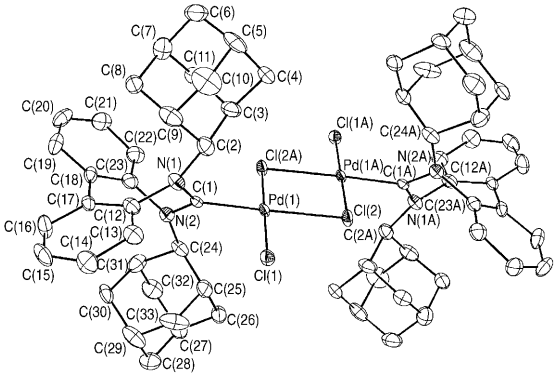

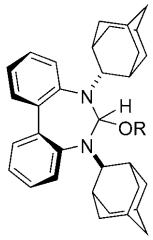

Figure 3. Molecular structure of **10**. Hydrogen atoms and solvent molecules are omitted for clarity. Thermal ellipsoids are shown at 30% probability.

The amidinium salt **8** and the NHC ligands in **9** and **10** exhibit axial symmetry arising from the torsional twist of the seven-membered ring. The torsional angle α between the two phenyl rings in **8** (C(1)-C(6)-C(6A)-C(1A)) is 46.1(4)°, which is similar to this angle in **9** and **10** (41.9(5) and 46.4(8)°, respectively). Another relevant metric is the torsional angle between the two N–C(2-ad) bonds, which reflects the spacial disposition of the adamantyl groups directed into the metal coordination sphere. This angle β in **8** (namely, $M = H^+$) is 56.2(5)° and expands to 72.3(8) and 79.7(1.3)° in the Pd^{II} complexes **9** and **10**, respectively. The larger size of the Pd^{II} center relative to a proton probably accounts for this increase. Overall, these torsional parameters highlight the utility of the seven-membered heterocycle to induce out-of-plane deviations in the orientation of the NHC substituents. Moreover, the C_2 symmetry of these structures supports their potential utility as templates for the preparation of non-fluxional, enantiomerically resolved analogues for use in asymmetric catalysis.

Thus far, attempts to isolate and characterize the free carbene have been unsuccessful. Numerous bases have been applied in these studies, including mesityl lithium, potassium hexamethyldisilazide, potassium *tert*-butoxide, sodium methoxide, and sodium hydride. ^{1}H NMR spectroscopic data reveals that alkoxide bases, which are the most effective reagents for the in situ preparation of NHC–Pd complexes form NHC–alcohol adducts **11a** and **11b**. Attempts to isolate the free carbene from such compounds by vacuum thermolysis[16] or trapping the released alcohol (in the case of the methanol adduct) in a Dean–Stark apparatus equipped with 4-Å molecular sieves and benzene at reflux were unsuccessful and only yielded slightly decomposed starting material in each case. These adducts do not react further in the presence of $[\{PdCl(allyl)\}_2]$ to form the NHC–PdCl(allyl) complex **9**. These results suggest that the preparation of **9** occurs by an in situ deprotonation of **8** by KO*t*Bu and competitive trapping of the free carbene by $[\{PdCl(allyl)\}_2]$ in solution.

11a: R = Me
11b: R = *t*Bu

Rzepa and co-workers analyzed a series of 8π-electron heterocycles, including seven-membered NHCs, by DFT computational methods.[6] These studies highlight the attenuation of antiaromatic character when such heterocyclic rings undergo a torsional twist. This conformational change enables partial Möbius aromatic stabilization[17] in addition to relief of the ring strain intrinsic to seven-membered rings. These calculations also suggest that coordination of these ligands to metal complexes results in higher inversion barriers between the two enantiomeric conformations.

In conclusion, we have prepared the first examples of metal complexes with a seven-membered N-heterocyclic carbene ligand that exhibits a tortional twist resulting in C_2 symmetry. This architecture can be readily altered with different substituents at the nitrogen atom and modifications to the biaryl backbone. Future studies will focus on the preparation of conformationally stable and enantiomerically resolved analogues, and their utility in asymmetric catalysis will be investigated.

Experimental Section

All manipulations were performed in an inert nitrogen atmosphere unless otherwise specified. Dry, oxygen-free solvents were employed. ^{1}H and ^{13}C NMR spectra were recorded on either a Bruker Homer-300, Bruker Athena-300, Varian Mercury-300, or Varian Inova-500 NMR spectrometer. ^{1}H NMR chemical shifts are reported in ppm relative to Me_4Si as the external standard, and the ^{13}C NMR chemical shifts are reported in ppm relative to $CHCl_3$. Please refer to the Supporting Information for the spectral data of all the compounds.

7a: Compound **7a** was synthesized by the adaptation of a literature procedure:[18] 2,2′-Dinitrobiphenyl (102.0 g, 417.5 mmol) and 10% Pd/C (16.4 g) were combined with EtOAc (300 mL) in a hydrogenation vessel. The vessel was pressurized to 40 psi H_2 for 3.5 h (when H_2 was no longer being consumed). The slurry was filtered through a plug of celite. Rotary evaporation followed by drying on a vacuum line gave the pure product as a light yellow–orange powder in 100% yield.

7c: 2,2′-Diaminobiphenyl (**7a**; 614 mg, 3.33 mmol) and 2-adamantanone (1 g, 6.65 mmol) were combined with *para*-toluenesulfonic acid (1% (per amine functionality)) in a Dean–Stark apparatus. The reagents were dissolved in toluene (ca. 200 mL) and refluxed for

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

72 h. The solvent was removed, and lithium aluminum hydride (122 mg, 3.22 mmol) was added followed by THF (ca. 200 mL). The reaction flask was heated to 50 °C for 2 h followed by a careful quenching with water (ca. 100 mL) and sat. NH_4BF_4 (10 mL). The resulting slurry was filtered through a plug of celite, and the plug washed with CH_2Cl_2. The aqueous layer was washed once with CH_2Cl_2 (ca. 100 mL). The organic layers were combined, dried over $MgSO_4$, filtered, and the solvent was removed, thus yielding pure **7c** in 100% yield.

(±)-**8**: 2,2′-Bis(2-adamantylamino)biphenyl (**7c**; 5.76 g, 12.7 mmol) and NH_4BF_4 (1.3 g, 12.7 mmol) were combined under nitrogen in a 500-mL round-bottomed flask and triethyl orthoformate (c.a. 200 mL) was added. The reaction was heated to 100 °C for 16 h, after which time the product precipitated as a white powder. The reaction mixture was allowed to cool to room temperature and filtered. The solid was washed with diethyl ether followed by pentane to give the amidinium salt (±)-**8** in 65% yield as a light fluffy white powder without further purification. Crystals suitable for X-ray analysis were achieved by vapor diffusion of *n*-pentane onto a solution of (±)-**8** in $CHCl_3$.

(±)-**9**: Aminidinium salt (±)-**8** (200 mg, 0.363 mmol) and [{PdCl(allyl)}$_2$] (78 mg, 0.213 mmol) were combined with KO*t*Bu (1.2 equiv) under nitrogen. The reaction mixture was stirred in THF for 12 h, filtered through celite, and purified by column chromatography under ambient conditions (SiO_2, diethyl ether/hexanes 1:1) to give the NHC–PdCl(allyl) complex (±)-**9** in 93% yield as a light yellow–tan solid. Crystals suitable for X-ray analysis were obtained by layering *n*-heptane onto a −20 °C ethereal solution of (±)-**9** followed by diffusion overnight at −20 °C. (±)-**9** crystallized as a mixture of diastereomers in a ratio of 73:27.

10: A 50-mL round-bottomed flask was charged with (±)-**9** (100 mg, 0.16 mmol) and ethereal HCl (2.0 mL, 2.0 M). The color of the reaction mixture instantly changed to bright yellow–orange. Diethyl ether (8.0 mL) was added, and the resultant suspension was stirred for 1 h. Volatiles were removed in vacuo, which left pure **10** as a bright yellow–orange powder in quantitative yield. Recrystallization was carried out by dissolving **10** in a small amount of toluene and adding excess *n*-pentane to cause precipitation (87% yield). Crystals suitable for X-ray analysis were achieved by vapor diffusion of *n*-pentane onto a solution of **10** in CH_2Cl_2.

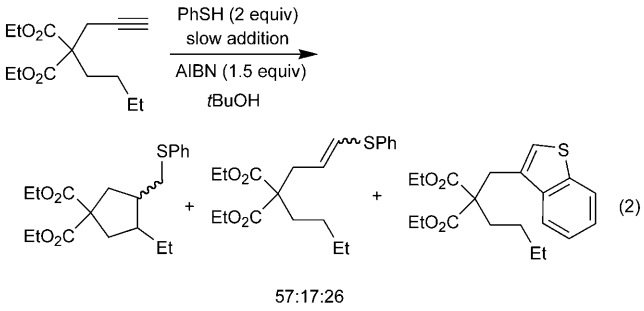
Dimethyl Phosphite Mediated Hydrogen Atom Abstraction: A Tin-Free Procedure for the Preparation of Cyclopentane Derivatives**

*Florent Beaufils, Fabrice Dénès, and Philippe Renaud**

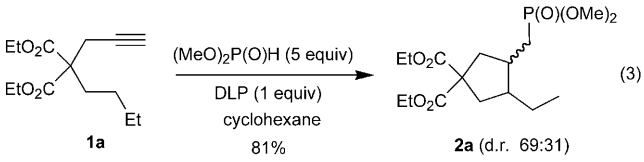


Radical reactions have been investigated intensively over the last two decades.[1] The new synthetic methods that have emerged from this work are complementary to ionic processes and are characterized by mild reaction conditions and broad functional-group tolerance. The potential of these reactions is immense, as demonstrated by their recent use in the synthesis of complex natural products. However, several aspects of this chemistry merit further investigation to increase the synthetic efficiency of the radical approach. Among these objectives, the development of nontoxic and environmentally friendly reagents to perform efficient radical reactions represents a challenging target.

The tin hydride mediated alkenyl radical translocation/cyclization process developed by Curran et al. represents a powerful procedure for the preparation of functionalized five-membered rings by selective activation of a C–H bond.[2,3] Recently, we reported an efficient tin-free version of this reaction involving thiophenol for the preparation of cyclopentane derivatives through a 1,5-hydrogen transfer/cyclization sequence [Eq. (1); AIBN = azobisisobutyronitrile].[4]

(1)

This method using thiophenol proved to be very efficient with a wide range of substrates but required high dilution (10^{-2} M of substrate) and the slow addition of thiophenol with a syringe pump [Eq. (1)]. Some limitations were also noticed, with some substrates undergoing slow hydrogen transfers. For example, the generation of a nonstabilized acyclic secondary alkyl radical proved to be difficult because of the reduction of the alkenyl radical and its cyclization onto the phenylthio group, thus leading to benzothiophene derivatives [Eq. (2)].[5]



(2)

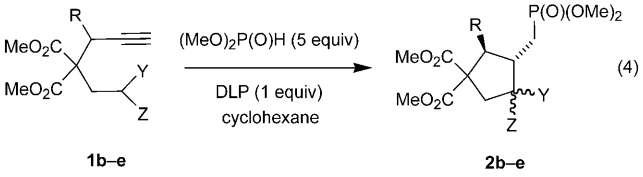
Recent developments in radical reactions involving phosphorus reagents have attracted our attention. Hypophosphorous acid and its corresponding 1-ethylpiperidine salt have been used to mediate radical cyclization reactions as an alternative to tributyltin hydride.[6,7] Diethyl phosphine oxide (DEPO)[8] and diethyl phosphite[9,10] were also recently used in radical processes.[11,12]

As diethyl phosphite is known to be a slower reducing agent than tributyltin hydride and thiophenol,[13] we were motivated to test the use of a phosphorus reagent in a radical cascade involving the addition of a P radical onto a triple bond followed by 1,5-hydrogen abstraction. To the best of our knowledge, only one radical addition of a dialkyl phosphite to a terminal triple bond has been reported, which was by Ishii and co-workers using $Mn(OAc)_2$ as a radical initiator in the presence of air.[14] Parsons and co-workers reported the failure of such a radical addition but presented one example of a clean addition of a thiophosphite to a terminal alkyne.[15] Herein, we report that dimethyl phosphite is a particularly efficient reagent for radical additions to terminal alkynes followed by 1,5-hydrogen transfer/cyclization processes.

Optimization of the reaction conditions were conducted on substrate **1a** [Eq. (3); DLP = dilauroyl peroxide]. Highly

(3)

reproducible results and excellent yields were obtained by treating a 0.1 M solution of the alkyne **1a** with five equivalents of dimethyl phosphite and one equivalent of DLP[16] in cyclohexane at reflux for 6 h. The desired cyclized product **2a** was obtained in 81 % yield, and no trace of the product from direct reduction was observed. In this particular example, neither the procedure using tin hydride developed by Curran and Shen[3] nor our procedure using thiophenol[4] [see Eq. (2)] gave satisfactory results because of the slow rate of the hydrogen-abstraction step.



Propargylmalonates **1b**–**e** were then tested according to Equation (4). The generation of a tertiary alkyl radical from **1b** is very efficient with dimethyl phosphite (Table 1, entry 1),

(6)

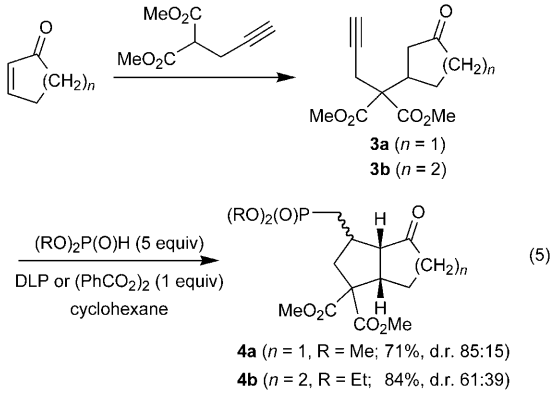

Table 1: Dimethyl phosphite mediated hydrogen abstraction [cyclization according to Eq. (4)].

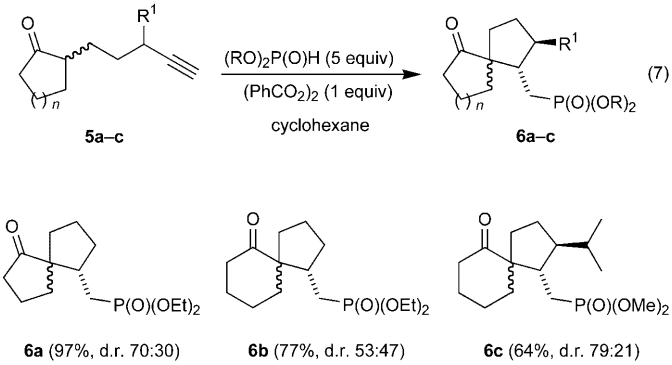
Entry	Substrate	R	Y	Z	Product	d.r.[a]	Yield [%][b]
1	**1b**	H	Me	Me	**2b**	–	91
2	**1c**	*i*Pr	CO_2Et	H	**2c**	82:18	91
3	**1d**	H	Ph	H	**2d**	92:8	55
4	**1e**	H	OTBS	H	**2e**	73:27	79

[a] Determined by GC or NMR analysis of the crude reaction mixture. [b] Yield of isolated product. TBS = *tert*-butyldimethylsilyl.

and the cyclic product **2b** is obtained in 91% yield. Substrates **1c** and **1d**, which bear an ester and a phenyl substituent, respectively, undergo a radical translocation/cyclization process to the desired substituted cyclopentanes **2c** and **2d** in 91 and 55% yield (entries 2 and 3), respectively. Finally, a radical reaction with substrate **1e** gave the cyclopentane derivative in 79% yield[17] (entry 4).



On the basis of these initial results, a method for the rapid assembly of fused bicyclic compounds was investigated [Eq. (5)]. Conjugate addition of dimethyl propargylmalonate

(5)

to cyclopentenone and cyclohexenone affords the radical precursors **3a** and **3b**, respectively. Reaction of **3a** and **3b** with dimethyl phosphite and diethyl phosphite proceeds [Eq. (5)] with complete regioselectivity and affords the fused bicycles **4a** and **4b** in 71 and 84% yield as a mixture of two diastereomers (d.r. 85:15 and 61:39, respectively). Radical stabilization by the ketone explains the regioselectivity. Interestingly, the deoxygenated compound **3c** gives the expected bicycloalkanes **4c** in 93% yield (d.r. 90:10) under similar reaction conditions, thus demonstrating that stabilization of the translocated radical is not a prerequisite for the formation of fused bicyclic systems [Eq. (6)].

The synthesis of spiro compounds through 1,5-hydrogen transfer has been reported recently employing an iodoalkenyl derivative.[18] However, this method suffers from the use of tin hydride and the difficulty of preparing the starting alkenyl iodides. On the other hand, substrates **5a–c** are readily prepared by alkylation of the corresponding β-keto ester followed by decarboxylation and are efficiently converted [Eq. (7)] into the spiro ketone **6a** (97%, d.r. 70:30), **6b** (77%, d.r. 53:47), and **6c** (64%, d.r. 79:21).

(7)

In conclusion, we have reported herein that dialkyl phosphites are powerful reagents for radical translocation/cyclization reactions that start from readily available terminal alkynes. A simple one-pot procedure has been developed. The excess reagent is easily removed by evaporation, and filtration through a short pad of silica gel affords a clean reaction product. The cyclic phosphonates produced by this reaction cascade are particularly attractive for further transformations.[11,19,20] Application of this process to the synthesis of natural products is currently underway.

Experimental Section

A mixture of **1b** (1.0 mmol, 226 mg), DLP (1.0 mmol, 398 mg), and dimethyl phosphite (5 mmol, 550 mg) in cyclohexane (10 mL) was heated at 80 °C for 6 h. After completion (monitoring by GC), the solution was cooled and the cyclohexane evaporated under reduced pressure. CH_3CN (10 mL) was added to precipitate the by-products derived from DLP. After filtration and evaporation, the residue was purified by flash chromatography (EtOAc/cyclohexane, 80:20) to afford the phosphonate **2b** (306 mg, 91%).

What Can a Metal Catalyst Do with Allenes? One-Step Formation of Steroid Scaffolds from Readily Available Starting Materials**

Shengming Ma, Ping Lu, Lianghua Lu, Hairong Hou, Jiemin Wei, Qiwen He, Zhenhua Gu, Xuefeng Jiang, and Xing Jin*

The diversity of available transition metals and organic ligands for the formation of organometallic catalysts offers the possibility of excellent selectivity and tunability in homogeneous transformations.[1–4] Alkynes and alkenes are two classes of well-studied compounds in organic chemistry that have formed the basis of the petroleum industry and modern organic chemistry.[5] It should be noted that 1–1.5 % of allene exists in propylene produced by the cracking of hydrocarbons in petroleum.[6] The large amount of propylene consumed means that the production of propadiene in considerable quantities is thus possible. Although van't Hoff predicted the correct structures of allenes and higher cumulenes as early as 1874,[7] for a long period of time allenes were considered to be highly unstable, which retarded the demonstration of their synthetic potential. However, the situation has changed dramatically during the last 8 to 10 years, and many new reactions have been developed based on the chemistry of allenes.[8–13] Steroids are characterized by a carbon skeleton with four fused rings, and their presence in plants and animals illustrates their immense biological importance.[14–17] Steroids are used for the treatment of cancer, arthritis, allergies, and in birth control. Thus,

efficient catalytic approaches to new steroid derivatives are still of current interest.[18–25] Recently, during our study of allene chemistry,[26] we identified a very efficient one-step transition-metal-catalyzed transformation of simple 1,5-bisallenes to steroid skeletons.

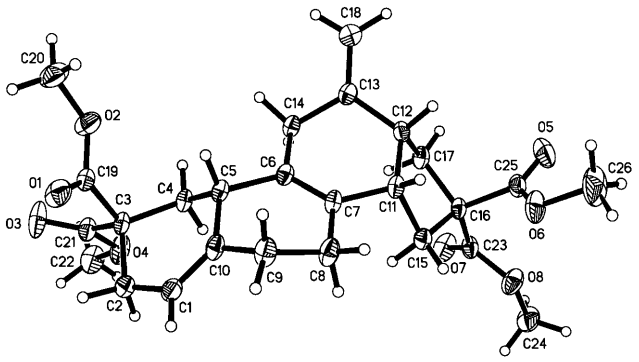
We prepared 5,5-bis(methoxycarbonyl)-1,2,7,8-nonatetraene (**1a**)[27] from the bisallenylation of diethyl malonate with 2,3-butadienyl bromide.[28] The reaction of **1a** in the presence of a catalyst of 5 mol% $[RhCl(PPh_3)_3]$ and 10 mol% $AgSbF_6$[29] afforded a product with a complicated ^1H NMR spectrum (entry 1, Table 1). The structure of this product was unambiguously established by X-ray diffraction studies to be the 18,19-norsteroid derivative **2a** (Figure 1).[30]

Table 1: Dimeric cyclization of **1a** in the presence of different catalysts.

1a **2a**

Entry	Catalyst	*t* [h]	Yield of **2a** [%]
1	$[RhCl(PPh_3)_3] + AgSbF_4$[a]	3	10
2	$[\{RhCl(cod)\}_2] + P(OPh)_3$[b]	12.5	15
3[c]	$[RhH(CO)(PPh_3)_2]$	2.5	31
4	$[\{RhCl(cod)\}_2] + PPh_3$[d]	12	38
5	$[RhCl(PPh_3)_3]$	2	38
6	*trans*-$[RhCl(CO)(PPh_3)_2]$	2	42
7	$[Rh(cod)_2]BF_4$	12	–
8	$PtCl_2$	4	–

[a] 10 mol% $AgSbF_4$ was added. [b] 10 mol% $P(OPh)_3$ was added. [c] The reaction was conducted at 0.125 M **1a** in toluene. [d] 10 mol% PPh_3 was added.



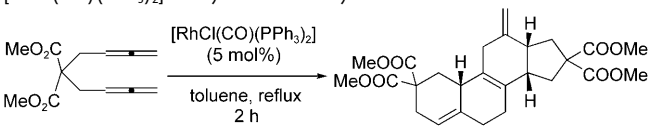


Figure 1. ORTEP representation of **2a**.

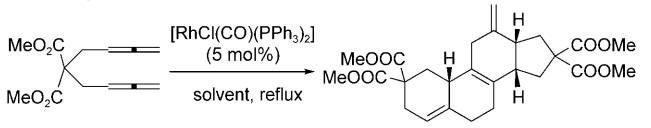
We screened a variety of catalysts using compound **1a** as the model, and some typical results are summarized in Table 1. The yields were improved when we used $[RhH(CO)(PPh_3)_2]$, $[RhCl(cod)]_2 + PPh_3$ (cod = cycloocta-1,5-diene), and $[RhCl(PPh_3)_3]$ without an Ag^+ salt (entries 3–5, Table 1). Further research showed that *trans*-$[RhCl(CO)(PPh_3)_2]$ was the best catalyst (entry 6, Table 1) while neither $[Rh(cod)_2]BF_4$ nor $PtCl_2$ showed any activity in this transformation (entries 7 and 8, Table 1).

Furthermore, a clear relationship between yields and concentrations was observed for this reaction (Table 2). It should be noted that the yield was greatly improved when a lower substrate concentration was used. We found that the reaction of **1a** at a concentration of 0.0417 M in toluene in the presence of 5 mol% *trans*-$[RhCl(CO)(PPh_3)_2]$ as the catalyst under reflux was very clean and afforded **2a** with a *cis* conjunction at the C/D rings in 73% yield as the only stereoisomer. It should be noted that no intermediate product was observed during the reaction process and no other stereoisomers were detected in the crude product by ^1H NMR spectroscopic analysis.

Table 2: Effect of the concentration of **1a** in toluene on the *trans*-$[RhCl(CO)(PPh_3)_2]$-catalyzed dimeric cycloisomerization of **1a**.[a]



1a **2a**

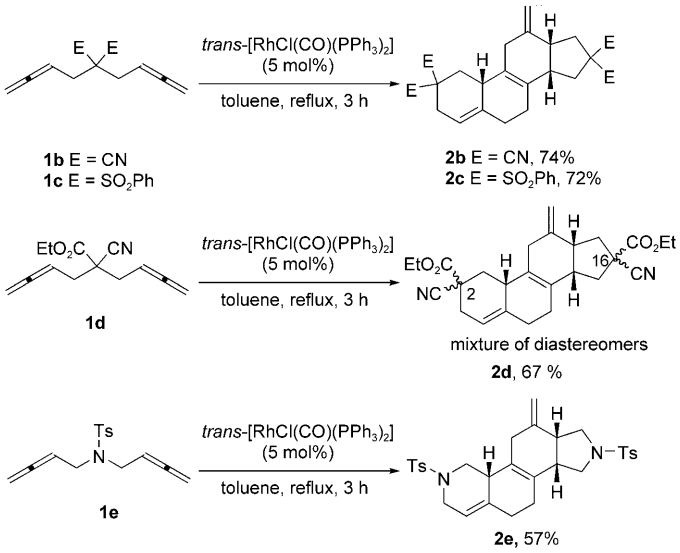
Entry	Concentration of **1a** [M]	Yield of **2a** [%]
1	0.25	42
2	0.125	55
3	0.0625	69
4	0.0417	73
5	0.0313	72

[a] The reaction was carried out using **1a** (0.25 mmol) and *trans*-$[RhCl(CO)(PPh_3)_2]$ (5 mol%) in toluene under reflux.

The effect of the solvent on this reaction are summarized in Table 3. Among the solvents tested, the best results were obtained in toluene (entry 1, Table 3). Furthermore, the yield and reaction rate both dropped when the reaction was carried out at a lower temperature (compare entries 2 and 1, Table 3).

Table 3: Effect of the solvent on the *trans*-$[RhCl(CO)(PPh_3)_2]$-catalyzed dimeric cycloisomerization of **1a**.[a]

1a **2a**

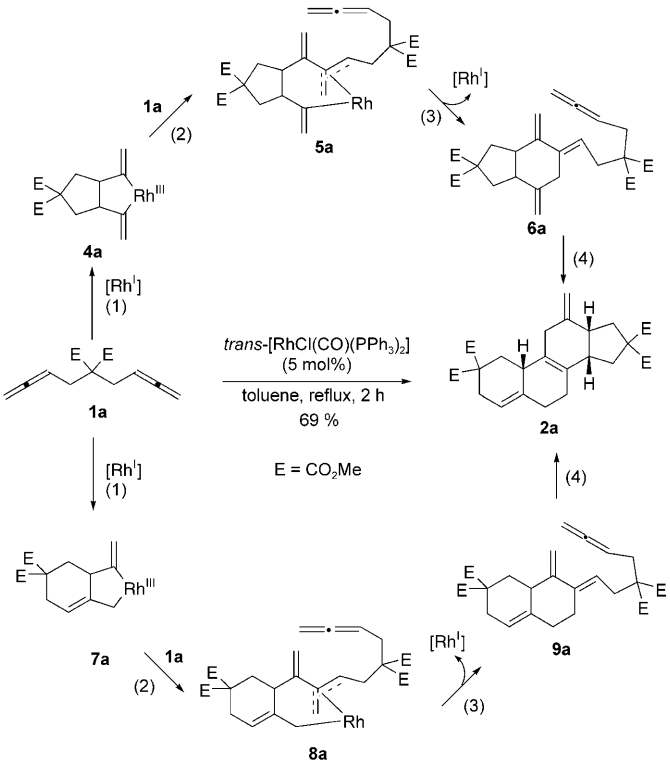


Entry	Solvent	*t* [h]	Yield of **2a** [%][b]
1	toluene	2	73
2[c]	toluene	57	43
3	CH_3CN	9.6	17
4	THF	6	36
5[d]	DMF	2.5	28
6	dioxane	2.5	41
7	benzene	7	54
8	xylene	2	41

[a] The reaction was carried out using **1a** (0.0417 M, 0.25 mmol) and *trans*-$[RhCl(CO)(PPh_3)_2]$ (5 mol%) in the specified solvent under reflux. [b] Yields determined by NMR spectroscopy by using 1,3,5-trimethyl benzene as the internal standard. [c] The reaction was conducted at 60 °C. [d] The reaction was conducted at 110 °C.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The reaction was also slow and the yield was quite low when CH_3CN was used as the solvent (entry 3, Table 3), while the use of benzene, xylene, and dioxane led to the formation of **2a** in yields of 41–54% (entries 6–8, Table 3). It should be noted that the ^1H NMR spectrum of the crude products indicated that only one stereoisomer was observed in all these cases.



With the optimized conditions in hand, we studied the scope of this reaction, and found that it is general for differently substituted bisallenes. 18,19-Norsteroid derivative **2c** was readily prepared (1.086 g, 72%) from 1.5 g of bisallene **1c**, which was prepared from $CH_2(SO_2Ph)_2$, 2,3-butandienyl bromide,[28] and NaH in quantitative yield. The nitrogen analogue **2e** can be prepared from the bis(2,3-allenyl)amine **1e**. The dimeric cyclization of **1d** resulted in a mixture of 2,16 epimers **2d** in 67% yield (Scheme 1).

Scheme 1. Dimeric cyclization of bisallenes **1** with a *trans*-[RhCl(CO)-$(PPh_3)_2$] catalyst. Ts = toluene-4-sulfonyl.

A possible mechanism was postulated on the basis of the above results (Scheme 2). The reaction may proceed through the cyclometalation[31] of **1a** to afford **4a** or **7a**, which may then undergo carbometalation with one of the two allene moieties in **1a** to afford **5a** or **8a**, respectively. Subsequent reductive elimination would afford **6a** or **9a**, which could then undergo a Diels–Alder reaction to form the 18,19-norsteroid **2a** (Scheme 2). The results obtained illustrate that the intramolecular Diels–Alder reaction between an allene moiety and an alkene partner can proceed either in the presence[31a] or absence[32] of a metal catalyst. The reaction was conducted at a low temperature in an attempt to capture any possible intermediate(s), but the reaction was very fast and no intermediate product was detected.

In conclusion, we have reported an efficient route to 18,19-norsteroid derivatives from bisallenes by using a catalytic amount of *trans*-[RhCl(CO)$(PPh_3)_2$]. Although some steroids have been prepared from acyclic precursors by long synthetic routes,[18–25] the availability of the starting materials and the catalyst as well as the simplicity of the current procedure makes this methodology a very efficient route to steroids with new structural and steric features. Thus, this route may open up a new direction in steroid-related science.

Scheme 2. A possible mechanism for the transition-metal-catalyzed transformation of simple 1,5-bisallenes to steroid skeletons. (1) Cyclometalation, (2) carbometalation, (3) reductive elimination, (4) Diels–Alder reaction.

Experimental Section

Typical procedure: A solution of **1c** (1.509 g, 3.76 mmol) and *trans*-[RhCl(CO)$(PPh_3)_2$] (130 mg, 0.19 mmol, 5 mol%) in dry toluene (90 mL) was heated at reflux under Ar for 3 h. After the reaction was complete, as monitored by TLC (eluent: CH_2Cl_2/MeOH 40:1), removal of the solvent by rotary evaporation and flash chromatography of the product on silica gel (eluent: CH_2Cl_2/MeOH 100:1) afforded 1.086 g (72%) of **2c**. M.p. 143–145°C (dichloromethane/diethyl ether); ^1H NMR (300 MHz, $CDCl_3$): $\delta = 8.18$–7.86 (m, 8H), 7.72–7.35 (m, 12H), 4.91 (br s, 1H), 4.75 (s, 1H), 4.71 (s, 1H), 3.02–2.50 (m, 9H), 2.42–2.20 (m, 3H), 2.15–1.90 (m, 4H), 1.70–1.62 ppm (m, 1H); ^{13}C NMR (75.4 MHz, $CDCl_3$): $\delta = 26.1$, 28.5, 30.2, 30.5, 31.9, 34.3, 36.1, 37.5, 46.4, 47.4, 87.9, 93.5, 110.7, 114.1, 126.9, 128.6(×2), 128.7, 128.8, 131.0, 131.2, 131.4(×3), 131.5, 134.3, 134.5, 134.6, 135.8, 136.0, 136.4, 136.7, 139.8, 142.3 ppm; IR (KBr): $\tilde{\nu} = 3066$, 2906, 1447, 1328, 1309, 1144 cm^{-1}; MALDI: m/z: 839 $[M+K]^+$, 823 $[M^+ + Na]$; HRMS calcd for $C_{42}H_{40}O_8S_4Na$ $[M+Na]^+$: 823.1498; found: 823.1497. Elemental analysis calcd for $C_{42}H_{40}O_8S_4$: C 62.98, H 5.03; found: C 62.96, H 5.47%.

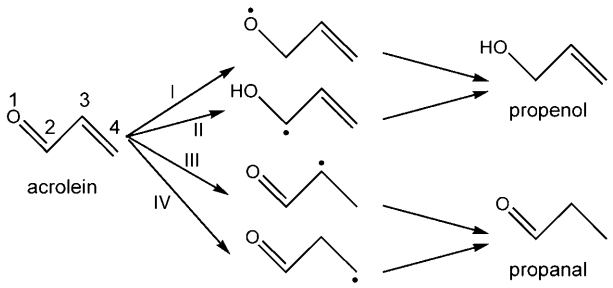
Catalytic Hydrogenation of Unsaturated Aldehydes on Pt(111): Understanding the Selectivity from First-Principles Calculations**

David Loffreda, Françoise Delbecq, Fabienne Vigné, and Philippe Sautet*

Selectivity is an essential aspect of chemistry in general and of heterogeneous catalysis in particular. It is commonly acknowledged that the C=C bond is more reactive than the C=O bond in the hydrogenation on metal surfaces of molecules with a vinyl or carbonyl bond.[1,2] Hence, according to this statement, the partial hydrogenation of α,β-unsaturated aldehydes containing conjugated C=C and C=O bonds should selectively produce the saturated aldehyde (SAL), which is the thermodynamic product, instead of the unsaturated alcohol (UOL), which is in practice the desired product in the pharmaceutical and fragrance industries. Although this rule is respected for the hydrogenation of acrolein (propenal) on Pt(111), which yields almost exclusively the SAL (93% of propanal versus only 2% of propenol), it is violated for prenal (methylbutenal), for which the selectivity is reversed in favor of the UOL.[2,3] Thus, understanding the selectivity requires a thorough knowledge of all the competitive steps involved in the reaction mechanism.



In this study we combine first-principles calculations for the exploration of elementary reaction steps and a kinetic model to understand how selectivity is controlled for a chemo-regioselective reaction occurring on a metallic surface. The simplest system chosen for illustration is the hydrogenation of acrolein (CH_2=CH−HC=O) on a Pt(111) catalyst which leads to the competitive formation of propanal (CH_3−CH_2−HC=O) and propenol (CH_2=CH−CH_2−OH).

The adsorption of acrolein has been previously studied on Pt(111)[4] and on Pt/Sn alloys.[5] Reaction barriers on Pt(111) and on Ag(111) have recently been proposed from an empirical approach with no connection with a kinetic model.[6] Our calculations are performed in the density-functional theory (DFT) periodic formalism. Only the hydrogenation pathways starting from the most stable adsorbed structure (the planar η^4-*trans* geometry where both C=C and C=O bonds interact with the surface) are considered here. This is not an important limitation since the molecule can easily adapt its geometry prior to hydrogenation in the approach used for calculating the reaction pathways.

Exploring the hydrogenation of such a molecule remains a complex task. There are four possibilities for the attack of the first H atom that give four surface intermediates adsorbed on the surface (Scheme 1). For each of them, there are three

Scheme 1. Competitive hydrogenation routes of an acrolein molecule (propenal). The first hydrogenation intermediates (allyloxy, hydroxyallyl, 1-formylethyl, and 2-formylethyl for pathways I, II, III, and IV, respectively) and the products in competition (propenol (UOL) and propanal (SAL)) are shown.

possibilities to add a second H atom, but the present study is limited to the formation of the unsaturated closed-shell species through further hydrogenation of the previously attacked double bond. The adsorbed propenol and propanal can then desorb, or be further hydrogenated (an event which will not be considered here).

First, the four surface intermediates are optimized on the Pt surface. In all cases, both the remaining double bond and the non-hydrogenated site interact with the surface to give structures bound by three atoms (η^3,μ_3). The adsorbed hydroxyallyl intermediate is much more stable than the other ones (Figure 1). As in the final products, propenol adsorbs through the C=C bond (η^2,μ_2) without participation of the O atom, and with an adsorption energy (104 kJ mol^{-1}) similar to that of η^4-*trans*-acrolein (102 kJ mol^{-1}). In contrast, the adsorption of propanal is weaker (22 kJ mol^{-1}) and can occur either through the C=O bond (η^2,μ_2) or through the O atom (η^1,μ_1).[7]

Several coadsorption geometries have been tested for a hydrogen atom and the adsorbate to be hydrogenated—either acrolein or the surface intermediates. The coadsorption states are 4 to 10 kJ mol^{-1} less stable than the reference state (adsorbate and H atom at an infinite distance on the surface). Generally, the H atom is in a ternary site, and less commonly in a bridging or a top position. For each reaction step, one coadsorption geometry is selected as the precursor state of the reaction, depending on the considered reactant.

The first hydrogenation on a C atom of the C=C bond has an energy barrier of 91 and 89 kJ mol^{-1} (see pathways III and IV, respectively, in Figure 1). This barrier is lowered to 60 kJ mol^{-1} for the attack on the C=O bond (see pathway I in Figure 1). The hydrogenation on the O atom (pathway II) occurs in three steps. First, the H atom migrates from one ternary site to another one closer to the molecule while the C=O bond decoordinates from the surface to give a (η^2,μ_2) precursor state (not shown in Figure 1). Then the H atom migrates again to a top position from which the hydrogenation occurs. The overall barrier associated with pathway II is 40 kJ mol^{-1}, hence the lowest one.

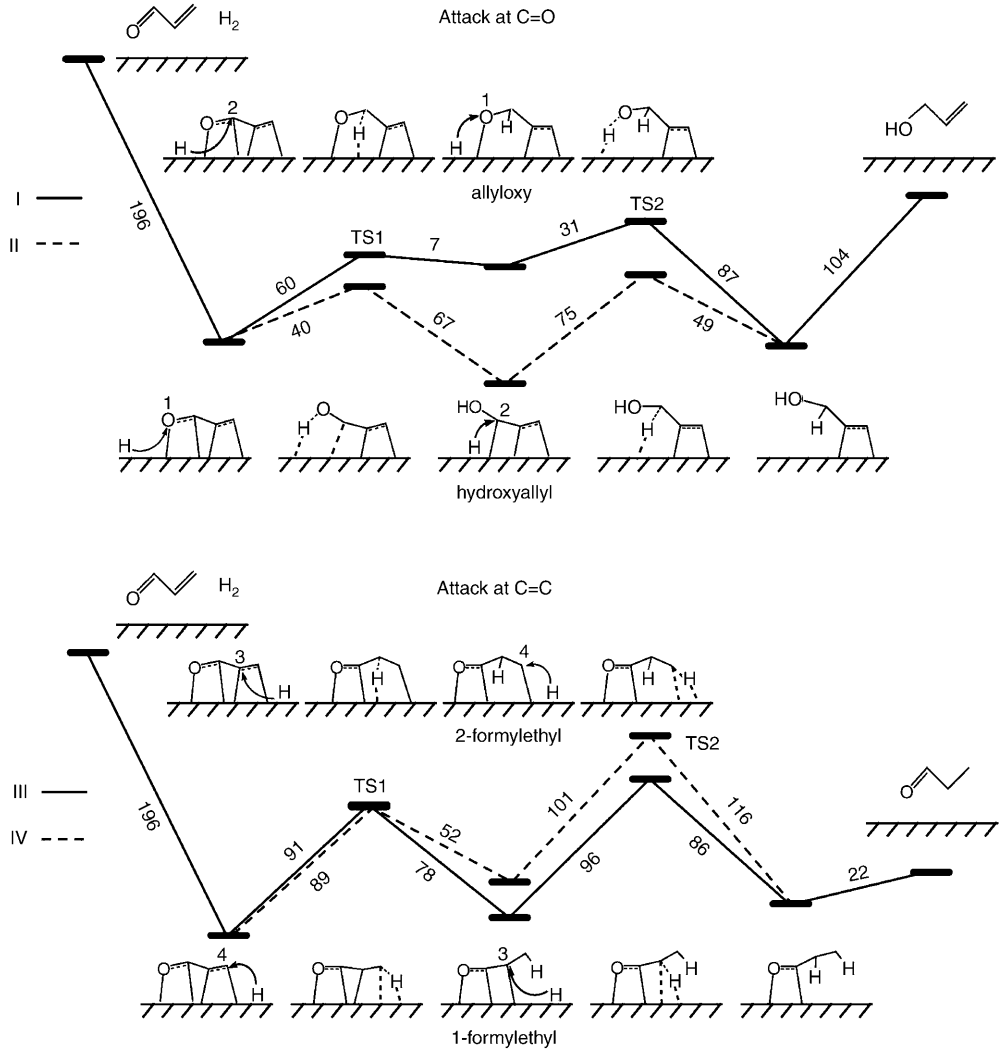

Figure 1. Energy profiles of hydrogenation pathways for acrolein on Pt(111): attack on the C=O bond (pathways I and II) and on the C=C bond (pathways III and IV). The energies (kJ mol^{-1}) refer to the initial state (H_2 + acrolein, gas phase). The adsorption energies of acrolein and two hydrogen atoms are summed in the initial coadsorption state. The transition states are labeled TS1 and TS2 for the first and the second hydrogenation, respectively.

The second hydrogenation takes place at a C atom for pathways II–IV. There is again a high barrier to the second attack at the C=C bond (96 and 101 kJ mol^{-1} for pathways III and IV, respectively) while the final saturation of the C=O bond is easier (75 kJ mol^{-1}, pathway II). The barrier for the attack at the O atom (pathway I) is again the lowest one (31 kJ mol^{-1}), with a mechanism similar to the one calculated for the first hydrogenation step. One important comment is that the barriers calculated by DFT differ significantly from the empirical results reported previously, with a maximum deviation of 100 kJ mol^{-1}.[6]

In agreement with the Hammond principle, the activation energy is small when the step is exothermic. This is the case for the hydrogenation on oxygen where the transition states are similar to the initial states with long OH bonds (1.60–1.63 Å, see Figure 2). In contrast, attack on the C=C

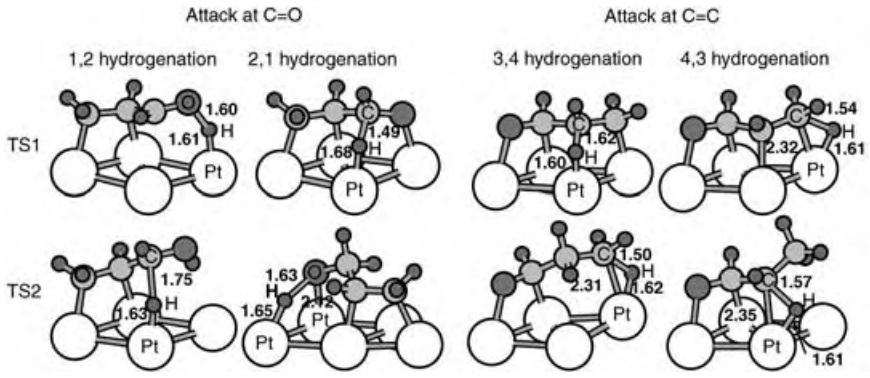

Figure 2. Geometries of the transition states for the first (TS1) and second (TS2) hydrogenation steps of acrolein on a Pt(111) catalyst. In each case, the lengths of the formed C–H or O–H bonds and the broken Pt–H bonds are given in Å.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

bond is mainly endothermic and the CH bonds formed are short (1.50–1.62 Å) in the corresponding transition states.

In summary, all the surface reaction barriers for hydrogenation of the C=O bond (pathways I and II) are smaller than those for hydrogenation of the C=C bond (pathways III and IV), which is opposite to the generally assumed hypothesis. These low energy barriers might suggest that the formation of propenol on the surface is a facile process, which is in apparent disagreement with the selective formation of propanal found experimentally. However, desorption of the product from the surface is a necessary last step. This step, which is found to be non-activated, is much easier for propanal (22 kJ mol^{-1}) than for propenol (104 kJ mol^{-1}). The key of the selectivity therefore resides in the competition between the surface reaction barriers and the desorption endothermicity.

The determination of the final balance between these two effects and of the product mixture thus requires a kinetic treatment. The fundamental assumptions of our model have been developed in the literature previously.[8] The elementary steps considered in the model are depicted in steps 1–7.

$$\text{(l)}\quad H_{2(gas)} \Leftrightarrow 2H_{(ads)}$$

$$\text{(2)}\quad \text{propenal}_{(gas)} \Leftrightarrow \text{propenal}_{(ads)}$$

$$\text{(3)}\quad \text{propenal}_{(ads)} + H_{(ads)} \Leftrightarrow \begin{cases} \text{allyloxy}_{(ads)} \\ \text{hydroxyallyl}_{(ads)} \\ \text{1-formylethyl}_{(ads)} \\ \text{2-formylethyl}_{(ads)} \end{cases}$$

$$\text{(4)}\quad \left.\begin{matrix} \text{allyloxy}_{(ads)} + H_{(ads)} \\ \text{hydroxyallyl}_{(ads)} + H_{(ads)} \end{matrix}\right\} \Leftrightarrow \text{propenol}_{(ads)}$$

$$\text{(5)}\quad \left.\begin{matrix} \text{1-formylethyl}_{(ads)} + H_{(ads)} \\ \text{2-formylethyl}_{(ads)} + H_{(ads)} \end{matrix}\right\} \Leftrightarrow \text{propanal}_{(ads)}$$

$$\text{(6)}\quad \text{propenol}_{(ads)} \Leftrightarrow \text{propenol}_{(gas)}$$

$$\text{(7)}\quad \text{propanal}_{(ads)} \Leftrightarrow \text{propanal}_{(gas)}$$

Steps 1 and 2 correspond to the adsorption of the two reactants, H_2 and propenal, respectively. Step 3 corresponds to the competitive first hydrogenation steps on the surface that lead to the four partially hydrogenated intermediates. In steps 4 and 5, a second H atom further hydrogenates the intermediates on the surface to yield the products (propenol and propanal); these steps are in competition. Steps 6 and 7 are the desorption steps of the products.

The partial pressures of the gas reactants are kept constant in our kinetic model. The adsorption (acrolein and H_2) and the desorption (propenol and propanal) steps are considered to be equilibrated, so the initial coverages of the reactants are imposed by the temperature and the partial pressures. The rate constants are calculated from our DFT activation barriers by using the transition-state theory,[9] and no empirical data are used. All the surface intermediate coverages are obtained by integration of the set of nonlinear differential equations with time. The selectivity is defined from the partial pressures of the desorbed products. An almost 100% selectivity to propanal is obtained from a mixture of acrolein (30 Torr) and hydrogen (900 Torr) at 350 K, a result which is in close agreement with experiments and which can be qualitatively related to the energy profiles. The rate-limiting step in the hydrogenation of the C=O bond is the product desorption, with a barrier of 104 kJ mol^{-1}, whereas for the hydrogenation of the C=C bond, it is the formation of the second C–H bond (101 kJ mol^{-1}). This second pathway is thus favored and propanal is selectively formed. The hydroxyallyl intermediate and hydrogen are the main species adsorbed during the reaction. The coverage of propenol increases on the surface, while propanal rapidly desorbs without accumulation. Hence, the species which is present to the greatest extent on the surface is not associated with the most abundant gas-phase product. As a result, product desorption appears to be a key factor in determining the reaction selectivity and can be used as a tuning parameter. If the energy for the desorption of propenol is numerically decreased by 30 kJ mol^{-1} without changing the other barriers, the calculated selectivity is reversed in favor of the unsaturated alcohol. This could explain qualitatively the change of selectivity observed experimentally for other reactants such as prenal on Pt(111), for which the desorption barriers of the corresponding UOL are decreased by this amount. Clearly, the determination of the other barriers are required to provide fully reliable conclusions in these other cases.

In this study, the partial hydrogenation of the C=C or the C=O bonds of acrolein on a Pt(111) catalyst has been studied by a theoretical approach based on first-principles calculations and a kinetic model. Total energy calculations have shown that the selectivity between the two competing products is controlled by the balance between the hydrogenation steps on the surface and the desorption of the partially hydrogenated products. The surface steps favor the attack at the C=O moiety to yield propenol, whereas desorption is easier for the product arising from the attack at the C=C bond (propanal). The kinetic model shows that the desorption step controls the selectivity in this case and almost 100% of propanal is obtained for a simulation under catalytic conditions (350 K and respective partial pressures of 30 and 900 Torr for acrolein and hydrogen reactants, respectively). Hence, the desorption energy of the product appears to be the critical tuning parameter for the selectivity.

Experimental Section

All the calculations were performed with the DFT formalism with the plane wave based VASP code.[10] The projector-augmented wave method[11] and the Perdew Wang 91 generalized gradient approximation[12] were used. The plane wave cutoff was set to 400 eV. The Pt(111) surface was modeled by a periodic four-layer slab with a vacuum region equivalent to five Pt layers. Adsorption took place on one side of the slab. A 3×3 unit cell was considered and gave a coverage of 1/9 monolayer. The Brillouin zone integration was performed on a $3 \times 3 \times 1$ grid. For the stationary points, the positions of the adsorbate and of the two uppermost layers were optimized. There are two main sources of error in the DFT adsorption energy: the systematic error arising from the limited thickness of the metallic slab, which is the largest one (10 kJ mol^{-1}), and the numerical error arising from the choice of the basis set and the k-point mesh, which is smaller (5 kJ mol^{-1}). The search for the transition states (TS) was performed with the climbing-image nudged elastic band method (CI-NEB).[13] The considered reaction surface intermediates did not show a spin-polarized electronic structure after adsorption. The transition-state structures were characterized by a vibrational analysis which showed one pure imaginary frequency.

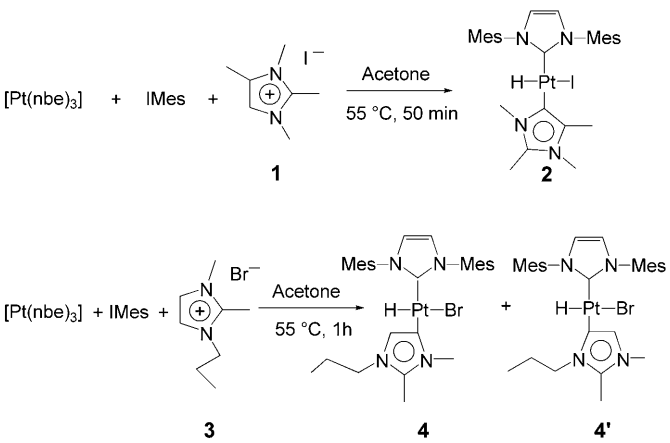
Carbene Ligands

DOI: 10.1002/anie.200500884

Platinum-Mediated Oxidative Addition and Reductive Elimination of Imidazolium Salts at C4 and C5**



Deborha Bacciu, Kingsley J. Cavell, Ian A. Fallis, and Li-ling Ooi*

Nucleophilic N-heterocyclic carbenes (NHCs) have attracted considerable interest as ligands in organometallic chemistry and catalysis.[1] This attention is largely because of the unique combination of strong σ-donor, poor π-acceptor, and steric properties.[2] Typical transition-metal NHC complexes show "normal" binding at C2 because of the acidity of the C2 proton in the precursor azolium salt.[3] "Abnormal" metalation at C5 of the NHC ring was first reported in elegant studies by Crabtree and co-workers for pyridyl- and picolyl-NHC dihydride complexes of Ir^{III};[4] blocking C2 with a substituent, such as Me or Ph groups, will also encourage binding at C5.[5] Nolan and co-workers have recently reported the structure and interesting catalytic reactivity of $[PdCl_2(NHC)_2]$ complexes containing NHC ligands bound the "wrong way" that are derived from imidazolium salts.[6] In both these studies, the carbene bound at C4/5 was generated through deprotonation by the addition of a base or use of basic ligands on the metal.

In previous studies on metal–carbene complexes, we identified a facile reductive-elimination process, in which the carbene is lost as an imidazolium salt.[7] Conversely, it was found that imidazolium salts (ionic liquids) add oxidatively to low-valent metal centers through C2 activation.[7–9] The combination of these two redox steps lead to a new atom-efficient catalytic reaction for the substitution of azolium salts at C2.[10] The nature of this reaction and its wider implications is of major interest; for example, ionic liquids may add oxidatively to metal complexes dissolved within them, which generates catalytically active (hydrido)metal(carbene) complexes, and ionic liquids may also be incorporated into the reaction products, thus both problems and opportunities are presented.[11]

Herein, we report a novel extension to our investigations on this redox behavior. Platinum hydride complexes have been synthesized that bear NHC ligands in an abnormal binding mode through the oxidative addition of imidazolium salts with the C2 position blocked by a methyl group.

Complexes **2**, **4**, and **4′** were prepared in one-pot reactions by mixing $[Pt(norbornene)_3]$,[12] 1,3-bis(2,4,6-trimethylphenyl)imidazolin-2-ylidene (IMes), and either 1,2,3,4-tetramethylimidazolium iodide (**1**), in the case of **2**, or 1,2-dimethyl-3-propylimidazolium bromide (**3**), in the case of **4** and **4′**, in a molar ratio of 1:1:1.8 (Scheme 1). The reactions yielded the desired products after washing the crude residues with *n*-hexane and extraction with THF. It is proposed that the reactions proceed through the initial

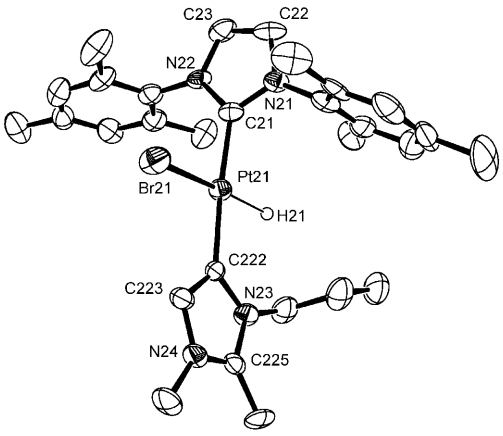
formation of a [Pt(IMes)(norbornene)$_2$] complex, which then undergoes oxidative addition of the C4,5–H bond of the imidazolium salt. This one-pot reaction provides a potentially valuable route to "wrong-way" (hydrido)metal(carbene) complexes, which may have applications in catalysis.

Complexes **4** and **4′** were characterized by ^{1}H and ^{13}C NMR spectroscopic analysis, which revealed a mixture of two isomers in a ratio of 3:1. The platinum center in the minor component **4′** is connected to C4, which is the carbon atom closest to the *N*-propyl chain, whereas the platinum center in the major component **4** is connected to C5, which is the carbon atom adjacent to the *N*-methyl group. Steric influences may produce the observed regioselectivity.

The hydride ligands in **4** and **4′** appear in the ^{1}H NMR spectra (CD_2Cl_2) at $\delta = -18.29$ ppm (^1J(Pt-H) = 1714 Hz) and $\delta = -18.31$ ppm (^1J(Pt-H) = 1711 Hz), respectively. The ^{13}C NMR spectra of **4** and **4′** show characteristic signals from C2 of the IMes unit at $\delta = 180.9$ and 180.7 ppm, respectively, and from C4 and C5 of the abnormal carbene moiety at $\delta = 124.4$ and 151.6 ppm for **4**, respectively, and at $\delta = 152.4$ and 126.3 ppm for **4′**, respectively. The presence of a metal-bound carbene is also indicated by the ^{13}C{^{1}H} NMR spectra, in which the signals from C4 and C5 in **4** and **4′** are shifted downfield relative to **3**. The ^{13}C NMR resonances for C4 and C5 are comparable with previously reported abnormally bound carbenes.[5,13]

A mixture of crystalline needles (**4′**) and plates (**4**) was grown by slow diffusion of hexane into a saturated solution of the crude product in acetone. Only the needles were found to be suitable for single-crystal X-ray analysis, and they showed an abnormally bound Pt carbene complex (Figure 1). The crystal contains one acetone molecule and two Pt carbene complexes in the asymmetric unit. Both Pt carbene complexes in the crystal are identical within experimental error. The molecular structure of **4′**[14] shows a slightly distorted square-planar coordination around the Pt^{II} center, with *trans*-NHC moieties and hydride and bromide ligands occupying the remaining coordination sites. The Pt–C(carbene) bond lengths for the IMes ligand (Pt21–C21: 2.018(8) Å) and for the carbene ligand coordinated at C5 (Pt21–C223: 2.041(8) Å) are comparable and consistent with Pt–C single bonds.[5,6,13,15]



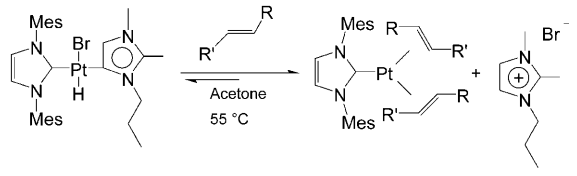


Figure 1. ORTEP diagram of **4′**. Some hydrogen atoms, the acetone molecule, and a molecule of **4′** are omitted for clarity. Selected bond lengths [Å] and angles [°]: Pt21-C21 2.018(8), Pt2-C222 2.041(8), Pt21-Br21 2.5622(9), Pt21-H21 1.8052, C21-Pt(21)-C222 175.6(3); C21-Pt21-Br21 91.4(2), C21-Pt21-H21 93.1, C222-Pt21-Br21 90.0(2), C222-Pt21-H21 85.2, Br21-Pt21-H21 173.2.

Although the mixture of **4** and **4′** is stable, both in the solid state and in solution with acetone at room temperature over two–three days, the mixture underwent reductive elimination[10,16,17] in the presence of alkenes (styrene or dimethyl fumarate) to regenerate **3** and form [Pt(η^2-alkene)$_2$(IMes)] complexes **5a** and **5b** (Scheme 2). Stirring a mixture of **4** and **4′** with five equivalents of dimethyl fumarate in acetone for three hours resulted in quantitative reductive elimination.[8] The equivalent reaction with styrene resulted in partial conversion with equilibrium concentrations of **4**, **4′**, **5**, and **3** being established.[16] The ^{1}H NMR spectrum of **5a** was identical to that observed for an authentic sample of [Pt(dimethyl fumarate)$_2$(IMes)] prepared by the reaction of [Pt(cod)$_2$] (cod = cyclooctadiene), IMes, and dimethyl fumarate.

5a: R = R' = COOMe t = 3 h 100%
5b: R = Ph, R' = H t = 8 h 50%

Scheme 2. Reductive elimination of imidazolium salts at C4/5–H from "abnormal" carbene complexes.

The observed reductive-elimination behavior is consistent with the π-acceptor ability of alkenes, the distribution of electron density within the complex, and the Pt–alkene bond strength. Interestingly, reductive elimination of the "normal" carbene and the products that result from insertion of alkenes into the Pt–H bond (e.g., Pt hydrocarbyl complexes or imidazolium salts substituted at C4/5) were not observed. The behavior reported herein provides clear indication that the substitution of ionic liquids at C2 may not be enough to prevent their involvement in reactions for which they are the solvent.[18]

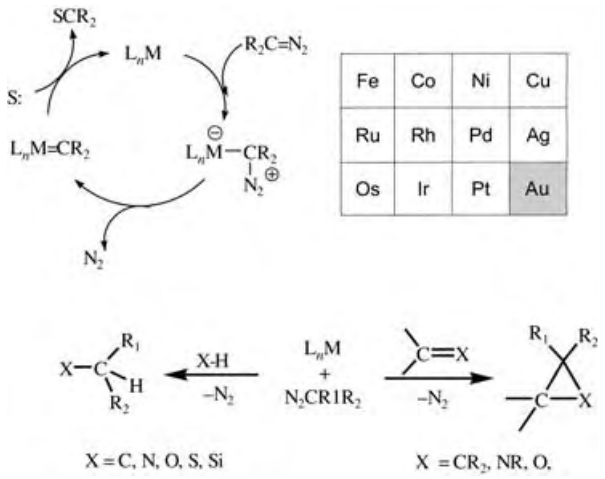
A Gold Catalyst for Carbene-Transfer Reactions from Ethyl Diazoacetate**

Manuel R. Fructos, Tomás R. Belderrain, Pierre de Frémont, Natalie M. Scott, Steven P. Nolan, M. Mar Díaz-Requejo,* and Pedro J. Pérez**

The use of transition-metal-based catalysts for the transfer of carbene units from diazo compounds constitutes a powerful tool in organic synthesis.[1] Several metals have been reported to mediate this transformation effectively, and the appropriate selection of ligands has permitted excellent selectivities. Highly chemo-, diastereo-, and/or enantioselective systems have been reported with rhodium-, copper-, or cobalt-containing catalysts. In fact, nearly all 12 elements of Groups 8–11 have been found to decompose diazo compounds and transfer a carbene unit to saturated or unsaturated organic substrates,[2] leading to the insertion or addition product, respectively (Scheme 1). Only one of these 12 elements remains unexplored in this chemistry: gold.[3] Although the other members of Group 11—copper and, to a lesser extent, silver—have been described to induce such transformations, conducting this type of catalytic reaction with gold remains a challenge. We therefore focused our attention on the development of a gold-based catalyst, as a result of our experience in the area of metal-catalyzed carbene transfer from ethyl diazoacetate (EDA).[4]



We recently reported the catalytic behavior of [(IPr)CuCl] (**1**, IPr = 1,3-bis(diisopropylphenyl)imidazol-2-ylidene) for the transfer of carbene from ethyl diazoacetate to olefins, amines, and alcohols to form cyclopropanes, amino acid derivatives, and ethers, respectively.[5] These promising results

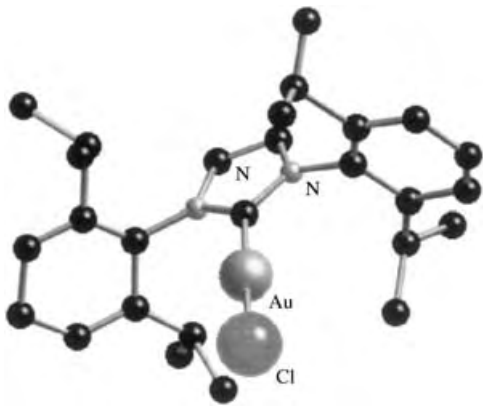
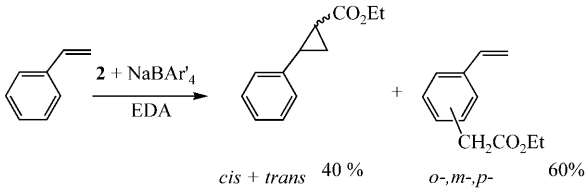
prompted us to examine the potential role of the gold analogue [(IPr)AuCl] (**2**), which was prepared from equimolar amounts of the IPr ligand and [AuCl(SMe$_2$)] [Eq. (1)].[6]

(1)

This new compound was spectroscopically characterized, and its structure confirmed by X-ray diffraction studies (Figure 1). The gold(I) atom is two-coordinate in an essentially linear environment with C-Au-Cl bond angles close to 180°, an arrangement similar to that previously found for **1**.





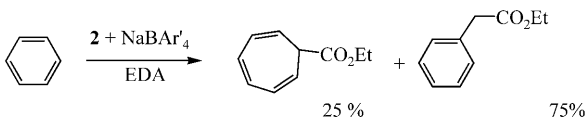


Figure 1. Ball-and-stick view of complex **2**; hydrogen atoms have been omitted for clarity.

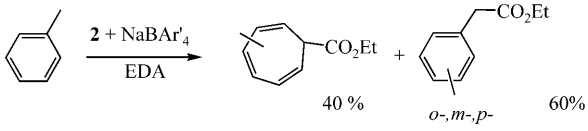


Once prepared and characterized, complex **2** was employed as a catalyst for the cyclopropanation of styrene with ethyl diazoacetate, a well-known model reaction. Our previous work with the copper complex **1** suggested that the chloride ion had to be removed from the metal center prior to reaction with EDA.[5] We therefore employed a modified method in which the active catalytic species was generated in situ by using an equimolar mixture of **2** and the sodium salt of the non-coordinating anion tetrakis(3,5-bis(trifluoromethyl)phenyl)borate (BAr′$_4$). The use of a 2.5% catalyst loading (with respect to EDA) in neat styrene (1 mL) led to the consumption of EDA within a few minutes (see the Experimental Section). Analysis of the reaction mixture by GC and GCMS showed, besides the expected *cis*- and *trans*-cyclopropanes, three other products with the same molar mass, namely, the *o*, *m*, and *p* isomers of the styryl acetate shown in Equation (2). These additional products are formed

(2)

(3)

(4)

by the formal insertion of the :CHCO$_2$Et unit into the sp^2 C–H bond of the aromatic ring of the styrene. To the best of our knowledge, this type of intermolecular reaction is unprecedented.[7] All published reports have shown that the double bond of styrene is preferentially converted into the cyclopropane product in this reaction. A second, but nonetheless important feature of this gold catalyst is that no diethyl fumarate or maleate formed as a result of EDA coupling, even though the diazo compound was added to the reaction mixture in one portion.

To see whether this unexpected insertion reaction can be generalized, we examined two common aromatic substrates, benzene and toluene [Eqs. (3), (4); yields determined by NMR spectroscopy]. Previous reports have shown that the metal-catalyzed addition of EDA to these compounds results in the formation of cycloheptatriene rings as the major product.[4h,8] In the case of toluene, a few catalysts have also promoted insertion into the methyl C–H bond to provide the dihydrocinnamate derivative[4h,8,9] but there are no examples of insertion into the aromatic sp^2 C–H bond. In contrast, the use of **2** and NaBAr′$_4$ as the catalyst precursor for the reaction

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of EDA and benzene led to a mixture of the expected cycloheptatriene as well as ethyl phenylacetate [Eq. (3)], the latter formed by formal insertion into the aromatic C–H bond. Similar behavior was observed with toluene as the substrate [Eq. (4)]: The expansion products were observed along with the three isomers of ethyl tolylacetate. The identities of the new products are unambiguous, as their spectroscopic and chromatographic data are identical to those of commercial samples (see the Experimental Section).

No EDA-coupling products—that is, diethyl fumarate and maleate—were observed in the above transformations, highlighting the chemoselectivity of this catalytic system. Even allowing EDA to react with complex **2** at room temperature for several hours did not lead to any transformation of the initial diazo compound. Heating of the reaction mixture at 60 °C and 80 °C did not induce any Au-catalyzed EDA decomposition, therefore indicating the stability of the diazo compound in the presence of **2**, as was observed for the copper analogue **1**.[5]

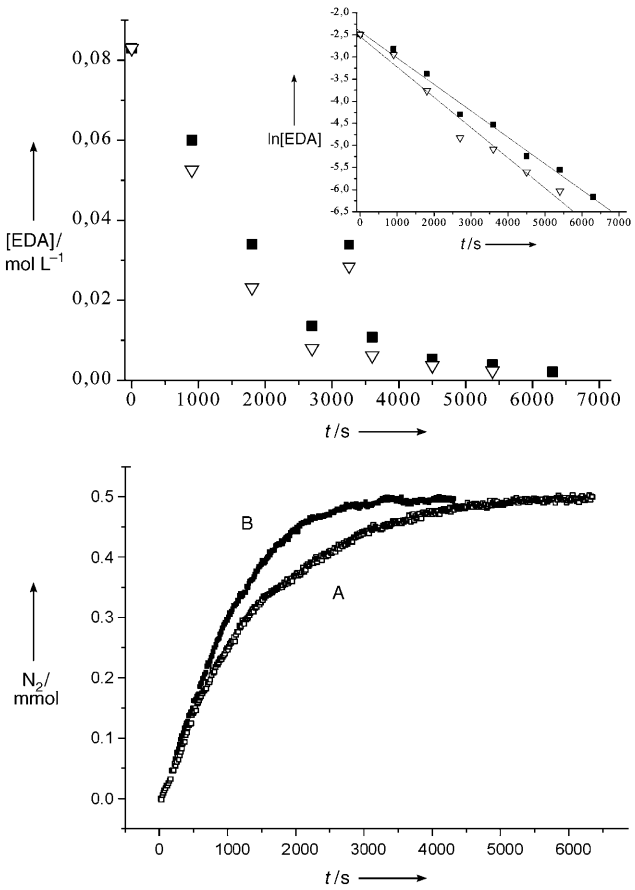
We next screened several substrates to explore the range of activity for the gold system (Table 1). The use of *cis*-cyclooctene as the olefin provided the expected mixture of *exo*- and *endo*-cyclopropanes. The insertion of EDA into N–H and O–H bonds was also studied with amines and alcohols; in all cases the corresponding amino acid derivatives and ethers were obtained quantitatively. Again, no EDA coupling products were detected in the mixture at the end of the reaction.

Table 1: The addition or insertion of EDA catalyzed by **2** + $NaBAr'_4$.

Substrate	Product	Yield [%][a]
		>99[b]
		>99[b]
		>99[b]
CH_3OH	$CH_3OCH_2CO_2Et$	>99[c]
CH_3CH_2OH	$CH_3CH_2OCH_2CO_2Et$	>99[c]

[a] No diethyl fumarate or maleate was detected in any experiment; see the Experimental Section for details. [b] Determined by NMR spectroscopy at the end of the reaction using an internal standard. [c] Determined by GC using an internal standard.

Kinetic experiments were performed using methanol as the substrate with complex **2** as the catalyst precursor both with and without the halide scavenger $NaBAr'_4$. First, the consumption of EDA was monitored in parallel experiments differing only in the presence or absence of $NaBAr'_4$. The two reactions lead to very similar decays that correspond to first-order behavior (Figure 2). Plots of ln[EDA] versus time provided k_{obs} values of 5.98×10^{-4} and $6.84\times10^{-4}\ s^{-1}$ for the experiments carried out in the absence and in the presence of the tetraarylborate anion, respectively; the latter reaction is slightly faster but of the same order of magnitude. Nearly identical values for k_{obs} were obtained from experiments in which the nitrogen evolution was measured (7.94×10^{-4} and $1.05\times10^{-3}\ s^{-1}$, respectively). These values compare well with those obtained from monitoring EDA consumption.



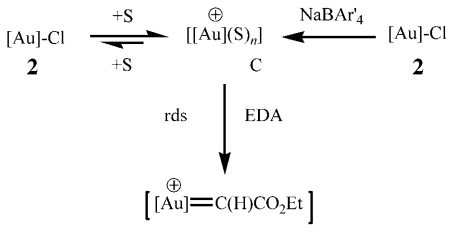


Figure 2. Top: Plot showing the consumption of EDA in the reaction of methanol and ethyl diazoacetate with **2** as catalyst in the absence (■) and presence of $NaBAr'_4$ (▽). Inset: Plot of ln[EDA] versus time t from which the following k_{obs} values were obtained: **2** as catalyst: $k_{obs}=5.98\times10^{-4}\ s^{-1}$; **2** + $NaBAr'_4$ as catalyst: $k_{obs}=6.84\times10^{-4}\ s^{-1}$. Bottom: Plot of nitrogen evolution under the same conditions. Exponential fitting provided the following values: $k_{obs}=7.94\times10^{-4}$ (**2** as catalyst, A), $k_{obs}=1.05\times10^{-3}\ s^{-1}$ (**2** + $NaBAr'_4$ as catalyst, B).

Scheme 2 illustrates a possible explanation for the experimental kinetic data. A cationic species **C**, probably containing coordinated methanol, is formed in both instances. The addition of $NaBAr'_4$ promotes the quantitative conversion of **2** into such a species; however, in the absence of $NaBAr'_4$, an equilibrium between the neutral **2** and the cationic **C** takes place. This also explains the slightly more sluggish reaction with **2** as catalyst since the amount of **C** is not equal to the

Scheme 2. Proposed mechanism for the generation of the catalytic species.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

initial amount of **2**. In contrast, the use of the arylborate salt ensures that $[\mathbf{C}] = [\mathbf{2}]_{init}$. The catalytic cycle starts from **C**, and the rate-determining step is the formation of a metallocarbene intermediate, as commonly proposed for this type of transformation.[1]. The observation of very similar rate constants from the monitoring of nitrogen generation and EDA consumption is in line with the absence of fumarate and maleate products.

In conclusion, we have described the first example of a gold-based catalyst for the decomposition of ethyl diazoacetate and the subsequent transfer of the :$CHCO_2Et$ unit to saturated and unsaturated substrates: Cyclopropanation of olefins as well as insertion into N–H and O–H bonds have been achieved. Even more interesting is the novel insertion of the carbene units into the C–H bonds of the aromatic ring of benzene, toluene, and styrene. Finally, this catalyst is very chemoselective, since no EDA coupling products are observed in any of the reactions studied.

Experimental Section

General: All reactions were carried out by using standard Schlenk techniques under an atmosphere of dry argon or in an MBraun glovebox containing dry argon or nitrogen. Anhydrous solvents were purchased from Aldrich and degassed prior to use. CD_2Cl_2 was either dried over CaH_2, or degassed with argon and dried over molecular sieves. The reagents (olefins, alcohols, amines) were also purchased from Aldrich and employed without further purification. IPr was synthesized by deprotonation of the imidazolium salt with base according to a literature procedure.[10] The immediate precursor, IPr·HCl, can be purchased from Strem Chemicals Inc. The ^1H and ^{13}C NMR spectra were collected on 400-MHz Varian Gemini and Varian Mercury spectrometers. The GC and GCMS were obtained in Varian 3800 and Saturn 2100 instruments, respectively. Elemental analyses were performed by Robertson Microlit Laboratories, Madison, NJ.

2: In a glove box a 100-mL Schenk flask was charged with IPr (686 mg, 1.8 mmol) and THF (35 mL), and then [AuCl(SMe_2)] (232 mg, 0.80 mmol) was added. The resulting solution was stirred at room temperature for 12 h. The solvent was removed under vacuum, and CH_2Cl_2 (5 mL) was added. The colorless solution was filtered, and hexane (10 mL) was added to the filtrate, resulting in precipitation of an off-white solid. The solid was washed with hexane (3×5 mL) and dried under vacuum. Yield: 770 mg (69 %). ^1H NMR (400 MHz, CD_2Cl_2): $\delta = 7.57$ (t, $J = 7.8$ Hz, 2H; ArH), 7.35 (d, $J = 7.8$ Hz, 4H; ArH), 7.24 (s, 2H; Imid-H), 2.57 (septet, $J = 6.8$ Hz, 4H; $CH(CH_3)_2$), 1.34 (d, $J = 6.8$ Hz, 12H; $CH(CH_3)_2$), 1.23 ppm (d, $J = 6.8$ Hz, 12H; $CH(CH_3)_2$); $^{13}C\{^1H\}$ NMR (125 MHz, CD_2Cl_2): $\delta =$ 175.09 ($C_{carbene}$), 145.78 (C_{Ar}), 134.05 (C_{Ar}), 130.68 (C_{Ar}), 124.28 (C_{Ar}), 123.32 (C_{imid}), 28.79 ($CH(CH_3)_2$), 24.17 ($CH(CH_3)_2$), 23.74 ppm ($CH(CH_3)_2$); elemental analysis: calcd for $C_{27}H_{36}N_2AuCl$ (621.69): C 52.11, H 5.79, N 4.50; found: C 51.70, H 5.61, N 4.38. Suitable crystals for crystallographic study were grown by slow evaporation of a saturated solution in acetone. CCDC-258274 (**2**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Catalytic experiments: The precatalyst **2** (0.025 mmol) was dissolved in neat substrate (1–3 mL), and $NaBAr'_4$[11] (1 equiv) was added to the solution. After 15 min of stirring, EDA (0.5 mmol) was added in one portion. After 1 h of additional stirring, the mixture was analyzed by GC and GCMS. The volatile components were then removed, and the residue analyzed by NMR spectroscopy to identify the products (see the Supporting Information). To establish the mass balance, an internal standard was employed.

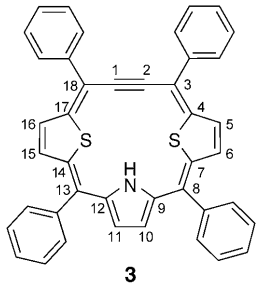
Dithiaethyneporphyrin: An Atypical [18]Triphyrin(4.1.1) Frame for Contracted Porphyrins**

Anna Berlicka, Lechosław Latos-Grażyński, and Tadeusz Lis*

The aza-deficent porphyrin 5,10,15,20-tetraaryl-21-vacataporphyrin (butadieneporphyrin, [18]triphyrin(6.1.1); **1**) is an

1



X, Y, Z = S, O, NH, NR

2

annulene–porphyrin hybrid.[1] In principle, vacataporphyrin **1** (paradoxically expanded porphyrin)[2–4] can be considered as a seminal molecule for the subclass of triphyrins, which are distinguished by the fact that they contain only three pyrrole or pyrrole-like rings, linked by two sp^2-hybridized *meso* carbon atoms to form the tripyrrolic brace. The macrocyclic structure of triphyrins is completed by a single chain of sp^2- and/or sp-hybridized carbon atoms. Besides vacataporphyrin, only [15]triphyrin(1.1.3), which was obtained serendipitously during the condensation of triisopropylsilyl propynal with 3,4-diethylpyrrole, meets the criterion outlined above.[5] Alternatively, the replacement of the six inner protons of [18]annulene by three oxygen, sulfur, or NH (NR) groups, or some combination of the three, as explored originally by Badger et al., leads to heteroatom-bridged annulenes **2**; that is, [18]triphyrin(2.2.2) or [18]heterotriphyrin(2.2.2).[6–8]

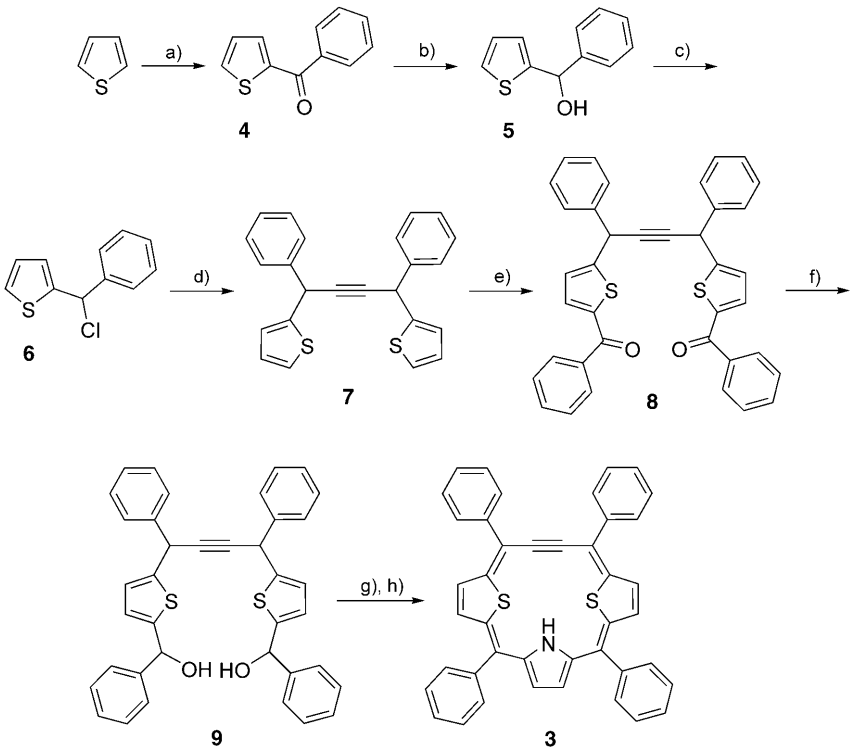
Herein, we report the synthesis and characterization of 3,8,13,18-tetraphenyl-19,21-dithiaethyneporphyrin (H(S_2-ETPP); **3**). This porphyrin derivative is a novel type of

3

contracted heteroporphyrin related to putative [18]triphyrin-(4.1.1) with an acetylene moiety embedded in the macrocyclic framework. It introduces a unique structural pattern for contracted porphyrins,[2,4] created by fusing the structural motifs of 21,23-dithiaporphyrin and acetylene.

The synthetic strategy for **3** (Scheme 1) resembles the [3+1] approach applied to prepare porphyrins, heteroporphyrins, and carbaporphyrinoids.[9] Retrosynthetic analysis led to the identification of 1,4-di(2-thienyl)-1,4-diphenyl-2-butyne (**7**) as the fundamental building block for the construction of **3**. Eventually, dithiaethyneporphyrin **3** was formed through a condensation reaction that is similar to the [3+1] procedure for porphyrins, although the *meso* carbon atoms here originated from **9** rather than the usual monopyrrolic fragment (12.7% yield).

The electronic spectrum of **3** (Figure 1) shows a distinct intense Soret-like band at $\lambda = 448$ nm accompanied by less-intense Q bands at 518, 553, 646, and 725 nm, resembling the spectroscopic features of aromatic 5,10,15,20-tetraphenyl-21,23-dithiaporphyrin, S_2TPP.[10] The ^{1}H NMR spectrum of **3** also resembled that of S_2TPP[10] and displayed resonances at positions consistent with an aromatic structure: porphyrinoid **3** retains macrocyclic aromaticity through an 18-π-electron delocalization motif. The scalar coupling detected between NH20 and the β-pyrrolic protons H10 and H11 confirms the molecular structure of **3** (Figure 2). The ^{13}C NMR chemical shifts of the four-carbon linker derived from 2-butyne reveals a symmetric structure, with $\delta = 116.8$ ppm for C1 and C2 and $\delta = 111.9$ ppm for C3 and C18.



Two canonical structures of **3** define 18-π-electron macrocyclic delocalization pathways (Scheme 2). Accordingly, the

Scheme 2. Canonical structures of **3**.

electronic structure of **3** can be described as reflecting a combination of acetylene (=C–C≡C–C=) and cumulene (–C=C=C=C–) character of the C18-C1-C2-C3 fragment. The relevant chemical shift values of carbon atoms for acetylene or cumulene units attached adjacent to aryl or 2-thienyl moieties were considered for comparison. The sp-hybridized carbon atoms of intermediate **7** gave a ^{13}C NMR signal at $\delta = 84.4$ ppm, that is, in the $\delta = 70$–95 ppm range typical for acetylene. Similarly, the ^{13}C NMR chemical shifts of cumulene fragments vary over quite a wide range: $\delta = 140.5$ ppm for tetra(2-thienyl)butatriene,[11] $\delta = 152.0$ ppm for tetraphenylbutatriene,[12] and $\delta = 134.5$ ppm for 6,7,18,19-tetradehydrotetrathia[24]annulene(4.0.4.0) (some admixture of the acetylenic structure was suggested for the latter structure).[13] Thus the ^{13}C NMR chemical shifts of **3** point out that canonical structure $\mathbf{3}_{ac}$ and $\mathbf{3}_{cum}$ (ac = acetylene; cum = cumulene) contribute to the overall electronic structure, although the acetylene character of the C_{sp}–C_{sp} moiety prevails. The detected chemical shifts of **3** were fairly typical for acetylene–cumulene porphyrinoids[14,15] and acetylene–cumulene annulenes.[16]

The structure of **3** was determined by X-ray diffraction studies and is shown in Figure 3.[17] The S···S distance is short

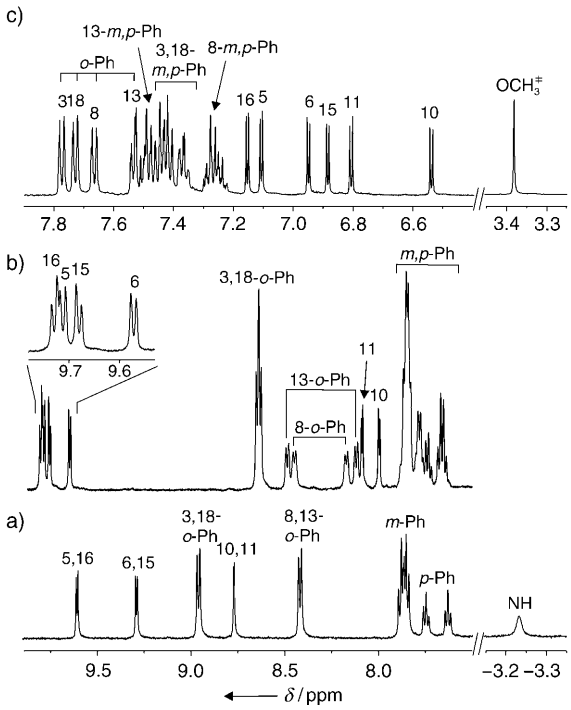

Figure 2. ^1H NMR spectra of a) **3** ($CDCl_3$, 298 K), b) **10** ($CDCl_3$, 240 K), and c) **11** (CD_2Cl_2, 298 K). Peak labels correspond to systematic position numbering or denote proton groups such as *o*,*m*,*p* positions of the *meso*-phenyl groups. Chemical shift values are relative to TMS (tetramethylsilane: $\delta = 0$ ppm). (≠): the intensity of the OCH_3 signal has been decreased by a factor of 5.

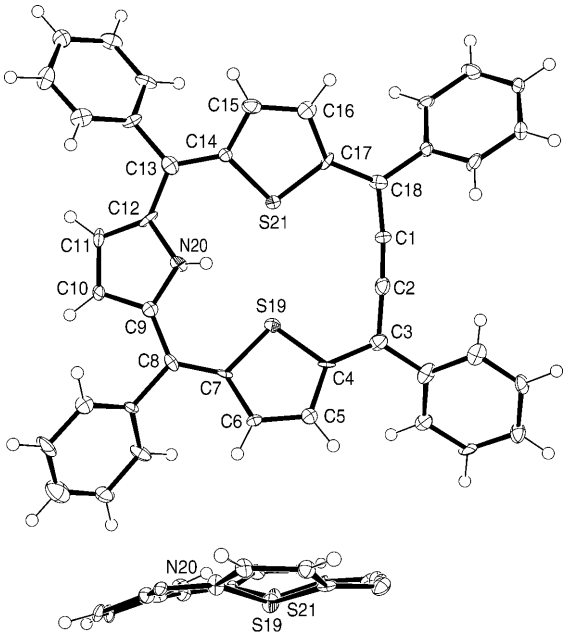

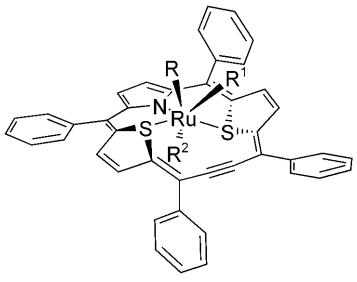

Figure 3. Crystal structure of dithiaethyneporphyrin **3**: a) top and b) side view (phenyl groups are omitted for clarity). The vibrational ellipsoids represent 50% probability. The bond lengths in the $C_{sp^2}C_{sp}C_{sp}C_{sp^2}$ (C18-C1-C2-C3) unit are 1.390(9) Å, 1.231(10) Å, and 1.418(10) Å, respectively. The dihedral angles between the plane defined by the four *meso* carbon atoms (C3, C8, C13, C18) and the planes of the five-membered rings are as follows: thiophene(S19) −19.0(2)°, pyrrole 17.6(3)°, thiophene(S21) −18.0(3)°.

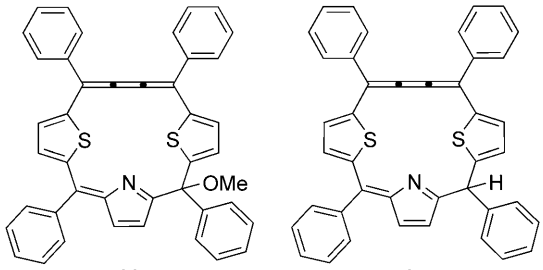
(3.113(3) Å), and only a small number of compounds that contain such close sulfur–sulfur contacts have been reported.[13,18–20] The C_{sp^2}-C_{sp}-C_{sp}-C_{sp^2} butyne moiety reveals a slight distortion from linearity, showing a bowlike deformation directed outward of the macrocycle (C18-C1-C2: 174.0(9)°; C1-C2-C3: 176.6(9)°).



Treatment of **3** with $[Ru_3(CO)_{12}]$ in chlorobenzene resulted in formation of $[(S_2ETPP)Ru^{II}(CO)_2Cl]$ (**10**), as

10: R, R^1, R^2 equal Cl and two CO

confirmed by high-resolution mass spectrometry. The ^{1}H NMR spectrum of complex **10** revealed a lowering of symmetry relative to **3**. The geometry of **10** as inferred from the ^{1}H NMR spectroscopic pattern (Figure 2b) reflects the balance between constraints of the macrocyclic ligand and the coordination requirement of ruthenium(II) for octahedral geometry. Dithiaethyneporphyrin **3** has to distort to accommodate Ru^{II} binding. Consequently, the two thiophene rings are severely tilted in opposite directions with respect to the macrocyclic plane to allow the pyramidal side-on coordination of ruthenium(II), in a similar manner as detected for $[(S_2TPP)Ru^{II}Cl_2]$.[21] The puckering of dithiaethyneporphyrin and the difference in coordination above and below the porphyrin plane explains the observed lowering of symmetry of **10** relative to **3**. The 2-butyne fragment is not involved in coordination, as the ^{13}C chemical shifts of non-equivalent atoms C1 and C2 in **10** ($\delta = 111.1$ and 113.7 ppm) resemble those for **3**.

Dithiaethyneporphyrin **3** reacts regioselectively with methanol (or ethanol) in the presence of silver acetate to produce *iso*-8-methoxy-3,8,13,18-tetraphenyl-19,21-dithiaethyneporphyrin (**11**). Derivative **11** is related to a feasible

11 *iso*-**3**

non-aromatic isomer of **3**, that is, *iso*-dithiaethyneporphyrin, *iso*-**3**. The UV/Vis spectrum of **11** confirms a loss of aromaticity, as evident by the smaller extinction coefficients (Figure 1). The ^{1}H NMR resonances of **11** were detected in the region that is typical for the conjugated but non-aromatic system. The ^{13}C NMR shift of C8 ($\delta = 83.1$ ppm) is consistent with its tetrahedral geometry, whereas those of atoms C1 and C2 ($\delta = 143.8$ and 147.2 ppm) comply with a cumulenic structure. Treatment of **11** with gaseous HCl results in partial recovery of **3**.

In conclusion, dithiaethyneporphyrin—a new aromatic contracted porphyrinoid—has been synthesized and characterized and displays the unique features of an [18]dithiatriphyrin(4.1.1) frame.

Experimental Section

3: Pyrrole (0.11 mL, 1.58 mmol), **9** (0.9 g, 1.55 mmol), and freshly distilled CH_2Cl_2 (750 mL) were placed in a 1-L flask. Nitrogen was bubbled through the solution for 30 min, then CH_3SO_3H (0.2 mL, 3.1 mmol) was added, and the mixture was stirred in the dark for 1 h under N_2. Triethylamine (0.49 mL, 3.5 mmol) and DDQ (2.1 g, 9.3 mmol) were added and the solution was stirred for a further 1.5 h. The solvent was partly evaporated, and the reaction mixture was purified by chromatography on silica gel. The first orange-brown fraction (product **2**) was eluted with dichloromethane and repurified through a second chromatographic procedure on silica gel with hexane/benzene (1:1 *V*/*V*) as eluant. Product **2** was recrystallized from CH_2Cl_2/CH_3OH (120 mg, 12.7%); UV/Vis (CH_2Cl_2): λ_{max} (logε) = 448 (5.2), 518 (4.4), 553 (4.1), 646 (3.4), 725 nm (3.3); ^{1}H NMR (500 MHz, $CDCl_3$, 298 K, TMS): $\delta = 9.61$, 9.29 (AB, ^3J(H,H) = 4.4 Hz, 4H; H5,16, H6,15), 8.96 (d, ^3J(H,H) = 7.7 Hz, 4H; 3,18-*o*-Ph), 8.77 (d, ^4J(H,H) = 1.5 Hz, 2H; H10,11), 8.42 (d, ^3J(H,H) = 7.7 Hz, 4H; 8,13-*o*-

Ph), 7.88 (t, ^3J(H,H) = 7.7 Hz, 4H; 3,18-*m*-Ph), 7.85 (t, ^3J(H,H) = 7.7 Hz, 4H; 8,13-*m*-Ph), 7.75 (t, ^3J(H,H) = 7.7 Hz, 2H; 8,13-*p*-Ph), 7.63 (t, ^3J(H,H) = 7.7 Hz, 2H; 3,18-*p*-Ph), −3.24 ppm (br s, 1H; NH); HR-MS (ESI): *m*/*z* calcd for $C_{42}H_{27}N^{32}S_2$ [M^+]: 609.1585; found: 609.1607; elemental analysis: calcd (%) for $C_{42}H_{27}NS_2$: C 82.27, H 4.65, N 2.50, S 10.45; found: C 82.72, H 4.46, N 2.30, S 10.52.

10: Compound **3** (20 mg, 0.033 mmol) and [$Ru_3(CO)_{12}$] (0.84 g, 1.32 mmol) in freshly distilled chlorobenzene (20 mL) were heated at reflux for 4 h under N_2. The solvent was evaporated to dryness and the residue was purified by chromatography on silica gel. After an initial orange-red fraction (recovered **3**) had been eluted with hexane/benzene (1:1 *V*/*V*), elution with benzene led to a second brown fraction, which was collected and identified as **10**. The second fraction was purified through a second column (silica gel with hexane/benzene (1:3 *V*/*V*) and recrystallized from $CHCl_3$/CH_3OH to yield the title product (9 mg, 34%). UV/Vis ($CHCl_3$): λ_{max} (logε) = 367 (4.3), 440 (4.5), 505 (4.6), 659 (3.8), 711 nm (3.4); ^{1}H NMR (500 MHz, $CDCl_3$, 240 K, TMS): δ = 9.83, 9.78 (AB, ^3J(H,H) = 5.2 Hz, 2H; H15, H16), 9.81, 9.67 (AB, ^3J(H,H) = 5.2 Hz, 2H; H5, H6), 8.65 (m, 4H; 3,18-*o*-Ph), 8.49 (d, ^3J(H,H) = 7.3 Hz, 1H; 13-*o*-Ph), 8.46 (d, ^3J(H,H) = 7.3 Hz, 1H; 8-*o*-Ph), 8.17 (d, ^3J(H,H) = 7.3 Hz, 1H; 8-*o*-Ph), 8.13 (d, ^3J(H,H) = 7.3 Hz, 1H; 13-*o*-Ph), 8.10, 8.00 (AB, ^3J(H,H) = 4.1 Hz, 2H; H10, H11), 7.85 (m, 7H; *m*-Ph), 7.78 (m, 2H; 8-*p*-Ph, 13-*m*-Ph), 7.74 (t, ^3J(H,H) = 7.3 Hz, 1H; 13-*p*-Ph), 7.66 ppm (m, 2H; 3,18-*p*-Ph); IR (KBr): $\tilde{\nu}$ = 2065, 2012 cm^{-1} (C≡O); HR-MS (ESI): *m*/*z* calcd for $^{12}C_{44}H_{26}NO_2{}^{32}S_2{}^{35}Cl^{102}Ru$ [M^+]: 801.0311; found: 801.0428; elemental analysis: calcd (%) for $C_{44}H_{26}NO_2S_2ClRu{\cdot}0.8\,CHCl_3{\cdot}1.4\,CH_3OH$: C 58.92, H 3.47, N 1.49; found: C 59.10, H 3.79, N 1.10.

11: UV/Vis (CH_2Cl_2): λ_{max} (logε) = 325 (4.4), 415 (4.6), 649 nm (3.9); ^{1}H NMR (500 MHz, CD_2Cl_2, 298 K, TMS): δ = 7.77 (d, ^3J(H,H) = 7.3 Hz, 2H; 3-*o*-Ph), 7.73 (d, ^3J(H,H) = 7.3 Hz, 2H; 18-*o*-Ph), 7.67 (d, ^3J(H,H) = 7.0 Hz, 2H; 8-*o*-Ph), 7.54 (d, ^3J(H,H) = 7.0 Hz, 2H; 13-*o*-Ph), 7.49 (m, 3H; 13-*m*,*p*-Ph), 7.45 (t, ^3J(H,H) = 7.3 Hz, 2H; 18-*m*-Ph), 7.42 (t, ^3J(H,H) = 7.3 Hz, 2H; 3-*m*-Ph), 7.37 (m, 2H; 3,18-*p*-Ph), 7.28 (m, 3H; 8-*m*,*p*-Ph), 7.16, 6.89 (AB, ^3J(H,H) = 4.0 Hz, 2H; H15, H16), 7.11, 6.95 (AB, ^3J(H,H) = 4.0 Hz, 2H; H5, H6), 6.81, 6.54 (AB, ^3J(H,H) = 4.4 Hz, 2H; H10, H11), 3.38 ppm (s, 3H; OCH_3); HR-MS (ESI): *m*/*z* calcd for $C_{43}H_{30}NO^{32}S_2$ [M−H]$^+$: 640.1769; found: 640.1793.

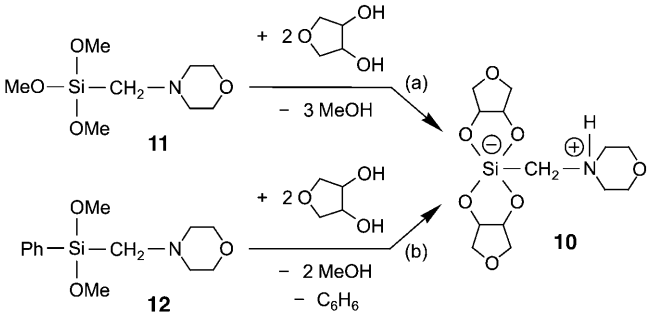
A Zwitterionic Spirocyclic Pentacoordinate Silicon Compound Synthesized in Water by Si–O and Si–C Bond Cleavage**



Reinhold Tacke, Rüdiger Bertermann, Christian Burschka, and Simona Dragota*

The chemistry of higher-coordinate silicon compounds is currently one of the main areas of research in silicon chemistry.[1] We have contributed to this field by systematic studies on zwitterionic λ^5*Si*-silicates that contain a pentacoordinate (formally negatively charged) silicon atom and a tetracoordinate (formally positively charged) nitrogen atom.[1d] The zwitterions **1**,[2] **2**,[3] **3**,[4] **4**,[5] **5**,[6] **6**,[7] **7**,[8] **8**,[9] and **9**[10] are examples of this type of compound. Generally,

these zwitterionic λ^5*Si*-silicates are quite sensitive to water and easily undergo hydrolytic Si–OC, Si–SC, and Si–NC bond cleavage. We have now succeeded in synthesizing a zwitterionic λ^5*Si*-silicate, namely, bis[*meso*-oxolane-3,4-diolato(2−)][(morpholinio)methyl]silicate (**10**), that shows remarkable stability in water.[11] Surprisingly, this pentacoordinate silicon compound could even be prepared in aqueous solution by Si–C bond cleavage. We report herein on the synthesis of **10** and its hydrate **10**·H_2O and their structural characterization in the solid state and in solution.

Compound **10** was synthesized according to Scheme 1, either through cleavage of three Si–O bonds (method a) or through cleavage of two Si–O bonds and one Si–C bond

Scheme 1. Syntheses of the zwitterionic λ^5*Si*-silicate **10**. For details see Experimental Section.

(method b), starting with trimethoxy[(morpholino)methyl]-silane (**11**)[12] (yield 87%) and dimethoxy[(morpholino)-methyl]phenylsilane (**12**)[12] (yield 53%), respectively. As the synthesis according to method b involves a relatively slow Si–C cleavage reaction as the rate-determining step,[13] product formation was significantly slower than with method a (see Experimental Section). The hydrate **10**·H_2O was synthesized analogously to **10** (Scheme 1, method a) by using water instead of acetonitrile as the solvent and was isolated, after crystallization from water, in 93% yield as a colorless crystalline solid.

The chiral λ^5*Si*-silicates crystallize in the space groups $P2_1/c$ (**10**) and *Cc* (**10**·H_2O), with one zwitterion (**10**) or with one zwitterion and one water molecule (**10**·H_2O) in the asymmetric unit.[14] As can be observed in Figure 1, the Si coordination polyhedra of **10** and **10**·H_2O in the crystal are strongly distorted trigonal bipyramids, in which each bidentate ligand spans one axial (O1, O3) and one equatorial site (O2, O4). The Si–O distances of the SiO_4C skeletons of **10** and **10**·H_2O range from 1.682(2) to 1.758(2) Å, and the axial Si–O bonds (1.7333(12)–1.758(2) Å) are significantly longer than the equatorial ones (1.682(2)–1.7114(11) Å). The Si–C distances are 1.913(3) (**10**) and 1.9168(14) Å (**10**·H_2O). Generally, the respective Si–O and Si–C bond lengths of **10** and **10**·H_2O are quite similar, whereas the distortions of the Si coordination polyhedra differ significantly (transition trigonal bipyramid→square pyramid: **10**, 26.8%; **10**·H_2O, 49.0%).[15]

Taking into account the different possible orientations of the two oxolane rings relative to the (morpholinio)methyl group, *syn*/*syn*, *anti*/*syn*, and *anti*/*anti* isomers must be considered for **10** (Figure 2). As can be seen in Figure 1, the *anti*/*syn* geometry is observed in the crystals of **10** and **10**·H_2O.

Hydrogen-bonding systems were observed in crystals of **10** and **10**·H_2O.[16] Compound **10** forms a trifurcate N–H···O1/O2/O3 hydrogen bond (intramolecular N–H···O1 and inter-

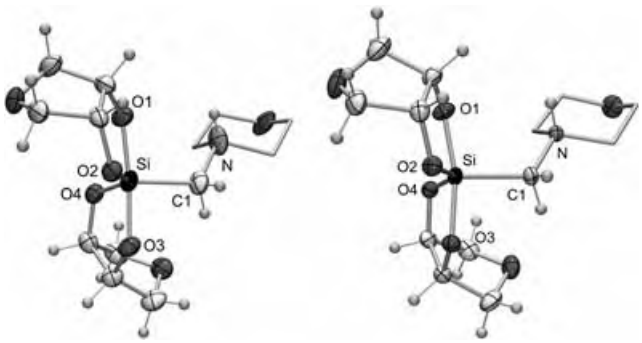

Figure 1. Molecular structure of **10** (Δ enantiomer, left) and the zwitterion of **10**·H_2O (Δ enantiomer, right) in the crystal (probability level of displacement ellipsoids 50%; morpholinio groups represented as stick model for clarity).[13] Selected bond lengths [Å] and angles [°] of **10** and **10**·H_2O (in parentheses): Si-O1 1.739(2) (1.7333(12)), Si-O2 1.702(2) (1.7114(11)), Si-O3 1.758(2) (1.7528(11)), Si-O4 1.682(2) (1.7007(11)), Si-C1 1.913(3) (1.9168(14)); O1-Si-O2 89.05(10) (89.01(5)), O1-Si-O3 172.98(10) (166.88(5)), O1-Si-O4 90.63(11) (87.96(5)), O1-Si-C1 95.17(13) (99.27(6)), O2-Si-O3 85.51(10) (84.85(5)), O2-Si-O4 130.78(10) (137.66(5)), O2-Si-C1 116.84(13) (111.59(6)), O3-Si-O4 89.57(10) (88.79(5)), O3-Si-C1 91.26(13) (93.78(6)), O4-Si-C1 112.20(12) (110.58(6)).

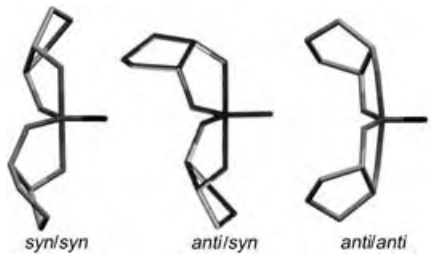

Figure 2. The three possible isomeric structures of the λ^5*Si*-silicate skeleton of **10** (*syn*/*syn*, *anti*/*syn*, *anti*/*anti*).

molecular N–H···O2/O3 interactions), and the zwitterion of **10**·H_2O forms a bifurcate intermolecular N–H···O2/O3 hydrogen bond, which lead to infinite one-dimensional chains along the [001] base vector in both crystal structures. In the case of **10**·H_2O, two additional intermolecular O–H···O hydrogen bonds between the water molecule (proton donor) and the zwitterion (proton acceptor) are observed.

Compounds **10** and **10**·H_2O were characterized by solution (^{1}H, ^{13}C, ^{29}Si) and solid-state (^{13}C, ^{15}N, ^{29}Si) NMR spectroscopy.[17] The solid-state NMR spectra were compatible with the crystal structures of the compounds. The isotropic ^{29}Si chemical shifts obtained in the solid-state NMR experiments (sharp resonance signals; full width at half height ca. 7.5–20 Hz) are very similar to those determined in aqueous solution (D_2O) and thus clearly demonstrate that the λ^5*Si*-silicate **10** exists in solution as well.

Upon dissolution of **10** and **10**·H_2O in D_2O, an equilibrium mixture of the *syn*/*syn*, *anti*/*syn*, and *anti*/*anti* isomers of the zwitterionic λ^5*Si*-silicate was observed. Whereas compounds **1–9** are hydrolytically sensitive, no tetracoordinate silicon species could be detected upon dissolution of **10** in water, that is, no hydrolytic decomposition occurred. This remarkable hydrolytic stability of **10** is emphasized by its direct synthesis in water in an NMR tube: upon addition of silane **11** to a solution of two molar equivalents of *meso*-oxolane-3,4-diol in D_2O, ^{1}H, ^{13}C, and ^{29}Si NMR measurements, performed 4 h after combining the reactants, afforded NMR spectra that were identical with those obtained upon dissolution of **10** and **10**·H_2O in water. A representative partial NMR spectrum resulting from a ^{29}Si,^{1}H HMQC experiment with a solution of **10** synthesized directly in an NMR tube is depicted in Figure 3.

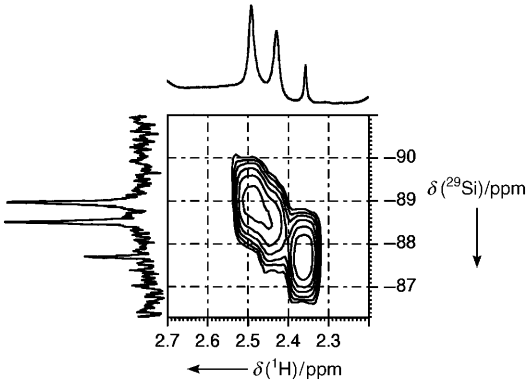

Figure 3. Partial spectrum obtained in a ^{29}Si,^{1}H HMQC experiment (23 °C, 300.1 MHz) with a 475 mM solution of **10** (pH 8.0 ± 0.1) synthesized directly in D_2O. The spectrum was measured 4 h after combining the reactants in an NMR tube. Top: ^{1}H NMR resonance signals of the $SiCH_2N$ protons of the three isomers of **10**. Left: ^{29}Si NMR signals of the three isomers of **10**.

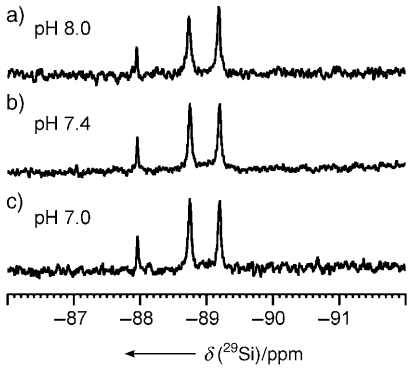
To obtain more information on the stability of **10** in water, ^{1}H, ^{13}C, and ^{29}Si NMR experiments with a 475 mM solution in D_2O were carried out at various pH values. Upon dissolution of **10** in D_2O, a value of pH 8.0 was measured. This pH value was decreased stepwise by addition of small amounts of concentrated hydrochloric acid, and ^{1}H, ^{13}C, and ^{29}Si NMR experiments were performed at pH 7.4 and pH 7.0. As can be seen from Figure 4, the resulting partial ^{29}Si NMR spectra



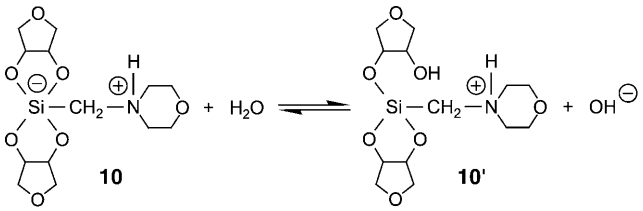


Figure 4. Partial spectra obtained in ^{29}Si NMR experiments (23 °C, 400.1 MHz) with 475 mM solutions of **10** (synthesized according to Scheme 1, method a) in D_2O at a) pH 8.0 ± 0.1, b) pH 7.4 ± 0.1, and c) pH 7.0 ± 0.1. The ^{29}Si NMR spectrum obtained for a 475 mM aqueous solution (D_2O) of **10** synthesized directly in the NMR tube was identical with spectrum a.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

indicate the existence of the three isomers of **10** in aqueous solution at all pH values studied (no tetracoordinate silicon species could be detected), and clearly demonstrate the stability of λ^5*Si*-silicate **10** in the range pH 7.0–8.0. The integrals extracted from the ^{1}H NMR spectra indicated that the ratio of the three isomers of **10** does not significantly depend on the pH value. Upon further acidification to pH 6, partial hydrolysis of **10** was observed (formation of tetracoordinate silicon species), and at pH 5, no ^{29}Si resonance signals for **10** could be detected at all (complete hydrolytic decomposition of **10**).

At first glance, the pH value of 8 measured for a 475 mM solution of **10** in water is quite surprising, because the ammonium moiety of the zwitterion should lead to an acidic milieu. The basic reaction of **10** in water might be explained by hydrolytic Si–OC cleavage to give the tetracoordinate silicon species **10′** and a hydroxide ion (Scheme 2); thus, one

Scheme 2. Equilibrium mixture of **10** and **10′** in aqueous solution.

could speculate on an equilibrium of the type **10**⇌**10′**. As can be observed from the measured pH value (8), this equilibrium should lie far to the left, and hence it should be very difficult (or even impossible) to detect the tetracoordinate silicon species **10′** by NMR spectroscopy.

Interestingly, aqueous solutions of **10** did not undergo gel formation at room temperature over a period of six months. Indeed, the hydrolytic stability of **10** in the pH range studied (pH 7.0–8.0) is quite remarkable, but cannot be satisfactorily explained so far. As the related λ^5*Si*-silicates **1**–**9** (including those with an SiO_4C skeleton) undergo spontaneous hydrolysis upon dissolution in water, special structural and/or electronic features of the *meso*-oxolane-3,4-diolato(2−) ligand must be considered to explain the hydrolytic stability of **10**. This particular ligand and related ligands derived from carbohydrates with *cis*-furanoidic diol moieties have already been reported to form anionic pentacoordinate silicon species in aqueous solution;[18,19] however, these anionic λ^5*Si*-silicates are only stable in strongly alkaline solution. Thus, it is likely that the zwitterionic nature of **10** (i.e., the presence of the (morpholinio)methyl group) also explains its hydrolytic stability. Future studies must elucidate whether this stability is a general feature of bis[*meso*-oxolane-3,4-diolato(2−)]-[(ammonio)organyl]silicates and if so, whether the chemistry of pentacoordinate silicon compounds in aqueous solution can be developed on the basis of this hydrolytic stability.

Experimental Section

10: Method a: **11**[12] (500 mg, 2.26 mmol) was added at 20 °C to a stirred solution of *meso*-oxolane-3,4-diol (471 mg, 4.52 mmol) in acetonitrile (10 mL), and the resulting mixture was transferred to a beaker (∅ 10 cm) and kept undisturbed at 20 °C for several hours (complete evaporation of the solvent). The solid residue was recrystallized from acetonitrile (40 mL) by cooling a boiling solution of **10** to 20 °C. After slow, complete evaporation of the solvent over a period of several hours, the solid product was washed with diethyl ether (3 × 20 mL) and recrystallized from dichloromethane/diethyl ether/*n*-pentane (1/1/1) at 20 °C (dissolution of **10** in dichloromethane (40 mL), subsequent addition of diethyl ether (40 mL) and *n*-pentane (40 mL), and slow evaporation of the solvent over 2 d). The resulting solid was washed with diethyl ether (3 × 20 mL) and dried in vacuo (0.01 Torr, 20 °C, 4 h) to give **10** in 87 % yield as a colorless crystalline solid (657 mg, 1.97 mmol); m.p. 180 °C; ^{13}C VACP/MAS NMR (ν_{rot} = 5 kHz; VACP: variable amplitude cross polarization): δ = 52.2 ($SiCH_2N$), 55.1 (NCH_2C), 59.8 (NCH_2C), 64.4 (2C, NCH_2CH_2O), 72.7 ($OCHC_2$), 73.2 ($OCHC_2$), 73.4 ($OCHC_2$), 74.0 ($OCHC_2$), 76.2 (2C, $CHCH_2O$), 76.5 ($CHCH_2O$), 77.3 ppm ($CHCH_2O$); ^{15}N VACP/MAS NMR (ν_{rot} = 5 kHz): δ = −327.7 ppm; ^{29}Si VACP/MAS NMR (ν_{rot} = 5.0 kHz): δ = −87.3 ppm; upon dissolution of **10** in D_2O (c = 475 mmol L^{-1}), the existence of three isomers was observed, with a molar equilibrium ratio **10a**:**10b**:**10c** of 0.65:0.24:0.11; NMR data for **10a**: ^{1}H NMR (D_2O, 400.1 MHz): δ = 1.81–2.06 (m, 2H, NCH_2C), 2.37 (s, 2H, $SiCH_2N$), 2.45–2.66 (m, 2H, NCH_2C), 3.40–3.48 (m, 4H, $CHCH_2O$), 3.45–3.64 (m, 4H, NCH_2CH_2O), 3.67–3.77 (m, 4H, $CHCH_2O$), 4.03–4.11 ppm (m, 4H, $OCHC_2$); ^{13}C NMR (D_2O, 100.6 MHz): δ = 45.8 (NCH_2C), 49.7 ($SiCH_2N$), 55.4 (NCH_2C), 65.8 (2C, NCH_2CH_2O), 70.8 (4C, $OCHC_2$), 71.3 ppm (4C, $CHCH_2O$); ^{29}Si NMR (D_2O, 79.5 MHz): δ = −89.2 ppm; NMR data for **10b**: ^{1}H NMR (D_2O, 400.1 MHz): δ = 2.30 ($SiCH_2N$), 2.80–2.95 (m, 2H, NCH_2C), 3.22–3.35 (m, 2H, NCH_2C), 3.22–3.35 (m, 4H, $CHCH_2O$), 3.45–3.66 (m, 4H, $CHCH_2O$), 3.45–3.66 and 3.78–3.90 (m, 4H, NCH_2CH_2O), 4.2 ppm (brs, 4H, $OCHC_2$); ^{13}C NMR (D_2O, 100.6 MHz): δ = 49.4 ($SiCH_2N$), 55.5 (2C, NCH_2C), 64.1 (NCH_2CH_2O), 64.3 (NCH_2CH_2O), 72.5 (4C, $OCHC_2$), 75.6 ppm (4C, $CHCH_2O$); ^{29}Si NMR (D_2O, 79.5 MHz): δ = −88.7 ppm; NMR data for **10c**: ^{1}H NMR (D_2O, 400.1 MHz): δ = 2.23 ($SiCH_2N$), 2.36–2.42 (m, 4H, NCH_2C), 3.22–3.35 (m, 4H, $CHCH_2O$), 3.45–3.66 (m, 4H, $CHCH_2O$), 3.45–3.66 and 3.78–3.90 (m, 4H, NCH_2CH_2O), 4.10–4.15 ppm (m, 4H, $OCHC_2$); ^{13}C NMR (D_2O, 100.6 MHz): δ = 48.9 ($SiCH_2N$), 53.8 (2C, NCH_2C), 63.8 (2C, NCH_2CH_2O), 72.4 (4C, $OCHC_2$), 75.1 ppm (4C, $CHCH_2O$); ^{29}Si NMR (D_2O, 79.5 MHz): δ = −87.9 ppm; elemental analysis (%) calcd for $C_{13}H_{23}NO_7Si$ (M_r = 333.41): C 46.83, H 6.95, N 4.20; found: C 46.6, H 6.8, N 4.2.

10: Method b: The synthesis was performed in a beaker (∅ 10 cm). Compound **12**[12] (500 mg, 1.87 mmol) was added at 20 °C to a stirred solution of *meso*-oxolane-3,4-diol (389 mg, 3.74 mmol) in water (6 mL), and an oily precipitate formed. The resulting mixture was kept undisturbed at 20 °C for 4 d (partial evaporation of water (ca. 3 mL)). The resulting oily residue was purified by crystallization from acetonitrile and then recrystallized from dichloromethane/diethyl ether/*n*-pentane as described for method a to give **10** in 53 % yield as a colorless crystalline solid (330 mg, 990 μmol); m.p. 180 °C; the NMR data of the product were identical with those obtained for the product prepared according to method a; elemental analysis (%) calcd for $C_{13}H_{23}NO_7Si$ (M_r = 333.41): C 46.83, H 6.95, N 4.20; found: C 46.4, H 6.8, N 4.1.

10·H_2O: The synthesis was performed in a beaker (∅ 10 cm). Compound **11**[12] (1.00 g, 4.52 mmol) was added at 20 °C to a stirred solution of *meso*-oxolane-3,4-diol (941 mg, 9.04 mmol) in water (2 mL), and the resulting mixture was stirred for 10 min (exothermic reaction) and then kept undisturbed at 20 °C for 2 d. The resulting precipitate was washed with water (3 × 0.3 mL) and dried in vacuo (0.01 Torr, 20 °C, 5 h) to give **10**·H_2O in 93 % yield as a colorless crystalline solid (1.48 g, 4.21 mmol); m.p. 179 °C; ^{13}C VACP/MAS NMR (ν_{rot} = 6 kHz): δ = 52.1 ($SiCH_2N$), 55.1 (NCH_2C), 59.8 (NCH_2C), 64.3 (2C, NCH_2CH_2O), 72.6 ($OCHC_2$), 73.2 ($OCHC_2$), 73.4 ($OCHC_2$), 74.0 ($OCHC_2$), 76.1 ($CHCH_2O$), 76.2 ($CHCH_2O$), 76.5

[14] Crystal structure analyses of **10** and **10**·H_2O: Suitable single crystals were mounted in inert oil (perfluoroalkyl ether, ABCR) on a glass fiber and then transferred to the cold nitrogen gas stream of the diffractometer (Stoe IPDS; graphite-monochromated $Mo_{K\alpha}$ radiation, $\lambda = 0.71073$ Å). The structures were solved by direct methods (SHELXS-97) and refined by full-matrix least-squares methods on F^2 for all unique reflections (SHELXS-97). For the CH hydrogen atoms, a riding model was employed, whereas the positions of the NH and OH hydrogen atoms were localized in difference Fourier syntheses and refined freely. CCDC-267545 (**10**) and CCDC-267546 (**10**·H_2O) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif. Selected data for **10**: single crystal of dimensions $0.4 \times 0.2 \times 0.1$ mm^3 obtained by crystallization from dichloromethane/diethyl ether/*n*-pentane (1/1/1; addition of diethyl ether and *n*-pentane to a solution of **10** in dichloromethane at 20 °C), $C_{13}H_{23}NO_7Si$, $M_r = 333.41$, analysis at 173(2) K, monoclinic, space group $P2_1/c$ (no. 14), $a = 9.941(2)$, $b = 17.028(3)$, $c = 10.100(2)$ Å, $\beta = 118.66(3)°$, $V = 1500.3(5)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.476$ g cm^{-3}, $\mu = 0.192$ mm^{-1}, $F(000) = 712$, $2\theta_{max} = 49.48°$, 13821 collected reflections, 2538 unique reflections ($R_{int} = 0.0691$), 176 restraints, 248 parameters, $S = 1.198$, $R1$ ($I > 2\sigma(I)$) = 0.0521, $wR2$ (all data) = 0.1232, max./min. residual electron density +0.214/−0.250 e Å^{-3}. Selected data for **10**·H_2O: single crystal of dimensions $0.4 \times 0.4 \times 0.2$ mm^3 obtained by crystallization from water (slow evaporation of the solvent at 20 °C over a period of two months; before starting the evaporation, a pH value of 7 was adjusted by adding concentrated hydrochloric acid), $C_{13}H_{25}NO_8Si$, $M_r = 351.43$, analysis at 173(2) K, monoclinic, space group Cc (no. 9), $a = 9.9705(8)$, $b = 16.9981(12)$, $c = 10.4368(8)$ Å, $\beta = 117.356(8)°$, $V = 1571.0(2)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.486$ g cm^{-3}, $\mu = 0.192$ mm^{-1}, $F(000) = 752$, $2\theta_{max} = 53.74°$, 9054 collected reflections, 3339 unique reflections ($R_{int} = 0.0313$), 3 restraints, 217 parameters, $S = 1.053$, $R1$ ($I > 2\sigma(I)$) = 0.0264, $wR2$ (all data) = 0.0692, absolute structure parameter 0.05(8), max./min. residual electron density +0.224/−0.207 e Å^{-3}.

All nine dihedral angles and the values for the reference geometry of the ideal square pyramid given in reference [15a] were considered for this calculation.

[16] The hydrogen-bonding systems were analyzed by using the program system PLATON: A. L. Spek, PLATON, University of Utrecht, Utrecht, The Netherlands, **1998**.

[17] NMR studies on **10** and **10**·H_2O: ^1H, ^{13}C, and ^{29}Si solution NMR spectra were recorded at 23 °C on a Bruker DRX-300 (^1H, 300.1 MHz; ^{13}C, 75.5 MHz; ^{29}Si, 59.6 MHz) or Bruker AVANCE-400 NMR spectrometer (^1H, 400.1 MHz; ^{13}C, 100.6 MHz; ^{29}Si, 79.5 MHz). D_2O was used as the solvent. Chemical shifts [ppm] were determined relative to internal HDO (^1H, $\delta = 4.70$ ppm) or external TMS (^{13}C, ^{29}Si; $\delta = 0$ ppm). Analysis and assignment of the ^1H NMR data was supported by ^1H,^1H COSY and ^{13}C,^1H, and ^{29}Si,^1H correlation experiments. Assignment of the ^{13}C NMR data was supported by DEPT 135 experiments. Solid-state ^{13}C, ^{15}N, and ^{29}Si VACP/MAS NMR spectra were recorded at 22 °C on a Bruker DSX-400 NMR spectrometer with bottom-layer rotors of ZrO_2 (∅ 7 mm) containing ca. 300 mg of sample (^{13}C, 100.6 MHz; ^{15}N, 40.6 MHz; ^{29}Si, 79.5 MHz); external standard TMS (^{13}C, ^{29}Si; $\delta = 0$ ppm) or glycine (^{15}N, $\delta = -342.0$ ppm); spinning rate 5–6 kHz; contact time 1 ms (^{13}C), 3 ms (^{15}N), or 5 ms (^{29}Si); 90° ^1H transmitter pulse length 3.6 μs; repetition time 4 s.

A Half Adder Based on a Photochemically Driven [2]Rotaxane**

*Da-Hui Qu, Qiao-Chun Wang, and He Tian**

Logic functions at the molecular scale are possible through a variety of approaches[1] that exploit the abilities of molecules to process information. The fundamental principles of logic operation have been demonstrated through detectable spectroscopic changes upon an ionic, electronic, or photonic input[1–6] and have led to the interpretation of complex molecular logic gates such as AND[2] and XOR functions.[3] Of course, mathematical calculations require the operation of several gates together. A half adder,[7] the combination of an AND gate and an XOR gate, could carry out elementary addition by using the XOR gate to generate the sum digit and the AND gate to generate the carry digit. Molecule-based logic gates with optical inputs and outputs would not require access for chemicals or wires and could operate on a fast timescale.[7d,f] Importantly, a single molecular platform that integrates multiple recognition sites for each input is expected to respond in parallel to a variety of reagents and thus provide logic functions at the molecular level.

Supramolecular systems[8–13] have attracted a great deal of attention in recent years because of their challenging construction as well as their potential application in molecular devices. Many supramolecular systems that function as simple logic gates have been reported.[1e,3,5] However, to the best of our knowledge, there has been no previous report of half adders based on a rotaxane system that uses light as an input. A rotaxane is a stable supramolecular system in which a linear subunit threads a macrocycle (wheel or bead) and is stoppered with two bulky end groups (dumbbell). Such a conformation is also similar to an abacus, the manual arithmetic calculator still used by some Chinese even today. Herein, we describe a new theoretical supramolecular half adder based on a [2]rotaxane, with optical inputs and outputs that can perform arithmetical functions directly by means of the position of the bead (wheel) on the axle. This abacus-type system can operate half-adder logic functions independently of any other reagents or chemical stimuli and may be the first step toward the construction of a supramolecular abacus for direct and complicated arithmetic.

[2]Rotaxane **1** comprises an α-cyclodextrin (α-CD) macrocycle locked onto a dumbbell that has two different photoswitchable binding sites, namely an azobenzene site and a stilbene site,[9,10a,13] and is end-trapped mechanically by two fluorescent naphthalimide moieties, 4-amino-1,8-naphthalimide-3,6-disulfonic disodium salt (stopper A) and 1,8-naphthalimide-5-sulfonic sodium salt (stopper B; Figure 1). The photoactive units can be switched independently by using light at different wavelengths (UV/Vis).[10c,14] The photochemical switching, which could mimic the function of a half adder that performs simple arithmetic addition, can be monitored by changes in the absorption of the supramolecular system and changes in the fluorescence of the end groups.

Molecular shuttle **1** is indeed a multistate [2]rotaxane that can be converted between a dynamic state and three static states in response to light and features dual fluorescence outputs. At room temperature in [D_6]DMSO, the state (*E*,*E*)-**1** as shown in Figure 1 is a dynamic state in which the α-CD bead moves back and forth between the azobenzene and stilbene units at a rate that cannot be followed on the NMR timescale. Rational nuclear Overhauser effects (NOEs)[14] can be observed between the resonances of the protons of the azobenzene and stilbene moities and protons H3 and H5 located inside the cyclodextrin annuli. This set of NOEs is not consistent with any single static geometry and shows that the cyclodextrin rapidly glides along the dumbbell. State (*E*,*E*)-**1** was converted into ($Z_{N=N}$,$E_{C=C}$)-**1** or ($E_{N=N}$,$Z_{C=C}$)-**1** by photoisomerization upon irradiation with at 380 nm or 313 nm, respectively. Finally, further irradiation of the $Z_{N=N}$,$E_{C=C}$ isomer at 313 nm or the $E_{N=N}$,$Z_{C=C}$ isomer at 380 nm can generate (*Z*,*Z*)-**1** (Figure 1).[15] Moreover, as shown in Figure 1, each photochemical reaction is fully reversible. The three *Z* isomers could be shifted back to the (*E*,*E*)-**1** isomer by irradiation with UV light of another wavelength, as shown in Figure 1, or by placing the sample in the dark for several hours. The initial *E*,*E* isomer could also be recovered upon heating solutions of each of the three *Z* isomers to 60 °C for 1 h and then cooling to room temperature. The various $E \rightarrow Z$ photoisomerization reactions of the [2]rotaxane **1** were also investigated by monitoring the changes in the ^{1}H NMR spectra and the two-dimensional ROESY spectra in [D_6]DMSO upon UV/Vis irradiation. Very different NOE patterns were observed for the three "Z" isomers,[14] consistent with the geometries of the three photostationary (PSS) states—$Z_{N=N}$,$E_{C=C}$ (PSS-ZE), $E_{N=N}$,$Z_{C=C}$ (PSS-EZ), and *Z*,*Z* (PSS-ZZ)—as shown in Figure 1. The NMR data[14] also support the idea that [2]rotaxane **1** can be photochemically converted between the dynamic-state *E*,*E* isomer (namely DS-EE)[16] and the three static states mentioned above.

The changes in absorption during the $E \rightarrow Z$ photoisomerism of [2]rotaxane **1** in solution were also investigated.[14] Compared with the absorption spectrum of the *E*,*E* isomer, those of the other three isomers were similar but showed an increased absorption at around 270 nm and a decrease in absorption at 350 nm with an isobestic point at 301 nm ($A_{301} = 0.165$). To indicate the magnitude of the change in absorption upon isomerization, the ratio of the difference in the

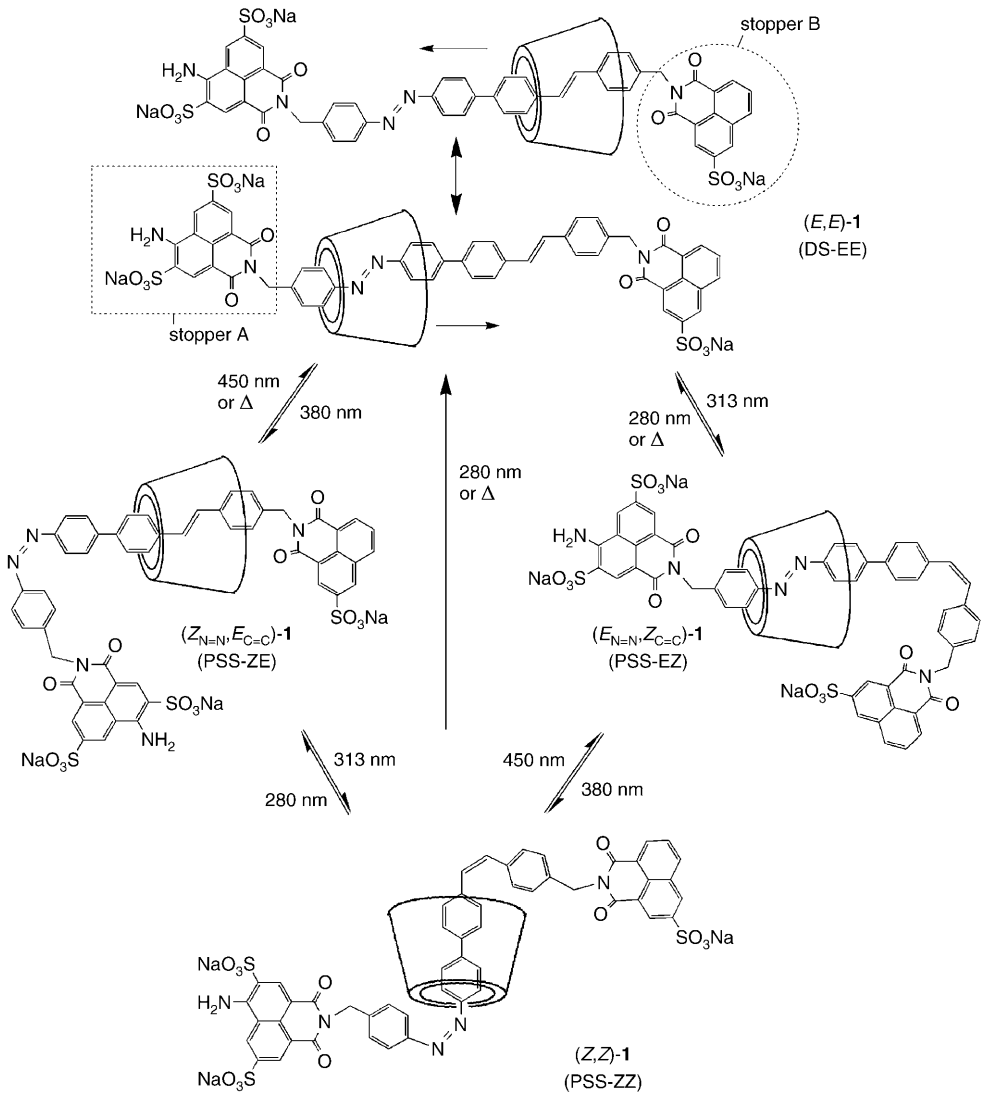

Figure 1. The intrinsic interconversion network of the α-cyclodextrin/azobenzene–stilbene [2]rotaxane **1** between the four states: one *E*,*E* isomer ((*E*,*E*)-**1**), two *E*,*Z* isomers (($Z_{N=N}$,$E_{C=C}$)-**1**), ($E_{N=N}$,$Z_{C=C}$)-**1**), and one *Z*,*Z* isomer ((*Z*,*Z*)-**1**). DS = dynamic state; PSS = photostationary state.

absorbances at 270 nm and 350 nm over the absorbance at 301 nm ($\Delta A = |A_{270} - A_{350}|/A_{301}$) was measured. For the *E* isomer, $\Delta A = 0.15$, whereas the values of ΔA calculated for the photostationary states (PSS-ZE, -EZ, and -ZZ) were 0.32 (PSS-ZE), 0.27 (PSS-EZ), and 0.73 (PSS-ZZ).[14]

A clear change was observed in the fluorescence spectra for [2]rotaxane **1** (see Supporting Information).[14] Relative to isomer (*E*,*E*)-**1**, the fluorescence intensity at $\lambda_{em} = 395$ nm (stopper B) increased by about 55% upon attaining the PSS-ZE state, while the fluorescence intensity at $\lambda_{em} = 520$ nm (stopper A) decreased by 14%. On the other hand, at the PSS-EZ state the fluorescence intensity at $\lambda_{em} = 520$ nm increased by about 52%, while a decrease of 15% in fluorescence intensity was observed at $\lambda_{em} = 395$ nm. For the PSS-ZZ state, the fluorescence intensities at both $\lambda_{em} = 395$ and 520 nm were similar to that of the *E* isomer but lower by 10%. The changes in the fluorescence spectra result from the rigidity of the α-CD ring. When the α-CD macrocycle is located near a fluorescent stopper, the vibrations and rotations of the methylene bonds between the stopper and the recognition site are hindered which leads to an increase in the fluorescence intensity of the stopper.[10] This was also confirmed by the weaker fluorescence observed for the lone dumbbell **2**, for which vibrations and rotations are relatively facile in the absence of the macrocycle.[14] Because of the total reversibility of the photoisomerization processes, the photoinduced shuttling motions of the α-CD ring on the dumbbell could be repeated and monitored by means of the reversible fluorescent output signals. By alternating irradiations at 380, 313, 450, and 280 nm, we verified that the photochemical processes are highly reproducible over more than 10 cycles.[14]

The above interconversions among the four states (*E*,*E*)-**1**, ($Z_{N=N}$,$E_{C=C}$)-**1**, ($E_{N=N}$, $Z_{C=C}$)-**1**, and (*Z*,*Z*)-**1** can be described with binary logic. The input (I) signals are UV light at wavelengths of 380 nm (I1) and 313 nm (I2). The difference in the absorption, ΔA, can be considered as one of the output signals, O1; O1 = 0 when ΔA is low (< 0.7), whereas O1 = 1 when ΔA is high (> 0.7). As mentioned above, only at the PSS-ZZ state does the photoisomerization about both azobenzene and stilbene occur. In this case, ΔA is high (> 0.7), but only upon simultaneous irradiation of both units at 380 nm and 313 nm (I1 = 1 and I2 = 1) is the output signal O1 = 1—otherwise, O1 = 0. Consequently, the difference in the change in absorption, ΔA, upon the external inputs of UV light at $\lambda = 380$ nm (I1) and 313 nm (I2) could be interpreted as an AND gate.

The change in the fluorescence intensity ΔF—defined as the difference in fluorescence intensity between two states at $\lambda_{em} = 520$ nm or at $\lambda_{em} = 395$ nm—of the rotaxane was selected as another output signal, O2. When the value of ΔF is low (< 50%), O2 = 0, whereas when the value of ΔF is high (> 50%), O2 = 1. Separate irradiation of the *E*,*E* isomer at either 380 nm (I1) or at 313 nm (I2) leads to the formation of either ($Z_{N=N}$,$E_{C=C}$)-**1** (PSS-ZE; $\Delta F = 55\%$ at $\lambda_{em} = 520$ nm)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

or ($E_{N=N}$,$Z_{C=C}$)-**1** (PSS-EZ, $\Delta F = 52\%$ at $\lambda_{em} = 395$ nm), respectively, and the ΔF output signal (O2) is high in both cases, that is, O2 = 1. Interestingly, under simultaneous irradiation at 380 nm (I1) and 313 nm (I2), (*Z*,*Z*)-**1** (PSS-ZZ) was formed and the resultant changes in the fluorescence intensity at $\lambda_{em} = 395$ and 520 nm were both small ($\approx 10\%$, therefore, O2 = 0). The changes in fluorescence (ΔF) in response to irradiation at 380 nm (I1) and 313 nm (I2) could be interpreted as an XOR gate.

The intrinsic network of the transformations of [2]rotaxane **1** between its four states leads to changes in absorption and fluorescence intensities of the two end groups, and these spectral changes can be interpreted as AND and XOR gates, respectively. The AND and XOR gates may function in parallel, as each photoswitchable unit (azobenzene or stilbene) in [2]rotaxane **1** can be switched with the inputs I1 and I2 independently.[14] Therefore, the spectral variations that result from the interconversion of the four states (DS-EE, PSS-ZE, PSS-EZ, PSS-ZZ) as shown in Figure 1 could be used to mimic the function of a half adder (Figure 2). Figure 2a shows a schematic diagram of the molecule-based half adder. In binary addition, the XOR gate output is the sum digit and the AND gate output is the carry digit. In the rotaxane-based half adder, the sum digit (n_S) is coded by the fluorescence change ΔF (O2) and the carry digit (n_C) is coded by the absorption change ΔA (O1). As shown in the truth table (Table 1) and Figure 2, each input and output of the half adder may be either ON (designated 1) or OFF (0). The AND gate gives an ON response only when both inputs I1 ($\lambda =$ 380 nm) and I2 ($\lambda = 313$ nm) are ON. The XOR gate generates an ON output when either input is ON but not when they are both ON or both OFF. After the readout, the half adder could be reset to its initial state by using light (280 nm) or heat energy. Because of the full reversibility of the photoisomerization processes, the current half adder can be used repeatedly.

Table 1: Truth table for a half adder with the sum digit n_S and the carry digit n_C.

I1 (380 nm)	I2 (313 nm)	O1 (ΔA) AND gate (n_C)	O2 (ΔF) XOR gate (n_S)	Binary sum
0	0	0	0	00
1	0	0	1	01
0	1	0	1	01
1	1	1	0	10

In summary, a photochemically driven (the inputs and the outputs are all photochemical) multistate [2]rotaxane that mimics a half adder with distinct AND and XOR logic gates has been demonstrated for the first time. After receiving inputs, the half adder remains in a static state for a while then gives rise to one of two optical outputs. The device can then be reset with light or heat, such that the half adder can be operated repeatedly. Most importantly, the realization that multistate [2]rotaxane operations which involve more than one logic expression are possible through a judicial choice of input and output signals has pointed a way to design complicated logic circuits based on one molecule. It is likely that by integrating these approaches, molecular logic gates with superior processing capabilities will emerge in the future.

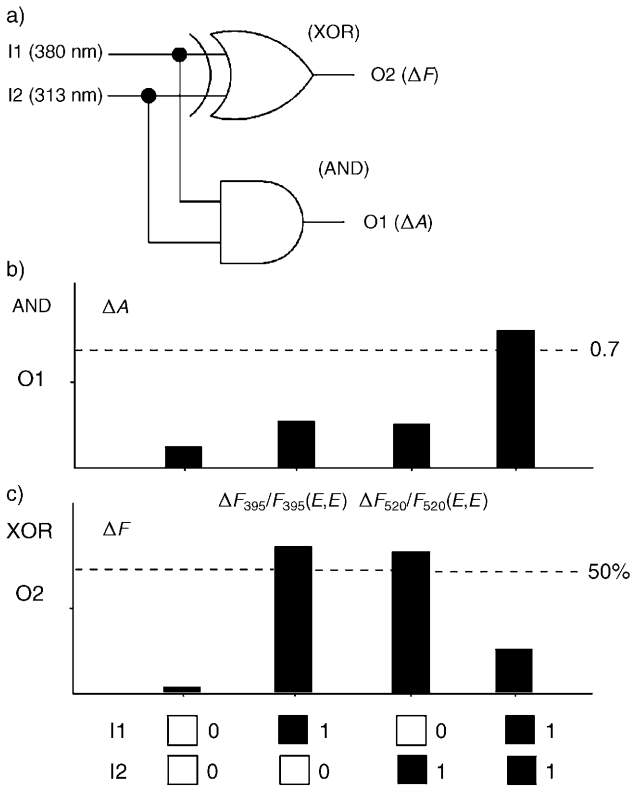

Figure 2. a) Schematic representation of the two-input half-adder logic circuit with [2]rotaxane **1** (I = input, O = output; *A* = absorbance, *F* = fluorescence). b) Experimental output O1 (ΔA) for the AND gate after irradiation of **1** at 380 nm (I1) and/or 313 nm (I2). c) Experimental output O2 (ΔF) for the XOR gate after irradiation at 380 nm (I1) and/or 313 nm (I2). The dashed line indicates the detection limit.

[14] The Supporting Information includes: ^{1}H NMR spectra, two-dimensional ^{1}H ROESY NMR spectra, and MALDI-TOF mass spectra of [2]rotaxane **1**; absorption and fluorescence spectra of dumbbell **2**, [2]rotaxane **1**, and the half-dumbbells; and detailed conditions for the photochemical reactions.

[15] The fractional conversion from (*E*,*E*)-**1** (DS-EE) to ($Z_{N=N}$,$E_{C=C}$)-**1** (PSS-ZE) is about 65%, and that to ($E_{N=N}$,$Z_{C=C}$)-**1** (PSS-EZ) is about 60%. The fractional conversion from ($Z_{N=N}$,$E_{C=C}$)-**1** (PSS-ZE) and ($E_{N=N}$,$Z_{C=C}$)-**1** (PSS-EZ) to (*Z*,*Z*)-**1** (PSS-ZZ) are slightly lower in comparison at about 53% and 57%, respectively.

[16] What station does the macrocycle prefer on the rotaxane: the azobenzene or the stilbene? The energy difference between the two translational isomers may determine the preferential location of the ring on one of the two sites. Fast shuttling of the ring between the two sites could make the determination of the population of the two translational isomers difficult, but if the entropy terms are sufficiently different then the relative binding affinity of the macrocycle for the two stations could be reversed by lowering the temperature.

Open-Framework Chalcogenides as Visible-Light Photocatalysts for Hydrogen Generation from Water**

*Nanfeng Zheng, Xianhui Bu, Hiep Vu, and Pingyun Feng**

The concern over the limited supply and the environmental effects of fossil fuels has led to increasing efforts directed towards the development of semiconductor photocatalysts for the production of hydrogen from water by using solar energy.[1–6] However, despite years of effort in this area of research, there are still many challenges that need to be met before such a photocatalytic process becomes economically feasible. The current limitations include the inadequate conduction-band energy levels for the photoreduction of

water and wide band gaps that correspond to UV light rather than visible light.[7]

Doping transition-metal cations or nitrogen anions into oxides is a commonly used strategy to create energy levels between valence and conduction bands so that the photocatalysts can be active in the visible-light region.[8–11] However, if the conduction-band level of a semiconductor is lower than the water-reduction potential, the doped semiconductor is usually photocatalytically inactive with respect to water reduction.

To overcome the above limitations and create a new generation of photocatalysts, it is necessary to develop a synthetic strategy that is capable of the systematic modification of both the electronic band gap and the energy level of each individual band. In addition, it is highly desirable to have a photocatalyst with a large number of active sites so as to increase quantum efficiency. Towards these goals, we have been developing methods for the synthesis of crystalline porous chalcogenide semiconductors with the expectation that such materials will have promising photocatalytic properties, particularly in the visible-light region.

We envision several unique advantages of photocatalysts based on crystalline porous semiconductors. By controlling framework architecture, it is possible to tune the band structure (both band positions and gap) of an open-framework solid within a given compositional domain. The open-framework construction also helps to increase the number of active reaction sites owing to a high surface area. The rate of charge recombination of the electron-hole pair is likely to be reduced because unlike a dense solid, the electron or hole does not need to travel all the way to the external surface of the catalyst particle for a reaction to occur. In addition to functioning as efficient photocatalysts on the basis of their framework composition and architecture, porous crystalline semiconductors can also serve as hosts for the incorporation of metal complexes, dyes, or other optically active species into their cavities. The synergetic effects in such hybrid materials are often highly desirable for enhancing photocatalytic efficiency.

Unfortunately, whereas open-framework materials have been extensively studied during the past several decades,[12–14] the vast majority of them are insulating oxides and therefore unsuitable for photocatalytic applications. There are also very few examples of hybrid materials between crystalline porous semiconductors and light-absorbing metal complexes (or dyes). Recently, a large family of crystalline chalcogenide open frameworks were developed.[15–19] These materials integrate tunable band gaps with an open-framework architecture and are potential candidates for efficient photocatalysts, particularly in the visible-light region. Herein we report photocatalytic properties of some select crystalline open-framework sulfides and demonstrate their unique features, particularly in comparison with some related dense semiconductors. This work represents our first step towards the development of efficient photocatalysts based on crystalline porous semiconductors.

The porous chalcogenides in this study were synthesized from solutions comprising In^{3+} and S^{2-} ions and one type of transition-metal cation (e.g., Cd^{2+}, Zn^{2+}, Mn^{2+}, Cu^{+}) under hydrothermal conditions. Two series of materials (denoted ICF-*m* and UCR-*m*) have been made. The ICF-*m* series contains hydrated inorganic cations (e.g., Li^{+}, Na^{+}) as extra-framework charge-balancing species and the UCR-*m* series contains protonated organic amines. The host framework of these materials is built from corner-sharing nanosized supertetrahedral clusters denoted as T*n*, in which *n* is the number of metal–sulfide layers in each cluster (Figure 1). UCR-7 has two interpenetrating cubic ZnS type lattices with T3 clusters

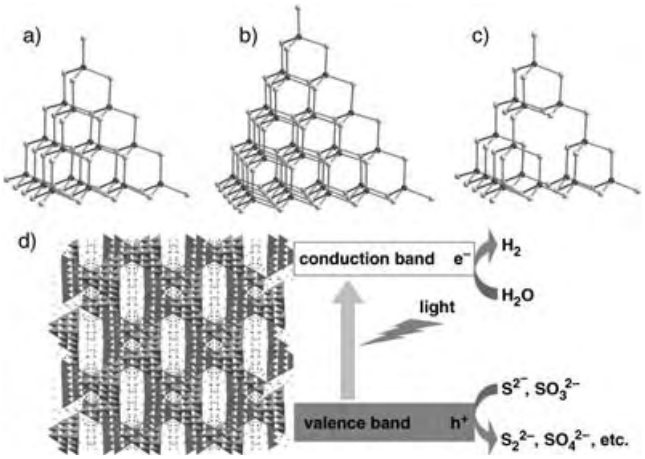

Figure 1. The structural and schematic diagrams of representative supertetrahedral clusters, chalcogenide frameworks, and their photocatalytic activity: a) T4 cluster; b) T5 cluster; c) coreless T4 cluster; d) the 3D diamond-type superlattice in ICF-5CuInS-Na: unconnected spheres are water molecules and Na^{+} sites.

($In_{10}S_{18}^{6-}$) at the tetrahedral nodes and UCR-20 has the sodalite-type structure with T2 clusters ($M_4S_8^{x-}$, M = In/Ge, In/Sn, Ga/Ge, and Ga/Sn) at the tetrahedral nodes. ICF-5, ICF-17, and ICF-22 all contain two interpenetrating cubic ZnS type lattices; however, tetrahedral nodes are occupied by T4 clusters (e.g., $Cu_3In_{17}S_{33}^{10-}$, $Cd_4In_{16}S_{33}^{10-}$) in ICF-5, T5 clusters (e.g., $Zn_{13}In_{22}S_{54}^{16-}$) in ICF-17, and the coreless T4 cluster ($In_{16}S_{32}^{16-}$) in ICF-22 (Figure 1). The size as measured between corner sulfur sites is 1.6 nm and 2.0 nm for T4 and T5 clusters, respectively. All these materials contain channels and cavities within 3D frameworks. A detailed discussion on the syntheses and structures of these materials was given elsewhere.[18–19]

A variety of compositions can be realized for these materials through the incorporation of different transition-metal cations, which provides a convenient route for the modification of the band gap. Figure 2 shows the UV/Vis–near-IR diffuse reflectance spectra of different ICF-*m* and UCR-*m* compounds and demonstrates how the band gap can be tuned from 2.0 to 3.6 eV. ICF-5InCuS-Na (formula: $Na_{14}In_{17}Cu_3S_{35}{\cdot}xH_2O$) is particularly interesting as it is compositionally related to $CuInS_2$, which is one of the most efficient photovoltaic materials. The introduction of Cu^{+} cations into the InS framework dramatically decreases the band gap to 2.0 eV, which makes this material particularly suitable for applications in the visible-light region.

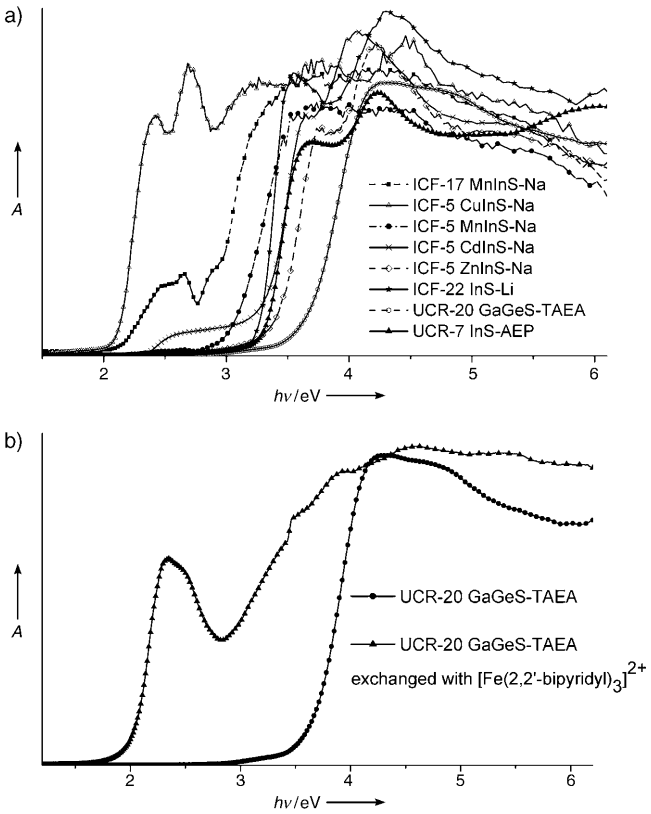

Figure 2. a) UV/Vis diffuse reflectance spectra of different open-framework chalcogenide materials. b) UV/Vis diffuse reflectance spectra of UCR-20GaGeS-TAEA before and after overnight ion exchange with 0.1 M $[Fe(2,2'\text{-bipyridine})_3]^{2+}$ solution. Data were measured on a Shimadzu UV-3101PC double-beam, double-monochromator spectrophotometer. $BaSO_4$ powder was used as reference (100% reflectance) and sometimes as base material for the coating of samples. Absorption (α/S) data were calculated from the reflectance data by using the Kubelka–Munk function: $\alpha/S=(1-R)^2/R$, in which R is the reflectance at a given wavelength, α is the absorption coefficient, and S is the scattering coefficient.

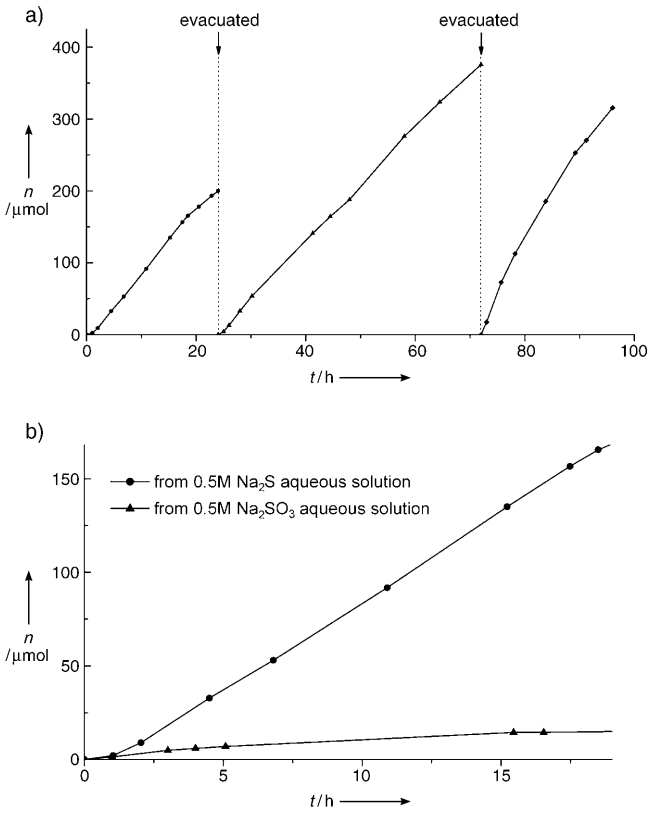

Figure 3. a) Photocatalytic H_2 evolution from an aqueous solution of Na_2S (0.5 M) over ICF-5 CuInS-Na (0.5 g); t: irradiation time, n: amount of H_2. b) Comparison of photocatalytic evolution of H_2 from an aqueous solution of Na_2S (0.5 M) and an aqueous solution of Na_2SO_3 (0.5 M) over ICF-5CuInS-Na (0.5 g). Light source: 300-W Xe lamp, $\lambda > 420$ nm.

A comparative study of porous sulfides and compositionally related dense phases showed that porous sulfides have a much higher photocatalytic activity. As shown in Figure 3 a, about 18 μmol h^{-1} g^{-1} of H_2 gas was produced over the ICF-5CuInS-Na catalyst under irradiation with the visible light. This activity was maintained for over 96 h and more than 890 μmol of H_2 gas evolved during this period. The turnover number—defined as the ratio between the moles of reacted electrons and the amount of the photocatalyst—exceeded 15 after 96 h, which indicates that the reaction proceeds photocatalytically. There was no difference in XRD patterns of the catalyst before and after the reaction. However, the light reddish reaction mixture might be related to the slow degradation of the catalyst. The quantum efficiency for ICF-5CuInS-Na was determined to be about 3.7% at 420 nm. Even though the number is lower than the quantum yield ($\approx$35%) of the well-known Pt/CdS photocatalyst, the efficiency is a considerable improvement on two anhydrous dense phases with similar compositions: $CuInS_2$ with the cubic ZnS structure; $CuIn_5S_8$ with the spinel structure. The quantum yield of $CuIn_5S_8$ with cocatalyst Ag_2S was reported smaller than 0.02% at 460 nm and 25 °C while the efficiency of $CuInS_2$ was even lower.[20]

When the photocatalytic reaction with ICF-5CuInS-Na was repeated under similar conditions but with 0.5 M Na_2SO_3 as the sacrificial agent instead of 0.5 M Na_2S, the amount of hydrogen produced was reduced substantially to about one tenth of that from the Na_2S solution (Figure 3 b). The production of hydrogen was negligible after 15 h of irradiation, which suggests that the SO_3^{2-} ion is a less effective sacrificial agent than the S^{2-} ion.

It is worth noting that ICF-5CuInS-Na is photocatalytically active without the use of a cocatalyst such as Pt. We have also observed hydrogen evolution over other porous chalcogenides such as ICF-17MnInS-Na (formula: $Na_{16}Mn_{13}In_{22}S_{54}{\cdot}x\,H_2O$) or ICF-5CdInS-Na (formula: $Na_{10}Cd_4In_{16}S_{33}{\cdot}x\,H_2O$) upon irradiation with visible light, again without any cocatalyst. Unlike typical dense semiconductors,[21–23] the presence of the Pt cocatalyst does not show an observable effect on the photocatalytic activity of these porous chalcogenides.

It is possible to engineer the band gap in the construction of an open framework. Similar to the effect that a decrease in conjugation leads to an increased energy gap in an organic

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

conjugated system, the generation of porosity in crystalline semiconductors leads to an increase in the band gap and energy level of the conduction band. For example, $NaInS_2$ is a layered dense phase with a band gap of 2.3 eV;[24] in comparison, the band gap of ICF-22InS-Li (formula: $LiInS_2 \cdot x\,H_2O$) is 3.3 eV (Figure 2 a).

An increase in the energy of the conduction-band level, which may be made possible through the construction of a porous architecture, can help generate water-reduction photocatalysts from inactive semiconductors in a compositional domain with an inadequate conduction energy level. For example, even under UV irradiation, no photocatalytic activity for the evolution of hydrogen was observed from In_2S_3, a 3D dense structure.[24] However, UCR-7InS-AEP (framework formula: $In_{10}S_{18}^{6-}$; AEP = protonated 1-(2-aminoethyl)piperazine) showed high photocatalytic activity for the hydrogen evolution under UV irradiation (Figure 4). In

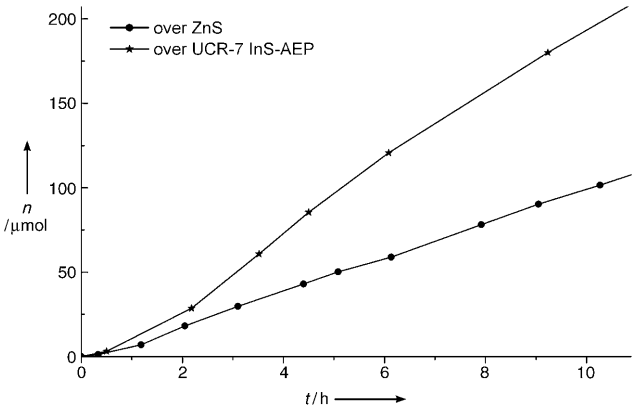

Figure 4. Comparison of photocatalytic H_2 evolution from 0.5 M Na_2SO_3 aqueous solution over 0.5 g UCR-7InS-AEP and ZnS. Light source, 300-W Xe lamp; *t*: irradiation time, *n*: amount of H_2.

the absence of any cocatalyst and under similar conditions, its activity is better than that of ZnS, a well-known UV-active photocatalyst.[25] A similar structural effect on photocatalytic activity has also been observed among oxide materials. For example, dense Nb_2O_5 shows little activity for the photoreduction of water due to its low conduction band. In comparison, a number of layered and tunneled structures based on niobium oxide are highly active in the UV region.[4]

In addition to the engineering of the band gap, the construction of an open framework makes it possible to create new composite visible-light photocatalysts by integrating porous semiconducting frameworks with optically active organic molecules or metal complexes. Upon incorporation into the pores of open-framework materials, dye molecules can function as sensitizers to enhance visible-light absorption and the subsequent transfer of energy to the semiconducting framework. The open-framework architecture can accommodate a high concentration of dye sensitizers, which is difficult to achieve by coating the surface of dense materials. The hybridization of crystalline porous semiconductors and metal complexes (or dyes) has the potential to make highly efficient use of solar energy and therefore significantly improve the photocatalytic efficiency.

In this work, the $[Fe(2,2'\text{-bipyridine})_3]^{2+}$ complex was incorporated into UCR-20GaGeS through ion exchange. XRD patterns before and after ion exchange were nearly identical; however, the absorption of the hybrid material was extended from the UV region to the visible-light region (Figure 2 b). The resulting red sample showed photocatalytic activity for the generation of hydrogen under irradiation with visible light ($\lambda > 420$ nm) for at least 24 h with SO_3^{2-} ions as the sacrificial agent. In comparison, the photocatalytic activity of both $[Fe(2,2'\text{-bipyridine})_3]^{2+}$ and UCR-20GaGeS-TAEA was also studied with SO_3^{2-} ions as the sacrificial agent (TAEA = protonated tris(2-aminomethyl)amine). They did not show observable activity in the visible-light region even though UCR-20 GaGeS-TAEA was found to exhibit activity under the UV light. Only after ion exchange of $[Fe(2,2'\text{-bipyridine})_3]^{2+}$ into UCR-20 did the resulting hybrid material show activity in visible light region.

In conclusion, a series of open-framework chalcogenides have been demonstrated to be efficient photocatalysts for the reduction of water. We have shown that novel hybrids of crystalline porous semiconductors and light-absorbing metal complexes can be prepared and these materials exhibit unique optical and photocatalytic properties. Compared with dense semiconductors, these porous semiconductors have received much less attention and their photocatalytic efficiency still requires further optimization. However, the unique advantages of porous semiconductors, such as having a high surface area and the easy incorporation of light sensitizers, provide new opportunities that can be explored to maximize photocatalytic efficiency, particularly in the visible-light region. We anticipate that the unique effects and advantages associated with the porous architecture are relevant to both porous sulfide and oxide semiconductor materials, which promise a new generation of photocatalysts for applications such as water reduction or splitting.

Experimental Section

The photocatalytic reactions were performed in a pyrex reaction cell connected to a closed gas-evacuation and circulation system.

In a typical procedure, the catalyst (0.5 g) was suspended in a solution of Na_2S or Na_2SO_3 (0.5 M, 270 mL). After the system had been evacuated, Ar gas was introduced into the reaction cell until a pressure of about 9.3 kPa was reached. The catalyst suspension was then irradiated with a 300 W Xe lamp equipped with an optical cut-off filter ($\lambda > 420$ nm) and a heat-absorbing filter. The amount of H_2 produced was analyzed by using an online gas chromatograph equipped with a thermal-conductivity detector (TCD). Quantum yield was measured at 420 nm by using a band-pass filter with a half width of 9.8 nm. The number of incident photons was determined by a chemical actinometry based on potassium ferrioxalate.

Trimethylyttrium and Trimethyllutetium**

*H. Martin Dietrich, Gabriele Raudaschl-Sieber, and Reiner Anwander**

Permethylated transition-metal complexes, as represented by neutral $M(CH_3)_x$ and anionic $[M(CH_3)_y]^{n-}$, have attracted considerable interest not only for displaying the simplest truly organometallic derivatives but also for their intrinsic bonding phenomena.[1,2] While structural and theoretical investigations have led to enormous progress for thermally labile homoleptic Group 4, 5, 6, and 7 derivatives, monometallic Group 3 and lanthanide congeners have remained elusive.[2,3] For example, the synthesis of rare-earth-metal–alkyl complexes such as $LnEt_3$ (Ln = Sc, Y) was claimed as early as 1938, however, striking evidence of their existence, be it spectroscopic data or clarifying follow-up chemistry, has never been reported.[4] Moreover, the ease of β-hydride elimination in such early transition-metal–alkyl complexes led to controversial discussions.[5,6] Nevertheless, a considerable number of silylalkyl complexes including homoleptic, donor-coordinated, donor-functionalized, and ate-type derivatives have been unambiguously identified.[7–11] In the early 1980s, Schumann et al. reported the synthesis of thermally stable ate complexes of the type $[Li_3(donor)_3][Ln(CH_3)_6]$ (donor = TMEDA (*N*,*N*,*N*′,*N*′-tetramethylethylenediamine), DME (1,2-dimethoxyethane)), which featured an octahedral coordination geometry, for the entire series of rare-earth metals.[12] Approximately ten years later, Evans et al. described permethylated derivatives $[Nd(GaMe_4)_3]$ and $[Ln(AlMe_4)_3]$ (Ln = Y, Nd, Sm) which can be viewed as trimethylgallium and trimethylaluminum adduct complexes, respectively, of the elusive $LnMe_3$.[13,14] Meanwhile, heterobimetallic derivatives $[Ln\{(\mu\text{-}Me)_2AlMe_2\}_3]$ are available for the entire Group 3 and 4f series except for scandium and promethium.[15,16] Herein, another ten years later, we describe the synthesis and derivatization of homoleptic trimethylyttrium and trimethyllutetium.

Donor (Do)-induced cleavage of tetraalkylaluminates (Do = THF, diethyl ether, pyridine) has been previously applied to convert heteroleptic lanthanidocene and half-lanthanidocene complexes, $[Cp'_2Ln(AlR_4)]$ and $[Cp'Ln(AlR_4)_2]$ (Cp' = substituted cyclopentadienyl), into the corresponding σ-bonded alkyl derivatives [Eqs. (1) and (2)].[17–20]

$$2\,[Cp'_2Y\{Al(CH_3)_4\}] + 2\,Do \rightarrow [Cp'_2Y(\mu\text{-}CH_3)]_2 + 2\,Al(CH_3)_3(Do) \quad (1)$$

$$3\,[Cp'Y\{Al(CH_3)_4\}_2] + 6\,Do \rightarrow [Cp'Y(\mu\text{-}CH_3)_2]_3 + 6\,Al(CH_3)_3(Do) \quad (2)$$

We found that homoleptic $[Y(AlMe_4)_3]$ (**1a**) and $[Lu(AlMe_4)_3]$ (**1b**) are also amenable to this donor-induced tetraalkylaluminate cleavage. Accordingly, addition of a stoichiometric amount of THF (3 equiv) to a solution of **1a** in hexane at ambient temperature produced a white precipitate, which was insoluble in aliphatic and aromatic solvents (Scheme 1). After several washings with hexane and drying under high vacuum, the white powder was identified as polymeric $[YMe_3]_n$ (**2a**). Optimized conditions for this cleavage reaction comprised the use of freshly sublimed **1a** as well as the less Lewis basic donor diethyl ether as a cleavage reagent, and a low reaction temperature (−35 °C).[21] ^{1}H NMR experiments in C_6D_6 confirmed $Al(CH_3)_3(OEt_2)$ as the only soluble byproduct of the cleavage reaction (δ = −0.42 (s, 9H, $AlCH_3$), 0.73 (t, 6H, CH_3), 3.25 ppm (q, 4H, OCH_2)). Note that owing to its relatively low sublimation point (80 °C at 10^{-3} mbar; > 90 % yield), compound **1a** is among the most volatile of rare-earth metal compounds.[22]

Scheme 1. Synthesis and derivatization of $[LnMe_3]_n$ (**2**). Detailed reaction conditions are given in the Supporting Information (Cn = 1,4,7-trimethyl-1,4,7-triazacyclononane).

Such optimized reaction conditions were crucial for the synthesis of pure $[LuMe_3]_n$ (**2b**). The precursor $[Lu(AlMe_4)_3]$ (**1b**) was most efficiently separated from the coproduct of the synthesis, $[Me_2Al(\mu\text{-}NMe_2)]$, by fractional sublimation (ca. 90 °C at 10^{-3} mbar; > 20 % yield).[23] (*Caution*! Compound **2b** which is also obtained quantitatively as a white powder like the yttrium derivative **2a** detonates spontaneously when exposed to air; it also decomposes spontaneously at elevated temperature under high vacuum (ca. 80 °C at 10^{-4} mbar) to yield a black powder.) In addition to the C,H microanalytical data, unambiguous evidence for the formation of compounds **2a**,**b** stemmed from the complete reversibility of this donor-induced cleavage reaction (Scheme 1).[18] That is, treatment of the precipitated compounds **2** (non-isolated, as formed from the initial reaction mixture) and likewise the isolated compounds **2**, which were resuspended in hexane, with 3 equivalents of $AlMe_3$ both led to quantitative re-formation of the homoleptic complexes **1**. Visually, thus was indicated by the immediate formation of a clear solution.

A uniform coordination environment at the rare-earth-metal center in compounds **2** was confirmed by solid-state FTIR and MAS NMR spectroscopy. Nujol mulls of $[LnMe_3]_n$ gave IR spectra that displayed a characteristic vibration at $\tilde{\nu}$ = 1191 and 1202 cm^{-1} for the yttrium and lutetium derivatives, respectively, and a broad, intense low-energy band featuring three maxima at $\tilde{\nu}$ = 522, 431, and 361 cm^{-1} (**2a**). The ^{1}H MAS NMR spectrum of **2a** showed a broad resonance centered at δ = −0.3 ppm that exhibited two well-resolved shoulders at around δ = 0.1 and 1.0 ppm. The ^{13}C CPMAS NMR spectra of compounds **2** are shown in Figures 1 a and b. For each, one signal was detected for the methyl carbon atoms at δ = 28.3 (**2a**) and 31.4 ppm (**2b**). For comparison, the yttrium precursor complex **1a** revealed two signals at $\delta \approx -10$ and 18.0 ppm which can be assigned to Y-CH_3-Al bridging and Al-CH_3 terminal methyl ligands (Figure 1 c), whereas the half-yttrocene $[Cp^*Y(\mu\text{-}Me)_2]_3$ ($Cp^* = C_5Me_5$), which is discussed later, exhibits ^{13}C resonances at δ = 11.9, 30.3, and 118.7 ppm that are attributed to carbon atoms of $CH_3(Cp^*)$ substituents, Y-CH_3-Y bridging methyl ligands, and the Cp* ring, respectively (Figure 1 d).[19] Similar solid-state NMR chemical shifts have been previously reported for the complex $[Cp^*_2Th(CH_3)_2]$ (Cp*: δ = 123.1 and 12.0 ppm; Th-CH_3(terminal): δ = 68.4 ppm).[24] These findings clearly indicate the formation of homoleptic complexes **2** (ether donor ligands can be ruled out by the ^{13}C CPMAS NMR spectra) and to the absence of any methyl groups bonded to aluminum centers.[25,26] Carbon resonances of "Al-CH_3" moieties were previously shown to appear upfield,[27] and this is also corroborated by the spectrum of precursor compound **1a** (Figure 1 c).

Preliminary investigations into the reaction behavior of $[LnMe_3]_n$ were performed using the yttrium derivative **2a**

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

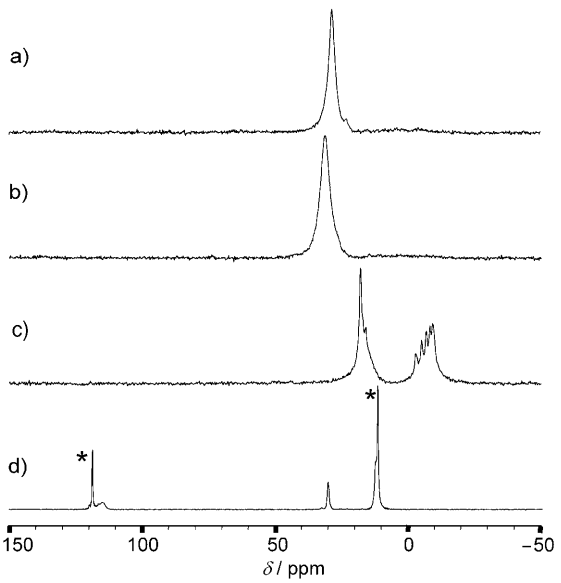

Figure 1. ^{13}C cross-polarization magic-angle-spinning (CPMAS) NMR spectra of a) neat $[YMe_3]_n$ (**2a**), b) neat $[LuMe_3]_n$ (**2b**), c) neat $[Y(AlMe_4)_3]$ (**1a**), and d) neat $[Cp^*YMe_2]_3$. Resonances due to C_5Me_5 (Cp*) are indicated by asterisks (*).

(Scheme 1). Although the isolation of simple ether adduct complexes, such as $[YMe_3(thf)_x]$, was not successful, addition of a stoichiometric amount of 1,4,7-trimethyl-1,4,7-triazacyclononane (Cn) to a suspension of $[YMe_3]_n$ in hexane gave $[CnYMe_3]$ (**3**) in almost quantitative yield.[28] The solid-state ^{13}C NMR spectrum of complex **3** (not shown) was similar to its spectrum in solution (C_6D_6) and gave signals at $\delta = 55.2$ (NCH_2), 48.7 (NCH_3), and 20.9 ppm (YCH_3). In the presence of TMEDA as an N-donor solvent, treatment of $[YMe_3]_n$ with 3 equivalents of MeLi gave Schumann's ate complex $[Li_3(tmeda)][Y(CH_3)_6]$ (**4**) in moderate yield.[12] Given the "reversibility" of the formation of $[LnMe_3]_n$, we anticipated that other strong Lewis acids might redissolve $[LnMe_3]_n$ as well. Accordingly, $AlEt_3$ and $GaMe_3$ form heterobimetallic/heteroleptic $[YAl_3Me_3Et_9]$ (**5**) and heterobimetallic/homoleptic $[YGa_3Me_{12}]$ (**6**) in almost quantitative yields (Scheme 1).[29] Whereas compound **5** was obtained as an oily residue, tetramethylgallate complex **6** yielded colorless crystals from solutions in hexane. Complex **6** shows a very broad ^1H NMR signal in C_6D_6 which is indicative of a decreased fluxional behavior of the bridging and terminal methyl ligands relative to tetramethylaluminate **2a**.

Instantaneous evolution of methane was observed when compound $[YMe_3]_n$ was treated with Brønsted acidic substrates such as $HN(SiMe_3)_2$, $HOCHtBu_2$, and HC_5Me_5 (HCp*) in hexane. The reactions of 3 equivalents of either the silylamine or the alcohol with **2a** gave the homoleptic complexes $[Y\{N(SiMe_3)_2\}_3]$ and $[Y(OCHtBu_2)_3]$, respectively, in high yields (see Supporting Information).[30,31] Owing to ligand scrambling, half-yttrocene complex $[Cp^*Y(\mu\text{-}Me)_2]_3$ did not form selectively upon addition of 1 equivalent of HCp* to compound **2a**, however, its presence could be identified by means of ^1H NMR spectroscopy.[19] A Me→Cl transformation with formation of YCl_3 occurred upon treatment of compound **2** with $AlMe_2Cl$ and documents the comparatively higher halophilicity of the rare-earth elements. Use of $AlEt_2Cl$ as a halogenating reagent afforded the mixed alkylaluminum $AlMeEt_2$ (**7**) as a coproduct.

In conclusion, we have shown that homoleptic rare-earth-metal–methyl complexes can be obtained through donor-induced tetraalkylaluminate cleavage of $[Ln\{(\mu\text{-}Me)_2AlMe_2\}_3]$ (Ln = Y, Lu). Compounds $[LnMe_3]_n$ are highly condensed materials. Notably, those derived from the smaller rare-earth-metal cations are stable at ambient temperature and accessible to a variety of ligand-exchange and addition reactions. Current investigations of $[LnMe_3]_n$ compounds are focused on 1) the accessibility of derivatives of the large rare-earth-metal cations, 2) the feasibility of controlled alkyl-elimination reactions, and 3) their potentials as catalysts.

Experimental Section

2a: In a glovebox, a solution of diethyl ether (3 equiv; 222 mg, 3.00 mmol) in hexane (5 mL) at −35 °C was added under vigorous stirring to a solution of $Y(AlMe_4)_3$ (**1a**; 350 mg, 1.00 mmol) in cold (−35 °C) hexane (10 mL). Instant formation of a white precipitate occurred. After stirring the reaction mixture for 10 min, the product was separated by centrifugation and washed three times with hexane to completely remove any soluble byproducts. After drying for 6 h under high vacuum, $[YMe_3]_n$ (**2a**) was obtained as a white powder in quantitative yield (133 mg). IR (Nujol): $\tilde{\nu} = 1191$ (vs), 522 (s), 431 (s), 361 (s), 320 cm^{-1} (w); far-IR (polyethylene): $\tilde{\nu} = 186$ cm^{-1} (w); ^1H MAS NMR (300.13 MHz, 25 °C): $\delta = 1.0$, 0.1, −0.3 ppm. ^{13}C MAS NMR (75.46 MHz, 25 °C): $\delta = 28.3$ ppm; elemental analysis (%): calcd for C_3H_9Y (134.010 g mol^{-1}): C 26.89, H 6.77; found: C 26.88, H 6.51.

Typical procedure for addition reactions, as shown for the synthesis of **6**: In a glovebox, a solution of $GaMe_3$ (3 equiv; 128 mg, 1.12 mmol) in hexane (5 mL) cooled to −35 °C was added under vigorous stirring to a suspension of $[YMe_3]_n$ (**2a**, 50 mg, 0.37 mmol) in hexane (5 mL) also cooled to −35 °C. The reaction mixture became clear after 15 min stirring. After a further 15 min, the reaction mixture was filtered, and the filtrate was retained. Evaporation of the solvent in vacuo yielded compound **6** as a white crystalline product (169 mg, 95%). IR (Nujol): $\tilde{\nu} = 1302$ (w), 1202 (s), 967 (w), 571 (s), 530 (s), 416 cm^{-1} (m); ^1H NMR (400 MHz, C_6D_6, 25 °C): $\delta = -0.10$ ppm; $^{13}C\{^1H\}$ NMR (100 MHz, C_6D_6, 25 °C): $\delta = 4.0$ ppm (v br); elemental analysis (%): calcd for $C_{12}H_{36}Ga_3Y$ (478.492 g mol^{-1}): C 30.12, H 7.58; found: C 31.30, H 7.34, N < 0.2.

Full experimental and physicochemical details for complexes **1–7** are available in the Supporting Information.

Highly Enantioselective Cu-Catalyzed Conjugate Additions of Dialkylzinc Reagents to Unsaturated Furanones and Pyranones: Preparation of Air-Stable and Catalytically Active Cu–Peptide Complexes**

*M. Kevin Brown, Sylvia J. Degrado, and Amir H. Hoveyda**

In recent years, a considerable amount of effort has been expended on the development of catalytic methods for asymmetric conjugate additions (ACA) of alkyl metal reagents to unsaturated carbonyls.[1] Research in these laboratories has led us to identify amino acid based phosphanes, such as **1**–**3** (Scheme 1), as chiral ligands for use in Cu-

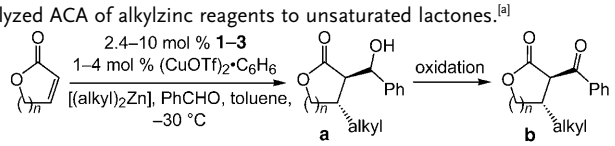
Chiral phosphanes:

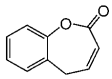
Substrates:

Scheme 1. Chiral amino acid based phosphanes used for Cu-catalyzed asymmetric conjugate additions (ACA) to various heterocyclic enones.

catalyzed ACA processes involving dialkylzinc reagents.[2] However, the majority of investigations have focused on transformations of unsaturated ketones;[2,3] more recently, a number of studies have involved Cu-catalyzed ACA of nitroalkenes.[4]

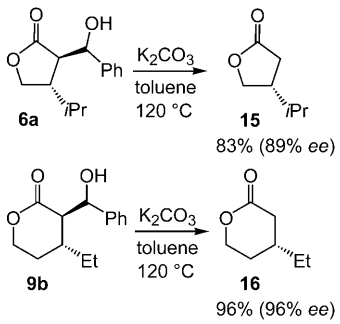


Catalytic ACA reactions of the less reactive cyclic or acyclic unsaturated carboxylic esters (e.g., **I**, Scheme 1) have received far less attention.[5] A number of studies have addressed the problem of catalytic additions of dialkylzinc reagents to unsaturated lactones.[6–8] In spite of high enantioselectivities (>90% *ee*) in select instances, the above disclosures address only reactions of one or two substrates (**I**, $n=1$ or 2) or nucleophiles (typically [Et_2Zn]; less frequently [Me_2Zn]). Due to complications that will be clarified later, in a number of cases, isolated yields are not indicated (only % conversion disclosed).[6a,b,d] In addition, two reports provide examples of Cu-catalyzed ACA of Grignard reagents to lactones (**I**, $n=2$);[9a–b] in one disclosure,[9a] high catalyst loading is required (32 mol%; 5–92% *ee*) and the other[9b] offers only a single example (82% *ee*). To the best of our knowledge, a report regarding catalytic ACA of an alkyl metal reagent to substrate types **II** or **III** (Scheme 1) has not appeared.



Herein, we disclose the first effective and general protocol for catalytic ACA of dialkylzinc reagents to unsaturated furanones and pyranones of varying steric and electronic properties (i.e., **I**–**III**, Scheme 1). Enantioselective additions proceed in the presence of optically pure phosphanes **1**–**3** to afford the desired products in high isolated yield and in up to >98% *ee*. We report the synthesis of catalytically active Cu^I–peptide complexes that are air stable, can be prepared from commercially available Cu salts and utilized after storage for at least a week.

Phosphanes **1**–**3** can be used to effect efficient and enantioselective ACA of alkylzinc reagents to small and medium ring unsaturated lactones (Table 1). A variety of dialkylzinc reagents, including the sterically demanding [$(i\text{Pr})_2Zn$] (entries 2 and 5) as well as the less reactive [Me_2Zn] can be employed (entries 3 and 7). To obtain high yield, reactions must be carried out in the presence of an aldehyde;[10] this is presumably due to adventitious ketene formation or intermolecular Michael addition if the enolate intermediate is not trapped in situ. The resulting aldol adduct can be oxidized to afford the corresponding diketone (>98% *anti*), or, as represented by the formation of **15** and **16** (Scheme 2), converted to the derived optically enriched β-alkyl carbonyl by an efficient retro-aldol process.



This phase of our studies pointed to a chiral ligand hierarchy: First, the simplest phosphane **3** was examined; in cases where ACA was sluggish, the more potent **1** was utilized (e.g., <10% conversion with 10 mol% **3** vs. >98% conversion with **1** in entry 7). Chiral phosphane **2** was employed when ACA products from reactions with **1** were judged not to

Table 1: Cu-catalyzed ACA of alkylzinc reagents to unsaturated lactones.[a]

be of sufficient optical purity (e.g., **5b** formed in 84% *ee* in the presence of ligand **1** vs. 97% *ee* with phosphane **2**).

As illustrated in entries 1 and 4 of Table 2, under conditions identical to those used for reactions of lactones (see Table 1), Cu-catalyzed ACA of pyranone **17** proceed to

Table 2: Cu-catalyzed ACA of alkylzinc reagents to pyranone **17**.[a]

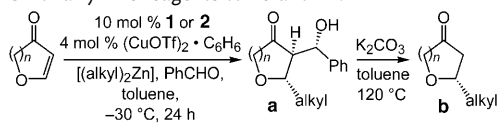
>98% conversion but with inferior enantioselectivity (64% and 56% *ee*). We surmised that the diminished asymmetric induction might be due to the neighboring Lewis basic oxygen atom directing the enantioselective addition of an alkyl–copper complex to the electronically activated ketone.[11] Accordingly, we examined the effect of coordinating solvents to disrupt the purported O→Cu chelation. As illustrated in entries 3 and 5 of Table 2, when the catalytic ACA are performed in THF **18** and **19** are generated in ≥98% *ee*; as shown in entry 2, the less Lewis basic Et$_2$O does not have as pronounced an effect. Remarkably, in the case of the more electron rich unsaturated lactones (Table 1), there is <2% conversion when THF is used as the solvent.

Next, we turned our attention to the least electrophilic class of ACA substrates (**III**, Scheme 1). As the data summarized in Table 3 indicate, amino acid based chiral phosphanes are effective with this group of heterocyclic enones: ACA products are formed efficiently in ≥98% *ee*. As was the case with transformations involving unsaturated lactones, the presence of an aldehyde trap is required (to circumvent β elimination or intermolecular Michael addition). A similar ligand hierarchy, as mentioned for studies summarized in Table 1, holds here as well. Unlike reactions in Table 1, the products **a** of the three-component asymmetric process, are generated in high diastereoselectivity (80 to >98% *de*), and, as with transformations in Table 1, can be converted to ACA products **b** in high yield (Table 3).



With an effective protocol for ACA of alkylzinc reagents to substrate classes **I**–**III** in hand, we focused our efforts on gaining insight regarding the nature of the chiral Cu complex. In this context, our efforts to synthesize and isolate a complex derived from a peptide phosphane and (CuOTf)$_2$·C$_6$H$_6$ was unsuccessful (presumably due to sensitivity of the Cu–triflate complexes). However, as depicted in Scheme 3, we have been

Scheme 3. Preparation of air-stable chiral Cu complexes **25** and **26**.

able to prepare the complexes derived from reaction of phosphane **1** with CuCl and CuI. Thus, treatment of unpurified commercial samples of CuCl and CuI with **1** at ambient temperature results in the formation of orange powders. These air-stable Cu complexes,[5c] for which we propose structures **25** and **26**, have been characterized spectroscopically (Scheme 3).[12] As the representative data summarized in Table 4 illustrate, not only are **25** and **26** effective ACA catalysts (entries 2 and 4), these chiral Cu complexes deliver improved enantioselectivity compared to when catalysts are prepared in situ (entries 1 and 3, Table 4). Higher catalyst loading (8 vs. 2 mol% in Table 1) is needed for reactions promoted by **25** and **26** (vs. **1**–**3**), likely due to lower activity of metal halide versus triflate complexes. Complex **25** is less stable than iodide **26**; whereas a week-old sample of **26** (stored in

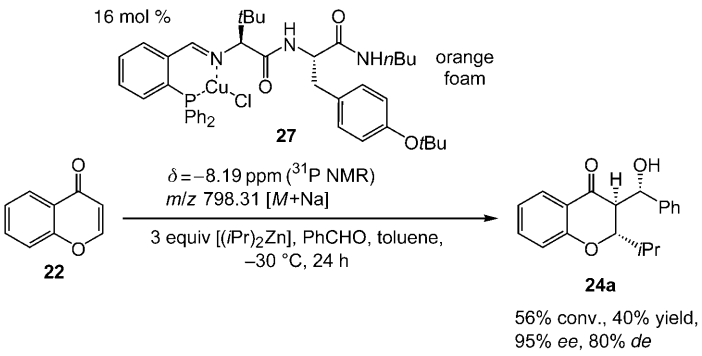
Table 4: Representative ACA catalyzed by **25** and **26**.[a]



$$\mathbf{7} \xrightarrow[2)\ \text{PCC, NaOAc}]{1)\ 8\,\text{mol}\%\ \text{catalyst, [Et}_2\text{Zn], PhCHO}} \mathbf{9b}$$

Entry	Catalyst	Conv. [%][b]	Yield [%][c]	*ee* [%][d]
1	**1** + CuCl	92	51	90
2	**25**	92	87	94
3	**1** + CuI	57	24	63
4	**26**	92	74	89

[a] [Et_2Zn] (3 equiv), −30 °C, toluene, 12 h, N_2. [b] Conversion determined by analysis of 400 MHz ^{1}H NMR spectra of unpurified mixtures. [c] Isolated yields after silica gel chromatography; oxidations proceed in ≈90% isolated yield. [d] Enantioselectivities determined by chiral HPLC analysis.

air) promotes ACA with equal efficiency and enantioselectivity, a similar batch of **25** affords **9b** in 87% yield and 72% *ee* (vs. 94% with a freshly prepared sample).

An additional example, shown in Equation (1), illustrates that isolation of Cu-peptide chiral complexes is not limited to

(1)

the derivatives of phosphane **1**. Thus, in the presence of **27** (16 mol%), derived through reaction of **2** ($\delta = -10.7$ ppm, ^{31}P NMR) with CuCl (1 equiv, CH_2Cl_2, 22 °C; 84% yield), heterocyclic enone **22** can be converted to **24a** in 95% *ee* and 80% *de*. Similar to reactions with **25** and **26**, the copper chloride complex is less effective than when the chiral catalyst is prepared in situ from $(CuOTf)_2{\cdot}C_6H_6$ and phosphane **2** (see entry 3, Table 3).

In summary, we report the first generally effective method for catalytic ACA of dialkylzinc reagents to unsaturated furanones and pyranones with different steric and electronic properties. The present method significantly enhances the general utility of Cu-catalyzed ACA of alkylmetal reagents to unsaturated carbonyls. Synthesis, isolation, and characterization of catalytically active and air-stable chiral Cu–peptide complexes **25**–**27** enhance the practical utility of these protocols and set the stage for future mechanistic investigations.

Water Condensation in Hydrophobic Nanopores**

There are many intriguing situations in everyday life where water is confined to spaces of nanoscopic dimensions by hydrophilic as well as hydrophobic substrates such as in colloidal particles,[1–4] protein cavities,[5] and inorganic solid walls.[6,7] Fundamental interest stems from the fact that the properties of confined water are believed to be very different from those of the corresponding bulk fluid at the same temperature and chemical potential.[8–11] Recently, it was shown that storage or dissipation of mechanical energy could be achieved by forced intrusion/extrusion of water into/from hydrophobic porous materials.[12–14] Intrusion of water into silicalite-1 zeolite at a hydraulic pressure of about 100 MPa at room temperature results in its condensation. A spontaneous capillary evaporation (drying) took place upon release of the pressure. Similar behavior was observed very recently in the case of hydrophobized MCM-41 mesoporous materials.[15] Interestingly, the intrusion/extrusion cycle was accompanied by a hysteresis effect in the latter case, but not in the former one. Situations were also encountered in which no extrusion of water took place upon release of the pressure (zeolite β and wide-pore MCM-41).[12–15] To shed light on these phenomena we have undertaken a molecular simulation study of the intrusion/extrusion of water into/from hydrophobic silicalite-1 zeolite. Some new experimental data are also reported. We have been able to reproduce, for the first time to our knowledge,the spontaneous condensation of water that is observed experimentally, and thus to investigate the properties of confined water in these hydrophobic nanopores at the molecular level.

The intrusion/extrusion process was investigated with silicalite-1 by using two different experimental devices. The same silicalite-1 sample, prepared according to a literature method,[12] was used in both cases. In the first device the water/silicalite-1 system was placed in a cell of variable volume (1.20 cm^3 under atmospheric pressure) which was immersed in an oil-containing vessel able to withstand very high hydrostatic pressure. The volume changes were determined at constant temperature by increasing the pressure progressively, as described in reference [16]. The compressibility curve obtained corresponds to that obtained by Eroshenko et al.[12,14] (Figure 1; dashed line). The method used in this first set of experiments is believed to be accurate for determining the water intrusion pressure, but the absolute

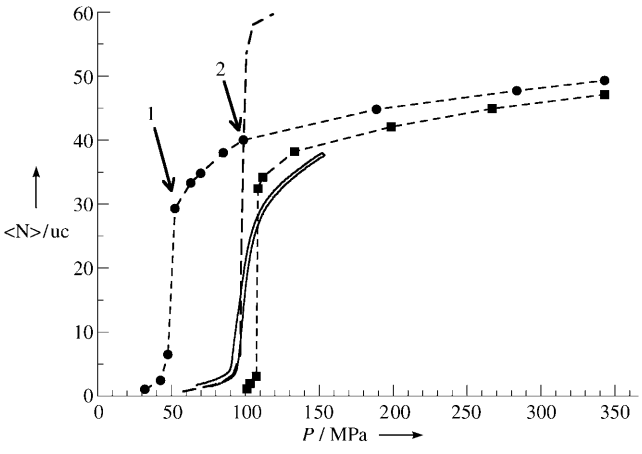

Figure 1. Condensation/drying isotherms of liquid water in silicalite-1 at 300 K. Solid line (displaying hysteresis): experimental data (this study); dashed line: experimental data;[12] circles: simulated isotherms with a silicon atomic charge of 1.4 a.u.; squares: simulated isotherm with a silicon atomic charge of 1.2 a.u. (see text). The dotted lines are a guide to the eye.

intruded volume seems to be overestimated. A second set of experiments was therefore performed which made use of a modified Carlo Erba mercury porosimeter, and a more realistic volume was obtained. In this case, the cell containing the water/zeolite system consisted of a 2-cm^3 polypropylene cylinder sealed by a mobile piston. This cell was introduced into the 15-cm^3 glass cell of the porosimeter which was filled with mercury. The variation in volume was determined from the conductivity measurement, which depends on the mercury height in the capillary tube of the glass cell. The maximum volume change was about 0.5 cm^3. We believe this methodology provides a more accurate measurement of the volume than the preceding case. The corresponding experimental intrusion/extrusion data are reported in Figure 1 (solid line). It is interesting to note that a porous volume of 0.18 cm^3 per gram of zeolite is obtained from the experimental intruded volume at 150 MPa and using the average computed water density of approximately 0.6 $kg\,m^{-3}$ (see below). This result is in complete agreement with the pore volume determined from nitrogen adsorption data.[12,13] This observation seems to demonstrate that the current volumetric data are much more accurate than the previously published ones. A very narrow hysteresis effect is observed during the intrusion/extrusion cycle; this effect was not observed in the first set of experiments. It is interesting to note that in a recent model proposed by Lefevre et al.,[15] it was predicted that the width of the intrusion/extrusion hysteresis in porous materials should progressively vanish as the pores get smaller. This prediction is in keeping with the current results.

We carried out Grand Canonical Monte Carlo (GCMC) simulations of the adsorption of water in silicalite-1. We used a rigid zeolite framework and used the atomic coordinates of the orthorhombic structure determined by Olson and et al.[17] We simulated a box of eight unit cells with periodic boundary conditions. We used the semiempirical TIP4P potential for water,[18] which was recently shown to provide a fairly good description of the adsorption of water in faujasite zeolites.[7,19] The host/guest potential is of the "Kiselev type":[20,21] It contains a single effective Lennard–Jones term that acts between the oxygen atoms of the framework and the oxygen atoms of the guest water molecules, together with a coulombic term that acts between the partial charges of the silicon and oxygen atoms and those of the guest molecules. We used the Lennard–Jones parameters for the zeolite oxygen atoms obtained from our previous work on the adsorption of hydrocarbons in silicalite-1[22] together with the Lorentz–Berthelot combining rules. The partial charge on the silicon atom was fixed at $+1.4$ a.u. (the zeolite oxygen atom bears a charge of -0.7 a.u. since the purely SiO_2 framework is neutral overall). There is an ongoing debate in the literature about the partial charge that a silicon atom should bear in silica-based materials; atomic charges have been reported in the range of 1.2 to 2.0 a.u., depending on the computational method used.[23–26] We found with the force-field model used here that the partial charge on the silicon atoms should be kept below approximately 1.7 a.u. for the silicalite-1 solid to exhibit hydrophobic character (namely, to prevent a capillary condensation phenomenon at a gas pressure below the saturation pressure of the bulk water). Details on this force-field adjustment will be reported elsewhere. We have chosen here the somewhat arbitrary value of 1.4 a.u. which corresponds to the Hartree–Fock calculation by Dovesi et al.[23] We have undertaken GCMC simulations of the adsorption of liquid water in silicalite-1. Thus, we have separately computed the relationship between the external pressure and the TIP4P chemical potential of liquid water at room temperature. GCMC simulations were then performed, at each pressure, by exchanging molecules between the zeolite sample and a fictitious external gas reservoir at the same chemical potential as the liquid water and at the pressure of interest. This method is similar to the one previously proposed by Snurr and coworkers for the adsorption of liquid alkanes.[27] Details of the GCMC algorithm and the statistical bias used can be found elsewhere.[22]

The adsorption data for the simulated liquid state at 300 K are reported in Figure 1. A stepwise condensation is observed at a pressure of about 50 MPa. The agreement with the experimental intrusion pressure is quite good, given that there is only a 3% difference in the chemical potential of liquid water between 50 and 100 MPa. An even better agreement with experimental data can be obtained by fixing an atomic charge of 1.2 a.u. on the silicon atom and -0.6 a.u. on each oxygen atom of the framework (Figure 1). The shape and the water loading of the computed intrusion isotherms are in good agreement with the currently reported experimental data. This observation is remarkable given the crudeness of the model used in the simulations. Simulations were also carried out using the MSPC/E semiempirical water potential model,[28] which is also known to reproduce quite well the saturation vapor pressure at room temperature. The computed adsorption curve (not shown here) was very similar to the TIP4P curve and also exhibited a stepwise, first-order-like condensation. This result is reminiscent of the two-state description of the water behavior in model carbon nanotubes[29] and nanoporous cylindrical channels[30] observed recently in molecular dynamics studies.

The computed isotherm shown in Figure 1 is reversible, within statistical uncertainties. This is generally what we expect for a Monte Carlo simulation, although it is known that GCMC adsorption isotherms may, in some special cases, exhibit hysteresis.[31] The computed isotherm displayed in Figure 1 can thus be considered as the equilibrium intrusion/extrusion curve of the model water/silicalite-1 system. It is the first time, to our knowledge, that this condensation/drying phenomenon has been reproduced theoretically.

We have examined in some detail the condensation mechanism in the molecular simulation model. The silicalite-1 framework (Figure 2) contains interconnected channels of pores of two types: straight channels which run in the direction of the *y*-axis and zigzag channels parallel to the *xz* plane. The Atlas of Zeolite structure types[32] denotes the silicalite-1 structure (MFI structure type) as being made of straight channels (SC) with a diameter of 5.4 Å, zigzag channels (ZC) with a diameter of 5.0 Å, and intersections (I). There are four SC, ZC, and I per unit cell, and they correspond to volume fractions of about 29, 33, and 38%, respectively. We have separately computed the local density of condensed water in these three subvolumes. This calcu-

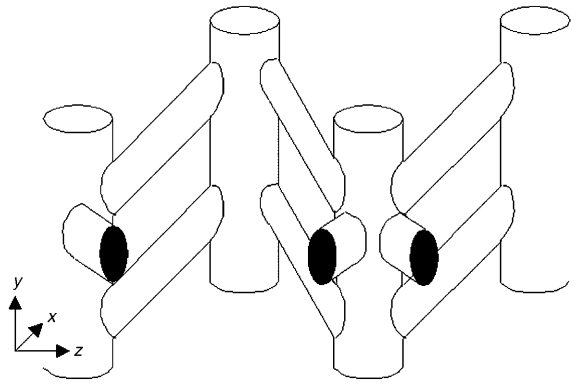

Figure 2. View of the interconnected pore channels in silicalite-1 (MFI-type structure).

lation is based on the determination of the void spaces in the zeolite model, which relies on a somewhat arbitrary definition of the "size" of the framework oxygen atoms. We have taken here a value of 1.5 Å for the van der Waals radius of the framework oxygen atoms. Consequently, the local density values shown in Figure 3, together with the average density

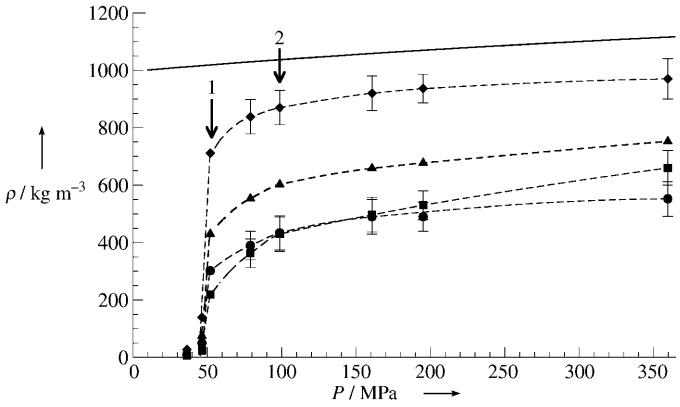

Figure 3. Density of condensed water in silicalite-1 as a function of pressure from GCMC simulations. Squares: local density in the zig-zag channels (ZC). Circles: local density in the straight channels (SC). Diamonds: local density in the intersections (I). Triangles: average water density in silicalite-1. Solid line: bulk water density. The dotted lines are a guide to the eye. No error bars are displayed for the average densities, for reasons of clarity.

and the bulk water density, depend on the criterion used for computing the void spaces, which leads to an uncertainty of about 10 % in the estimates of these local density values. The trends however (for example, the ratio of the intersection/straight channels densities and the way it changes with pressure) depend only weakly on this criterion.

The stepwise condensation phenomenon is observed in all three regions of the zeolite at a pressure of approximately 50 MPa. At this pressure (marked "1" in Figures 1 and 3) the average density of the condensed water is less than half that of the bulk water density under the same thermodynamic conditions. The condensed fluid is extremely inhomogeneous. The density in the intersections is three times as large as that of the fluid in the straight or zigzag channels. The average occupancy is 5 water molecules at an intersection, while there are only 1.5 molecules on average in the SC or ZC. At this stage, the filling of the channels (SC or ZC) is also highly inhomogeneous. Some of the sections of the channels are empty, while others contain 2–3 molecules. There is clearly a clustering effect in this first condensation step. The formation of water clusters in silicalite-1 was already suggested in some previous molecular dynamics studies.[33–35] The same behavior seems to hold true in the case of carbon nanopores.[36,37] The current results are in keeping with the observation of Vaitheeswaran et al.[37] that linear chains of water molecules inside a narrow cylindrical pore are less stable than the water clusters in a spherical nonpolar cavity of comparable volume.

A second condensation regime takes place as the pressure is increased from 50 to about 100 MPa. At the point marked "2" in Figures 1 and 3, each intersection is now occupied by six molecules and the SC and ZC by two water molecules. The channel filling now becomes homogeneous, with each channel section containing approximately the same number of molecules. At this stage, the water density in the intersection has reached 85 % of the bulk fluid value, while the density in the channels is lower by a factor of two.

A progressive filling of the silicalite-1 nanopores is observed upon pressure increases above 100 MPa. Given the uncertainties in the density calculations, it is hard to tell whether or not the density at the intersections reaches the bulk value at a sufficiently high pressure. However, it seems clear that the water density in the channels is always lower by a factor close to two. This fact can be interpreted by considering that the 3D-like geometry of the pore intersections enables water molecules to pile up in more or less the same way as in the bulk liquid. On the other hand, the pseudo-1D channel geometry prevents such a bulklike state from being reached. It is worth mentioning that the strong depletion of fluid observed in these simulations cannot simply be accounted for by a failure of the water force-field. The TIP4P intermolecular potential was checked to provide very accurate values for the density of bulk water at high pressure.

The observed water depletion is attributed to the hydrophobic (nonwetting) character of the purely siliceous nanopores studied here. Silicalite-1 zeolite consists of a three-dimensional network of SiO_4 tetrahedra connected to each other through shared oxygen atoms. This arrangement enables the build up of a purely siliceous open framework material without surface defects (bond breaking, presence of silanol groups).[12] Conversely, amorphous silica surfaces are highly defective, and thus display hydrophilic character. This is the case, for example, for the mesoporous MCM-41 materials. Hydrophobicity is generated in MCM-41 by covalent grafting of nonpolar siloxane chains.[15] In a recent study Engemann et al.[38] reported experimental evidence of interfacial melting of ice in contact with amorphous silica. The

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

authors observed a quasiliquid layer with an enhanced density ($\rho \approx 1.2$) relative to bulk water. This fact can be tentatively attributed to the hydrophilic character of the amorphous silica surface.

One lesson that can be learned from this study is that simple models and simulation methods found useful for studying gas adsorption in nanoporous materials can be extended to describe the intrusion/extrusion cycle of a nonwetting fluid in a hydrophobic solid. We have reproduced for the first time the condensation transition of water in silicalite-1 zeolite at room temperature. The condensation process disclosed by computer simulations is much more complex than initially expected from the intrusion/extrusion experiments. The picture of water confined to hydrophobic spaces of nanoscopic dimensions that emerges from this study is one of a strongly depleted and highly inhomogeneous fluid.

Phenoxyl Radicals Hydrogen-Bonded to Imidazolium: Analogues of Tyrosyl D· of Photosystem II: High-Field EPR and DFT Studies**

Laurent Benisvy, Robert Bittl, Eberhard Bothe, C. David Garner, Jonathan McMaster, Stephanie Ross, Christian Teutloff, and Frank Neese**

Tyrosyl radicals play a crucial role in many biological systems.[1] The remarkably stable tyrosyl radical, Tyr_D· in photosystem II (PSII)[2] is suggested to be hydrogen-bonded to an imidazol(ium) proton from a nearby histidine residue[3] (His 190 in higher plants; His 189 in cyanobacteria). Oxidation of Tyr_D to Tyr_D· probably proceeds via proton-coupled electron transfer (PCET) with migration of the phenoxyl proton to the imidazole group of the adjacent histidine.[4] Production of chemical analogues of Tyr_D· is of much current theoretical and experimental interest. Three recent studies have reported the oxidation of an α-alkylaminophenol derivative by a quasireversible PCET process, to form a phenoxyl radical hydrogen-bonded to an alkylammonium center.[5]

We have reported the synthesis and characterization of (**1**–**3**)H,[6] each of which has an intramolecular hydrogen bond involving the phenolic proton and an imidazole nitrogen atom. (**1**–**3**)H undergo a reversible, one-electron oxidation to form the corresponding radical cation, $[(\mathbf{1}–\mathbf{3})H]^{\bullet+}$. The oxidation of (**1**–**3**)H (see Scheme 1) could occur either by

Scheme 1. Possible mechanisms for the oxidation of (**1**–**3**)H to $[(\mathbf{1}–\mathbf{3})H]^{\bullet+}$.

PCET to produce an $R–O^{\bullet}\cdots H–N^{+}$ arrangement (designated $[(\mathbf{1}–\mathbf{3})H_N]^{\bullet+}$) or by electron transfer (ET) to produce an $R–O^{+\bullet}–H\cdots N$ arrangement (designated as $[(\mathbf{1}–\mathbf{3})H_O]^{\bullet+}$). Herein, we report the results of high-field EPR studies and DFT calculations that provide a definitive interpretation of the geometric and electronic structure of these $[(\mathbf{1}–\mathbf{3})H]^{\bullet+}$ radical cations.

The X-band EPR spectra of $[(\mathbf{1}–\mathbf{3})H]^{\bullet+}$ in CH_2Cl_2 at 77 K each consist of a single isotropic signal, centered at $g \approx 2.004$ with a linewidth of about 10 G and no discernible hyperfine splitting.[6] The absence of hyperfine splitting and the unresolved *g*-tensor anisotropy preclude any geometric and electronic structural information being obtained from the X-band EPR spectra alone. The lack of resolved proton hyperfine splittings may be taken as evidence for the presence of the $[(\mathbf{1}–\mathbf{3})H_N]^{\bullet+}$ forms of the radicals. However, a more positive experimental proof for this conjecture is required and is provided by high-field EPR. W-band (94.0 GHz) high-field EPR spectra, recorded for electrochemically generated $[(\mathbf{1}–\mathbf{3})H]^{\bullet+}$ in CH_2Cl_2 solution (1 mM) at 80 K (Figure 1 and Supporting Information) show three well-resolved *g* values; each spectrum was simulated successfully with $g_x = 2.0063–2.0067$, $g_y = 2.0043$, and $g_z = 2.0022/3$ (Table 1).

Density functional calculations were performed to interpret the W-band EPR spectra of $[(\mathbf{1}–\mathbf{3})H]^{\bullet+}$ and to investigate whether these data discriminate between the possible structures $[(\mathbf{1}–\mathbf{3})H_N]^{\bullet+}$ and $[(\mathbf{1}–\mathbf{3})H_O]^{\bullet+}$ (Scheme 1). As a calibration, the DFT calculations were performed initially for (**1**–**3**)H. In each case, the calculated structural parameters were in good agreement with the corresponding data obtained by X-ray crystallography;[6] the value of each bond length was reproduced to an accuracy of not worse than ±0.03 Å (see Supporting Information). For the corresponding $[(\mathbf{1}–\mathbf{3})H]^{\bullet+}(g)$ radical cations, DFT calculations were performed for the two forms $[(\mathbf{1}–\mathbf{3})H_N]^{\bullet+}$ and $[(\mathbf{1}–\mathbf{3})H_O]^{\bullet+}$, and in each

$[\mathbf{3}H_O]^{\bullet+}$	calcd	2.0044	2.0038	2.0022	2.0035

case convergence to a distinct energy minimum occurred. The difference in energy of the two forms of $[(\mathbf{1}–\mathbf{3})H]^{\bullet+}(g)$, $\Delta E = [E([(\mathbf{1}–\mathbf{3})H_N]^{\bullet+}) - E([(\mathbf{1}–\mathbf{3})H_O]^{\bullet+})]$, is calculated as -4.8, $+7.7$, and $-26.4\ kJ\,mol^{-1}$ for **1**H, **2**H, and **3**H, respectively. These results suggest that $[(\mathbf{1}–\mathbf{3})H_N]^{\bullet+}$ (the proton-transferred species) is favored for $[\mathbf{1}H]^{\bullet+}(g)$ and $[\mathbf{3}H]^{\bullet+}(g)$, but not for $[\mathbf{2}H]^{\bullet+}(g)$.

The bond lengths calculated for the geometry-optimized structures of $[(\mathbf{1}–\mathbf{3})H_N]^{\bullet+}$ and $[(\mathbf{1}–\mathbf{3})H_O]^{\bullet+}$ are listed in Table SI2. Each optimized structure involves an intramolecular hydrogen bond: for $[(\mathbf{1}–\mathbf{3})H_O]^{\bullet+}$, the H···N distances are calculated as 1.600 (**1**H), 1.623 (**2**H), and 1.435 Å (**3**H); for $[(\mathbf{1}–\mathbf{3})H_N]^{\bullet+}$, the O···H distances are calculated as 1.832 (**1**H), 1.781 (**2**H), and 1.867 Å (**3**H; see Supporting Information).

The g-tensor parameters calculated by DFT for $[(\mathbf{1}–\mathbf{3})H_N]^{\bullet+}$ and $[(\mathbf{1}–\mathbf{3})H_O]^{\bullet+}$ are compared with those observed experimentally in Table 1. In each case, the g values calculated for $[(\mathbf{1}–\mathbf{3})H_N]^{\bullet+}$ correspond very closely (within 100 ppm) to those observed experimentally; however, this is not true for the g values calculated for $[(\mathbf{1}–\mathbf{3})H_O]^{\bullet+}$: in particular, each g_x is calculated to be significantly lower (2000–3000 ppm) than the experimental value. Moreover, the W-band EPR spectrum of each $[(\mathbf{1}–\mathbf{3})H]^{\bullet+}$ is consistent with the presence of only a single species. Therefore, we conclude that all of the radical cations $[(\mathbf{1}–\mathbf{3})H]^{\bullet+}$ in CH_2Cl_2 solution at 80 K are present as $[(\mathbf{1}–\mathbf{3})H_N]^{\bullet+}$. Consequently, the slight energetic preference ($+7.7\ kJ\,mol^{-1}$) for $[\mathbf{2}H_O]^{\bullet+}(g)$ given by the DFT calculations is considered to be in error.

The nature of the singly occupied molecular orbital (SOMO) and the corresponding unpaired spin-density distribution were analyzed for both $[(\mathbf{1}–\mathbf{3})H_N]^{\bullet+}$ and $[(\mathbf{1}–\mathbf{3})H_O]^{\bullet+}$ (Figure 2 and Supporting Information). Each $[(\mathbf{1}–\mathbf{3})H_O]^{\bullet+}$

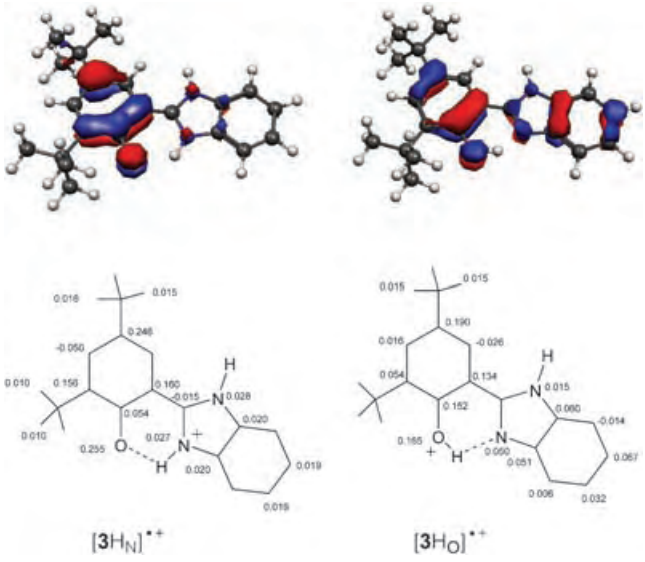

Figure 2. SOMO orbitals (top) and the spin populations (bottom) for $[\mathbf{3}H_N]^{\bullet+}$ and $[\mathbf{3}H_O]^{\bullet+}$.

involves a SOMO that extends over the phenol and imidazole rings with phenol/imidazole distributions of the unpaired spin population of approximately 70:30, 40:60, and 25:75 for $[\mathbf{3}H_O]^{\bullet+}$, $[\mathbf{1}H_O]^{\bullet+}$, and $[\mathbf{2}H_O]^{\bullet+}$, respectively. In contrast, the SOMO of each $[(\mathbf{1}–\mathbf{3})H_N]^{\bullet+}$ is localized primarily on the phenol ring, and the phenol/imidazole distribution of the unpaired spin population is approximately 90:10, 80:20, and 65:35 for $[\mathbf{3}H_N]^{\bullet+}$, $[\mathbf{1}H_N]^{\bullet+}$, and $[\mathbf{2}H_N]^{\bullet+}$, respectively. Thus, these calculations indicate that the electronic structure of $[\mathbf{3}H_N]^{\bullet+}$ is essentially that of a phenoxyl radical hydrogen-bonded to an imidazolium cation.

For the phenol ring of each $[(\mathbf{1}–\mathbf{3})H_N]^{\bullet+}$, the typical[5b,7] pattern of an alternating spin-density distribution is obtained with a significant amount of positive spin population located at the O, C_{ortho}, and C_{para} atoms (Figure 2 and Supporting Information). Also, there is a positive spin population at the phenolic carbon atom that is indicative of a redistribution of the spin density from that of an isolated phenoxyl radical and is attributed to hydrogen-bond formation.[7] The length of the C–O bond is calculated (Table SI2) to be significantly longer in $[(\mathbf{1}–\mathbf{3})H_O]^{\bullet+}$ (1.332 (**1**H), 1.343 (**2**H), and 1.307 Å (**3**H)) than in $[(\mathbf{1}–\mathbf{3})H_N]^{\bullet+}$ (1.265 (**1**H), 1.270 (**2**H), and 1.261 Å (**3**H)). The latter values are in excellent agreement with: 1) the length of the C–O bond of $\mathbf{1}^{\bullet}$ (1.264(5) Å) in the Cu^{II}–phenoxyl radical complex $[Cu(\mathbf{1}^{\bullet})(\mathbf{1})](BF_4)$[6a,b] and 2) those calculated (1.26–1.27 Å) for the C–O bond of a phenoxyl radical hydrogen-bonded to an imidazolium group.[7]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The above analysis of the g tensors has illustrated that this approach represents a powerful tool for determining the nature of a phenoxyl radical. Theoretical[7,8] and experimental studies[4,5b,9] have indicated that hydrogen bonding to a phenoxyl (or tyrosyl) radical results in a considerable lowering of the g_x value but leaves g_y and g_z essentially unaffected. The g_x values observed for each $[(\mathbf{1}–\mathbf{3})H_N]^{\bullet+}$ (2.0065–2.0067, Table 1) are very similar to those observed for hydrogen-bonded tyrosyl radicals; for example, for γ-irradiated crystals of tyrosine·HCl, $g_x = 2.0067$;[10] $Tyr_D^{\bullet}$ of PSII, $g_x = 2.00643$ (radical generated at cryogenic temperature)[4] and $g_x = 2.00756$ (radical generated at physiological temperature);[11] $Tyr^{\bullet}$ of HSV1 RNR: $g_x = 2.0076$[12] and hydrogen-bonded phenoxyl radical compounds (g_x ranging from 2.0061 to 2.0066).[5b] These g_x values are significantly lower than those observed for non-hydrogen-bonded tyrosyl radicals; for example, $Tyr^{\bullet}$ of *E. coli* RNR, $g_x = 2.0087$,[9] or of *S. typhimurium* RNR,[13] $g_x = 2.0089$.

Theoretical studies of the g tensors of aromatic free radicals[14] indicate that variations in the g_x value of a phenoxyl radical may be understood as arising from a combination of two effects: 1) changes in the unpaired spin population at the oxygen atom, the constituent atom with the largest spin–orbit coupling constant; and 2) changes in the relative energies of two oxygen-based orbitals, the out-of-plane p_z orbital, which makes a significant contribution to the SOMO of a phenoxyl radical, and the in-plane p_y lone pair orbital, the contribution of which to the g shift arises as a result of spin–orbit coupling with the electron in the SOMO. This latter effect produces a magnetic moment along the C–O axis that increases the value of g_x. Formation of an in-plane hydrogen bond stabilizes the p_y lone pair, increases the energy difference between this orbital and the SOMO, and results in less effective spin–orbit coupling and a decrease in the g_x value (vide infra). In this respect, the species $[(\mathbf{1}–\mathbf{3})H_O]^{\bullet+}$ represent extreme cases in which the p_y lone pair is directly involved in the O–H bond and therefore, is not involved in efficient spin–orbit coupling with the SOMO, which explains the very low g_x values calculated for these species. For the $[(\mathbf{1}–\mathbf{3})H_N]^{\bullet+}$ radical cations, the DFT calculations indicate that the strength of the hydrogen bond increases across this series, that is, the O···HN distance decreases (1.867, 1.832, and 1.781 Å, respectively; see Supporting Information) and leads to a decreased g_x value. For these $[(\mathbf{1}–\mathbf{3})H_N]^{\bullet+}$ systems, in addition to the effect of hydrogen bonding on the g_x value, the extent of the delocalization of the unpaired electron onto the imidazole ring must be considered. Across this series, the unpaired spin population at the oxygen atom ($\rho(O) = 0.255$, 0.230, and 0.189, respectively; see Figure 2 and Supporting Information) decreases as a result of the increased delocalization of the unpaired spin density onto the imidazole ring (vide infra), and this also will lead to a decrease in the g_x value. Thus, these two effects operate in the same sense, consistent with the relative magnitudes of the g_x values of $[\mathbf{3}H_N]^{\bullet+}$ (2.0067), $[\mathbf{1}H_N]^{\bullet+}$ (2.0065), and $[\mathbf{2}H_N]^{\bullet+}$ (2.0063).

In conclusion, we have demonstrated that the one-electron oxidation of (**1**–**3**)H occurs by a PCET mechanism and produces the corresponding $[(\mathbf{1}–\mathbf{3})H_N]^{\bullet+}$; that is, a phenoxyl radical hydrogen-bonded to an imidazolium cation. The resolution of the principal g values by W-band EPR spectroscopy and the interpretation of these data by DFT calculations were essential in determining the nature of the $[(\mathbf{1}–\mathbf{3})H]^{\bullet+}$ radical cations. Furthermore, the DFT calculations provided valuable insight into the electronic structure of these species. The g_x value of the $[(\mathbf{1}–\mathbf{3})H_N]^{\bullet+}$ radical cations is lower than that of a simple phenoxyl radical owing to delocalization of the unpaired spin and orbital-stabilization effects, both of which are directly related to the formation of an O···HN hydrogen bond. These $[(\mathbf{1}–\mathbf{3})H_N]^{\bullet+}$ radical cations, notably $[\mathbf{3}H_N]^{\bullet+}$, represent valuable chemical analogues of $Tyr_D^{\bullet}$ in PSII, and further spectroscopic and theoretical studies of these species are currently being undertaken in our laboratories.

Experimental Section

Each radical cation was generated electrochemically by controlled potential coulometry with a platinum-grid working electrode, an $Ag/AgNO_3$ reference electrode, and a platinum brush in a counter electrode compartment. Each experiment was performed under dinitrogen at −25 °C with the compound (1 mM) in degassed CH_2Cl_2 containing $[n\mathrm{Bu_4N}](BF_4)$ (0.2 M) as background electrolyte. The solution was transferred under exclusion of dioxygen into a W-band quartz tube (inner diameter 0.7 mm, length 3 cm) with a microsyringe. Each tube was inserted into a cryovial which was immediately frozen and stored in liquid nitrogen.

All calculations were performed with the ORCA program.[15] Geometry optimizations were performed in redundant internal coordinates by using the pure density functional[16] BP[17] method with the TZVP[18] basis set on all atoms. For both the geometry optimization of the radical species and the g-tensor calculation, the CH_2Cl_2 solvent ($\varepsilon = 9.08$) was simulated by the COSMO dielectric continuum approach.[19] The B3LYP[20] hybrid DFT method, together with the EPR-II[21] basis set, was employed for the calculation of the magnetic properties at the optimized geometries of the radical species. Molecular g tensors were calculated by the coupled-perturbed Kohn–Sham method[22] and the multicenter, spin–orbit mean-field[23] (SOMF) spin-orbit coupling operator in the resolution-of-the-identity approximation.[24]

W-band (94 GHz) spectra were recorded on a Bruker Elexsys E680 spectrometer at 80 K with a microwave power of 0.32 μW, 5 G field modulation amplitude at 10 kHz modulation frequency, and a lock-in time constant of 82 ms. The magnetic field was calibrated against a LiLiF g standard[25] at microwave frequencies measured by the integrated frequency counter; all spectra were normalized to 94.0 GHz. The simulated spectra and the associated parameters were obtained with Bruker Simfonia software.

Mesoporous Silicates

DOI: 10.1002/anie.200500113

Synthesis of Mesocage Structures by Kinetic Control of Self-Assembly in Anionic Surfactants**

Alfonso E. Garcia-Bennett, Natalia Kupferschmidt, Yasuhiro Sakamoto, Shunai Che, and Osamu Terasaki*

Molecular self-organization is the topic of numerous fundamental and applied studies for its potential in diverse applications in areas ranging from catalysis to photonic crystals, from biomimetic chemistry to sensor technology.[1–3] The study of such systems is central to physics, mathematics, biological systems, and materials chemistry alike. Innovative methods for the assembly of ordered structures with self-assembling building units at various length scales are constantly proposed. Among these, the self-assembly of lyotropic liquid crystals to form mesoporous structures, as pioneered by Kresge et al.,[4] is the center of a large academic and industrial effort due to the high potential to tailor porous properties of high-surface-area inorganic frameworks through variations in the self-assembling surfactant template and synthesis conditions. Functionalization of their internal surfaces renders them suitable for applications. New synthetic methods for the preparation of mesoporous structures are being developed. For example, the enlargement of pore sizes by the use of polymeric surfactants has led to mesoporous solids with enhanced diffusion and transport properties such as SBA-15 (*p6mm*), FDU-5 ($Ia\bar{3}d$), and SBA-16 ($Im\bar{3}m$).[5,6] Low-symmetry mesostructures have been reported previously, obtained using bolaform surfactants, as in the case of two-

dimensional SBA-8 (*c2mm*),[7] and by evaporation-induced self-assembly (EISA).[8,9]

Recently, the preparation of highly ordered mesoporous structures using anionic surfactants and co-structure-directing agents (CSDAs) was reported.[10] This synthesis route has proven successful for the formation of several novel mesoporous phases. A face-centered cubic structure ($Fd\bar{3}m$), named anionic mesoporous solid (AMS-*n*) AMS-8, was identified and modeled by electron crystallography.[11] Furthermore, a hexagonal structure with chiral arrangement of the pores has been prepared.[12] The diversity of structure types that are possible using *N*-acyl amino acid anionic surfactants is already impressive, but little is known about the interaction of the CSDA with the anionic head group of the surfactant and its role in the synthesis mechanism.

A third structure, formed by the use of *N*-lauroyl glutamic acid as anionic surfactant and (3-aminopropyl)trimethoxysilane (APS) as CSDA, has been proposed. Named AMS-2, this mesocage silicate is composed of nonperiodic structural modulations observable as unit cell shifts of one-half.[13] Spherical micelles, which are used as templates for mesocage solids such as AMS-2, form in lipid/water and surfactant systems and undergo thermal, compositional, and time-dependent kinetically controlled structural transformations. Transitions can be described in terms of the surfactant packing parameter *g*, which is dependent on the kinetic surfactant chain length, the effective head-group area at the micelle surface, and the total surfactant volume. In practice, few phases are observed and it is difficult to control kinetics in structural transformations.[14]

Herein we demonstrate the possibility of inducing structural transformations in the synthesis of mesocage materials by delaying the time of addition of the silica source (tetraethyl orthosilicate, TEOS) with respect to the CSDA, the importance of which is clearly associated with precise control of the micellar (local) and structural (mesoscale) characteristics of the resulting porous solid.

A phase transformation expanding four different cubic structures was studied. Powder X-ray diffraction (XRD) data are unable to yield detailed structural information despite the increased order of AMS-*n* mesostructures. In contrast, electron microscopy investigations clearly show that it is possible to form mesoporous structures of lower symmetry with counterparts in atomic-scale materials such as intermetallic compounds.

These investigations open up avenues in synthesis, characterization, and application that are central to the development not only of mesoporous structured materials but also nanotechnology and materials engineering.

Figure 1 shows high-resolution transmission electron microscopy (HRTEM) images recorded along high-symmetry zone axes of calcined mesostructures synthesized with different APES-*t*-TEOS, for which *t* denotes the time in minutes between the addition of the CSDA and TEOS, *N*-lauroyl glutamic acid as self-assembling anionic surfactant, and aminopropyltriethoxysilane (APES) as CSDA. Tilt-series selected-area electron diffraction (SAED) patterns were recorded to determine the structural characteristics of each sample and confirmed the presence of four separate meso-

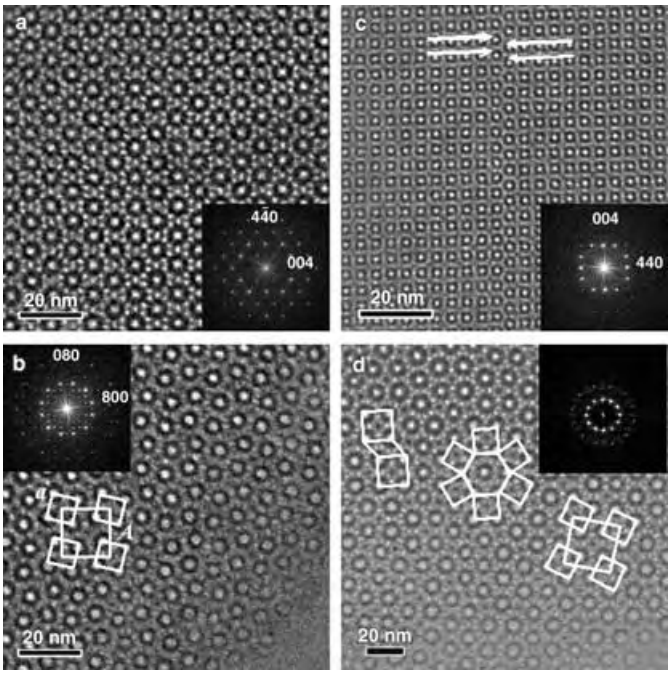

Figure 1. HRTEM images of mesocage structures synthesized by using *N*-lauroyl glutamic acid as surfactant and APES as CSDA. Images are viewed along a) [110] (AMS-8, $Fd\bar{3}m$), b) [001] (AMS-9, $P4_2/mnm$), c) [100] (SBA-1-type, $Pm\bar{3}n$), and d) (AMS-2; modulated structure). White insets show the periodic zigzag arrangement of cages in AMS-9 and the resulting superlattice, where $a = 84$ and $A = 168$ Å (b), and the nonperiodic arrangement of domains in AMS-2, composed of two distinct units, namely, slabs of $Pm\bar{3}n$ and $P4_2/mnm$ structures, as well as other motives and defects of the stacking-fault type (d). The insets show in all cases corresponding Fourier transform diffractograms.

structures in the *N*-lauroyl glutamic acid/APES system reported here. All samples display a high degree of periodicity over large areas and stability under the electron beam. Figure 1 a shows an HRTEM image recorded along the [110] orientation of APES-0-TEOS. Electron microscopy investigations are consistent with a cubic structure, and extinction conditions allow the space group symmetry to be confirmed as $Fd\bar{3}m$.

At first instance it is possible to deduce a lattice unit based on a cubic unit cell ($Pm\bar{3}n$) with $a = 84.0$ Å for a calcined sample of APES-2-TEOS (Figure 1 b). Periodic stacking faults characterized by unit cell shifts of one-half are clearly observed. The faults are arranged regularly to form a 2D antiphase boundary. From this image and the corresponding diffraction pattern a superlattice unit cell is easily determined, as outlined in Figure 1 b (inset). From a series of HRTEM tilt-series images and diffraction patterns it is possible to determine the crystal class and unit cell lattice parameters. The new superstructure is tetragonal, with lattice constants $(A)a = 167.9$ and $c = 84.0$ Å. This novel structure has been named AMS-9 (anionic surfactant-templated mesoporous silica 9). The formation of similar superstructures from cubic phases is well documented for intermetallic compounds and liquid crystals.[15,16] This strongly suggests that the formation of lower-symmetry 3D structures can be achieved at the mesoscale.

Figure 2 shows SAED patterns recorded along the [001], [110], [101], and [111] directions of AMS-9. The unusually numerous reflection spots at higher scattering angles in comparison with other mesoporous materials indicate a highly ordered mesostructure and a sharp density boundary between cage cavity and wall. Observable reflections can be summarized with the following general conditions: hkl, $hk0$, hhl, $hh0$: no condition, $0kl$: $k+l=2n$, $00l$: $l=2n$, $0k0$: $k=2n$, reducing the possible space-group symmetry to $P4_2nm$, $P\bar{4}n2$, or $P4_2/mnm$. The latter was chosen for its highest symmetry.

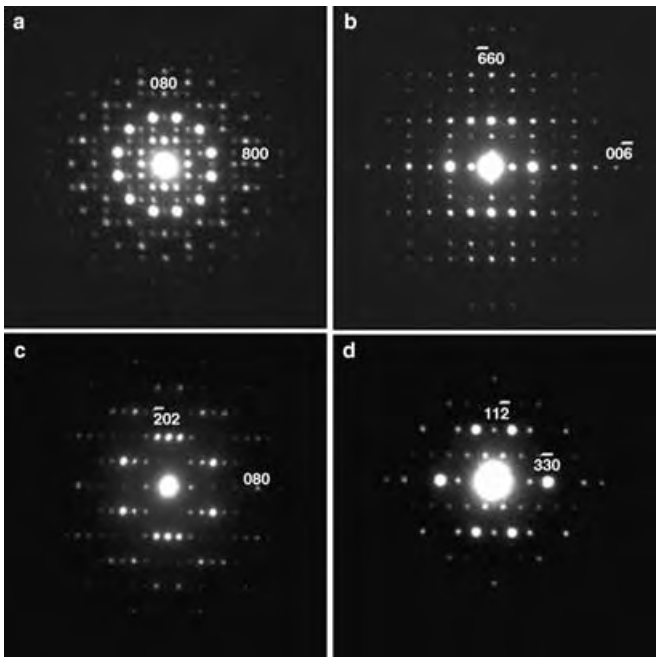

Figure 2. SAED patterns of calcined AMS-9 recorded along a) [001], b) [110], c) [101], and (d) [111] directions. Patterns are indexed on the basis of a tetragonal unit cell with lattice constants $a=167.9$ and $c=84.0$ Å. Reflection conditions are consistent with the space-group symmetry $P4_2/mnm$.

A 3D reconstruction of the structure,[17] based on analysis of Fourier transform (FT) diffractograms taken from thin parts of crystals (see Supporting Information), along high-symmetry zone axes of AMS-9 was conducted. Phase and amplitude of the structure factors were extracted from the 16 strongest reflections. Amplitudes were normalized by using common reflections obtained from images along [001], [101], [111], and [110] orientations. However, a unique set of phases could not be extracted from these four images due to the small number of common reflections encountered in tetragonal systems along these directions. The most probable data set (see Supporting Information) out of four possibilities can be deduced by considering neighboring cubic cage-type structures $Pm\bar{3}n$ and $Fd\bar{3}m$. From electrostatic potential density maps, it follows that cages in AMS-9 are arranged with space group $P4_2/mnm$. Figure 3a shows three 2D-sliced electrostatic potential density maps of the unit cell of AMS-9.

To obtain quantitative data about cage size and connectivity between cages from reconstructed data, an accurate estimation of the contrast transfer function (CTF) must be conducted. Almost all strong reflections of AMS-9 are at higher scattering angles than those of other mesoporous materials, so the relative intensity of each reflection is more sensitive to the CTF correction. A tentative model of the cage arrangement can be constructed based on $Pm\bar{3}n$ structural units (Figure 3b). The unit cell of AMS-9 is composed of 30 cages. Further analysis is being conducted to determine the size and connectivity of cages, and our findings will be reported shortly.

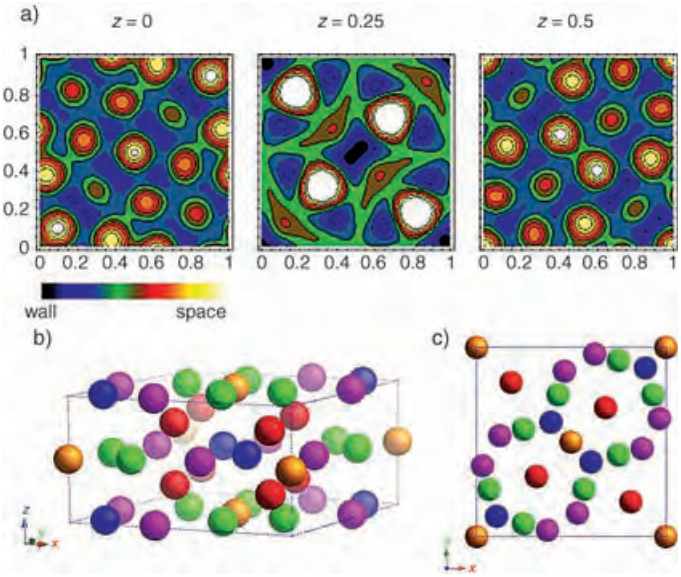

Figure 3. a) 2D electrostatic potential density maps derived from electron microscopy of the unit cell of AMS-9, shown parallel to the [001] plane. The unit cell slices are taken with $z=0$, 0.25, and 0.5. White contrast represents the pore space, and black contrast the silica wall. b), c) Model of the packing arrangement of cages in AMS-9, based on a $Pm\bar{3}n$ unit cell containing 30 cages (b), and viewed along the [001] direction (c). Each color represents a different crystallographic site of $P4_2/mnm$.

Samples synthesized in the range APES-6 $<t>$ 9-TEOS showed modulated structures that often contained a large number of defects of the stacking-fault type. Figure 1d shows a typical HRTEM image recorded on AMS-2 (APES-6-TEOS). Two structural units can be observed, based on $Pm\bar{3}n$ and $P4_2/mnm$ mesocage solids AMS-9 and SBA-1, in addition to stacking faults and motives showing the typical arrangement of cages.

A transition with time following the sequence $Fd\bar{3}m \rightarrow P4_2/mnm \rightarrow Pm\bar{3}n \rightarrow$ modulated structure $\rightarrow Fd\bar{3}m$ is observed when materials are prepared at 60 °C in the range APES-0 $<t>$ 10-TEOS. All structures obtained are mesocage materials. The apparent return to $Fd\bar{3}m$ is not fully understood. The proximity of all four structures in the phase diagram of *N*-lauroyl glutamic acid is a representation of the small differences in stabilization energy between each structure type. It is evident that small changes in the local environment of the spherical micelles caused by interaction and hydrolysis of the CSDA have a pronounced effect on the overall packing arrangement of the micelle. Similar structural transitions have been observed in systems using *N*-lauroyl glycine, lauric acid, and pluronics as surfactants, and APS, *N*-trimethoxysilyl-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

propyl-*N*,*N*,*N*-trimethylammonium chloride (TMAPS), and (3-mercaptopropyl)triethoxysilane (MPTS)[18] as CSDAs.

Mesostructures with $Fd\bar{3}m$ and $Pm\bar{3}n$ space-group symmetries have been reported previously,[11,16] and are the subject of continued structural and applied research as a result of their intricate 3D network of mesocages, connected to each other by small (< 20 Å) pore windows which can be used for the entrapment of functional guests such as dyes, metal oxides, or metal centers. The unit cell parameters for each of these structures as derived from TEM data are $a =$ 162.6 and $a = 82.8$ Å for the $Fd\bar{3}m$ and $Pm\bar{3}n$ phases, respectively. Both $Fd\bar{3}m$ (named AMS-8) and $Pm\bar{3}n$ (SBA-1-type) mesostructures (Figure 1a and c) are formed by self-assembly and cubic packing of spherical or pseudospherical micelles of different sizes. In the case of AMS-2 and AMS-9, the formation of new types of spherical cages is evident from electron microscopy. Evidence of a transition mechanism based on stacking faults can be clearly observed by electron microscopy (see Supporting Information). The connectivity and pore arrangement of intermediate phases are expected to be considerably different from samples that show no structural defects.

The structural and porous characteristics of samples reported here are summarized in Table 1. Raw-data nitrogen adsorption isotherms and pore size distribution curves are shown in the Supporting Information. From the capillary condensation steps it is possible to identify a structural change in samples synthesized with different APES-*t*-TEOS. An extra step is observed in the capillary condensation region of AMS-8, owing to a significant difference in cage size between its larger cage (44.5 Å) and smaller cage (40.3 Å). The adsorption curves of cubic structures SBA-1 and AMS-9 follow similar adsorption/desorption paths and show no hysteresis in the desorption branch; this indicates similarities in the packing arrangement of these two structures. However AMS-9 shows a higher total pore volume and a slight shift to higher pressures owing to the presence of larger cages. The modulated structure of AMS-2 shows decreased adsorption capacity and a smaller cage size. In this modulated structure it is possible that cages may be blocked to the external surface of the mesoporous particles, as a darkening of this sample is observed after calcination of the surfactant. Pore size distribution curves for all structures show additional peaks centered around 10 Å. These can be assigned to adsorption in the small connecting channels between cages.

The ^{29}Si MAS NMR spectra of calcined and extracted samples of AMS-9 are shown in Figure 4. The presence of T^3 and T^2 peaks between 50 and 65 ppm, attributed to $(R)Si(OSi)_3$ and $R(HO)Si(OSi)_2$, respectively, in the ^{29}Si MAS NMR spectra of a solvent-extracted sample of AMS-9 is evidence for the functionalization of the amorphous silicate framework with aminopropylsilane groups. The T^n/Q^n ratio of the as-synthesized (4.6:1) and extracted samples (3.2:1) of AMS-9 both indicate high incorporation of the CSDA. The data obtained by deconvolution agree well with the ratios derived from the integrals. This constitutes a direct method for incorporation of organic functional groups and offers considerable advantages for further functionalization of mesoporous structures over grafting and post-synthetic treatments.[19]

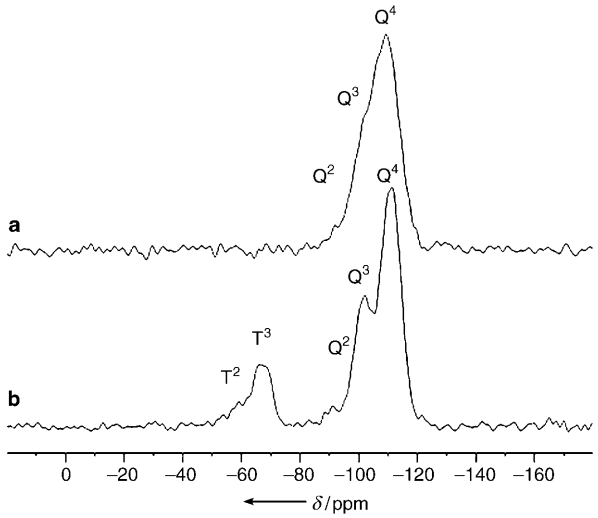

Figure 4. ^{29}Si CP-MAS NMR spectrum of calcined AMS-9 (a), and ^{29}Si MAS NMR spectrum of an extracted sample of AMS-9 (b). Peaks at $\delta = -92$, -100, and -109 ppm are attributed to Q^2, Q^3,and Q^4 silicon atoms ($Q^n = Si(OSi)_n(OH)_{4-n}$). T^3 and T^2 peaks can be attributed to $(R)Si(OSi)_3$ and $R(HO)Si(OSi)_2$, respectively.

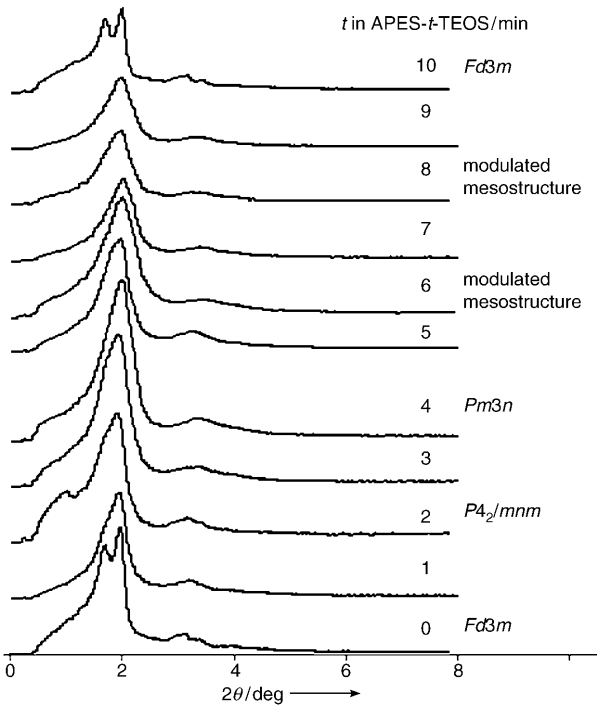

Figure 5. XRD patterns of calcined samples of mesostrucures synthesized by variation of the time of addition of the silica source with respect to the CSDA (APES-*t*-TEOS).

to the proximity of diffraction peaks at low scattering angles and the various defects associated with each structure. A typical example is the case of the $P4_2/mnm$ structure (APES-2-TEOS), where both SAED patterns show many very sharp reflections at low scattering angle.

In the system described herein the interaction between the CSDA and the hydrophilic head group of the anionic surfactant governs the phase transformation and allows control of the structural features of the desired phase. This might be due to an increase in the hydrophobicity at the interface between the surfactant head group and the CSDA. The use of organoalkoxysilanes has been noted to cause a stabilization of the structural properties of the resulting silicate products.[19] The rate of hydrolysis of the organoalkoxysilane (APES) is considerably slower than that of the tetraalkoxysilane (TEOS) due to the presence of the organic group bonded to Si. The addition of the latter allows the stabilizing anionic surfactant/CSDA micelle to "freeze" prior to condensation of the framework.

Bimodal spherical micelles are formed in this system in a ratio that varies considerably as the CSDA is hydrolyzed and interacts electrostatically with the surfactant head group, forcing the micellar interface to undergo conformational changes in shape and size. The possibility to study these changes through silicate intermediate phases offers the potential to control not only the structure but also the cage shape and connectivity with increased accuracy. This has been demonstrated by use of a CSDA to form a new structure, named AMS-9 ($P4_2/mnm$).

Analysis by HRTEM and fast Fourier transform (FFT) clearly shows the evolution with time of the CSDA effect. Ordered structures with long-range order are observed, in contrast to XRD evidence that reveals broad diffraction peaks suggesting disordered pore structures.

A fast and simple method with potential to form new structures, to design the extent of defects and size and shape of mesocages, and to functionalize the internal surface of mesoporous materials has been described. This approach has been applied in different anionic surfactant/CSDA systems and is largely extendable to different interactions by charge matching with the corresponding CSDA. Further synthetic and structural studies are being conducted and will be reported shortly.

Experimental Section

In a typical synthesis 0.2 g of *N*-lauroyl L-glutamic acid (C_{12}GlutA) was dissolved in 20 mL of deionized water with stirring at 80 °C overnight. The solution was cooled to 60 °C before 0.36 g of APES was added with rapid stirring (300 rpm). Tetraethyl orthosilicate (TEOS, 1.5 g) was added after a period of between 0 and 10 min (APES-*t*-TEOS) to give a final TEOS/APES/C_{12}GlutA/H_2O molar ratio in the gel of 1:0.21:0.085:154.

The pH value of the starting surfactant solution was 3.54 and rose rapidly to 9.30 (within seconds) on addition of the CSDA. The pH value of the reaction gel was 9.30 prior to the addition of TEOS. The pK_a values for the carboxylate groups in C_{12}GlutA were estimated on the basis of data for the free amino acid to be 2.19 and 4.25, while the isoelectronic point is 3.22. This implies that under the conditions of synthesis a strong electrostatic interaction between the surfactant head group and the CSDA is expected. The resultant silica gel solution was stirred for 10 min at 60 °C to promote hydrolysis of the CSDA and the silicate precursor. The reaction gel was then allowed to stand at 60 °C for 1 d with no stirring and for a further 2 days at 100 °C. After the reaction was complete the precipitate was collected by filtration, washed with 100 mL of H_2O, and dried overnight at room temperature. The surfactant was removed by calcination at 550 °C (1 h in flowing N_2, then 6 h in O_2) to give the porous AMS-*n* silicates. Alternatively, the surfactant was removed by solvent extraction in a Soxhlet apparatus with ethanol for 3 days.

XRD patterns were recorded on an STOE powder diffractometer equipped with $Cu_{K\alpha}$ radiation (40 kV, 20 mA) at a rate of 1.0 deg min^{-1} over the range of 1.0 to 10.0°.

The N_2 adsorption/desorption isotherms were measured at −196 °C on an ASAP 2020 Micromeritics Instrument. Calcined mesoporous AMS-*n* was outgassed for 6 h at 200 °C and 0.3 kPa. The BET specific surface area was evaluated from the adsorption data in the relative pressure range from 0.05 to 0.3. The total pore volume was estimated from the amount adsorbed at a relative pressure of 0.96. Pore size distribution curves were derived by NLDFT by assuming a spherical model of cages.

TEM was carried out with a JEOL JEM-3010 microscope operating at 300 kV ($C_s = 0.6$ mm, resolution 1.7 Å). Images were recorded with a CCD camera (model Keen View, SIS analysis, 1024 × 1024 pixels, pixel size 23.5 × 23.5 μm) at 30000–100000 × magnification under low-dose conditions.

^{29}Si MAS NMR spectra were measured on a Bruker Avance 500WB spectrometer with a 4-mm MAS probe under the following experimental conditions: 2.2 μs π/4 pulses, 30 s recycle delay, 2400 scans, and a spinning rate of 10 kHz.

pH-Switchable Through-Space Interaction of Organic Radicals within a Self-Assembled Coordination Cage

Koji Nakabayashi, Masaki Kawano, and Makoto Fujita**

Whereas the control of the through-space interaction of organic radicals by external stimuli promises the development of a variety of molecular scale magnetic devices, it has been achieved only in the solid state and never in solution.[1] We recently reported the through-space interaction of non-associative stable organic radicals in aqueous solution by accommodating two organic radicals in a self-assembled coordination cage **1**.[2] Owing to restriction by the cage, two

1

2

organic radicals are fixed in the cavity such that the two radical centers are in close proximity. If such a through-space interaction could be switched by a slight change in the environment, molecular magnetic devices that are responsive

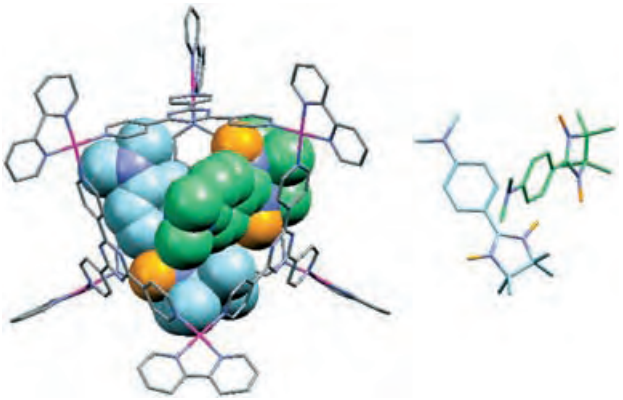
to external stimuli in solution could be prepared. Accordingly, we demonstrate herein the pH-responsive switching of spin–spin interactions between stable organic radicals.[3] Radical **2**[4] has an amine group that may be protonated, and upon doing so the affinity of radical **2** for the host should be significantly lowered as a result of cationic repulsion.[5] We show that the pH response of the through-space magnetic interaction between accommodated **2** is quite sensitive and digitalized.[6]

An excess of powdered **2** (4.1 mg, 15×10^{-3} mmol) was suspended in a solution of **1** (20.5 mg, 5.0×10^{-3} mmol) in H_2O (1.0 mL) at 80 °C for 1 h. After filtration of surplus **2**, a solution of the clathrate compound **1**·(**2**)$_2$ (5 mM) remained.[7] The solution of the clathrate was diluted with H_2O (9 mL) and used for ESR and UV/Vis spectroscopy measurements. A single crystal of **1**·(**2**)$_2$ suitable for X-ray diffraction was obtained by slow evaporation of H_2O from the solution at room temperature for 2 days. The crystal structure of **1**·(**2**)$_2$ is shown in Figure 1.



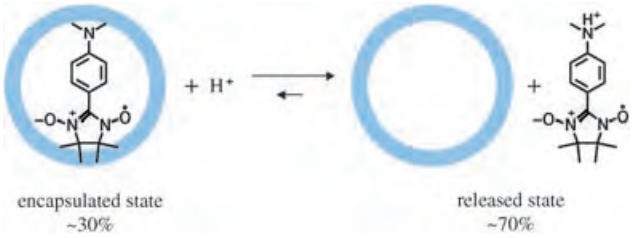


Figure 1. Molecular structure of the clathrate complex **1**·(**2**)$_2$ (left). Host **1**: stick representation (Pt magenta, N dark blue, C gray); guest **2**: space-filled representation (O yellow, N dark blue, C green/pale blue). The configuration of the radicals within the cage is shown more clearly by the stick representation on the right.

An advantage of using a discrete host is that the array of the guests is fixed regardless of whether they are in solution or in the solid state. Namely, the orientation of the guest depends upon the nature of the cavity in the host rather than the guest or the environment. In crystalline **1**·(**2**)$_2$, the guests are suitably oriented so that two spin centers[8] are in close proximity for efficient spin–spin interaction. The average distance between the spin centers is approximately 6.3 Å,[9] and we suggest that this orientation is fixed even in solution.

As expected from the X-ray diffraction study, the encapsulated guests in the cage showed intermolecular triplet-state spin–spin interactions. An intriguing feature of this clathrate complex is that the spin–spin interaction can be switched by pH.[10] As illustrated in Scheme 1, we observed the reversible process of release and reencapsulation of **2** in the pH range of 1.3 to 6.5 by ESR spectroscopy. Around pH 7, the ESR spectrum of the aqueous solution (frozen) of **1**·(**2**)$_2$ at 103 K[11] showed a split allowed transition ($\Delta m_s = 1$) at 321 mT and a forbidden transition ($\Delta m_s = 2$) at 160 mT; the

Scheme 1. Equilibrium in the acidified solution of host and guest, **1**·(**2**)$_2$.

observation of the latter is a proof of a triplet state that is derived from two interacting radicals in the cage (Figure 2a). When the solution was acidified to pH ≈ 1.3 with HNO_3, the

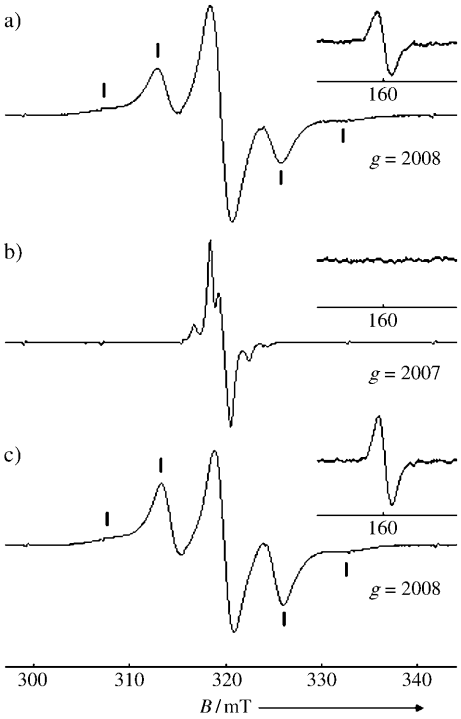

Figure 2. ESR spectra of clathrate compound **1**·(**2**)$_2$ (0.5 mM, 103 K): a) the initial solution (pH ≈ 6.5), b) the acidified solution (pH ≈ 1.3; with HNO_3), and c) the neutralized solution (pH ≈ 6.5; with K_2CO_3). The insets show forbidden transition; vertical bars indicate the signals derived from a triplet state. g = splitting factor.

triplet signal was completely suppressed and only a doublet signal with a hyperfine structure (due to coupling with the nitrogen nucleus) was observed. This observation strongly suggests that the protonated radical, **2**H$^+$, was released from the cage (Figure 2b). The profile of the doublet signal agreed with that of the signal of **2**H$^+$ in the absence of **1**.[12] The decapsulation of **2** from **1** is probably caused by a decreased hydrophobic interaction as well as coulombic repulsion between the host and the guest. When the solution was treated with K_2CO_3 to pH ≈ 6.5, the released guest returned to the cavity of **1** and the triplet signals reappeared (Figure 2c).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The pH-dependent UV/Vis absorption spectra of $\mathbf{1}\cdot(\mathbf{2})_2$ also supported the pH-switchable encapsulation of **2**. Radicals **2** and $\mathbf{2}H^+$ showed absorption bands ascribed to an n–π* transition at 650 nm and 560 nm, respectively (Figure 3a).

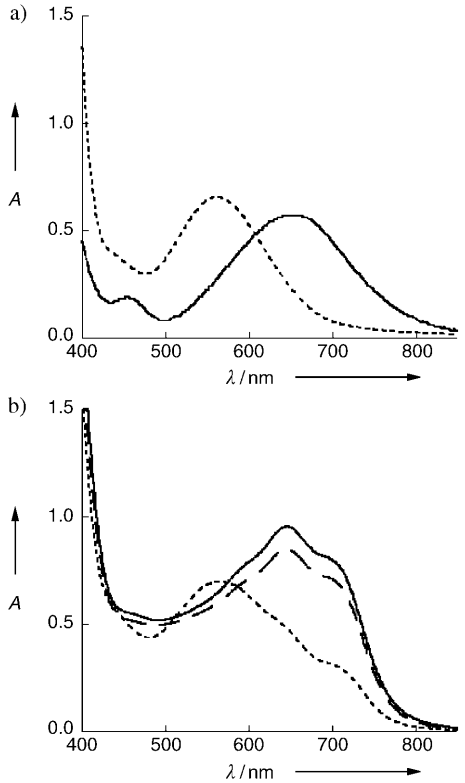

Figure 3. a) UV/Vis spectra of radical **2** (——, saturated solution, pH 6.5) and the protonated radical $\mathbf{2}H^+$ (-----, saturated solution, pH 1.3) at 293 K. b) UV/Vis spectra of clathrate compound $\mathbf{1}\cdot(\mathbf{2})_2$ (0.5 mM) at 293 K. ——: the initial solution at pH ≈ 6.5; -----: the acidified solution at pH ≈ 1.3 (HNO_3); – – –: the neutralized solution at pH ≈ 6.5 (K_2CO_3).

Under neutral conditions, $\mathbf{1}\cdot(\mathbf{2})_2$ showed an absorption band at 650 nm accompanied by a vibronic coupling derived from **2**. The presence of the vibronic coupling indicated that **2** remained in the hydrophobic environment (Figure 3b). The acidified solution of $\mathbf{1}\cdot(\mathbf{2})_2$ showed absorption bands at both 560 nm and 650 nm, which suggests that $\mathbf{2}H^+$ (out of the hydrophobic pocket of **1**) and **2** (encapsulated in **1**) were in equilibrium (Scheme 1). Deconvolution analysis of the spectrum of $\mathbf{1}\cdot(\mathbf{2})_2$ in acidified solution clarified that the ratio of the released and encapsulated guests was 7:3. When treated with K_2CO_3 (pH ≈ 6.5), the solution showed a similar spectrum to that observed initially, confirming that the released guest was reencapsulated in **1**.

In conclusion, we have demonstrated the pH-controlled doublet–triplet switching of organic radicals accommodated in a self-assembled coordination host. The facile solution-state control of the spin interaction is ascribed to the encapsulation effect of the cage: radicals are fixed in the host under neutral conditions, whereas they are expelled under acidic conditions. By applying such an encapsulation effect of a cage, new molecular magnetic materials that are responsive to other stimuli (particularly light) may be developed.

Experimental Section

$\mathbf{1}\cdot(\mathbf{2})_2$: An excess of powdered **2** (4.1 mg, 15×10^{-3} mmol, $M_w = 276.35$) was suspended in a solution of **1** (20.5 mg, 5.0×10^{-3} mmol, 5 mM) in H_2O (1.0 mL) at 80 °C for 1 h to give a solution of the clathrate compound (5 mM) after filtration of surplus **2**.[7] The solution of the clathrate was diluted tenfold with H_2O (9 mL) and was used for ESR and UV/Vis spectroscopy. A single crystal of $\mathbf{1}\cdot(\mathbf{2})_2$ suitable for X-ray diffraction studies was obtained by slow evaporation of H_2O from an aqueous solution of the clathrate at room temperature for 2 days. Crystal data for **2**: $C_{15}H_{22}N_3O_2$, $M_r = 276.36$, monoclinic, $P2_1/n$, $a = 13.018(2)$ Å, $b = 9.434(1)$ Å, $c = 13.505(2)$ Å, $\alpha = \gamma = 90$, $\beta = 116.840(2)°$, $V = 1479.9(3)$ Å^3, $Z = 4$, $T = 90.0(1)$ K, $\rho_{calcd} = 1.258$ g cm^{-3}, $\lambda(Mo_{K\alpha}) = 0.71073$ Å; 5418 reflections were measured of which 3305 were unique ($R_{int} = 0.0919$) and were used in all calculations. The structure was solved by direct method (SHELXL-97) and refined by full-matrix least-squares methods on F^2 with 187 parameters. $R_1 = 0.0968$ ($I > 2\sigma(I)$) and $wR_2 = 0.2418$, GOF = 1.146; max./min. residual density 0.870/−0.494 e Å^{-3}. All the diffraction data were measured on a Siemens SMART/CCD diffractometer ($Mo_{K\alpha}$ radiation: $\lambda = 0.71073$ Å). Non-hydrogen atoms were refined anisotropically and hydrogen atoms were fixed at calculated positions and refined using a riding model. CCDC-271224 (**2**) and CCDC-271223 ($\mathbf{1}\cdot(\mathbf{2})_2$) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Förster-Type Energy Transfer along a Specified Axis**

*Claudia Minkowski and Gion Calzaferri**

Förster transfer of electronic excitation energy in 3D[1–3] and 2D[4,5] systems has been studied in many laboratories. Kuhn extended the Förster theory of long-range energy transfer in 3D systems to 2D and 1D systems.[6] The theory of the time dependence of this process in 1D and 2D cases was studied by Hauser et al.[7] and later extended to fractal dimensions by several groups.[8,9] Nevertheless, only little experimental evidence has been published to prove 1D energy transfer. In the strict sense, one-dimensionality can be understood as a transport along a line or at least along an isolated file. However, one-dimensionality in the 3D space of an object of, for example, cylindrical morphology can also mean that the nett transport of the individual transfer steps goes along the *c* axis of the cylinder, that is, along a well-defined axis. We call this quasi-1D to avoid any confusion.

One way to try to realize the conditions in which quasi-1D transport of excitation energy should be favored is by using dye molecules in a crystalline host that consists of 1D channels. Panchromatic chromophore mixtures in an $AlPO_4$–5 molecular sieve show interesting luminescence properties.[10] We have shown that zeolite L, with its 1D channels, is a very versatile material with which to build artificial host–guest antenna systems.[11] The channels are occupied by energy-transporting dyes (donors, D) and energy-trapping dyes (acceptors, A); strongly luminescent dyes are usually selected. The energy-transfer process that occurs when an excited donor transports its excitation energy to an unexcited acceptor proceeds with a Förster-type mechanism and its rate constant k_{DA} can be expressed according to Equation (1), in which ϕ_D and τ_D are the

$$k_{DA} \propto \frac{\phi_D}{\tau_D} J_{DA} \frac{\kappa^2_{DA}}{R^6_{DA}} \quad (1)$$

fluorescence quantum yield and lifetime, respectively, of the donor, J_{DA} is the spectral overlap integral between the donor emission and the acceptor absorption spectra, κ_{DA} describes the relative orientation of the electronic transition moments, and R_{DA} is the distance between D and A.

R_{DA} has a strong effect on the energy-transfer rate constant. It can be tuned, for example, by varying the loading of the dye molecules[12], which changes the overall dye–dye distance. Another elegant way to study the distance dependence of the transfer of excitation energy is to introduce a spacer molecule between the donors and the acceptors to separate them locally, as illustrated in Figure 1. To realize this introduction, a defined quantity of acceptor molecules was first incorporated into the channels of zeolite L. In the second step, different quantities of spacer molecules were incorporated into the channels that already contained acceptor dyes, thus forming spacer layers of different thicknesses. In the third step, the same quantity of donor dyes was always added. As the conditions are such that the dyes cannot glide past each other, the crystal is divided into compartments in which the density of one dye is dominant. By selectively exciting the donor, the behavior of the excitation energy can be observed as it depends on the amount of spacer molecules and therefore on the distance R_{DA}. Is the transport of electronic excitation energy preferentially quasi-1D along the cylinder axis?

With the dye molecules listed in Scheme 1, we investigated three systems. Two systems have been synthesized according to Figure 1 A, in which Py^+ acts as donor and Ox^+ as acceptor. Owing to its favorable spectral properties and its

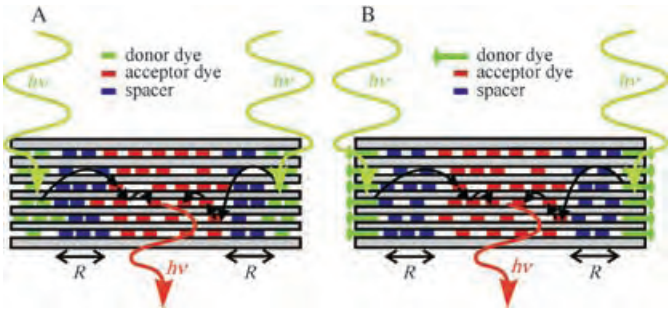

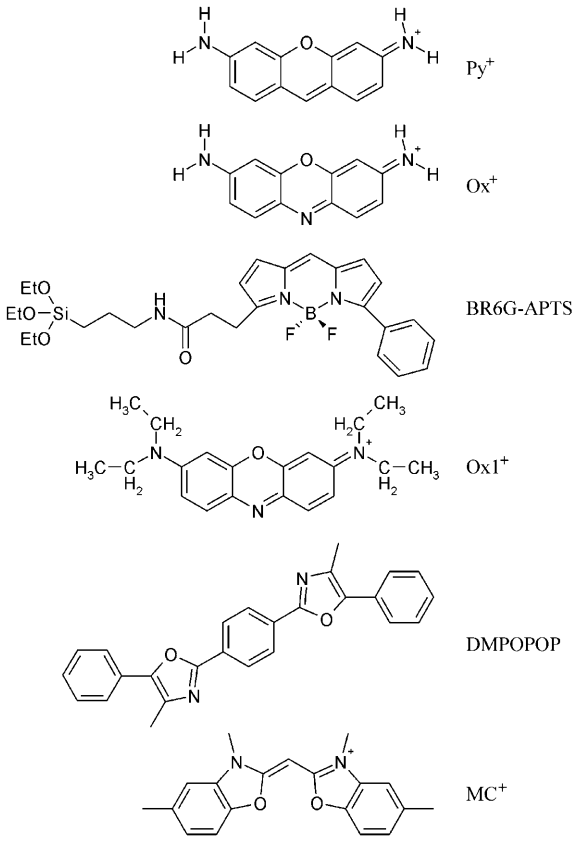

Figure 1. Schematic representation of zeolite L, which illustrates the parallel channels that run along the *c* axis of the crystal. The channels contain red-light-emitting dyes in the middle, followed by different amounts of spacer molecules (blue) that form spacer layers of different average thicknesses, and finally green-light-emitting donors at both ends. A) The donor–spacer and spacer–acceptor phase boundaries are diffuse. B) The donor dye is a stopper molecule with a tail that enters the channels but a head that is to large to enter. All donors are fixed at the same position and only the spacer–acceptor phase boundary is diffuse.

Scheme 1. Dyes used for the loading of zeolite L: Py^+ and BR6G-APTS (donors), Ox^+ and $Ox1^+$ (acceptors), and DMPOPOP and MC^+ (spacers).

high fluorescence quantum yields, this donor–acceptor pair exhibits a remarkable ability to transport excitation energy through Py^+ energy carriers to luminescent Ox^+ traps. The third system has been synthesized according to Figure 1B, in which BR6G-APTS acts as a "stopper" donor and $Ox1^+$ as the acceptor. Specific attachment of the triethoxysilyl group of this stopper donor at the entrance of the channels was carried out according to a previous report.[13] The spacer molecules—in our case dyes as well—must be chosen so that they do not participate in the energy-transfer process; that is, they should not absorb in the spectral region where the donor is excited and they should not trap the energy from the donor. In the first and third systems, DMPOPOP was used as the spacer to give the antenna systems Py^+/DMPOPOP/Ox^+–zeolite L (**1**) and BR6G-APTS/DMPOPOP/$Ox1^+$–zeolite L (**3**), whereas in the second system, MC^+ was used to give the antenna system Py^+/MC^+/Ox^+–zeolite L (**2**). For **1** and **2**, zeolite L crystals of 840 nm length were used, whereas for **3**, the crystals were 300 nm long. The left column of Figure 2 shows the excitation and emission spectra of the individual dye molecules inserted into zeolite L.

For each of the three systems, a series of four samples were synthesized. The amount of donor and acceptor was kept constant, whereas the amount of spacer, namely DMPOPOP and MC^+, was increased from samples 1 to 4 in each series. From the amount of spacer, the average number of spacer molecules per spacer layer (n) can be calculated. This value determines the mean distance between the donor and acceptor molecules. Emission spectra of the different samples were recorded. The donor was selectively excited and the spectra were scaled to the same height of the donor emission (Figure 2, right column). In all three systems, the first sample with the smallest spacer layer shows the highest acceptor fluorescence intensity. With an increasing number of spacer molecules per layer, less and less energy transfer occurs and thus the acceptor fluorescence intensity decreases.

The distance dependence of the probability P for Förster-type long-range energy transfer from an electronically excited donor to an acceptor can be simplified according to Equation (2). R_0 is the Förster radius; the exponent α is 6 for 3D

$$P = \frac{1}{1 + (R_{DA}/R_0)^{\alpha}} \qquad (2)$$

systems,[1] 4 for 2D systems,[3] and 2 for 1D systems.[6] We do not have direct access to the mean value of R_{DA} ($\bar{R}_{DA}$). However, the average number of spacer molecules per spacer layer is proportional to this mean distance. Therefore, we have plotted the acceptor fluorescence intensity versus $1/(1+n^{\alpha})$ for different values of α ranging from 6 to 1 and we found that all data obey an $\alpha = 2$ dependence (Figure 3). I_{rel} does not go to zero at $(1+n^2)^{-1} \rightarrow 0$ as the acceptor absorbs to a small degree at the wavelength of excitation. The numbers of spacer molecules in these experiments are reported in Table 1.

It is not possible to estimate $\bar{R}_{DA}$ by multiplying the number of spacer molecules by their lengths (2.02 nm for DMPOPOP and 1.48 nm for MC) as energy transfer is not restricted to individual channels (see Figure 1 and Figure 4). The spectral overlap integrals and the corresponding Förster radii in parenthesis, which are calculated for a numerically estimated κ^2_{DA} value of about 1 and an estimated refractive index of 1.4, are $J_{Py^+,Ox^+} = 2.3 \times 10^{-10}\ cm^6\,mol^{-1}$ (6.1 nm) and $J_{BR6G\text{-}APTS,Ox1^+} = 5.6 \times 10^{-10}\ cm^6\,mol^{-1}$ (7.1 nm).[14]

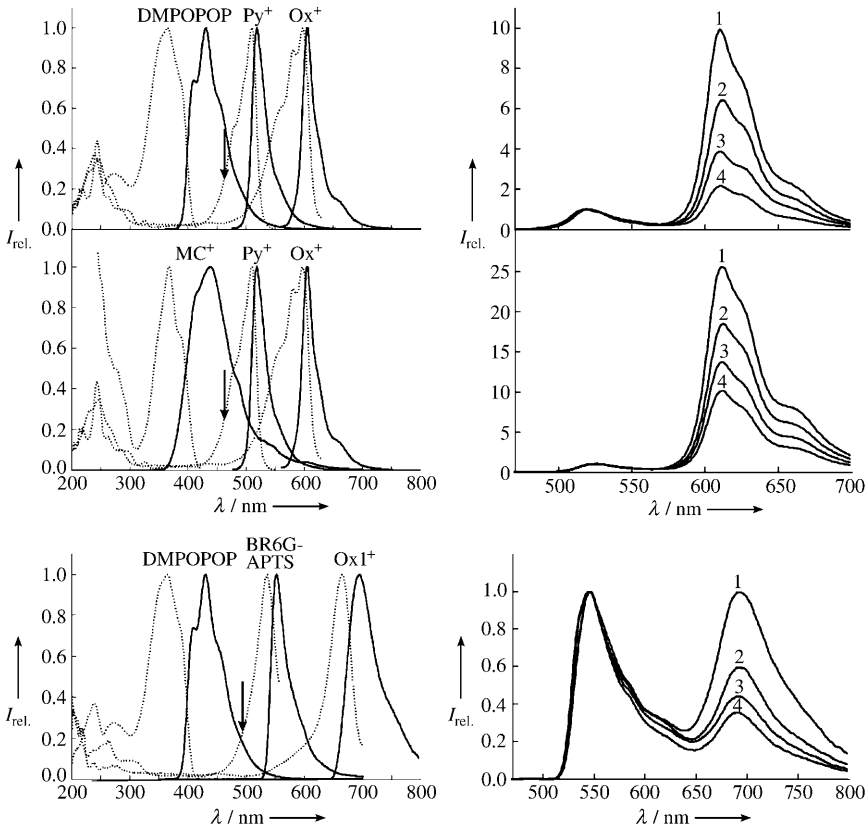

Figure 2. Left: Excitation (dotted lines) and emission (solid lines) spectra of the applied dye molecules. Right: Fluorescence spectra (scaled to the maximum of the donor emission) for **1** (top), **2** (middle), and **3** (bottom), with different amount of spacer, after selective excitation of the donor at the wavelengths indicated by the arrows in the left spectra. Average number of spacer molecules per spacer layer (n) for 1–4: top: 8.5, 11, 16, 22.5; middle: 15, 17.5, 24, 36.5; bottom: 2.7, 4, 6, 10.

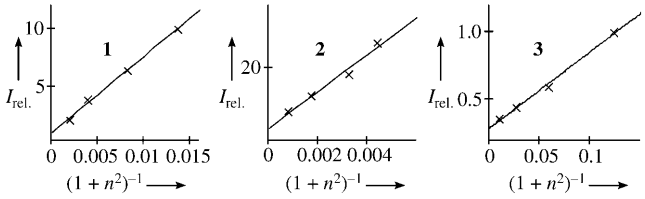

Figure 3. Intensities I_{rel} of the acceptor fluorescence versus the averaged number of spacer molecules per spacer layer (n) in **1**–**3** confirming the value of $\alpha = 2$.

Table 1: Values of n and the relative luminescence intensities of the acceptors for all the samples studied.

	1		**2**		**3**	
Sample	n	I_{rel}	n	I_{rel}	n	I_{rel}
1	8.5	9.92	15	25.55	2.7	0.99
2	11	6.4	17.5	18.44	4	0.59
3	16	3.86	24	13.70	6	0.44
4	22.5	2.15	36.5	11.10	10	0.35

One difficulty in analyzing the data in Figure 3 and Table 1 according to Equation (2) is that n is proportional but not equal to (R_{DA}/R_0). We can write this as follows $(R_{DA}/R_0) = cn$, in which c is a constant. What we know is that R_{DA} must be in the order of R_0 because the amount of energy transfer is substantial in all samples. R_0 is the radius at which the energy-transfer probability is 50%. From this we can estimate that c is less than 1 but we also know that R_{DA} cannot be smaller than the distance between the centers of two channels, which is 1.84 nm; thus $1 > c > 0.2$. With this range for c, it is easy to verify numerically that plotting the relative intensities versus $1/(1+n^{\alpha})$ allows us to discriminate between different α values and only $\alpha = 2$ is consistent with the measurements for all three materials.

In **1** and **2**, the donors are dyes that also enter the channels. The dyes cannot glide past each other within a channel, but their positions can overlap with neighboring channels to reveal a staggered profile of the phase boundaries (see Figure 1 and Figure 4). Replacing the donors with stopper molecules as in **3**, which have a tail that can enter the channel but a head too large to enter, results in a less-diffuse phase boundary. In this case, all stopper donors are fixed at the same position and only one staggered phase boundary from the spacer to the acceptor remains.

We report time-resolved data for the luminescence decay of the donor for each of the four samples of **1** and **2** (Table 2). The data were evaluated with a biexponential fit with lifetimes τ_1 and τ_2, with the factor f_1 indicating the number of photons that decay with lifetime τ_1. A Py^+–zeolite L sample with a loading of 0.02 decays with a mean lifetime $\langle\tau\rangle$ of 2.4 ns.[15] The decay of the donor in sample 4 of **1** is much faster than that of Py^+–zeolite L due to energy transfer, and the rate of decay increases from sample 4 to 1. This observation is in agreement with the steady-state emission spectra of these samples. The

Table 2: Decay [ns] of the luminescence of donor Py^+ in **1** and **2**.[a]

System	Sample	$\langle\tau\rangle$	τ_1	τ_2	f_1
Py^+–zeolite L		2.4			
1	1	0.13	0.007	1.26	0.90
1	2	0.27	0.105	2.00	0.91
1	3	0.45	0.11	1.43	0.75

luminescence decay of the donor of **2** is already very fast for sample 4 and increases slightly from sample 4 to 1. As can be observed in the steady-state spectra (Figure 2), the acceptor fluorescence intensities of the samples of **2** are higher than those of **1**.

We have added some theoretical reasoning to explain better the system. First we focus on the distribution of the dye molecules at the phase boundaries. We can assume a uniform distribution of the dyes, as proposed by the results of a Monte Carlo calculation.[15] Figure 4A reveals the staggered profile of the borders. Figure 4B shows the same $\alpha = 2$ dependence for a calculated system in which the energy-migration and energy-transfer steps are described as a random walk by means of Markov chains.[16]

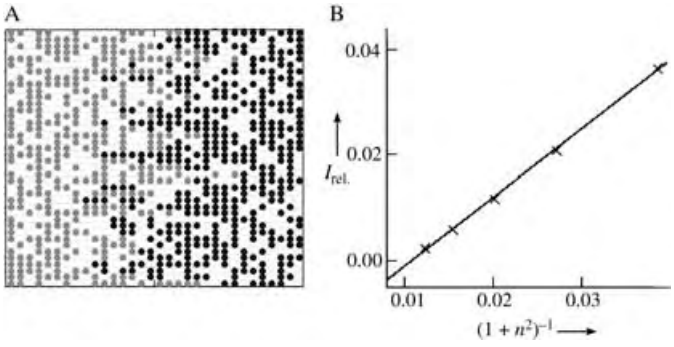

Figure 4. A) Simulated image of a zeolite L crystal containing 40 channels with each channel containing 32 sites, obtained by a Monte Carlo calculation; it illustrates the phase boundary. The sites are randomly filled with one type of dye molecule (dark dots), while after virtually sealing the right channel entrances another type of dye (light dots) was added from the left side. The overall occupation of both dye molecules per available site is 60%. The phase boundaries extend over about 10 sites. B) Calculated intensities of I_{rel} of the acceptor fluorescence versus averaged number of spacer molecules (n) between donor and acceptor for $\alpha = 2$.

The experimental data reported in Figures 2 and 3, and in Tables 1 and 2 can only be understood in terms of the long-range energy transfer of Förster. A trivial mechanism would not cause a shortening of the lifetime of the donor luminescence. There would also be no or a much weaker dependence on distance for the efficiency of the energy transfer because the change in distances is more than one order of magnitude smaller than the wavelength of the light. We found that varying n has a strong effect on the rate of energy transfer, as can be observed in the fluorescence intensities of the acceptors in samples in which the number of spacer molecules is different. This can also be observed in the time-resolved measurements in which the mean lifetimes $\langle\tau\rangle$ of the donor increase with an increase in n due to a decrease in energy transfer to the acceptor. System **2** has a much shorter $\langle\tau\rangle$ value than **1**, although the number of spacer molecules per layer is higher for **2** than for **1**. Thus we assume that MC^+ is more packed than DMPOPOP.

The correlation of the acceptor fluorescence intensity versus the number of spacer molecules per layer leads to a linearization at $1/(1+n^2)$. The same result is observed in the theoretical simulation. The individual transfer steps can also occur to a neighboring channel, but the statistical mean of the energy transfer in the dye-loaded zeolite L crystals is directed along the c axis of the cylinder. Hence, the transport of electronic excitation energy in all three systems is quasi-1D. This observation is of considerable interest for the development of highly anisotropic optoelectronic devices, some of which have already been proposed.[11]

Experimental Section

Zeolite L crystals were synthesized and characterized as described previously. [17]. The potassium-exchanged form was used, which had an average crystal length of 840 nm for **1** and **2**, and 300 nm for **3**. Py^+ and Ox^+ were synthesized and purified according to a reported procedure.[18]. DMPOPOP (Fluka), MC^+ (CIBA-GEIGY AG), and Cryptofix 222 (Fluka) were used as received. BR6G-APTS was made by substituting BODIPY-RG6 (succinimidyl ester of 4,4-difluoro-5-phenyl-4-bora-3a,4a-diaza-*s*-indacene-3-propionic acid, Molecular Probes), with (3-aminopropyl)triethoxysilane (Fluka). The two compounds were dissolved in CH_2Cl_2 and stirred for 1 h, the CH_2Cl_2 was removed by evaporation, and the resulting precipitate was washed twice with cyclohexane.[19]

1: Zeolite L was suspended in water and sonicated for 20 min to avoid aggregation of the crystals. An aqueous solution containing the required amount of Ox^+ was added and the resulting mixture was heated at reflux for 7 h. The Ox^+-loaded zeolite L crystals were washed with methanol to remove the Ox^+ from the surface. Insertion of DMPOPOP:[11] Ox^+-loaded zeolite L crystals were transferred into a glass ampoule and dehydrated under vacuum (3×10^{-2} mbar) at 80 °C for 24 h to empty the adsorption sites in the channels. The required amount of DMPOPOP was added and the ampoule was sealed. The sealed ampoule was heated in a rotating furnace at 150 °C for 6 days, after which the DMPOPOP/Ox^+-zeolite L crystals were washed with *n*-butanol and rehydrated in an exsiccator that contained a saturated solution of potassium acetate. Incorporation of Py^+: The DMPOPOP/Ox^+–zeolite L was suspended in water, and an aqueous solution of Py^+ was added and the mixture heated at reflux for 30 min. Compound **1** was washed again with methanol to remove dye molecules on the crystal surface.

2: First step as described for **1**. The incorporation of MC^+ was more involved and was carried out stepwise to obtain higher loadings: Ox^+-Zeolite L was suspended in a mixture of *n*-butanol and water (1:10) and sonicated for 20 min. A solution of MC^+ in the same *n*-butanol/water mixture was added to the suspension, which also contained an excess of Cryptofix 222.[18] The mixture was then heated at 65 °C for over 48 h to obtain a loading of about 40 to 50% of the preset amount of MC^+. The MC^+/Ox^+-zeolite L crystals were then washed with methanol and the insertion was repeated up to four times. MC^+/Ox^+-zeolite L was suspended in water and an aqueous solution containing the required amount of Py^+ was added; this mixture was heated at reflux for 30 min. Compound **2** was washed again with methanol.

3: Zeolite L was suspended in toluene and sonicated for 20 min. A solution of $Ox1^+$ in toluene and an excess of Cryptofix 222 was added and the resulting mixture was heated at 65 °C for 7 h. The $Ox1^+$-loaded zeolite L crystals were washed with methanol. Insertion of DMPOPOP as outlined for **1**. BR6G-APTS was added by dissolving the DMPOPOP/$Ox1^+$-zeolite L in Cl_2CH_2 and adding the required amount of the stopper molecule. The mixture was sonicated for 30 min and stirred at room temperature for 20 h.[13] Compound **3** was dried, dissolved in *n*-hexane, heated at reflux for 2 h, and again washed with methanol. The amount of dye molecules inside the channels was determined by destroying the zeolite framework with HF: A solution of HF (8%, 100 μL) was added to a solution of *n*-butanol (3.9 mL) containing the dye-loaded zeolite L (1 mg) in a

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

polypropylene tube and this mixture was sonicated for 5 min. The amount of dye entering the solution was determined by UV/Vis spectroscopy.[12]

Thin-layer preparation: Dye-loaded zeolite L (100 μL) suspended in *n*-butanol (≈1 mg in 300 μL) was dropped onto a quartz plate (∅1.6 cm) and the solvent was evaporated in air. The quartz plate was then covered with a Petri dish. Emission and excitation spectra were recorded on a Perkin Elmer LS 50B luminescence photospectrometer. Compounds **1** and **2** were excited at 460 nm with a cut-off filter at 490 nm; compound **3** was excited at 490 nm with a cut-off filter at 510 nm. The samples were measured as thin layers on quartz. Time-resolved measurements were carried out according to a reported procedure.[15]. Samples were excited at 465 nm and detected at 520 nm; slit widths = 4 nm. Optical fluorescence microscopy images were carried out on an Olympus BX 60 device equipped with a Kappa CF 20 DCX Air K2 CCD camera.[11]

Molecular Recognition of RNA by Neomycin and a Restricted Neomycin Derivative**

*Fang Zhao, Qiang Zhao, Kenneth F. Blount, Qing Han, Yitzhak Tor, and Thomas Hermann**

Aminoglycoside antibiotics such as neomycin (**1a**) and paromomycin (**1b**) bind to ribosomal RNA (rRNA) at the decoding site and thereby interfere with the accuracy of protein synthesis, ultimately leading to bacterial cell death (Figure 1). In addition to the decoding site in 16S rRNA, several other RNA motifs form well-defined complexes with individual aminoglycosides, which makes these antibiotics excellent model ligands for the study of RNA recognition.[1,2] The target "promiscuity" of the aminoglycosides has been attributed to two major factors: 1) their highly charged nature, which is responsible for their eletrostatically driven RNA-binding mode and 2) their conformational adaptability. Although rotation around the glycosidic bonds that link the saccharide building blocks is restricted, the remaining limited flexibility explains some adaptability toward diverse RNA targets.[2] This restricted conformational flexibility attenuates

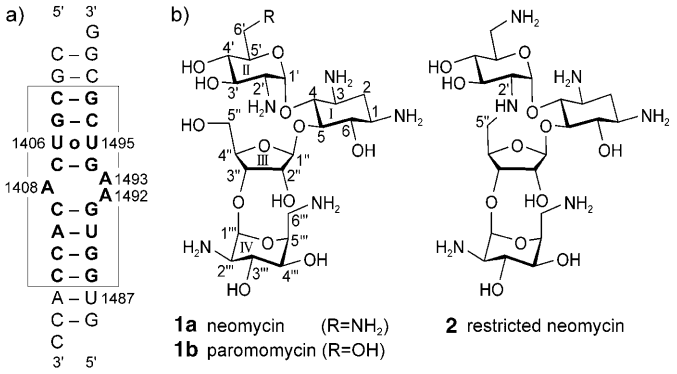

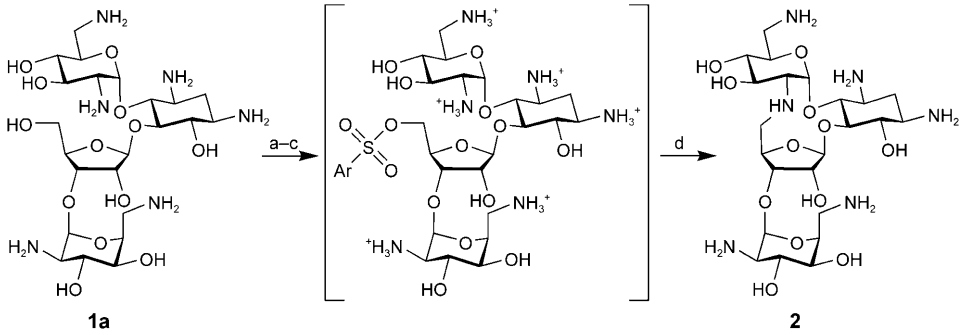

Figure 1. a) Secondary structure of the decoding-site oligonucleotide used for X-ray crystallography and structure determination. The box indicates the region that corresponds to the bacterial RNA sequence. Flanking nucleotides were added to enhance crystal packing. Residues are numbered according to the *Escherichia coli* 16S rRNA sequence. For multiwavelength anomalous diffraction experiments, U1487 was replaced by 5-Br-U. b) The natural aminoglycosides neomycin (**1a**) and paromomycin (**1b**) which differ at the 6′ position, and the semisynthetic restricted neomycin **2** in which rings II and III are linked through the 2′ and 5″ positions.

the contribution of charged interactions between RNA and the aminoglycosides, resulting in the formation of well-defined drug complexes that are distinct from nonspecific interactions of nucleic acids with flexible polyamines such as spermidine. The term structural electrostatic complementarity has been coined for this promiscuous yet target-specific binding of aminoglycosides to RNA.[2]

Aminoglycosides derived from 4,5-disubstituted 2-deoxystreptamine (2-DOS, ring I), including neomycin (**1a**) and paromomycin (**1b**), bind to a variety of RNA sequences. Examination of structurally characterized aminoglycoside complexes reveals that the relative orientation of rings I and II is very similar, whereas the conformation around the linkages to rings III and IV is significantly variable depending on the RNA target.[3] The apparent rigidity of the ring I/II system underlines the importance of this module for RNA recognition, attested by the fact that the 2-DOS and ring II moieties participate in key interactions that are responsible for target binding in decoding-site complexes with aminoglycosides.[1,4–6] Whereas higher thermal factors of rings III and IV in the crystal structure of paromomycin might suggest that these sugars generally contribute less to target-specific interactions,[4,5] the results presented herein suggest that the affinity of neomycin for the cognate decoding-site RNA and thus the antibacterial activity of this compound depend on an exquisitely balanced interplay of all four rings.

Previous investigations of aminoglycoside mimetics derived from neamine and paromamine, both of which lack rings III and IV, confirm the key role that the ring I/II core plays in decoding-site binding.[7,8] In the crystal structure of the related aminoglycoside paromomycin (**1b**) complexed with bacterial decoding-site RNA,[4,5] the distance between the 2′-amino group of ring II and the 5″-C atom of ring III is ≈3.7 Å, which suggests that cross-linking these positions may yield an aminoglycoside that retains the decoding-site-bound conformation of the parent drug. To support this hypothesis, we determined the X-ray crystal structures of neomycin (**1a**), among the most potent aminoglycoside antibiotics of therapeutic relevance, and its conformationally restricted analogue **2** bound to a decoding-site oligonucleotide (Figure 1a). Herein, we analyze the structural characteristics of both RNA–small-molecule complexes and discuss the structural basis of aminoglycoside ligand affinity along with general implications on the understanding of RNA recognition.

For the synthesis of restricted neomycin **2** we devised an intramolecular and regioselective cyclization strategy of an unprotected 5″-activated neomycin intermediate under high-dilution conditions that exploits the proximity of the 2′-amino and 5″-hydroxymethyl groups (Scheme 1).[3] The sulfonate-activated intermediate was obtained after Boc protection of the amino groups of neomycin, reaction of the primary alcohol at the 5″ position with 2,4,6-triisopropylbenzene sulfonyl chloride,[9] and cleavage of the Boc protecting groups with trifluoroacetic acid. High dilution of the activated intermediate to favor the intramolecular reaction and neutralization to deprotonate the ammonium groups for subsequent nucleophilic substitution eventually furnished the restricted aminoglycoside **2**.[3]

Scheme 1. Synthesis of restricted neomycin **2**: selective formation of **2** from neutralization of the unprotected sulfonate intermediate relied on the proximity of the 2′-amino and 5″-hydroxy groups. Neomycin (**1a**) was fully Boc-protected (a: Boc_2O, NEt_3, dioxane/H_2O; 75%) and activated as an aryl sulfonate at the 5″ position (b: 2,4,6-triispropylbenzenesulfonyl chloride, pyridine; 70%).[7] After acidic removal of the Boc protecting groups (c: TFA/$CHCl_3$ (1:1)), the sulfonate intermediate was highly diluted and neutralized to yield **2** (d: NEt_3, DMF, 10 days; 12% for steps c and d; a final Boc protection (not shown) was performed to facilitate purification).[3] Ar = 2,4,6-triisopropyl benzene; Boc = *tert*-butoxycarbonyl; TFA = trifluoroacetic acid; DMF = *N*,*N*-dimethylformamide.

Both neomycin (**1a**) and restricted neomycin **2** were co-crystallized with an oligonucleotide that contains the decoding-site sequence and flanking bases, which facilitated crystal packing (Figure 1a). Similar small RNAs have been shown to provide authentic model systems that retain the structural and dynamic characteristics of the ribosomal decoding site.[5,6,10,11] Three-dimensional structures of the RNA complexes of **1a** and **2** were determined by X-ray diffraction by using anomalous dispersion of the halogen atom in the 5-Br-U1487 residue. For comparison, the structure of the unbound decoding site was solved as well (Supporting Information).

The electron density of the decoding-site complexes clearly revealed the identity of the bound aminoglycoside ligands (Figure 2a,b). Specifically, the 5″-hydroxymethyl group in neomycin gave rise to a characteristic extension of the electron density envelope which was lacking for the cyclized derivative **2**. Both **1a** and **2** bind to the decoding site at the same position as paromomycin (**1b**).[4,5] Complex formation induces a more compact structure of the RNA around the ligand-binding site as indicated by the base of A1408 and the sugar–phosphate backbone of A1492 and A1493 pulled closer to the aminoglycoside (Supporting Information). The hydrogen-bonding contacts between neomycin and the RNA are identical to those of paromomycin, including the interaction of the distinctive 6′ substituent (Figure 3a). The N1 atom of A1408 in the decoding site forms a hydrogen bond with either the 6′-hydroxy group of paromomycin or the 6′-amino substituent of neomycin which helps stabilize the base-pair-like interaction between ring II and the A1408 residue.[5]

The position of rings I and II within restricted neomycin **2** relative to the decoding-site RNA coincides with the binding site of these rings in the neomycin–RNA complex (Figure 2c). Consequently, the hydrogen-bonding network between the RNA and rings I and II is identical for the restricted derivative and neomycin as well as paromomycin (Figure 3). Distinct patterns are, however, observed for the interactions of rings III and IV. Intramolecular cyclization imparts to **2** with a slightly more compact overall structure than that of the parent neomycin, reflected by differences in the positioning of rings III and IV (see also Supporting Information). Ring IV of **2** interacts with the phosphate group of G1491, whereas hydrogen bonds are formed to the phosphate group of G1405 in the opposite RNA strand for the complexes formed with neomycin and paromomycin[5] (Figure 3). The covalent link between rings II and III in **2** pulls ring III away from the bottom of the RNA deep groove which leads to disruption of a hydrogen-bond interaction to C1407 that involves the 2″-hydroxy group; this interaction is present for complexes with neomycin and paromomycin. Another contact of the 5″-hydroxy substituent in the natural aminoglycosides with G1491 is absent for the restricted neomycin. Interestingly, the contacts to rings III and IV, which were considered to play a secondary role for decoding-site binding, are sacrificed upon binding of **2** to the decoding site. This is not the case for the interactions with rings I and II, the importance of which in RNA target recognition is underscored once again.

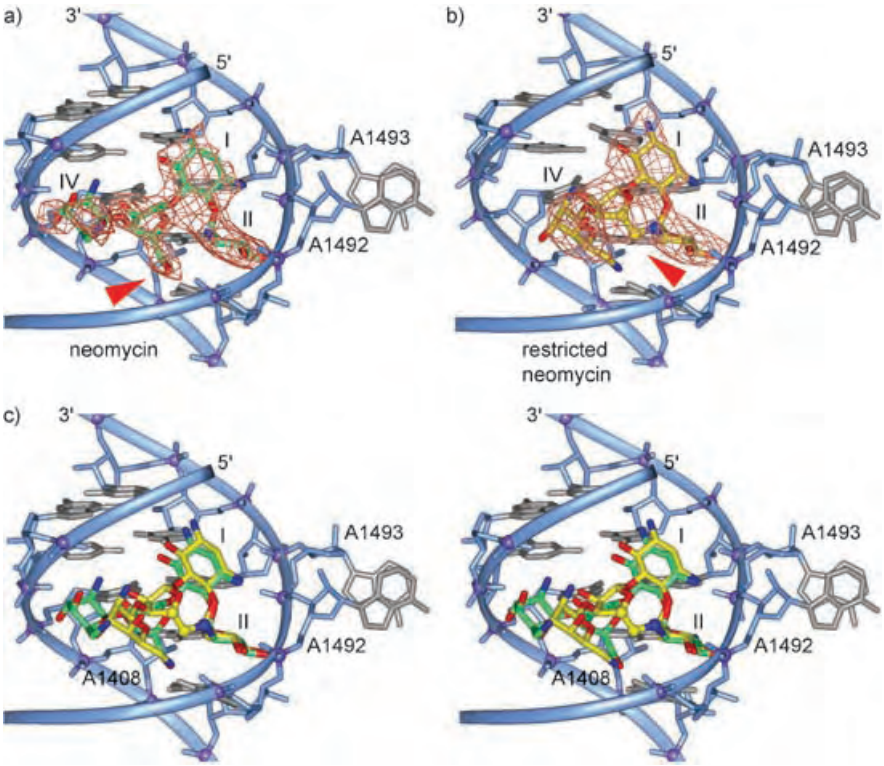

Figure 2. X-ray crystal structures of a) neomycin (**1a**) and b) restricted neomycin **2** complexed with decoding-site RNA. Aminoglycoside rings are numbered according to the structure shown in Figure 1b. Electron density ($2F_o-F_c$, contoured at 1.0σ around the ligands) reveals the identity of the aminoglycosides, specifically the extended 5″-hydroxymethylene group in neomycin, which is absent in the restricted ligand (red arrows). c) Stereo view of neomycin (**1a**, green) superimposed with its restricted derivative **2** (yellow) bound to the decoding site. (The superimposition is based on phosphate coordinates; only the RNA of the neomycin complex is shown.) The link between the 2′ and 5″ positions in **2** is highlighted in ball-and-stick representation.

Comparison of the binding affinities of neomycin (**1a**) with its cyclized derivative **2** for the decoding site revealed a 20-fold lower K_d value for the restricted derivative at pH 7.5,[3] in line with a similarly decreased antibacterial potency under physiological conditions.[12,13] The overall loss of direct hydrogen bonds between ring III and the RNA might explain the lower target affinity of **2**. However, at a lower pH value (5.8) similar to the crystallization conditions (pH 6.2), the K_d value of **2** decreased as a result of increasing protonation of the amino groups and thus domination of the ligand–RNA interaction by electrostatic forces.[3] It is well-documented

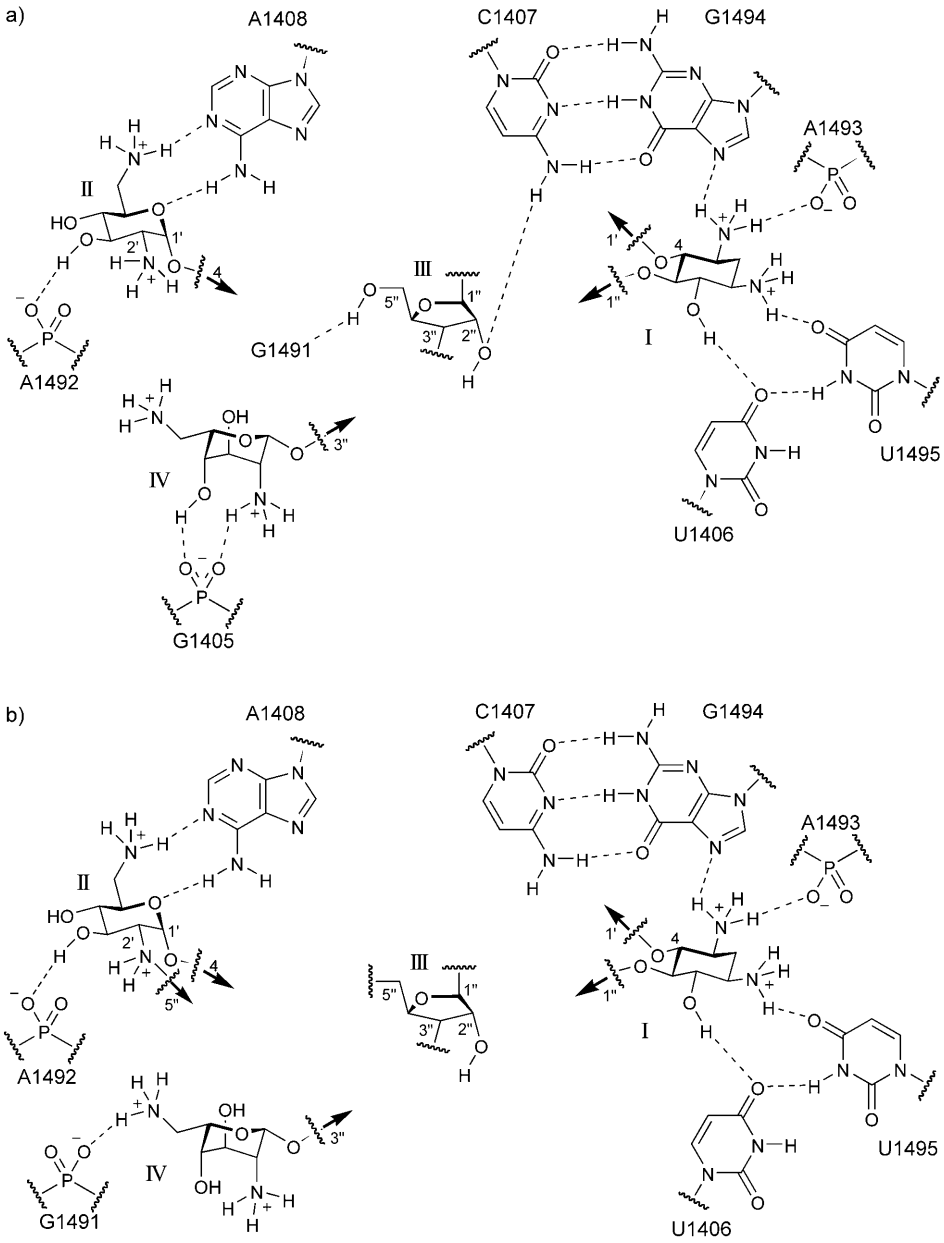

Figure 3. Schematic illustration of the dominant interactions of a) neomycin (**1a**) and b) restricted neomycin **2** with the decoding-site RNA. Unlike the case for the neomycin complex, the ribose moiety III of the restricted derivative does not participate in direct contacts with the target. The hydrogen-bonding network in the neomycin complex is identical to that previously observed in the decoding-site complex of paromomycin (**1b**).[4,5] Whereas there is a considerable range of pK_a values for the amino groups in **1a** and **2**,[3] protonated states dominate at the buffer conditions used (pH 6.2) which contribute an important electrostatic component to hydrogen-bonding interactions with the RNA.[3,21]

that the differences in RNA-binding affinities of various aminoglycosides carrying the same number of amino groups disappear at lower pH values, as electrostatic interactions of the protonated amino groups are the primary factors in complex formation.[3,19,20] Interestingly, the basicity of the secondary 2′-amino group, which covalently links rings II and III, is the lowest (pK_a 6.4 in **2**, versus pK_a 8.1 for the corresponding amine in **1a**).[3] Under physiological conditions, it is likely a combination of the decreased number of hydrogen-bond interactions between **2** and the decoding site, and diminished electrostatic contribution by the only partially protonated 2′-amino group that might cause the decreased binding affinity and antibacterial potency of the restricted neomycin derivative.[13]

A second aminoglycoside-binding site was observed in the crystal structure of both neomycin (**1a**) and restricted neomycin **2**. This site is located in the deep groove at the interface of two continuously stacking RNA constructs and displays features of ligand recognition that are radically different than those of the decoding site (Figure 4; and Supporting Information). Therefore, the complexes of **1a** and **2** described herein allow a direct comparison between distinct ligand-

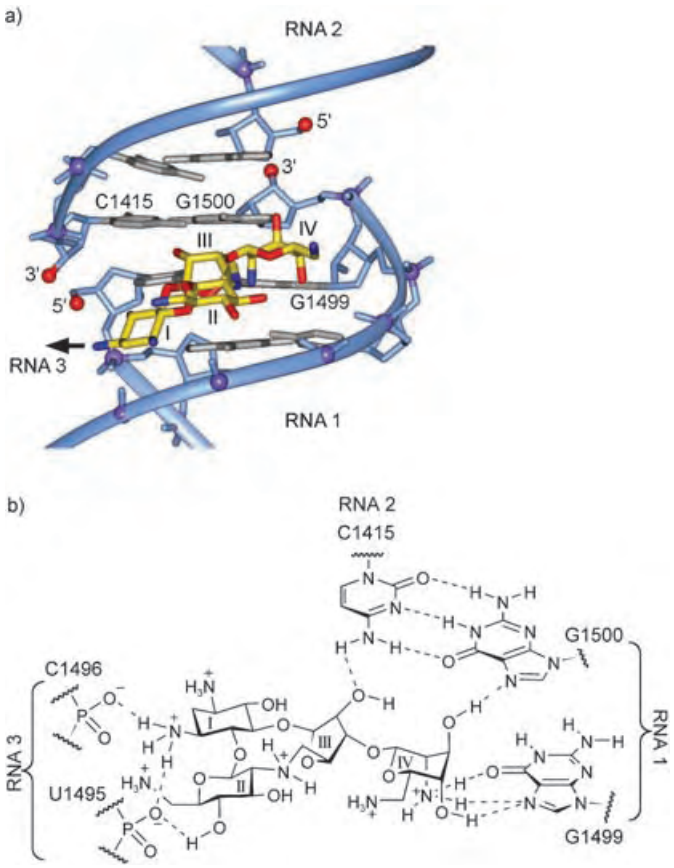

Figure 4. a) The second binding site of neomycin and restricted neomycin in the deep groove at the interface of coaxially stacked RNA helices (RNA 1 and 2). Only the structure of the complex with restricted neomycin is shown. The binding geometry at this site is identical to that of the complex with neomycin. Base-pair formation between the 3′-overhanging nucleotides of the decoding-site constructs promotes formation of pseudo-continuous helices in the crystal. A third, laterally docking RNA provides contacts with rings I and II of the aminoglycoside (RNA 3 not shown). b) Hydrogen-bonding interactions of **2** with RNA at the second binding site, which involves three RNA molecules.

recognition sites within the same RNA target. This provides the first "intramolecular" showcase for the promiscuity of aminoglycoside–RNA interactions.

At the interfacial site, the aminoglycoside forms hydrogen bonds with two mutually stacking RNA molecules and a third RNA helix that docks laterally. The interaction pattern differs remarkably from that observed at the decoding site in which rings I and II are involved in base-specific contacts, whereas rings III and IV play accessory roles. At the secondary binding site, ring IV docks in a coplanar manner between G1499 and G1500 and forms hydrogen bonds to the Hoogsteen edges of these bases. This is facilitated by a pyranose conformation that projects the 2‴, 3‴ and 4‴ substituents in an axial position (Figure 4). An additional hydrogen bond to the base of C1415 in a second RNA construct is provided by the 2″-hydroxy group of ring III. Rings I and II are projected outward from the RNA deep groove and are aligned along the sugar–phosphate backbone where they form hydrogen bonds exclusively with phosphate groups of a laterally docked third RNA helix (Figure 4). The geometry of the secondary aminoglycoside binding site is identical in the neomycin and restricted neomycin complexes. The small differences in the orientation of rings I and II that are induced by the intramolecular cyclization in **2** are accommodated by nonspecific interactions of these rings with phosphate groups. Interestingly, the docking site of ring IV at G1499 and G1500 in the aminoglycoside complexes corresponds to a magnesium ion binding site at the Hoogsteen face of consecutively stacked guanine residues. This metal ion binding site has been observed in RNA crystal structures, including the group I self-splicing intron[14] and 5S rRNA[15] (Supporting Information). The alternative occupancy of a magnesium binding site by neomycin, and the restricted derivative **2** is a further elegant example of structural electrostatic complementarity between cation binding sites in RNA and aminoglycosides.[2]

In summary, we have used X-ray crystallography to determine the three-dimensional structure of decoding-site RNA complexes of the aminoglycoside antibiotic neomycin (**1a**) and a synthetic restricted derivative **2** that was designed as a rigidified analogue of the natural product.[16] Conformational restriction by intramolecular cyclization is an established principle of drug design,[17] which we have applied to RNA-directed ligands.[3] The key requirement for conformational restriction is maintenance or induction of an active ligand conformation that allows target recognition. Our structural studies on RNA decoding-site complexes of neomycin (**1a**) and the restricted derivative **2** demonstrate that the intramolecular 2′–5″ cross-link introduced into the natural product is compatible with target binding. Comparison of the crystal structures of **1a** and **2** complexed to the decoding site reveals the exquisite sensitivity of aminoglycoside target recognition toward even slight modifications of the architecture of the natural product. Whereas key interactions of the aminoglycoside ligand are undisturbed by the modification, minimal differences in the overall conformation of **2** relative to **1a** disable hydrogen-bond contacts to the target.

Structural analysis revealed that neomycin, which is among the most potent aminoglycoside translation inhibitors, binds to the decoding site in the same conformation and at the same site as the structurally similar paromomycin, which is a considerably weaker inhibitor of bacterial translation.[7,18] The identical geometries for the decoding-site-bound neomycin and paromomycin suggest that the higher binding affinity of neomycin for the RNA target[7,18] may be due to the stronger N6′−H···$N1_{A1408}$ H bond relative to the O6′−H···$N1_{A1408}$ interaction in the paromomycin complex. A similar conclusion was drawn by Böttger and co-workers, who analyzed aminoglycoside binding to decoding-site mutants.[19] The identity of the 6′ substituent might also impact the basicity of other amino groups in the antibiotic, leading to a synergistic enhancement of neomycin binding over paromomycin. The interplay of amino group substitution pattern and basicity in aminoglycosides is well-established,[20] as is the importance of amino group protonation for ligand–RNA binding interactions.[21]

As an unexpected finding, a secondary aminoglycoside-binding site was discovered in the decoding-site complexes of both neomycin and the restricted derivative **2**. Interactions of the aminoglycosides at the secondary site involve the docking

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of an amino-sugar moiety of the ligand at a metal ion binding site of the RNA, following the principle of structural electrostatic complementarity.[2]

Conservation of Chirality in a Hierarchical Supramolecular Self-Assembled Structure with Pentagonal Symmetry**

Marie-Christine Blüm, Elizabeta Ćavar, Marina Pivetta, François Patthey, and Wolf-Dieter Schneider*

Molecular and supramolecular chiral recognition governs fundamental processes in living systems.[1] Its importance for disciplines such as biology, pharmaceutics, chemistry, and physics stems from the different properties the two chiral forms exhibit in the presence of chiral phenomena, such as, for example, chiral enzymes and drugs,[2] β-rays,[3] circularly polarized light,[4] and spin-polarized electrons.[5] The differ-

ences in physical and chemical characteristics should become important for the design of molecular electronic and optoelectronic devices.[6] The first steps have been made through the study of the self-organizing behavior of chiral organic molecules by scanning tunneling microscopy (STM) and the determination of the chirality of individual molecules and supramolecular assemblies.[7] Herein we present the first direct observation of all stages of a nested self-assembly of π-conjugated chiral molecules into cyclic supramolecular structures. We have followed by STM the hierarchical self-organization of single molecules into individual pentagonal supermolecules which then act as building blocks for the formation of supramolecular decagons. We show the spontaneous chiral resolution of the racemate into disjointed homochiral complex architectures and demonstrate the possibility to monitor directly the evolution of chiral recognition processes on the molecular and supramolecular level.

The aromatic hydrocarbon 5,6,11,12-tetraphenylnaphthacene (rubrene, $C_{42}H_{28}$) is chiral and nonplanar as a result of intramolecular steric hindrance[8] which causes a twisting of the central tetracene backbone around its axis and forces the four phenyl groups to rotate around their σ bonds (Figure 1a). Its highly efficient luminescence can be induced by a variety of methods, such as incident light,[9] chemical reactions,[10] and electronic excitation. The latter property established the success of rubrene as a dopant for organic light emitting diodes which led to the improvement of the efficiency and stability of the devices.[11] The high charge carrier mobility measured on the surface of the crystals[12] led to their integration into organic field-effect transistors[13] that can be switched by light[14] as a consequence of the reversible photooxidation behavior of the molecule.[15] Despite this growing interest in the application of rubrene, there have been no investigations of the self-assembly process and the molecular and supramolecular chirality of rubrene at the nanoscale.

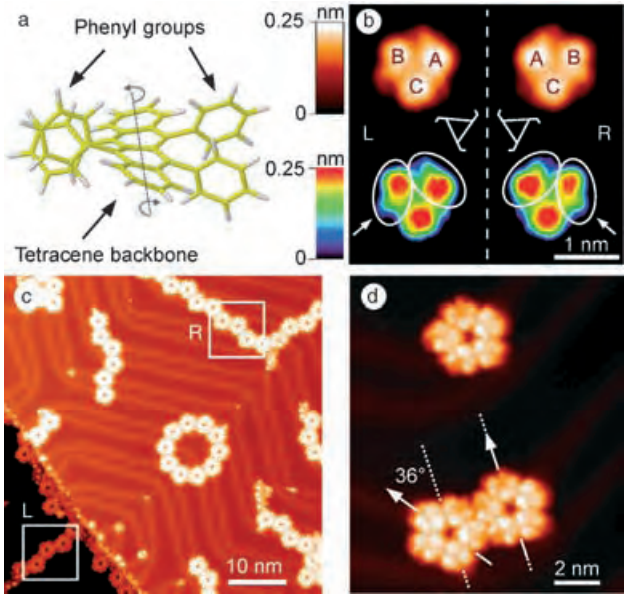

Figure 1. Monomers and self-assembled structures of rubrene on gold. a) Twisted 3D conformation of rubrene in the gas phase. b) STM image of two adsorbed monomers of opposite chirality represented in two different color codings. The arrows indicate the shoulders of feature B for the two enantiomers L and R. c) STM image showing the supramolecular structures on the herringbone-reconstructed Au(111) surface. Two terraces separated by a monatomic step are visible. The squares denoted L and R indicate areas shown in Figure 2c and d, respectively. d) STM image of an isolated supramolecular pentagon and two interlocked supermolecules resembling gear wheels.

Figure 1b shows an STM image of two individual molecules of rubrene adsorbed on an Au(111) surface. Three unequally shaped features (denoted by A, B, and C) with an apparent height of approximately 0.25 nm can be detected in each molecule. The monomer on the left has a counterclockwise arrangement of these lobes (BAC), while the one on the right follows a clockwise orientation (ABC), thus the molecules are mirror images of each other and reflect the chiral conformation of the molecule in the gas phase. The same STM image represented in a different color coding in the lower part of Figure 1b reveals the existence of shoulders (green/blue bulges) belonging to the features A and B which appear either on the left side of each maximum or on the right side, as viewed from the center of the molecule. This characteristic arrangement of asymmetric features determines the molecular chirality and allows the classification of the adsorbed molecules as L or R enantiomers, as shown schematically by the chiral triangles. The independence of these features on an applied voltage between -2 V and $+2$ V indicates that a modulation of the electronic substrate states by broadened molecular levels gives rise to the observed molecular contrast,[16] thus suggesting that the characteristic appearance of the molecules in the STM images reflects their nonplanar and twisted conformation.

The spontaneous self-assembly of single rubrene molecules results in the formation of complex supramolecular structures (Figure 1c). The STM image shows disjointed chains and rings which are constructed out of small building blocks. These structures are incommensurate with the hexagonal periodicity of the Au(111) substrate, but are stabilized by the domain walls of the herringbone-reconstructed surface and at step edges. A smaller scale image reveals that the observed building units of the supramolecular chains are molecular assemblies on their own (Figure 1d). More interestingly, they contain exactly five molecules which are linked into a pentagonal supermolecule with a radius of 1 nm. The appearance of regular pentagons in our experiment is very surprising, given that C_5 symmetries are mainly found in living organisms, but are a rarity in nonliving matter because of the impossibility of a periodic space-filling arrangement with pentagons. Supramolecular self-assembly of adsorbed molecules is the result of a competition between molecule–substrate interactions and noncovalent intermolecular attractions arising from van der Waals forces, hydrogen bonds, and electrostatic interactions. The absence of any permanent dipole in the molecule and the chemical structure of rubrene suggest that the observed self-assembly is the result of an interplay of van der Waals forces and CH···π hydrogen bonds. The incommensurability of the structures rules out site-specific bonding to the surface and indicates that the observed supramolecular assembly is determined by intermolecular forces.

A new level of supramolecular self-assembly is reached by a second organization step that follows the first assembly into stable fivefold structures (Figure 1d). The pentagonal supermolecules diffuse on the surface in a similar manner as the individual molecules and link to each other to form nanometer-sized gearlike wheels. This interlocking of the supermolecules is realized by one pentagonal gear wheel rotating by exactly 36° with respect to the other, which leads to a final distance of approximately 3 nm between their centers. This assembly of two individual supramolecular entities results in a stable individual structure to which other pentagons can join to build supramolecular architectures of higher complexity.

A fascinating aspect of this progression of supramolecular structures is that the molecular chirality is conserved and transferred to the next higher organizational level. A detailed analysis of the pentagonal supermolecules from the first assembly step reveals the existence of two different types of fivefold structures. Pentagons are found that consist of five L-type molecules (Figure 2a), while others are made out of five R-type molecules (Figure 2b). This observation shows that

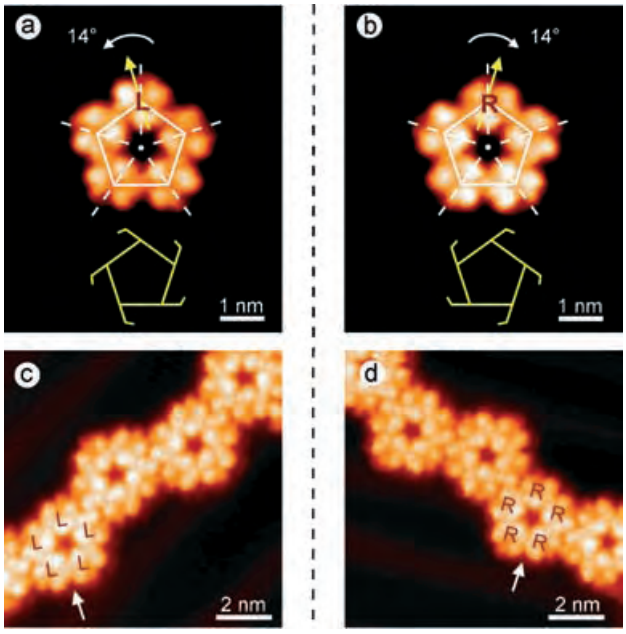

Figure 2. STM images of the enantioselective self-assembly into left- and right-handed supramolecular structures that are mirror images. a, b) Chiral pentagons formed by L-type (a) and R-type (b) molecules, rotated into opposite directions around their centers. c, d) Magnified image of the areas indicated in Figure 1c. Self-assembled chiral chains of interlocked L-type (c) and R-type (d) pentagons.

the spontaneous self-assembly of the individual chiral molecules is enantioselective, and results in two versions of homochiral pentagons. Furthermore, each molecule in the structures is rotated by approximately 14° around its center to optimize the interlocking between the molecules (Figure 2a, b). The direction of rotation is dependent on the molecular chirality: counterclockwise for the L-type molecules and clockwise of the R-type species. This rotation of the molecules, together with the homochirality of the whole assembly, results in the creation of L-type and R-type pentagons (Figure 2a, Figure 2b). The impact of this chiral property on the second step of self-assembly results in the formation of nested chiral structures. STM images of supramolecular chains (Figure 2c, 2d) clearly demonstrate that chirality is conserved in the spontaneous interlocking of pentagonal supermolecules. This observation proves that the two enantiomers of the molecule, as well as the pentagonal supermolecules, are not acting equally in the bonding process as this would result in chirally mixed supramolecular architectures. On the contrary, chiral recognition is of decisive importance for the supramolecular self-assembly and results in a spontaneous self-resolution of the original racemic mixture into nanometer-sized homochiral architectures.

An entirely new and especially beautiful result of the enantiomerically pure self-organization is the creation of a second generation of cyclic size-defined structures (Figure 3).

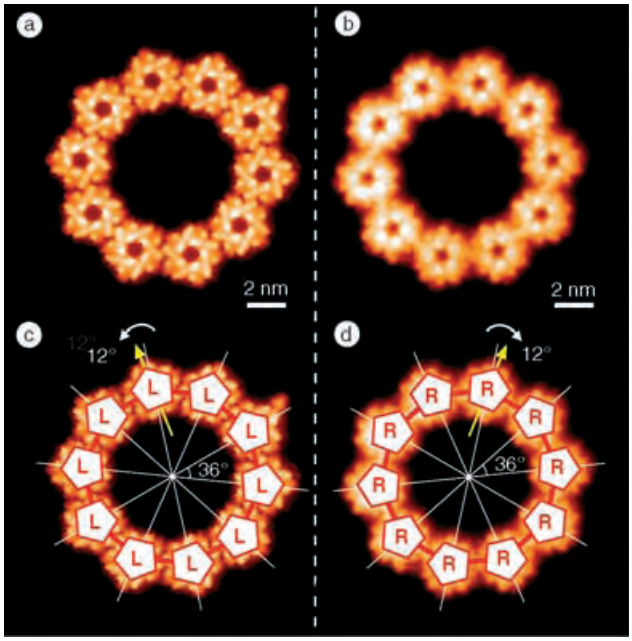

Figure 3. Formation of chiral supramolecular decagons of pentagonal supermolecules. a, b) STM images of a left-handed (a) and a right-handed (b) homochiral decagon. c, d) Construction of the decagons out of ten counterclockwise rotated L-type pentagons (c) and clockwise rotated R-type pentagons (d).

These planar decagons are composed of ten pentagonal supermolecules of the same chirality and rotated by approximately 12° around their centers. The orientation of the rotation depends on the chirality of the pentagonal building blocks and determines the chirality of the decagons (Figure 3a, Figure 3b). The overlaid picture in Figure 3c describes the finding that the decagon shown is a homochiral assembly of exclusively L-type pentagonal supermolecules. Since each pentagon is constructed out of five L-type molecules, we obtain a hierarchically organized architecture of $10 \times 5 = 50$ molecules of the same chirality. This fact, together with the counterclockwise orientation of each

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

pentagon, yields an L-type chirality of the tenfold supramolecular structure. The creation of the mirror image of this chiral pattern, namely the R decagon made out of clockwise-rotated R pentagons, is the result of analogous but mirrored building rules as the L-type structure (Figure 3d). The rotation of neighboring pentagonal supermolecules by 36° illustrates that the chiral supramolecular decagons are a special result of the formation of supramolecular chains. The white arrows in Figure 2c and d indicate the docking sites the last pentagons of the chains would have to take to continue the arclike arrangement of the three previous ones. If ten such chirally selected pentagons join together in this way, their assembly leads to the construction of a supramolecular decagon with a diameter of 10 nm. In contrast to the combination of the first three pentagons, which always construct the basis for a cycle, the arriving supermolecules from the forth unit on have only a 50% chance of occupying the "correct" site. This reduces the probability for the development of a complete decagon to less than 1%, a value which explains the rarity of these nested patterns.

Our results demonstrate the surprising hierarchical complexity of the two-dimensional supramolecular assembly of rubrene on gold (Figure 4a). We have identified its three

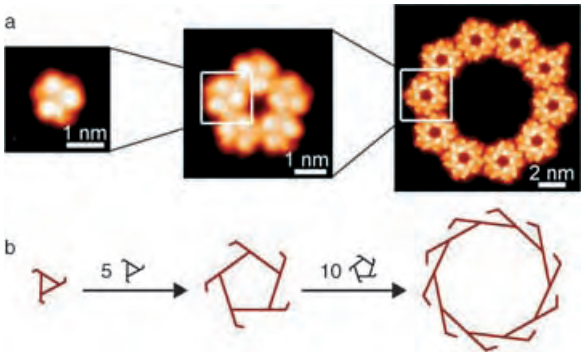

Figure 4. Hierarchy and conservation of chirality in the spontaneous two-dimensional supramolecular assembly. a) STM images representing the three generations of the nested two-staged self-organization. b) Enantioselective assembly from L-type monomers to L-type pentagons and further on to L-type decagons.

successive generations: single molecules, pentagonal supermolecules, and supramolecular decagons. The chirality of the individual molecules is conserved in both assembly steps, and both resulting generations of the progression are chiral as a result of the chirality-dependent rotation of the building blocks (Figure 4b). Since this self-organization of increasing complexity is enantioselective on the molecular and supramolecular level, we obtain a spontaneous resolution of the original racemic mixture of individual molecules into homochiral architectures. Our findings on the conservation and recognition of chirality at all stages of the supramolecular self-assembly of rubrene may have an impact on the development of chiral molecular electronic and optoelectronic devices, and exemplify the working principle of basic processes in nature.

Experimental Section

Experiments were performed using a home-built scanning tunneling microscope in an ultrahigh vacuum system at a base pressure of 2×10^{-11} mbar and a temperature of 5 K. Typical tunneling parameters were: $I_t = 20$ pA and $V_S = -0.8$ V. The rubrene molecules were deposited at low coverage (0.3 monolayers) in situ by sublimation from a home-built evaporator onto a clean Au(111) substrate at room temperature.

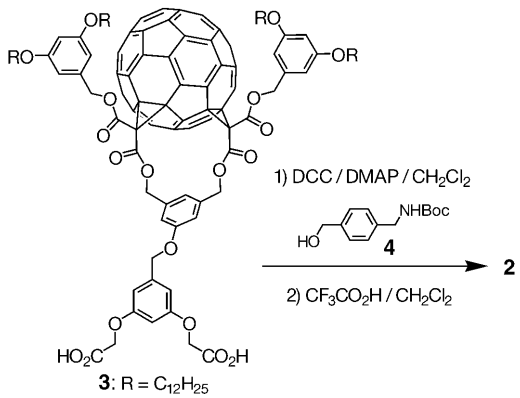
Supramolecular Click Chemistry with a Bisammonium-C_{60} Substrate and a Ditopic Crown Ether Host**



Uwe Hahn, Mourad Elhabiri, Ali Trabolsi, Haiko Herschbach, Emmanuelle Leize, Alain Van Dorsselaer, Anne-Marie Albrecht-Gary,* and Jean-François Nierengarten**

Fullerenes and their derivatives have shown a wide range of chemical and physical properties which make them attractive candidates for a variety of interesting applications in supramolecular chemistry.[1] Indeed, spectacular noncovalent architectures incorporating fullerene moieties have been described over the past few years. Examples include rotaxanes,[2] catenanes,[3] self-assembled coordination compounds,[4] liquid-crystalline inclusion complexes,[5] and photoactive supramolecular devices.[6–10] As part of this research, we have recently reported supramolecular donor-fullerene systems based on the self-assembly of C_{60} derivatives bearing an ammonium unit with crown ethers.[7–9] However, the ammonium–crown ether interaction is itself weak.[7] Consequently, the binding constants are rather low and only a small fraction of the two components are effectively associated in solution. This result prompted us to design systems with additional recognition elements to increase the binding constants.[8,9] For example, evidence of π-stacking interactions between the C_{60} sphere and the porphyrin moiety in a supramolecular array has been obtained from a porphyrin–crown ether conjugate and a fullerene derivative bearing an ammonium unit.[8] In this case, the association constant (K_a) for the complex is increased by two orders of magnitude relative to K_a values for the complexation of the same ammonium cation with other crown ether derivatives. We now report the preparation and the characterization of a very stable supramolecular complex obtained from bis(crown ether) receptor **1**[9] and bisammonium fullerene ligand **2**. As a result of the perfect complementarity of the two components, biscationic substrate **2** can be "clicked"[10] onto the ditopic crown ether derivative **1**, thus leading to a noncovalent macrocyclic 1:1 complex.

1: R = C_8H_{17} **2**: R = $C_{12}H_{25}$

The synthesis of **2** is depicted in Scheme 1. The C_s symmetrical fullerene bisadduct precursor **3** was prepared in nine steps according to a literature procedure.[11] Treatment of diacid **3** with alcohol **4**[7] and *N*,*N*′-dicyclohexylcarbodiimide (DCC) in the presence of 4-dimethylaminopyridine (DMAP) and 1-hydroxybenzotriazole (HOBt) gave bisamine **5** protected with *tert*-butyloxycarbonyl (Boc) groups in 37% yield.

3: R = $C_{12}H_{25}$

Subsequent treatment with CF_3CO_2H afforded **2** as its trifluoroacetate salt in 84% yield.

The binding behavior of bisammonium **2** with the bis(crown ether) receptor **1** in $CDCl_3$ was first investigated by ^{1}H NMR spectroscopy at 298 K. Comparison of the ^{1}H NMR spectra of **1**, **2**, and an equimolar mixture of both components revealed complexation-induced changes in chemical shifts (Figure 1). In particular, a dramatic downfield

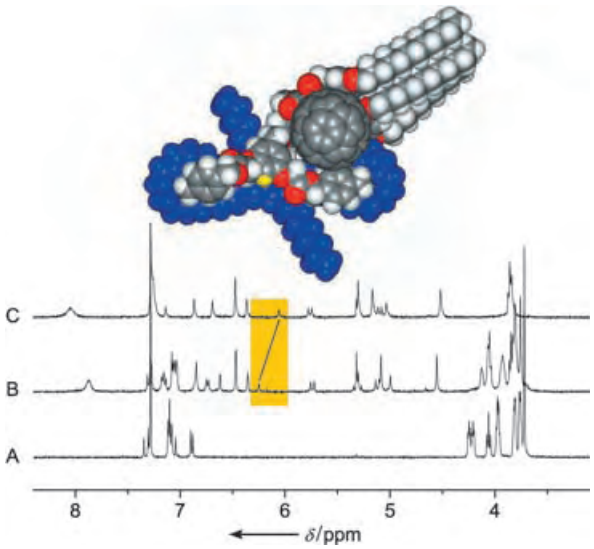

Figure 1. Top: calculated structure of the macrocyclic supramolecular complex [(**1**)·(**2**)] (molecular modeling studies were performed with Spartan). Bottom: ^{1}H NMR spectrum (400 MHz, 25 °C) of equimolar $CDCl_3$ solutions of **1** (A), **2** (C), and a 1:1 mixture of **1** and **2** (B); the downfield shift of the signal corresponding to proton H_K (shown in yellow) upon addition of **1** shows that this proton must be close to the π-conjugated system of **1** in the supramolecular complex, which is in good agreement with the proposed structure.

shift is seen for the signal of H_K of **2** upon addition of **1**. This downfield shift indicates the formation of a macrocyclic 1:1 supramolecular complex where proton H_K is located on top of the conjugated π system of **1**.

Further evidence for the formation of a 1:1 macrocyclic complex was obtained by electrospray mass spectrometry (ESMS).[12] The ES mass spectrum (positive mode; Figure 2) recorded under mild conditions (extracting cone voltage V_c = 200 V) of a 1:1 mixture of **1** and **2** is dominated by a doubly charged ion signal at *m*/*z* 1723.1 which can be assigned to the 1:1 complex after loss of the trifluoroacetate counteranions (calculated *m*/*z* 1723.11). A very minor signal corresponding to the 2:1 complex was also detected at *m*/*z* 2226.7 (calculated *m*/*z* 2226.76). Under harsher conditions (V_c = 400 V) the spectrum was still dominated by the doubly charged ion signal at *m*/*z* 1723.1 and no significant fragmentation of the supramolecular assembly [(**1**)·(**2**)] could be observed. Indeed, the spectra are almost identical regardless of the V_c value. This behavior is in sharp contrast to the ESMS analysis of supramolecular complexes of **2** with simple crown ether derivatives in which important fragmentation occurs at high V_c values (see Supporting Information). These observations

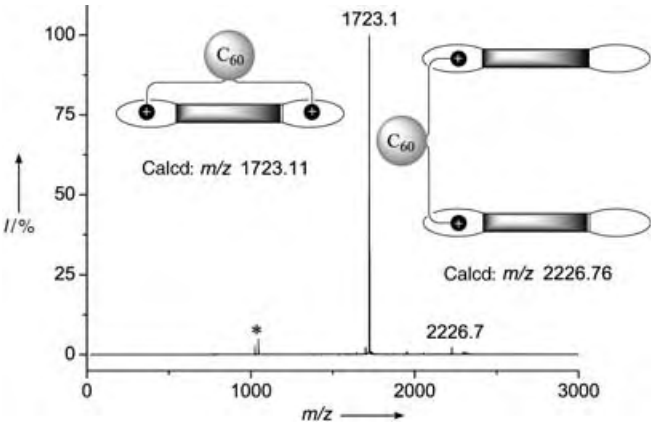

Figure 2. ES mass spectrum (V_c = 200 V) of a 1:1 mixture of **1** and **2** in CH_2Cl_2 ([(**1**)] = [(**2**)] = 5×10^{-6} M); the signal at *m*/*z* 1046.2 (*) is assigned to $[\mathbf{1}+K]^+$ (calculated *m*/*z* 1046.40).

show the high stability of the noncovalent array [(**1**)·(**2**)]. It is also worth noting that the major signal obtained in the ES mass spectra of a 10:1 mixture of **1** and **2** corresponds to the [(**1**)·(**2**)] complex. Under these conditions, the intensity of the signal corresponding to the 2:1 complex [(**1**)$_2$·(**2**)] is lower than 5% of the signal corresponding to the macrocyclic 1:1 complex, thus providing additional evidence for the high stability of [(**1**)·(**2**)].

To quantify the interactions between **1** and **2**, complexation was investigated in CH_2Cl_2 by UV/Vis binding studies, in which changes in the spectrum upon addition of increasing amounts of **2** to a solution of **1** in CH_2Cl_2 were monitored (see Supporting Information). The processing[13] of these data allowed the characterization of a single supramolecular complex [(**1**)·(**2**)] in solution ($\log K_1 = 6.3 \pm 0.4$), which is in excellent agreement with the ESMS and NMR spectroscopic data. Nevertheless, the rather weak complexation-induced changes in the adsorption spectrum prompted further investigation into the binding of **1** and **2** by luminescence experiments. As previously observed for related systems,[7–9] the strong emission of the π-conjugated system of **1** (λ_{em}^{max} = 450 nm, $\phi_{fluo} = 0.65 \pm 0.06$) is quenched upon binding of **2** through an efficient intramolecular process within the [(**1**)·(**2**)] complex, thus allowing the facile determination of the binding constant by luminescence titrations (Figure 3). Collisions and reabsorption events (see Supporting Information) could be neglected under our experimental conditions. Therefore, the decrease in the luminescence intensity observed in the presence of **2** (Figure 3) is attributed solely to intramolecular photochemical processes. By using a modified Stern–Volmer relationship[14] ($F_0/F = (1 + K_{SV}[(\mathbf{2})]) \times \exp(K_1[(\mathbf{2})])$) and assuming $K_{SV}[(\mathbf{2})] \ll 1$, the stability constant of [(**1**)·(**2**)] was obtained ($\log K_1 = 6.40 \pm 0.01$).[15] This value is in excellent agreement with the result obtained from the absorption binding studies.

Comparison of our results with thermodynamic data available in the literature show that coordination is more than three orders of magnitude stronger in the current system than in related systems (crown ethers and ammonium derivatives).[7] This result is mainly attributed to the two-center

host–guest topography. In a similar manner to the "click chemistry" concept introduced by Sharpless and co-workers,[10] the "supramolecular click chemistry" principle described herein is a powerful and selective process for the preparation of stable macrocyclic noncovalent arrays. This approach is modular and it appears that it can be easily applied to a wide range of functional groups for the preparation of new supramolecular architectures with tunable structural and electronic properties.

Experimental Section

ESMS: High-resolution ESI mass spectra in the positive mode were acquired on a time of flight mass spectrometer (microTof, Bruker Daltonics, Bremen, Germany). The instrument was calibrated using a solution of cesium iodide (1 mg mL^{-1}) in water/isopropanol (50/50 (v/v)). CsI clusters of the types $[(CsI)_nCs]^+$ or $[(CsI)_nCs_2]^{2+}$ generate ions with m/z values up to about 16000. The ESI-source was heated to 100 °C. Sample solutions were introduced into the mass spectrometer source with a syringe pump (Cole Parmer, Vernon Hills, Illinois, USA) with a flow rate of 5 μL min^{-1}. Scanning was performed over an m/z range of 100–12000, and then the data were averaged for 1 min and smoothed using the Gaussian algorithm. To ensure that the species detected by ESI-MS reflect the species present in solution, the instrument parameters, for example, the sample cone voltage V_c, have been varied.

UV/Vis and luminescence binding studies: the experimental conditions have been described in detail in Ref. [9].

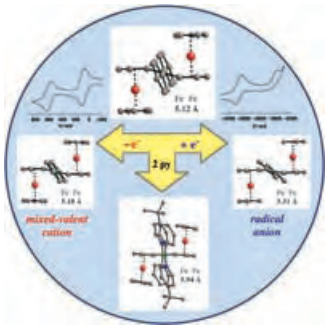
Cover Picture

Brian K. H. Yen, Axel Günther, Martin A. Schmidt, Klavs F. Jensen,* and Moungi G. Bawendi*



The two-phase flow of the gas–liquid segmented flow reactor with multiple temperature zones shown in the cover picture makes it possible to realize both rapid mixing of reagents and narrow residence-time distributions. The reactor design allows the preparation of colloidal CdSe quantum dots (bottom right) with excellent size distributions at high temperature. For more details, see the Communication by K. F. Jensen, M. G. Bawendi, and co-workers on page 5447 ff. (The authors thank Jane Rempel for assistance with the cover picture.)

Fullerene Chemistry
In their Minireview on page 5374 ff. N. Martín, D. M. Guldi, and L. Sánchez describe how supramolecular structures are formed and modulated by combinations of fullerenes and hydrogen bonds.

Biaryl Syntheses
Axially chiral biaryl compounds are increasingly common structural units. G. Bringmann, M. Breuning, and co-workers describe strategies for the atroposelective synthesis of these challenging compounds in their Review on page 5384 ff.

Ferrocenes
In their Communication on page 5428 ff., F. Jäkle and co-workers describe an electrochemical and structural study of a highly rigid 1,2-diborylated diferrocene that shows unusually strong electronic coupling between the ferrocene groups upon partial oxidation.

Molecules with Exceptionally Small HOMO–LUMO Gaps

Mind the gap: HOMO–LUMO gaps less than 0.5 eV have been recently engineered in small organic molecules through extended conjugation and donor–acceptor covalent coupling approaches (see picture). Such compounds reveal a number of unusual electronic properties such as thermo-excited intramolecular electron transfer (in solution) and metallic conductivity (in the solid state).

Minireviews

Supramolecular chemistry of C_{60} is leading the way for the use of C_{60} as a unique photo- and electroactive building block. Arrays of hydrogen bonds ensure a high degree of order on the nanometer scale, a feature that will be critical in the application of the resulting noncovalently bound ensembles as molecular materials or supramolecular catalysts (see scheme; eT = electron transfer, ET = energy transfer).

Hydrogen-Bonding Motifs in Fullerene Chemistry

Reviews

Not only classic, atroposelective biaryl couplings lead to stereochemically pure, axially chiral biaryl compounds (see scheme); recently, novel, highly original strategies have also emerged. The authors present a discussion of the structural preconditions of axial chirality and the most successful and innovative of these strategies.

Atroposelective Synthesis of Axially Chiral Biaryl Compounds

Communications

Two Bs in a pod: The first 1,2-diborylated ferrocene (see structure) was obtained upon reaction of $PhBCl_2$ with 1,1′-bis(trimethylstannyl)ferrocene. Conformational changes in this highly rigid species are triggered either through redox chemistry or the binding of nucleophiles, to render the complex an interesting candidate for the design of new types of molecular machines.

The challenging structure and potent growth inhibition properties against a variety of human cancer cell lines make Spongistatin 1 (**1**) an exciting target for total synthesis. Enantioselective total synthesis has been achieved by exploiting a latent element of pseudo-symmetry (-----= pseudo-C_2 axis) within the ABCD bis(spiroketal) fragment (red substructure).

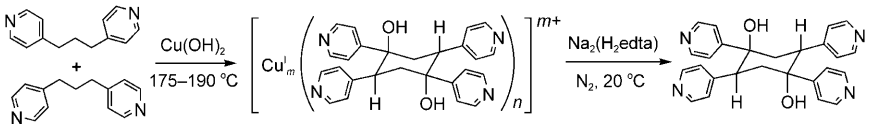
A DNA–Protein Nanoengine for "On-Demand" Release and Precise Delivery of Molecules

A DNA aptamer (green in the scheme), an antisense DNA strand (purple), and an enzyme (blue) form a nanoengine that responds to a small-molecule input (red) and dispatches a DNA output. The addition of the input promotes the first stroke of the nanoengine, the action of the enzyme the second stroke. Joint exploration of all components could lead to bionanodevices that can detect a biological malfunction and initiate a repair.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

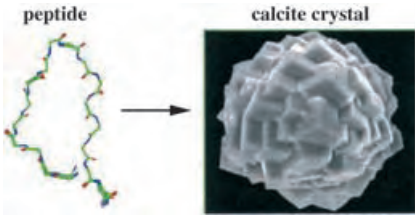


What controls reactivity of ylides? Computational data show that reactivity in the reactions shown in the scheme is mainly determined by the leaving group ability of the onium group, and this decreases for both intrinsic and thermochemical reasons in the order O > S > N > P. The results are consistent with experimental observations and account for the dearth of examples of phosphorus ylides in these reactions.

Reactivity Studies

V. K. Aggarwal,* J. N. Harvey,* R. Robiette ——— **5468 – 5471**

On the Importance of Leaving Group Ability in Reactions of Ammonium, Oxonium, Phosphonium, and Sulfonium Ylides

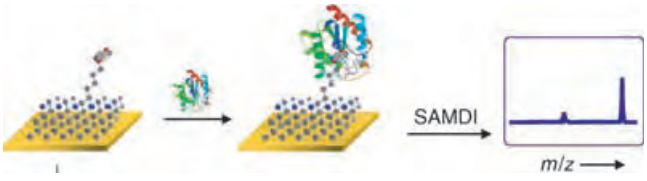


The hydrothermal reaction of 1,3-di(4-pyridyl)propane with $Cu(OH)_2$ in the presence of 1,4-cyclohexanedicarboxylic acid and dilute HCl generates an unprecedented tetratopic ligand (chtpy) and a family of interesting coordination networks in situ (see scheme). The topological diversification of the Cu^{I}–chtpy nets can be controlled simply by changing the molar ratio of the starting materials.

Coordination Polymers

S. Hu, J.-C. Chen, M.-L. Tong,* B. Wang, Y.-X. Yan, S. R. Batten ——— **5471 – 5475**

Cu^{2+}-Mediated Dehydrogenative Coupling and Hydroxylation of an N-Heterocyclic Ligand: From Generation of a New Tetratopic Ligand to the Designed Assembly of Three-Dimensional Copper(I) Coordination Polymers



An eggshell finish: Designed peptides can be used as a tool to unravel the structure–activity relationships of eggshell matrix proteins. The ordered arrangement of doublets of charged residues on the peptide and its self-assembling characteristics play a key role in the biomimetic nucleation of polycrystalline calcite crystal aggregates (see picture), which models that initiated by the goose eggshell matrix protein, ansocalcin.

Biomineralization

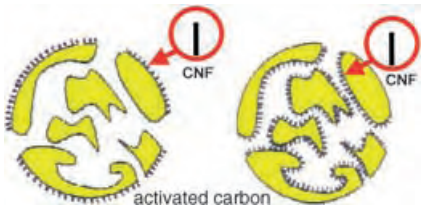
Structure Elucidation

A.-V. Mudring,* A. Babai, S. Arenz, R. Giernoth ——— **5485 – 5488**

The "Noncoordinating" Anion Tf_2N^- Coordinates to Yb^{2+}: A Structurally Characterized Tf_2N^- Complex from the Ionic Liquid [mppyr][Tf_2N]

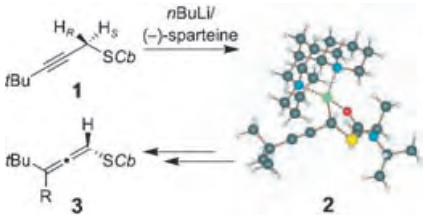
Not as innocent as it looks: The first anionic Tf_2N^- complex, $[Yb(Tf_2N)_4]^{2-}$, has been prepared in the ionic liquid [mppyr][Tf_2N] (see crystal structure; blue: N, yellow: S, gray: C, green: F, orange: Yb, red: O; mppyr = 1-methyl-1-propyl-pyrrolidinium, Tf = trifloromethanesulfonyl). The coordination of the presumed noncoordinating ("innocent") Tf_2N^{2-} ion could have a decisive influence on reactions in ionic liquids.



Carbon Nanoparticles

D. S. Su,* X. Chen, G. Weinberg, A. Klein-Hofmann, O. Timpe, S. B. A. Hamid, R. Schlögl **5488 – 5492**

Hierarchically Structured Carbon: Synthesis of Carbon Nanofibers Nested inside or Immobilized onto Modified Activated Carbon

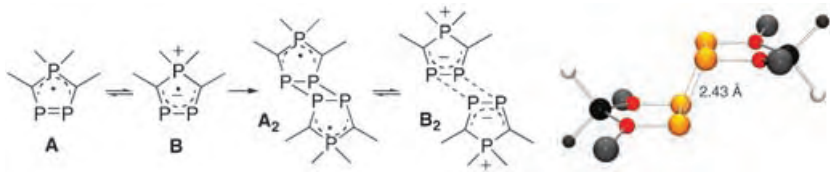


Filling in the gaps of activated carbon by chemical vapor decomposition of ethylene results in hierarchically structured carbon with carbon nanofibers (CNFs) nested inside and immobilized on the surface (see picture). The adsorption experiments show that this nanostructuring of carbon creates novel functions on the surface of activated carbon.

Asymmetric Synthesis

R. Otte, R. Fröhlich, B. Wibbeling, D. Hoppe* ——— **5492 – 5496**

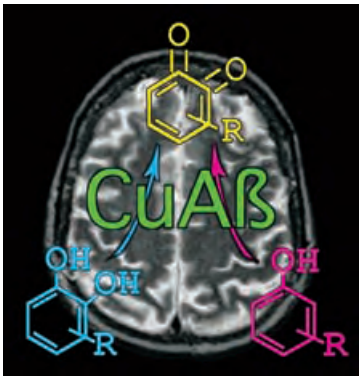
Solid-State Structure and Enantioselective Reactions of a Complex of a 1-Thio-Substituted Propargyllithium and (−)-Sparteine



A useful transformation in enantioselective synthesis: (−)-Sparteine-assisted lithiation of the propargylic 1-thiocarbamate **1** (*Cb* = CON*i*Pr$_2$) forms the enantiomerically and diastereomerically pure lithium (−)-sparteine complex **2**. Its solid-state structure and application in the asymmetric synthesis of highly enantioenriched 1-thioallenes **3** were investigated.

Odd-Electron Bonds

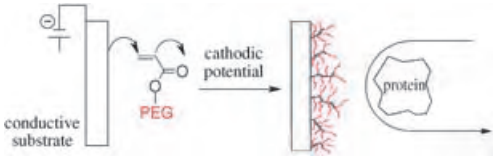
T. Kato, H. Gornitzka, W. W. Schoeller, A. Baceiredo, G. Bertrand* **5497 – 5500**



Dimerization of a Cyclo-1σ^4,3σ^2,4σ^2-Triphosphapentadienyl Radical: Evidence for Phosphorus–Phosphorus Odd-Electron Bonds

How odd! The title radical can be represented by resonance structures **A** and **B**. From **A**, dimerization refers to a [$\pi^2+\pi^2$] reaction and results in the formation of two inter-ring P–P single bonds, whereas from **B**, only one unpaired electron is supplied from each radical unit, which leads to two inter-ring P–P one-electron bonds. As a consequence, the isolated dimer features "short" P–P half-bonds.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



A gray area in gray matter: The Cu^{II} complex of a truncated β-amyloid, $CuA\beta_{1-20}$, catalyzes the oxidation of catechol and the hydroxylation and oxidation of phenol (see picture) with dramatic rate accelerations ($\approx 10^5$–10^6-fold increases). The Cu–oxygen chemistry of CuAβ may offer both a better understanding of the chemical effect in the brains of patients who suffer from Alzheimer's disease as well as possible treatment strategies of this disease.

Bioinorganic Chemistry

Joint Meeting on Medicinal Chemistry in Vienna**

Rainer E. Martin,* Peter Mohr, Wylie Palmer, and Henri Stalder

The fourth Austrian, German, Hungarian, Italian, Polish, and Spanish Joint Meeting on Medicinal Chemistry was held this year at the University of Vienna, the oldest university within the German-speaking part of Europe, founded in 1365 by Duke Rudolph IV. The conference was held in the magnificent banquet hall of the university, which holds recently restored paintings by Gustav Klimt (1862–1918), including the famous painting of Hygieia, who, according to the Greek mythology, was a daughter of Asclepius and the goddess associated with the prevention of sickness and the continuation of good health; could there have been a better location for a medicinal chemistry congress?

The meeting was attended by about 500 people from all over Europe, roughly two-thirds of whom come from academia with the remaining one-third from industry. In total, 25 lectures and 11 oral short communications covered a broad range of topics including chemogenomics, combinatorial chemistry, developing fields in medicinal chemistry, computer-aided molecular design, virtual screening, lead- and drug-likeness, oncology, Alzheimer's disease and central nervous system disorders, medicinal chemistry case studies, and natural product synthesis. The scientific discussion was further stimulated by two poster sessions with more than 200 contributions on display.

The synthesis of biologically relevant low molecular weight combinatorial compound libraries continues to be a challenge for the pharmaceutical industry, and numerous design strategies have been discussed over the past few years. The use of natural product scaffolds as biologically pre-validated and evolutionarily selected starting points for the design of molecules with potential in vivo activity seems to be a particularly appealing concept. The first plenary lecture was presented by Herbert Waldmann (Max Planck Institute for Molecular Physiology, Dortmund, Germany) on protein structure similarity clustering (PSSC) as a guiding principle for chemical genomics.[1] Recent results in structural biology and bioinformatics have shown that despite the wide diversity of proteins, their ligand binding pockets (folds) are fairly conserved. The idea that "similar folds bind to similar ligands" was exploited for the identification of an appropriate substructure for the generation of a compound library. A group of proteins (Cdc25A phosphatase, acetylcholinesterase (AChE), and 11β-hydroxysteroid dehydrogenase (11β-HSD1)) was clustered based on structural similarities of their domain cores and not by sequence homology, as is commonly done. The decalin substructure from dysidiolide, a known natural ligand of Cdc25A, was identified as an appropriate scaffold for library design. A focused library containing more than 500 compounds was synthesized providing hits for 11β-HSD1 with IC_{50} values in the nanomolar potency. The library also contained compounds with activity for Cdc25 and AChE, thereby validating the structural analysis method of identifying relevant templates.

The explosion of the number of solved protein structures and biological data in recent years has created the difficulty of efficiently organizing the flood of information for the extraction of knowledge in the form of trends, rules, or models that correlate chemical and biological properties. The ability to retrieve knowledge from databases is partly limited by the way data is stored. Jordi Mestres (University Pompeu Fabra, Barcelona, Spain) discussed options for data mining in the huge datasets available for receptors, enzymes, and their interactions with various ligands. An essential prerequisite for an efficient use of these data is a systematic application of hierarchical classification schemes for both chemical (e.g., the *m*olecular *eq*uivalence *num*ber (MEQNUM)) and biological entities. Knowledge generation based on well-organized and properly stored annotated biochemical data should also facilitate the shift from target-focused to pathway-directed drug discovery.

Exploration of the vast chemical space has just begun. If one considers only molecules with a molecular weight below 500 Da and less than seven rings, there are an unimaginable 65 quadrillion unique structure possibilities. Tudor I. Oprea (University of New Mexico School of Medicine, Albuquerque, USA) highlighted the large need for efficient tools to investigate and mine this huge chemical space to identify the most promising druglike seed structures. He provided a number of examples of how knowledge can be extracted from current databases to better guide the lead discovery process.[2]

Ulrich Stilz (Aventis Pharma, Frankfurt am Main, Germany) provided some illustrative examples of knowledge-based approaches for lead finding and lead optimization by using experimental and computational approaches such as 2D similarity searching, re-scaffolding and biased library design, and ligand- and structure-based modeling. These four approaches were successfully combined in the identification of a Kv1.5 channel inhibitor that targets atrial fibrillation. The result is a drug candidate which has recently entered phase II development.

Today G-protein-coupled receptors (GPCRs) constitute one of the largest families of physiologically relevant targets in the pharmaceutical industry. However, rhodopsin is the only three-dimensional structure of a GPCR available and unfortunately little is known

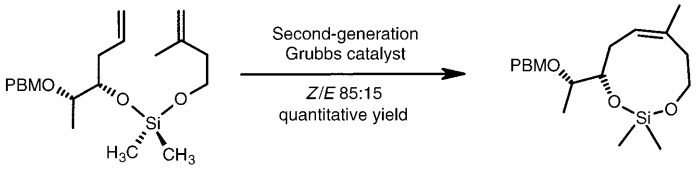
about the higher-order structures of GPCRs and how they might relate to biologically important processes such as dimerization, internalization, and signal transduction within and between cells. By using in silico methods, Slawomir Filipek (International Institute of Molecular and Cell Biology, Warsaw, Poland) studied the cooperative interactions of rhodopsin. These studies revealed that rhodopsin can form dimeric, tetrameric, and even higher-order oligomeric structures. He also showed that proteins such as arrestin bind to rhodopsin dimers by a perfect geometrical and electrostatic match.[3] The lipid bilayer membrane can also play a critical role in the clustering and functioning of receptors. Wolfgang H. Binder (Vienna University of Technology, Austria) presented the latest advances on the use of artificial vesicle systems as models for biological membranes to study the mobility, distribution, and clustering of embedded lipid conjugates by using thermal, fluorescence, and AFM methods.[4]

Alzheimer's disease is a complex neurological disorder characterized by memory loss and progressive deficits in various cognitive abilities with a multifaceted etiology. Multiple explanations for the pathogenic process have been proposed, such as the cholinergic, amyloid-β, and tau-protein hypotheses; oxidative stress and disruption of cerebral metal ion homeostasis have also been suggested as causes. Carlo Melchiorre (University of Bologna, Italy) introduced the concept of a multifunctional drug in which distinct pharmacophores and properties of different drugs are combined into a single hybrid molecule. Memoquine is a symmetric tetraamine structure with a central quinone moiety that combines AChE inhibition, muscarinic M2 antagonism and antioxidative properties in a single molecule. It was demonstrated to effectively inhibit amyloid-β formation in vitro and thus might be an interesting lead structure for further optimization.

In contrast to this multitarget approach, researchers traditionally aim for highly selective chemical entities to avoid potential side effects caused by the action on non-disease-related targets. László G. Hársing (EGIS Pharmaceuticals Ltd., Budapest, Hungary) presented recent results in 2,3-benzodiazepine research. Despite their rich pharmacology mediated by binding to



AMPA and $GABA_A$ receptors, 2,3-benzodiazepines have been explored much less than the well-known and intensely studied 1,4-benzodiazepine regioisomers. Fine tuning of the in vitro and in vivo properties led to the identification of EGIS-8858, a $GABA_A$-selective compound that elicited anxiety relief effects in two standard behavioral tests. Most interestingly, EGIS-8858 shows no signs of causing sedation, it does not induce dependency or amnesia, and anxiety symptoms do not return upon withdrawal.[5]

Barbara Malawska (Jagiellonian University, Kraków, Poland) discussed in detail the structure–activity relationship of arylpiperazines as potent antagonists of the α_1-, α_2- and α-adrenergic receptors. The distance between a phenyl ring and a basic nitrogen atom was found to be crucial for pharmacological activity. The most promising α_1-adrenergic receptor antagonists, with binding affinity in the low nanomolar range, are currently being profiled in animal models.

Angelo Carotti (University of Bari, Italy) showed that a comparative analysis of the two monoamine oxidase (MAO) A and B crystal structures, which only recently became available, allowed a ligand-based design of novel, orally bioavailable, nontoxic MAO-B inhibitors with potency in the low nanomolar range and more than 500-fold selectivity over MAO-A. These structures exhibit a favorable pharmacokinetic profile and might thus become interesting candidates for the treatment of Parkinson's disease.

Despite significant progress that has been made over the past few years, cancer is still a major cause of mortality in the industrialized world. Mario Varasi (Nerviano Medical Sciences, Milan, Italy) gave an interesting overview on the history of cancer treatment with all its hopes, hypes, and setbacks, starting in the middle of the last century, when only unselective cytotoxic treatments were available, to today's modern therapeutic agents, which selectively target cancerous cells. Sequencing the human genome has revealed more than 500 protein kinases, the selective modulation of which has become a cornerstone in the strategy to combat this human plague. New and promising CDK2 and Aurora inhibitors were designed based on the 3-aminopyrazole moiety, a well-known adenine mimetic that represents a widely used pharmacophore motif for kinase inhibitors. The most potent compounds displayed significant tumor-growth suppression in a human leukemia xenograft model. In his excellent presentation, Johann Mulzer (University of Vienna, Austria) referred to another promising class of anticancer agents: the microtubule-stabilizing epothilones. A key reaction in the synthesis of epothilone B was the intramolecular ring-closing metathesis reaction of a silicon-tethered precursor to produce a 9-membered advanced intermediate. With a second-generation Grubbs catalyst, the *Z*/*E* ratio was improved from 1:1 to 85:15 (Scheme 1). Another highlight was the synthesis of laulimalide, in which the application of an intramolecular Sharpless kinetic resolution obviated the need for a protecting-group strategy, thereby underscoring the power and reliability of this method.

Scheme 1. A key step in the synthesis of epothilone B in which an intramolecular ring-closing metathesis reaction increases stereoselectivity; PMB = *para*-methoxybenzyl.

The production of steroid hormones in the body is regulated by steroid sulfatase, an enzyme responsible for the hydrolysis of the sulfate esters of 3-hydroxy steroids. As Peter Nussbaumer (Novartis, Vienna, Austria) pointed out, it offers an attractive target for the treatment of estrogen- and androgen-dependent diseases. Nussbaumer not only provided a comprehensive overview of the current knowledge in this area, he also presented the endeavors of his own research group to transform a promising HTS hit into an interesting chromenone-based lead structure suited for further optimization toward a novel treatment for hormone-dependent hair loss and acne.[6]

An estimated 170 million people suffer from chronic hepatitis C virus (HCV) infection, a leading cause of the need for liver transplants in the US. In a showcase of modern drug discovery, Michael Bös (Boehringer Ingelheim, Laval, Canada) summarized the identification of specific antiviral benzimidazole 5-carboxamides that were demonstrated to specifically inhibit HCV RNA polymerase activity through a novel and specific mechanism. This may provide an opportunity for the development of novel HCV therapies.

A very entertaining lecture was delivered by Hugo Kubinyi (University of Heidelberg, Germany), who gave an excellent overview of lead optimization and general medicinal chemistry topics.[7] Among the many examples, he discussed the concept of privileged structures, (bio)isosteric replacement of atoms and groups, selective optimization of side activities (SOSA approach), fragment-based ligand design, and virtual screening methods. Especially informative were the case histories of Captopril, Sildenafil, Omeprazole, Imatinib and Tamiflu, which show in retrospect that successful development of a drug requires not only a lot of hard work and scientific excellence, but also a good slice of luck.

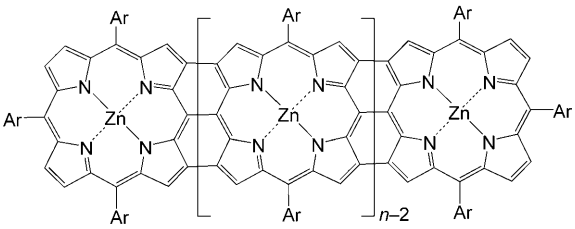
Molecules with Exceptionally Small HOMO–LUMO Gaps**

Dmitrii F. Perepichka and Martin R. Bryce**



Keywords:
electrochemistry · electron transfer · fullerenes · HOMO–LUMO gap · tetrathiafulvalenes

The engineering of small band gaps in π-conjugated heteroaromatic polymers by chemical manipulation has been widely studied for the last 20 years in the search for materials with tailored optoelectronic properties,[1] such as intrinsic conductivity, infrared electrochromic displays, and charge-storage capability.[2] The two most successful approaches are 1) tuning bond-length alternation in the π-system by stabilizing quinonoid character (polyisothionaphthalene (PITN) is the classical example[3]) and 2) alternating heteroaromatic donor and acceptor units.[1,4] Most of these materials are modified thiophene derivatives, obtained by chemical or electrochemical polymerization. A band gap of 0.5 eV and smaller, usually determined by the on-set of absorption or the difference in oxidation/reduction on-set potentials, has been reported.[1] However, if the absorption or redox peak maxima are considered, rather than ill-defined on-set values, there are very few examples of polymers with electrochemical or optical gaps smaller than 1.0 eV.[4]

The attraction of molecular systems is their precise chemical structure and better defined frontier-orbital levels that are unperturbed by supramolecular band formation, which makes them ideal models for basic studies of electron-transfer phenomena as well as potential objects for molecular electronics.[5] There are two established approaches to decreasing the HOMO–LUMO gap (HLG) in a molecule: one is to extend the conjugation, the other is to covalently link electron-donor (high HOMO) and electron-acceptor (low LUMO) fragments. However, the design and synthesis of very-small-HLG systems (<0.5 eV) present considerable challenges.

Early predictions that large polyacenes (that is, conjugated polyaromatic hydrocarbons (PAHs) with linearly fused benzene rings) may behave as one-dimensional conductors with a zero band gap are contradicted by the most recent calculations.[6] The HOMO–LUMO gap of hexacene determined from both the UV/Vis spectra and density functional theory (DFT) calculations is approximately 1.8 eV; higher homologues are calculated to have an open-shell singlet ground state.[6] Also, the aromatic stabilization in graphene-type PAHs is predicted to keep the HLG above 1 eV even for large (over 200 carbon atoms) graphene molecules,[7] although the band formation in the solid state reduces the (band) gap for PAH $C_{222}H_{42}$ to about 0.6 eV (determined by absorption on-set).[8]

It was, however, demonstrated that conjugation over the planar π-electron platform in the triply linked, fused-porphyrin ribbons **1** results in exceptionally small HLGs which are manifested in remarkably red-shifted absorption spectra.[9] The longest fused array, a dodecamer $\mathbf{1}_{12}$ of approximately 10-nm length, has the longest wave-length absorption band at $\lambda_{max} \approx 2900$ nm (3500 cm^{-1}; Figure 1), which corresponds to an electron transition energy of as low as 0.45 eV to < -0.25 V versus $Ag/AgClO_4$. The one-electron-oxidation potential decreases progressively with an increase in the number of porphyrin units. Unfortunately, the electrochemical reduction of these molecules, which is expected to occur at easily accessible potentials, has not been investigated. Most unexpectedly, in spite of such low oxidation potentials the molecules are claimed to be air-stable, and prospective applications in near-IR and IR sensors, and conducting molecular wires, were suggested.

$\mathbf{1}_n$

Another way to attain a small HLG is to couple electron-donor (high HOMO) and electron-acceptor (low LU-

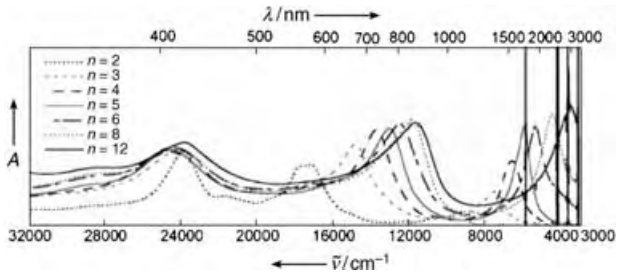

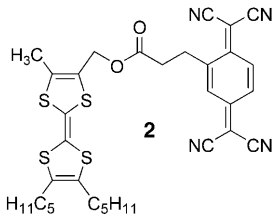

Figure 1. Electronic absorption spectra of porphyrin ribbons **1** with different numbers of units ($n = 2$–12).[9b]

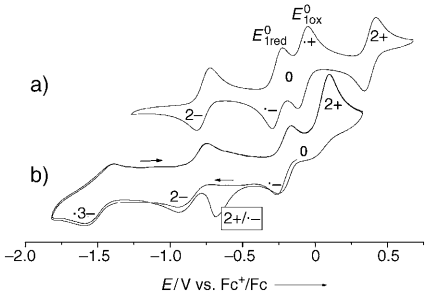
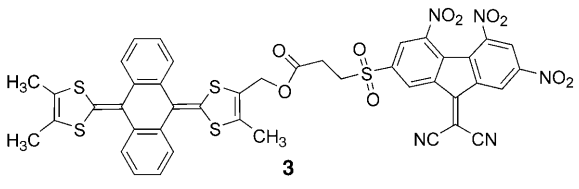
MO) fragments in a single molecule. A significant difference between the previously described conjugated systems (which generally fit within a broader concept of small-band-gap materials) and the covalent donor–acceptor molecules is that different location of the HOMO and LUMO orbitals hinders the electron transition between them. Thus, a donor–acceptor molecule with zero HLG is not expected to show metallic (non-activated) conductivity, although this limited HOMO–LUMO interaction may be attractive for other applications. The first interest in such systems was presented in a famous proposal by Aviram and Ratner where a hypothetical TTF-σ-TCNQ molecule (TTF = tetrathiafulvalene; TCNQ = tetracyanoquinodimethane) with an HLG of 0.3 eV was predicted to act as a unimolecular rectifier.[10] Since then, this type of molecule has been a target for many research groups, although the challenge of preparing such a highly electrochemically amphoteric molecule was only overcome recently. Thus, the reaction of a TTF lithium alcoholate and a TCNQ acid chloride at −100 °C favored covalent coupling (i.e. ester formation) over electron-transfer processes, and the TTF–TCNQ diad **2** was prepared in

analytically pure form.[11,12] Two reversible oxidations and two reversible reductions in cyclic voltammetry (CV) experiments are characteristic of the TTF and TCNQ moieties, respectively, and the difference between the E^0_{1ox} and E^0_{1red} values suggests an HLG of only 0.17 eV (Figure 2a). Such a low barrier allowed the first observation of a thermo-excited electron-transfer in an organic molecule. Indeed, the solution ESR signal of **2** increases at higher temperatures (approximately 1% of the molecules are in a biradical form $TTF^{\bullet+}$-σ-$TCNQ^{\bullet-}$ at room temperature).





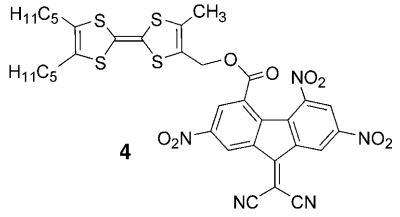


Figure 2. a) Amphoteric multiredox behavior of **2** in CV experiments; b) generation of a charge separated state $2+/^{\bullet-}$ of **3** in CV experiments at −15 °C; Fc = $[(\eta\text{-}C_5H_5)_2Fe]$.

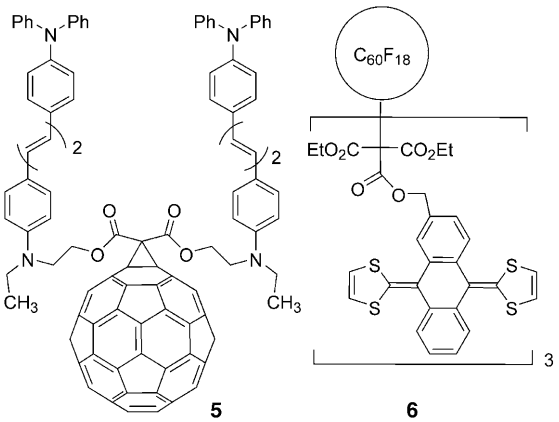
Other novel electron-transfer phenomena are likely to arise in small-HLG molecules. Combining a π-extended TTF donor (TTFAQ) with a polynitrofluorene acceptor affords the diad **3**, in

which the small gap between the oxidation and reduction, combined with quasi-reversibility of the TTFAQ oxidation (that is, re-reduction of $TTFAQ^{2+}$ required a lower potential than the initial oxidation) result in a remarkable property:[13] When the potential was initially scanned in the positive region (forming the dication) and then reversed, the reduction peak (arising to formation of the fluorenone radical anion) preceded the re-reduction of the TTFAQ dication to the neutral species (Figure 2b). Consequently, a most unusual charge-separated state of **3**, D^{2+}-σ-$A^{\bullet-}$, was formed (D = donor, A = acceptor).[13]



A molecular electronics application of TTF-based donor–acceptor diads with small HLG was recently demonstrated for the TTF–fluorene diad **4** (HLG 0.3 eV). When **4** was immobilized

in Langmuir–Blodgett monolayers between n-doped silicon and titanium or gold and thiol-protected mercury electrode pairs, asymmetric rectifying electrical characteristics were observed.[14] The molecular origin of the current–voltage (I–V) asymmetry was demonstrated by the alignment dependence of the rectification, which changed direction for monolayers transferred onto the electrode in opposite orientations (X and Z deposition).

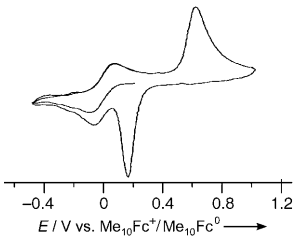
Buckminsterfullerene is another prominent example of an electron-acceptor molecule, although its reduction potential (−1.06 V versus Fc/Fc^+) is too low to attain a gap of less than around 1 eV in diads with air-stable electron donors (donors with an oxidation potential less than approximately −0.1…−0.2 V vs. Fc/Fc^+ are usually doped when exposed to air). Numerous donor–C_{60} diads with gaps of 1–2 eV have been synthesized and used for fundamental studies of photoinduced electron-transfer processes, and as photovoltaic materials.[12,15] A fullerene–arylamine based D–A compound **5** with an electrochemical gap of about 1 eV was recently exploited as a

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

5 6

unimolecular rectifier.[16] The junctions prepared with Langmuir–Schaefer (horizontal transfer) monolayers sandwiched between two gold electrodes were found to be very robust up to ±5 V and reveal a rectification of approximately 16:1 at high biases (with a symmetric *I–V* behavior at lower voltage). Interestingly, the rectification direction is the same as found in other D-σ-A molecules (**4**), but opposite to that revealed by D-π-A molecules.

The HLG in fullerene systems can, however, be pushed below 1 eV by employing fluorinated C_{60} derivatives which are much stronger acceptors. Thus, the cyclic voltammetry of TTFAQ–$C_{60}F_{18}$ compound **6** (Figure 3) demonstrates high electrochemical amphotericity, with a reversible reduction of the fullerene moiety and a quasi-reversible two-electron oxidation of the TTFAQ moiety, with the gap between the oxidation and reduction peaks of the two-electron event being nearly 0.5 eV.[17] Time-resolved fluorescence studies suggested formation of a charge-separated state ((TTFAQ$^{\bullet+}$)-σ-($C_{60}F_{18}^{\bullet-}$)) whose low energy resulted in a very long life-time of around 1 μs.



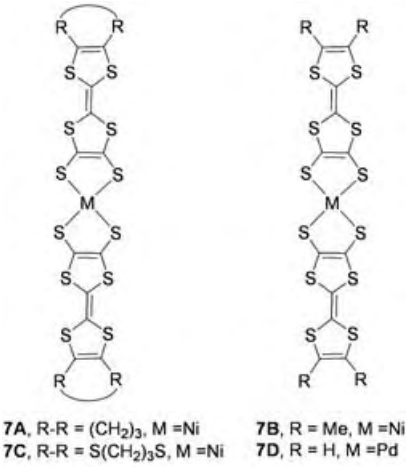


Figure 3. The cyclic voltammogram of compound **6**. Redrawn from ref. [17]; $Me_{10}Fc = [(\eta\text{-}C_5Me_5)_2Fe]$.

An approach which combines both the extended conjugation and the donor–acceptor concepts is exemplified by TTF–dithiolato metal complexes **7** (Figure 4). Based on electronic-absorption spectral bands that are shifted into the IR region, the neutral nickel complexes **7** are remarkably small-band-gap molecular solids.[18] The first electronic transition of dialkyl–TTF complexes **7A** and **7B** in the solid state occurs in the mid-IR region at $h\nu_{max} = 0.27$ eV and a nearly zero band gap can be assumed based on the absorption on-set (Figure 4). Performing band-structure calculations and fitting with the experimental spectral data, a molecular HLG of 0.14 ± 0.06 eV was predicted. Although the accuracy of the extended-Hückel calculations might be disputable, a D–A complexation in the solid state may result in increased optical gap versus the molecular HLG. Furthermore, electrochemical data for the anion of **7C** in which the difference between the first and the second oxidation potentials (0.3 V)[19] should correspond to the HLG of the neutral complexes, is also lower than the optical gap ($h\nu_{max}$) of the solid complex **7C** (0.58 eV).[18]

7A, R-R = $(CH_2)_3$, M =Ni **7B**, R = Me, M =Ni
7C, R-R = $S(CH_2)_3S$, M =Ni **7D**, R = H, M =Pd

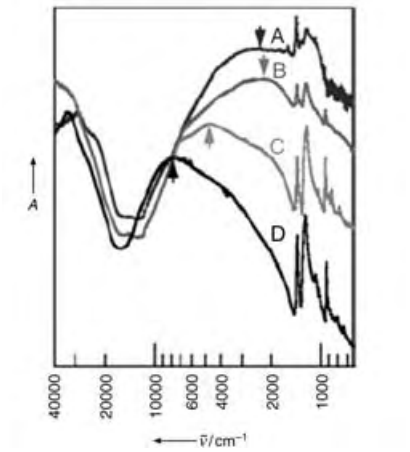

Figure 4. Electronic absorption spectra of TTF–M complexes **7A**–**D**.[18]

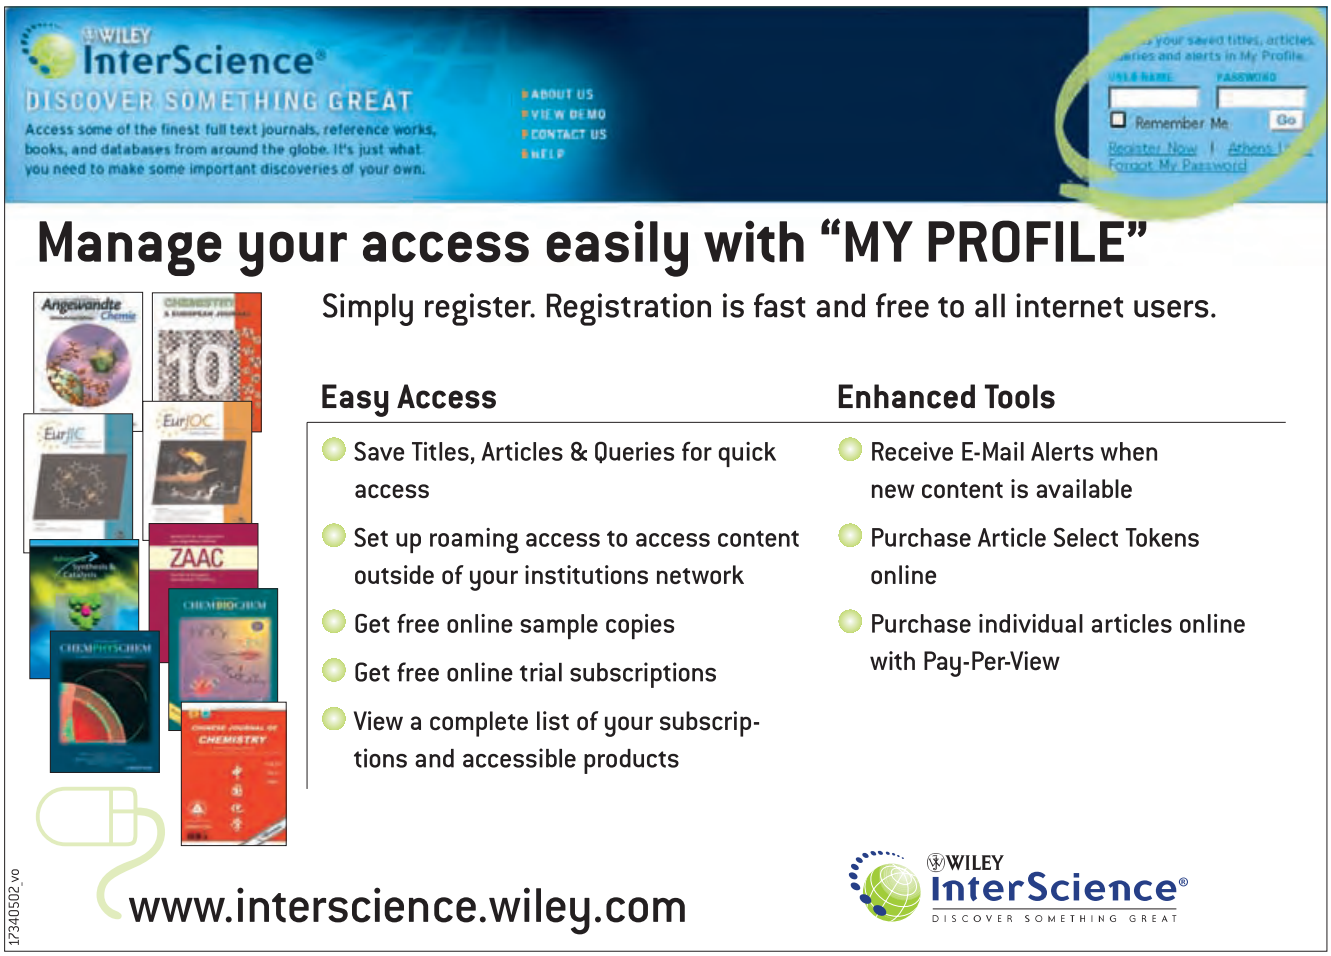
In contrast to small-band-gap polymers, where intrinsic conductivity was envisaged but has never been observed, the TTF–metal complexes with exceptionally small HLGs are single-component molecular metals with high conductivity down to 0.6 K ($\sigma_{rt} = 400\ S\,cm^{-1}$ for **7A**, $350\ S\,cm^{-1}$ for **7B**).[20] Notably, the higher HLG for the complexes **7C** and **7D** (optical gaps of 0.58 and 0.97 eV, respectively) results in semiconducting properties ($\sigma_{rt} = 7\ S\,cm^{-1}$ and $0.5\ S\,cm^{-1}$, respectively).[18]



Thus, in the recent years molecules with exceptionally small (< 0.5 eV) HOMO–LUMO gaps have become synthetically achievable targets. A variety of unusual optoelectronic properties and electron-transfer phenomena have already been demonstrated for these compounds, making them as very desirable targets for further physical studies and electronics applications.

Fullerene Chemistry

Hydrogen-Bonding Motifs in Fullerene Chemistry

Luis Sánchez, Nazario Martín, and Dirk M. Guldi**

Keywords:
fullerenes · hydrogen bonds · molecular devices · self-assembly · supramolecular chemistry

In memory of Juan C. del Amo

The combination of fullerenes and hydrogen-bonding motifs is a new interdisciplinary field in which weak intermolecular forces allow modulation of one-, two-, and three-dimensional fullerene-based architectures and control of their function. This Minireview aims to extend the scope of fullerene chemistry to a truly supramolecular level from which unprecedented architectures may evolve. It is shown that electronic communication in C_{60}-based hydrogen-bonded donor–acceptor ensembles is at least as strong as that found in covalently connected systems and that hydrogen-bonding fullerene chemistry is a versatile concept for the construction of functional ensembles.

1. Introduction

In Nature, both covalently and noncovalently bound motifs are widely spread organization principles that regulate the size, shape, and function of all living species on a molecular (nano-) scale. One of the most fascinating and cited examples is double-stranded DNA. In this biopolymeric dimer, cooperativity between noncovalent interactions—involving multiple hydrogen bonds—and hydrophobic interactions generates exceptionally stable architectures. Nature thus provides inspiration for the design of organized structures that perform specific functions.

To engineer multimolecular arrays of nanometer dimensions, a wealth of noncovalent interactions are at our disposal. These comprise ion–ion, ion–dipole, hydrogen-bond, dipole–dipole, and π–π-stacking interactions. Typically, their binding energies range from a few $kJ\,mol^{-1}$ up to several hundred $kJ\,mol^{-1}$.[1] Among these interactions, hydrogen bonding has emerged as the most useful, with binding energies between 4 and 120 $kJ\,mol^{-1}$. The specificity of hydrogen bonding and its high degree of directionality attracts a lot of attention, as it is responsible for governing many three-dimensional structures in chemical and biological systems.[2]

One approach to overcome the poor stability of single hydrogen bonds relies on arrays of multiple hydrogen bonds. Alternatively, high values of binding constants have been obtained by combining hydrogen bonds with additional supramolecular interactions such as hydrophobic or electrostatic forces. In this Minireview, we survey some of the most relevant hydrogen-bonding arrays that are known, as well as those few examples in which hydrogen bonds are combined with other noncovalent interactions, such as complementary guanidinium– or amidinium–carboxylate bridges (Figure 1a and b, respectively).[3] Association constants (K_a) of around $10\,M^{-1}$ are observed in $CHCl_3$ for the simplest donor–acceptor (DA) arrays that are built upon one donor (D) and one acceptor (A) site. Triple hydrogen-bonding motifs (e.g. DAD, see Figure 1c), as pioneered and tested by Whitesides et al.,[4] Zimmerman and Corbin,[5] and Meijer and co-workers,[6] reveal K_a values as large as 10^2–$10^3\,M^{-1}$($CHCl_3$). Even higher association constants of $K_a \approx 10^5\,M^{-1}$ ($CHCl_3$) are observed in self-complementary quadruple hydrogen-bonding motifs (e.g. DADA) as shown in Figure 1d.[7] If, however, association constants greater than $10^7\,M^{-1}$ ($CHCl_3$) are to be realized, self-complementary DDAA motifs become necessary. Meijer and co-workers[8a] demonstrated the unusual binding strength of a DDAA motif with 2-ureido-4-pyrimidinones (Figure 1e).

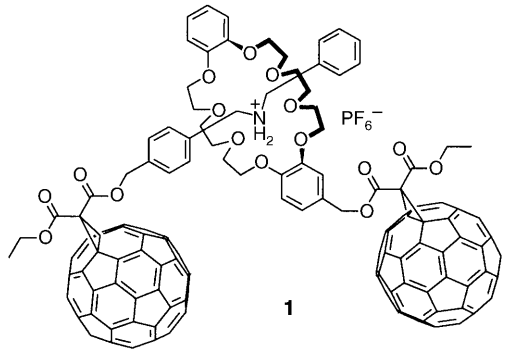
Despite the importance of hydrogen-bonding motifs for the design of supramolecular architectures, their application to fullerenes has only recently been reported. This Minireview has three principle aims: 1) to extend the scope of fullerene chemistry to a truly supramolecular level from which unprecedented architectures evolve, 2) to show that electronic communication in C_{60}-based donor–acceptor ensembles that are connected through hydrogen bonds is at least as strong as that found in covalently connected systems, and 3) to highlight fullerene hydrogen-bonding chemistry as a versatile concept to construct functional ensembles such as molecular machines and optoelectronic devices.

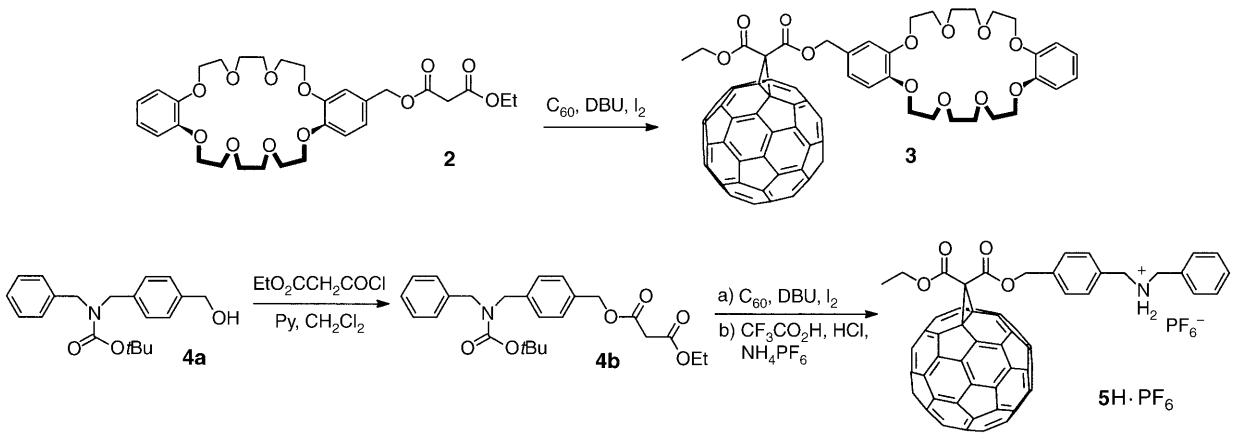
Luis Sánchez received his PhD in organic chemistry in 1997 from the Universidad Complutense de Madrid (UCM; Spain). In 1998 he joined the faculty at the Department of Organic Chemistry at UCM and was promoted to Associate Professor in 2002. During 1999–2000 he was a postdoctoral researcher with Prof. Jan C. Hummelen (University of Groningen, The Netherlands) and worked on the synthesis of C_{60} derivatives and their application in the preparation of organic solar cells. His current research interests are focused on new supramolecular C_{60}-based ensembles in the study of electron-transfer processes and photovoltaic applications.



Nazario Martín received his PhD from the Department of Organic Chemistry at the Universidad Complutense de Madrid (Spain) in 1984. After a year in industry, he worked as a postdoctoral fellow (1987–1988) with Prof. M. Hanack at the Institut für Organische Chemie der Universität Tübingen (Germany) on electrically conducting organic materials. Since 1989 he has been Professor of Organic Chemistry at UCM. His research interests focus on electroactive molecules, with emphasis on the covalent and supramolecular chemistry of fullerenes, electron-donor tetrathiafulvalenes, and p-conjugated systems in the context of electron-transfer processes and photovoltaic applications.

Dirk M. Guldi studied chemistry at the University of Cologne (Germany) and received his PhD in 1990. He then carried out postdoctoral research at the National Institute of Standards and Technology (Gaithersburg, USA) and at the Hahn-Meitner-Institute, Berlin, and he joined the faculty at the Notre Dame Radiation Laboratory in 1995. He completed his Habilitation at the University of Leipzig in 1999, and since 2004 he is Professor of Physical Chemistry at the Friedrich-Alexander University in Erlangen. His primary research interests include new multifunctional carbon-based nanostructures within the context of light-induced charge separation and solar-energy conversion.

2. Hydrogen-Bonded Fullerene Ensembles



In 1999, Diederich et al. reported the dimer **1** (K_a = 970 M^{-1} in $CHCl_3$).[9] In this ensemble, N$^+$–H···O and C–H···O hydrogen bonds together with contributions from ion-pairing and dispersive interactions are the driving forces for noncovalent, pseudorotaxane-like geometries. On the way to supramolecular dimer **1**, Bingel reactions were carried out between C_{60} and malonate-appended crown **2** and dibenzylamido malonate **4b**, respectively, to afford the methanofullerene **3** and the precursor to **5**H·PF_6 (see Scheme 1). Consecutive deprotection (CF_3CO_2H/CH_2Cl_2), protonation (HCl), and ion exchange (NH_4PF_6/H_2O/acetone) led finally to **5**H·PF_6.

Highly stable hydrogen-bonded fullerene dimers **9** and **12** were prepared through self-complementary 2-ureido-4-pyrimidinone (UP) moieties (Scheme 2). The first step in the preparation of **9** was the 1,3-dipolar cycloaddition of the anion of *p*-tosylhydrazone **6** to C_{60}. Photoisomerization of the formed fulleroid quantitatively yielded methanofullerene **7a**, which was transformed into the acyl azide **7d** through routine chemistry. The final step involved heating of **7d** in the

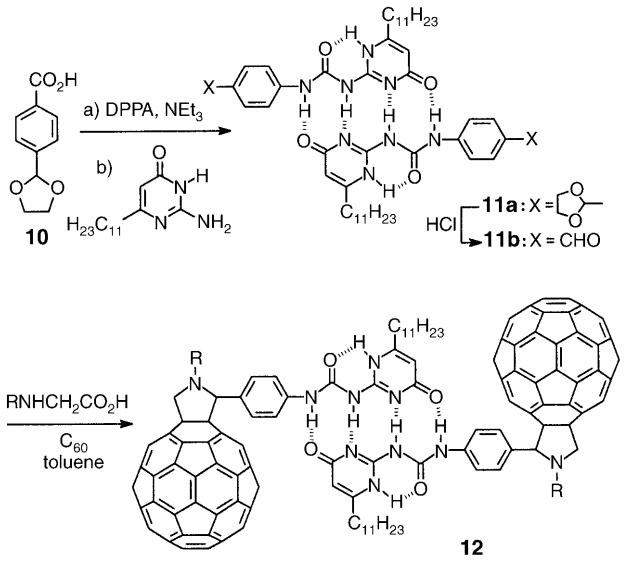
Scheme 1. Synthesis of precursors for noncovalently linked C_{60} dimer **1**. DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene; Py = pyridine.

presence of 6-methylisocytosine (**8a**) to afford the monomeric unit of **9** in 71% yield (Scheme 2).[10]

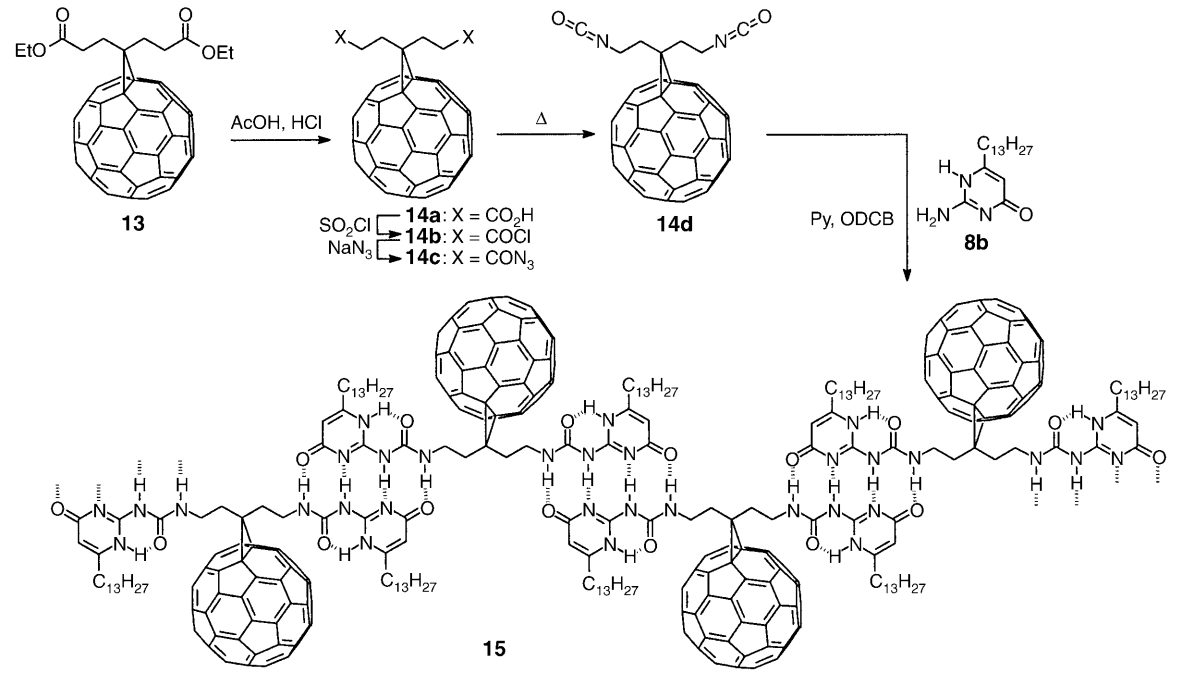


The key step in the synthesis of **12** was the reaction between C_{60} and a bisazomethine ylide generated in situ from dialdehyde **11b** (Scheme 3).[11] Electrochemical studies of **9** and **12** in the ground states confirmed the absence of

Scheme 2. Synthesis of supramolecular C_{60} dimer **9**. Ts = *p*-toluenesulfonyl; ODCB = *o*-dichlorobenzene.

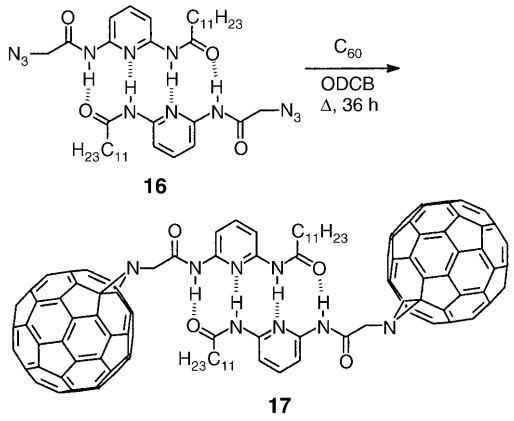
interactions between the C_{60} units. However, differences were seen when the reactivity of the monomers and dimers in their excited states were studied.[11] Specifically, the photophysical findings pointed to strong electronic coupling between the C_{60} termini, mediated through the hydrogen-bonding edges.

Sánchez, Rispens, and Hummelen reported soon afterwards the synthesis of the supramolecular C_{60} polymer **15**[12] from the C_{60}-diester derivative **13** (Scheme 4). The dynamic behavior of **15** was investigated by ^{1}H NMR spectroscopy. At



Scheme 3. Synthesis of supramolecular C_{60} dimer **12**. DPPA = diphenylphosphoryl azide; $R = CH_3(OCH_2CH_2)_3$.

low concentrations (10 mM) different sets of multiple signals were observed. A likely rationale infers the presence of polymeric and low-molecular-weight cyclic aggregates, as has been proposed for related systems.[13] A fairly high association constant, $K_a = 6 \times 10^7\,M^{-1}$, was determined for polymer **15** in chloroform.[14] The electrochemical behavior of polymer **15** was virtually identical to that of the analogous dimer **9**, and neither **9** nor **15** exhibit notable interactions between the fullerenes.



In line with the DADA concept, 2,6-bis(acylamino)pyridines were probed to integrate two aziridinofullerenes into the supramolecular C_{60} dimer **17**.[15] This dimer was prepared through 1,3-dipolar cycloaddition of the corresponding hydrogen-bonded azide **16** to C_{60} (Scheme 5). Interestingly, when dilute solutions of **17** were analyzed by scanning electron microscopy (SEM), spherical nanoparticles with diameters of typically around 15 nm were observed which resulted from aggregation.

Bassani and co-workers characterized a variety of supramolecular ensembles resulting from the reaction of fullerene-

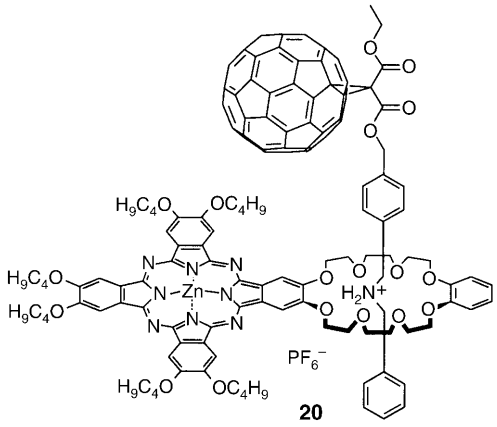
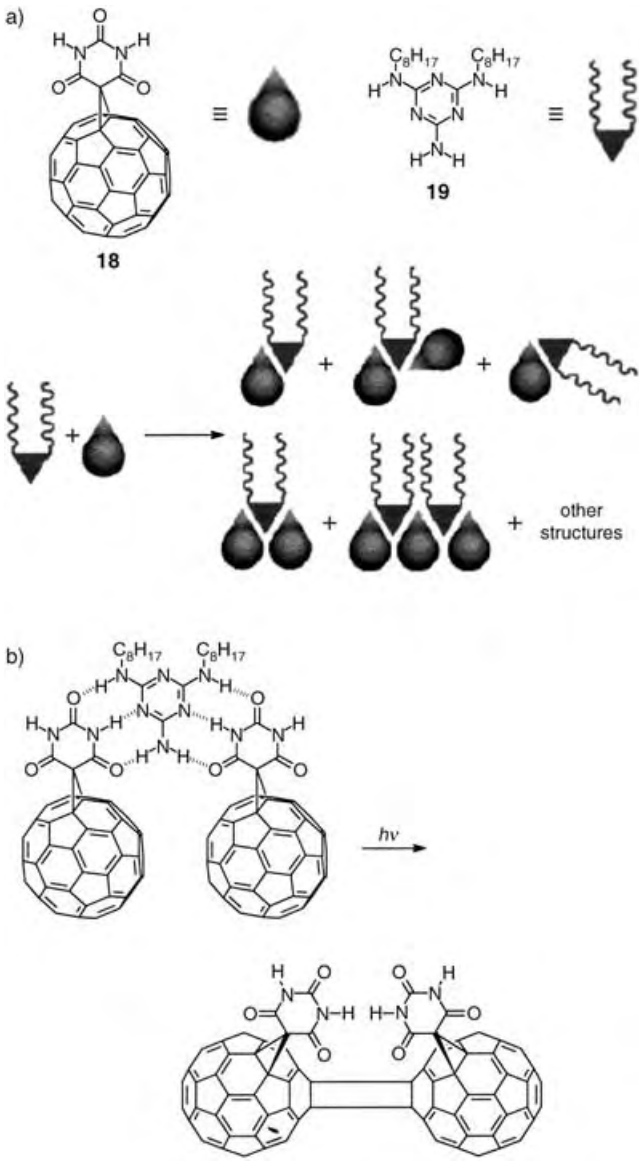
Scheme 5. Synthesis of DADA hydrogen-bonded C_{60}-based dimer **17**.



barbituric acid **18** and the melamine derivative triaminotriazine **19**.[16] Scheme 6, part a, shows several of the resulting architectures obtained. An interesting feature of [60]fullerenes is their susceptibility to undergo topologically controlled [2+2] photocycloaddition reactions. The resulting structures are similar to that obtained through the intermolecular photodimerization of the 1:2 complex formed from melamine template **19** and two molecules of **18** (Scheme 6, part b). Bassani's supramolecular approach represents the first instance of intermolecular photodimerization of a fullerene derivative in solution and an interesting example of supramolecular catalysis.

The above cases outline the structural sophistication obtained by combining noncovalent interactions with the covalent chemistry of fullerenes. The integration of hydrogen bonds has led to new supramolecular fullerene architectures that range from dimers to polymers.



3. Hydrogen-Bonding C_{60}–Donor Ensembles

Given the importance of natural photosynthetic processes, the quest for simple models with focus on primary photosynthesis events is one of the most intriguing tasks in chemistry. In this regard, C_{60} is an excellent candidate for the preparation of photo- and redox-active model systems.

In electron-donor/electron-acceptor ensembles, light excitation typically forces a thermodynamically driven charge-separation (CS) process.[17] In the case of C_{60}, the lifetimes of such charge-separated radical-ion pairs lie between picoseconds and seconds. In the past, most of these donor–acceptor ensembles were covalently linked[18] and much less attention was given to hydrogen-bonded model systems.[19] Only recently did the first examples appear in which C_{60} is linked to an electron-donor unit through a hydrogen-bonding network. Pseudorotaxane-like molecular recognition motifs that lead to fullerene–(zinc phthalocyanine) (C_{60}-ZnPc) ensembles **20** were reported by Guldi, Torres, Prato, and co-

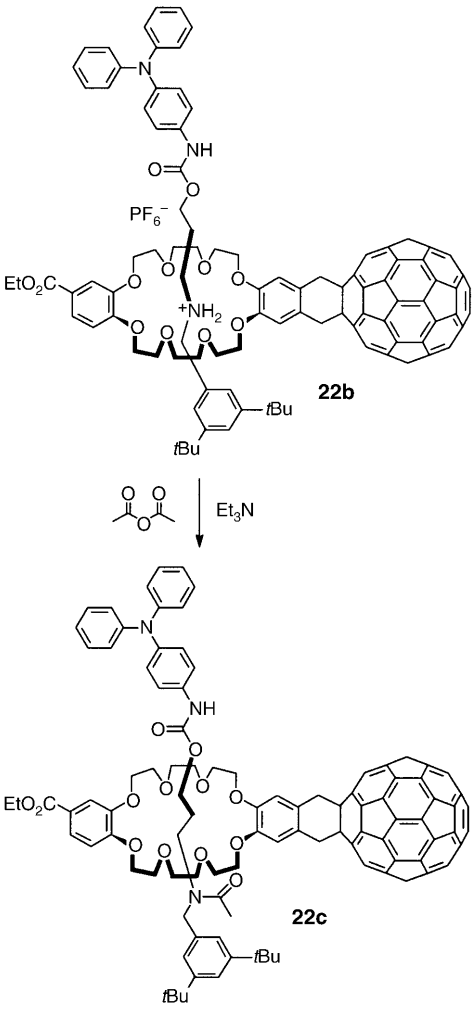
workers.[20] Charge-separated states (i.e. $C_{60}^{\bullet-} \cdot ZnPc^{\bullet+}$) with lifetimes of microseconds evolved from an efficient intracomplex electron-transfer process that started from the excited state of the ZnPc fragment. For the sake of comparison, a similar but covalently linked C_{60}-ZnPc dyad that exhibits lifetimes for the radical-ion pair of only 3 ns has been reported.[21]

Although numerous examples of porphyrin (P)-linked donor–acceptor systems are known,[22] including several that comprise C_{60} as an acceptor, no hydrogen-bonded fullerene–porphyrin (C_{60}-P) model systems were reported until recently. One such example was the rotaxane C_{60}-ZnP dyad **21** prepared by Takata, Ito, and co-workers.[23] Whereas **21** displays a lifetime of 180 ns for its radical-ion pair, covalently



linked C_{60}-P dyads exhibit a longer lifetime of 770 ns.[24] Takata and co-workers have also synthesized new rotaxanes **22**, in which the [60]fullerene moiety makes up either the axle (**22a**)[25a] or the wheel (**22b**,**c**, Scheme 7)[25b] of the supra-

molecular structure. An attractive interaction between the two chromophores in **22a**, that is, C_{60} and ZnP, has been established. The consequence of this favorable interaction is noted through the acceleration of the end-capping process, which thus enhances its overall efficiency. Ensembles **22b**,**c**, which bear triphenylamine (TPA) electron-donor units, showed that noncovalent interactions can be modulated through the positive charge that is placed at the nitrogen atom in the middle of the axle (**22b**, Scheme 7). Acylation of the positively charged amine in **22b** to furnish the neutral amide group in **22c** evoked a shift of the axle with respect to the C_{60} wheel. In **22b**,**c** a through-space, intrarotaxane, photoinduced electron-transfer process gives rise to a long-lived CS state, $C_{60}^{\bullet-} \cdot TPA^{\bullet+}$, whose lifetimes range between 170 and 300 ns. Interestingly, the lifetimes of $C_{60}^{\bullet-} \cdot TPA^{\bullet+}$ in the rotaxanes appear to be longer than those measured for the corresponding covalently bound C_{60}-TPA dyad.[25b]

Highly stable supramolecular $C_{60} \cdots ZnP$ complexes **23**, held together through a two-point binding strategy, are well-defined with regards to distance and orientation.[26] Time-resolved emission and absorption studies have revealed efficient charge-separation processes, with rate constants of

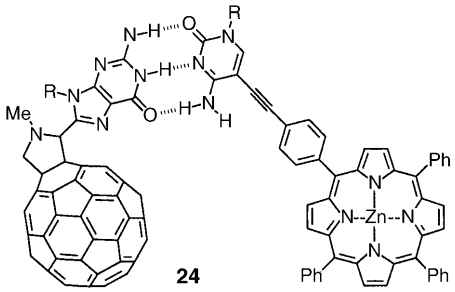
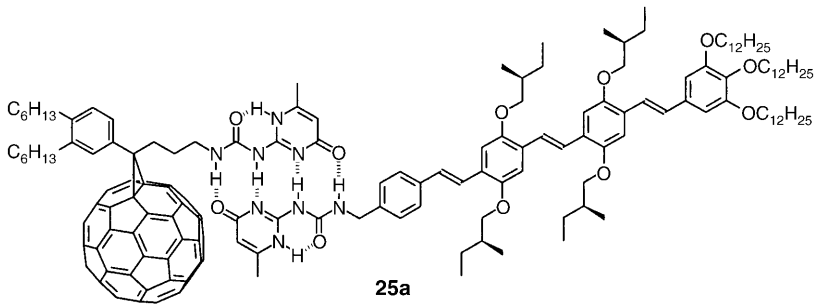
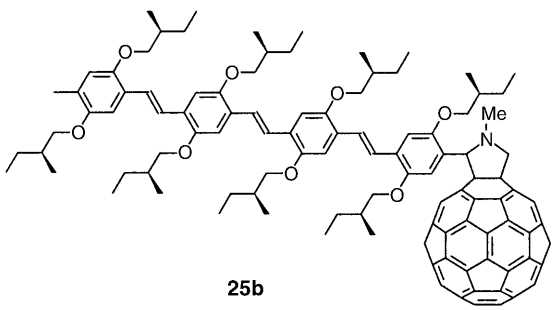


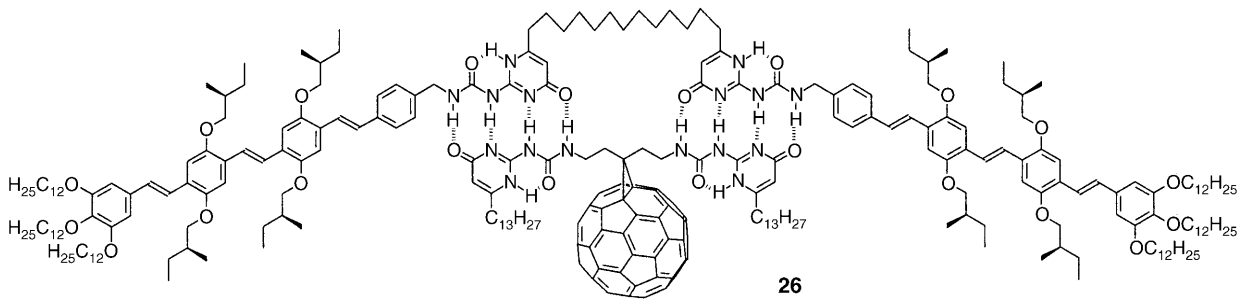
Scheme 7. C_{60}–TPA ensembles tethered by rotaxane structures.

6.3×10^7 and 3.1×10^9 s^{-1} observed for the formation of the CS states in **23a** and **23b**, respectively.



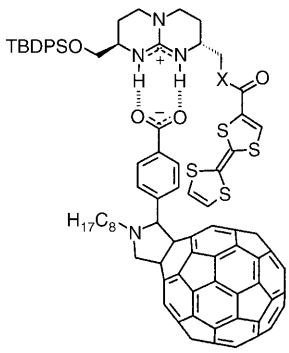
Another remarkable impact on the lifetime of the photogenerated radical-ion pair is seen when C_{60} is paired with a porphyrin moiety in the form of **24**. The lifetime of the radical-ion pair in **24**, in which C_{60} and ZnP are tethered by means of a guanosine–cytidine scaffold[27] is 2.02 μs. This value is higher than those reported for related covalently linked C_{60}-ZnP dyads[22–24] as a result of the beneficial effect of the hydrogen bonds.



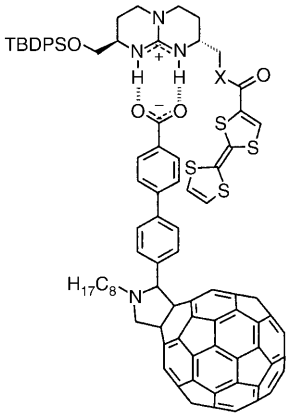


To control the organization in active layers of photovoltaic cells, **25a** is prepared by mixing **9** (Scheme 2) with an oligophenylene vinylene (OPV) system that bears complementary UP moieties.[28] In both **25a** and the "covalent" analogue **25b**,[29] a strong quenching of the OPV fluorescence is observed. Energy transfer from the singlet excited state of OPV to the fullerene is responsible for the quenching. In the covalently bound **25b**[29] an ultrafast electron-transfer process is followed by an intramolecular energy-transfer process, whereas this sequence does not occur in hydrogen-bonded **25a** as a consequence of the low electronic coupling between the electroactive units in **25a**.[30]

The combination of polymer **15** (Scheme 4) with OPVs functionalized with UP groups allowed the formation of heterodimers linked through quadruple hydrogen bonds. This strategy resulted in new supramolecular donor–acceptor dyads.[31] Remarkably, in contrast to previous examples in which the self-complementary nature of such hydrogen-bonding motifs led to a statistical mixture of homo- and heterodimers, dyad **26** represents the first example of



© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



26

preferential formation of functional supramolecular heterodimers linked by UP moieties.

Recently, in collaboration with Mendoza's group we reported a series of hydrogen-bonded C_{60}·TTF ensembles, **27a–d** (TTF = tetrathiafulvalene, TBDPS = *tert*-butyldiphenylsilyl),[32] in which the tetrathiafulvalenes act as electron donors.[33] In these cases, the photoactive units are held together not only through complementary hydrogen bonds but also by strong electrostatic interactions through guanidinium and carboxylate ion pairs. To tune the molecular architecture, two chemical spacers of different lengths (phenyl versus biphenyl) as well as two functional groups (ester and amide) were used. The solvent-dependent nature of the fluorescence quenching in C_{60}·TTF dyads as well as the formation of the $C_{60}^{\bullet-}$·$TTF^{\bullet+}$ radical-ion pairs, together with the flexible nature of the spacer, reflect through-space electron-transfer processes. The lifetimes measured for the radical-ion pair states are in the range of hundred of nanoseconds, thus several orders of magnitude higher than those reported for covalently linked C_{60}-TTF dyads.[34]

4. Applications of Hydrogen-Bonded Supramolecular Fullerene Complexes

π-Conjugated oligomers/polymers as well as C_{60} are widely used as building blocks for optoelectronic devices such as light-emitting diodes (LEDs)[35] and organic solar cells.[36] In 2001, Meijer and co-workers reported hydrogen-bonded polymers that comprised oligo(*p*-phenylenevinylene) (PPV) moieties connected through multiple self-complementary fourfold hydrogen-bonding motifs.[37] A photovoltaic device was prepared by mixing this supramolecular polymer with a methanofullerene derivative, and the ensemble was successfully used in the preparation of bulk heterojunction organic solar cells.[36]

Li, Zhu, and co-workers presented a three-point hydrogen-bonding assembly between C_{60} and a π-conjugated PPV polymer (**28**·**29**).[38] In this particular case the noncovalent linkage was established between the uracil moiety, bound to polymer **28**, and 2,6-diacylamidopyridine **29**, linked to C_{60}. Fluorescence experiments revealed a strong interaction between PPV and C_{60}.

28 · 29

Perylene bisimides (PERYs) are another important class of materials for solar cells. The main features of PERYs include good electron-acceptor capabilities and good light absorption in the visible region. Both features are essential to guarantee good conversion efficiencies.[39] Diaminopyridine–C_{60} **29** has been used together with the tetraalkoxy-PERY system **30** (Figure 2a).[40] Irradiation of (**29**)$_2$·**30** films on indium tin oxide (ITO) electrodes with white light (63.2 mW cm^{-2}) generates a steady, rapid, and highly stable anodic photocurrent response. Importantly, the response to on/off cycling is prompt and reproducible (Figure 2b).

5. Summary and Outlook

In summary, the synthesis and applications of multiply hydrogen-bonded C_{60} derivatives have been reviewed here.

Implementing the chemistry of fullerene into supramolecular chemistry has led to original examples of molecular organization that might find application in promising fields such as molecular materials or supramolecular catalysis. Supramolecular chemistry of fullerenes is a thriving field that should furnish future avenues for the integration of C_{60} as an outstanding photo- and electroactive building block in nanoscience and nanotechnology.

This work was supported by the MCYT of Spain, Comunidad de Madrid (Projects BQU2002-00855 and HSE/MAT0633-04). The US Department of Energy Basic Energy Sciences (NDRL 4613 from the Notre Dame Radiation Laboratory) is also acknowledged.

A rotationally hindered and thus stereogenic biaryl axis is the structurally and stereochemically decisive element of a steadily growing number of natural products, chiral auxiliaries, and catalysts. Thus, it is not surprising that significant advances have been made in the asymmetric synthesis of axially chiral biaryl compounds over the past decade. In addition to the classic approach (direct stereoselective aryl–aryl coupling), innovative concepts have been developed in which the asymmetric information is introduced into a preformed, but achiral—that is, symmetric or configurationally labile—biaryl compound, or in which an aryl–C single bond is stereoselectively transformed into an axis. This Review classifies these strategies according to their underlying concepts and critically evaluates their scope and limitations with reference to selected model reactions and applications. Furthermore, the preconditions required for the existence of axial chirality in biaryl compounds are discussed.

1. Introduction

Since the first resolution of tartaric acid by Louis Pasteur in 1848,[1] the stereoselective synthesis of compounds containing one or more stereogenic centers has emerged as one of the most important fields in chemistry. Numerous excellent diastereo- and enantioselective procedures have been developed which belong nowadays to the standard repertoire of synthetic chemistry.[2] Axial chirality, by contrast, as a stereogenic element in rotationally hindered biaryl compounds of natural and synthetic origin, has often been overlooked or treated as an "academic curiosity".[3] This, however, has changed with the recognition that the configuration at a biaryl axis can be a decisive factor in governing the pharmacological properties of a bioactive compound[4] and that axial chirality is the fundamental basis for useful reagents and catalysts in asymmetric synthesis.[5]

Natural products equipped with a rotationally hindered biaryl axis are far more widespread and structurally diverse than initially assumed.[4] Many representatives of this class of axially chiral metabolites exhibit remarkable bioactivities, like the famous antibiotic heptapeptide vancomycin (**1**, Figure 1).[6,7] This molecule contains three types of stereoelements—numerous stereogenic centers, two "chiral" planes, and a stereogenic biaryl axis, which together impose the rigid 3D structure necessary for an efficient binding to peptides of bacterial cell walls.[6] Knipholone[8] (**2**) possesses solely axial chirality and occurs with varying degrees of enantiomeric purity in nature;[9] compounds of this family of 1-phenylanthraquinones have recently been shown to exhibit good antimalarial[10] and antitumor[11] activities, the latter particularly when *M* configured. Mastigophorene A (**3**), a C_2-symmetric bisphenol bearing additional stereogenic centers, has been found to stimulate nerve growth.[12] The class of axially chiral natural products is, however, not restricted to C–C-coupled biaryl compounds. (*M*)-Murrastifoline-F ((*M*)-**4**), for example, is a biscarbazole with the two—otherwise identical—"halves" connected by a heterobiaryl C–N bond.[13]

Axially chiral biarylic auxiliaries and catalysts exhibit excellent chirality transfer properties.[5] A prime example is the diphosphine binap (**5**, Figure 2),[14] which is the ligand of choice in Ru-catalyzed asymmetric hydrogenations of C=C and C=O bonds.[15] The more complex epoxidation catalyst **6** possesses two axially chiral binaphthyl subunits embedded in a sterically demanding backbone.[16] More recently, attention has been focussed on non-C_2-symmetric biaryl compounds such as the tertiary aminophenol **7**, which catalyzes the enantioselective addition of diethylzinc to aldehydes.[17] The isoquinoline-containing phosphine quinap (**8**) is an example of an axially chiral heteroaromatic biaryl; it has been used as a ligand in Pd-catalyzed asymmetric allylic alkylation reactions.[18]

Owing to the importance of axially chiral biaryl compounds, a variety of excellent methods for their directed, atroposelective construction have been developed. Herein, we present an overview of the most efficient and practicable methods presently known for the atroposelective synthesis of axially chiral biaryl compounds.[19–24] Major consideration is

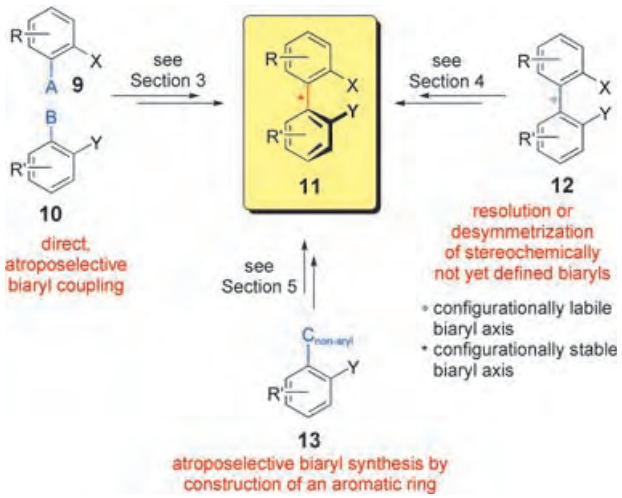
given to the different fundamental strategies elaborated: their conceptual classification, the stereochemical principles that govern the asymmetric induction at the axis, their applicability, and their limitations.

As the phenomenon of axial chirality relies on the rotational stability of an aryl–aryl single bond, important preconditions for this stability, as well as the different mechanisms of atropisomerization, are discussed in Section 2. As outlined in Scheme 1, three fundamentally different strategies have, to date, been realized for the atroposelective synthesis of axially chiral biaryl compounds. The classic concept, which is discussed in Section 3, involves biaryl formation in a single step by C–C coupling, with the two aromatic portions being joined with simultaneous asymmetric induction (**9** + **10**→**11**).[19,22,23] The second approach, by contrast, relies on the atroposelective transformation of an existing, but stereochemically not yet defined, biaryl system (Section 4).[20,21] Within this two-step approach, a nonstereoselective coupling step thus precedes the introduction of the stereochemical information at the axis (**12**→**11**). Finally, Section 5 summarizes the few known methods in which a C–C bond between an arene and a precursor substituent is transformed into a chiral biaryl axis by construction of an

Gerhard Bringmann studied chemistry in Giessen and Münster (Germany) and received his PhD with Prof. B. Franck in 1978. After postdoctoral studies with Prof. Sir Derek H. R. Barton in Gif-sur-Yvette (France), and his habilitation in 1984 at the University of Münster. He became a full professor of Organic Chemistry at the University of Würzburg in 1987. In 1998 he declined an offer of the position of a director at the Leibniz Institute of Plant Biochemistry in Halle. His research interests lie in the field of analytical, synthetic, and computational natural products chemistry.

Paul Keller completed his BSc (Hons) (1985) and PhD (1991) at the University of New South Wales (Australia), before taking up an Alexander von Humboldt funded postdoctoral fellowship in Germany. Since 1994, he has worked at the University of Wollongong, Australia, and is currently Associate Professor in Organic and Medicinal Chemistry. His interests lie in drug design and development, the development of synthetic fullerenyl chemistry, and the design and synthesis of chiral catalysts.



Anne J. Price Mortimer was born in Stoke-on-Trent (UK) in 1977. She studied chemistry at St. John's College, University of Oxford, before going on to complete a DPhil under the supervision of Prof. S. G. Davies in 2003, investigating the synthesis of β-amino acid natural products. From 2003 to 2005 she was a postdoctoral researcher in the group of Prof. G. Bringmann, developing novel methodologies for the synthesis of axially chiral biaryls, and held an Alexander von Humboldt research fellowship from 2004.

Mary J. Gresser, born in 1981, completed her BSc (Hons) at the University of Wollongong (Australia). She commenced her PhD in 2003 under the supervision of Associate Professor Paul A. Keller, investigating the synthesis of chiral ligands for palladium-based catalysis.

aromatic ring, usually with a central-to-axial chirality transfer (**13**→**11**).

2. Preconditions for Axial Chirality and Mechanisms of Atropisomerization

2.1. The Phenomenon of Axial Chirality

Optical activity due to axial chirality has been known since the early 20th century and was first correctly described by Christie and Kenner in 1922.[25] The term "atropisomerism" (from the Greek, *a* = not and *tropos* = turn) was introduced by Kuhn[26] in 1933 and originally referred solely to biaryl compounds. In general, there are two necessary preconditions for axial chirality in biaryl molecules (Figure 3):[27,28] a rotationally stable axis and the presence of

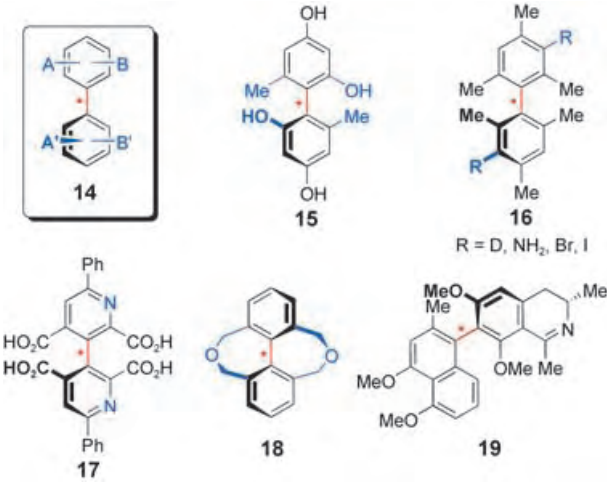

Figure 3. Selected substitution patterns that result in axial chirality.

different substituents on both sides of the axis as indicated in **14**, that is, A ≠ B and A′ ≠ B′. If A = A′ and B = B′, the molecule has C_2 symmetry (but is still chiral) as in **15**, **16**, and **17**. Surprisingly to the casual observer, even biaryl compounds with four constitutionally identical substituents may be chiral if these are connected pairwise through two bridges as in the D_2-symmetric diether **18**.[29] Axially chiral biaryl compounds that bear different *ortho* substituents, such as the dimeric orcinol (**15**),[30] are found ubiquitously (compare most of the biaryl species discussed in this article). Although less common, axial chirality may also result from an inequivalence of *meta* substituents, as found in the bimesityls **16**[31] and in the naphthylisoquinoline alkaloid ancistrocladisine (**19**).[32] Furthermore, heteroaromatic systems provide the possibility to introduce chirality merely from the position of the heteroatom, as found in the dipyridyl quateraryl **17**.[33]

The absolute axial configuration can be denoted by analysis of a Newman projection along the biaryl axis (Figure 4). After assignment of priority to the *ortho* (or *meta*) substituents according to the CIP rules,[34] the analysis is done by following the shortest 90° path from the substituent of highest priority at the proximal ring to the highest-ranking one at the distal ring (i.e. here from A to A′). If this 90° turn is counterclockwise as in **20**, the absolute configuration is *M* (for **m**inus); if it is clockwise as in *ent*-**20**, then the descriptor is *P* (for **p**lus).[35,36]

For the stereochemical assignment of pairwise enantiotopic substituents in prochiral biaryl compounds of type **21**, the arc between the substituent of interest and the substituent of highest priority on the other aryl ring is considered, giving rise to the descriptors pro-*M* and pro-*P* (see Figure 4, bottom), after the system of Hanson and Helmchen.[37,38]

The other crucial precondition for atropisomerism is the rotational stability of the biaryl axis. The temperature has a profound influence: On the one hand, even biaryl compounds

James Garner, born in 1976, studied chemistry at the University of Newcastle (Australia), before going on to complete a PhD in 2003 under the supervision of Dr Adam McCluskey, on the development of structurally unprecendented CRH_1 antagonists. He is currently a postdoctoral research fellow under the direction of Associate Professor Paul A. Keller, investigating the synthesis of 6,6′-bisindoles.

Matthias Breuning, studied chemistry at the University of Würzburg (Germany), where he completed his PhD in 1999 under Prof. G. Bringmann. After a postdoctoral stay with Prof. E. J. Corey at Harvard University (USA), he joined Bayer AG in 2001 as a senior research scientist. Since 2002 he has been working on his habilitation at the University of Würzburg, supported by an Emmy-Noether fellowship of the DFG. His main research interests lie in the field of asymmetric synthesis, in particular in the development of novel catalysts and their application in natural products synthesis.

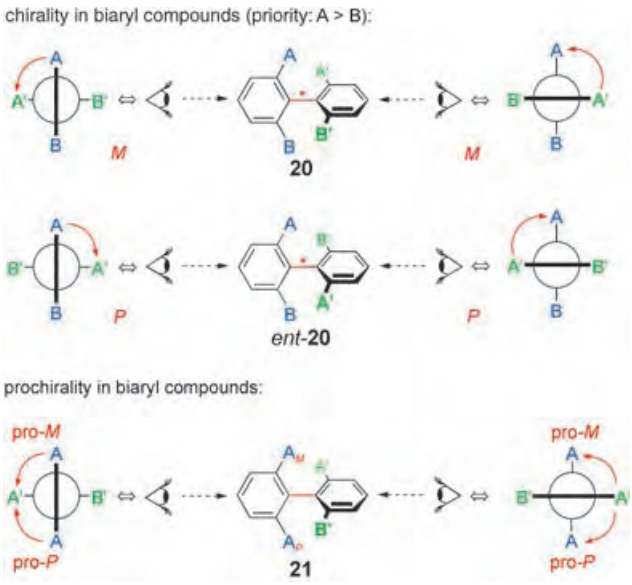

Figure 4. Assignment of absolute configuration in chiral biaryl species and descriptors for paired substituents in prochiral biaryl compounds (note that the same descriptor results, regardless of the position of the observer).[38]

with a low degree of steric hindrance will suffer impeded rotation if sufficiently cooled down,[39] and split up into atropoenantiomers or -diastereomers if unsymmetrically substituted; on the other hand, biaryl species that are axially chiral at room temperature may start to atropisomerize upon heating, resulting in thermodynamically controlled equilibrium mixtures (i.e. in a full loss of chiral information in the case of enantiomers).[40,41] As an arbitrary, but useful definition,[42] atropisomers are recognized as physically separable species when, at a given temperature, they have a half-life τ of at least 1000 s (16.7 min). Thus the minimum free energy barrier $\Delta G^{\ddagger}$ required varies with temperature (e.g. $\Delta G^{\ddagger}_{200\,K} = 61.6\ kJ\,mol^{-1}$, $\Delta G^{\ddagger}_{300\,K} = 93.5\ kJ\,mol^{-1}$, and $\Delta G^{\ddagger}_{350\,K} = 109\ kJ\,mol^{-1}$). The configurational stability of axially chiral biaryl compounds is determined by three major factors:

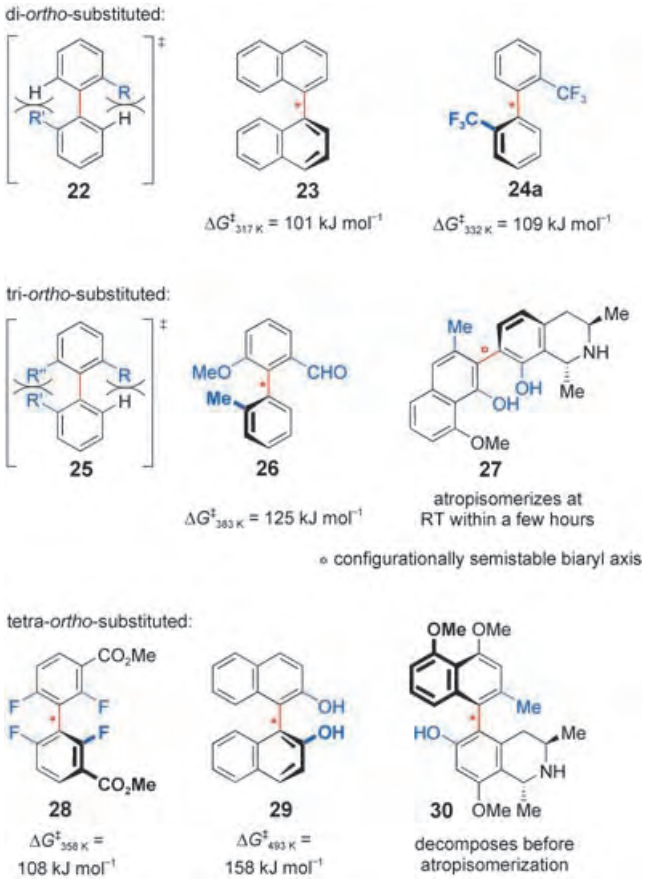
1) the (combined) steric demand of the substituents in proximity to the axis;
2) the existence, length, and rigidity of bridges; and
3) the involvement of atropisomerization mechanisms different from a merely physical rotation about the axis, for example, by photochemically or chemically induced processes.

2.2. Atropisomerization by Physical Rotation

Physical—that is, thermal—rotation about a biaryl axis has, in selected cases, been shown by quantum-chemical calculations to occur through twisted (i.e. nonplanar) transition states in which the bonds to the *ortho* substituents and the aryl rings are distorted, thus permitting the substituents to pass each other more easily than in a rigid planar transition state.[41,43–45] In many cases, the barrier to rotation can be rationalized in terms of substituent effects.

2.2.1. Effects of Nonbridging Substituents

ortho Substituents increase the atropisomerization barrier in nonbridged biaryl compounds by their steric repulsion (compare **22** and **25**, Figure 5), corresponding largely to the van der Waals radii of the substituents, that is, I > Br > Me > Cl > NO_2 > CO_2H > OMe > F > H.[46]



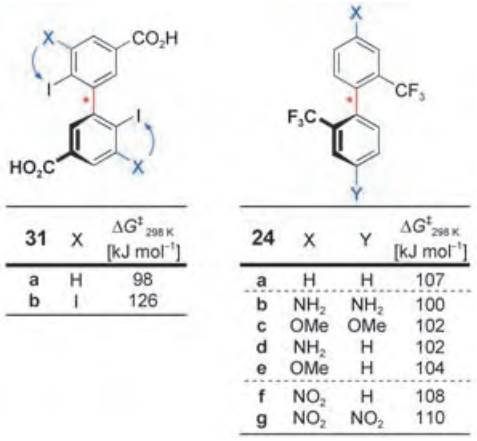


Figure 5. Configurational stability of di- to tetra-*ortho*-substituted biaryl compounds.

Open-chain (i.e. nonbridged), mono-*ortho*-substituted biaryl compounds do not form stable atropisomers at room temperature. With two substituents next to the axis, atropisomerism at room temperature is only observed if both groups are bulky, as in 1,1′-binaphthyl (**23**)[47] and in 2,2′-bis(trifluoromethyl)biphenyl (**24a**),[48] so that in the transition state **22** even the interactions of R and R′ with the small hydrogen atoms provide sufficient steric repulsion for restricted rotation.[49] As a rule, tri-*ortho*-substituted biaryl compounds form stable atropisomers; in the transition state **25**, two substituents now must pass one another for rotation to occur, rather than a substituent passing a hydrogen atom. The biphenyl **26**[50,51] is an example of such an axially chiral biaryl system. Nevertheless, sterically less demanding substituents may still permit slow axial rotation as observed with the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

naphthylisoquinoline alkaloid dioncophylline E (**27**), whose atropisomerization occurs within a few hours at room temperature.[52] Conformational stability is virtually guaranteed for tetra-*ortho*-substituted biaryl compounds, even if the substituents are all small, as in the tetrafluorobiphenyl **28** ($\Delta G^{\ddagger}_{358\,K} = 108\ kJ\,mol^{-1}$).[53] The rotational barriers can be extremely high, as in the auxiliary binol (**29**, $\Delta G^{\ddagger}_{493\,K} = 158\ kJ\,mol^{-1}$),[41] making these compounds configurationally stable even under forcing conditions; in many cases the atropisomerization temperature is so high that it cannot be reached without decomposition.[54] Ancistrocladine (**30**), as an example, can be dehydrogenated at 200 °C without loss of atropisomeric purity;[55] at higher temperatures, the molecule disintegrates.

Bulky substituents in the *meta* positions increase the configurational stability of biaryl compounds by "buttressing" the *ortho* substituents, thus preventing their bending out of the way in the transition state.[46,56,57] For example, rotation in the tetraiodobiphenyl **31b** (Figure 6) is considerably more difficult than in its diiodo analogue **31a** ($\Delta G^{\ddagger}_{298\,K} = 126\ kJ\,mol^{-1}$ vs. $\Delta G^{\ddagger}_{298\,K} = 98\ kJ\,mol^{-1}$).[56]

f	NO_2	H	108
g	NO_2	NO_2	110

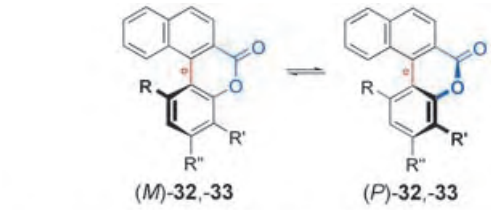

Figure 6. The effect of *meta* (left) and *para* (right) substituents on the configurational stability of biaryl compounds.

para Substituents influence the rotational barrier mainly by electronic effects,[43,57] as evidenced by the 4,4′-substituted biphenyls **24**.[57] Electron donation by resonance from the substituent at C4 increases the sp^3 character at C1, thus facilitating the out-of-plane bending at these positions. This decreases the strain in the transition state and, therefore, lowers the barrier to rotation (**24b–e**). By the same token, electron-withdrawing groups, which restrict the out-of-plane bending by decreasing the electron density at C1, raise the barrier (**24f,g**).[58]

2.2.2. *Bridged Biaryl Systems*

The effect of a bridging ring on the restricted rotation of a biaryl system varies greatly with the ring size. In systems in which two of the *ortho* substituents are replaced by a single bridging atom (i.e. a five-membered ring is formed), rotation is usually not hindered at room temperature.[59]

The presence of a six-membered bridge still considerably facilitates rotation, but to a lesser extent. A comparative study was done on the benzonaphthopyranones **32** and **33** (Figure 7), which exist as racemic mixtures of their helically

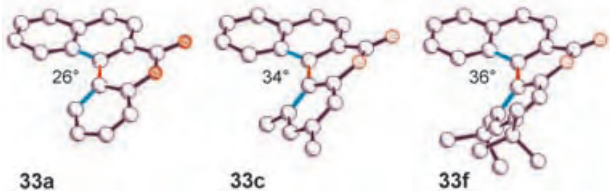

Figure 7. Atropisomerization barriers and structures of six-membered lactone-bridged biaryl compounds **32a–e** and **33a,c,f**. Note that the *M*/*P* descriptors given apply to **32a,c–e** and **33a,c,f**.[63]

distorted atropoenantiomers (*M*)- and (*P*)-**32** and -**33** (torsion angles from 26° for **33a** to 36° for **33f**).[45,60,61] $\Delta G^{\ddagger}_{298\,K}$ increases with the steric demand of the *ortho* substituent R.[62] Thus, **32a–d** (R = H, OMe, Me, Et) atropisomerize quickly at room temperature with half-lives $\tau_{298\,K} < 1$ min, whereas the lactone **32e** (R = *i*Pr) is at the brink of atropisomerism ($\tau_{298\,K} = 28$ min). The enantiomers of the largely distorted derivative **33f** (R = *t*Bu; see X-ray crystal-structure diagram, Figure 7, bottom) are configurationally stable and can be resolved by both physical and chemical methods.

Stereogenic centers in the bridge can strongly influence the—now atropodiastereomeric—equilibrium as, due to the exocyclic substituents (axial or equatorial), the bridge adopts the thermodynamically favorable conformation. In the acetal **34** (Figure 8), which has a single stereogenic center, the conformer with the methoxy group in an axial position is preferred (ax-**34**/eq-**34** = 91:9), apparently as a consequence of an *exo*-anomeric effect.[64] The atropodiastereomerization processes eq-**34**⇄ax-**34**, however, are still fast[62] and are comparable to those for the related lactone **32c** (see Figure 7). The biaryl compounds **35**[65] and **36**[66] are configurationally unstable at room temperature, and occur as 1:1 mixtures of atropodiastereomers, despite the presence of two stereogenic centers in the bridge, whereas **37**, with the dioxolane system enforcing a di-equatorial conformation, exists as a single diastereomer.[66]

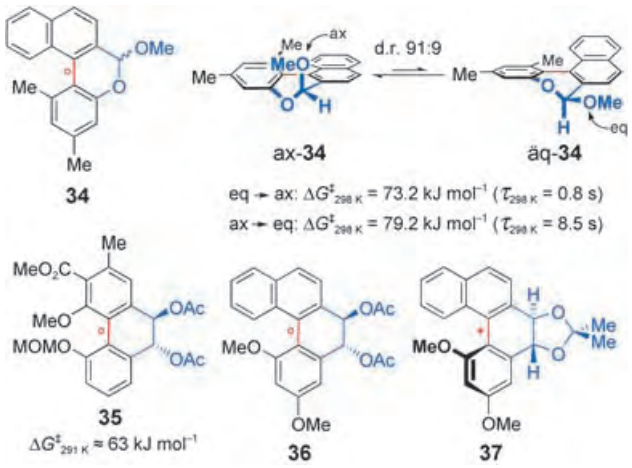

Figure 8. The configurational stability of six-membered bridged biaryl compounds that bear stereogenic centers in the bridge.

Biaryl compounds containing seven-membered rings exhibit rotational stabilities almost comparable to those of their unbridged analogues.[67] Larger bridges, including those formed by hydrogen bonding,[68] can induce atropisomerism by geometrical constraints of the ring, even in biaryl systems with relatively little axial hindrance. The synthetic biphenyls **38**[40,69] and **39**[70] are examples of such compounds that have just two substituents next to the axis, but are configurationally stable at room temperature (Figure 9). Even the tripeptide

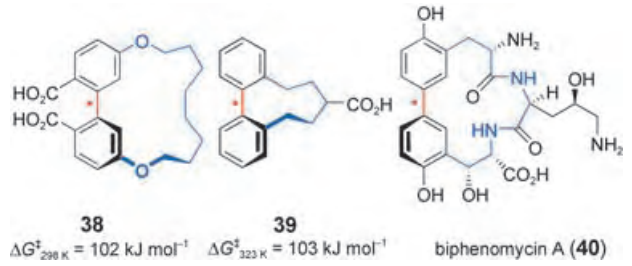

Figure 9. Macrocyclic bridged biaryl compounds that are axially chiral despite low steric hindrance in the proximity of the axis.

antibiotic biphenomycin A (**40**), which does not have any *ortho* substituents next to the axis, occurs as a single atropodiastereomer.[71] It is, however, not clear whether **40** is conformationally stable (high barrier) or, rather, labile with the atropodiastereomeric equilibrium completely shifted towards that isomer (thermodynamic effect).

2.3. Photochemically Induced Atropisomerization

In a number of cases, photoracemization of enantiomerically enriched biaryl compounds has been observed; the mechanisms suggested vary according to the particular molecular structure.[72–74] For example, 1,1′-binaphthyl (**23**), which is configurationally stable at room temperature (see Figure 5), racemizes readily via the triplet excited state **41** (Figure 10).[73] It has been proposed that, due to the diradical

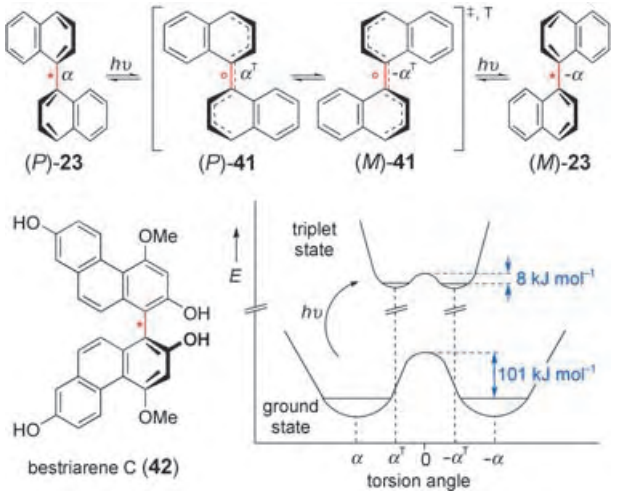

Figure 10. Photoracemization of 1,1′-binaphthyl (**23**) and bestriarene C (**42**).

character of the triplet state, the bond order of the aryl–aryl linkage increases, which causes a flattening of the structure (smaller torsion angle α^T); the electronic stabilization energy thus gained greatly lowers the rotational barrier ($E_{act,triplet} = 8\ kJ\,mol^{-1}$), despite the stronger steric interactions resulting from the shorter biaryl bond. The naturally occurring 1,1′-biphenanthrene, bestriarene C (**42**), undergoes remarkably swift photoracemization:[74] Illumination with a fluorescent lamp leads to a rapid loss of optical purity ($\tau_{295\,K} = 30$ min).

2.4. Chemically Induced Atropisomerization

The chemical conditions may substantially lower the rotational barrier of a biaryl compound if they lead to intermediates that are more prone to atropisomerization. The ubiquitously used chiral auxiliary binol (**29**) is configurationally stable even at elevated temperatures (see Figure 5); no loss of optical purity is observed upon heating at 100 °C for 24 h under neutral conditions.[75] In acidic media (e.g. 1.2 N HCl in dioxane/water), however, **29** racemizes within 24 h at 100 °C (Figure 11).[75] The de-aromatized cationic species **43**,

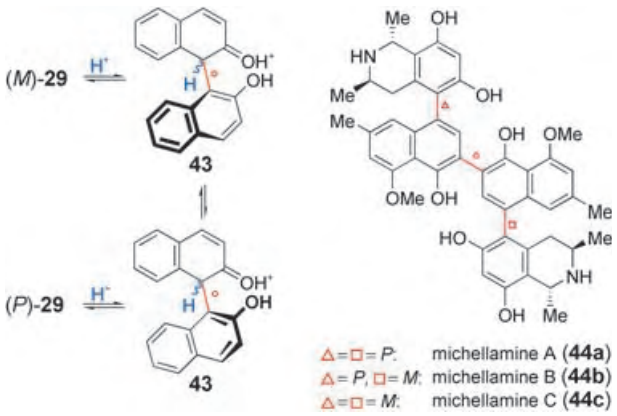

Figure 11. Acid-catalyzed racemization of binol (**29**) via the protonated intermediate **43**; structures of michellamines A–C (**44a–c**).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

which has a $C(sp^3)$–$C(sp^2)$ bond instead of the original biaryl axis, has been proposed as the intermediate that facilitates the racemization. The acid-catalyzed atropodiastereomerization of a binaphthyl-bridged bipyridyl in Scheme 55 is another example.[76,77] Binol (**29**) also racemizes upon heating in a basic environment (e.g. 0.67 N KOH in butanol); its dianionic bisphenolate has been suggested to promote the interconversion (for the electronic effects of donor groups on the rotational barrier, see Figure 6).[75,78] In a similar way, the michellamines A–C (**44a–c**), which possess a central axis that is configurationally unstable and two outer, configurationally stable ones, can be interconverted under basic conditions (0.5 M aq KOH, MeOH, RT, 6 days).[79] This led to the discovery that, in contrast to michellamines A and B (**44a,b**), michellamine C (**44c**), which had initially also been isolated, is not a natural product, but an artifact of the workup conditions.[79,80]

The seven-membered bridged biaryl lactam (*P*)-**45** (Figure 12), although configurationally stable at 140 °C for 7 days, undergoes acid-catalyzed atropisomerization to the

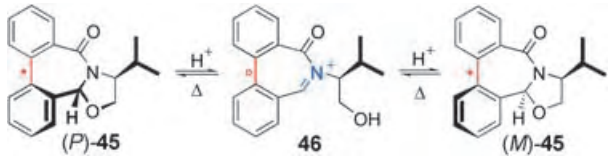

Figure 12. Proton-catalyzed atropodiastereomerization of the seven-membered bridged biaryl amide **45**.

thermodynamically more stable diastereomer (*M*)-**45** (46 % *de*) within 3 days upon addition of a catalytic amount of *p*-toluenesulfonic acid.[81] The acyliminium species **46**, formed reversibly by protonation, facilitates the interconversion due to its more planar structure (all bridging atoms sp^2 hybridized) and, in particular, due to the intermediate destruction of the five-membered oxazolidine ring annellated to the bridge, which rigidifies the biaryl system in **45** (compare also the dioxolane-annellated **37** and **36**, Figure 8).

In some cases, it is the reactivities of the *ortho* substituents themselves that are the origin of unexpectedly low rotational barriers. For example, the enantiomerically pure hydroxy aldehyde (*M*)-**47** (Figure 13), a fourfold *ortho*-substituted biaryl compound and thus anticipated to be configurationally fully stable, still racemizes slowly at room temperature even under neutral conditions ($\Delta G^{\ddagger}_{296\,K} = 99\ kJ\,mol^{-1}$, $\tau_{296\,K} = 6.5$ h).[62,82] Quantum-chemical calculations[83] and experimental work[64,82] show that the formation of the lactol intermediate **48** is the reason for this type of chemically induced atropisomerization. As a biaryl system bridged with a six-membered ring, **48** has a low atropisomerization barrier. A solely physical rotation about the axis can be excluded since the O-protected analogue (*M*)-**49** is configurationally stable.[82] Such a chemically induced atropisomerization process via a lactol-bridged species has been postulated[84] to be the reason for the lack of optical activity in the natural product cynandione A (**50**).[85]

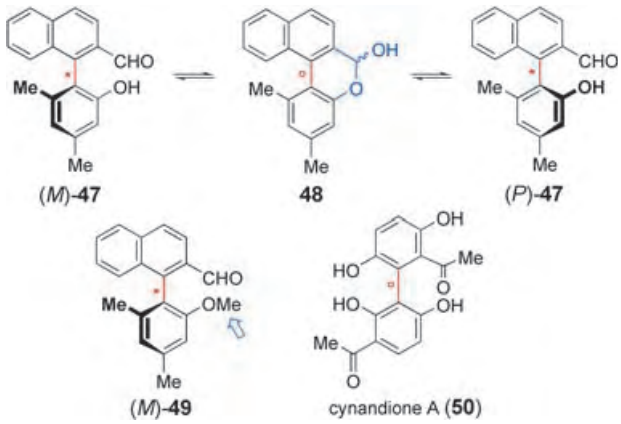

Figure 13. Atropisomerization of the biaryl hydroxyaldehyde **47** via its lactol **48**; structure of the natural product cynandione A (**50**).

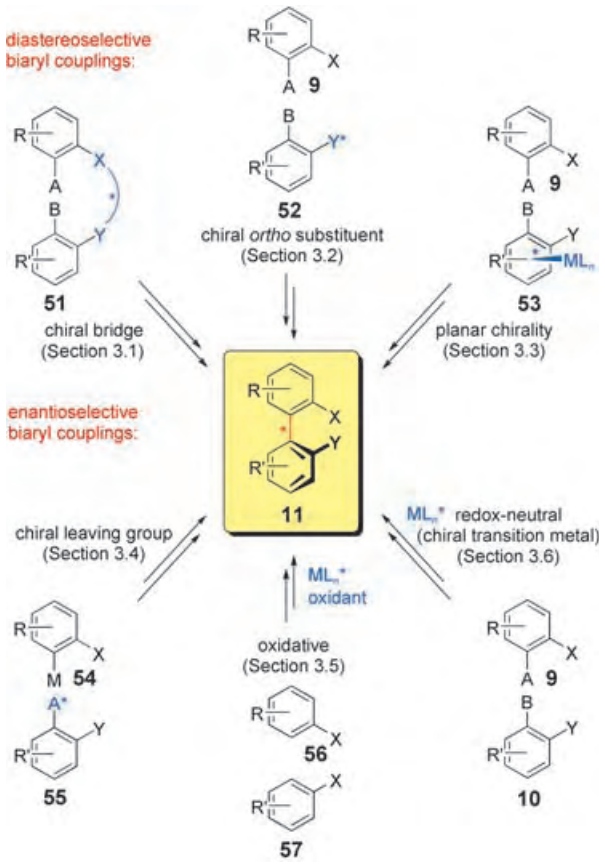

In summary, the occurrence of atropisomerism strongly depends on the temperature, the steric demand of the *ortho* substituents, and the length and rigidity of bridges, be they constitutive or transient. The effects of *meta* and *para* substituents and the chemical mechanism of atropisomerization also have to be taken into account.

3. Biaryls by Asymmetric C–C Coupling

The classic approach to the synthesis of axially chiral biaryl compounds entails a direct, atroposelective aryl–aryl coupling step, that is, the construction of the axis occurs simultaneously with the asymmetric induction. There are several options to introduce the stereochemical information, roughly divisible into diastereo- and enantioselective approaches (Scheme 2). Diastereoselective biaryl couplings have been realized by three different strategies: The simplest involves the incorporation of a chiral bridge (often sourced from the chiral pool) to prelink the two aryl substrates, subsequently permitting a favorable intramolecular reaction (**51**→**11**), as discussed in Section 3.1. Diastereoselective intermolecular coupling reactions can be effected by utilizing arenes that are modified by a chiral auxiliary, normally in one of the *ortho* positions next to the coupling site (as in **9** + **52**→**11**, see Section 3.2), or by using a (tracelessly) removable chiral element, for example, in the form of planar-chiral η^6-chromium complexes or *ansa* compounds (as for **9** + **53**→**11**, see Section 3.3).

An overall enantioselective approach has been achieved by employing a chiral leaving group, as in **55**, which is eliminated in the coupling step (**54** + **55**→**11**, see Section 3.4). An enantioselective biaryl coupling will also result if the stereochemical information is induced through a chiral additive. Both stoichiometric and catalytic oxidative dimerizations have been realized with metal-based reagents (e.g. with Cu) by using chiral ligands, usually amines, to induce the axial configuration (**56** + **57**→**11**, see Section 3.5). Furthermore, based on redox-neutral couplings (**9** + **10**→**11**, for example, Suzuki reactions), enantioselective procedures have

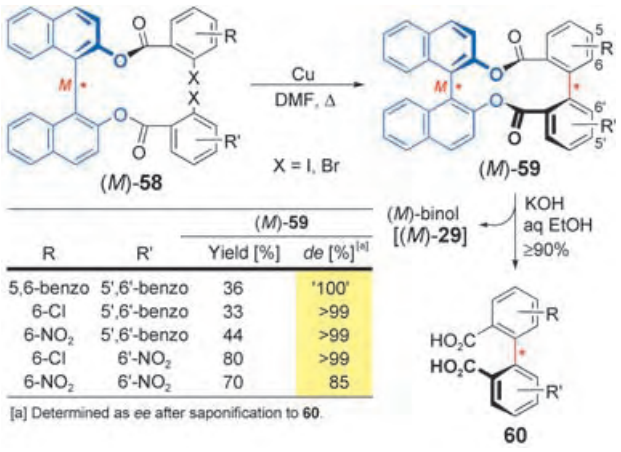
Scheme 2. Basic strategies for the direct, atroposelective construction of biaryl axes.



recently been developed, typically employing catalytic quantities of chiral bidentate N,P-ligands (see Section 3.6).

It is important to keep in mind that the construction of a configurationally stable biaryl compound is, by definition, a sterically hindered reaction, which often requires "forcing" conditions to provide the coupled products in reasonable yields. This, on the other hand, can cause a concomitant atropisomerization at the axis, hence leading to diminished atroposelectivities. Thus, care has to be taken that the reaction conditions employed are still mild enough not to interfere with the stereochemical integrity of the biaryl axis.

3.1. Intramolecular Coupling with Chiral Tethers

The coupling of two aryls units, pre-fixed through a chiral bridge, is a popular strategy in asymmetric biaryl synthesis since it provides two clear advantages: good yields for the intramolecular aryl–aryl bond formation, and the possibility to produce both homo- and cross-coupled biaryl compounds. The approaches of this type can be divided into two principal categories: those in which the bridge, or the chiral parts thereof, are part of the intended product, and those in which the tether is an artificial auxiliary (i.e. not part of the final target) that has to be eliminated in the end.

Miyano et al. pioneered this method in the early 1980s by employing diester-bridged systems of type (*M*)-**58** (Scheme 3); these are accessible from (*M*)-binol ((*M*)-**29**) and the corresponding aromatic diacids by twofold (symmetric, R = R′) or sequential (unsymmetric, R ≠ R′) esterification.[86] Ullmann coupling of (*M*)-**58** led to (*M*)-**59** with

R	R′	(*M*)-59 Yield [%]	*de* [%][a]
5,6-benzo	5′,6′-benzo	36	'100'
6-Cl	5′,6′-benzo	33	>99

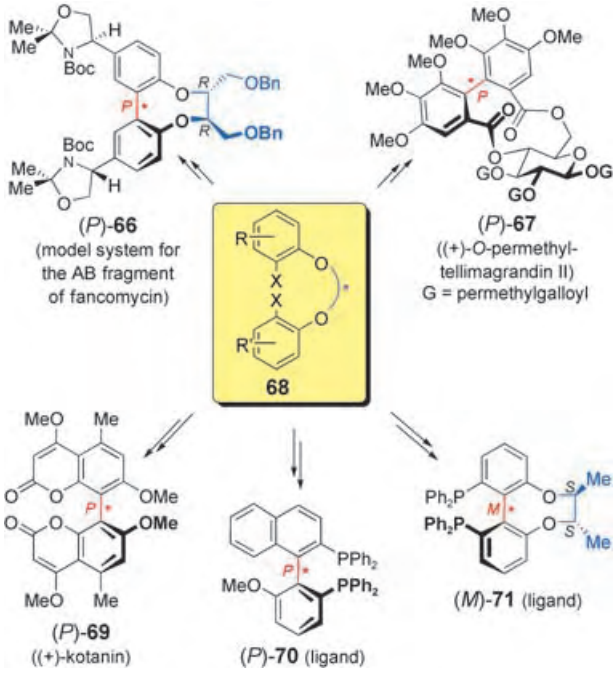
excellent stereocontrol (up to "100%" *de*), albeit in low chemical yields if a sterically hindered axis was created. Hydrolysis of (*M*)-**59** afforded the biaryl diacids (*M*)-**60** with recovery of (*M*)-**29**. Further studies on other diester tethers revealed that the rigidity of the binol bridge is crucial to attain high asymmetric inductions.



Significant progress was made in this area by Lipshutz et al.,[87] who introduced diether bridges combined with a more efficient coupling method via higher-order cuprates.[88] The best chirality transfers were obtained with C_2-symmetric bridges derived from tartaric acid which bear two stereogenic centers (Scheme 4),[89] as in the reaction of (*R*,*R*)-**61** to give (*P*)-**62** ("100%" *de*). The biaryl 2,2′-diol thus obtained are valuable both as ligands and as precursors to natural products. Sargent and co-workers proposed that the cyanocuprate intermediates preferentially adopt the *gauche* conformation **63A** rather than the diaxial conformation **63B**, thus leading to the observed stereochemical outcome.[90] Sugimura et al. successfully introduced 1,3-diol-derived tethers.[91] For example, the intramolecular coupling reactions of **64** gave (*M*)-**65** in 54% (R = Me) or 78% (R = Ph) yield with > 99% *de*.

This strategy has found application in the (partial) synthesis of natural products (and derivatives)[92–96] and ligands for catalytic asymmetric synthesis;[97–100] some examples are shown in Scheme 5. Lipshutz et al. synthesized (*P*)-**66**,[92] a model system for the AB system of vancomycin (**1**, Figure 1), and *O*-permethyltellimagrandin II ((*P*)-**67**),[96] a member of the ellagitannin family. The natural product kotanin ((*P*)-**69**) was constructed by Lin and co-workers.[93,94] The enantiomerically pure diphosphines (*P*)-**70** and (*M*)-**71**, used as the chiral ligands in catalytic asymmetric hydrogenations, were prepared by Genêt, Marinetti, and co-workers[97,98] and by Chan and co-workers,[99] respectively.

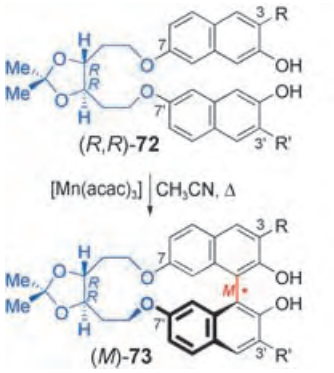
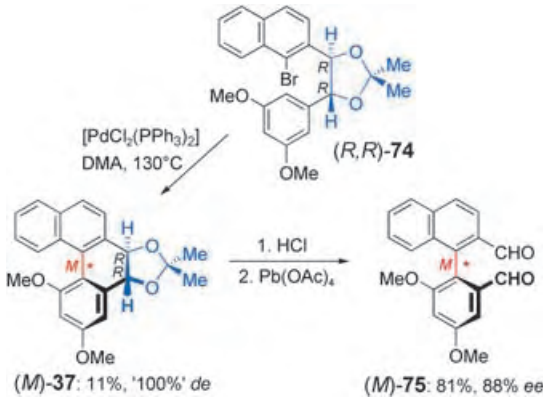


Scheme 4. The use of diether tethers bearing two stereogenic centers in the diastereoselective synthesis of biaryl compounds.

Scheme 5. Use of diethers of the type **68** in the atroposelective synthesis of biaryl ligands and natural products.

The use of 2,2′-linked chiral tethers allows an efficient and versatile preparation of axially chiral biaryl compounds. The asymmetric inductions observed are good to excellent, and, if atropodiastereomeric product mixtures are obtained, these are normally easy to resolve. Both C_2-symmetric and, by sequential etherification, heterocoupled products are obtainable, and although substitution patterns are constrained by the tethering site, a range of valuable products have been synthesized by this method. Drawbacks to this approach are the additional steps required to introduce and remove the tether, in combination with the harsh conditions (e.g. BBr_3) needed to cleave some of the ether bridges. In view of the fact that these are intramolecular coupling reactions, the yields are relatively modest in many cases (generally 50–80%).

Lipshutz and co-workers extended this methodology to 7,7′-bridged 2-naphthols of type (*R*,*R*)-**72** (Scheme 6),[101,102]



R	R′	Yield [%]	*de* [%]

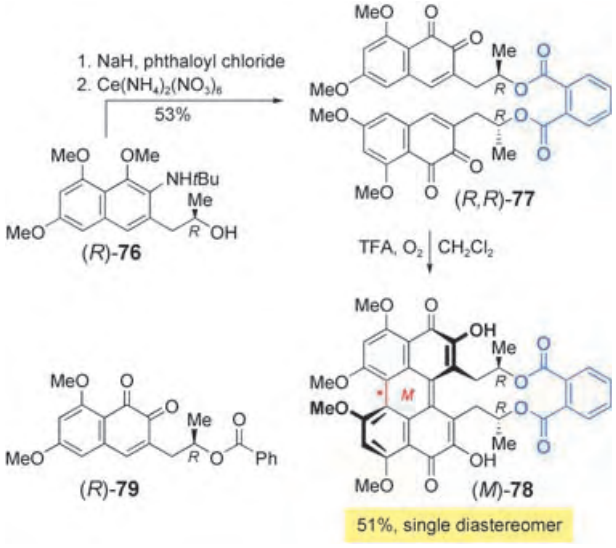
Scheme 6. Atroposelective synthesis of the binaphthols (*M*)-**73** by using a remote 7,7′-tether.

with the option to prepare unsymmetrical biaryl compounds by sequential etherification. Oxidative biaryl coupling with Mn^{VI} gave the macrocyclic binaphthols (*M*)-**73** in good yields and excellent diastereoselectivities of up to 97%. Furthermore, the chiral bridge of (*M*)-**73** can be used as a linker for polymer attachment. The resulting solid-supported ligands were used successfully in a range of catalytic asymmetric reactions.[103] 2-Amino-2′-hydroxy binaphthyls (so-called "nobin"-ligands) have also been assembled through this route.[104]

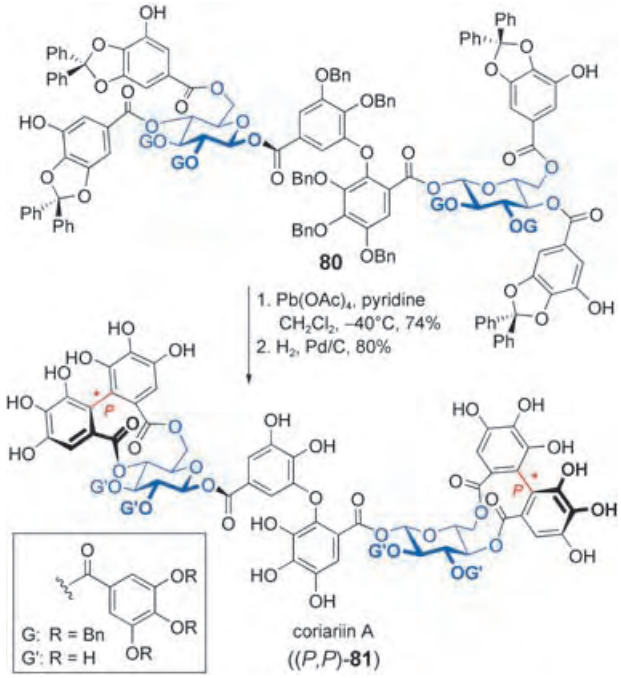
Intramolecular coupling reactions of arenes employing an all-carbon chiral bridge have also been undertaken.[66,105] Our group made use of an acetonide-protected diol tether,[66] as in (*R*,*R*)-**74** (Scheme 7); the extra rigidity due to an additional ring annellated to the bridge creates a configurationally stable biaryl axis after coupling, thus compensating for the labilizing effect of the short bridge (compare Figure 8). Although biaryl



Scheme 7. Atroposelective intramolecular biaryl formation by using the all-carbon-tethered precursor (*R*,*R*)-**74**.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

formation occurred with excellent stereocontrol to give (*M*)-**37** as a single diastereomer, the yield of the coupling reaction was low. Another problem was the lack of stereochemical integrity at the axis upon acetal cleavage in (*M*)-**37**, as the intermediate diol is configurationally semistable owing to the central six-membered ring, thus leading to a lower enantiopurity in the ring-opened product (*M*)-**75**.

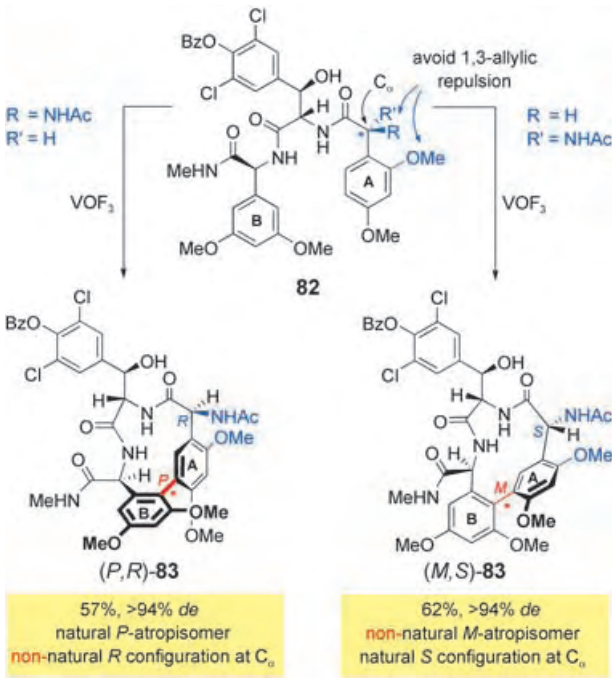


If the target biaryl system itself bears stereogenic centers, the artificial bridge between the two coupling partners does not need to carry stereochemical information. As part of their synthesis of derivatives of calphostine, Merlic et al. bridged the naphthalenes (*R*)-**76** with phthaloyl chloride to give, after oxidation, the bis(*ortho*-naphthoquinone) (*R*,*R*)-**77** (Scheme 8).[106] Oxidative coupling delivered the perylenequinone (*M*)-**78** as a single diastereomer in 51% yield. The additional rigidity induced by the phthaloyl linkage is responsible for the excellent stereocontrol, as evident from the analogous intermolecular coupling of the benzoyl derivative (*R*)-**79**, which proceeded with only 33% *de*.[107]

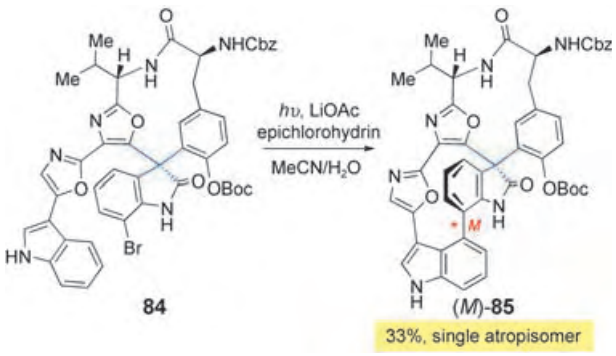
Scheme 8. Highly atropodiastereoselective intramolecular oxidative coupling in (*R*,*R*)-**77** to give the perylenequinone (*M*)-**78**.

The second large field of application of atropodiastereomeric intramolecular coupling reactions targets biaryl compounds that contain a chiral bridge as a structural element. Although very specialized, this (often biomimetic) approach has been used successfully in the synthesis of several complex natural products.

The ellagitannins are plant secondary metabolites characterized by one or more atropisomeric hexahydroxydiphenoyl moieties attached to a glucopyranose core,[108] which has been postulated to control the axial configuration in the biosynthetic oxidative coupling step.[109] Along these lines, Feldman and co-workers developed a biomimetic synthetic strategy, which, besides validating the theory, has led to the successful preparation of several simplified model biaryl compounds and a number of natural products under virtually complete stereocontrol.[110,111] For example, coriariin A ((*P*,*P*)-**81**),[112] a dimeric ellagitannin with antitumor activity,[113] was synthesized from **80** (74% yield). The stereochemically decisive step was a twofold oxidative biaryl formation, which afforded both axes in a *P*-configured form (Scheme 9).[114]



Scheme 9. Total synthesis of the ellagitannin coriariin A ((*P*,*P*)-**81**) through a twofold biomimetic oxidative biaryl coupling.



The atroposelective construction of the biarylic AB fragment was one of the major challenges in the total synthesis of vancomycin (**1**) and was successfully achieved by Evans et al.[115,116] In this biomimetic approach, the additional (non-natural) *ortho* methoxy group at the A ring of the tripeptide **82** (Scheme 10), as required to permit an oxidative biaryl coupling, had a strong impact on the asymmetric induction at the biaryl axis formed, as a result of its interaction with stereocenter C_α of the chiral backbone: The epimer (*S*)-**82**, with the natural *S* configuration at C_α (R = H, R′ = NHAc) delivered the non-natural atropodiastereomer (*M*,*S*)-**83** with 94% *de*, whereas the non-natural *R* epimer at C_α, (*R*)-**82** (R = NHAc, R′ = H), gave (*P*,*R*)-**83** with 94% *de* and the naturally occurring *P* configuration at the biaryl axis. It was argued that a *syn*-coplanar conformation of the artificial Ar–OMe bond and the hydrogen atom at C_α is maintained throughout the coupling step, thus avoiding the destabilizing 1,3-allylic repulsion between the larger NHAc group at C_α and Ar-OMe that would occur during formation of the minor atropisomers. For a subsequent "correction" of the wrong axial configuration, see Scheme 57.

More recently, Nicolaou et al. reported the completion of the first total synthesis of the complex, polycyclic secondary metabolite diazonamide A[117,118] (Scheme 11, for an alternative approach, see Scheme 53). Witkop-type[119] photocyclization of the chiral bridged aryl bromide **84** afforded the

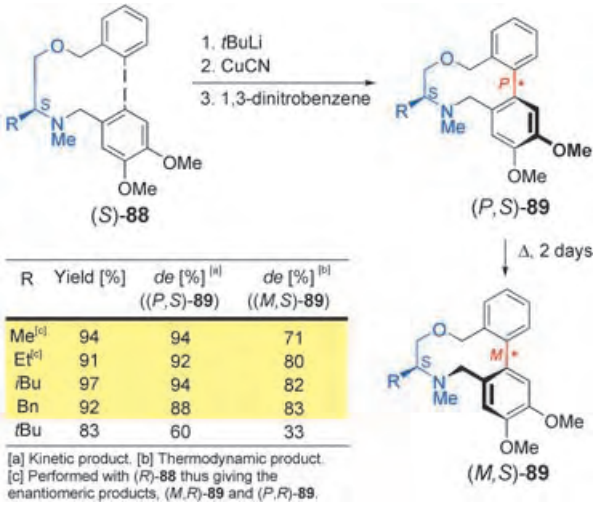
macrocyclic biaryl (*M*)-**85**. Although the yield was modest, (*M*)-**85** was the only atropodiastereomer observed.



The stegane series of lignans is another family of axially chiral bridged biaryl compounds that can be synthesized atroposelectively through oxidative intramolecular coupling by taking advantage of stereogenic centers present in the bridge,[120] again following the biosynthetic pathway.[121] In a recent example shown in Scheme 12, Waldvogel and co-workers synthesized the lignan (*M*,*S*,*S*)-**87** in 50% yield from the precursor (*S*,*S*)-**86** in the presence of molybdenum pentachloride, with no evidence of formation of the diastereomeric product.[122]

Among the numerous biaryl coupling reactions mentioned in this Review, the only one directed at a diversity-

Scheme 12. Atropodiastereoselective synthesis of the lignan (*M*)-**87**.

oriented atroposelective preparation of a large number of axially chiral biaryl compounds (e.g. for the evaluation of structure–activity relationships in high-throughput assays) was published by Schreiber and co-workers.[123] A highly diverse family of N,O-bridged biaryl compounds **89** was prepared from (*S*)-**88** with good to excellent diastereoselectivities by coupling via higher-order cuprates (a small selection of substances of this library is shown in Scheme 13). The kinetic product (*P*,*S*)-**89** initially obtained gave rise to the other atropodiastereomer (*M*,*S*)-**89** upon heating, often with good *de* values.

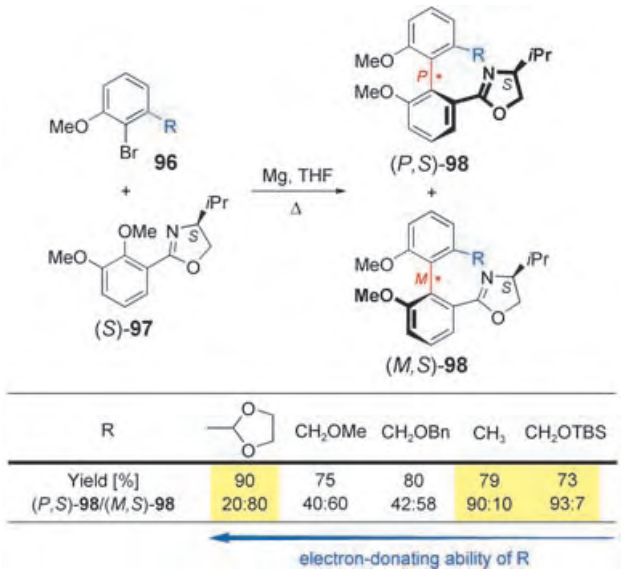

Scheme 13. Synthesis of a family of tethered biaryl compounds **89** with either desired axial configuration.

The method was applied to the polymer-supported synthesis of a library of >400 axially chiral biaryl compounds (Scheme 14). The chiral β-amino alcohols **91** and the two aryl subunits **92** and **93** were attached stepwise to the pregrafted linker **90** to give the polymer-fixed dibromide **94**. Biaryl coupling, optional atropisomerization, and eventual release afforded the compounds **95**. Points of diversity for this library were the substitutions at the biaryl compound (R, R′) and at the tether (R*) and the axial configuration. Biological testing of this archive in phenotype and protein-binding screens was moderately successful.

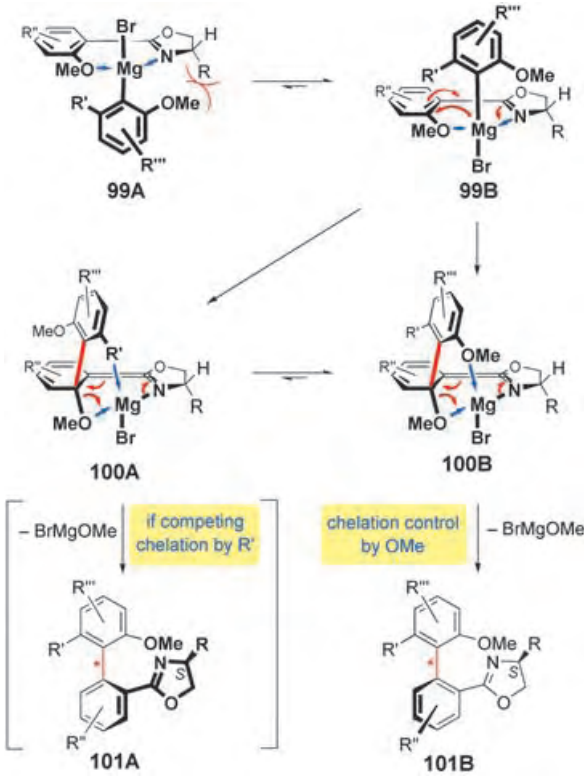


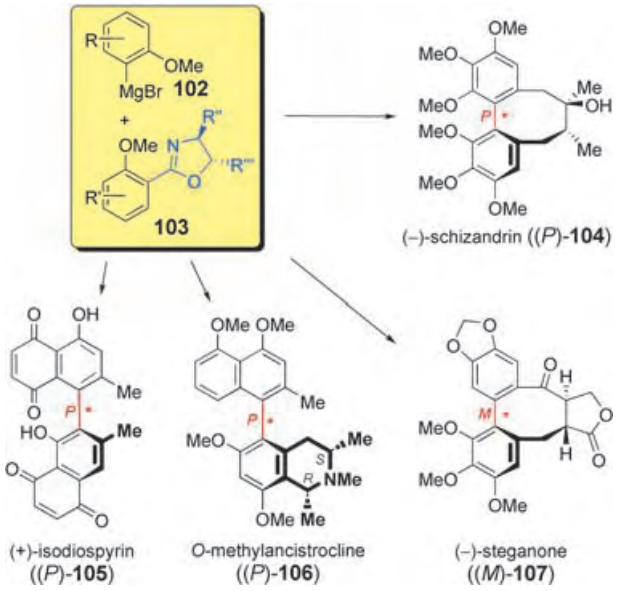
Scheme 15. Synthesis of axially chiral biphenyls **98** by S_N2 Ar reaction of oxazolinylbenzene (*S*)-**97** and influence of the electron-donating properties of the *ortho* substituent R of the aryl Grignard reagent on the asymmetric induction.

3.2. *Intermolecular Coupling with Chiral* ortho *Substituents*

In contrast to intramolecular diastereoselective biaryl coupling reactions, intermolecular variants require only one of the two aromatic moieties to be chemically modified (only by a chiral auxiliary, not by a bridge!), thus allowing a relatively free substitution pattern at the second arene ring. To ensure efficient chirality transfer, the asymmetric information is normally located in one of the *ortho* substituents, that is, close to the coupling site.

The coupling of aryl carboxylic esters that bear a chiral alcohol function should be a convenient access to axially chiral biaryl systems. All such attempts, however, have as yet failed to give atroposelectivities $>50\%$ *de*.[124,125] The major breakthrough in this field came from Meyers and co-workers, who developed an efficient method for the stereoselective construction of axially chiral biaryl compounds by nucleophilic aromatic substitution (S_N2 Ar) of chiral *ortho*-methoxy-(oxazolinyl)arenes with aryl Grignard reagents. The oxazoline moiety carries the chiral information and, additionally, facilitates the nucleophilic attack by stabilizing the developing negative charge.

L-Valinol-derived oxazolines such as (*S*)-**97** (Scheme 15), which are easily prepared from the corresponding benzoic acid, are the chiral coupling partners of choice in most cases.[126–129] Regioselective nucleophilic displacement of the *ortho*-methoxy function in (*S*)-**97** by aryl Grignard reagents (prepared from **96** and magnesium) delivered the tetra-*ortho*-substituted biphenyls **98**. The sense of the asymmetric induction and the levels of atropodiastereoselectivity strongly depend on the relative electron-donating abilities of the two *ortho* substituents of the aryl Grignard reagent.[127,130,131] In general, at least one *ortho* substituent with an accessible free electron pair (most commonly, OMe) is required to ensure a well-defined transition state (see mechanism, Scheme 16). Thus, the biphenyls (*P*,*S*)-**98** were obtained with $>80\%$ *de* if



Scheme 16. The stereochemical course of the S_N2 Ar reaction of aryl Grignard reagents on chiral aryl oxazolines.

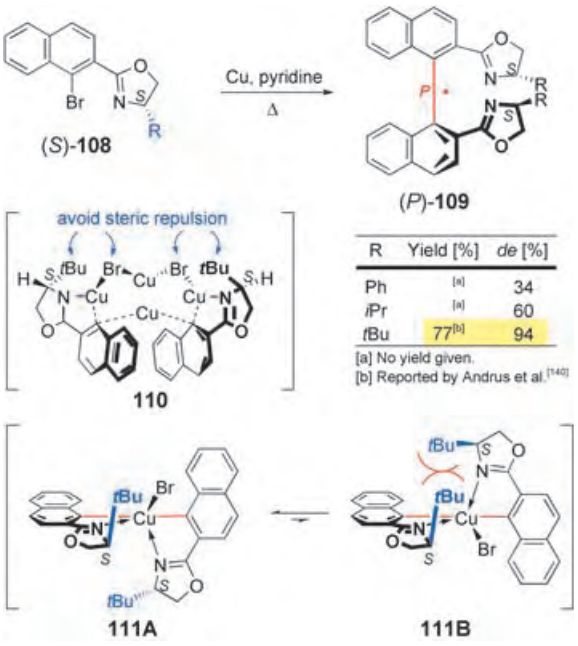
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the second *ortho* substituent R exhibited no (R = Me) or very low (R = CH_2OTBS) electron-donating abilities. The *M*-configured atropodiastereomer (*M*,*S*)-**98**, however, was preferentially formed (60% *de*) if the electron-donor character of R was superior to that of OMe (e.g. R = 1,3-dioxolan-2-yl). In the case of comparable donating abilities, as for R = CH_2OMe or CH_2OBn, the reactions proceeded with low stereocontrol ($\leq$20% *de*). Steric effects, such as the relative size of R and OMe, are of minor importance, as highlighted by the fact that with R = Me and R = CH_2OTBS the same *M*-configured diastereomers (*M*,*S*)-**98** were obtained, with similar asymmetric inductions.

As a consequence of these experimental observations, the reaction is believed to proceed through an addition–elimination mechanism, with the overall diastereoselectivity determined by both steps (Scheme 16).[127,130] Initially, a chelate complex is formed between the aryl Grignard reagent and the *ortho*-methoxy(oxazolinyl)arene. Of the two possible diastereomeric arrangements, **99B** is strongly favored over **99A**, as the former avoids the steric repulsion of the substituent R of the oxazoline moiety with the *ortho* substituents of the Grignard reagent. Nucleophilic addition in **99B** leads to the aza-enolates **100A** and **100B**. If the substituent R′ does not exhibit significant chelating abilities, complexation of the methoxy group to the magnesium center strongly favors the intermediate **100B**. After elimination of MeOMgBr, the stereochemical alignment of the two aryl moieties thus fixed is transferred into the axially chiral biaryl product **101B**. However, if R′ is also able to act as a chelator to Mg^{II}, the aza-enolates **100A** and **100B** are formed in ratios that reflect the relative donating abilities of R′ and OMe, thus leading preferentially to **101A** or **101B** or mixtures thereof.

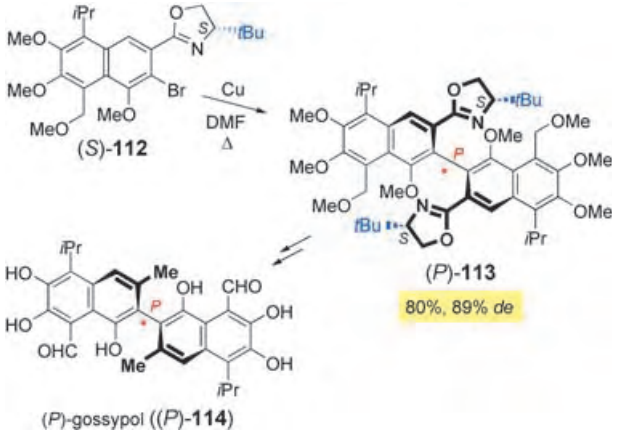
This technique was used to produce several axially chiral biaryl natural products and derivatives,[128,132–135] some of which are shown in Scheme 17: (−)-schizandrin ((*P*)-**104**)[128] and (+)-isodiospyrin ((*P*)-**105**)[132] (both the non-natural enantiomers), *O*-methylancistrocline ((*P*)-**106**),[133] and (−)-steganone ((*M*)-**107**).[134]

Scheme 17. Biaryl natural products prepared by nucleophilic aromatic substitution of aryl Grignard reagents **102** on aryl oxazolines of type **103**.



The main advantages of this method, which allows convenient access to cross-coupled (i.e. non-C_2-symmetric biaryl systems), are its simplicity, reliability, and robustness. The chiral oxazoline substituent is easily prepared from the corresponding aromatic acid and the amino alcohol, and can be transformed, after biaryl formation, into a variety of functional groups. Some limitations arise from the use of an aryl Grignard reagent and its structural requirements: To attain high atropodiastereoselectivities, one of the substituents *ortho* to the coupling position (usually OMe) must possess a free electron pair to chelate the magnesium, while the other one must not. However, the substitution pattern of the biaryl products formed, namely an *ortho*-methoxy group and a C_1 unit from the oxazoline in the *ortho′* position, is common to many natural products and so this route has a wide field of application.

Chiral *ortho*-bromo(oxazolinyl)arenes are also suitable starting materials for asymmetric Ullmann homocoupling reactions to give C_2-symmetric biaryl products with high diastereomeric purities. This section deals only with those cases that are known to proceed through a stereoselective aryl–aryl bond-formation step; many homocouplings of sterically less congested phenyls are first-order transformations,[136] that is, the (more or less) racemic biaryl compound initially produced is subsequently resolved by diastereoselective formation of a copper–chelate complex, and are, as such, treated in Section 4.2.4.



The Ullmann homocoupling of the 1-bromo-2-oxazolinylnaphthalenes (*S*)-**108** gave the binaphthyls (*P*)-**109** with diastereoselectivities that were strongly dependent on the steric demand of the substituent R of the oxazoline moiety;[126,137,138] only with the bulky *t*Bu group was an excellent 94% *de* achieved (Scheme 18).[139] Meyers and Nelson proposed the diaryl cuprates **111** as the stereochemically decisive species.[137,138] Intermediate **111A**, which leads to the observed product (*P*)-**109** by reductive elimination of Cu^I, avoids the steric repulsion between the two *t*Bu groups of the oxazoline portions and is, thus, energetically favored over **111B**. More recently, based on X-ray crystal structures of related aryl–copper species, Andrus et al. suggested an alternative intermediate.[140] It was argued that an eight-membered Cu_4 aggregate of type **110** might be formed, with the two naphthyl rings arranged in a more or less antiparallel fashion. According to this model, the stereoselectivity would be controlled by the steric interactions of the flanking *t*Bu groups with the bridged bromine atoms; intermediate **110**, in which these repulsions are avoided, is energetically favored over the diastereomer with *t*Bu and the bridging Br atom both on the same side (not shown).

The method has found application in the atroposelective synthesis of the cotton-seed-derived natural binaphthyl (*P*)-gossypol ((*P*)-**114**, Scheme 19).[141,142] Treatment of the naphthyl oxazoline (*S*)-**112** with copper in refluxing DMF delivered the biaryl (*P*)-**113** in 80% yield and with a high asymmetric induction of 89% *de*. Further transformation of (*P*)-**113** into the target (*P*)-**114** was straightforward.

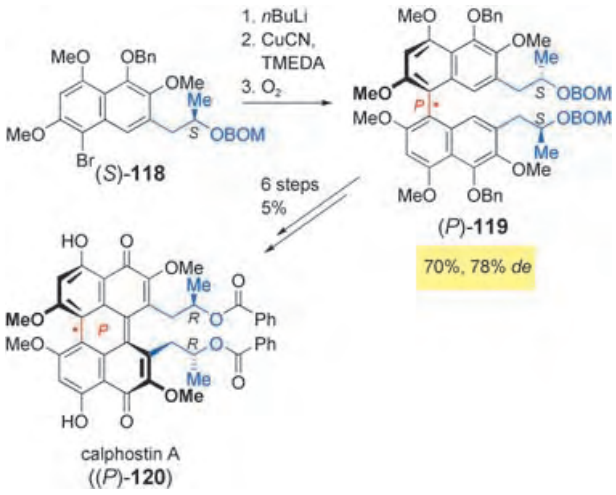
Scheme 19. Atroposelective synthesis of the natural product (*P*)-gossypol ((*P*)-**114**).

The Ullmann coupling of aryl oxazolines provides efficient access to C_2-symmetric binaphthyls, but a drawback is the high price of the *tert*-leucinol-derived oxazoline required for high stereocontrol. It should be noted again that many examples of Cu-mediated reductive coupling reactions are not based on a stereoselective aryl–aryl bond-formation step, but on a subsequent deracemization of a biaryl species initially produced in a more or less racemic form (see Section 4.2.4).

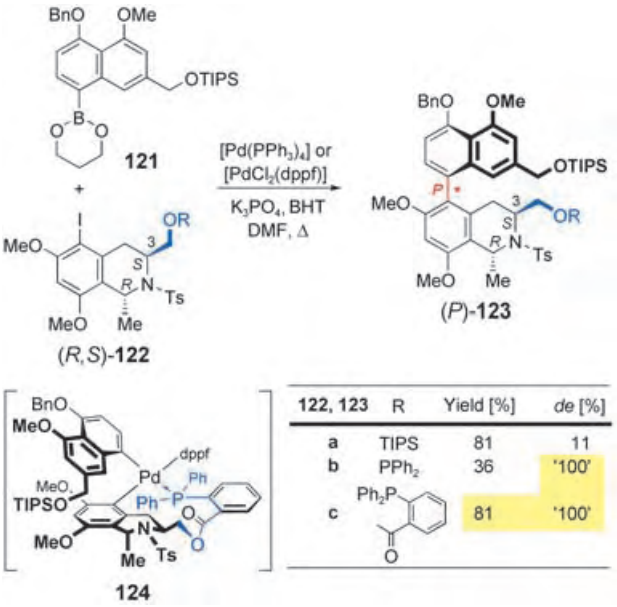
Apart from these well-investigated cases with oxazolines as the chiral *ortho* substituents,[143] an α-methoxy-β-sulfinyl side chain next to the coupling position was found to be an effective asymmetric inductor in stereoselective Suzuki reactions, as demonstrated by Colobert and co-workers in 2003 (Scheme 20).[144] Coupling of the iodides (*R*,*R*)-**115**,

Scheme 20. The α-methoxy-β-sulfinyl side chain as an effective chiral controller in the atroposelective Suzuki coupling reactions of (*R*,*R*)-**115** with **116**; the absolute configuration of the products (*R*,*R*)-**117** at the biaryl axis is unknown.



which are accessible in three steps from the corresponding esters, with the boronic acids **116** delivered the biaryl products (*R*,*R*)-**117** (absolute axial configuration unknown) in high to excellent yields (up to 99%) with almost complete asymmetric induction (>98% *de*). Both stereogenic elements in the side chain are required for the high chirality transfer: Removal of the stereocenter at the sulfoxide by oxidation to the sulfone led to diminished atropodiastereoselectivities (70% *de*), while inversion of the configuration of the methoxy-substituted C_α atom failed to give any significant asymmetric induction (10% *de*, "mismatched case"). The "opposite" couplings of phenyl boronic acids with 1-bromo-2-(α-methoxy-β-sulfinyl)naphthalenes were less stereoselective (only up to 70% *de*). Further investigations into the development of efficient procedures for desulfurization and removal of the chiral side chain are necessary to allow an extension of this promising method to the atroposelective synthesis of a wider range of biaryl systems.

Besides the element of axial chirality, many biaryl natural products bear additional stereocenters, which can be used as the chiral controlling units for the atroposelective construction of the biaryl axis. Two examples of such (rather special) approaches with internal asymmetric induction are described below.[145–147]



The perylenequinone calphostin A ((*P*)-**120**), a potent protein kinase C inhibitor, contains two chiral β-benzoyloxypropane side chains; this stereochemical information was used in the atroposelective total synthesis of (*P*)-**120** by Coleman et al. (Scheme 21).[145] Oxidative homocoupling of the chiral naphthalene (*S*)-**118** via a higher-order aryl cuprate delivered the binaphthalene (*P*)-**119** in 70% yield. In view of the remote position of the stereocenter, the 78% *de* obtained was remarkable. Transformation of (*P*)-**119** into the target (*P*)-**120** was achieved in six steps.

Most members of the rapidly growing class of naphthylisoquinoline alkaloids (for examples, see Schemes 26, 64, and 67) bear a methyl group at the C3 stereogenic center of the isoquinoline portion. Lipshutz et al. investigated whether an appropriate substituent at this position can induce a good central-to-axial chirality transfer (Scheme 22).[146] Suzuki

coupling of the naphthyl boronic ester **121** with the OTIPS derivative (*R*,*S*)-**122a** gave the biaryl product (*P*)-**123a** with low selectivity (11% *de*), thus indicating that steric bulk alone is not sufficient for good stereocontrol. The situation changed dramatically when a diphenylphosphanyl group, which can act as an additional binding site for the palladium catalyst, was attached, as in (*R*,*S*)-**122b** and **c**. In both cases, the *P*-configured biaryl compounds (*P*)-**123b** and **c** were obtained exclusively; the benzoic ester linked PPh_2 derivative (*R*,*S*)-**122c** showed an increased redox stability and gave a better yield than the diphenylphosphanyl alkoxide (*R*,*S*)-**122b**. The origin of the nearly complete chirality transfer in the reaction of (*R*,*S*)-**122b** with **121** was explained by formation of the intermediate **124**, in which the chelating PPh_2 group efficiently blocks the bottom face of the palladium atom. The naphthyl moiety is forced into a position above the face of the Pd center, with the bulky OTIPS substituent directed away from the dppf ligand. Reductive elimination of Pd^{II} in **124** should lead to the observed product (*P*)-**123**.

Even though the latter approaches have been developed for the atroposelective synthesis of relatively special target biaryl systems, they clearly demonstrate that remote stereogenic centers can also induce high levels of central-to-axial chirality transfer.

3.3. Intermolecular Coupling with the Element of Planar Chirality

The methods described in the preceding section require the presence of a chiral auxiliary attached to an appropriately modified *ortho* substituent. Thus, a worthwhile strategy would be based on a fixed (but not covalently bound), tracelessly removable stereogenic element. These conditions are fulfilled by planar-chiral transition-metal–arene complexes in which the metal fragment activates the arene by η^6-coordination and, at the same time, serves as a source of chiral information.

This concept was realized by Uemura and co-workers with [(arene)$Cr(CO)_3$] complexes such as **126** (Scheme 23).[22] For

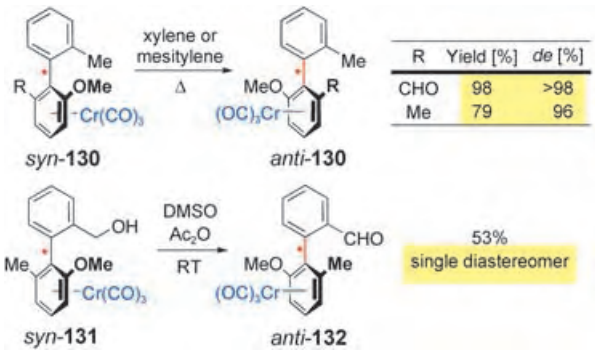
exploratory model reactions these planar-chiral substrates were used in a racemic form. Pd-catalyzed Suzuki coupling of the phenyl boronic acids **125** with **126** delivered the biaryl chromium complexes *syn*-**127** or *anti*-**127** with excellent atropodiastereoselectivities (up to "100% *de*"),[148–151] generally leading to the sterically more congested atropodiastereomer *syn*-**127**, in which the substituent R is directed towards the $Cr(CO)_3$ fragment (Scheme 23, entries 1–3). If an *ortho* carbonyl group is present, the thermodynamically more favored atropodiastereomer *anti*-**127** may also be obtained as the sole product (Scheme 23, entries 4 and 5), probably due to subsequent isomerization at the biaryl axis under the reaction conditions, as the consequence of the lower rotational barrier (see below). There is, however, no clear trend as the analogous reactions of [(*ortho*-formyl arene)$Cr(CO)_3$]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

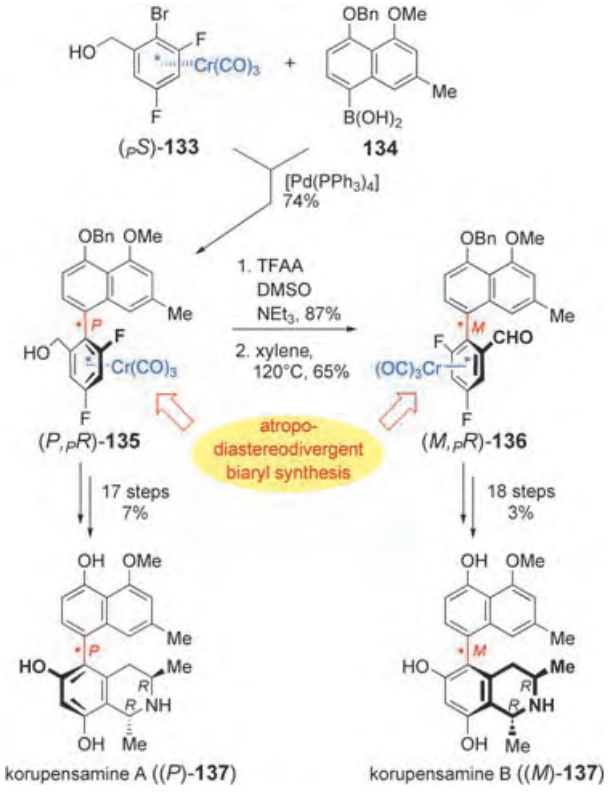
complexes gave stereochemically inconsistent results (Scheme 23, entries 6 and 7). In general, the electron-withdrawing $Cr(CO)_3$ fragment must be located on the aryl halide portion as it accelerates the oxidative addition to Pd^0.[22,152] The alternative coupling of an aryl halide with a $\{Cr(CO)_3\}$-complexed aryl boronic acid resulted in poor coupling yields. Extension of the method to di-*ortho*-substituted aryl boronic acids and 2-substituted 1-naphthyl boronic acids led, in many cases, to diminished yields and stereoselectivities.[22,149,153]



It has been proposed that the initial formation of the thermodynamically less stable *syn* product is caused by steric repulsions in the two relevant diastereomeric *cis*-diorganopalladium intermediates **128A** and **128B** (Scheme 24).[22,149]

Scheme 24. Stereochemical origin of the observed formation of the thermodynamically less stable [(biaryl)$Cr(CO)_3$] complexes *syn*-**129**. The blue arrow indicates the rotation that occurs upon biaryl-bond formation.

In both species, the $\{Cr(CO)_3\}$ fragment is directed towards the other arene moiety thus avoiding severe steric interactions with the bulky PPh_3 ligands, but **128A** is thermodynamically favored due to the weaker steric repulsions between H and R_L relative to those between R and R_L in **128B**. The rate-determining reductive elimination in **128A** leads, under kinetic control, to the chromium biaryl complex *syn*-**129** as the simultaneous rotation around the forming biaryl axis proceeds in a way that minimizes the steric interactions: The H atom is turned "outside" towards the bulky PPh_3 ligand and the substituent R moves "inside" towards the $\{Cr(CO)_3\}$ moiety.



By heating in aromatic solvents, the trisubstituted biaryl compounds *syn*-**130** can be isomerized to give the thermodynamically more stable atropodiastereomers *anti*-**130** (Scheme 25, top).[149,154,155] Similar attempts with naphthalene biaryl chromium complexes resulted in lower conversion rates owing to increased steric bulk restricting rotation around the biaryl axis. Functionalization of one of the *ortho* substituents may also lead to a thermodynamically driven axial rotation, even at room temperature.[149,154,156] This occurs preferentially (but not necessarily)[154] if the steric demand of the substituent

Scheme 25. Atropodiastereomerization of *syn*-**130** to give *anti*-**130** under thermal conditions and axial rotation upon oxidation of *syn*-**131** to give *anti*-**132** (all compounds racemic).

decreases, for example, in the oxidation of the CH_2OH substituent of *syn*-**131** to the respective formyl group of *anti*-**132** (Scheme 25, bottom).

Planar-chiral [(arene)$Cr(CO)_3$] complexes have been used in the atropoenantioselective synthesis of the AB fragment of vancomycin (**1**, for the structure, see Figure 1),[157,158] of the naturally occurring biaryl compounds (−)-steganone ((*M*)-**107**; Scheme 17),[159] and of korupensamines A ((*P*)-**137**) and B ((*M*)-**137**).[160,161] The latter two were prepared in an atropodivergent approach (Scheme 26) from the enantiomerically pure planar-chiral [(arene)$Cr(CO)_3$] complex ($_PS$)-**133**.[160,162,163] Its Suzuki coupling with the naphthyl 1-boronic acid **134** delivered the planar and axially chiral biaryl ($P,_PR$)-

Scheme 26. Atropodivergent synthesis of korupensamines A ((*P*)-**137**) and B ((*M*)-**137**) starting from the enantiomerically pure [(arene)$Cr(CO)_3$] complex ($_PS$)-**133**.

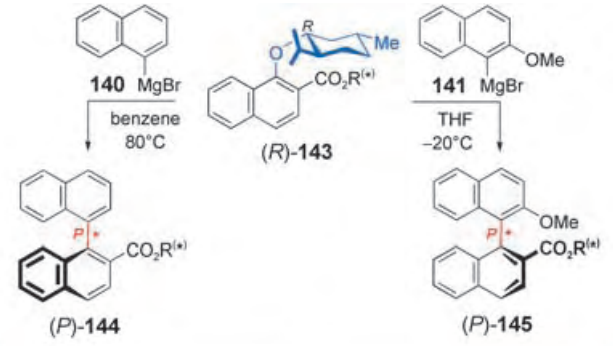
135 in 74% yield. After oxidation of the CH_2OH group to the aldehyde, the axial configuration can be inverted by thermal diastereomerization to give the *M*-configured biaryl (*M*,$_P$*R*)-**136** in 65% yield. Both biaryl compounds (*P*,$_P$*R*)-**135** and (*M*,$_P$*R*)-**136** were demetalated and used as intermediates in a total synthesis of (*P*)- and (*M*)-**137**.[164,165]

The major advantages of the "[(arene)Cr(CO)$_3$] method" are the high yields and the excellent, in many cases almost complete, stereoselectivities achieved in the aryl–aryl coupling step, and that both atropisomers are, in principle, accessible from a single planar-chiral precursor by thermal axial isomerization. The {Cr(CO)$_3$} fragment can be removed by photooxidative demetalation (*hv*, O_2) with yields between 50 and 90%, depending on the substrate. Besides the toxicity of the chromium compounds, the most problematic limitation is the restricted and laborious access to the enantiomerically pure [(aryl halide)Cr(CO)$_3$] complexes that are crucial for the preparation of stereochemically homogeneous biaryl systems.[166] Furthermore, the otherwise excellent coupling yields and diastereoselectivities decrease with increasing steric hindrance at the coupling sites, thus hampering the atroposelective synthesis of, for example, tetra-*ortho*-substituted biaryl compounds. The range of tolerated substituents is limited; there seems to be no general rule and extensive trials are required to find the respective optimum system. To date, Suzuki couplings of more-sophisticated (and, thus, harder-to-access) [(aryl halide)Cr(CO)$_3$] complexes have not been reported.

An elegant approach without any transition-metal complex was reported by Miyano and co-workers (Scheme 27).[167] Nucleophilic attack of enantiomerically pure dioxocyclophane ($_P$*R*)-**139** by the naphthyl Grignard reagents **140** and **141** with concomitant cleavage of the ansa chain delivered (*P*)-**138** and (*P*)-**142**, respectively, in high yields and *ee* values. The opposite stereoarrays at the biaryl axes of (*P*)-**138** and (*P*)-**142** appear to be a result of the coordination abilities of the *ortho*-methoxy group versus the steric demand of the naphthalene ring.[63]

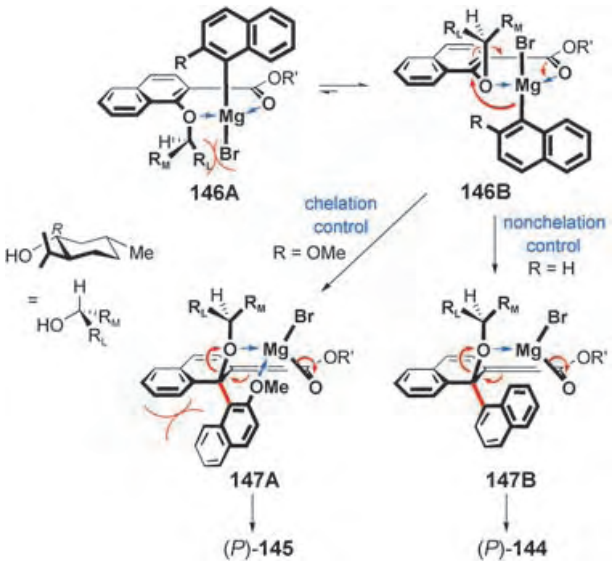


Scheme 27. Atroposelective synthesis of (*P*)-**138** and (*P*)-**142** by Grignard coupling of **140** and **141** with the planar-chiral dioxocyclophane ($_P$*R*)-**139**.[63]

3.4. Intermolecular Coupling with Chiral Leaving Groups

Biaryl synthesis by nucleophilic aromatic substitution (S_NAr) offers the chance to use a chiral leaving group as the source of the asymmetric information. This concept usually provides the advantage of an easy introduction of the chiral auxiliary into the molecule; it is then automatically replaced in the aryl–aryl bond formation, without the necessity of an additional removal step. Furthermore, with the asymmetric information located so close to the reaction center, high levels of chirality transfer should be achievable. This promising and—overall—enantioselective approach has been realized in the coupling of aryl Grignard compounds with chirally modified alkoxy arenes and aryl sulfoxides. As with the related Meyers methodology (see Schemes 15–17),[126,137] an ester (or oxazoline) function *ortho* to the leaving group is necessary to stabilize the intermediate negative charge and to ensure formation of a rigid and stereochemically well-defined transition state.

As early as 1982 Wilson and Cram screened several chiral alcohols for their suitability as chiral leaving groups, but only (*R*)-menthol was found to give satisfactory optical purity and chemical yields in the coupling step.[168] Later, Miyano and coworkers investigated coupling reactions of the alkyl 1-(*R*)-menthoxynaphthalene-2-carboxylates (*R*)-**143** with the naphthyl Grignard reagents **140** and **141**.[169] The binaphthyls (*P*)-**144** and (*P*)-**145** were obtained in high yields with up to 98% *ee* (Scheme 28). The influence of additional stereochemical information in the ester group on the enantioselectivity is inconsistent and negligible (see also beginning of Section 3.2).



Yield [%]	*ee* [%]	R(*)	Yield [%]	*ee* [%]

93	76	(*R*)-menthyl*	81	98
74	91	(*R*)-phenylethyl*	85	91

Scheme 28. Atropoenantio- or atropodiastereoselective biaryl synthesis by S_NAr on the chirally modified 1-(*R*)-menthoxy naphthalenes (*R*)-**143**.[63]

The two products, (*P*)-**144** and (*P*)-**145**, have opposite axial configurations (despite their identical stereodescriptors),[63] which was explained by chelate versus nonchelate control (Scheme 29):[169,170] Of the two possible chelate complexes **146** formed between the two reactants in the initial step, the diastereomer **146B** is thermodynamically favored over **146A** owing to the asymmetry of the menthol leaving group. Aryl migration in **146B** preferentially leads to the conformer **147A** if a coordinating group, in this case OMe, is present. Its strong intramolecular ligation to the magnesium center overrides the steric repulsion between the two naphthyl moieties. In the absence of a coordinating substitu-

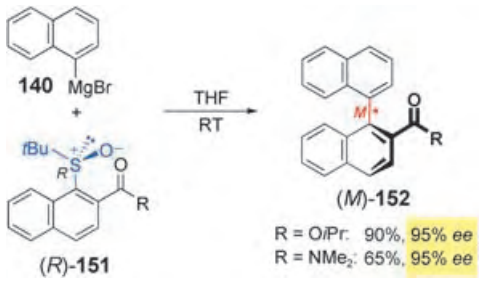
Scheme 29. Chelation versus nonchelation control in atropoenantioselective biaryl formation through S_NAr reaction with chiral leaving groups.



ent (R = H), conformer **147B** is favored, in which the destabilizing steric interactions are minimized. The respective axial twists are conserved into the products (*P*)-**145** and (*P*)-**144**.

In contrast to the formation of binaphthyls, the analogous preparation of biphenyls proved to be more difficult, with tri-*ortho*-substituted examples giving mainly modest atropoenantioselectivities.[171] The reaction of **148** with (*R*)-**149** to afford the tetra-*ortho*-substituted biphenyl (*M*)-**150** did, however, proceed in high chemical yield and optical purity (Scheme 30).

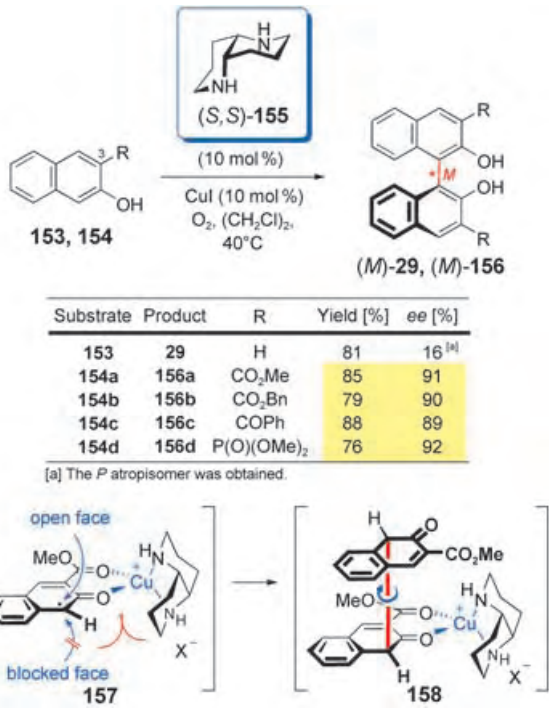
Scheme 30. Highly atropoenantioselective coupling of **148** with the aryl (*R*)-menthylether (*R*)-**149** to give (*M*)-**150**.

Chiral sulfoxides as non-ether-based leaving groups were evaluated by the groups of Baker and Sargent (Scheme 31).[172] Grignard coupling of **140** with the naphthyl 1-sulfoxides (*R*)-**151** delivered the binaphthyls (*M*)-**152** in good to high yields and with excellent stereocontrol (95% *ee*). Nevertheless, this approach is hampered by several disadvantages: No coupling reaction was observed with the sterically more demanding 2-methoxy derivative of **140**, and the preparation of (*R*)-**151** in enantiopure form is rather labor-

Scheme 31. Atropoenantioselective binaphthyl syntheses by using the chiral sulfoxides (*R*)-**151** as starting materials.

intensive. The more easily accessible tolyl analogue of (*R*)-**151**, in which *t*Bu is replaced by *p*Tol, is less suited for this type of biaryl coupling since it racemizes under the reaction conditions, thus leading to diminished atropoenantioselectivities (60–82% *ee*).

Even though the initial investigations were done more than 20 years ago, this approach is still in its infancy. Chiral leaving groups that are more widely applicable and easier to attach chiral leaving groups need to be developed to make this method, which relies on a stoichiometric use of the chiral auxiliary, more flexible and therefore competitive to other Grignard-based biaryl coupling reactions.



3.5. Oxidative Homocoupling in the Presence of Chiral Additives

The oxidative coupling of phenols is by far the most widespread pathway in the biosynthesis of biaryl natural products; it is also a common laboratory method for the formation of binol (1,1′-dinaphthalene-2,2′-diol) derivatives from the respective 2-naphthols.[173] Owing to the good availability of the "monomeric" substrates, the convenient reaction protocols, and the importance of the products as chiral auxiliaries in asymmetric synthesis, many attempts have been undertaken to translate this chemistry into atroposelective syntheses.

The most widely investigated catalysts to fulfill this goal have been chiral amine–copper salts, mainly due to the ease of ligand screening. It should be noted that the first preparation of highly enantiomerically pure binaphthyls reported by Brussee et al., by the homocoupling of 2-naphthol in the presence of $CuCl_2$ and amphetamine, was shown to be a dynamic kinetic resolution of binol and not the consequence of an atropoenantioselective biaryl coupling step, and will thus be covered in Section 4.2.4.[174]

Highly successful and truly enantioselective oxidative biaryl couplings[175] catalyzed by Cu^I in the presence of a chiral amine were published by Kozlowski and co-workers in 2001,[176–179] with the C_2-symmetric (*S*,*S*)-1,5-diazadecalin (*S*,*S*)-**155** as the ligand and O_2 as the stoichiometric oxidant (Scheme 32). In the presence of CuI and (*S*,*S*)-**155** (10 mol% each), the homocoupling of the 2-naphthol derivatives **154** to give (*M*)-**156** proceeded in good yields with up to 92% *ee*. A coordinating substituent at C3 (carboxylic or phosphonate ester, benzoyl) is crucial to attain high atroposelectivities, as is clear from the low stereocontrol achieved in the preparations

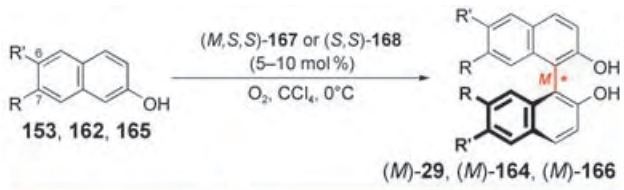
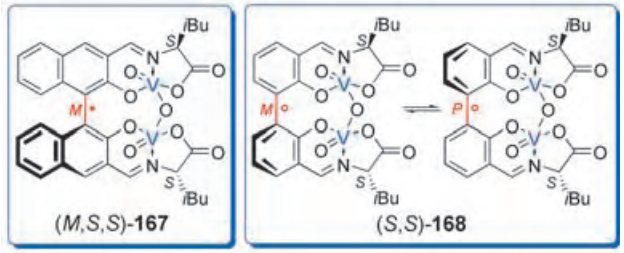
of binol itself (**29**, 16% *ee*). Thus, the stereochemical outcome was rationalized by bidentate coordination of the substrate to the chiral amine–copper complex.[176,180] As exemplified for the homocoupling of **154a**, electron transfer should lead to the formation of the tetrahedral $[Cu^{I}]$ complex **157**, which carries a C-centered radical.[176] The second substrate should approach from the less-hindered top face to give **158** stereoselectively. Tautomerization along with clockwise rotation around the forming biaryl axis should then establish the observed axial configuration.



Although the requirement for a suitable substituent at C3 to aid bidentate coordination is an obvious limitation to its scope, this method does provide efficient catalytic enantioselective access to chiral binol derivatives. The synthetic potential of this approach was demonstrated by the enantioselective preparation of the perylenequinone (*M*)-**161** catalyzed by CuI/(*S*,*S*)-**155** (Scheme 33).[181,182]



The oxidative homocoupling of 2-naphthols in the presence of ruthenium(II)–salen catalysts (Scheme 34) developed by Katsuki and co-workers involves a single-electron transfer upon irradiation with visible light.[183] (*M*)-Binol ((*M*)-**29**) and its derivatives (*M*)-**164a** and **b** were obtained in reasonable chemical yield and optical purity (65–68% *ee*), whereas a low *ee* value of 33% was found for the methoxy-substituted biaryl (*M*)-**164c**. The ester **162d** failed to give a coupling product. With regard to the structural requirements in the salen catalyst (*P*,*P*)-**163**, changes in the chiral bridge did not significantly affect the stereoselectivity. Substitution of the two axially chiral binaphthyl moieties by simple aryl groups, however, decreased the enantioselectivity considerably, indicating the crucial role of the two binaphthyl units around the metal center for the chirality transfer.

A variety of V^{IV}-based catalysts have also been studied for their application in asymmetric oxidative biaryl couplings.[184,185] Most successful so far have been "dimeric" oxovanadium(IV) complexes of chiral Schiff bases with a biaryl backbone (Scheme 35). With 5 or 10 mol% of (*M*,*S*,*S*)-**167** or (*S*,*S*)-**168** as the chiral catalyst and O_2 as the stoichiometric oxidant, the homocoupling of 2-naphthol (**153**) and its derivatives **162** and **165**, which bear substituents at C6 or C7, proceeded in high yields with excellent stereocontrol (up to 97% *ee*).[184] Intriguingly, the complex (*S*,*S*)-**168**, which contains a configurationally labile biphenyl axis and, thus, may exist as a mixture of (possibly interconverting) diastereomers, is as selective as (*M*,*S*,*S*)-**167** with its configurationally stable *M*-binaphthyl scaffold.

In general, all the oxidative couplings described so far[186] were performed on 2-naphthol-derived substrates to give homodimeric 2,2′-dihydroxy-1,1′-binaphthalenes. The recent development of more-effective catalytic systems resulted, in many cases, in high chemical yields and optical purities with model substrates, but the potential of these methods for application to more-sophisticated substrates remains to be proven, also in terms of a wider tolerance towards functional

groups. Despite the limited range, the synthetic importance of the products thus easily accessible may lead to prominent applications of the method to the large-scale production of enantiopure C_2-symmetric binaphthols in the future.

Besides such chemically induced oxidative biaryl couplings of 2-naphthols, there is a single report on an electrochemical variant, utilizing a TEMPO-modified graphite-felt electrode in the presence of a stoichiometric amount of (−)-sparteine ((−)-**173**, Scheme 36), by Osa et al.[187] (*P*)-Binol ((*P*)-**29**) and its derivatives (*P*)-**171** and (*P*)-**172** were obtained in high yields (>90%) and with excellent atropoenantioselectivities (99, 94, and 98% *ee*, respectively). This electro-oxidative method, however, has three disadvantages: 1) It is not catalytic with respect to the chiral auxiliary (−)-**173**; 2) the (+) enantiomer of (−)-**173**, which is necessary to produce the *M* atropoenantiomers, is not commercially available; and 3) the equipment needed is not found in standard synthetic laboratories.

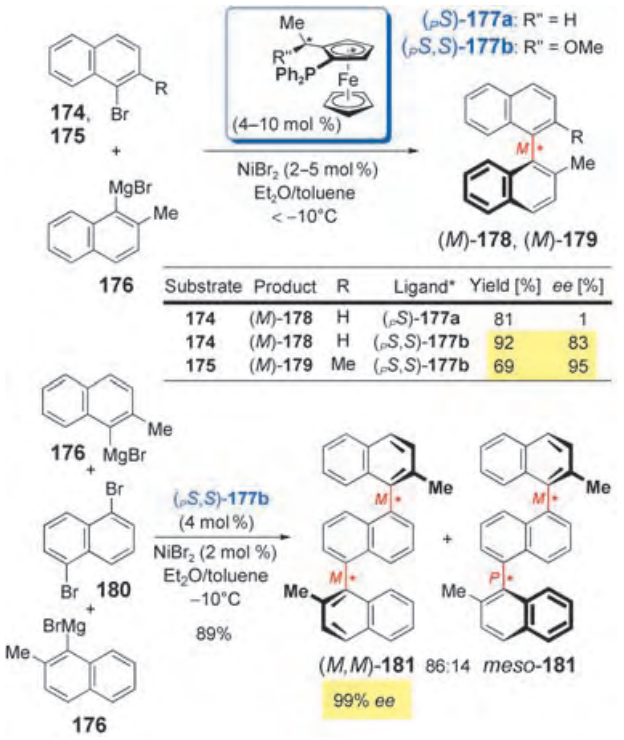
3.6. Redox-Neutral Cross-Coupling Catalyzed by Chiral Metal Complexes



Redox-neutral biaryl couplings, widely used in nonstereoselective biaryl synthesis,[19] provide several benefits: They proceed under relatively mild conditions, they are not restricted to a specific substitution pattern, and they allow regioselective cross-coupling of two different aromatic moieties—in contrast to the homocouplings described in the preceding section. The catalytic enantioselective version offers two additional advantages, making such an approach a nearly ideal method: First, the target biaryls are often accessible with all the substituents required already in place, thus avoiding any subsequent modification, for example, as in the case of diastereoselective coupling procedures with an attached chiral auxiliary. Second, with a chirally modified transition metal as the carrier of asymmetric information, it is one of the few methods that allows the catalytic and, thus, highly economical use of the chiral information. Despite all these favorable premises, there has been, as yet, only limited research activity in the field.

Based on initial investigations by the Kumada group,[188] Hayashi, Ito, and co-workers achieved the first successful atropoenantioselective cross-coupling of aryl halides with aryl Grignard reagents (Kumada cross-coupling).[24,189] The axially chiral binaphthalenes (*M*)-**178** and (*M*)-**179** were obtained in excellent yields and enantiopurities (up to 95% *ee*) from **174** or **175** and **176** in the presence of ≤5 mol% of $NiBr_2$, chirally modified with the ferrocenylphosphine ($_P$*S*,*S*)-**177** (Scheme 37).[162,190,191] This principle was extended to the atroposelective preparation of ternaphthalenes.[192] Cross-coupling of 2 equivalents of **176** with 1,5-dibromonaphthalene (**180**) catalyzed by Ni–($_P$*S*,*S*)-**177b** delivered the desired ternaphthalene (*M*,*M*)-**181** and *meso*-**181** in a 84:16 ratio. The nearly complete stereocontrol (99% *ee*) in the formation of (*M*,*M*)-**181** was interpreted as a result of the twofold asymmetric induction over both cross-coupling steps.[193] The methoxy group in the ligand ($_P$*S*,*S*)-**177b** is crucial for a good chirality transfer (($_P$*S*)-**177a**: 1% *ee* vs. ($_P$*S*,*S*)-**177b**: 83% *ee*). It was postulated that this group functions as a coordination site for the magnesium cation of the incoming Grignard reagent in the transmetalation step, thus creating the required defined stereochemical array (see the Meyers mechanism, Scheme 16).[189]

Due to the very few examples to date of the atropoenantioselective Kumada cross-coupling,[191] an evaluation of the scope and limitation of this method is not yet possible. The use of aryl Grignard reagents, however, makes this approach incompatible with several usual functional groups.

The Suzuki cross-coupling[194] is a most convenient method for the preparation of biaryl compounds as it utilizes aryl boronic acids or esters as the nucleophilic arene species; these are easy to handle (air-stable and storable) and are tolerant of a wide range of other functional groups. On the other hand, the Suzuki coupling normally requires relatively high temperatures and is susceptible to steric hindrance, which hampered its application in asymmetric biaryl synthesis for a long time. Recent solutions to these problems,[195]

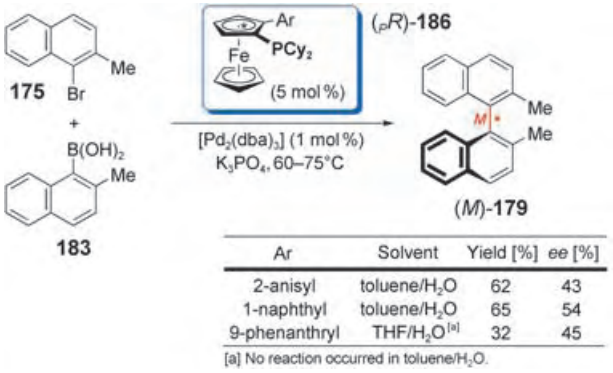
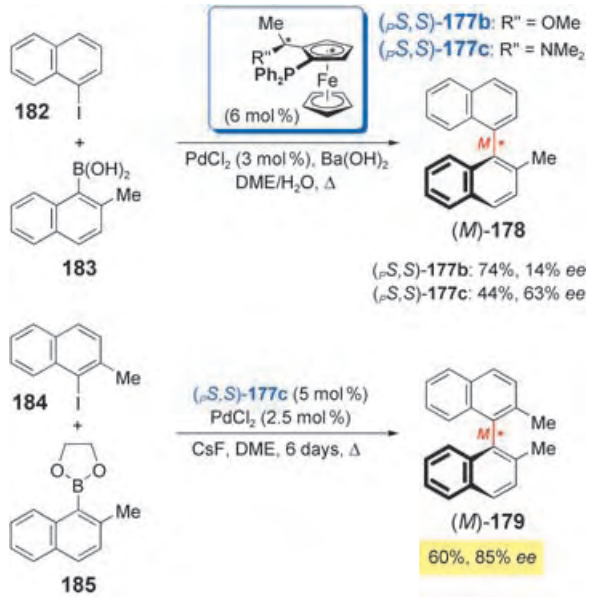


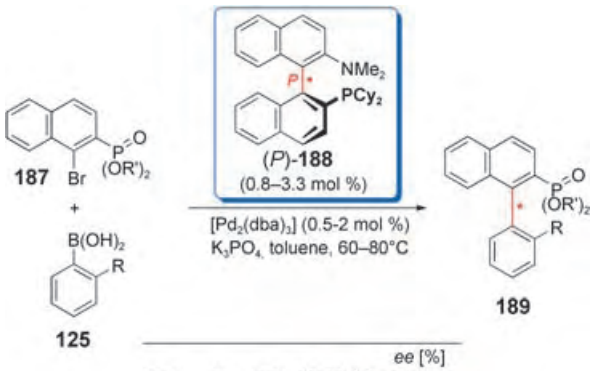
Scheme 37. Nickel-catalyzed atropoenantioselective Kumada cross-coupling of 1-bromonaphthalenes with the 2-methyl-1-naphthyl Grignard reagent **176** in the presence of the chiral ferrocenylphosphine ($_pS$,*S*)-**177b**.



however, triggered exploratory research in asymmetric Suzuki cross-couplings.

First investigations by Cammidge et al. in 2000 used 1-iodonaphthalene (**182**) and 2-methylnaphthalene-1-boronic acid (**183**) as model substrates (Scheme 38) with $PdCl_2$ (3 mol %) modified by the ferrocene-derived bidentate ligands ($_pS$,*S*)-**177** (6 mol %) as the catalytic systems.[196,197] With ($_pS$,*S*)-**177b**, which bears a methoxy substituent, the binaphthyl (*M*)-**178** was obtained in a good yield but with a disappointingly low 14 % *ee*; the P,N-derivative ($_pS$,*S*)-**177c** allowed a reasonably good enantioselectivity (63 % *ee*), albeit compromised by a mediocre chemical yield (44 %). This result is in contrast to the Kumada coupling (see preceding Scheme), in which ($_pS$,*S*)-**177b** was used successfully and ($_pS$,*S*)-**177c** failed to promote the coupling.[197] It was proposed that the stronger donor character of the NMe_2 group is necessary to precoordinate the less basic boronic acid in the same way that the methoxy substituent does with the magnesium cation of the aryl Grignard reagent in the Kumada coupling.[197] Suzuki cross coupling of the sterically more demanding aryl iodide **184** with the cyclic boronic ester **185** delivered the bis-*ortho*-substituted binaphthyl derivative (*M*)-**179** in 60 % yield with a good 85 % *ee*.[196,197]

In the group of Johannsen, the air-stable ferrocenyl-derived monophosphines ($_pR$)-**186** have been utilized as the chiral ligands for the [Pd_2(dba)$_3$]-catalyzed preparation of (*M*)-**179**[198] from **175** and **183** (Scheme 39).[199] Depending on the aryl substituent of ($_pR$)-**186**, selectivities of 43–54 % *ee* were attained.



Scheme 39. Asymmetric synthesis of the dinaphthalene (*M*)-**179** in the presence of the planar chiral ferrocenyl monophosphine ($_pR$)-**186**.[198]

Scheme 38. Atropoenantioselective Suzuki couplings with the bidentate ferrocenylphosphines ($_pS$,*S*)-**177** as the chiral ligands.

The most successful[200] asymmetric Suzuki couplings have so far been published by Buchwald and co-workers.[201] Initial screening showed that [Pd_2(dba)$_3$] and the electron-rich biaryl aminophosphine (*P*)-**188** were the catalytic system of choice. As shown by the examples given in Scheme 40, cross-coupling of the naphthyl phosphonate **187** with several phenyl boronic acids **125** delivered the axially chiral biaryls (+)-**189** (absolute configuration not determined) in excellent yields (as high as 98 %) with up to 92 % *ee*. These are the only asymmetric Suzuki couplings reported so far in which a phenyl (instead of a naphthyl) boronic acid was used. The amount of Pd/(*P*)-**188** (ratio 1.2:1) can be lowered to as little as 0.2 mol % without any decrease in the optical purity (Scheme 40, entries 5 and 6). As shown in separate experiments, the phosphonate group is not necessary to achieve the high stereocontrol; it can, however, be converted into a PPh_2 substituent, thus permitting easy access to axially chiral monodentate phosphines.

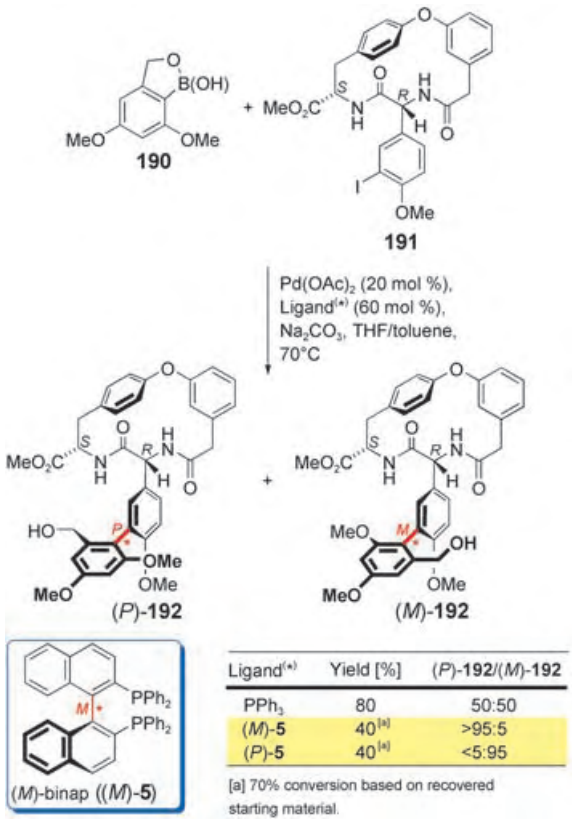

Scheme 40. Selected examples of the asymmetric Suzuki cross-coupling of **187** with different phenyl boronic acids **125** in the presence of the biaryl aminophosphine (*P*)-**188**.

There are very few applications of the asymmetric Suzuki cross-coupling in the directed synthesis of biaryl natural products; one notable example was reported by Nicolaou et al. (Scheme 41).[202,203] In model studies towards the atroposelective synthesis of the biaryl fragment of vancomycin (**1**), the Pd-catalyzed cross-coupling of the iodophenyl **191** and the cyclic boronic acid **190** to give **192** was investigated. Even though **191** is chiral, the two stereogenic centers do not influence the configuration at the biaryl axis in **192**, as is evident from the coupling in the presence of PPh_3 (0% *de*). However, (*M*)-**192** and (*P*)-**192** were obtained with high atroposelectivities (>90% *de*) in the presence of (*M*)-binap ((*M*)-**5**) and (*P*)-binap ((*P*)-**5**), respectively, as the chiral ligands.[204] Although the stereocontrol was excellent, the low chemical yields and the high amount of the chiral ligands used were not satisfactory.

The easy handling of the aryl precursors, the lack of dependence on particular substitution patterns, the relatively mild reaction conditions, and the catalytic nature of the reaction with regard to the chiral ligands all add up to make the asymmetric Suzuki coupling an attractive reaction strategy. However, only recent improvements have allowed its application in stereoselective biaryl synthesis, and there are, as yet, no standard procedures available; each new catalyst and substrate still requires time-consuming optimization of the particular reaction conditions (compare the different reaction conditions used in Schemes 38–41). Furthermore, the applicability of the method is often hampered by very long reaction times (up to 1 week) and the occurrence of hydrodeboronation, which requires excess aryl halide. New, more-effective ligands that deliver good and reliable chemical yields and optical purities under standardized conditions for a broad variety of substrates (including more-sophisticated systems) will have to be designed. The Suzuki cross-coupling could then become one of the most important methods for atroposelective biaryl coupling.

No asymmetric biaryl couplings with other aryl metal species such as aryl zinc (Negishi coupling) or aryl stannanes (Stille coupling) have so far been reported, but there is a single example of the use of a C_{arene}–$C(sp^3)$ cleavage with *ipso* substitution (Scheme 42).[205] Treatment of **193** with 2-(1-naphthyl)-2-propanol (**194**) in the presence of $Pd(OAc)_2$ and (*M*)-binap ((*M*)-**5**) delivered 2-methoxy-1,1′-binaphthalene (**195**) in 83% yield with a moderate 63% *ee* under extrusion of acetone. As this procedure avoids the use of any aryl metal species, it may offer new perspectives for atroposelective biaryl cross-couplings.

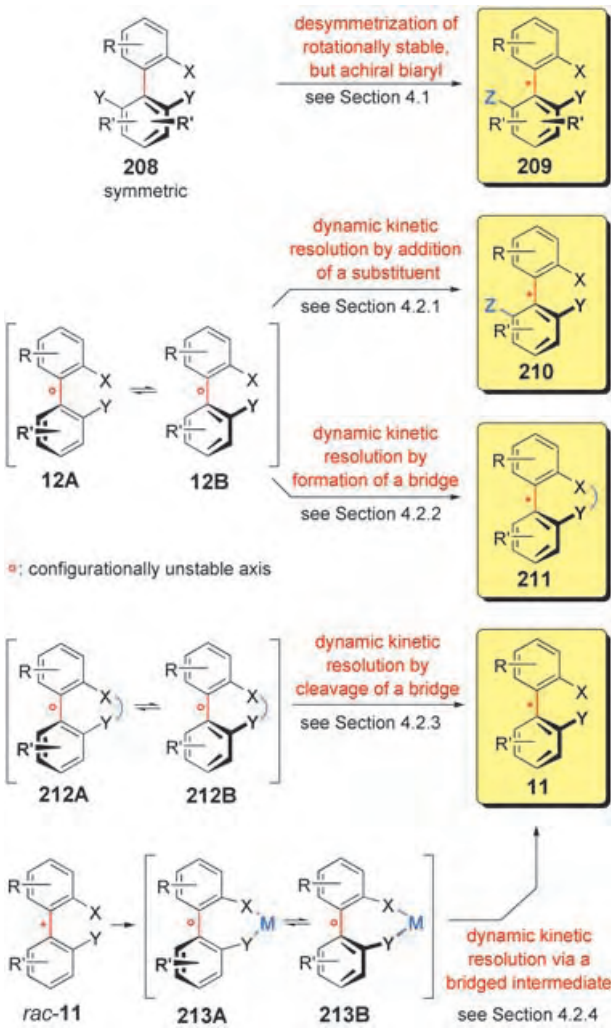
cations and lithiated phenols as the nucleophiles, was presented by Yamamoto and co-workers (Scheme 43).[206] In the presence of excess brucine (**201**) as the chiral auxiliary of choice, cross-coupling of lithiated 2-naphthol (Li-**153**) with

Scheme 43. Asymmetric coupling of aryl lead complexes with lithiated phenols in the presence of brucine (**201**).

the aryl lead **196** furnished the biaryl (*M*)-**197** in 83% yield with 89% *ee*, whereas the analogous reaction with aryl amines as the substrates occurred less stereoselectively, probably due to concomitant autocatalysis of the generated amine. The method was also applied successfully to the synthesis of teraryls. For example, treatment of **198** with **199** (2.5 equiv) in the presence of **201** delivered (*M*,*M*)-**200** in 99% yield with >98% *de* and 61% *ee*.[207] The use of brucine in catalytic amounts gave similar *ee* values but lower chemical yields. The observed selectivity was rationalized by coordination of brucine (**201**) and the phenolate to the lead atom to give, after reductive elimination of $Pb(OAc)_2$, either (*R*)-**202** or (*S*)-**202** as the intermediates, both of which have the correct stereochemical pre-*M* orientation at the future biaryl axis. Fast tautomerization conserves the axial configuration in the product (*M*)-**197**.

Tomioka and co-workers reported an efficient transition-metal-free asymmetric synthesis of biaryl compounds by nucleophilic aromatic substitution; the chiral information is provided by a catalytic amount of the chelating agent (*R*,*R*)-**205** (Scheme 44).[208] 1-Naphthyl lithium (**203**) forms a complex with (*R*,*R*)-**205** that adds stereoselectively to the 1-aryl fluoride **204** bearing an aldimine side chain, to give the postulated intermediate **206**. Elimination of LiF and central-to-axial chirality transfer affords (*M*)-**207**, with concomitant regeneration of the diether (*R*,*R*)-**205**. The reaction was, however, sensitive to small changes in the reaction conditions, and there has been little exploration of the substitution patterns tolerated.



Scheme 44. Asymmetric biaryl synthesis by nucleophilic aromatic substitution with the chiral chelating agent (*R*,*R*)-**205**.

4. Atroposelective Transformations of Prostereogenic Biaryl Compounds

Besides the conventional approach of direct, atroposelective biaryl coupling described in the preceding section, highly efficient alternative strategies have been found in which the construction of the target biaryl species is carried out over two separate steps: a nonstereoselective C–C coupling reaction and a second step that finally establishes the absolute configuration at the biaryl axis. This concept permits an optimization of each of the two steps independently.

For such an introduction of the stereochemical information at a preformed axis, the biaryl substrate has to be either rotationally hindered but achiral or chiral but configurationally unstable. The first criterion is met if (at least) one of the two aromatic portions is constitutionally symmetric, as in **208** (Scheme 45). An enantiotopos-differentiating transformation of one substituent (here Y→Z) will reduce the symmetry and, thus, lead to axially chiral biaryl products of type **209**. Concrete realizations of this approach are discussed in Section 4.1. Nonsymmetric biaryl compounds such as **12** and **212** that are macroscopically achiral owing to rapid atropisomeric interconversion can be used as substrates for dynamic kinetic resolution. One option, though rarely used, is the atropoenantiomer-differentiating introduction of another *ortho* substituent, which establishes and simultaneously "locks" the axial conformation as in **210** (see Section 4.2.1). Alternatively, atropoenantiomer-differentiating bridging of the two aromatic "halves" of **12** delivers axially chiral biaryl species of the type **211** if this process is associated with an increase in the rotational barrier sufficient to reach configurational stability (see Section 4.2.2). Vice versa, the cleavage of a short bridge that causes configurational instability, as in **212 A**⇄**212 B**, allows an elegant access to axially chiral biaryl products (see Section 4.2.3). Moreover, biaryl compounds that are configurationally stable under normal conditions can undergo atropodiastereomerization if transiently bridged by a transition metal; this protocol can be used for the dynamic kinetic resolution of biaryl species that are stereochemically stable under ordinary conditions, for example, *rac*-**11**→(**213 A**⇄**213 B**)→**11** (see Section 4.2.4).

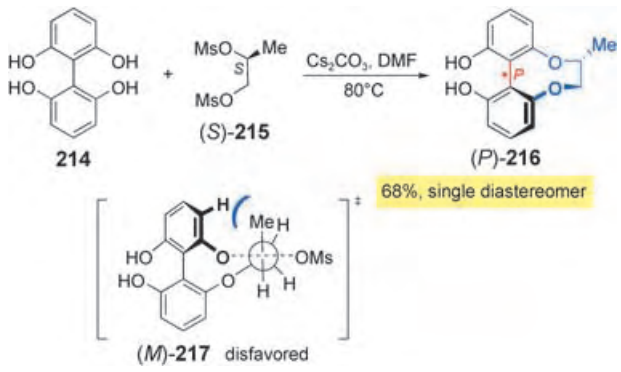
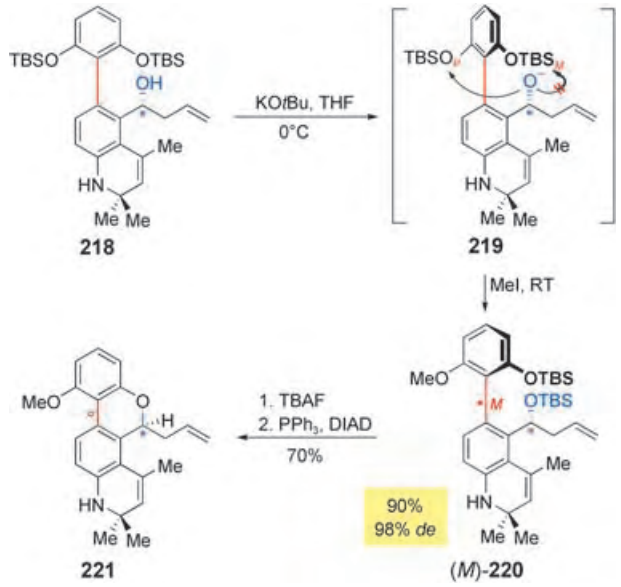


Scheme 45. Concepts for the atroposelective synthesis of biaryl compounds with preformed, but stereochemically not yet undefined biaryl precursors.

Before going into details, it should be noted that these methods, which rely on a separation of the coupling step and the introduction of the stereogenic information, are not necessarily more labor-intensive than the direct asymmetric coupling procedures described in the preceding section. The diastereoselective aryl–aryl bond-formation reactions, for example, necessitate the introduction and removal of a chiral auxiliary, and therefore require at least three steps for the atroposelective construction of a biaryl axis.

4.1. Desymmetrization of Configurationally Stable but Achiral Biaryl Compounds

The transformation of rotationally fixed, but symmetric (and hence achiral) biaryl species into axially chiral products requires a desymmetrization of the arene moiety which can be realized by an atropoenantiotopos or atropodiastereotopos modification of one of its substituents.

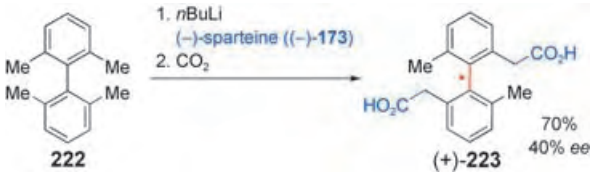


Harada and co-workers even succeeded in breaking the symmetry of the D_{2d}-symmetric tetra-*ortho*-hydroxybiphenyl (**214**) by atropodiastereoselective formation of an eight-membered diether bridge (Scheme 46).[209,210] Upon etherification of **214** with the chiral dimesylate (*S*)-**215**, the biaryl (*P*)-**216** was obtained in a diastereomerically pure form.[211]

Scheme 46. Desymmetrization of **214** by atropodiastereoselective formation of a diether bridge.

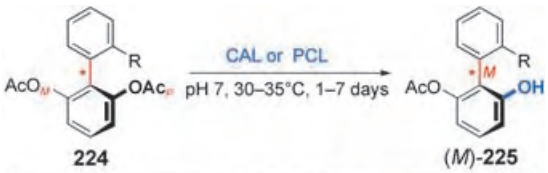
The excellent stereocontrol was rationalized to result during the formation of the second ether linkage: Of the two diastereomeric S_N2-type transition states, (*M*)-**217** is disfavored owing to the steric interactions of the methyl substituent with one of the aromatic rings. The method is limited to symmetrically substituted 2,2′,6,6′-tetrahydroxy biaryl compounds, but further modification of the two remaining hydroxy functions in the resulting biaryl diethers is possible[210,211] (e.g. by conversion into the corresponding ditriflates followed by Pd-catalyzed cross-coupling), thus broadening the scope of the method.

As part of the enantioselective synthesis of the antiinflammatory drug candidate A-240610.0 (**221**, Scheme 47), Ku and co-workers discovered an elegant central-to-axial chirality transfer. Upon O-deprotonation to **219**, the axially



Scheme 47. Desymmetrization of **218** using an internal central-to-axial chirality transfer.

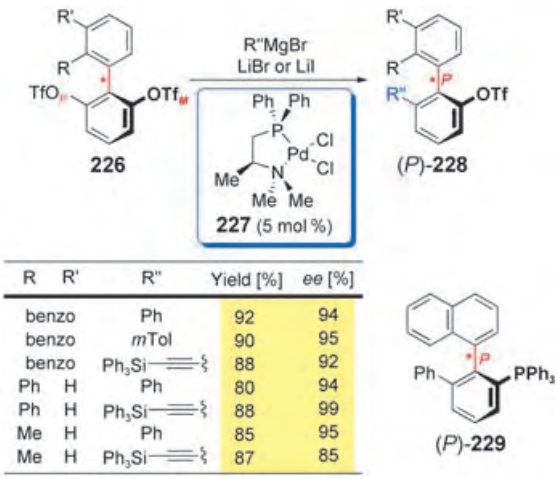
© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



prostereogenic, but centrochiral biaryl **218** underwent an atropodiastereotopos-differentiating migration of the sterically more accessible $OTBS_B$, energetically driven by the formation of a phenolate from an alkoxide, with an excellent 98% *de*.[212] This remarkable reaction was, however, not taken advantage of stereochemically, as the targeted drug candidate **221** does not actually have a configurationally stable biaryl axis owing to the labilizing effect of the ether bridge. Nevertheless, the route via the axially chiral biaryl (*M*)-**220** was necessary to obtain good yields in the final etherification step.[213] Despite its limitation to compounds that bear an α-chiral alcohol substituent in the *ortho* position, the approach allows access to axially chiral biaryl compounds otherwise difficult to prepare.[212]

An enantioselective dilithiation of the "axially pro-prostereogenic" tetra-*ortho*-methylated biphenyl **222** in the presence of the chiral auxiliary (−)-sparteine ((−)-**173**), followed by an electrophilic quench with carbon dioxide, was reported by Raston and co-workers (Scheme 48).[214] The biaryl diacid (+)-**223** was obtained with moderate stereocontrol (40% *ee*).

Scheme 48. Desymmetrization of **222** via enantioselective di-lithiation; the absolute configuration of (+)-**223** is unknown.



In an approach by Matsumoto et al. in which enzymes are used for the desymmetrization of prochiral biaryl compounds,[215] 2,6-diacetoxy-2′-alkyl biaryls **224** (Scheme 49) were enantioselectively monohydrolyzed at the OAc_P group with *Candida antarctica* lipase (CAL) and *Pseudomonas cepacia* lipase (PCL). The axially chiral 2-acetoxy-6-hydroxy-biaryls (*M*)-**225** were obtained in moderate to high yields (51–94%) and excellent enantioselectivities (≥96% *ee*), even for derivatives bearing small substituents R (e.g. R = Me). In all cases, the *M* atropisomer predominated, for which, however, no stereochemical rationalization was given.

PCL: *ee* [%] (yield [%])	99 (86)	96 (67)	98 (51)	98 (94)

Scheme 49. Desymmetrization of **224** by atropoenantiotopos-differentiating enzymatic O-deacetylation using CAL (*Candida antarctica* lipase) or PCL (*Pseudomonas capacia* lipase).

A remarkable enantiotopos-differentiating cross-coupling reaction was developed by Hayashi and co-workers.[216] Treatment of the achiral 2,6-ditriflates **226** (Scheme 50) with Grignard reagents in the presence of the chiral palladium

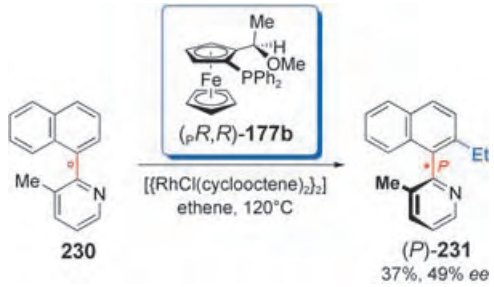
complex **227** delivered the axially chiral biaryl compounds (*P*)-**228** in good yields and high to excellent enantioselectivities (up to 99% *ee*). The stereochemical origin of the asymmetric inductions observed was not discussed. Even though most cross-couplings were performed with the naphthyl derivative of **226** (R, R′ = benzo), biphenyls with smaller substituents such as R = Me also allowed good stereocontrol. Because bulky Grignard reagents R″MgBr were used exclusively, no statement is possible about the steric size of R″ necessary for attaining high enantioselectivities. The remaining OTf group in the products (*P*)-**228** can be subjected to a second cross-coupling reaction, thus providing access to a wider range of biaryl compounds. The method is of appreciable synthetic potential; it has, for example, been used in the synthesis of the biaryl monophosphine ligand **229**, a catalyst for asymmetric hydrosilylation reactions.

The pioneering work on the desymmetrization of configurationally stable, but achiral biaryl species has led to intriguing novel asymmetric approaches to axially chiral biaryl products. The enantioselectivities have been good to excellent. Still, all these methods lack a broader applicability due to the substitution patterns required in the starting materials and the not yet fully explored tolerance of functional groups and more-sophisticated substrates.



4.2. Atroposelective Conversion of Axially Chiral but Configurationally Unstable Biaryl Compounds

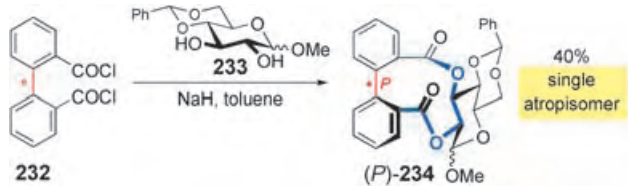
4.2.1. Atropoenantioselective Introduction of Another ortho *Substituent*

The conceptually simplest way to produce chiral biaryl compounds from configurationally labile biaryl species is to

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

introduce, in an enantiomer-differentiating manner, a further *ortho* substituent, thereby locking the axial configuration. Murai and co-workers reported the atropoenantioselective alkylation of 2-(1-naphthyl)-3-methylpyridine (**230**) through rhodium-catalyzed aryl C–H/olefin coupling (Scheme 51).[217] The yields and enantioselectivities were mediocre with all chiral catalysts screened; the best result (37 % yield, 49 % *ee*) was achieved with the planar- and centro-chiral catalyst (*pR*,*R*)-**177b**.

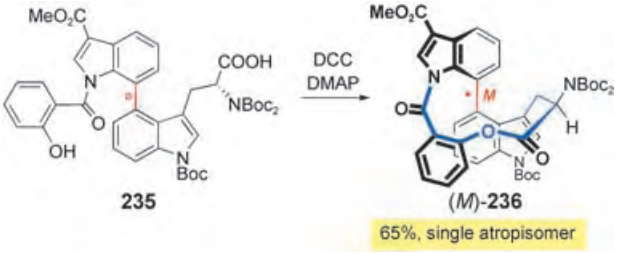
Scheme 51. Atroposelective *ortho* ethylation of **230**.



Owing to the aforementioned problems of enantioselectivity and the poor reactivity and regioselectivity, this direct approach has, as yet, been little used.

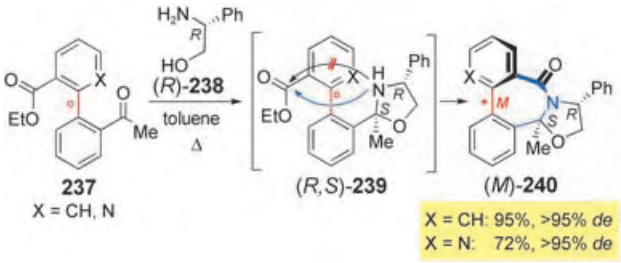
4.2.2. *Atropodiastereoselective Bridge Formation*

The bridging of *ortho* substituents to give medium to large rings can provide considerable rotational stability relative to the corresponding open-chain system (see **38** and **39**, Figure 9). Therefore, asymmetric syntheses have been envisaged in which the chiral information is introduced by a diastereoselective formation of a bridge, whereby an initially rotationally labile and hence macroscopically achiral biaryl system is "locked" into one of the two possible atropodiastereomeric forms.



In their studies towards ellagitannin derivatives, Nativi and co-workers found that treatment of racemic, configurationally unstable 2,2′-dibenzoyl dichloride (**232**) with the glycopyranose derivative **233** resulted in the formation of the sugar-bridged biaryl product (*P*)-**234** as a single atropodiastereomer, albeit in low yield (40 %, Scheme 52).[218] The rigid scaffold of **233** was pivotal to ensure efficient resolution, as analogous esterifications of **232** with more flexible rhamnose derivatives led to low *de* values.

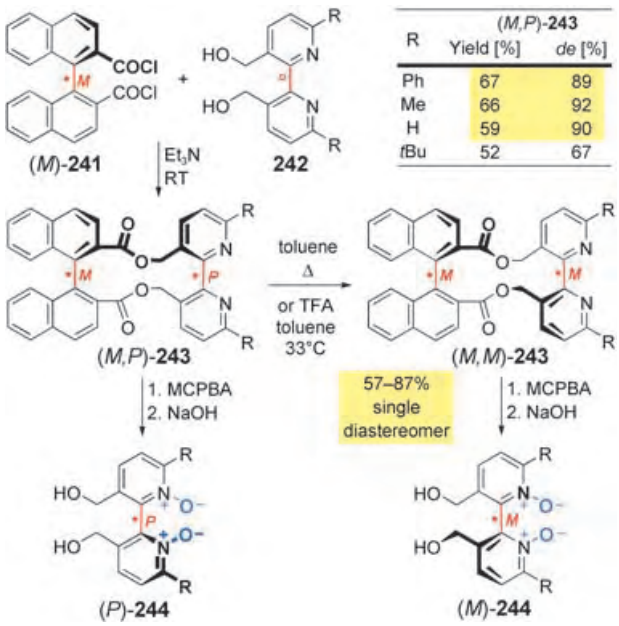
As part of their investigations towards the synthesis of the cytotoxic marine natural product diazonamide A, Feldman



Scheme 52. Dynamic kinetic resolution of 2,2′-dibenzoyl dichloride (**232**) by a glucopyranose-based scaffold.

et al. discovered a noteworthy atropodiastereoselective macrolactonization reaction.[219] Ring closure of the configurationally flexible model bisindole **235** afforded (*M*)-**236** as a single isomer (Scheme 53). The bulk of the $NBoc_2$ group was found to be pivotal for the excellent atropodiastereomeric differentiation; with the sterically less demanding NHBoc substituent, no preferred axial configuration was obtained.

Scheme 53. Atropodiastereoselective synthesis of the diazonamide A model (*M*)-**236** by macrolactonization.



Levacher and co-workers discovered an intriguing dynamic kinetic resolution through the formation of a lactam bridge.[220,221] Thus, configurationally unstable iso- or heterocyclic biaryl compounds **237**, equipped with ester and keto functions in the *ortho* positions, react with (*R*)-phenylglycinol ((*R*)-**238**) to afford the bicyclic lactams (*M*)-**240** with excellent diastereoselectivities (> 95 % *de*; Scheme 54). The axial configuration is dictated by the newly generated N,O-acetal stereocenter in the oxazolidine moiety of the intermediate **239**.[222]

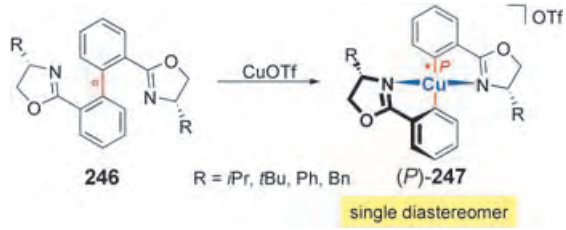
Scheme 54. Atropodiastereoselective synthesis of the biaryl lactams (*M*)-**240**.

An efficient reaction sequence in which the chiral bridge is used temporarily was developed by Hayashi and coworkers.[76] Upon esterification with the dichloride (*M*)-**241** of (*M*)-1,1′-binaphthyl-2,2′-dicarboxylic acid, the configurationally unstable bipyridine diols **242** gave the respective dilactones (*M*,*P*)-**243** with 67–92 % *de* (Scheme 55). These diastereomers constitute the kinetic products, since the axial configuration in the bipyridyl moieties can be completely inverted by thermal equilibration (accelerated considerably by addition of acid)[77] to give the pure atropodiastereomers (*M*,*M*)-**243**, without any decrease in stereochemical purity at the binaphthyl axis. Subsequent N-oxidation of (*M*,*P*)-**243** and (*M*,*M*)-**243** enhanced the rotational barrier at the bipyridine axis so that upon cleavage of the chiral auxiliary,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 55. Synthesis of the 2,2′-bipyridine *N*,*N*′-dioxides (*P*)-**244** or, optionally, (*M*)-**244**.

the 2,2′-bipyridine *N*,*N*′-dioxides (*P*)-**244** and (*M*)-**244**, respectively, were obtained as configurationally stable products. Therefore, this is one of the very few overall enantiodivergent methods that permit access to either of the two biaryl atropoenantiomers in high purity by using the same chiral auxiliary. The obtained *N*,*N*′-dioxides (*M*)-**244** have been successfully applied as catalysts in enantioselective allylations of aldehydes.



Such a secondary, thermodynamically driven inversion of an initially installed axial configuration was used in the synthesis of the aglycone of vancomycin (**1**, Figure 1) by Evans et al.,[116] as the biaryl axis formed at an earlier stage was of the undesired, non-natural *M* orientation (see Scheme 10). After construction of the planar-chiral CD ring system, the "wrong" axial configuration was elegantly "corrected" through complete axial inversion (Scheme 56): Thermal equilibration of (*M*)-**245** at 55 °C gave the desired natural axial isomer (*P*)-**245** with high diastereoselectivity.

Scheme 56. "Correcting" a "wrong" initial axial configuration by thermodynamic control: inversion of the axial configuration of (*M*)-**245** by thermal equilibration to give the naturally configured diastereomer (*P*)-**245**, a precursor to the vancomycin aglycone.

An alternative approach is the dynamic kinetic resolution of configurationally labile biaryl compounds by locking one of the two possible atropodiastereomeric conformations by chelation with a transition metal. This can be achieved if either the metal is chirally modified by another ligand[223] or if the biaryl substrate itself bears stereogenic centers.

A Cu^{I}-mediated deracemization of biaryl compounds was described by Ikeda and co-workers.[224,225] Upon addition of CuOTf, the 2,2′-bis(2-oxazolinyl)biphenyl derivatives **246**, which are configurationally labile at the axis (e.g., for R = *t*Bu: $\tau_{283\,K} = 0.07$ s), gave the complexes (*P*)-**247** as single diastereomers (Scheme 57). These complexes can be used as catalysts in asymmetric cyclopropanation reactions. The formation of the respective *M* atropisomers (*M*)-**247** is energetically disfavored owing to severe steric interactions between the substituents R (Scheme 69).

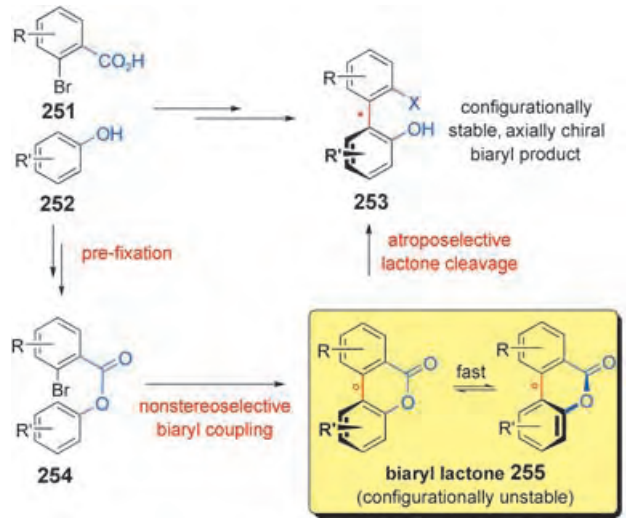
Scheme 57. Atropodiastereoselective bridging of the bisoxazoline-substituted biphenyls **246** by CuOTf.

More widely investigated is the dynamic kinetic resolution of configurationally labile biaryl–metal complexes by coordination of a second chiral ligand. This topic was recently reviewed[223] and thus will be dealt with only briefly here.

A classic example of such complexes, as given by Mikami, Noyori, and co-workers in 1999,[226,227] is the ruthenium complex **250** (Scheme 58), which was obtained by treatment

Scheme 58. Control of the axial configuration in the Ru-complex (*P*)-**250**.

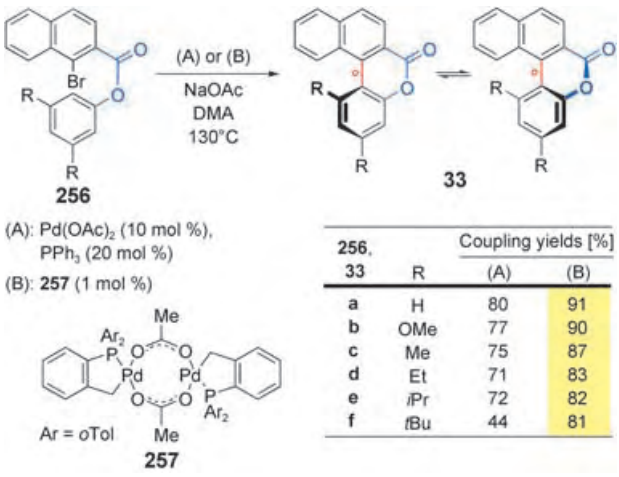
of racemic, configurationally labile [$RuCl_2$(biphep)] (*rac*-**248**) with the enantiopure diamine (*S*,*S*)-**249**. Although initially there was no preference for one diastereomer, atropodiastereomerization occurred upon heating to give the thermodynamically more stable complex (*P*)-**250** in a diastereomerically pure form. Compounds of this type have been used as enantioselective hydrogenation catalysts.



In summary, the bridging of conformationally flexible biaryl compounds can also provide stability in di-*ortho*-substituted biaryl systems at room temperature. An obvious

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

synthetic limitation of this approach is that the auxiliary bridge must remain part of the ultimate product, as its cleavage will lead back to a configurationally unstable biaryl compound, unless further transformations are undertaken. Therefore, this strategy has found its main field of application in the synthesis of biaryl natural products (or analogues) that bear appropriate functionality (i.e. a bridge and a controlling stereoelement), but has so far found limited use in general asymmetric biaryl synthesis. The kinetic resolution of biaryl compounds by chelation to a chirally modified metal center allows the application of otherwise achiral ligands in asymmetric catalysis. The approach is normally restricted to the formation and thus use of only one of the two possible atropodiastereomeric complexes—thus excluding the possibility to differentiate between a matched and a mismatched situation for application in asymmetric synthesis. Still, the strategy takes advantage of the well-known benefits of a chiral biaryl backbone in such catalytic systems, whilst avoiding the costly asymmetric synthesis or resolution of rotationally stable biaryl ligands.



4.2.3. *Stereoselective Cleavage of a Bridge*

Stereochemically labile lactone-bridged biaryls are the key intermediates of a very efficient—and practicable—strategy developed by our group for the asymmetric synthesis of even highly hindered biaryl compounds.[20] As is the case with the other concepts described in this section, this approach separates the aryl–aryl bond formation from the introduction of the stereochemical information at the biaryl axis, thus avoiding a direct asymmetric biaryl-coupling step. The principle of this strategy is depicted in Scheme 59. Initial pre-fixation of *ortho*-bromobenzoic acids **251** and phenols **252** delivers bromoesters **254**, which give the configurationally unstable biaryl lactones **255** by Pd^{II}-catalyzed aryl–aryl coupling. Atropoenantio- or atropodiastereoselective cleavage of the bridge by using a variety of possible chiral nucleophiles establishes the axial configuration at the resulting, now configurationally stable (as it is open-chained) biaryl products **253**.

Scheme 59. The principle of the lactone strategy.

The first crucial step of this approach, the synthesis of the biaryl lactones, is straightforward, as demonstrated for a whole series of model compounds **33** with a variety of steric bulk at the axis (Scheme 60). The easily accessible esters **256**

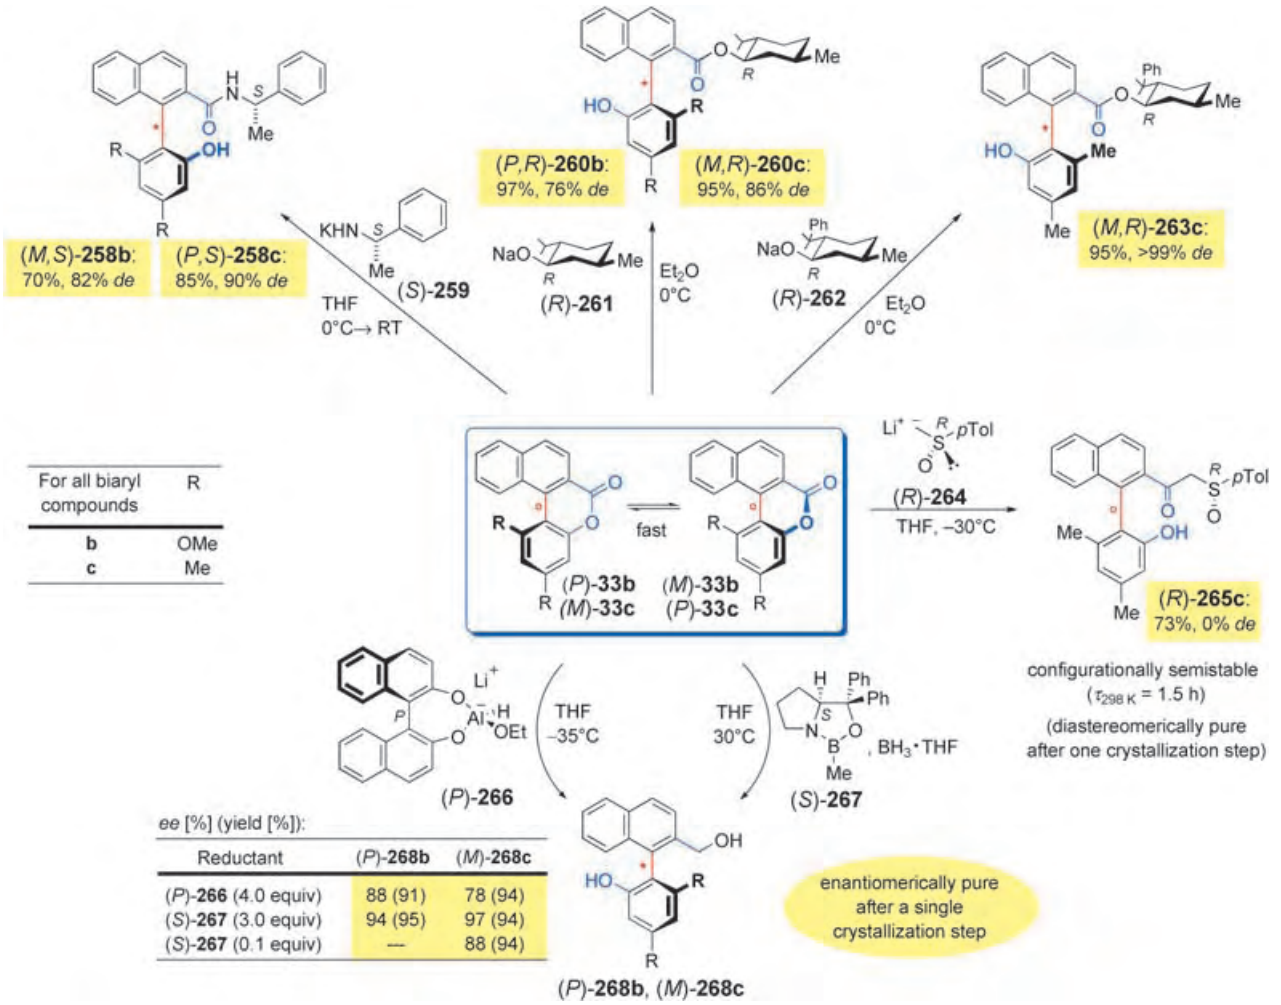

Scheme 60. Preparation of the biaryl lactones **33**.

undergo smooth aryl–aryl cross-coupling in the presence of catalytic amounts of $Pd(OAc)_2$ or the more reactive palladacycle **257**.[61,228] Owing to the favorable pre-fixation of the two aromatic units, the formation of the biaryl bond to form the six-membered ring occurs regioselectively and in high yields (up to 91%), even in cases of severe steric hindrance (for the structures and dynamics of such lactone-bridged biaryl species **33**, see Figure 7). As an example, the sterically severely distorted *t*Bu-substituted lactone **33f** is obtained in excellent yield (81%) with **257** as the catalyst.

The second crucial step requires the atroposelective transformation of the axially prostereogenic lactones **33** into configurationally stable biaryl compounds, which can be achieved simply by cleavage of the bridge with chiral O, N, or H nucleophiles (Scheme 61).[20,229,230] Potassium (*S*)-1-phenylethylamide ((*S*)-**259**) and sodium (*R*)-menthoxide ((*R*)-**261**) were the N and O nucleophiles of choice for the atropodiastereoselective ring opening of **33b** and **33c**, leading to the respective biaryl amides **258** and esters **260** in good yields (70–97%) and diastereoselectivity (74–90% *de*).[231–233] Almost complete control of the configuration at the biaryl axis was attained in the atropodiastereoselective cleavage of **33c** with the sterically more demanding sodium (*R*)-8-phenylmenthoxide ((*R*)-**262**), delivering exclusively the ester (*M*,*R*)-**263c** in 95% yield.[232]

The atropoenantioselective reduction of **33** was successfully accomplished either with (*P*)-binal-H ((*P*)-**266**) or, even better, with borane in the presence of the (*S*)-CBS reagent ((*S*)-**267**).[228,234] The biaryl diols (*P*)-**268b** and (*M*)-**268c** were obtained in high yields (>90%) and with up to 97% *ee*. Even if only catalytic amounts of (*S*)-**267** were used, the stereocontrol was preserved to a large degree (88% *ee* with 0.1 equiv vs. 97% *ee* with 3.0 equiv).[228,234] The size of the *ortho* substituent next to the axis (and the structure of the lactone **33** in general) usually has no influence on the

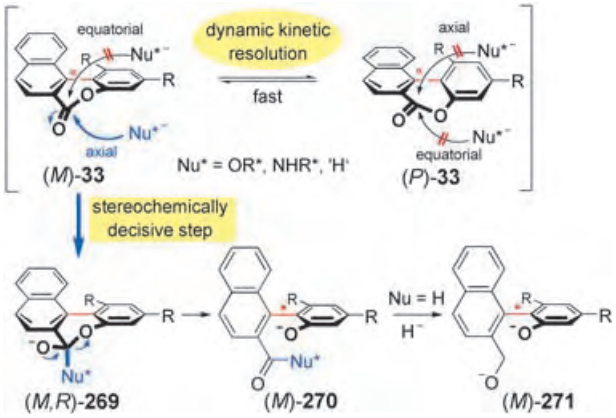
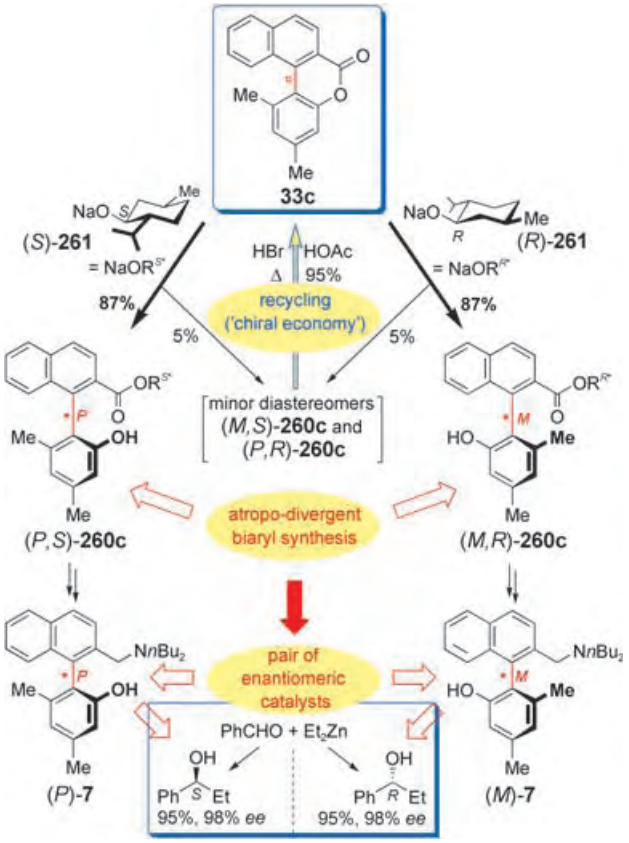


Scheme 61. Atroposelective ring opening of the lactones **33b,c** with chiral N, O, and H nucleophiles.[63]

direction of chirality transfer, making the ring-opening reactions not only efficient with respect to the chemical yields and optical purities, but also reliable with respect to the expected configuration.

No predominant axial configuration was found upon ring cleavage with chiral C nucleophiles.[235] The β-ketosulfoxide (*R*)-**265c**, for example, was obtained as a 1:1 mixture of its atropodiastereomers after treatment of **33c** with (*R*)-**264**. This is apparently not due to a nonstereoselective attack, but the consequence of the low configurational stability of (*R*)-**265c** at the axis. As is the case with most of the known biaryl compounds that bear an *ortho*-hydroxy and an *ortho'*-keto function,[62,64,82,84] (*R*)-**265c** is configurationally semistable at the axis ($\tau_{298\,K} = 1.5$ h; see also Figure 13), and thus rapidly loses any stereochemical information possibly attained in the ring-opening reaction. It can, however, be obtained diastereomerically pure by a single crystallization step.[236]

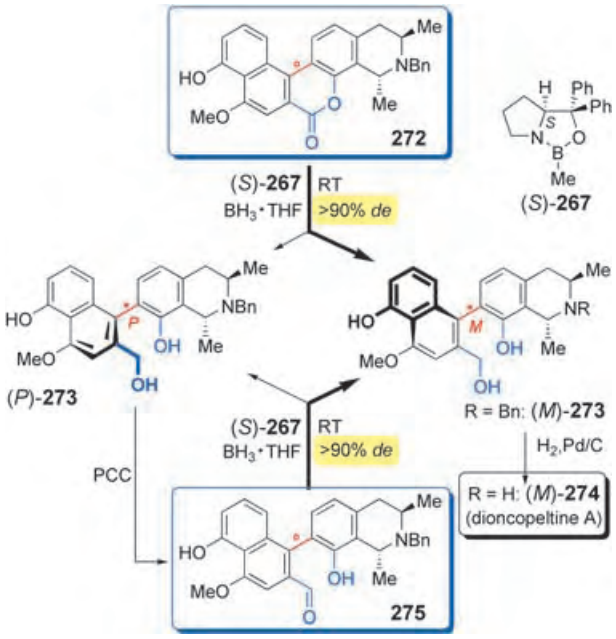
From a stereochemical point of view, the transformation of the lactones **33** into axially chiral biaryl compounds[20] can be considered as a dynamic kinetic resolution[237] (Scheme 62). The chiral nucleophile selectively attacks only one of the two atropoenantiomers of **33**, say (*M*)-**33**, which is steadily resupplied from the remaining enantiomer (*P*)-**33** through the rapid (*M*)-**33**⇄(*P*)-**33** equilibrium (see Figure 7),[238] thus allowing conversion of the entire racemic material of **33** into a stereochemically homogeneous product of either configuration. For the approach vector of the



Scheme 62. The assumed mechanistic course of the lactone cleavage with chiral nucleophiles; the stereodescriptors have been arbitrarily given for R = H, alkyl.[63]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

nucleophile, an axial attack is strongly favored over an equatorial one, as predicted by quantum-chemical calculations.[239,240] Consequently, the initial attack of **33** with an ideal chiral N or O nucleophile Nu^{*-} leads to just a single tetrahedral (orthoester-like) intermediate, for example, only to (*M*,*R*)-**269**, which will—more or less irreversibly—burst open to give (*M*)-**270** and, after protonation, lead to the axially chiral biaryl ester or amide. The same pathway, followed by a rapid second hydride transfer to (*M*)-**270** to give (*M*)-**271**, probably also accounts for the atroposelective reduction of the lactones **33** with chiral H nucleophiles.[241]

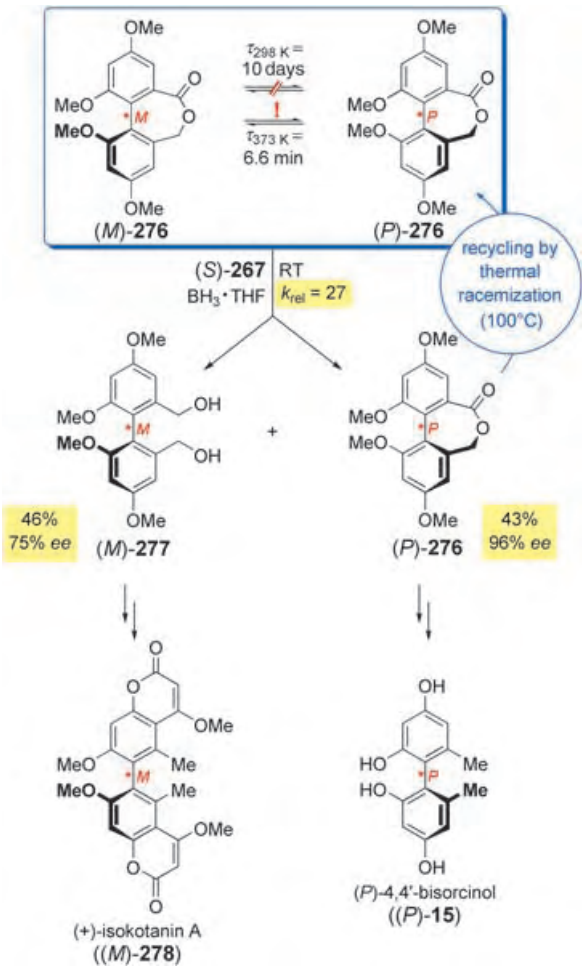


In addition to the versatility and the smooth conditions under which the atroposelective ring opening of **33** can be accomplished, the lactone approach offers another important advantage: the possibility to prepare either of the two atropisomers from the same precursor ("atropodivergence"). This feature is highly attractive in the synthesis of chiral auxiliaries and catalysts, which for a broad applicability of the method should be accessible in both enantiomeric forms. Such a demand is easily met with the lactone method as all the nucleophiles used to cleave the bridge (see Scheme 61) are commercially available in both enantiomeric forms. An example is the atroposelective synthesis of the biaryl amino alcohols (*P*)-**7** and (*M*)-**7** (Scheme 63), which have been demonstrated to be efficient catalysts for the enantioselective addition of diethylzinc to aldehydes (up to 98% *ee*).[17] In the key step, ring opening of **33c** with sodium (*S*)-menthoxide

Scheme 63. Two further advantages of the lactone method: atropodivergence and "chiral economy", illustrated in the directed synthesis of (*P*)-**7** or (*M*)-**7**.

((*S*)-**261**) delivered the ester (*P*,*S*)-**260c** in 87% yield, while the analogous reaction with the enantiomeric reagent (*R*)-**261** gave (*M*,*R*)-**260c**.[232] Furthermore, the minor product diastereomers, (*M*,*S*)-**260c** and (*P*,*R*)-**260c**, also obtained in the alcoholysis of **33c**, are not wasted, but can be easily recycled by acid-catalyzed recyclization back to the lactone.[242] Though not always required, this is a worthwhile option allowing economical use of precious material, for example, in multistep natural product syntheses.

The concept presented here is not restricted to six-membered biaryl lactones, but can be extended to other configurationally labile biaryl by the permanent or transient existence of short bridges, such as *ortho*-hydroxy-*ortho*′-aldehydes. An example is the naphthylisoquinoline **275** (Scheme 64). As discussed in Section 2 (Figure 13), these



Scheme 64. The atroposelective reduction of biaryl hydroxyaldehydes as a complement to the lactone cleavage, in this case applied to the synthesis of the natural product dioncopeltine A ((*M*)-**274**).

compounds do not form stable atropisomers, despite their formally ring-opened structure, because they are in equilibrium with their cyclic—and thus configurationally labile—lactol isomers. If the substituents next to the axis are small,[243,64] the stereoselective reduction of such hydroxyaldehydes (**275**→(*M*)-**273**, >90% *de*) provides a useful alternative to the lactone reduction (**272**→(*M*)-**273**, >90% *de*), as illustrated in the atroposelective synthesis of the antimalarial naphthylisoquinoline alkaloid dioncopeltine A ((*M*)-**274**).[244]

The seven-membered lactones **276** (Scheme 65) have significantly higher atropisomerization barriers than their six-membered analogues **33** (Figure 7). The interconversion rate of **276** is too slow ($\tau_{298\,K} \approx 10$ days) to be used in a *dynamic* kinetic deracemization, but a normal (i.e. nondynamic) kinetic resolution with subsequent thermal recycling of the unconverted starting material is possible.[245,246] Thus, reduc-

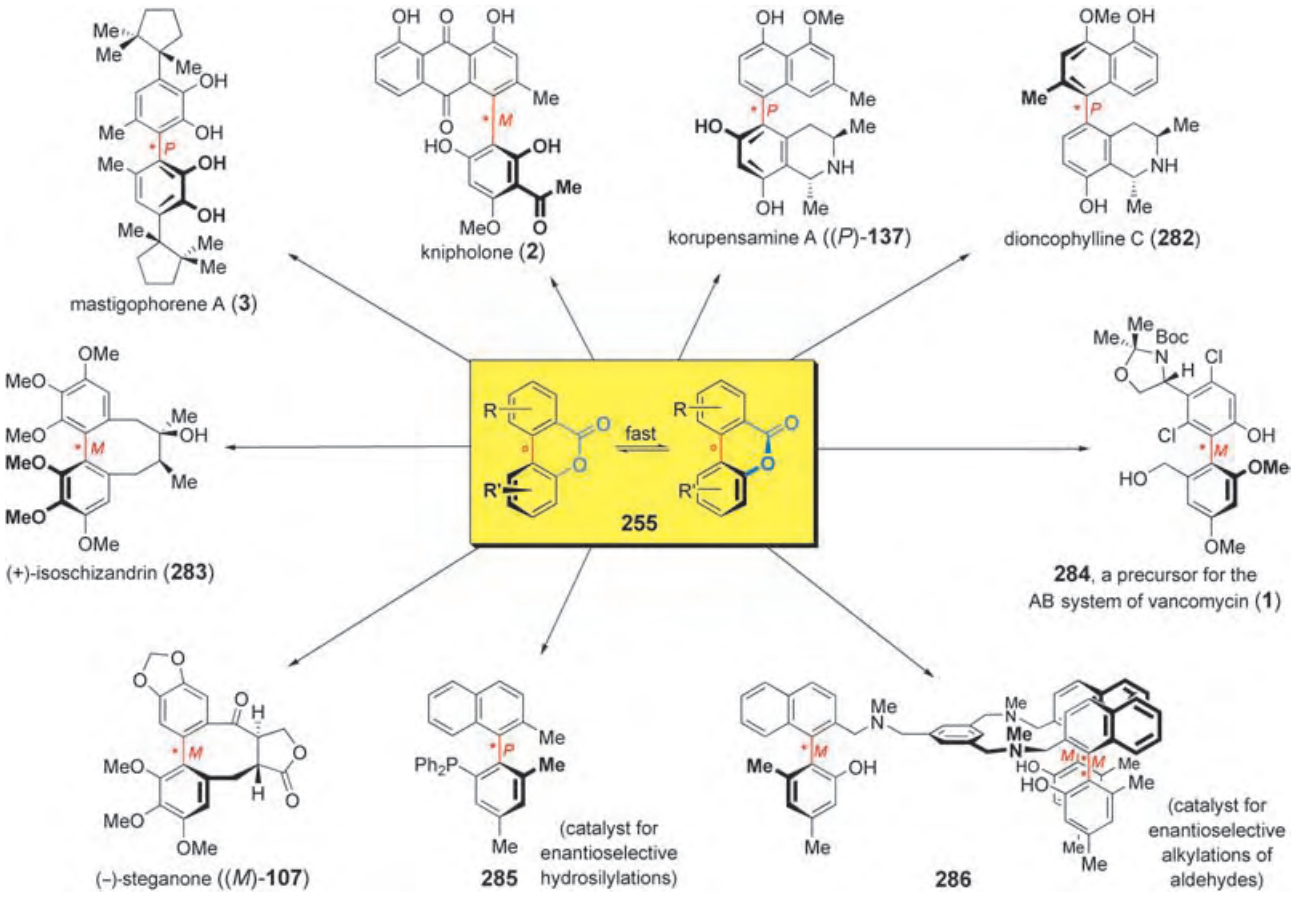
Scheme 65. Atropoenantioselective synthesis of (*P*)-4,4′-bisorcinol ((*P*)-**15**) and (+)-isokotanin A ((*M*)-**278**) by kinetic resolution of the configurationally stable biaryl lactone **276**.

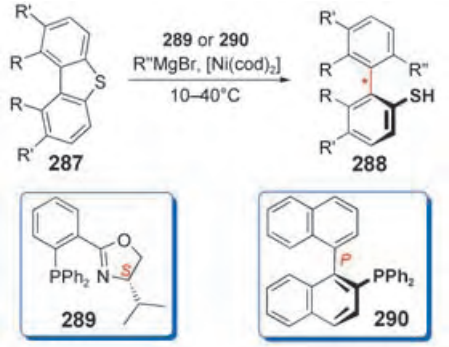
tion of racemic **276** with borane in the presence of the (*S*)-CBS reagent ((*S*)-**267**) delivered the diol (*M*)-**277** in 46% yield with 75% *ee* (95% *ee* after crystallization) and the lactone (*P*)-**276** in 43% yield with 96% *ee*, when the reaction was quenched at 56% conversion. The relative rate constant k_{rel} was calculated to be 27.[247] The lactone (*P*)-**276** can be recycled by thermal racemization at 100 °C ($\tau_{298\,K} = 6.6$ min) and resubmitted to a renewed ring cleavage with kinetic resolution; alternatively it can used as an enantiopure precursor for further synthesis. In the application presented here, (*P*)-**276** was converted into (*P*)-4,4′-bisorcinol ((*P*)-**15**), while the diol (*M*)-**277** was transformed into (+)-isokotanin A ((*M*)-**278**), both with high enantiomeric purities.

Within the lactone concept, a joint collaboration between Uemura and co-workers and our group showed that the element of planar chirality is excellently suited for transferring chiral information to the axis.[248] Treatment of the configurationally unstable lactones **279a** and **279b** (Scheme 66), which bear an *R*-configured 1-hydroxyethyl substituent *ortho* to the biaryl axis, with $[CpRu(CH_3CN)_3]PF_6$ delivered the centro-, axial-, and planar-chiral complexes (*M*,*R*,*pR*)-**280a** and (*P*,*R*,*pR*)-**280b**[163] regio- and diastereoselectively, owing to the directing effect of the OH function.



Scheme 66. Atropodiastereoselective biaryl lactone formation by using planar chirality as the chiral inductor, with subsequent ring cleavage and conversion into the metal-free biaryl products **281**.[63,162]

Cleavage of the lactone bridge with sodium methoxide and subsequent decomplexation gave the axially chiral biaryl compounds (*M*,*R*)-**281a** and (*P*,*R*)-**281b** as single diastereomers.



The potential and practicability of the lactone method has been demonstrated by its application in the atroposelective synthesis of more than 30 natural products and several useful catalysts,[20] some examples of which are presented in Scheme 67.[249–252] The lactone method is compatible with a variety of functional groups, works under mild conditions, and permits flexible and reliable access to a broad spectrum of structurally diverse biaryl species with any desired configuration at the axis. The carboxy- and phenol-derived *ortho* functions resulting from the ring-opening do not necessarily have to be part of the product, as they can easily be transformed or removed (see **282** and **285**). The lactone approach has also been used, among others, by Molander et al. in the total synthesis of (+)-isoschizandrin (**283**)[250] and by Abe, Harayama, and co-workers in a formal total synthesis of (−)-steganone ((*M*)-**107**).[251] Severe limitations of the method are not yet known.[253] The key six-membered biaryl lactone intermediates are C_1-symmetric and thus require the availability of two different building blocks (the phenolic moiety and the acid component). Hence the advantages of the method over other procedures are of particular significance for constitutionally *unsymmetrical* target molecules, whereas for simple C_2-symmetric products other procedures (e.g. homocoupling with subsequent racemate resolution if required) may be competing alternatives.

One other example in which an even shorter bridge—this time in a five-membered ring—is cleaved atropoenantioselectively, was reported by Hayashi and co-workers.[254] The asymmetric nickel-catalyzed cross coupling of the dibenzothiophenes **287** with Grignard reagents in the presence of chiral phosphines, including **289** and **290**, delivered the biaryl thiophenols **288** (Scheme 68). In some cases, both the chemical (up to 97%) and optical yields (up to 95% *ee*) were excellent, but this was not always true and the success of

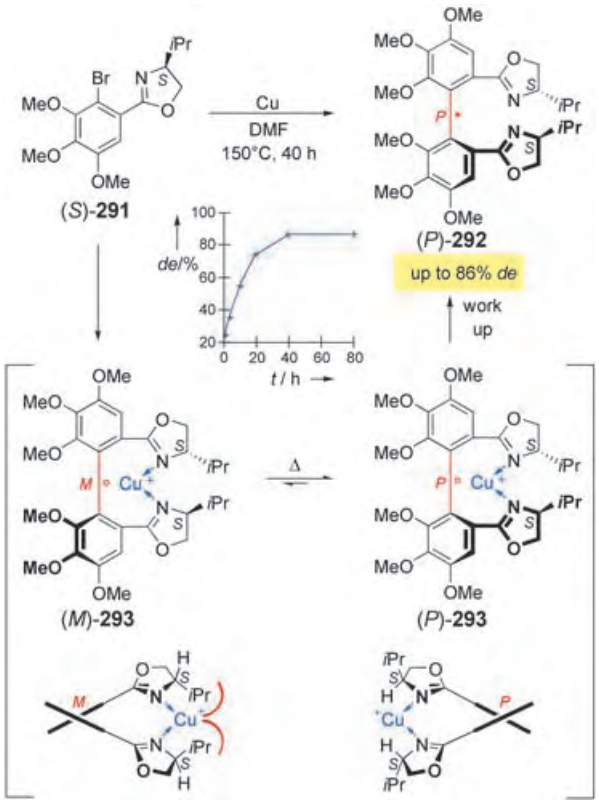
this intriguing reaction varied both with the size of the Grignard reagent employed and the nature of the original *ortho* substituents. It is believed that the nickel catalyst first inserts into the C–S bond, with the stereochemically deciding step being the transmetalation of the Grignard reagent or the following reaction.

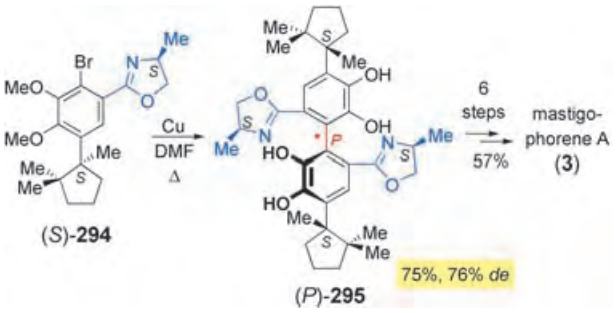


4.2.4. ***Transient Formation of a Short Metal Bridge***

As a rule, biaryl compounds with four *ortho* substituents are configurationally stable, even under forcing conditions (compare Figure 5). If equipped with two chelating groups next to the axis (e.g. binol (**29**)), however, an (albeit rather slow) atropisomerization can occur in the presence of an appropriate transition metal such as $Cu^{I/II}$, permitted by the resulting metallacycle with its (slightly) lower rotational barrier (see Section 2.2.2). If the metal or the substrate itself is chirally modified, this opens the possibility for the conversion of a racemic biaryl substrate into atropisomerically pure material by dynamic kinetic resolution, often already in situ, in the course of its formation.

Many Ullmann couplings of chiral *ortho*-halogenated oxazolinylbenzene derivatives, as developed by Meyers and co-workers,[126,137] are examples of the latter situation (for purely kinetically controlled atroposelective Ullmann cou-

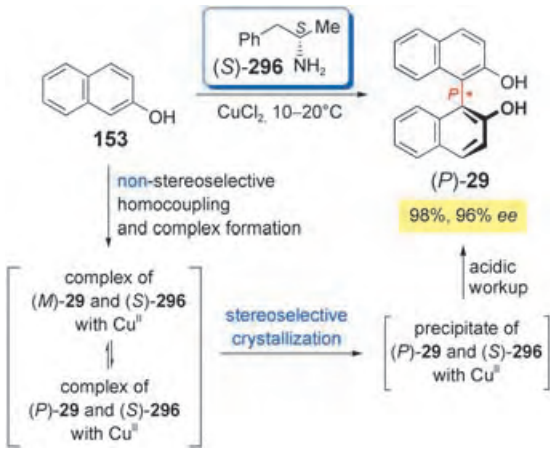
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



plings,[255] see Section 3.2). For example, the copper-mediated homocoupling of the L-valinol derived oxazoline (*S*)-**291** in DMF gave, after extended heating for 40 h, the atropodiastereomer (*P*)-**292** in 58% yield with 86% *de* (Scheme 69).[256,257] However, if the reaction was stopped

Scheme 69. Ullmann coupling of (*S*)-**291** with subsequent dynamic kinetic resolution by isomerization to the thermodynamically favored Cu^{I} complex (*P*)-**293**.

after 1 h, after which time all the starting material had already been consumed, (*P*)-**292** was isolated with much lower selectivity (24% *de*). As shown by the graph in Scheme 69, the *de* value of (*P*)-**292** increases with prolonged heating until a plateau is reached after 40 h. This proved that the high degree of stereoselectivity was not caused by an asymmetric coupling step, but was the consequence of a thermodynamically controlled deracemization (first-order asymmetric transformation).[136,258] It was postulated that the copper complexes formed initially, (*P*)-**293** and (*M*)-**293**, slowly interconvert at the elevated reaction temperature, thus leading to the preferred formation of the diastereomer (*P*)-**293** and alleviating the steric repulsion between the two isopropyl groups of the oxazoline moieties. The product (*P*)-**292** was further used in a short synthesis of an ellagitannin.[114,259]

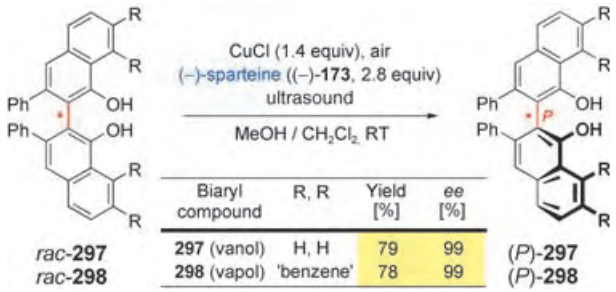


This strategy was further applied to the total synthesis of the axially chiral natural product mastigophorene A (**3**).[260] A key step of this approach was the asymmetric Ullmann homocoupling of the L-alaninol-derived aryl oxazoline (*S*)-**294**,[261] which gave the biaryl compound (*P*)-**295** in 75% yield with 76% *de* (Scheme 70).

Scheme 70. Total synthesis of mastigophorene A (**3**, Figure 1) by diastereoselective Ullmann coupling of the L-alaninol-derived aryl oxazoline (*S*)-**294**.

The Ullmann coupling of *ortho*-bromo(oxazolinyl)arenes with in situ dynamic kinetic resolution allows efficient access to axially chiral biaryl products with good to high stereocontrol. The prolonged heating required may, however, not be suitable for biaryl compounds with more-sensitive functional groups. Advantageously, the direct kinetically controlled Ullmann couplings of *ortho*-bromo(oxazolinyl)arenes (see Section 3.2) and the thermodynamic isomerizations described here always lead to the same stereochemical array at the biaryl axis, thus making the resulting axial configuration predictable and independent of the actual mechanism involved.

A spectacular early example of an atropoenantioselective biaryl synthesis by dynamic kinetic resolution was reported by Brussee et al.[174,262] (*P*)-Binol ((*P*)-**29**) was prepared in 98% yield with 96% *ee* by $CuCl_2$-induced oxidative homocoupling of 2-naphthol (**153**) in the presence of a large excess of amphetamine ((*S*)-**296**) (Scheme 71). The high enantiomeric purity, however, was not the result of an asymmetric coupling step, as initially assumed, but the consequence of stereoselective crystallization. Of the two intermediately formed diastereomeric complexes composed of Cu^{II}, (*S*)-**296**, and (*M*)- or (*P*)-**29** (no more details were given), only that containing the *P*-configured enantiomer of **29** crystallized,

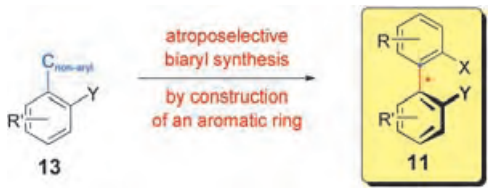


Scheme 71. Atropoenantioselective preparation of (*P*)-binol ((*P*)-**29**) by oxidative coupling of 2-naphthol (**153**) with concomitant stereoselective crystallization in the presence of amphetamine ((*S*)-**296**).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

steadily resupplied by concomitant atropisomerization of the remaining complex in solution (second-order asymmetric transformation).[136] The applicability of this reaction seems to be restricted to binol, and even in this important case, stereoselective crystallization only occurs within a narrow temperature range.

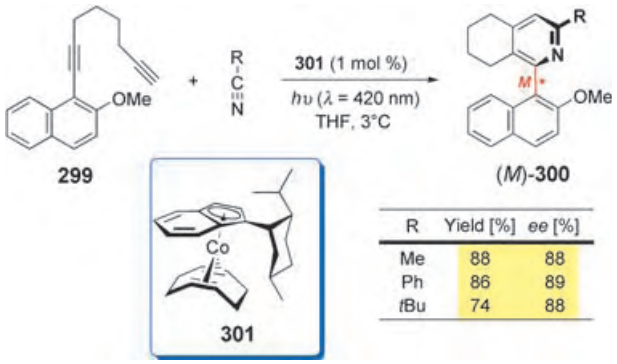
Recently, Wulff and co-workers published a highly enantioselective deracemization that is independent of any particular coupling step (Scheme 72).[263] Sonication of the



Scheme 72. Deracemization of *rac*-**297** and *rac*-**298** by using a complex of Cu^{2+} and (−)-sparteine ((−)-**173**).

racemic, *ortho*-dihydroxylated biaryl ligands vanol (**297**) and vapol (**298**)[264] in the presence of a chiral Cu^{II} complex, prepared in situ from CuCl and (−)-sparteine ((−)-**173**) by air oxidation, delivered the respective *P*-configured compounds nearly enantiopurely and in good yields. This deracemization, which occurred in homogeneous solution, is again a first-order asymmetric transformation that relies on the lowered rotational barrier and the relative thermodynamic stabilities of the intermediate Cu^{II} complexes formed. The mechanism is also supported by calculations that indicate that the complex [(*P*)-**297**/Cu^{II}/(−)-**173**] is more stable than its *M* diastereomer by as much as 16.4 kJ mol^{-1}. The deracemization also worked for binol (up to 94% *ee*). Such (−)-sparteine-mediated transformations are more generally applicable than that described above, which relies on a diastereoselective crystallization; nevertheless, despite the good *ee* values attained, definite drawbacks are the large excess of auxiliary required together with its availability in only one enantiomeric form.

5. Asymmetric Biaryl Synthesis by Construction of an Aromatic Ring

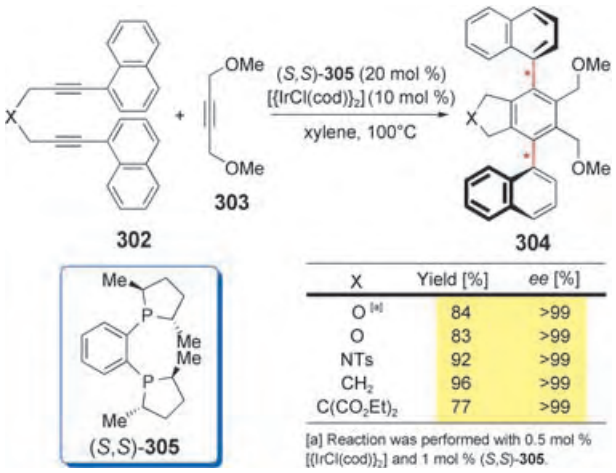


Besides the more classical direct asymmetric coupling reactions (as described in Section 3) and the atroposelective transformations on already prepared biaryl systems (see Section 4), a fundamentally new strategy for the construction of chiral biaryl compounds has emerged recently. In this concept, a preformed aryl–C single bond is transformed atroposelectively into the biaryl axis upon construction of the second arene ring from an aryl C substituent (Scheme 73). The chirality transfer to the axis results from a stereogenic center or by enantioselective catalysis. Only a few methods, which often involve asymmetric organometallic catalysis,

Scheme 73. The concept of atroposelective biaryl synthesis by construction of an aromatic ring.

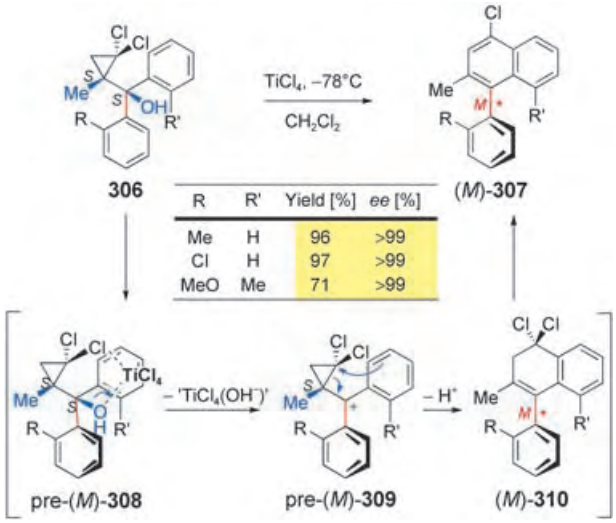
have been used to realize this exciting—though less general—idea.

Thus, the groups of Gutnov and of Heller synthesized axially chiral 2-aryl pyridines by a catalytic asymmetric [2+2+2] cycloaddition.[265] The reaction of the 1-naphthyl diyne **299** with alkyl or aryl nitriles in the presence of the cobalt catalyst **301** (Scheme 74) gave the pyridines (*M*)-**300** in good



Scheme 74. Atropoenantioselective synthesis of the 1-aryl-5,6,7,8-tetrahydroisoquinolines (*M*)-**300** by asymmetric [2+2+2] cycloaddition.

chemical yields and optical purities (up to 89% *ee*). The analogous reaction of a naphthyl nitrile with an alkyl diyne, however, led only to poor yields and moderate *ee* values.



Independently, Shibata et al. reported related, but iridium-catalyzed [2+2+2] cycloadditions of diynes of type **302** with the alkyne **303** to construct the twofold axially chiral teraryls **304**. (*S*,*S*)-Me-duphos ((*S*,*S*)-**305**) was used as the chiral ligand (Scheme 75).[266] Excellent diastereoselectivities (the *meso* form was not observed) and enantioselectivities (> 99% *ee*) were achieved. Furthermore, the catalyst loading could be lowered to 0.5 mol% with no significant loss of selectivity. Besides such teraryls, a biaryl compound was also synthesized by this method, albeit with only up to 81% *ee*.

Nishii, Tanabe, and co-workers published a central-to-axial chirality transfer in the formation of (*M*)-1-arylnaphthalenes (*M*)-**307** from the enantiomerically pure dichlorocyclopropane precursors (*S*,*S*)-**306** (Scheme 76).[267] The Lewis acid promoted benzannellation produced chiral biaryl products with almost complete enantiomeric purity. The high degree of stereocontrol was rationalized by the conformational constraints upon formation of the intermediate carbocation (**306**→pre-(*M*)-**308**→pre-(*M*)-**309**), with the *ortho* substituent R being orientated away from the eliminating, Lewis acid bound hydroxy group. Conjugation between the cyclopropyl methyl cation and the benzene ring ensures that

Scheme 77. Enantioselective synthesis of (*M*)-**314** from the α-substituted ketone (*R*)-**311** with an intermediate central-to-axial chiraliy transfer.

A reaction that has received much attention in this area is the Dötz benzannellation of Fischer carbenes with alkynes. The stereochemical array at the new biaryl axis was controlled by chiral bridges[270] and stereogenic centers in the *ortho* position.[271,272] In a pioneering study, Wulff and co-workers[270] treated two chromium carbenes connected by a chiral tether (i.e. (*R*,*R*)-**315**) with the 1,3-butadiyne **316** (Scheme 78). Both

Scheme 78. Double benzannellation of a bis(chromium carbene) species (*R*,*R*)-**315** to give (*P*)-**317**.

free rotation about the single bonds in pre-*M* carbocation **309** is sufficiently hampered such that this conformation is fully conserved in the axial configuration of the dihydronaphthalene (*M*)-**310** and, thus, in the biaryl product (*M*)-**307**.

Another efficient conversion of C centrochirality into axial chirality was utilized by the research groups of Hattori and Miyano to synthesize the 1,1′-binaphthalene (*M*)-**314** (Scheme 77).[268,269] In this case, the α-substituted chiral cyclohexanone (*R*)-**311** served as a precursor to the new aryl ring. Diastereoselective addition of the naphthyl Grignard **141** in the presence of $Yb(OTf)_3$ delivered (*R*,*R*)-**312**, which was dehydrated to give the axially chiral arene–olefin intermediate (*M*)-**313** with 95% *ee*. Oxidation with DDQ afforded the desired chiral biaryl species (*M*)-**314** in 74% overall yield. Although this method is somewhat indirect, it does have the advantage that chiral α-substituted ketones are accessible by standard procedures.

aromatic rings of (*P*)-**317** were assembled in a single step with essentially complete control of the configuration of the biaryl axis, albeit in low yield and with concomitant formation of other products.

The synthetic strategy for the construction of chiral biaryl compounds by the assembly of one (or both) of the aromatic rings is highly innovative. This work is still in its infancy and the generality of the concept is, as yet, largely limited in terms of functional-group compatibility and substitution patterns accessible.

6. Summary and Outlook

With the continuously increasing importance of axially chiral biaryl compounds as chiral auxiliaries and ligands for

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

asymmetric synthesis and as the structurally decisive element in bioactive natural products, formidable efforts have been undertaken recently to develop efficient methods for their atroposelective synthesis. The approaches shown in this Review are characterized by their conceptual diversity and can be divided into three major classes:

1) the "classic" atroposelective aryl–aryl coupling reactions (Section 3), which allow the preparation of axially chiral biaryl compounds directly from their (suitably modified) aromatic halves;
2) approaches that rely on the atroposelective conversion of preformed, but stereochemically not yet differentiated (i.e. achiral or configurationally labile) biaryl species to give axially chiral products (Section 4); and
3) specialized methods in which a non-aryl substituent on an aromatic ring is atroposelectively converted into the second aromatic ring (Section 5).

Despite the originality and efficiency of some of these approaches and regardless of whether the aryl–aryl coupling and the asymmetric induction are achieved simultaneously or stepwise, the stereoselective preparation of (complex) biaryl compounds remains a challenging goal. Most currently available methods meet only some, but not all of the following demands:

1) excellent chemical yields and optical purities, even for biaryl compounds with high steric hindrance (e.g. tetra-*ortho*-substituted derivatives) and biaryl species in which the steric differentiation between the *ortho* substituents is small—or even in cases in which the *ortho* substituents are identical and axial chirality results only from groups in the *meta* position;
2) access to virtually any substitution pattern, and compatibility with common functional and protecting groups;
3) use of cheap and easily accessible starting materials, chiral catalysts, or auxiliaries (which should be available in both enantiomeric forms); the latter have to be easy to attach and remove;
4) mild and convenient reaction conditions that prevent undesired atropisomerization at the biaryl axis formed;
5) possibility to synthesize either atropisomer from the same precursor ("atropodivergence") and to recycle any unwanted minor atropisomer ("chiral economy"); and
6) the applicability to the atroposelective construction of concrete functionalized target molecules such as complex natural products.

Taking all this into account, it is understandable why, despite the intense efforts and enormous progress of the past decades, a reliable and generally applicable procedure that fulfills all these demands satisfactorily is still lacking. Many of the intriguing concepts described reflect the chemical creativity of the researchers and provide excellent approaches to a specific class of target biaryl compounds, but are restricted to a distinct substitution pattern (e.g. a particular functional group in the *ortho* position), or fail if the steric hindrance increases (e.g. tetra-*ortho*-substituted biaryl targets).

The methods that are currently most widely applied in the asymmetric synthesis of complex axially chiral biaryl compounds are the "lactone concept" (Section 4.2.3) among the stepwise (atropoenantio- or atropodiastereoselective) techniques, and the Meyers oxazoline method (Section 3.2) among the direct (atropodiastereoselective) coupling procedures. Catalytic enantioselective aryl–aryl couplings such as the Suzuki coupling (Section 3.6), although still hampered by several restrictions, are gradually improving and might, owing to the economical use of the chiral catalysts, become further methods of choice in the future.

Abbreviations

acac	acetylacetonate
BHT	2,6-di-*tert*-butyl-4-methylphenol
binap	2,2′-bis(diphenylphosphanyl)-1,1′-binaphthyl
binol	1,1′-binaphthyl-2,2′-diol
Bn	benzyl
Boc	*tert*-butyloxycarbonyl
BOM	benzyloxymethyl
Bz	benzoyl
Cbz	benzyloxycarbonyl
Cp	cyclopentadienyl
cod	1,5-cyclooctadiene
dba	dibenzylideneacetone
DCC	1,3-dicyclohexylcarbodiimide
DDQ	2,3-dichloro-5,6-dicyano-1,4-benzoquinone
DIAD	diisopropylazodicarboxylate
DMA	*N*,*N*-dimethylacetamide
DMAP	4-(dimethylamino)pyridine
DME	ethylene glycol dimethyl ether
DMF	*N*,*N*-dimethylformamide
DMSO	dimethyl sulfoxide
dppf	1,1′-bis(diphenylphosphanyl)ferrocene

[36] This, now recommended, *M*/*P* nomenclature is more convenient than the older (and somewhat counterintuitive) *aR*/*aS* definition: If A-(via B′)→B→A′ is clockwise: *aR*; if anticlockwise: *aS*; in all cases, $aS = P$ and $aR = M$. The *M*/*P* convention does not need the more complicated 270° arc required for the *aR*/*aS* denotation and avoids any confusion with centrochiral

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

elements—and it is in better agreement with the denotation for planar chirality.

Uang, *Chem. Commun.* **2001**, 980 – 981; d) S.-W. Hon, C.-H. Li, J.-H. Kuo, N. B. Barhate, Y.-H. Liu, Y. Wang, C.-T. Chen, *Org. Lett.* **2001**, *3*, 869 – 872.

[186] There is one additional report on an asymmetric photocatalytic oxidative biaryl coupling with a centro- and helically chiral Ru catalyst to give (*M*)-binol ((*M*)-**29**) with low enantioselectivity (16% *ee*): T. Hamada, H. Ishida, S. Usui, Y. Watanabe, K. Tsumura, K. Ohkubo, *J. Chem. Soc. Chem. Commun.* **1993**, 909 – 911.

[187] T. Osa, Y. Kashiwaga, Y. Yanagisawa, J. M. Bobbit, *J. Chem. Soc. Chem. Commun.* **1994**, 2535 – 2537.

[188] Initial attempts by Kumada and co-workers gave only poor stereocontrol: a) K. Tamao, A. Minato, N. Miyake, T. Mastuda, Y. Kiso, M. Kumada, *Chem. Lett.* **1975**, 133 – 136; b) K. Tamao, H. Yamamoto, H. Matsumoto, N. Miyake, T. Hayashi, M. Kumada, *Tetrahedron Lett.* **1977**, *18*, 1389 – 1392.

[189] T. Hayashi, K. Hayashizaki, T. Kiyoi, Y. Ito, *J. Am. Chem. Soc.* **1988**, *110*, 8153 – 8156.

[190] The Kumada cross-coupling of **175** with **176** catalyzed by Ni/(*P*,*S*,*S*)-**177b** to give (*M*)-**179**, was successfully performed on a large scale (up to 20 g): a) S. L. Colletti, R. L. Halterman, *Tetrahedron Lett.* **1989**, *30*, 3513 – 3516; b) J. M. Harris, R. McDonald, J. C. Vederas, *J. Chem. Soc. Perkin Trans. 1* **1996**, 2669 – 2674.

[191] For less successful enantioselective Kumada cross-couplings of **175** with **176**, see: a) T. Frejd, T. Klingstedt, *Acta Chem. Scand.* **1989**, *43*, 670 – 675; b) A. Terfort, H. Brunner, *J. Chem. Soc. Perkin Trans. 1* **1996**, 1467 – 1479; c) L. Dahlenburg, V. Kurth, *Inorg. Chim. Acta* **2001**, *319*, 176 – 182.

[192] T. Hayashi, K. Hayashizaki, Y. Ito, *Tetrahedron Lett.* **1989**, *30*, 215 – 218.

[193] A large portion of the "wrong" *P* enantiomer of the intermediate binaphthyl initially formed will ultimately, by the strong renewed external asymmetric induction again with preferential formation of *M* in the second step, become the *meso*-configured *P,M* compound (and not the *P,P* product) and thus formally further enhance the *ee* value of the *M,M* product.

[194] For reviews on Suzuki cross-couplings, see: a) "Palladium-Catalyzed Aryl-Aryl Coupling" L. Anastasia, E. Negishi, in *Handbook of Organopalladium Chemistry for Organic Synthesis, Vol. I* (Eds. The doubly boron-bridged diferrocene [CpFe{$C_5H_3(BPh)_2C_5H_3$}FeCp] represents the first example of a 1,2-diborylated ferrocene. Controlled conformational changes in this rigid redox-active bifunctional Lewis acid species can be triggered either through redox chemistry or the binding of nucleophiles. For more details, see the Communication by F. Jäkle and co-workers on the following pages.

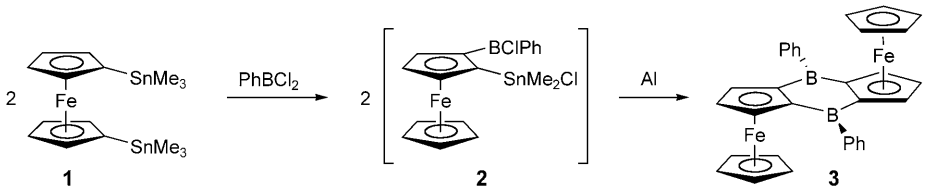
Reversible Expansion and Contraction of a 1,2-Diborylated Ferrocene Dimer Promoted by Redox Chemistry and Nucleophile Binding**



*Krishnan Venkatasubbaiah, Lev N. Zakharov, W. Scott Kassel, Arnold L. Rheingold, and Frieder Jäkle**

Diboraanthracenes **A** have been extensively used as precursors to various di- and multimetallic (and multidecker) sandwich complexes,[1–3] and more recently a perfluorinated derivative (X = H, R = C_6F_5) was employed as an activator in the polymerization of olefins.[4,5] Boracycles in general also serve as fluorescent materials, as probes for anions, and as building blocks for the assembly of new materials.[6] Finally, the "doping" of boron into larger organic π systems such as fullerenes and conjugated organic polymers continues to attract much interest owing to potentially interesting electronic effects.[7,8]

We previously showed that heteronuclear bidendate Lewis acids comprised of Lewis acidic boron and tin groups adjacent to one another are readily available through a rearrangement reaction from 1,1′-bis(trimethylstannyl)ferrocene (**1**) and boron halides.[9] For instance, the 1-stannyl-2-borylferrocene **2** is formed as the major product upon reaction of **1** with an excess of $PhBCl_2$ (Scheme 1). However, examples of ferrocenes that contain metals or semi-metals in neighboring positions at the same cyclopentadienyl (Cp) ring are generally still rare.[10] Among diborylated ferrocenes, for example, only 1,1′-diborylated species have been isolated and 1,3-diborylated isomers have been confirmed as minor byproducts by NMR spectroscopy.[11] Herein, we report the synthesis and properties of the first example of a 1,2-diborylated bisferrocene, in which two CpFe fragments are bridged by the novel dibora-*s*-indacenediyl ligand **B**.

When the reaction mixture of **1** and $PhBCl_2$ was kept for an extended period of time in an aluminum-capped vial, dark red crystals of the novel 1,2-diborylated ferrocene dimer **3** formed reproducibly in approximately 36% yield. The presence of aluminum was found to be critical, as confirmed by the lack of formation of product in the absence of a source of Al. While addition of Al powder to the reaction mixture accelerated the reaction, the selectivity for **3** was diminished. The ^{1}H NMR spectrum of **3** showed a doublet ($\delta = 4.89$ ppm, 4H) and a triplet ($\delta = 5.05$ ppm, 2H) with a coupling constant of $^3J = 2.5$ Hz, which is characteristic of a 1,2-disubstituted ferrocene.[10] A broad signal in the $^{11}B\{^1H\}$ NMR spectrum at $\delta = 57.7$ ppm is indicative of the formation of a triarylborane. The mass spectrum of **3** clearly shows a peak for the molecular ion at $m/z = 544$, which is consistent with the proposed dimeric structure.

Scheme 1. Formation of diboracycle **3**.

Single-crystal X-ray diffraction analysis of **3** confirmed that two ferrocene units are doubly bridged with two tricoordinate boron atoms (Figure 1).[12] The CpFe moieties adopt a *trans* configuration relative to the central B_2C_4 ring.[13] A pronounced tilting of the boron atoms towards the iron center (Cp_{cent}-C6-B1 = 167.9°; Cp_{cent}-C10-B1* = 164.4°) is evident, as is also observed in other ferrocenyl boranes; recent studies based on a combination of X-ray crystallography, cyclic voltammetry, Mössbauer spectroscopy, and theoretical calculations show that this feature results from a delocalized through-space interaction between iron and boron.[14] This interaction leads to a strong deviation from planarity for the diboraindacene ligand in **3** with an interplanar angle between the substituted Cp rings and the central B_2C_4 cycle of around 15.9° (see Figure 3a). In comparison, the related diboraanthracenes, **A**, are planar in the absence of steric strain.[2,4,15] The B–C bond lengths in **3** are similar to

Selected interatomic distances [Å] and angles [°]: B1–C6 1.546(2), B1–C10* 1.546(2), B1–C11 1.564(2), B1···B1* 3.103, Fe1···B1 3.032, Fe1···B1* 2.957, Fe1···Fe1* 5.123, C6-B1-C10* 115.8(1), C6-B1-C11 123.7(1), C10*-B1-C11 120.4(1), C10-C6-B1 121.6(1), C6-C10-B1* 122.5(1).

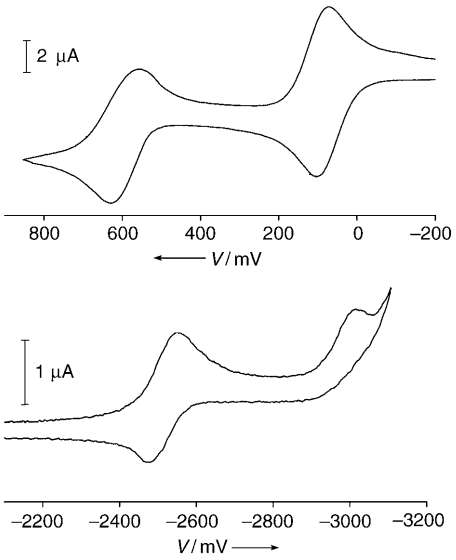

Figure 2. Cyclic voltammogram of **3** (vs. FcH/FcH^+). a) Oxidation waves of **3** (10^{-3} M) at 100 $mV s^{-1}$ with $Bu_4N^+B(C_6F_5)_4^-$ (0.1 M) in CH_2Cl_2 as the supporting electrolyte; b) reduction waves of **3** (10^{-3} M) at 100 $mV s^{-1}$ with $Bu_4N^+PF_6^-$ (0.1 M) in DME as the supporting electrolyte.

those in 9,10-diboraanthracenes **A** with organic substituents at the boron center (1.554–1.580 Å).[2,4,15] However, the B–C bonds to the Cp rings (1.546(2) Å) are significantly shorter than the exocyclic B–C bonds to the phenyl groups (1.564(2) Å), which suggests a significant contribution of the chinoid resonance structure of **B**.[9,16]

An intriguing feature of **3** is the presence of both redox-active ferrocene and triorganoborane moieties, which may allow one to electrochemically trigger conformational changes based on changes in the nature of the Fe···B interaction as suggested by DFT calculations by Wagner and co-workers[14] Such processes have attracted much interest recently with regard to the design of molecular machines that can be addressed through external stimuli.[17]

Cyclic voltammograms of **3** were recorded in $CH_2Cl_2/Bu_4N^+PF_6^-$ as well as $CH_2Cl_2/Bu_4N^+B(C_6F_5)_4^-$ (Figure 2a). In both cases two separate one-electron oxidation events were observed. However, improved chemical reversibility was achieved with $Bu_4N^+B(C_6F_5)_4^-$ as reported by Geiger and co-workers for related systems.[18] The first oxidation of **3** occurs at $E_{1/2} = +60$ mV (versus the ferrocene/ferrocenium (FcH/FcH^+) couple; $E_{1/2} = +88$ mV with PF_6^-), which is slightly higher than that reported for $FcBMe_2$ ($E = +9$ mV).[14] The second oxidation takes place at a much higher potential of $E_{1/2} = +570$ mV ($E_{1/2} = +432$ mV with PF_6^-). The pronounced difference between the results for the two electrolytes is due to differences in the degree of ion-pairing interactions.[18] In either case the separation between the two oxidation waves ($\Delta E = 510$ mV in $CH_2Cl_2/Bu_4N^+B(C_6F_5)_4^-$; $\Delta E = 344$ mV in $CH_2Cl_2/Bu_4N^+PF_6^-$) is considerably larger than those for the related doubly silyl-bridged ferrocenes [CpFe{Cp(SiR_2)$_2$Cp}FeCp] ($\Delta E = 195$–210 mV for R = Me, Et, and *n*Bu in propionitrile/$Bu_4N^+PF_6^-$),[19] which indicates unusually strong electronic coupling through the dibora-*s*-indacene bridge. However, the interaction is smaller than that for the all-carbon analogue, the *s*-indacene-bridged dimer [Cp*Fe{Cp(CH)$_2$Cp}FeCp*] (Cp* = pentamethylcyclopentadienyl), which shows a splitting of $\Delta E = 820$ mV and forms a fully valence-delocalized cation upon mono-oxidation.[20]

The mono-oxidized mixed-valence species $(\mathbf{3}^+)I_3 \cdot I_2$ was prepared in 85% yield upon treatment of **3** with an excess of I_2 in CH_2Cl_2/toluene and crystallization at −37 °C. The X-ray crystal structure shows two independent molecules, ($\mathbf{3}^+$)-1 and ($\mathbf{3}^+$)-2, along with I_3^- counterions and co-crystallized molecules of I_2.[12,21] There are two independent half cations on inversion centers, which render the Fe atoms in each of the dimers ($\mathbf{3}^+$)-1 and ($\mathbf{3}^+$)-2 equivalent. The latter has been shown to be indicative of valence delocalization owing to very rapid electron transfer.[22] In line with this interpretation, the Cp_{cent}–Cp_{cent} distances of 3.355 Å and 3.357 Å for ($\mathbf{3}^+$)-1 and ($\mathbf{3}^+$)-2, respectively, are intermediate between those of **3** (3.308 Å) and those of typical oxidized ferrocenes (ca. 3.4 Å). In contrast, the mixed-valent zwitterion ferricenyl(III)-trisferrocenyl(II)borate (Fc_4B), which contains a coordinatively saturated boron bridge, shows distinct ferrocene and ferrocenium moieties with Cp_{cent}–Cp_{cent} distances of 3.291–3.320 Å for the former and 3.428 Å for the latter.[23] The geometric parameters for ($\mathbf{3}^+$)-1 and ($\mathbf{3}^+$)-2 (Figure 3b) are similar apart from the tilting of the C_4B_2 ring relative to the Cp ring.[21] The interplanar angle of 16.5° for ($\mathbf{3}^+$)-1 is larger than that of 13.8° for ($\mathbf{3}^+$)-2 and even larger than in the free acid **3** itself. This unexpected feature is likely a result of packing effects involving the counterions, which form infinite helical chains $\{I_3^- \cdot I_2\}_n$ through short intermolecular I···I contacts.[21]

Hendrickson and co-workers have shown that IR spectroscopy may also serve as a convenient tool to evaluate the valence detrapping in diferrocene-type species. Particularly sensitive to oxidation of Fe is the perpendicular C–H bending vibration, which occurs at 815 cm^{-1} in ferrocene and is shifted to approximately 850 cm^{-1} in ferrocenium salts.[22a,b] A KBr pellet of the mixed-valence species $(\mathbf{3}^+)I_3 \cdot I_2$ shows a single broad band at 841 cm^{-1}, which is shifted relative to the neutral

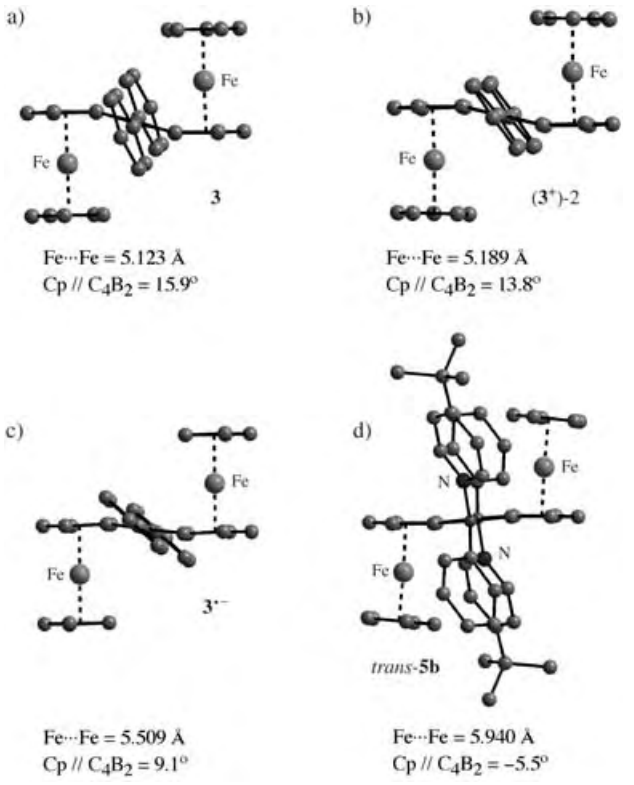

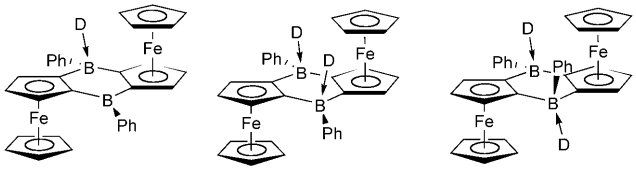

Figure 3. Comparison of structures of **3**, (**3**$^+$)-2, **3**$^{\bullet-}$, and *trans*-**5b**; hydrogen atoms are omitted for clarity; Cp//C_4B_2 denotes the interplanar angle between the Cp and C_4B_2 rings.

molecule **3** (820 cm^{-1}) and thus further indicates rapid electron transfer on the IR timescale (ca. 10^{12} s^{-1}).[21,22a,b]

The electrochemical reduction of **3** was studied by cyclic voltammetry in 1,2-dimethoxyethane (DME, Figure 2b) and revealed a quasi-reversible reduction wave at $E_{1/2} = -2.52$ V (vs. FcH/FcH$^+$) followed by an irreversible reduction at $E_{p2} = -3.02$ V. These data suggest the boracycle in **3** to be considerably more electron-rich than the respective diboraanthracene (**A**, R = Me), which was reported to show reversible reduction waves at −1.41 and −2.07 V in DME versus the saturated calomel electrode (SCE; or ca. −1.80/−2.46 V vs. FcH/FcH$^+$).[2] The latter is to be expected if extensive delocalization between the electron-rich ferrocene moieties and the boron atoms is present, which is evident from the relatively short endocyclic B–C bonds and the significant tilting of the boryl groups towards the iron atoms in the X-ray crystal structure of **3**.

The diboracycle **3** was chemically reduced by treatment with potassium in THF in the presence of 18-crown-6 (18-c-6). ESR spectroscopy of the solution in THF at −50 °C showed a signal, from which the ^{11}B hyperfine coupling could not be resolved. Dark brown thermally labile single crystals of the monoreduced species [K(18-c-6)(THF)$_2$][**3**$^{\bullet-}$] were obtained by crystallization from THF at −35 °C.[12,21] The bending of the boryl groups in **3**$^{\bullet-}$ towards Fe and the interplanar angle of 9.2° between the Cp rings and the C_4B_2 ring are significantly smaller than those in the parent compound **3** (interplanar angle: 15.9°), which in turn results in partial flattening of the dibora-*s*-indacene moiety and a significant increase in the Fe···Fe separation from 5.123 to 5.509 Å (Figure 3c). Both boryl groups are bent towards Fe at a similar angle (170.5° and 171.4°) which suggests that the electron is delocalized. A shortening of the B–C bond lengths within the six-membered diboracycle, as reported by Siebert and co-workers for the reduced diboraanthracene [K(18-c-6)(THF)$_2$][**A**$^{\bullet-}$] in comparison to the neutral diboraanthrancene **A** (R = Me),[2] is not observed. In this context, note that reduction of 1,8-bis(diphenylboryl)naphthalene, which shows a B···B separation of 3.002 Å similar to that of **3**, has been studied by Gabbaï and co-workers.[24] Upon chemical or electrochemical reduction, a monoanionic species was detected, for which a one-electron σ bond between the two boron centers has been proposed on the basis of EPR spectroscopy and DFT calculations. The calculations predict a shortening of the B···B distance upon reduction.[25] Although reduction apparently leads to a delocalized radical anion in our system, a decrease in the B···B distance (3.111 Å) in **3**$^{\bullet-}$ is not observed. The latter is due to incorporation of boron into the rigid ring system in **3**$^{\bullet-}$ which does not allow for direct overlap of the p orbitals of the two boron atoms.

Lewis acid/Lewis base binding offers yet another opportunity to trigger conformational changes in **3**.[14,26] Adducts **5a** and **5b** were obtained upon treatment of **3** with two equivalents of pyridine (py) and *tert*-butylpyridine (*t*Bu-py), respectively.[21] Weak binding of pyridine to **3** is evident from partial dissociation into the monoadducts **4** and the free acid **3** in solution. Single crystals of *trans*-**5b** were obtained by slow evaporation of solvent from a 1:2 mixture of **3** and *tert*-butylpyridine in chloroform.[12,21] A strong effect of the binding of pyridine on the geometric features is observed. In contrast to the free acid **3**, the central C_4B_2 ring of the dibora-*s*-indacene moiety is slightly bent away from the CpFe fragments, with interplanar angles between the Cp and C_4B_2 rings of 5.5° (Figure 3d). The latter is a result of electronic saturation and steric congestion around boron[26] which ultimately leads to expansion of the molecule and a much greater Fe···Fe distance of 5.940 Å relative to that of 5.123 Å in **3**.

In conclusion, the first 1,2-diboradiferrocene **3** was readily prepared from 1,1′-distannylferrocene and shows unusually strong electronic coupling between the ferrocene groups upon partial oxidation, which is indicative of fast electron transfer through the dibora-*s*-indacene ligand framework. Conformational changes in this highly rigid diferrocene can be triggered either through redox chemistry or through the binding of nucleophiles to render **3** an interesting candidate for the design of new types of molecular machines.

Experimental Section

Experimental procedure for **3**: Neat $PhBCl_2$ (0.62 g, 3.90 mmol) was added to a solution of **1** (2.00 g, 3.90 mmol) in toluene (15 mL) at room temperature. The reaction mixture was kept for three months in an aluminum-capped vial. Large dark red crystals of **3** formed and were filtered off, washed with hexanes, and dried under high vacuum (0.38 g, 36 %). ^{1}H NMR (500 MHz, CD_2Cl_2, 25 °C): $\delta = 7.94$, 7.49–7.48 (m, 10H, Ph), 5.05 (t, $J = 2.5$ Hz, 2H, Cp-4), 4.89 (d, $J = 2.5$ Hz, 4H, Cp-3,5), 3.88 ppm (s, 10H, C_5H_5); ^{13}C NMR (125.69 MHz, CD_2Cl_2, 25 °C): $\delta = 144.5$ (br, *i*-Ph), 135.5 (*o*-Ph), 130.9 (*p*-Ph), 129.5 (*m*-Ph), 84.1 (br, Cp-1,2), 83.3 (Cp-3,5), 81.4 (Cp-4), 72.1 ppm (C_5H_5); ^{11}B NMR (160 MHz, CD_2Cl_2, 25 °C) $\delta = 57.7$ ($w_{1/2} = 1280$ Hz); GC-MS: *m*/*z*: 544 [M^+] (100 %); UV/Vis (CH_2Cl_2, 10^{-4} M): λ_{max} (ε) = 498 (6040), 411 (4360), 335 nm (5810 $cm^{-1}M^{-1}$); Elemental analysis (%) calcd for $C_{32}H_{26}Fe_2B_2$: C 70.67, H 4.82; found: C 70.72, H 4.78. See Supporting Information for further experimental details.

Total Synthesis of Spongistatin 1: A Synthetic Strategy Exploiting Its Latent Pseudo-Symmetry**

*Matthew Ball, Matthew J. Gaunt, David F. Hook, Alan S. Jessiman, Shigeru Kawahara, Paolo Orsini, Alessandra Scolaro, Adam C. Talbot, Huw R. Tanner, Shigeo Yamanoi, and Steven V. Ley**

The spongistatins comprise an important family of architecturally complex marine macrolides that display extraordinary antitumor activities against a variety of human cancer cell lines. These unique natural products were isolated independently by Pettit, Kitagawa and Fusetani in 1993,[1] although the absolute structure remained unknown until confirmation by synthesis in 1997.[2] The spongistatin family includes 9 macrolides, all of which possess remarkable growth inhibition properties against the US National Cancer Institute's panel of sixty human cancer cell lines. Spongistatin 1 (**1**) was extremely potent against a subset of highly chemoresistant tumor types, with typical GI_{50} values of $2.5–3.5 \times 10^{-1}$ M. Cell lines derived from human melanoma were also found to be especially sensitive to Spongistatin 1,[1f,h] the most active of this family of macrolides (Scheme 1).

Scheme 1. Structure and retrosynthetic analysis of Spongistatin 1 (**1**). TES = triethylsilyl, TBS = *tert*-butyldimethylsilyl, PMB = *p*-methoxybenzyl.

Spongistatin 1 (**1**) comprises a 42-membered macrolide ring, 24 asymmetric centers, a chlorodiene sidechain, two spiroketals (of which only one contains full anomeric stabilization) and two pyranyl units. The complex molecular architecture and exciting biological profile of these natural products have attracted significant interest resulting in total syntheses by six groups.[2–3] Our initial synthetic analysis for **1** was consistent with established endgame strategies and corresponded to a C1–C41(OH) macrolactonization and C28–C29 Wittig olefination, resulting in two advanced fragments (ABCD fragment **2** and EF fragment **3**) and hence enabling a convergent approach to the target (Scheme 1).[2–3] Furthermore, we recognized the utility of the *anti*-selective aldol coupling demonstrated by the groups of Evans,[2a] Paterson,[3d] Heathcock[3f] and more recently Smith[3a] and Crimmins,[3e] to join the AB and CD units together to form the basis of fragment **2** in their total syntheses. Accordingly, we envisaged that appropriately protected AB aldehyde **4** and

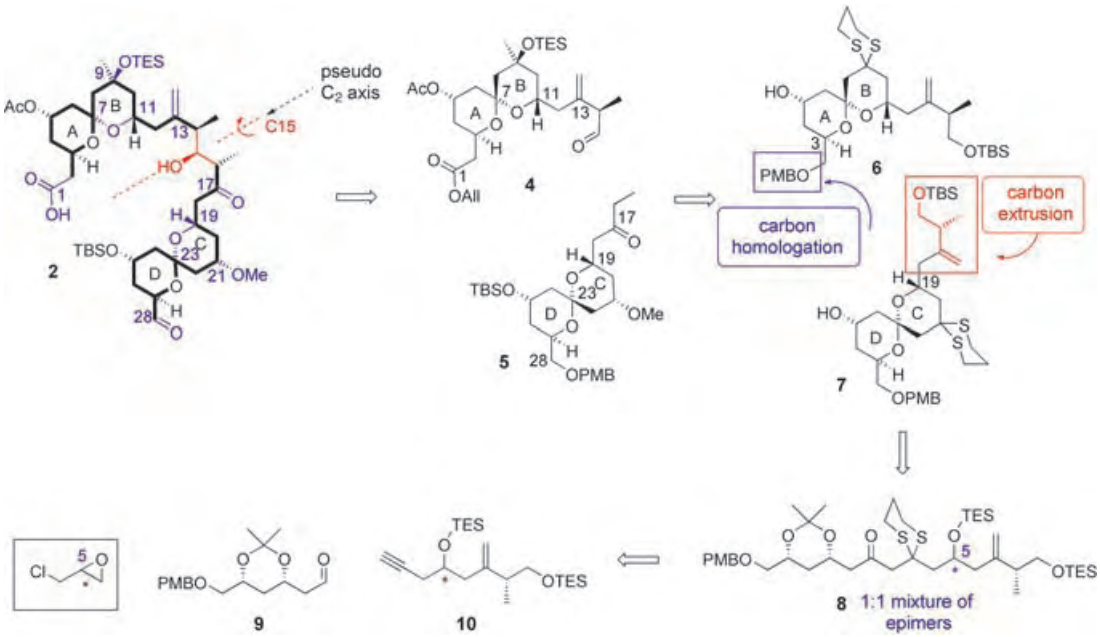
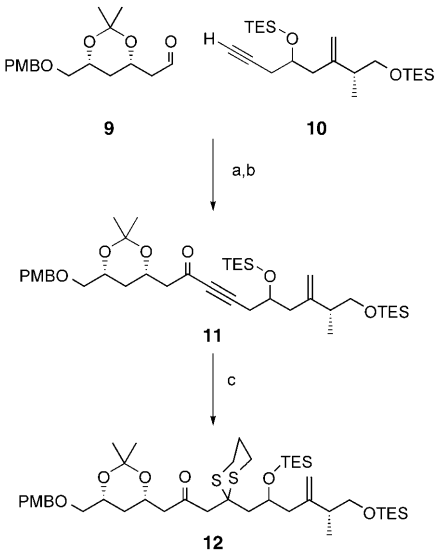
CD ketone **5** would be suitable coupling partners for this transformation (Scheme 2).



We have previously reported independent syntheses of both the AB (**4**) and CD (**5**) fragments,[4] employing acetylide–aldehyde C–C-bond formation–oxidation followed by addition of 1,3-propanedithiol to the resulting ynone as the key coupling approach for polyketide synthesis. Despite the high efficiency in these syntheses (average yield per step: 89% (**4**); 92% (**5**)), we felt that the overall sequence length, (64 discrete steps to assemble the ABCD precursors) precludes the synthesis of significant quantities of the spongistatins. As a result, we have developed an innovative second-generation route towards the ABCD bis(spiroketal) moiety **2**, which is reported here along with completion of the synthesis of the natural product.[5]

Close examination of the ABCD fragment **2** of Spongistatin 1 reveals a high level of latent C_2-symmetry about the C15 atom namely, the carbon framework from C1 to C14 is very similar to that of C16 to C28 (Scheme 2).[6] The A and D rings of the spiroketals are essentially identical and differ principally due to their anomeric arrangements and the C11 and C19 stereocenters, which are oppositely configured. We have already shown that the functionality at both C9 and C21 can be introduced through a carbonyl group interconversion.[4] Therefore, C1–C12 and C18–C28 differ by only one carbon atom and one stereocenter. Furthermore, the sp^2-carbon atoms at C13 and C17 are pseudo-symmetric about C15, as are the methyl groups at C14 and C16. These observations suggest that it may be possible to access the C1–C15 and C15–C28 fragments from an epimeric mixture of acyclic precursor **8**, dramatically decreasing the number of steps required to assemble the ABCD fragment (Scheme 2).

From an acyclic precursor **8**, one C5 epimer will furnish the AB spiroketal core **6**, whilst the opposite C5 epimer would yield the CD framework **7**. Post-spiroketalization modification should enable interception of our original routes to AB (**4**) and CD (**5**) subunits. Towards this goal, the AB spiroketal unit **6** requires one-carbon homologation in the C3 sidechain to generate the allyl ester **4**. In contrast, the CD unit **7** requires conversion of the exocyclic alkene into a ketone followed by effective formyl extrusion (via decarboxylation) from the C19 terminus to afford the ethyl ketone **5**. The utility of this pseudo-symmetric strategy hinges upon the ability to efficiently facilitate sidechain interconversion and is of central importance to the success of our second-generation synthetic strategy (Scheme 2).



The synthesis begins with the preparation of the acyclic precursor **8**. We have previously prepared key aldehyde **9** from (*S*)-glycidol in the first-generation synthesis of the CD ketone.[4a] Formation of alkyne **10** as an epimeric mixture at C5 was achieved by adaptation of previously developed chemistry towards the AB spiroketal, in this case employing racemic epichlorohydrin as the central electrophilic component.[4b] Addition of the anion of alkyne **10** (formed through treatment with *i*PrMgCl) to aldehyde **9** generated a propargylic alcohol as a 1:1 mixture of diastereomers in 85% yield. Oxidation with Dess–Martin periodinane lead to ynone **11**, which afforded acyclic spiroketal precursor **12** in excellent yield by double conjugate addition of 1,3-propanedithiol (83% over 3 steps, Scheme 3).

Treatment of ketone **12** with dilute perchloric acid generated three different spiroketals corresponding to the AB double anomeric stabilized unit **13** (AB_{AA}) and the two CD anomeric isomers, bis-anomeric **14** (CD_{AA}) and mono-anomeric **15** (CD_{AE}), in a ratio of $AB_{AA}/CD_{AA}/CD_{AE}$ 1.00:0.74:0.26 (Scheme 4). The three spiroketals were separated by preparative HPLC[7] to afford the key cores of the AB and CD fragments in a total of only 26 discrete steps (17 longest linear sequence). The bis-anomeric **14** (CD_{AA}) spiroketal was equilibrated under calcium perchlorate epi-

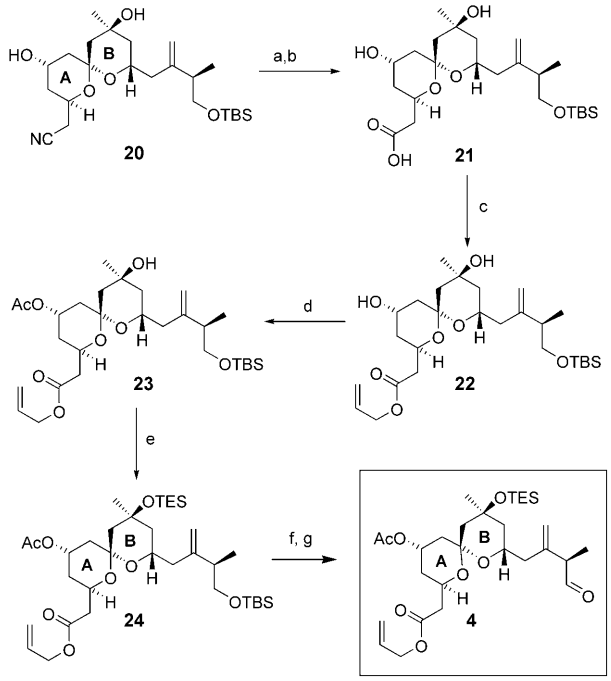
merization conditions[3a,4] and cleanly converted into the desired mono-anomeric spiroketal **15** (CD_{AE}) (87 % yield after a 3-step recycle sequence). The equilibration process required 16 h to afford a 3:1 mixture in favor of the desired isomer. Interestingly, the presence of the primary hydroxy group in the C19 sidechain increased the proportion of **15** (CD_{AE}) after equilibration. This observation is in agreement with the results of Evans et al.[2a] and Smith et al.[3a] and in accord with our findings in our earlier CD fragment synthesis, which lacked oxygen substitution in the C19 sidechain[4a] (first generation $CD_{AA}/CD_{AE} = 1.0:2.2$, second generation $CD_{AA}/CD_{AE} = 1.0:3.0$). With an efficient method for the formation of both AB and CD spiroketal core structures now available, we investigated subsequent side-chain manipulation to afford the aldol-coupling fragments **4** and **5**.



Elaboration of spiroketal **13** began by the selective protection of the primary hydroxy group as its silyl ether followed by iodine-facilitated cleavage of the dithiane unit[8] to afford the corresponding ketone **17** in excellent yield over two steps (Scheme 5). Methyl group addition mediated by the organocerium reagent derived from MeLi and $CeCl_3$ formed the tertiary alcohol **18** as a single diastereomer (d.r. > 20:1). Oxidative cleavage of the *p*-methoxybenzyl ether with DDQ and subsequent mono-tosylation of the resulting primary alcohol activated the C3 sidechain for carbon homologation. Tosylate displacement with NaCN[9] afforded **20** in good yield.

Cyanide **20** was converted into the corresponding acid **21** via reduction to the aldehyde followed by Pinnick oxidation (Scheme 6).[10] Alkylation of the carboxy group by allyl bromide–cesium carbonate furnished the full AB spiroketal skeleton **22**. Selective acetylation of the secondary alcohol followed by TES protection of the tertiary hydroxy group formed **24** in good yield over two steps. HF–pyridine complex removed the *tert*-butylsilyl group and subsequent oxidation of the primary hydroxy group using Dess–Martin periodinane[11]

Tfa = trifluoroacetyl.

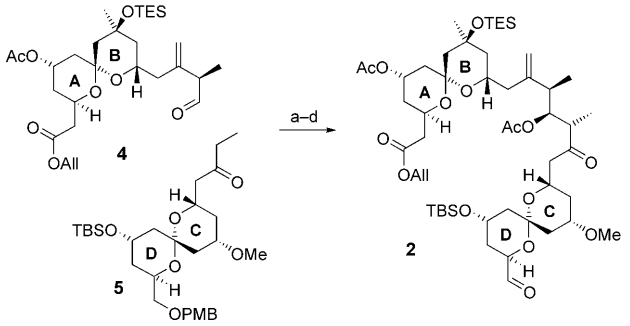
afforded key aldehyde **4** that was used immediately in the aldol coupling.

After efficient generation of the anomeric **15** (CD_{AE}) spiroketal unit we began its manipulation towards the CD ethyl ketone **5** (Scheme 7). Initially, two-step dithiane cleavage via the dimethylketal afforded ketone **25** in good yield; this procedure circumvents product decomposition that occurred under a variety of other cleavage conditions.[4a,12] Treatment of diol **25** with TBSCl and imidazole in DMF formed the bis(silyl ether) in excellent yield over the opening sequence (82% over 3 steps). Reduction under modified Luche conditions[13] afforded the desired equatorial C15 alcohol as essentially one diastereomer **27** (d.r. > 20:1), arising from the expected axial hydride delivery. Methylation proceeded with excellent yield, followed by selective primary silyl ether cleavage, forming the basis for investigation into the required carbon extrusion chemistry. Results from model studies on formyl group expulsion indicated that decarboxylation of a β-ketoacid would be the most reliable tactic.

To this end, oxidation of alcohol **29** with Dess–Martin periodinane[11] followed by Pinnick oxidation[10] afforded the acid **30**, and brief treatment with ozone in dichloromethane cleanly delivered the β-ketoacid **31** without affecting the primary *p*-methoxybenzyl ether (Scheme 8). The crude material could be smoothly decarboxylated with gentle heating in a toluene/pyridine (2:1) mixture, efficiently delivering the CD



Scheme 8. Reagents and conditions: a) Dess–Martin periodinane, CH_2Cl_2, RT, 1 h; b) $NaClO_2$, *t*BuOH, 2-methyl-2-butene, pH 7 buffer, RT, 2 h; c) O_3, CH_2Cl_2, −78 °C, 3 min; then Me_2S, concentrate; d) toluene/pyridine (2:1), 40 °C, 3 h, 57% over four steps.

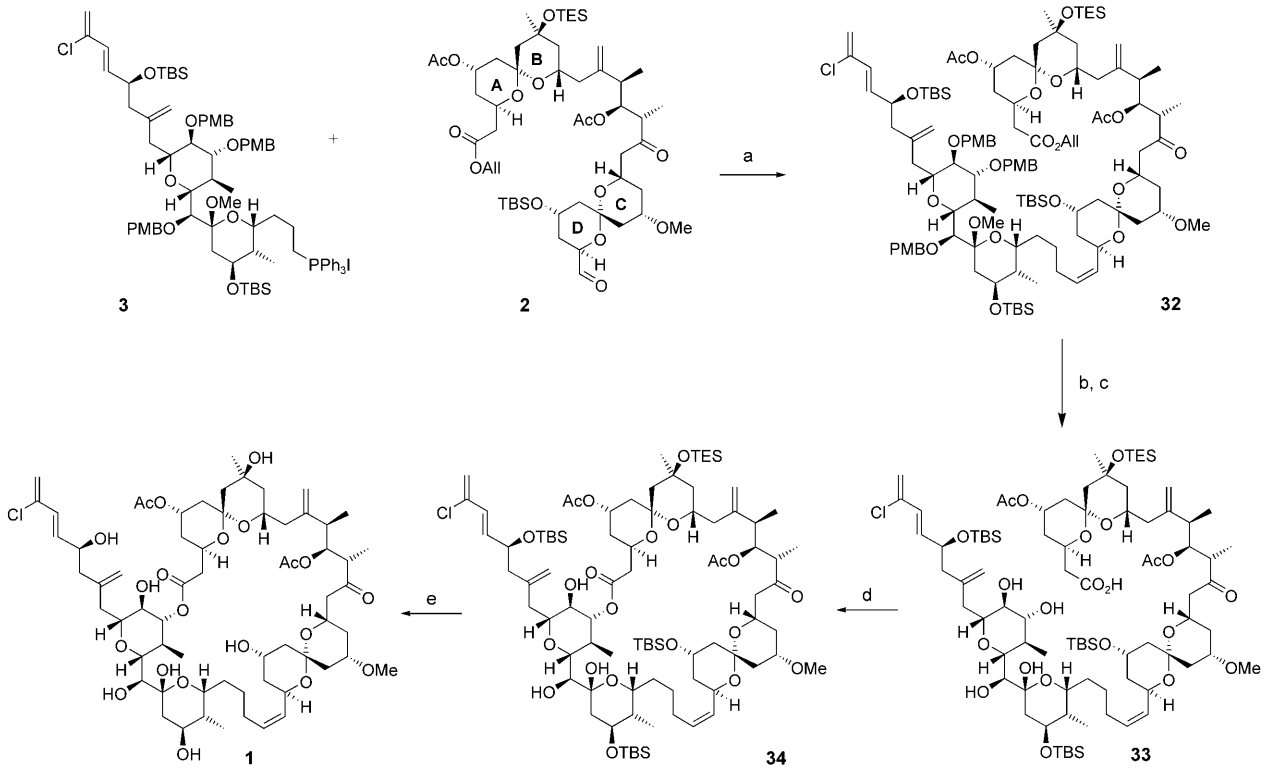
ethyl ketone spiroketal unit **5** ready for use in the aldol coupling.



With gram-quantities of the key fragments available, we investigated the aldol union of the CD ketone **5** and AB aldehyde **4** (Scheme 9). Initially, we used the aldol conditions

Scheme 9. Reagents and conditions: a) BCy_2Cl, Et_3N, Et_2O, −78 °C→0 °C, 10 min; 0 °C→−78 °C; **4**, 1 h; −78 °C→−30 °C, 16 h, 78%, d.r. = 5:1; b) Ac_2O, pyridine, 0 °C→RT, 5 h; c) DDQ, CH_2Cl_2–pH 7 buffer, 0 °C, 5 h; d) Dess–Martin periodinane, CH_2Cl_2, RT, 3 h, 66% over three steps. Cy = cyclohexyl.

described by Evans' group employing pentane as the solvent. Treatment of ketone **5** with dicyclohexylboron chloride formed the *E*-boron enolate and following reaction with aldehyde **4** formed the *anti*-aldol product as an 8:1 mixture of diastereomers (45% yield of desired diastereoisomer). Given the subtle structural differences between our substrates and the Evans fragments[2a] we initiated a solvent screen which showed that upon switching to diethyl ether[3d] the reaction efficiency was greatly increased (78% yield) to afford a 5:1 mixture of diasterosiomers (65% of desired *anti*-adduct). Subsequent acetylation, PMB ether cleavage and oxidation proceeded in high yield to furnish ABCD aldehyde **2**, ready for Wittig coupling with the EF phosphonium salt **3**.

We have previously reported model studies[14] and recently the completion of the EF phosphonium Wittig salt **3**,[15] which we subsequently employed in hemisphere unification. The difficulties associated with late-stage Wittig coupling between ABCD aldehyde **2** and EF phosphonium salt **3** have been widely reported[2,3] and are in accord with our experience (Scheme 10). After experimentation with a variety of literature conditions, we used a modification of the procedure reported by Heathcock and co-workers[3f] (MeLi·LiBr), employing CaH_2 to remove residual water that may reduce yields due to hydrate formation. Furthermore, the addition of HMPA facilitated ylide formation and subsequent treatment with aldehyde **2** afforded the *cis* alkene **32** with comparable[3f] efficiency and selectivity (yield 50%). Oxidative removal of all *p*-methoxybenzyl protecting groups in a biphasic solvent system (CH_2Cl_2–THF–pH 7 buffer) was accompanied by complete hydrolysis of the C37 methoxyketal. Cleavage of the allyl ester protecting group with Pd^0 efficiently furnished the key secoacid intermediate **33**. Macrolactonization of **33** under modified Yamaguchi conditions[2a] yielded silyl-protected Spongistatin 1 **34**. Global

Scheme 10. Reagents and conditions: a) **3** treated with MeLi·LiBr, THF, −78 °C; then **2** (after drying over CaH_2), −78 °C→RT, 50%; b) DDQ, THF–CH_2Cl_2–pH 7 buffer, RT, 65%; c) $[Pd(PPh_3)_4]$, morpholine, RT; d) 2,4,6-trichlorobenzoylchloride, iPr_2NEt, DMAP, toluene, 90 °C, 56% over two steps; e) 48% HF, CH_3CN, −21 °C, 57%.

silyl group removal by treatment with 48% HF yielded Spongistatin 1 (**1**), which was identical in all respects to an authentic sample.[16]

We have completed a synthesis of Spongistatin 1 (**1**) using established synthetic procedures and methods developed within our research group, including the introduction and subsequent manipulation of β-keto dithiane precursors. Furthermore, the pseudo-symmetric strategy used in forming the ABCD bis(spiroketal) unit **2** represents a new approach towards the family of Spongistatin natural products. The AB spiroketal unit **4** was prepared in 36 steps (overall yield 10% over a 27 step longest linear sequence, average yield 90% per step) and the CD fragment **5** in 37 steps (overall yield 6% over a 28 step longest linear sequence, average yield per step 89%). By applying the pseudo-symmetric approach we are able to access much larger quantities of the key ABCD fragment **2** than from our original route, hence providing the basis for a pragmatic and expedient assembly of the ABCD fragment. By application of the pseudo-symmetric strategy the route is decreased from 65 to only 46 discrete steps from commercially available starting materials. Ongoing work in our laboratories is focusing on further improving the efficiency and scale of the synthetic sequences towards the goal of producing significant quantities of Spongistatin 1.

Extension of the Applicable Range of Fluorescein: A Fluorescein-Based Probe for Western Blot Analysis**

*Mako Kamiya, Yasuteru Urano, Nobuyoshi Ebata, Masami Yamamoto, Jyunichi Kosuge, and Tetsuo Nagano**

Western blot immunoanalysis is a powerful method for detecting proteins of interest on a nitrocellulose or polyvinylidene fluoride (PVDF) membrane.[1–3] The presence of a target protein is usually detected by using a secondary antibody conjugated with an enzyme such as alkaline phosphatase (ALP), which allows marked signal amplification,[4] in combination with a chromogenic, fluorescent, or chemiluminescent probe.[5–7] Among these techniques, only fluorescence detection offers high sensitivity and the possibility of multicolor labeling.[8,9] Furthermore, fluorescence signals, unlike transient chemiluminescence signals, can be imaged several times and are stable on a dried blot. However, the range of fluorescence probes applicable to Western blot analysis is limited at the present time. In particular, probes based on the fluorescein molecule have rarely been used in this analysis despite their extensive exploitation in other biological techniques.[10–13] For example, fluorescein diphosphate (FDP),[14–17] a fluorescein-based ALP probe, is seldom used to detect the activity of the widely used secondary detection enzyme ALP in Western blot analysis. Nevertheless, the superior optical properties of fluorescein, such as high molar extinction coefficients and high quantum yields of fluorescence in aqueous media as well as efficient excitation by an argon ion laser (488 nm), make the development of fluorescein-based probes for ALP suitable for Western blot analysis highly desirable. Herein, we report a new probe for ALP based on a fluorescein derivative that we developed recently[18] which works effectively even on Western blots and makes it possible to perform multicolor labeling.

A critical requirement of probes for Western blot analysis is that the hydrolysis product has adequate affinity for the blot. We confirmed that fluorescein generated by ALP-catalyzed hydrolysis of FDP, lacks sufficient affinity for the blocked membrane in Western blotting (Figure 1), and we suggest that this low affinity may be attributed to the carboxylic group of the fluorescein molecule which makes the hydrophilicity rather high. We then examined the affinity of 2-Me TG, one of our recently reported fluorescein derivatives (TokyoGreens, TG),[18] in which the carboxylic group of the traditional fluorescein molecule is replaced with a methyl group. We found that a spot of a solution of 2-Me TG dropped onto the membrane remained well defined and was not readily washed out (see Supporting Information). This result suggested that TokyoGreens, which do not have a carboxylic group, are more suitable than traditional fluorescein as the fluorophore in probes for Western blot analysis. TokyoGreens also offer the advantage of precise control of the fluorescence emission output. We thus considered 2-Me-4-OMe TG (Figure 1), which shows strong fluorescence (as fluorescein does) and becomes essentially nonfluorescent upon alkylation of its phenolic group, as a suitable core fluorophore for our new probe. Incorporation of a phosphate group into the phenolic group of 2-Me-4-OMe TG gave TG-Phos, a new probe for ALP whose hydrolysis product has a high affinity for Western blots, unlike the hydrolysis product of FDP (Scheme 1).

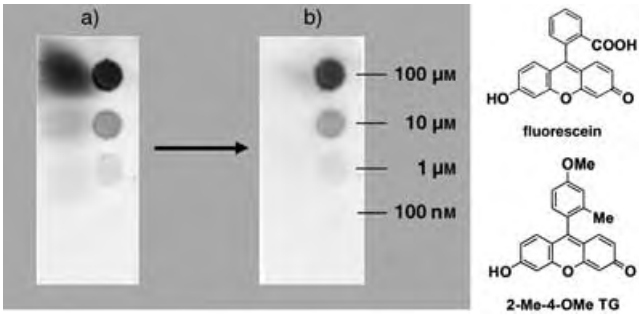

Figure 1. Difference in affinity for the blot between 2-Me-4-OMe TG and fluorescein. Solutions of various concentrations (100 μM, 10 μM, 1 μM, 100 nM) of 2-Me-4-OMe TG (right lane) and fluorescein (left lane) were dropped onto a blocked nitrocellulose membrane and imaged a) before and b) after washing.

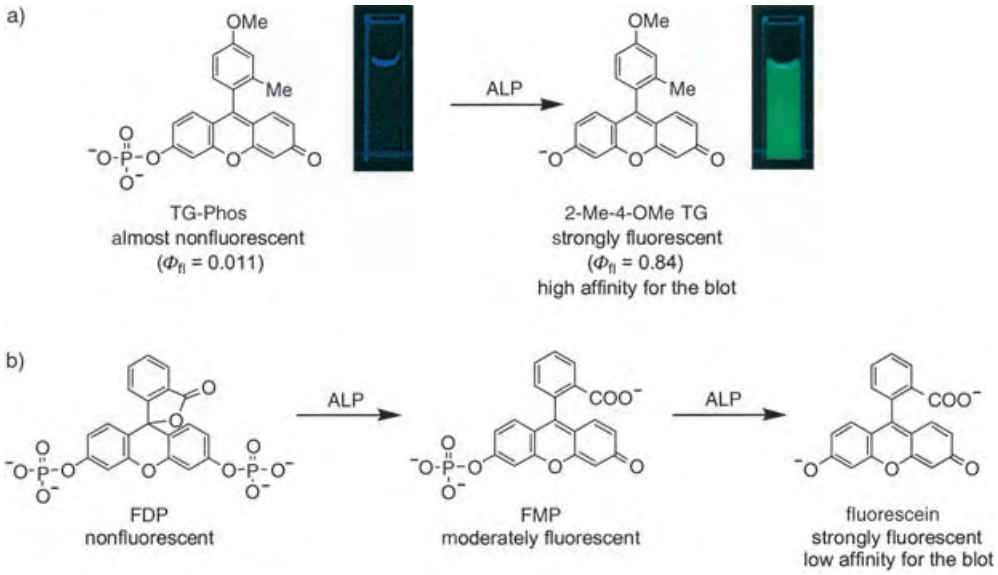

TG-Phos is stable and almost nonfluorescent, but is converted into strongly fluorescent 2-Me-4-OMe TG upon one-step hydrolysis by ALP (see Scheme 1a, Figure 2a, and Supporting Information). We observed a linear relationship between ALP activity and the initial rate of increase of fluorescence intensity (Figure 2b). In the case of FDP, which is hydrolyzed first to moderately fluorescent fluorescein monophosphate (FMP) and then to strongly fluorescent fluorescein, the rate of increase of fluorescence is slow (Scheme 1b, Figure 2a). Additionally, there is poor linearity

Scheme 1. Reaction scheme of a) TG-Phos and b) FDP with ALP to yield fluorescent hydrolyzed products.

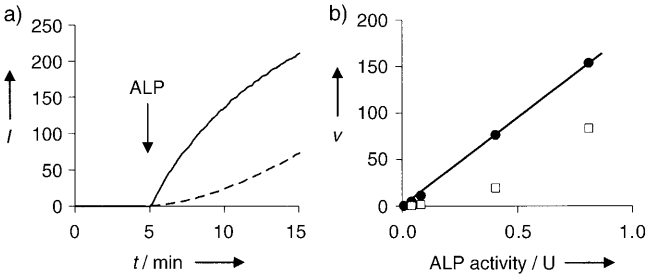

Figure 2. In vitro reaction of TG-Phos or FDP with ALP. a) Increase in fluorescence of 1 μM solutions of TG-Phos (——) and FDP (-----) upon reaction with ALP. b) Correlation between ALP activity and the initial rate of increase of fluorescence using TG-Phos (●) or FDP (□). I = increase in fluorescence (a.u.); v = initial rate of increase of fluorescence (a.u. min^{-1})

between ALP activity and the initial rate of increase of fluorescence owing to the involvement of the two-step hydrolysis (Figure 2b). The results of a dot-blot assay indicated that TG-Phos is greatly superior to ELF97 phosphate and shows about two-times higher sensitivity than DDAO phosphate, both of which have been used as fluorescence probes for Western blots (see Supporting Information). These results indicate that TG-Phos is a superior probe for ALP and allows the quantitative detection of ALP activity with high sensitivity.

We then examined if a protein of interest could be visualized on the blot by using TG-Phos after SDS-polyacrylamide gel electrophoresis (SDS-PAGE) and electroblotting. CYP3A2 was employed as the target protein, and detection with an ALP-labeled secondary antibody and TG-Phos yielded sharp, CYP3A2-specific green-fluorescent bands whose intensity was proportional to the amount of protein. The development of the fluorescence signal was very rapid, occurring in seconds to minutes, and CYP3A2 could be detected at the nanogram level. Furthermore, the fluorescence signal was not easily washed out and was stable on dried blots. In contrast, the green-fluorescent bands derived from FDP were poorly defined and could be easily washed out, making it difficult to detect CYP3A2 on the blot (see Supporting Information).

We next examined simultaneous green/red dual detection of CYP3A2 and total proteins on the same blot. The blot was stained with an amine-reactive BODIPY dye (BODIPY TR-X, succinimidyl ester) to detect total proteins, followed by TG-Phos in combination with an ALP-conjugated secondary antibody to visualize CYP3A2. We succeeded in visualizing all the proteins in the profile as red-fluorescent signals, together with CYP3A2 as a green-fluorescent signal at the same time on the same blot (Figure 3). Such simultaneous two-color detection is a powerful method because it becomes

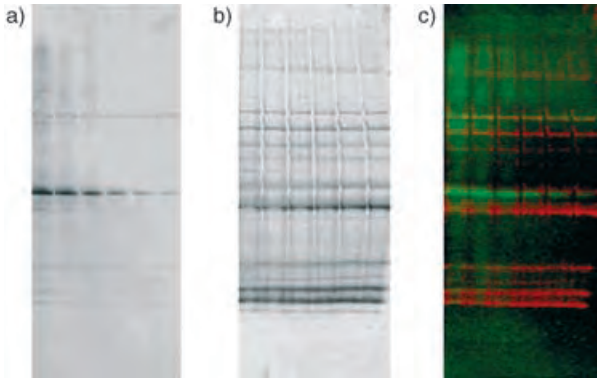

Figure 3. Green/red dual detection of CYP3A2 and total proteins on the same blot after SDS-PAGE and electroblotting onto a PVDF membrane. a) Specific staining of CYP3A2 using ALP-conjugated antibody and TG-Phos. b) Detection of total protein using BODIPY TR-X, succinimidyl ester. c) Simultaneous dual detection of CYP3A2 as green-fluorescent bands and total proteins as red-fluorescent bands. The six lanes contain protein molecular-weight standards (250 ng) and decreasing amounts of CYP3A2 (250 ng, 125 ng, 62.5 ng, 31.2 ng, 15.6 ng, 7.8 ng).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

possible to detect two kinds of proteins on a single blot and obviates the need to make a replica for visualizing total proteins, as is usually required for chemiluminescent or colorimetric detection.

In conclusion, we have developed a fluorescence probe for alkaline phosphatase based on the TokyoGreen scaffold which is suitable for Western blot analysis. The new probe, TG-Phos, yields the strongly fluorescent hydrolysis product, 2-Me-4-OMe TG, which has a high affinity for the blot, in a one-step reaction with ALP. Moreover, TG-Phos provides high sensitivity and a good linear response to ALP and is suitable for multicolor labeling. The design strategy presented here is not limited to ALP but could be extended to other detection enzymes and may provide a general method for simple and rapid detection of proteins on Western blots.

Small-Molecule-Induced Folding of a Synthetic Polymer**

*Suhrit Ghosh and S. Ramakrishnan**

The remarkable range of chemical functions that evolution has elicited from biopolymers has inspired chemists to design synthetic systems that can mimic both the structural and functional features of these elegant long-chain molecules. Although the efforts to mimic functions such as molecular recognition, catalysis, and so forth has led to the development of systems such as molecular-imprint polymers,[1] the attempts to understand and emulate structural features has given rise to the area of foldamers.[2] In most such systems, the core design element utilizes multiple inter- or intramolecular noncovalent interactions that can be stabilized/destabilized by an external trigger. The cooperativity and reversibility of these weak noncovalent interactions are, thus, of paramount importance in the design of synthetic analogues that can emulate biological systems.

Supramolecular science, which deals with the design and utilization of noncovalent interactions to build superstructures with small molecular building blocks, has witnessed intense activity over the past decade.[3] The extension of these ideas has resulted in the generation of supramolecular polymers in solution, formed through multiple hydrogen-bonding interactions[4] or through metal–ion coordination between monomeric building blocks.[5] In the context of conventional polymer molecules, a similar approach in which noncovalent interactions occur between neighboring (or equispaced) segments within a single polymer chain, has been explored to stabilize specific conformations (secondary structures) in solution.[2] On the basis of these considerations, several research groups have examined new types of oligomers and polymers, which adopt well-defined conformations in solution guided by hydrogen-bonding interactions along the backbone,[6] steric and/or bond-angle constraints,[7] solvophobic effects, and so forth.[8] Although the large majority of foldamers are based on precisely defined oligomers with relatively rigid backbones, far fewer are based on flexible systems.[9]

Recently, we demonstrated that truly flexible synthetic macromolecules can be designed to fold under the influence

of several relatively weak intrachain intersegment interactions, such as formation of a charge-transfer (CT) complex, solvophobic effects, and metal–ion complexation, working in tandem.[10] Detailed spectroscopic studies of these (donor–spacer–acceptor–spacer)$_n$ type polymers, in conjunction with studies of model systems, have suggested the formation of extended donor–acceptor stacks by suitable folding of single polymer chains.[11] In a bid to develop simpler polymeric systems that can fold under similar conditions, we present herein a conceptually new approach for the folding of synthetic polymers based on a polyimide that contains only acceptor units linked by hexaoxyethylene (6OE) spacers of the type (acceptor–spacer)$_n$. In this design, we utilize an external small-molecule folding agent (donor type) that is designed to interact simultaneously with two adjacent segments along the polymer chain so that the polymer folds in a predetermined manner. As depicted in Scheme 1, the design specifically entails the formation of a CT complex between the donors of the folding agent and the acceptors along the polymer chain, in tandem with the complexation of the ammonium group of the folding agent with the 6OE spacer.[12] The latter interaction is expected to restrict the conformation of the flexible OE spacer so that the two adjacent acceptor units along the polymer chain can be brought close enough to form an effective CT interaction with the donor unit in the folding agent. Such a multiple-point interaction, which is key to the development of supramolecular science, has been extensively utilized to enhance associations between small molecules, as well as between polymers and small molecules.[13] An interesting example of the latter is the work of Meijer and co-workers,[14] in which they describe anchoring (clicking-in) small functional molecules onto the periphery of dendrimers through the simultaneous use of electrostatic and hydrogen-bonding interactions.

Scheme 1. Folding of a synthetic polymer aided by two-point interactions with a folding agent.

The polyimide PI-6OE was prepared from the appropriate diamine (derived from hexaethylene glycol)[15] and pyromellitic anhydride under standard conditions for polyimide synthesis.[16] Two folding agents, namely, D2-NH_3^+ and D3-NH_3^+, that contain a naphthalene donor linked to an ammonium group through a two- or a three-carbon-atom spacer, respectively, were prepared along with 1,5-dimethoxynaphthalene (D) that serves as a model donor which is devoid of the ammonium group (see Scheme 2). The structures of the various model compounds and polymer were confirmed by standard spectroscopic techniques, and the molecular weight M_n of PI-6OE was determined to be 20500 Da (polydispersity index (PDI) = 1.7) by gel-permeation chromatography (GPC).[17] PI-6OE forms a colorless solution, but an intense yellow color develops in the presence of D2-NH_3^+ because of the characteristic CT absorption band at 450 nm.

Scheme 2. Structures of the polymer, model compounds, and folding agents.

The interaction of PI-6OE with the folding agents was investigated by monitoring the intensity of the CT band by UV/Vis spectroscopic analysis and by following the chemical shift of the aromatic protons of the pyromellitic diimide acceptor unit by ^{1}H NMR spectroscopic analysis. Figure 1 depicts the variation in the ^{1}H NMR spectra of PI-6OE with increasing amounts of D2-NH_3^+. The signal marked by an arrow, from the pyromellitic diimide unit in the polymer, is seen to move continuously upfield on addition of increasing amounts of the donor species. The remaining signals in the aromatic region are from the naphthalene ring of the folding agent, the intensities of which increase and are accompanied by a small downfield shift.[18]

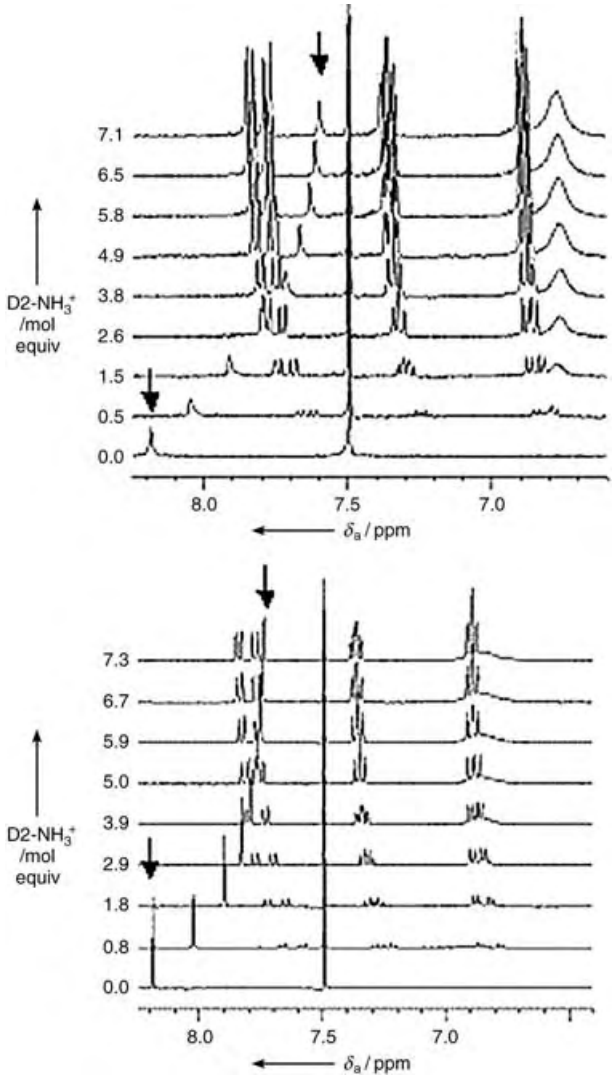

Figure 1. Variation in the aromatic region of the ^{1}H NMR spectra of PI-6OE (top) and AA-6OE (bottom) as a function of the addition of increasing amounts of D2-NH_3^+. The signal that arises from the pyromellitic diimide acceptor protons is indicated by an arrow. The solvent used is a $CDCl_3/CH_3CN$ mixture (1:1, v/v).

A plot of the variation in the chemical shift of the acceptor proton as a function of the concentration of the two different folding agents D2-NH_3^+ and D3-NH_3^+, along with the simple model donor D as a control experiment, is shown in Figure 2. It is evident that although both the folding agents that contain an ammonium group cause a dramatic change in the δ value, the simple donor molecule that does not contain this group causes only a marginal variation. This upfield shift of the acceptor proton suggests the formation of donor–acceptor CT stacks, as was elaborated in our earlier report.[11] Similarly, a significant increase in the intensity of the CT band in the UV/Vis spectra of the polymer solution occurs in the presence of the two donors that contain ammonium groups while only a marginal increase is seen in the presence of the simple donor (Figure 2), despite the fact that both the control experiments were done in the presence of an equimolar quantity of NH_4SCN with respect to D. The independent complexation of the ammonium ion with the OE loop would be expected to at least partially aid the CT interaction with D. These compa-

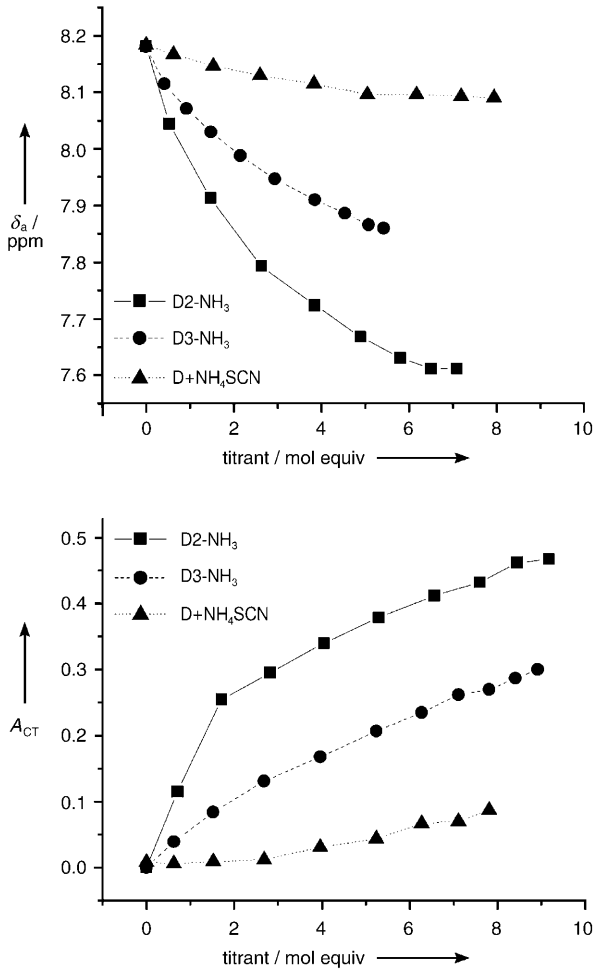

Figure 2. Variation in the chemical shift of the acceptor ring protons δ_a in PI-6OE in the presence of D + NH_4SCN, D2-NH_3^+, and D3-NH_3^+ (top) and variation in the CT band intensity A_{CT} in the presence of D + NH_4SCN, D2-NH_3^+, and D3-NH_3^+ (bottom). rative studies clearly demonstrate the importance of the cooperative two-point interaction, namely, the coordination of the ammonium group with the OE loop and the concomitant CT interaction between the donor and acceptor units, in the generation of the postulated folded structure. Furthermore, as anticipated, the length of the spacer that connects the ammonium group to the naphthalene donor also plays an important role in governing the efficacy of the CT interactions. It is apparent from the variations in the UV/Vis and NMR spectra that D2-NH_3^+ is a more effective folding agent than D3-NH_3^+ (see Figure 2).[19] This dependence on the spacer length reaffirms the importance of the crown ether type complexation of the ammonium group with the OE segment of the polymer in directing the formation of the postulated folded structure.

To probe the extent of the folding, model compound AA-6OE (see Scheme 2) which contains two acceptor units linked by a hexaoxyethylene spacer was synthesized[20] and its interaction with the folding agents studied by both UV/Vis and NMR spectroscopic analysis. The variation in the aromatic region of the ^{1}H NMR spectra of AA-6OE as a function of increasing concentration of the folding agent D2-NH_3^+ is compared with that of the polymer in Figure 1. It is apparent that a significant upfield shift of the acceptor protons is seen in this case as well, although the extent of the shift is clearly smaller in the model compound than in PI-6OE. The variation of the chemical shift of the acceptor proton upon interaction with the two folding agents in the case of the polymer is compared with that of the model compound AA-6OE in Figure 3. For both folding agents, it is clear that the extent of the shift is significantly higher for the polymer than for the model compound. This enhanced shift is clearly a reflection of the fact that the acceptor units in the model can never be sandwiched between two donors, unlike in the case of the polymer in which extended stacking would cause the acceptor units to be sandwiched between two donors. Interestingly, the final chemical shifts of the donor (naphthalene) protons are nearly identical for both the polymer and the model compound (see Figure 1), as expected, because in both cases the donor could become sandwiched between the acceptor units. In addition, as anticipated, the extent of folding exhibits strong temperature dependence, as is evident from the significant upfield shift upon cooling (see inset in Figure 3).[11] Again, it is seen that the polymer exhibits much stronger temperature dependence than the AA-6OE model, thus causing the difference in their chemical shifts to become as large as 0.3 ppm at the lowest temperature probed. We ascribe this difference to the formation of extended stacks in the case of the polymer.[21] To gain further insight into the extent of the stacking, a Job plot was constructed from the absorbance of the CT band, which suggested that the acceptor/donor ratio was 1:0.85 for the polymer PI-6OE (the maximum value in the Job plot was seen at approximately 0.46, see the Supporting Information). Although, in a general sense a ratio of 1:1 need not imply the formation of an extended stack, in our case, however, it can be reasoned that it does confirm the formation of a stack. It is apparent in the present system that the interaction of the ammonium group with the OE spacer is essential for the formation of a CT complex and, more importantly, leads to the sandwiching of the donor between two adjacent acceptors to form an acceptor-donor-acceptor type unit. Evidence for this sandwiching also comes from the Job plot of the model compound AA-6OE, which suggests the formation of an exact 1:1 complex (see the Supporting Information for details). Thus, an acceptor/donor ratio of 2:1 in case of the polymer would suggest the formation of only acceptor–donor–acceptor-type interactions with no extended stacking. On the other hand, if all the OE spacer sites form complexes with the ammonium group of the folding agent, as expected with an acceptor/donor ratio of 1:1, then the formation of an infinitely extended stack is implied. Although the exact scale of the stacking continues to be a challenging problem, a rough estimate on the basis of the Job plot of our polymer suggests the formation of stacks that consist of six donor–acceptor pairs on average.

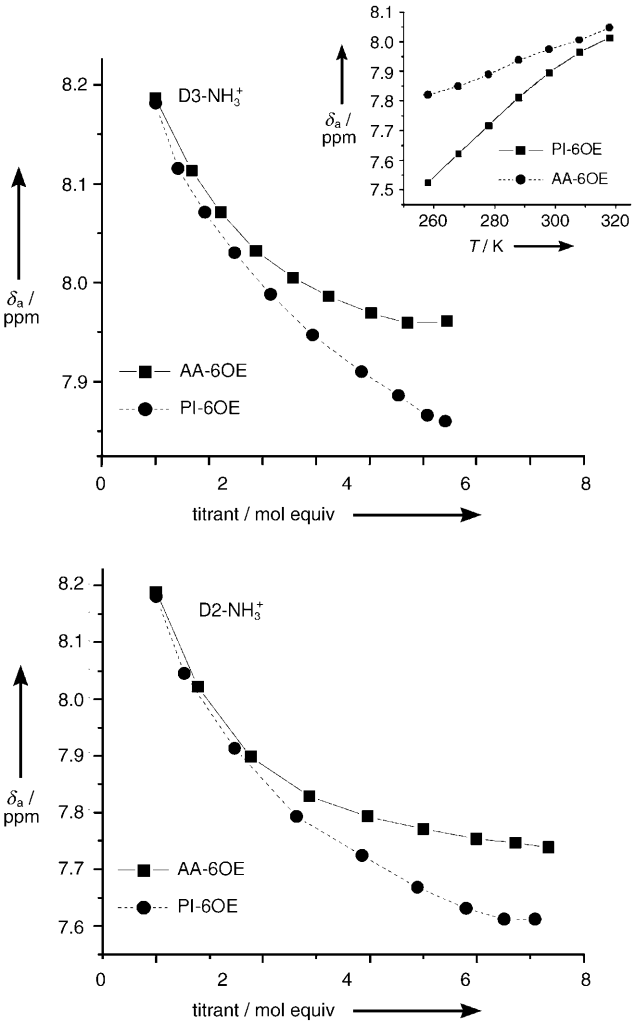

Figure 3. Variation in the chemical shift of the acceptor ring protons δ_a in PI-6OE and AA-6OE in the presence of D3-NH_3^+ (top) and D2-NH_3^+ (bottom). Inset: Effect of temperature on the chemical shift of PA-6OE and AA-6OE in presence of D3-NH_3^+ (the ratio of D3-NH_3^+ to polymer repeating unit/model compound was 4:1).

To test the reversibility of such an interaction-induced folding, an experiment to extricate the folding agent with a crown ether was carried out. Thus, PI-6OE in the folded state (in the presence of 8 equiv of D2-NH_3^+) was titrated with [18]crown-6, which is known to bind very strongly with ammonium ions.[22] In Figure 4, the variation of the chemical shift is plotted, first for the addition of increasing amounts of the folding agent to the polymer and subsequently for the addition of increasing amounts of [18]crown-6. It is clear from the plot that there is a complete reversal of the chemical shift, as a signal with nearly the same value as that for the unfolded polymer is observed, although slightly more than one equivalent of [18]crown-6 was required to effect this complete reversal. The color of the solution changes from deep yellow to nearly colorless at the end of the titration with the crown ether, which is consistent with the complete disappearance of the CT band in the UV/Vis spectra (Figure 4). These experiments clearly confirm that the folding is completely reversible and also suggest that the folding/unfolding equilibrium can be controlled by an appropriate external agent.

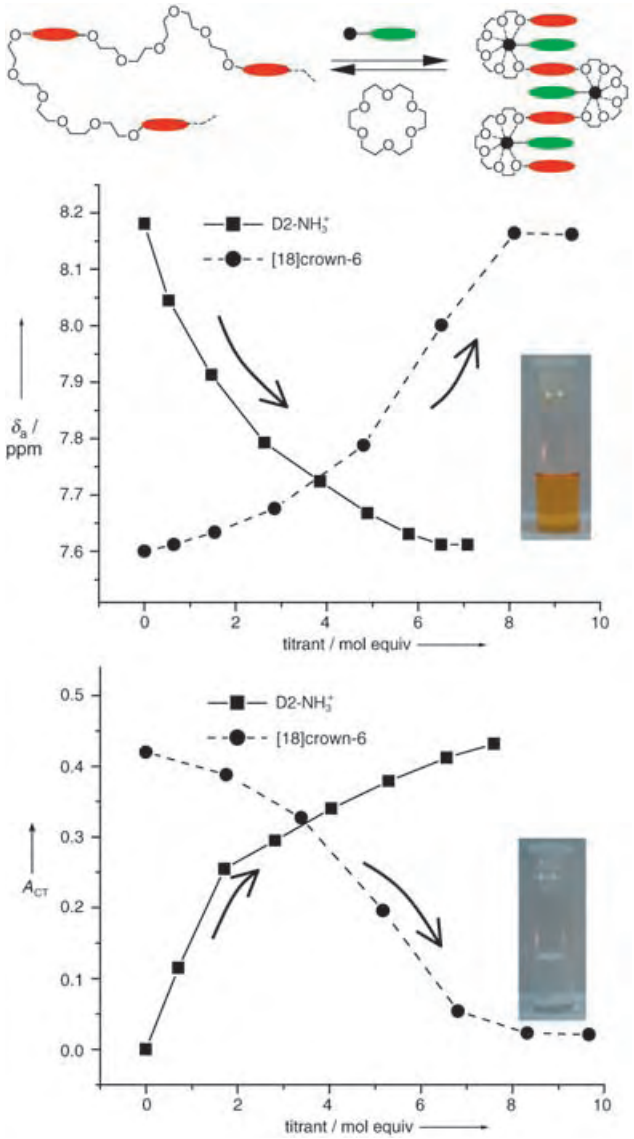

Figure 4. Reversal of the chemical shifts of the acceptor protons δ_a of PI-6OE (top) and the disappearance of CT absorption band (bottom) in the presence [18]crown-6. The mole equivalents were calculated with respect to the polymer repeating unit.

In conclusion, we have demonstrated a new approach to folding a flexible synthetic polymer in solution by utilizing a small molecule as a folding agent. The folding agent was designed to interact cooperatively with two adjacent segments of the polymer chain, such that one interaction facilitates the other, thus leading to the formation of a stacked structure. An ammonium cation in the folding agent forms a complex with a hexaoxyethylene spacer thereby aiding the CT interaction between a naphthalene donor and a pyromellitic diimide acceptor in the polymer. Control experiments with a model naphthalene donor, along with an equimolar amount of an ammonium salt, clearly helped delineate the importance of linking the two interacting subunits in the folding agent, and thereby confirmed the importance of cooperativity in such a folding process. Importantly, the folding was also shown to be completely reversible and the polymer unfolds when the folding agent is extricated by formation of a stronger complex with [18]crown-6. Further work to explore the generality and utility of such a small-molecule-induced folding of synthetic polymers would be of great interest and is currently being studied.

Experimental Section

Pyromellitic dianhydride and 1,5-dihydroxynaphthalene were purchased from the Aldrich Chemical Co. and were purified by sublimation and recrystallization (from nitromethane), respectively. Dry and purified solvents were used in all the syntheses and spectroscopic studies. All the solvents and common synthetic reagents were purified according to standard procedures.[23] The NMR experiments were performed using a Bruker 400 MHz spectrometer and UV/Vis spectra were measured using a Ocean Optics spectrometer. The molecular weights were determined by GPC with chloroform as the eluent at 35 °C, two PL-gel mixed-bed columns were used for separation, and a Viscotek TDA Model 300 was used as the detector. The universal calibration method based on a polystyrene standard was used to estimate the molecular weights. Isothermal titration calorimetry (ITC) experiments were performed with a VP-ITC Microcal LLC instrument in a $CHCl_3/CH_3CN$ solvent mixture (1:1). Mass-spectrometric data were obtained on a Q-TOP Micromass spectrometer. Elemental analysis was performed with a Carlo Erba 1106 CHN analyzer.

Folding studies: In a typical NMR titration experiment, a polymer solution (1.5 mL, 1.92 mM) was prepared in $CDCl_3/CH_3CN$ (1:1 v/v; solution A). An aliquot of this solution (0.6 mL) was placed in the NMR tube and a large excess ($\approx$10–15 equiv) of donor molecule was dissolved in the remaining solution (solution B). Solution A was then titrated with solution B (20–150-μL steps), which resulted in a series of solutions of fixed polymer concentration but with various amounts of donor. Similarly, the UV/Vis experiments were performed in $CHCl_3/CH_3CN$ (1:1).

In the experiment with the crown ether, a solution containing a polymer/donor mixture in a 1:7 ratio in $CHCl_3/CH_3CN$ (1:1) was titrated with a solution of [18]crown-6 in $CHCl_3/CH_3CN$ (1:1) that also contained a polymer/donor mixture in a 1:7 ratio. Therefore, the concentration and relative molar ratios of the polymer and donor molecules were kept constant, and the only variable was the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

concentration of [18]crown-6. The Job plot experiment based on UV/Vis spectroscopic analysis was performed in $CHCl_3/CH_3CN$ (1:1), and the total concentration (polymer + folding agent) was maintained at 12 mM for the polymer and 6 mM for the model compound.

Synthesis of the polymer: Hexaethylene glycol diamine[15] (0.494 g, 1.76 mmol) was placed in the reaction vessel and dissolved in freshly distilled *m*-cresol (3 mL). The purified pyromellitic dianhydride (0.384 g, 1.76 mmol) was added to this solution in one portion, and the reaction mixture was stirred at 85 °C for 2 h under a continuous flow of N_2 gas. The reaction mixture was cooled to room temperature, and *m*-cresol (2 mL), dry toluene (5 mL), and isoquinoline (8 drops) were added. The reaction mixture was stirred at 185 °C for another 6 h in an inert atmosphere with continuous azeotropic removal of water. The reaction mixture was cooled to room temperature, and the viscous liquid was poured into methanol (50 mL). The fine powdery precipitate was centrifuged, redissolved in a minimum volume of chloroform, and reprecipitated from methanol to obtain the desired polymer as a white fibrous material. The product was dried under vacuum at 100 °C for 3 h. Yield: 62 %.

For fractionation, methanol was added dropwise to a solution of the polymer (150 mg) in chloroform (10 mL) until the solution became cloudy. The mixture was stirred for another 15 min as a colorless oil separated and stuck to the walls of the vessel. The supernatant was decanted, and the oil was dissolved in chloroform (1 mL) and reprecipitated from methanol to form the fibrous colorless polymer. The product was dried under vacuum for 3 h at 100 °C, and the recovery was found to be approximately 30 %.

[12] K^+ and NH_4^+ ions are known to have similar size-selective preferences on complexation with crown ethers. We have shown that a donor–acceptor polymer that contains a 6OE spacer forms complexes most strongly with K^+ ions.[10,11] Therefore, a polyimide that contains 6OE spacers was chosen in the present study. [18] The increase in intensity is simply a reflection of the increase in the concentration of the donor species, whereas the downfield shift arises from the mole-fraction weighted average of the free and complexed naphthalene units. It may be recalled that formation of a CT complex generally causes an upfield shift of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

both the donor and acceptor units,[11] however, the downfield shift of the donor protons in this case arises from the overwhelming presence of free donor species.

[19] The association constants of the two folding agents with AA-6OE were determined from the variation in the chemical shift of the acceptor ring protons as a function of the folding-agent concentration by using computer program EQNMR version 2.10. (Freeware, M. J. Hynes, Chemistry Department, University College Galway, Ireland). The *K* values were found to be 850 and 600 M^{-1} for D2-NH_3^+ and D3-NH_3^+, respectively, but only 30 M^{-1} for D + NH_4^+, thus confirming the cooperativity of the interaction, as well as the importance of the spacer length for effective binding and folding. The association constant for D2-NH_3^+ was also determined from ITC and was found to be 1050 M^{-1}, which is comparable to that obtained with NMR spectroscopic analysis. Similar attempts to determine the association constant for the polymer with ITC was difficult as a simple plot that assumed a single association constant failed to give a good fit. A probable reason for this failure is that several different values of association constants could, in principle, be required in the case of the polymer. Nevertheless, it is clear from the values of *K* obtained for the model AA-6OE that linking the two interacting segments in the folding agent is critical for the generation of a folded structure in the polymer.

[20] For synthetic details, see the Supporting Information.

[21] The variable temperature experiment was done using D3-NH_3^+ as the folding agent at a ratio of 4:1 molar equivalents with respect to the polymer repeating unit to ensure that the ammonium salt did not precipitate on cooling.

[22] [18]Crown-6 is known to form a very strong complex with ammonium ions with an association constant *K* in the order of 10^6 M^{-1}; see reference [12a].

A Microfabricated Gas–Liquid Segmented Flow Reactor for High-Temperature Synthesis: The Case of CdSe Quantum Dots**

Brian K. H. Yen, Axel Günther, Martin A. Schmidt, Klavs F. Jensen, and Moungi G. Bawendi**

Microfluidic reactors enable a number of advantages over conventional chemical processes including enhanced control of heat and mass transfer, lower reagent consumption during optimization, and sensor integration for in-situ reaction monitoring.[1,2] Reactors are usually fabricated from either silicon, glass, or polymers; those made of silicon or glass are advantageous because they can tolerate a broad range of chemistries and high temperatures. Microreactors for the large class of homogeneous liquid-phase reactions are often based on single-phase laminar flow designs in which reagent streams are brought into contact. However, such designs are limited in terms of slow diffusive reagent mixing and broad residence time distributions (RTDs). Recirculation within segments in a two-phase segmented flow approach (gas–liquid or liquid–liquid) overcomes such limitations by providing a mechanism of exchanging fluid elements located near the channel walls with those at the center.[3–5] This recirculatory motion has the dual effect of narrowing the RTD and improving reactant mixing. In contrast to single-phase designs, segmentation makes it possible to drive reactions to required yields over significantly shorter times owing to the enhanced mixing, while maintaining narrow RTDs.

WILEY InterScience

Gas–liquid rather than liquid–liquid segmented flow offers the most versatility in terms of the range of chemistries that can be performed in a microfluidic system. Gas–liquid flow is preferable for performing reactions at elevated temperatures, as most solvents experience increased miscibility at higher temperatures. Moreover, it is possible to obtain uniform segmentation in gas–liquid flows over a very large range (over two orders of magnitude) of bubble velocities and therefore reaction timescales.[4,5] Liquid–liquid segmented flow systems are operated over a much narrower range with typical droplet velocities varying over one order of magnitude.[3,6] Finally, in gas–liquid segmented flow, the reaction solution is present as a continuous liquid phase within the channel (Figure 1) so that it is possible to

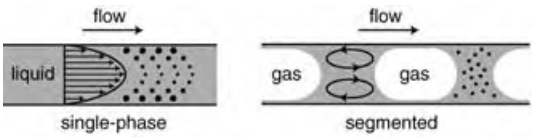

Figure 1. Mixing and residence time distribution (RTD) effects in a) single-phase and b) segmented gas–liquid flow. In the single-phase laminar flow, diffusion is the only means of mixing. As a result of the parabolic fluid-velocity profile, particles near the wall spend more time in the reactor than those in the center, resulting in broad RTDs. In the two-phase case, recirculation within each liquid slug brings material from the wall to the center of the channel. This facilitates mixing, which narrows the RTD, and results in narrower size distributions.

inject additional reactants or withdraw reaction aliquots in a continuous, controllable manner. In liquid–liquid segmented flow, the reaction solution is usually the dispersed (droplet) phase; subsequent addition of reactants is challenging, as it requires synchronized merging of discrete droplets.[6] The withdrawal of small aliquots without disturbing the flow is also difficult. Herein, we demonstrate a silicon-based microreactor that incorporates both gas–liquid segmented flow and multiple temperature zones. The reactor represents a general platform for high-temperature synthesis under very well-defined reaction conditions (mixing times and narrow RTDs).

As a model system for the reactor, the preparation of CdSe quantum dots (QDs) was chosen, as the chemistry a) requires high temperatures and b) highlights the advantages of the segmented-flow approach over single-phase and conventional batch processes. In the batch method, semiconductor QDs (diameters = 2–10 nm) are synthesized by the rapid injection of precursors into a heated flask containing a mixture of solvents and ligands.[7–10] Factors such as the injection process, local temperature and concentration gradients, mixing rate, and cooling rate strongly influence QD nucleation and growth, but are difficult to control. Single-phase continuous flow reactors in which precursor solutions are delivered into a heated reaction section have addressed some of these reproducibility problems.[11] However, these reactors suffer from slow mixing and broad RTDs, which are detrimental to the particle size distribution (Figure 1). It has been challenging to adapt QD chemistry to a chip-based segmented flow system owing mainly to the reaction temperatures required (> 250 °C). Liquid–liquid segmented flow has been used to prepare QDs at room temperature in a polydimethylsiloxane device,[6] but solvent miscibility and polymer degradation at high temperatures make it difficult to use this approach to prepare monodisperse, luminescent particles.

The introduction of segmenting gas into heated capillaries has also been implemented, but the uniformity of such gas–liquid flows and their effect on QD formation were not extensively characterized.[12,13] We demonstrate herein the success of our microreactor design in rapid mixing and extremely uniform segmentation behavior at the high temperatures required for QD synthesis. The QD sample size distributions and reaction yields are superior to those attainable in single-phase flow, with the improvement significantly more pronounced at short reaction times. As the improvement is a direct consequence of the rapid mixing and narrow RTD features of segmented flow, the reactor greatly decreases the time required to produce high-quality particles in comparison with existing single-phase approaches. Moreover, the reactor is applicable to a variety of nanoparticle chemistries because it offers access to a wide range of reaction timescales without a compromise in acceptable size distributions.

The reactor shown in Figure 2 allows rapid initial mixing of the precursors, controlled QD growth, and on-chip quenching of the reaction. The silicon reactor accommodates a reaction channel length of approximately 1 m (hydraulic diameter ≈ 380 μm) and two shallow side channels for collecting reaction aliquots. A halo etch region makes it possible to localize multiple temperature zones for reaction (> 260 °C) and quenching (< 70 °C) on the device. Precursor solutions are delivered separately into the heated section and an Ar gas stream introduced further downstream results in a segmented gas–liquid flow. Recirculation within the liquid slugs rapidly mixes the heated precursors, thereby initiating the reaction. The fluids initially pass through a meandering section to induce good mixing across the channel[3–5] before reaching a longer straight-channel section where the majority of the particle growth occurs. The reaction is stopped when the fluids enter the cooled outlet region of the device. The segment lengths are very uniform during conditions of a typical QD synthesis (Figures 2a and b). Figure 2c shows a long-time-exposure image of the cooled outlet region of the device under continuous UV excitation. At the high reaction temperatures, the QD photoluminescence (PL) is completely quenched (top portion of Figure 2c), but once the fluid reaches the cooled region (< 70 °C), yellow PL is observed. The image illustrates our ability to maintain the required ≈ 200 °C temperature gradient within a single reactor chip.

The quality of the segmentation shown in Figures 2a and b deserves further discussion, as the slug-length distribution can contribute to the RTD and therefore the ultimate QD size distribution. We systematically examined the slug statistics over a range of flow conditions by varying either the total fluid flow rate under conditions of constant gas-to-liquid flow rate (v_g/v_l) or by varying v_g under conditions of constant v_l.[14] The resulting liquid slug-length distributions over this range of residence times are shown in Figure 3a. The liquid lengths are on the order of the channel hydraulic diameter and typically have a relative standard deviation of ≤ 10 %.

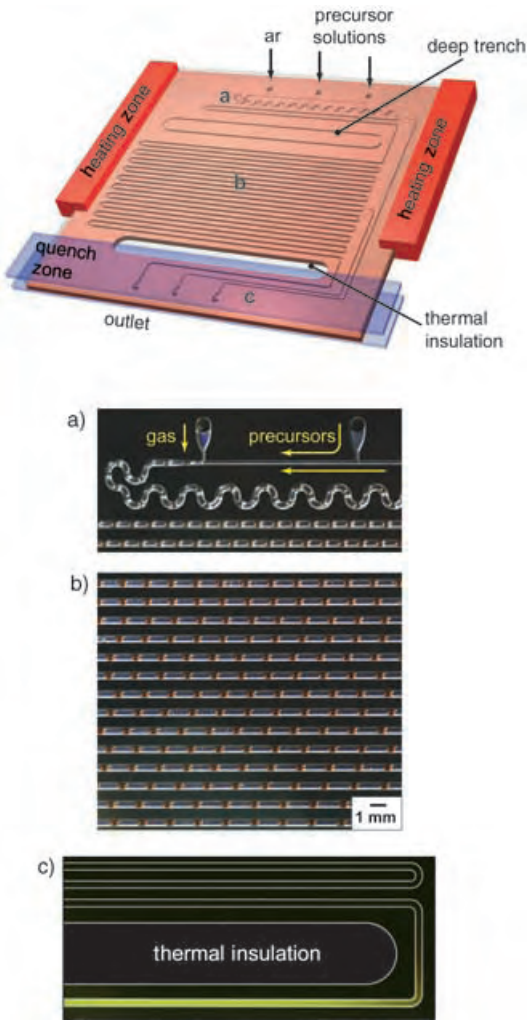

Figure 2. Reactor with heated reaction region and cooled outlet zone: a through-etch section ensures that the two regions are thermally isolated; a) heated inlets and b) main channel section: red segments = QD reaction solution; dark segments = Ar gas; c) time-exposure image of the cooled outlet region under UV irradiation. $T = 260\,°C$, $\nu_g = 60\ \mu L\,min^{-1}$, $\nu_l = 30\ \mu L\,min^{-1}$, Se/Cd = 5.0.

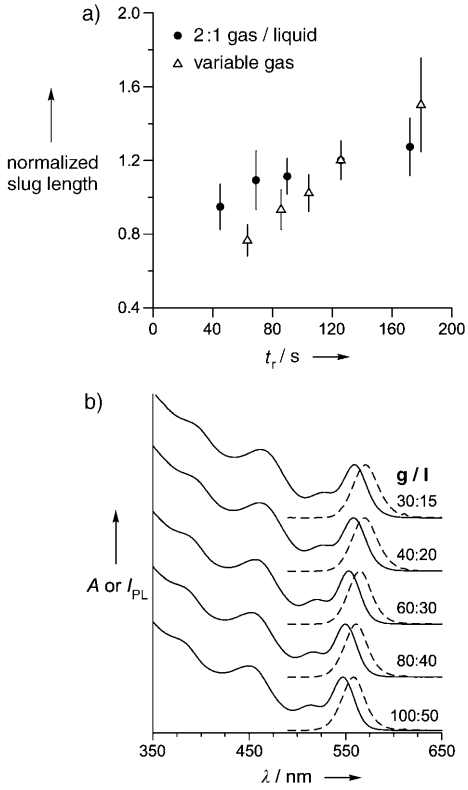

Figure 3. a) Ratio of average liquid slug length to hydraulic diameter (≈380 μm) over a range of flow rates (residence times, t_r) at 260 °C; error bars indicate the standard deviation of the liquid length for a given flow condition; ● = gas/liquid flow rates of: 100/50, 80/40, 60/30, 40/20, and 30/15 $\mu L\,min^{-1}$ (ratio kept equal to 2); △ = flow rates of: 100/20, 80/20, 60/20, 40/20, and 30/20 $\mu L\,min^{-1}$ (liquid flow rate kept at 20 $\mu L\,min^{-1}$). b) Absorbance (——) and photoluminescence (PL) (-----) spectra for QDs prepared under the flow conditions represented by (●) in part a).

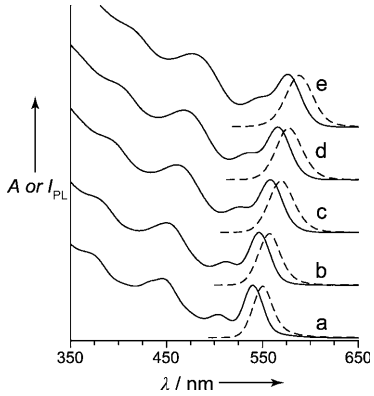

Figure 4. Absorbance (——) and photoluminescence (PL) (-----) spectra for QDs obtained by varying the precursor feed ratio ($T = 260\,°C$). The total gas and liquid flow rates were kept constant ($\nu_{l(Se)} + \nu_{l(Cd)} = 20\ \mu L\,min^{-1}$, $\nu_{g(Ar)} = 40\ \mu L\,min^{-1}$). Spectra correspond to the flow rates ($\nu_{l(Se)}/\nu_{l(Cd)}$) and resulting concentration ratios (Se/Cd) of a) 3.0 and 15, respectively; b) 1.67 and 8.3; c) 1.0 and 5.0; d) 0.60 and 3.0; e) 0.33 and 1.7.

This dispersion in the slug lengths is small enough so that it does not contribute to the overall RTD.[15] The resulting spectra of the QD samples indicate narrow size distributions (Figure 3b) and are similar to the best samples obtained by the batch process. The band-edge absorbance and several higher transitions are clearly resolved, and the PL line widths remain narrow over the entire range of flow rates. In the figure, the PL full-width-at-half-maximum (fwhm) varies between 28 and 31 nm (112 and 119 meV, depending on wavelength).

In Figure 3b, the QDs were prepared with a constant precursor composition and represent a fairly limited spectral range (< 10 nm variation in band-edge position). As discussed previously, it was found that size tuning is more readily accomplished through variation in the ratio Se/Cd rather than the reaction time.[12] Figure 4, illustrates such an effect from varying the Cd and Se precursor flow rates while the keeping the total liquid and gas flow rates constant (at 20 and 40 $\mu L\,min^{-1}$, respectively). In contrast to Figure 3b, a change in the ratio Se/Cd from 15 to 1.7 made it possible to tune the effective band gap of the QDs over a much larger spectral

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

range of ≈40 nm yet maintain narrow size distributions. The average QD radius decreases with an increase in the Se/Cd ratio owing to the strong dependence of the nucleation rate on the precursor ratio. The samples represented in Figure 4 were produced by using the same temperature (260 °C) and mean residence time (≈140 s). By varying the temperature and reaction time in addition to the precursor feed ratios, it would be possible to tune the effective band gap over an even larger spectral window.

In general, it was found that spectra of QDs produced in single-phase operation ($\nu_g = 0$) were significantly broader than those obtained with gas–liquid flow. The poorer performance observed in the single-phase case results primarily from the combination of two effects: initial mixing and broad RTD. In single-phase flow, the two precursor streams combine slowly by diffusion, in contrast to the convective mixing induced by the introduction of a segmenting gas.[16] Slow initial mixing makes it difficult to realize a rapid nucleation burst, and the resulting QD samples are polydisperse. Once the reagents are completely mixed, the RTD effect is still present; QDs near the channel wall spend a longer time in the reactor than those in the channel center. In segmented flow, recirculation within the liquid brings fluid from the channel wall to the center which facilitates rapid mixing, lower dispersion in residence times, and therefore narrower QD size distributions (Figure 1).

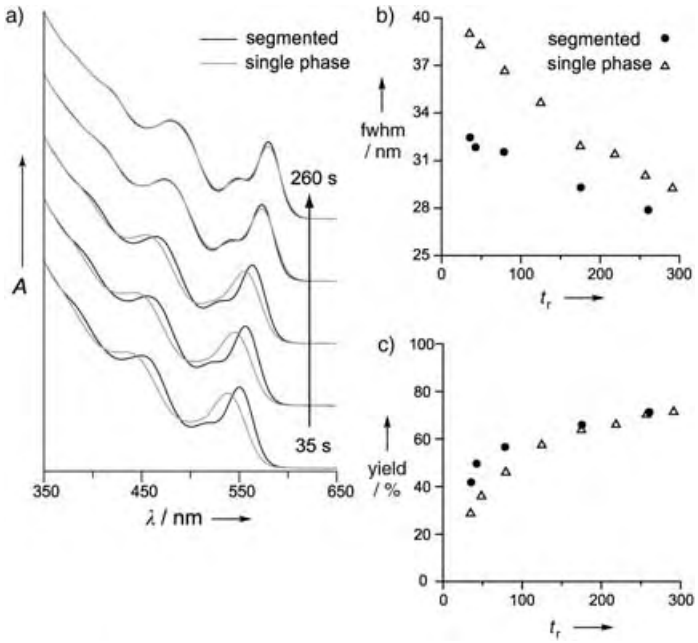

Figure 5. a) Absorbance spectra of QDs prepared with segmented and single-phase flow. Each pair of spectra corresponds to approximately the same mean residence time. b) PL full-width-at-half-maximum (fwhm) and c) reaction yield of QD samples prepared in segmented (●) and single-phase (△) flow. For segmented flow, ν_g/ν_l was varied between 15/10 and 100/40 μL min^{-1}. For single-phase flow, ν_l was varied between 34 and 250 μL min^{-1}. $T = 280$ °C, Se/Cd = 1.0.

To isolate the RTD contribution from the effects of initial mixing, we cooled the inlet region of the reactor and premixed the precursors inline with a miniature convective mixer. A deep trench feature (Figure 2) allowed us to keep the inlets thermally isolated from the main reaction channel. Cooling the inlets ensures that the pre-mixed precursors do not react until they reach the heated reaction section. In this way, we eliminated the effect of initial reagent mixing and were able to directly observe the RTD effect on the QD size distribution. The spectra in Figure 5a illustrate the improvement of the size distribution resulting from segmentation. Figure 5b is a plot of the fwhm of the PL peak for samples prepared at several flow conditions (mean residence times). For reaction times shown in Figure 5b, the PL fwhm varies between 28 and 32 nm (99–128 meV) for segmented flow, and 29 and 39 nm (104–158 meV) for single-phase flow. In both plots in Figure 5b, the PL peak width decreases with time, and this general trend (size distribution focusing) has been explained as evidence of the presence of a mass-transfer component in the particle growth rate.[17,18] However, the absorbance and PL spectra of QDs produced in gas–liquid flow are generally sharper in than those produced in single-phase scenarios. Furthermore, the difference shown in Figures 5a and b between single- and two-phase flow becomes more pronounced at shorter timescales. This behavior at short times results from the fact that the RTD broadens significantly with flow rate in single-phase flow,[12] whereas the RTD does not have such a strong flow-rate dependence in the segmented case. Notably, cooling the inlets is not the normal mode of operation for the device. Upon introduction of the gas at low temperature, the slug uniformity is substantially poorer than the uniform segments shown in Figures 2a and b. This flow destabilization results primarily from rapid expansion of gas and the large change in liquid viscosity when the fluids reach the heated section. In spite of such non-uniform segmentation, a significant improvement in QD size distribution is still observed.

Figure 5c reveals an additional reason for the larger improvement in size distribution at shorter reaction times. In segmented flow, the mixing timescale that is governed by recirculation within liquid slugs decreases almost linearly with flow rate.[5] Therefore, a shorter reaction time (faster flow rate) is compensated by more intense stirring, and vice versa. The inverse relationship between stirring intensity and reaction time is manifested in the reaction yield curves shown in Figure 5c. At shorter times (high flow rates), the QD reaction is driven to higher yields than those of the single-phase operation. The increased growth rate causes the QD population distribution to focus more quickly than in the single-phase case. Consequently, the difference in the two curves in Figure 5b is more pronounced at short times. At lower flow rates, the recirculatory stirring is slower, but the reaction time is longer, thus the yield curve converges with that for single-phase flow. Even at the longest reaction times (when the yields are similar for the two cases), the PL spectra for gas–liquid flow is still somewhat narrower, indicating that the improved RTD effect on size distribution is still present. In summary, the synthesis of acceptable QD samples by the single-phase approach requires long reaction times to allow the size distribution focusing and narrowing of the RTD time to fully develop. In segmented flow, the enhanced mixing

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

accelerates the particle formation process, thereby decreasing the time required for focusing the size distribution, and a narrow RTD is sustained even at high flow rates. For example, from Figure 5b, the narrow size distribution obtained in 42 s with segmented flow requires over fourfold more time ($\approx$175 s) to achieve with single-phase flow.

In conclusion, we have designed a gas–liquid segmented flow reactor with multiple temperature zones. The reactor is applicable to a range of chemistries because it is possible to operate at high temperatures, yet maintain excellent mixing and RTD characteristics. To illustrate the unique features of the design, it was applied to the synthesis of CdSe QDs. Under the reaction conditions reported, segmentation is very uniform and the resulting monodisperse samples exhibit excellent optical properties. Relative to single-phase flow, the enhanced mixing and narrow RTD characteristics of the reactor result in a significant improvement in reaction yield and size distribution, especially at short reaction times. Such attributes are highly desirable from the standpoint of chemical production, as it is possible to increase throughput without sacrificing narrow size distributions. Furthermore, the reactor is applicable to particle systems in which the optimal reaction timescales are shorter than that of CdSe QDs, in contrast to single-phase devices, which are limited to long reaction times. In addition to its use as a synthesis tool, variation of the mean slug velocity and length in the reactor channel provides a way to reproducibly control the mass-transfer rate during particle formation, which is not possible in single-phase flow or the conventional batch method. This makes the reactor design ideally suited for the systematic study of the mechanism of QD formation.

Experimental Section

The reactor was fabricated with standard silicon micromachining techniques. Channels were fashioned by deep reactive ion etching (DRIE) of a silicon wafer ($\varnothing = 15$ cm; thickness = 0.65 mm). An oxide layer (0.5 μm) was grown on the silicon surface, and the entire device was capped and sealed with an anodically bonded pyrex wafer (thickness = 0.76 mm). High-temperature fluidic connections were made by using glass solder (Diemat) to seal Kovar tubing to the reactor inlets. Standard 1/16-inch (1.6 mm) chromatography fittings (Upchurch) were used to connect the Kovar tubing to gas and liquid lines. Syringe pumps (Harvard PHD 2000 and KD Scientific 210) were used to deliver both precursor solutions and segmenting gas. A heated aluminum block in contact with the reaction section of the device was used for thermal control. The inlet and quenching regions were cooled with water-chilled aluminum blocks. Images of the reactor channel were taken with a consumer digital camera equipped with a macro lens and flash. For each flow condition, several hundred individual slug lengths were measured. The liquid fraction (liquid volume/total channel volume) was determined from the average slug lengths, and the mean residence time was calculated from the fraction and syringe pump flow rates.

The Cd and Se precursors were prepared as described previously with a few minor modifications.[12] All manipulations were performed under air-free conditions. Briefly, the Cd precursor was prepared by heating a suspension of cadmium 2,4-pentanedionate (1 mmol, 98%, Alfa) in squalane (9 mL, 98%, Alfa) and oleic acid (2.2 mmol, >99%, Alfa) at 150°C for 10 min. The optically clear solution was then placed under vacuum at 100°C for $\approx$1.5 h before the addition of 4 mL oleylamine (97%, Pfaltz and Bauer). A stock solution of tri-*n*-octylphosphine selenide (TOPSe, 1.5 M) was prepared by dissolving an appropriate amount of selenium shot (99.999%, Alfa) in tri-*n*-octylphosphine (TOP, 97%, Strem). The Se precursor solution consisted of the suitable amount of TOPSe (1.5 M) diluted in squalane. The two precursor solutions were degassed thoroughly at 90°C before loading into separate syringes.

Samples for the measurement of absorbance and PL spectra were prepared by diluting the raw QD solutions in hexanes. Optical absorption spectra were acquired with a Hewlett-Packard 8452 diode array spectrometer. Photoluminescence spectra were acquired with an Ocean Optics SD2000 fiber-optic spectrometer and a handheld UV lamp as an excitation source. Reaction yields were determined from the optical density at $\lambda = 350$ nm and the measured absorbance cross-section for CdSe QDs.[19]

[14] The reported gas flow rates do not include the significant, although steady, gas leakage from the syringe and tubing fittings leading up to the reactor. We found this to be the case even with nominally gas-tight syringes. However, the slug lengths were measured directly from images taken of the reactor channel, so the reported mean residence times are accurate.
[15] The standard deviation of the *mean* of the liquid slug length gives rise to an uncertainty in the residence time: $\sigma_{t_r}/t_r = \sigma_l/(l_{avg}\sqrt{N})$ in which t_r is the residence time, l is the length of an individual slug, and N is the number of liquid slugs in the reactor (typically $\approx$300). As $\sigma_l/l_{avg} \approx 10\%$, $\sigma_{t_r}/t_r < 0.6\%$. In other words, the liquid slug length distribution does not contribute significantly to the overall residence time dispersion.
[16] From Ref. [5], we estimate the mixing time for segmented flow in our system to be $\approx$1% of the average residence time. For the single-phase case, the diffusive mixing time can be >50% of the average residence time depending on the flow rate.

In Vivo Optical Imaging of Amyloid Aggregates in Brain: Design of Fluorescent Markers**

*Evgueni E. Nesterov, Jesse Skoch, Bradley T. Hyman, William E. Klunk, Brian J. Bacskai, and Timothy M. Swager**

Neuroimaging is emerging as a way to noninvasively identify and monitor neurodegenerative diseases during the preclinical and early clinical stages.[1] Alzheimer's disease (AD) stands out among the neurodegenerative diseases as the fourth leading cause of death in the United States and the most common cause of acquired dementia.[2] Early detection of AD is imperative in enabling the understanding and clinical treatment of this disorder, as well as in preventing its progression. The characteristic signature of AD is the deposition of amyloid-β plaques and neurofibrillary tangles in the patient's brain,[3] which parallel the disease but can only be diagnosed with certainty after death by an autopsy.

A significant advance in the field has been the development of radiolabeled small-molecule agents capable of entering the brain and specifically targeting plaques and tangles for imaging with positron emission tomography (PET) and single-photon emission computerized tomography (SPECT).[1] A major limitation of these methods is the requirement for the markers to be labeled with short-lived isotopes, such as ^{11}C with a half-life of about 20 min for PET. An attractive noninvasive alternative is in vivo optical imaging using specific far-red (near-IR) fluorescent contrast agents. These contrast agents make use of the inverse fourth-power relationship between the wavelength and light scattering, thus allowing the longer-wavelength light penetration through the living tissues necessary for direct brain imaging.[4a] Long-wavelength detection methods also benefit from the low auto-fluorescence of biological matter beyond 600 nm.[4] The requirements for a successful optical marker of AD are: 1) a suitable wavelength interval of absorption and emission (600–800 nm), 2) the ability to rapidly enter the brain after intravenous injection, and 3) specific labeling of the amyloid-β deposits with rapid clearing of the unbound dye. Another unique advantage of optical imaging is the possibility to attain substantial differences in the photophysical/optical properties between the bound and unbound forms of the marker (requirement 4). This would allow a significant increase in imaging contrast which cannot be exploited with techniques based on radioligands.

Among the known amyloid-staining compounds, Congo Red (CR) provides historically the most standardized way of staining amyloid plaques, and is still employed in post mortem histological analysis of AD brain, as the binding is specific.[5] Thioflavin T (ThT) is another dye to use in analysis of aggregated amyloid proteins. It binds slightly weaker than CR, but makes up for this deficiency by exhibiting a green fluorescence, that becomes more than 1000 times brighter upon binding to amyloid plaques.[6] The understanding of what makes these simple molecules so specific to senile plaques is the starting point for the rational design of improved markers. Studies[7] suggest that the origin of the specific binding of CR to amyloid-β aggregates is due to the combination of electrostatic interactions between the negatively charged CR's sulfonate groups with the positively charged amino acid residues in the antiparallel protein

β sheets, and CR's shape is complementary to features in an amyloid fibril's surface. The latter recognition likely involves hydrophobic interactions with the planarized aromatic π system of the dye molecule.[7c] Although the binding of ThT to amyloids has received less attention, it is likely to involve similar shape-specific recognition.[6,8] Thus, it is our opinion that the presence of hydrophobic planarized (or easily planarizable) π system is an important design feature to obtain high binding specificity.

A potential biomarker must be able to rapidly enter the brain after an intravenous injection. To exhibit high blood–brain barrier (BBB) permeability, the molecule needs to be relatively lipophilic (but not highly lipophilic as this will lead to its aggregation and accumulation in blood proteins and red blood cell membranes), and should not bear ionic groups. High BBB permeability also requires the marker to be relatively small, with an upper molecular weight limit of about 600 Da. These simple empirical rules are extremely robust, and, for example, both CR and ThT, as charged molecules, are not capable of crossing the BBB. It is also highly probable that any charged molecules like compound 2C40, a recently proposed fluorescent marker for AD found by combinatorial screening of a library of 320 compounds,[9] will be similarly incapable of in vivo imaging. In contrast, substantial increase of the BBB permeability was achieved with uncharged analogues of CR and ThT. For example, in the CR analogue Chrysamine G (CG), the replacement of the sulfonate group by a less ionizable carboxy group significantly increased the BBB permeability without compromising the high binding specifity.[10] A ThT uncharged analogue, 6-OH-BTA-1, which is commonly referred to as Pittsburgh compound B (PIB), is highly efficient both in crossing the BBB and in selective binding to AD amyloid aggregates, and is currently under clinical tests as an amyloid marker with PET imaging.[11]

To develop an effective in vivo imaging dye, we have merged these empirical requirements with electronic structure design to produce a compound possessing a suitable spectral range of the absorption and emission bands along with a potential to produce additional imaging contrast. We have employed a classical push–pull architecture with terminal donor and acceptor moieties that are interconnected by a highly polarizable bridge. Various donor and acceptor groups can be used to manipulate the relative energies of HOMO and LUMO, with better donor and better acceptor leading to a smaller HOMO–LUMO gap and to the desired long wavelength absorption/emission bands. Finally, to obtain greater imaging contrast, we required a molecule to possess a substantial degree of conformational freedom when unbound in solution, but it would be conformationally restricted upon binding to the protein. Such a "rigidification" decreases the vibrational-rotational processes that couple the excited and ground states, thereby decreasing the radiationless decay rate and increasing the fluorescence quantum yield of the protein-bound molecule.[12]

The proof-of-approach near-IR Alzheimer's dye NIAD-4[13] was designed to satisfy all four of the requirements above. This dye with a molecular weight of 334 Da is likely to be among the simplest possible structures. It uses a dithienylethenyl π-conjugated bridge between donor and acceptor. The highly polarizable bridge was chosen to provide a substantial bathochromic shift in both absorption and emission spectra of the dye. The rigid rodlike aromatic core of NIAD-4 is hydrophobic and readily planarizable, and has a shape similar to that of ThT for achieving a high binding specificity to amyloid aggregates. In unbound NIAD-4 free rotation around the single bonds leads to facile vibrationally coupled radiationless excited-state deactivation. Reduction of these processes upon binding to the protein aggregate was expected to enhance its fluorescence quantum yield. The donor and acceptor groups were chosen to balance between the need for a high electron-donating/accepting ability to achieve a substantial spectral bathochromic shift and the requirement to avoid charged or easily ionizable groups to improve the BBB permeability. The dicyanomethylene group was chosen as the acceptor, and the hydrophilic *p*-hydroxyphenyl group was selected as a donor to compensate for the high hydrophobicity of the bridge. Both groups are relatively small and were instrumental in maintaining the low molecular weight of NIAD-4.

The synthesis of NIAD-4 is shown in Scheme 1. The silyl-protected aldehyde **4** was prepared by Stille coupling.

Scheme 1. Synthesis of dye NIAD-4: a) $[PdCl_2(PPh_3)_2]$ (3 mol%), toluene, 70°C, 36 h; b) *n*BuLi, TMEDA, hexanes, −70°C, 2 h; c) DMF, −70°C→RT, 12 h; d) $CH_2(CN)_2$, EtOH, piperidine (cat.), 60°C, 18 h; e) HCl, 60°C, 6 h. DMF: *N*,*N*-dimethylformamide; TMEDA: *N*,*N*,*N*′,*N*′-tetramethylethylenediamine.

Condensation with malononitrile followed by in situ deprotection afforded NIAD-4 as a dark-red material, which exhibits a bright red fluorescence in methanol solution (Figure 1). This contrast marker is slightly soluble in aqueous media, although it forms micelles/aggregates at the concentrations above 10 μM.[14] The aqueous solutions of NIAD-4 only have trace emission (quantum yield ≈0.00008), which may be in part due to the greater stabilization in aqueous media of the non-emissive intramolecular charge transfer state as opposed to the emissive planar excited state.[15] An in vitro spectral study with aggregated synthetic amyloid-β 1–

40 protein displayed a significant red shift ($\Delta\lambda \approx 70$ nm) of the absorption maximum along with about 1.3-fold increase in its extinction coefficient (Figure 2). This phenomenon is a

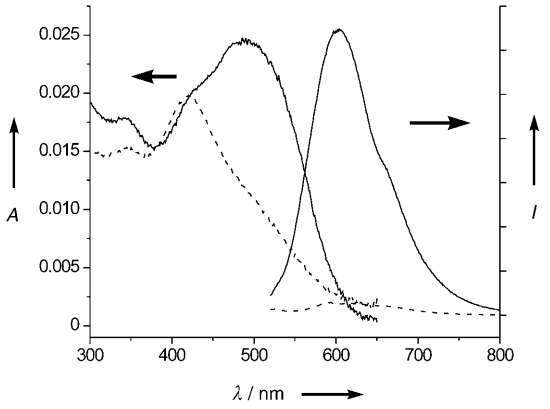

Figure 2. Absorption and fluorescence spectra of NIAD-4 in aqueous PBS solution in the presence of aggregated amyloid-β protein (solid line) and without the protein (dashed line). Concentrations: NIAD-4 4.1 μM, amyloid-β ≈10 μM. PBS: phosphate buffered saline.

consequence of the strong binding between the dye and the aggregated amyloid fibrils. The fluorescence maxima of the bound and unbound forms do not differ appreciably, and, as expected, the binding is accompanied by a dramatic enhancement of the fluorescent emission (about 400-fold, quantum yield 0.05), which is visible by simple visual inspection even at the micromolar concentrations used in the experiment. Apparently, the protein-bound dye is preorganized in a geometry that is similar to the planarized geometry of the emissive excited state after it has reached its equilibrium nuclear coordinates. Furthermore, binding to the amyloid fibrils places the dye in a lower dielectric constant environment that decreases detrimental relaxation into a non-emissive intramolecular charge transfer state.[15]

The binding studies with artificially aggregated amyloid protein assays revealed that NIAD-4 binds to the same site as BTA-1 with a binding affinity K_i of 10 nM. This affinity is much higher than that of ThT ($K_i = 580$ nM), and is close to that of high-affinity amyloid-binding compounds like PIB ($K_i = 4.3$ nM).[11b] The excellent performance of NIAD-4 for in vivo staining of amyloid plaques was demonstrated by using transgenic mice with AD-like pathology prepared with cranial windows to allow direct monitoring of the brain surface.[16] The dye readily crosses the BBB after an intravenous injection and labels specifically both the plaques and cerebrovascular amyloid angiopathy in the living brain thus making them easily detectable by the characteristic red fluorescence (see Figure 3 and Supporting Information). The high specificity of labeling the amyloid deposits is also clearly observed with in situ histochemical staining of fixed sections from transgenic mouse brain (Figure 3). In both in vivo and in situ experiments, the fluorescent images reveal exact position and size of the aggregated amyloid deposits, therefore providing the best demonstration of the high labeling specificity of NIAD-4.

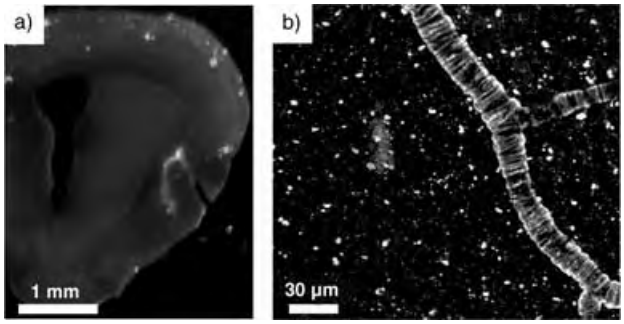

Figure 3. In vivo targeting and in situ specificity of NIAD-4 for amyloid deposits in the brain. a) A fluorescent image of a coronal section of brain from an aged APP transgenic mouse labeled with a 10 μM solution of NIAD-4 in DMSO/propylene glycol for 15 min at RT. b) In vivo fluorescent detection of both senile plaques and amyloid angiopathy using multiphoton microscopy immediately following intravenous injection of 2 mg kg^{-1} of NIAD-4. The images demonstrate the egress of dye through the BBB in a living mouse as well as the specific, sensitive targeting of amyloid-β deposits in the brain.

The remarkably strong bathochromic shift in absorption concomitant with the increase of absorption intensity upon binding combine for the high contrast optical imaging. To support our model that these changes are in part due to the planarization of NIAD-4 upon binding, we have calculated the geometry-optimized structure of the dye molecule (Figure 4a). Although both thienyl rings are nearly coplanar (dihedral angle 4.5°), the benzene ring is markedly twisted with respect to the plane of the neighboring thienyl group (dihedral angle 24.5°). This geometry still allows a π conjugation, and both HOMO and LUMO are substantially delocalized over the entire molecule (Figure 4c). Interestingly, just a small geometry change towards further planarization (which is likely to happen upon binding to amyloid fibrils) significantly increases the conjugation, resulting in even more delocalized frontier orbitals and a smaller HOMO–LUMO gap. The computed electrostatic potential distribution over the electron density surface (Figure 4b) is very similar to that of CR, with the highly hydrophobic neutral core and negative charge density localized at the

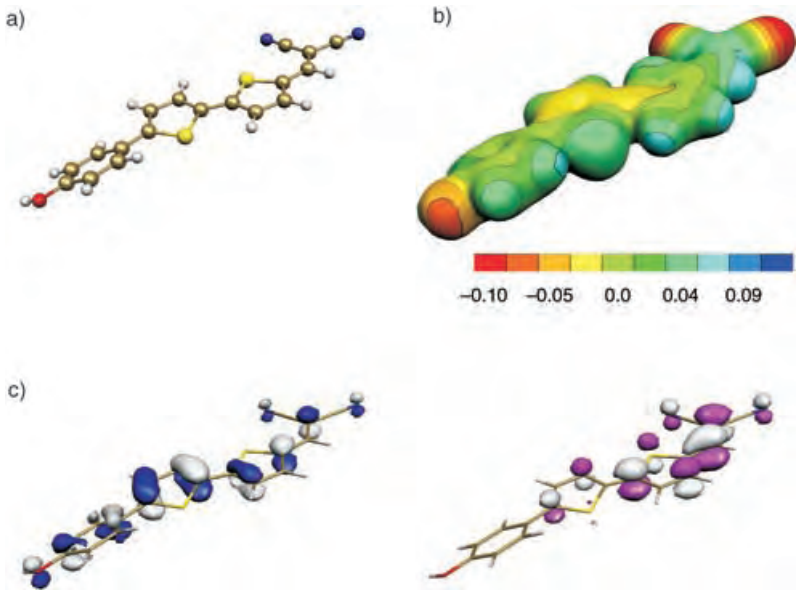

Figure 4. Optimized ground-state geometry of NIAD-4 (a), color-coded electrostatic potential mapped over electron density surface (b), and frontier molecular orbitals (c): HOMO (left) and LUMO (right). The computations were performed in gas phase at B3LYP/6-31G(df,p) level of theory. For this geometry, the computed absorption maximum (TD-B3LYP/6-31G(df,p)) was found to be 481 nm, which is in excellent agreement with the experimental value (475 nm).

molecule's termini. This feature may be in part responsible for the high binding selectivity of NIAD-4 to aggregated amyloid protein.[17]

In conclusion, we have demonstrated that the targeted rational design of in vivo fluorescent markers for amyloid protein aggregates can be successfully accomplished with a set of very simple qualitative rules. The designed contrast agent NIAD-4 shows remarkable promise for the optical imaging of amyloid plaques in brain. It may also be useful for the detection of peripheral amyloidoses. Clearly, its practical application in human Alzheimer's disease research and diagnostics requires further red-shifting of its spectral characteristics and increasing fluorescence quantum yield to allow truly noninvasive monitoring of the brain surface, without the need for the cranial window. It also requires detailed and thorough toxicity studies which we have not performed at this stage.[18] Still this is a remarkable milestone demonstrating great power of the simple design principles outlined herein for development of a practical AD biomarker. Regardless of the spectral properties of this new compound, a radiolabeled version of NIAD-4 may also be advantageous for PET or SPECT imaging. Directed modifications of the structure of NIAD-4 with the purpose to further red-shift the spectral characteristics, increase fluorescence quantum yields, and generally improve performance, as well as gain deeper understanding of these markers, are currently underway.

[12] The phenomenon of increasing the emission quantum yield in viscous solvents, where a conformationally labile molecule is vibrationally-restricted, is well documented for ThT (ref. [6]), as well as for some other fluorescent molecules (K. A. Willets, O. Ostroverkhova, M. He, R. J. Twieg, W. E. Moerner, *J. Am. Chem. Soc.* **2003**, *125*, 1174 – 1175).
[13] NIAD-4 is one of a series of contrast agents that we have been developing and testing. Additional NIAD compounds will be reported in the future.
[14] The 10 μM aggregation threshold, determined by a simple visual inspection, is a very approximate estimate, and strongly depends on the way the solution was prepared. The solutions used in the experiments reported herein had at least twice lower concentration, and their absorbance did not change after passing through a syringe filter with 0.2 μm pore size. Based on this, we can reasonably assume that NIAD-4 was not aggregated in the solutions.

[17] Alternatively, the spectral changes upon binding to amyloid may be explained by change in protonation of the phenolic hydroxy group upon binding of the dye to a protein aggregate. This behavior should be similar to the deprotonation at higher pH values, which can be employed to study the deprotonation effect. Although these experiments showed an anticipated change in optical properties at increasing pH (Figure S1 in the Supporting Information), the overall trend does not correspond to the spectral changes found upon binding to amyloid. This allowed us to safely rule out the explanation based on the protonation change.
[18] Injection of NIAD-4 into living mice did not result in any substantial alteration of their normally expected lifespan, or showed any visually detectable abnormalities. Although this does not exclude the need for thorough toxicology experiments, it may indicate that the dye is not significantly toxic.

Label-Free Electronic Detection of Thrombin in Blood Serum by Using an Aptamer-Based Sensor**

*Yi Xiao, Arica A. Lubin, Alan J. Heeger, and Kevin W. Plaxco**

Aptamers are DNA or RNA sequences selected in vitro for their ability to bind specific molecular targets.[1–3] Due to the ease with which novel aptamers can be fashioned and their generally impressive selectivity and affinity, they are widely regarded as ideal recognition elements for biosensor applications.[4,5] Consistent with this claim, aptamers have been employed in a variety of sensing technologies,[6–11] including a very promising optical approach termed "aptamer beacons". Aptamer beacons employ a large-scale, binding-induced conformational change in order to modulate the emission of a covalently bound fluorophore.[12] To date, aptamer beacons have been reported for such diverse targets as the small molecule cocaine[13] and the proteins Tat,[14] Taq DNA polymerase,[15] platelet-derived growth factor,[16] and thrombin.[6]

Aptamer beacons are rapid, label-free, and exceptionally selective.[12,17] As beacons are an optical approach, however, they suffer from several potential drawbacks relative to electronic-sensing strategies. These include a requirement for generally bulky, expensive, and power-intensive light sources, detectors, and monochromators, a susceptibility to photobleaching, and potential false signals arising from contaminating fluorophores or quenchers.[18] In contrast, the impressive miniaturization of modern microelectronics and the relative stability and environmental insensitivity of electroactive labels suggest that electronic sensors might avoid many of these pitfalls.[19] Previously described electronic aptamer-based sensors, however, require either the addition of exogenous reagents or are susceptible to interference from contaminants. For example, while impressive sensitivity and detection speed have been demonstrated by using aptamer sensors based on the quartz crystal microbalance[10] or on surface plasmon resonance,[20] both approaches are prone to false positives arising from nonspecific binding. Similarly, while the electrochemical detection of an aptamer–thrombin interaction has been reported, the approach requires complex, multistep preprocessing and the addition of an exogenous redox label.[11]

Here we describe a relatively general solution to the problem of electronic aptamer-based (E-AB) sensors. The sensor that we have developed, which is directed against the blood-clotting enzyme thrombin, is sensitive, selective, and reusable, and it does not require modification of the analyte. Instead, signal generation occurs upon a large, binding-induced conformational change in a redox-modified, electrode-attached aptamer upon target binding.

The E-AB sensor is analogous to the E-DNA sensor, a previously described, reagentless, electronic DNA sensing technology.[21] The E-AB sensor is constructed by covalently attaching a methylene blue (MB) labeled, thrombin-binding DNA aptamer (oligomer **1**) to a gold electrode by well-established self-assembling monolayer chemistry.[21] In the absence of target, the immobilized 32-base aptamer is thought to remain relatively unfolded,[6] thereby allowing the attached MB to collide with (or weakly bind to) the electrode and transfer an electron (Figure 1, left). Upon thrombin binding, electron transfer is inhibited, presumably due to a binding-induced conformational change in the aptamer (Figure 1, right)[6,22] that significantly alters the electron-tunneling distance and/or pathway (Figure 2, left). We assume that the immobilized aptamer (oligomer **1**) is in a conformational equilibrium between its unfolded state and the folded, binding-competent G-quartet conformation.[9] Since thrombin binds only the G-quartet conformation, the target protein

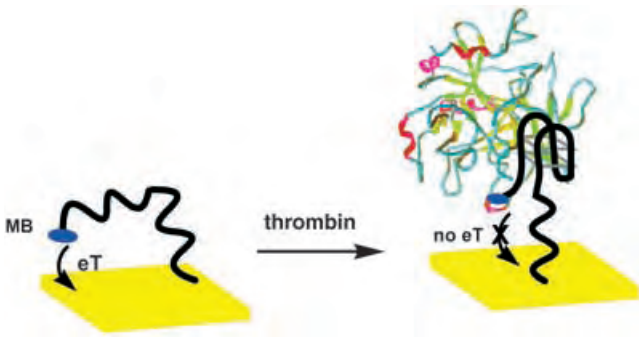

Figure 1. A schematic of the E-AB sensor. In the unbound state (left), the aptamer is thought to be highly dynamic,[6] allowing rapid collisions (or complex formation) between the MB redox tag and the electrode. This, in turn, presumably allows the efficient electron transfer (eT) that is observed in the absence of target. Upon target binding (right), electron transfer is inhibited, presumably because the aptamer forms a stable, rigid structure.

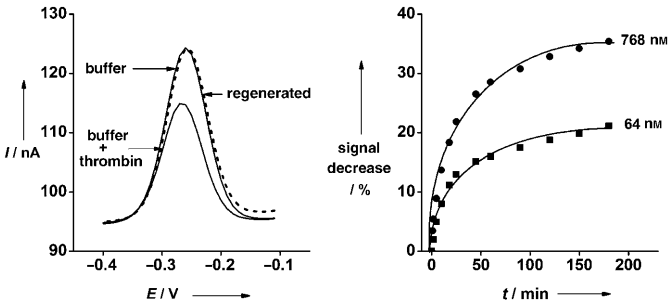

Figure 2. Left: The E-AB sensor responds robustly to 64 nM thrombin in buffered saline and can be regenerated by an eight-minute, room-temperature wash with 6 M guanidine hydrochloride. Even after two cycles of use and regeneration, we can recover 93% of the original sensor signal (dashed line). Right: Time dependence of the sensor response after a 3 h incubation ($t = 0$ min).

drives the equilibrium towards this state, thereby producing the observed signal.

As the modified aptamer is covalently attached to the sensing electrode, the E-AB sensor is readily regenerated (see dashed line in Figure 2, left). By contrast, several methods previously employed for the regeneration of antibody-based sensors (0.2 M NaOH; 0.25% sodium dodecyl sulfate at pH 10; 6 M urea; 0.2 M HCl; 0.2 M glycine, 30% methanol at pH 2; and 10% isopropyl alcohol in phosphate buffer at pH 7) produced little, if any, regeneration (data not shown). When compared to other, commonly employed sensing strategies, such as ELISAs,[23] the E-AB sensor is reasonably rapid; while a 3 h incubation is required to achieve signal saturation, the majority of the signal change occurs within minutes (Figure 2, right). The use of the Laviron equation[24] to calculate the interfacial electron-transfer rate between MB and the electrode gives rate constants of 88 s^{-1} and 58 s^{-1} before and after the reaction with thrombin, respectively (data not shown). The similarity in these rates suggests that unbound aptamers produce a similar electron-transfer rate irrespective of whether neighboring aptamers are bound to thrombin and that the electron-transfer rate becomes undetectably slow upon binding.

As signaling is based on a specific, binding-induced conformational change[25]—as opposed to a less specific physical change, such as adsorption—the E-AB sensor should be relatively insensitive to nonspecific binding. In order to test this, we have shown that 64 nM thrombin taken up in blood serum (diluted 50% with buffered saline)—a realistically complex and contaminant-ridden clinical material—produces a large (35%) reduction in peak current (Figure 3, right). By contrast, blood serum lacking exogenously added thrombin produces only a small ($\approx$7%) reduction in peak current (Figure 3, left).

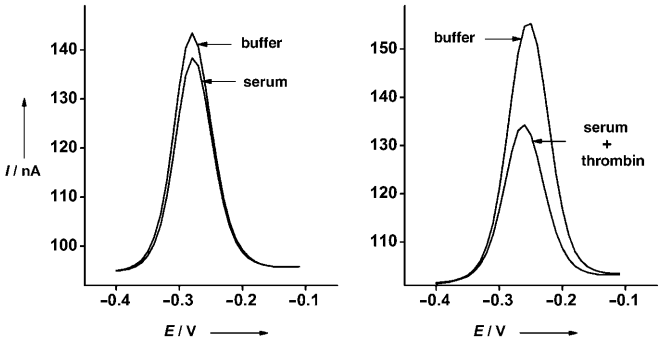

Figure 3. The E-AB sensor can detect thrombin even in a complex, contaminant-ridden sample such as blood serum. The sensor signals arising from thrombin-free buffered saline, from 50% fetal calf serum, and from 50% serum doped with 64 nM thrombin are shown.

The origin of the small signal drop observed in the absence of added thrombin is unclear. Possible sources include degradation of the aptamer or nonspecific interactions mimicking, to a limited extent, the binding-induced sequestration of the MB. However, neither an MB-tagged stem loop (oligomer **2**) nor a second, MB-tagged control oligonucleotide (oligomer **3**; of identical sequence composition and 81% sequence identity to oligomer **1**, but known not to bind thrombin[1]) exhibit any measurable signal drop when incubated in serum (data not shown), a result suggesting that these mechanisms are not significant. It is difficult to rule out the possibility that the signal change arises due to the presence of thrombin which, as a blood-clotting enzyme, may be present in the undoped serum; while resting (non-clotting) serum thrombin levels are very low, active concentrations soar to several hundred nanomolar during clotting.[26] Given that the blood serum employed is fetal calf serum (a safe proxy for human blood) that was harvested from calves in utero, some activation of the blood-clotting cascade may have occurred, thereby producing detectable levels of thrombin.

The sensitivity and dynamic range of the E-AB sensor span the physiological concentrations of thrombin in resting and activated blood, which range from low nanomolar to low micromolar, respectively.[8] Except at the very lowest thrombin concentration that we have investigated (6.4 nM), peak currents are linear with the logarithm of thrombin concentration (Figure 4). This linear relationship holds up to the highest thrombin concentrations that we have investigated (768 nM). Relative signal changes, however, are dependant on

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

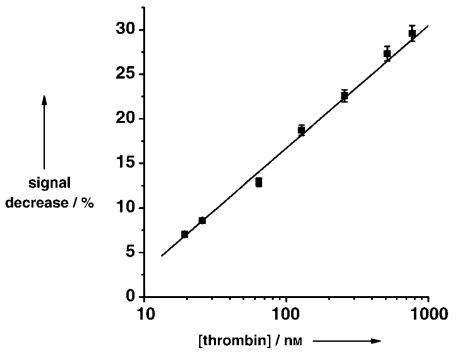

Figure 4. The dynamic range of the E-AB sensor covers physiologically relevant concentrations, which range from a few nanomolar (resting blood) to several hundred nanomolar (when the clotting cascade is activated). The error bars represent the standard deviation of four measurements conducted with a single electrode at each thrombin concentration. Multiple electrodes were used to collect this data set.

surface coverage; at lower surface coverage than that employed here, we observe smaller absolute signals but higher relative signal changes (data not shown). We presume this to be a consequence of reduced steric blocking of unbound aptamers by thrombin binding.

In conclusion, we have demonstrated a novel, label-free electronic method for the specific and quantitative detection of the blood-clotting factor thrombin. The E-AB sensor, which is based on a binding-induced conformational change in a highly selective, high-affinity thrombin-binding aptamer, detects the blood protein at nanomolar concentrations without any more cumbersome preprocessing than sample dilution with buffered saline. Moreover, because signal generation does not rely on simple physical adsorption, the sensor is quite insensitive to nonspecific binding and thus readily detects physiological thrombin levels, even in complex, contaminant-ridden samples such as blood serum. Lastly, the E-AB sensor is reasonably rapid and, given its label-free, fully covalent nature, readily regenerated.

The E-AB sensor platform is limited to targets for which DNA aptamers are available that undergo a large-scale, binding-induced conformational change. Such aptamers, however, may be relatively common. For example, as described above, a number of groups have reported optical aptamer-beacon sensors that utilize a ligand-induced folding event to segregate a fluorophore–quencher pair.[12] Additionally, Ellington and co-workers have reported an in vitro selection technique for the generation of aptamer-beacon-like molecules against arbitrary targets.[6b] The present study demonstrates a presumably general means by which the binding of such aptamers to their targets can be monitored electronically, thus opening a new direction for the development of rapid, reusable, and sensitive detection of multiple analytes in complex, contaminant-ridden clinical samples.

Experimental Section

Labeled DNA oligonucleotides were synthesized by BioSource Int. (Foster City, CA) and purified by C18 HPLC and PAGE; their structures were confirmed by mass spectrometry. The sequences of the three oligomers employed are:

1: 5′-HS-$(CH_2)_6$-TAAGTTCATCTCCCCGGTTGGTGTGGTTGGT-$(CH_2)_2$-MB-3′

2: 5′-HS-$(CH_2)_6$-GCGAGGTAAAACGACGGCCAGTCTCGC-$(CH_2)_7$-MB-3′

3: 5′-HS-$(CH_2)_6$-TAAGTTCATCTCCCCGGTGGTGGTTGTGGTT-$(CH_2)_2$-MB-3′

MB was conjugated to the 3′ end of these probes through succinimide ester coupling (MB–*N*-hydroxysuccinimide was obtained from EMP Biotech, Germany).[27] Inspection of a model of the solution structure of the thrombin–aptamer complex suggests that bases 4–12 of the aptamer bind to the anion-binding exosite of thrombin and that the remainder of the aptamer is relatively solvent-exposed.[22,28] This, in turn, suggests that the MB label, which is covalently attached to the 3′-terminal base, should not interfere with thrombin binding.

The human α-thrombin used in this study was purchased from Haematologic Technologies Inc. (Essex Junction, VT; specific activity: 3545 U mg^{-1}) and diluted with sterile water as appropriate. Fetal calf serum was purchased from Sigma-Aldrich, Inc. (USA) and used without further processing.

The E-AB sensor was fabricated by using polycrystalline gold disk electrodes (1.6 mm diameter; BAS, West Lafayette, IN). The electrodes were prepared by polishing with diamond and alumina (BAS), sonication in water, and electrochemical cleaning (a series of oxidation and reduction cycling in 0.5 M NaOH, 0.5 M H_2SO_4, 0.01 M KCl/0.1 M H_2SO_4, and 0.05 M H_2SO_4) before being modified with the probe DNA. The clean gold surface was interacted with a 0.1 μM solution of thrombin DNA aptamer (oligomer **1**) containing 1 μM tris-(2-carboxyethyl) phosphine hydrochloride (TCEP, which is included to reduce disulfide bound oligomers) in 100 mM tris(hydroxymethyl)aminomethane (Tris) buffer at pH 7.4 for 16 h. The surface was then rinsed with deionized water and subsequently passivated with 6-mercaptohexanol (1 mM in 10 mM Tris buffer, pH 7.4) for 3 h. The electrodes were rinsed again with 100 mM Tris buffer at pH 7.4 before being measured by alternating-current voltammetry with a CHI 603 potentiostat (CH Instruments, Austin, TX) in a standard cell with a platinum counter electrode and an Ag/AgCl reference electrode. Control electrodes modified with oligomers **2** and **3** were prepared on the gold surface as described for the immobilization of the thrombin aptamer (oligomer **1**). The surface coverage of the DNA was $(2.5 \pm 0.2) \times 10^{-12}$ mol cm^{-2}.

Sensor measurements were conducted by monitoring the electrode in buffered saline (0.1 M Tris (pH 7.4) with 140 mM NaCl, 20 mM MgCl, and 20 mM KCl). Neither increasing the final KCl concentration to 150 mM nor changing the pH value to 8.5 significantly affected the sensor response (data not shown). Thrombin detection was carried out either in buffered saline, or in fetal calf serum diluted with buffered saline. (The serum samples were diluted to 50% with 0.2 M Tris (pH 7.4). Saline (50 μL), 2.94 M in NaCl, 0.42 M in $MgCl_2$, and 0.42 M in KCl, was then added to this mixture (1 mL).) For all thrombin detection measurements, except the time-course study (Figure 2, right), electrodes were incubated in each sample for 3 h at room temperature. E-AB sensors were regenerated by soaking in 6 M guanidine hydrochloride (Pierce, Rockford, IL) for 8 min at room temperature, followed by rinsing with deionized water.

Paramagnetic Platinum–Rhodium Octamers Bridged by Halogen Ions To Afford a Quasi-1D System**

Kazuhiro Uemura, Kôichi Fukui, Hiroyuki Nishikawa, Saiko Arai, Kazuko Matsumoto, and Hiroki Oshio*

One-dimensional (1D) materials have long fascinated physicists and chemists because of their unusual physical properties.[1,2] It has been recognized that stacks of mixed-valent organic and inorganic molecules exhibit unusual electrical properties owing to the alternate donor–acceptor interactions within the stack column, as found in [(TTF)(TCNQ)] (TTF = tetrathiafulvalene, TCNQ = tetracyanoquinodimethane), square-planar $[Pt(CN)_4]^{n-}$, and $K_2[Pt(CN)_4]X_{0.3}$ (X = Cl, Br).[3] The future goal in this area is to prepare "synthetic metals" and establish the superconducting state in low-dimensional materials.[2] To rationally synthesize 1D chains of conducting materials, a judicious choice of mixed-valent metal complexes (Pt, Rh, etc.) is necessary.[4] "Platinum blue" has a linear tetranuclear metal–metal bonded backbone with mixed valency $(Pt^{2.25+})_4$, and the one unpaired electron of the complex is delocalized over the four platinum centers,[5,6] whose redox properties based on $Pt^{III/II}$ have been well-studied and applied to catalysis.[5] Introduction of this fascinating structure into 1D conducting materials has, to our knowledge, not been attempted. Herein, we report the

synthesis, X-ray crystal structure analysis, and magnetic properties of the infinite chain of Pt_6Rh_2 moieties bridged by Cl^- ions.

Our strategy for the synthesis of a 1D chain is to rationally align dinuclear basic units doubly bridged with amidate ligands as found in platinum blue backbones. We previously reported the synthesis and structure of $[Pt(PVM)_2(NH_3)_2]\cdot 2H_2O$ (**1**, PVM = pivalamidate),[7] which can easily bind a second metal ion with the noncoordinated oxygen atoms of the amide moieties[8] to afford various dinuclear and trinuclear Pt complexes (Scheme 1).[7] For example, a simple mixture of **1** and $RhCl_3\cdot 3H_2O$ in MeOH provides the dinuclear complex, $[PtRh(PVM)_2(NH_3)_2Cl_3]$.[9,10] Such facile dimerization is attributed to the thermal instability of **1** in the solution state which is manifested by the release of PVM upon addition of excess $NaPF_6$ to **1** in MeOH[11] to give yellow-green crystals of $[Pt_2(PVM)_2(NH_3)_4](PF_6)_2\cdot H_2O$ (**2**). The oxidized **2**—platinum blue—was synthesized from the reaction of **1** and the hydrolysis product of *cis*-$[PtCl_2(NH_3)_2]$ and was isolated as dark green $[Pt_4(PVM)_4(NH_3)_8](PF_6)_4(ClO_4)\cdot 2H_2O$ (**3**). Figure 1 shows the crystal structures of **2** and **3**. Both single crystals of **2** and **3** consist of tetranuclear platinum chains (Figure 1 a and c). It is known that tetraplatinum chain structures are achieved only with head-to-head (HH) dimers and that dimer–dimer interactions are generally stabilized by a Pt–Pt bond and/or four hydrogen bonds formed between the oxygen atoms of the amidate and the hydrogen atoms of the ammine ligands. These tetranuclear structures are essentially identical to those reported previ-

Scheme 1. Reaction scheme for $[Pt(PVM)_2(NH_3)_2]\cdot 2H_2O$ (**1**), which can easily bind a second metal ion to afford various di- and trinuclear Pt complexes as shown.

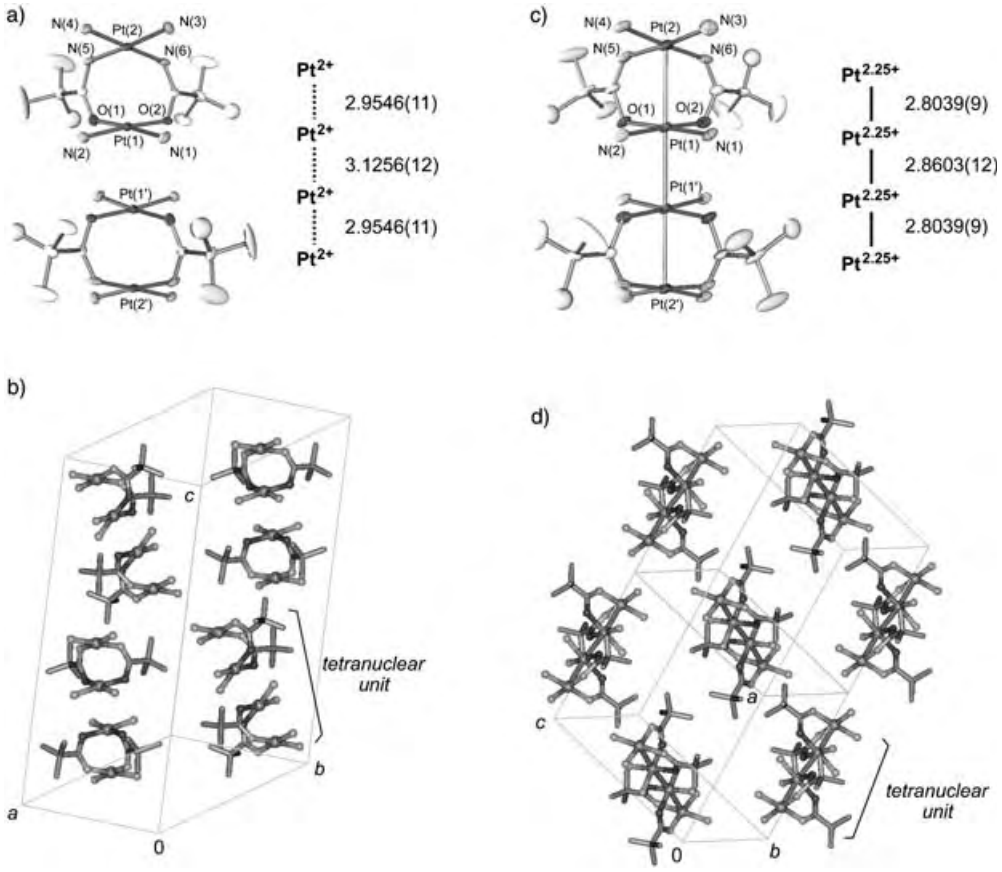

Figure 1. a) Crystal structure and b) packing diagram of $[Pt_2(PVM)_2(NH_3)_4](PF_6)_2\cdot H_2O$ (**2**), and c) crystal structure and d) packing diagram of $[Pt_4(PVM)_4(NH_3)_8](PF_6)_4(ClO_4)\cdot 2H_2O$ (**3**, platinum blue). Schematic drawings for the oxidation states of platinum atoms and metal–metal bonding lengths are also shown in (a) and (c). Hydrogen atoms, PF_6^- and ClO_4^- ions, and solvent molecules (H_2O) are omitted for clarity.

ously with other amidate ligands.[6,12,13] Each platinum atom in the dimer is *cis*-coordinated to two ammine ligands and to either two oxygen atoms or two deprotonated nitrogen atoms of the PVM ligands. X-ray diffraction analysis revealed that four PF_6^- anions are present per tetranuclear unit in **2** and **3**, with an additional ClO_4^- ion present in the latter structure, and therefore the average oxidation state of platinum in **2** and **3** is +2 and +2.25, respectively. In both crystal structures, the tetrameric platinum units are packed without significant interaction with each other (Figure 1b and 1d).

The precursors to the two complexes, dinuclear $[PtRh(PVM)_2(NH_3)_2Cl_3]$ and tetranuclear **2**, were mixed together in a vessel, and brown single crystals of $\{[PtRh(PVM)_2(NH_3)_2Cl_{2.5}]_2[Pt_2(PVM)_2(NH_3)_4]_2(PF_6)_6{\cdot}2\,MeOH{\cdot}2\,H_2O\}_n$ (**4**) with metallic luster were successfully obtained upon evaporation of the solution in air. Figure 2 shows the crystal structure of **4**. The most remarkable structural feature is that the complex cation is an infinite repetition of the octameric segment of Pt_6Rh_2 bridged by the Cl^- ion, with a crystallographic inversion center at the center of the octamer. The Pt_6Rh_2 octameric segment consists of four dimeric units (inner dimers; Pt(1)–Pt(2), Pt(1′)–Pt(2′), outer dimers; Rh(1)–Pt(3), Rh(1′)–Pt(3′)), each doubly bridged by PVM ligands. The inner tetrameric platinum unit (Pt(2)-Pt(1)-Pt(1′)-Pt(2′)) has a structure that is quite similar to those of **2** and **3**. The central interdimer interaction is reinforced by four hydrogen bonds between the oxygen atoms of PVM and the hydrogen atoms of the ammine ligands. The distance between the PVM-bridged platinum atoms (Pt(1)–Pt(2): 2.8450(7) Å) is shorter by 0.218 Å than the inner Pt(1)–Pt(1′) distance of 3.0634(10) Å. The outer dimers, $[PtRh(PVM)_2(NH_3)_2Cl_2]^{n+}$ (Pt(3)–Rh(1) 2.5987(11) Å), are bonded to both ends of the tetranuclear platinum unit at a Pt(2)–Rh(1) distance of 2.7337(11) Å and a typical torsion angle of 45°. Additionally, the Pt_6Rh_2 octameric segments are bridged by Cl^- ligands (Pt(3)–Cl(3) 2.5959(6) Å) to give a very attractive pseudo-1D infinite chain expressed as $[\text{-Pt-Rh-Pt}_4\text{-Rh-Pt-Cl-}]_n$. Three types of crystal structures based similarly on the tetrameric platinum unit have been reported to date, namely 1) the octameric platinum oligomer,[14] 2) the Cl^--bridged platinum tan[6f] like M_4X-type chain, and 3) the infinite platinum wire.[4h] In contrast, the present system is a quasi-1D system, which is distinct from the previous systems on the grounds that two kinds of metals are conjugated in the system which leads to the unique metal–metal interactions and magnetic properties observed.

Table 1 summarizes the selected bond lengths and angles of the tetrameric platinum units in **2**–**4**. Both the inter- and intradimer Pt–Pt distances in **4** are slightly longer than the corresponding lengths of **3**, but still much shorter than those in **2**. Also, the lengths of the hydrogen bonds observed between the amide oxygen and ammine nitrogen atoms in the interdimers in **4** are intermediate between the lengths of the corresponding bonds in **2** and **3**. The tilt angle (τ) between the Pt(1) and Pt(2) coordination planes increases as the Pt–Pt distance increases, as observed also in the series α-pyrrolidonate-tan,[13a] -blue,[6f] and -yellow.[12e] The charge of +19 for the Pt_6Rh_2 octameric segment in **4** was determined from the number of independent PF_6^- ions, which is exactly

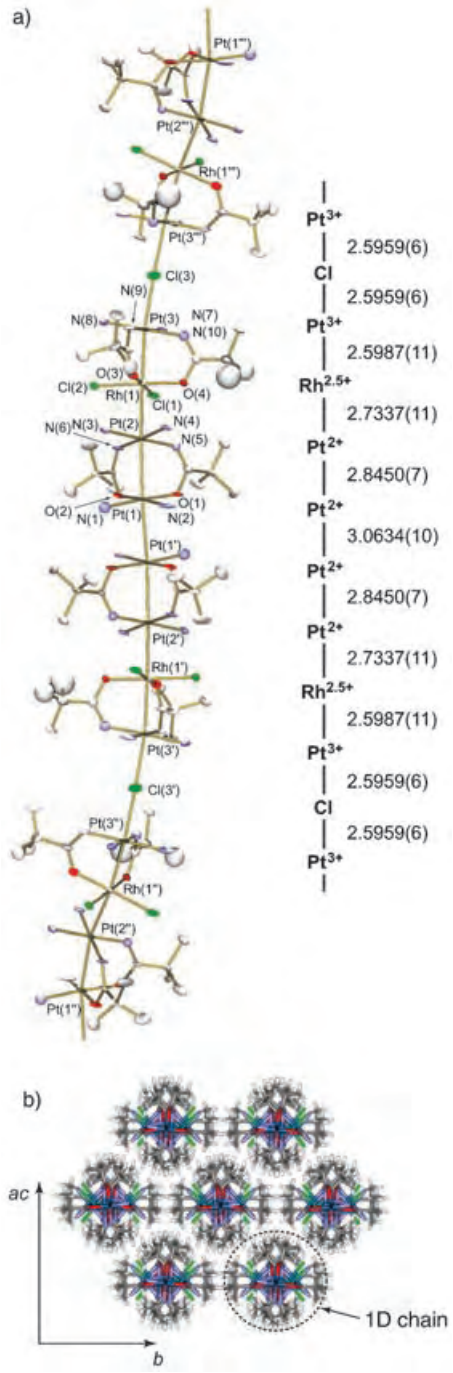

Figure 2. a) Crystal structure of $\{[PtRh(PVM)_2(NH_3)_2Cl_{2.5}]_2[Pt_2(PVM)_2(NH_3)_4]_2(PF_6)_6{\cdot}2\,MeOH{\cdot}2\,H_2O\}_n$ (**4**) with a schematic drawing of the metal–metal bond lengths (hydrogen atoms, PF_6^- ions, and solvent molecules (MeOH and H_2O) are omitted for clarity). b) Crystal packing diagram of the 1D chains in **4** (PF_6^- ions and solvent molecules (MeOH and H_2O) are omitted for clarity).

Table 1: Selected bond lengths [Å] and angles [°] for **2**, **3**, and **4**.

	2	**3**	**4**
Pt(1)–Pt(2)	2.9546(11)	2.8039(9)	2.8450(7)

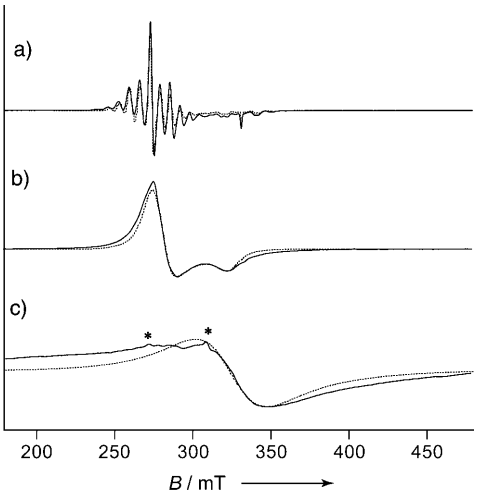
six, in the X-ray refinement of the ion occupancies. These results provide convincing evidence that the material is composed of Pt and Rh atoms with one unpaired electron per Pt_6Rh_2Cl unit. The increase in the Pt–Pt distance with a decrease in the average oxidation state of platinum is widely observed in this class of compound.[13a] Assuming this relationship holds in **4**, the average oxidation state of the inner tetrameric platinum unit in **4** appears to be between +2.0 and +2.25.

Figure 3 shows the EPR spectra of **3** in a water/ethylene glycol (1:1 v/v) glass and powder samples of **3** and **4** measured at 77 K. The EPR spectrum of **3** in the glass exhibits sharp perpendicular and parallel peaks, each split into at least nine lines due to ^{195}Pt nuclei ($I = 1/2$ with an abundance of 33.7 %). The EPR parameters have been determined by computer simulations as $g_\perp = 2.393$, $g_\parallel = 1.979$, $A_{1\perp} = 429$ MHz, $A_{1\parallel} = 499$ MHz, $A_{2\perp} = 861$ MHz, and $A_{2\parallel} = 679$ MHz. These values are similar to those reported for platinum blue.[6b,15] Powdered **3** shows a broad axial-type signal with no resolved hyperfine splittings ($g_\perp = 2.350$, $g_\parallel = 2.030$; peak-to-peak line width, $W_\perp = 12.5$ mT, $W_\parallel = 12.5$ mT), whereas the powder sample of **4** exhibits a much broader ($W = 45.0$ mT) signal centered at a smaller value of g_{av} ($g_{av} = 2.032$).



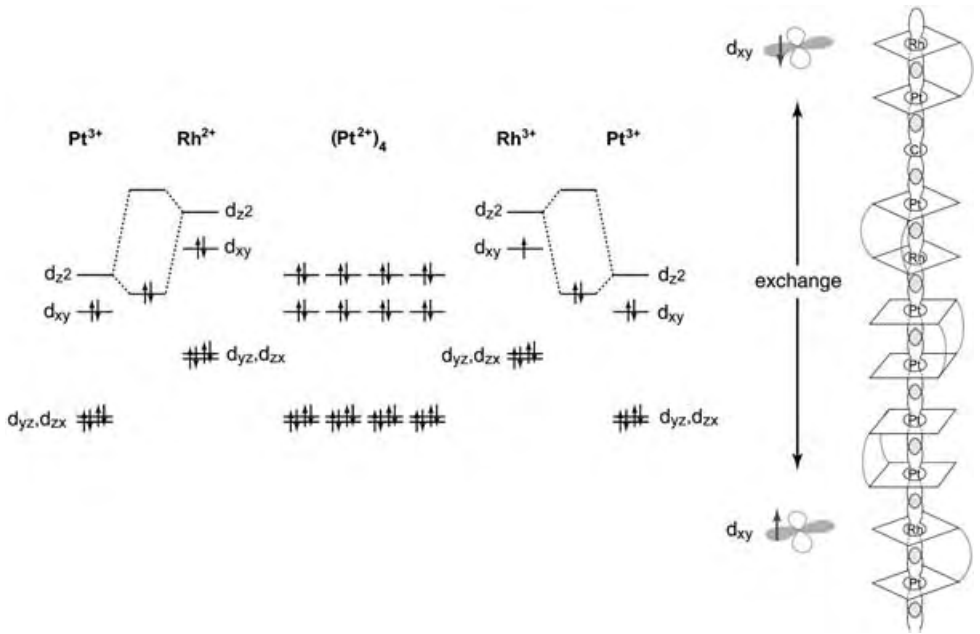


Figure 3. Continuous wave EPR spectra measured at 77 K for a) **3** in a water/ethylene glycol (1:1 v/v) glass, b) **3** (powder sample), and c) **4** (powder sample). Experimental settings: microwave frequency: 9.1826 (a), 9.2022 (b), and 9.1988 GHz (c); microwave power: 5 mW; field modulation (100 kHz): 0.1 mT. Asterisks indicate the platinum blue impurity (around 270 mT); solid lines are the measured spectra, and dotted lines are the simulations.

The g values obtained for **3** are well interpreted in terms of a d_{z^2}-hole state (the z axis lies along the mean Pt chain) with an admixture of the lower-lying d_{xz} and d_{yz} states due to spin–orbit coupling.[15] Typical examples for d_{z^2}-type Pt complexes are Pt^{IV}-doped $[Pt(NH_3)_4][PtCl_4]$ ($g_\perp = 2.504$, $g_\parallel = 1.939$, $g_{av} = 2.316$),[16] *cis*-diammineplatinum α-pyridone blue ($g_\perp = 2.381$, $g_\parallel = 1.975$, $g_{av} = 2.246$),[6b] and $[K_2Pt(CN)_4Br_{1/3}]\cdot 3H_2O$ (KCP, $g_\perp = 2.336$, $g_\parallel = 1.946$, $g_{av} = 2.206$).[17] All these values are attributed to the d_{z^2}-hole state of Pt^{III}. On the other hand, the EPR spectrum of **4** is quite different from that of **3** and features 1) a relatively small g_{av} value and 2) a broad spectrum profile. If it is taken into account that the g_{av} value of **4** ($g_{av} = 2.032$) is much smaller than those of the d_{z^2}-type Pt complexes, it is unlikely that the unpaired electron occupies the d_{z^2} state in **4**. It is important to note that the d_{z^2}-type Rh^{II} complexes exhibit a relatively large g_{av} value in similar fashion to Pt^{III} (e.g. $g_{av} = 2.176$ for [(TTiPP)Rh^{II}] (TTiPP = tetrakis(1,3,5-triisopropylphenyl)porphyrin)).[18] Considering the small g_{av} value of **4**, which is different from both Pt^{III} and Rh^{II}, the singly occupied orbital in **4** is attributed most likely to the Rh^{II} d_{xy} orbital, which is raised in energy above d_{z^2} through π interactions with the amidate ligands (Scheme 2). The broad nature of the EPR spectrum of

Scheme 2. Molecular orbital diagram of $\{[PtRh(PVM)_2(NH_3)_2Cl_{2.5}]_2[Pt_2(PVM)_2(NH_3)_4]_2(PF_6)_6\cdot 2\,MeOH\cdot 2H_2O\}_n$ (**4**) with schematic structural view.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

4 can be attributed to a long-distance exchange interaction. The magnetic susceptibility measurement of **4** shows that the μ_{eff} ($\propto (\chi T)^{1/2}$) value decreases with a decrease in temperature.[19] The plot of $1/\chi_m$ versus T follows the Curie–Weiss law with a Weiss constant $\theta = -31.9$ K, which indicates an antiferromagnetic interaction between the paramagnetic Pt_6Rh_2 segments.

Additionally, the single-crystal electrical conductivity of **4** (four probes, direct current) revealed semiconducting character of the material (3.52×10^{-6} S cm^{-1}) at room temperature.[20] Compound **4** shows a typical semiconducting behavior in the temperature range measured (267–295 K), and the activation energy was estimated as 1.0 eV (see Supporting Information).

In summary, the present results demonstrate that the linear chain structure of the amidate-bridged platinum tetramer can be extended to the octameric segment Pt_6Rh_2, which is further extended infinitely by Cl^- bridges. The Pt–Rh bond between the Pt–Rh dimer and the Pt tetramer is the first example of metal–metal bond formed between the tetranuclear platinum chain and any other metal, and suggests that by selecting suitable metal ions the tetranuclear platinum chain can be incorporated into a longer chain by metal–metal bonds. Note, in complex **4** the unpaired electron does not occupy the d_{z^2} orbital of the tetranuclear platinum chain[15] but, different from our expectation, occupies the d_{xy} orbital of the rhodium atom and hops from one rhodium atom to another. This type of long-distance exchange is rare and possibly leads to new electric and magnetic properties. Attempts to prepare a wider variety of heterometallic chain complexes by tailoring the ligands and selecting suitable metals are currently in progress.

Experimental Section

$[Pt_2(PVM)_2(NH_3)_4](PF_6)_2 \cdot H_2O$ (**2**): $NaPF_6$ (0.5 mmol, 0.084 g) was added to a solution of $[Pt(PVM)_2(NH_3)_2] \cdot 2H_2O$ (0.1 mmol, 0.047 g) in MeOH (2 mL). Yellow-green square crystals were obtained after one month (20% yield). Elemental analysis (%) calcd for $C_{20}H_{68}F_{24}N_{12}O_6P_4Pt_4$: C 12.43, H 3.55, N 8.70; found: C 12.58, H 3.34, N 8.08; IR (KBr pellet): $\tilde{\nu}$: C=O stretching, 1622 cm^{-1} (m), 1583 cm^{-1} (s); PF_6^- ion, 841 cm^{-1} (vs).

$[Pt_4(PVM)_4(NH_3)_8](PF_6)_4(ClO_4) \cdot 2H_2O$ (**3**): $AgClO_4$ (2 equiv, 1.0 mmol, 0.207 g) was added to an aqueous solution (2 mL) of *cis*-$[Pt(NH_3)_2Cl_2]$ (0.5 mmol, 0.150 g), and the mixture was stirred for 18 h in the dark. AgCl was then removed by filtration, and the colorless filtrate was warmed at 40 °C for 30 min before the addition of 1 equiv of $[Pt(PVM)_2(NH_3)_2] \cdot 2H_2O$ (0.5 mmol, 0.235 g) and $NaPF_6$ (1.0 mmol, 0.167 g). The mixture was stirred at 40 °C for a further 14 h, then the solution (dark blue) was left to stand for a week before dark blue crystals were separated (61% yield). Elemental analysis (%) calcd for $C_{20}H_{68}ClF_{24}N_{12}O_{10}P_4Pt_4$: C 11.82, H 3.37, N 8.27; found: C 11.89, H 3.27, N 7.73; UV/Vis (KBr pellet): $\lambda_{max} = 621$ nm; IR (KBr pellet): $\tilde{\nu}$: C=O stretching, 1637 cm^{-1} (m), 1583 cm^{-1} (s); ClO_4^- ion, 1097 cm^{-1} (s, br); PF_6^- ion, 843 cm^{-1} (vs).

$\{[PtRh(PVM)_2(NH_3)_2Cl_{2.5}]_2[Pt_2(PVM)_2(NH_3)_4]_2(PF_6)_6 \cdot 2MeOH \cdot 2H_2O\}_n$ (**4**): $RhCl_3 \cdot 3H_2O$ (0.05 mmol; 0.013 g) in MeOH (1 mL) was added to a solution of $[Pt(PVM)_2(NH_3)_2] \cdot 2H_2O$ (0.1 mmol, 0.047 g) and $NaPF_6$ (0.5 mmol, 0.084 g) in MeOH (1 mL). The mixture was placed in a tube for a month. Dark brown crystals formed during this time and were separated, washed with water, and dried (22% yield). Elemental analysis (%) calcd for $C_{42}H_{128}Cl_5F_{36}N_{20}O_{12}P_6Pt_6Rh_2$: C 14.29, H 3.66, N 7.94; found: C 14.07, H 3.57, N 8.16; UV/Vis (KBr pellet): $\lambda_{max} = 475$ nm, 599 nm, 720 nm (sh); IR (KBr pellet): $\tilde{\nu}$: C=O stretching, 1647 cm^{-1} (m), 1566 cm^{-1} (s); PF_6^- ion, 841 cm^{-1} (vs).

Crystal structure determination for **2**–**4**: Measurements were carried out on a Bruker SMART APEX CCD diffractometer equipped with a normal focus Mo-target X-ray tube ($\lambda = 0.71073$ Å) operated at 2000 W power (50 kV, 40 mA) and a CCD two-dimensional detector. A total of 1315 frames were collected with a scan width of 0.3° in ω with an exposure time of 20 (**2**), 40 (**3**), and 60 (**4**) s per frame. The frames were integrated with the SAINT software package with a narrow frame algorithm. Absorption correction was applied by using SADABS. All the structures were solved by direct methods with subsequent difference Fourier syntheses and refinement with the SHELXTL (version 5.1) software package. Non-hydrogen atoms were refined anisotropically, and all hydrogen atoms were placed in the ideal positions.

Crystal data for **2**: $C_{10}H_{20}F_{12}N_6O_3P_2Pt_2$, $M_w = 952.44$, monoclinic, space group $I2/a$, $a = 11.461(4)$, $b = 18.095(6)$, $c = 26.256(10)$ Å, $\beta = 98.543(6)°$, $V = 5385(3)$ Å^3, $Z = 8$, $\rho_{calcd} = 2.350$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 10.605$ mm^{-1}, $F(000) = 3520$, crystal size: $0.60 \times 0.50 \times 0.05$ mm^3, $T = 120$ K; $\lambda(Mo_{K\alpha}) = 0.71073$ Å, $\theta_{min-max} = 1.4$–$27.5°$, total data = 14338, unique data = 5795, $R_{int} = 0.0583$, observed data ($I > 2\sigma(I)$) = 4898, $R = 0.0750$, $R_w = 0.1961$, GOF = 1.066.

Crystal data for **3**: $C_{20}H_{40}ClF_{24}N_{12}O_{10}P_4Pt_4$, $M_w = 2004.33$, triclinic, space group $P\bar{1}$, $a = 14.231(3)$, $b = 14.722(3)$, $c = 15.642(3)$ Å, $\alpha = 75.007(3)$, $\beta = 84.237(3)$, $\gamma = 73.648(4)°$, $V = 3036.3(10)$ Å^3, $Z = 2$, $\rho_{calcd} = 2.192$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 9.457$ mm^{-1}, $F(000) = 1858$, crystal size: $0.50 \times 0.40 \times 0.10$ mm^3, $T = 120$ K; $\lambda(Mo_{K\alpha}) = 0.71073$ Å, $\theta_{min-max} = 2.4$–$26.9°$, total data = 18819, unique data = 12951, $R_{int} = 0.0433$, observed data ($I > 2\sigma(I)$) = 8401, $R = 0.0621$, $R_w = 0.1666$, GOF = 1.055.

Crystal data for **4**: $C_{42}H_{80}Cl_5F_{36}N_{20}O_{12}P_6Pt_6Rh_2$, $M_w = 3480.69$, monoclinic, space group $C2/c$, $a = 24.956(3)$, $b = 12.3284(14)$, $c = 34.205(4)$ Å, $\beta = 106.377(2)°$, $V = 10097(2)$ Å^3, $Z = 4$, $\rho_{calcd} = 2.290$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 8.945$ mm^{-1}, $F(000) = 6500$, crystal size: $0.60 \times 0.05 \times 0.05$ mm^3, $T = 120$ K, $\lambda(Mo_{K\alpha}) = 0.71073$ Å, $\theta_{min-max} = 2.0$–$27.0°$, total data = 30284, unique Data = 11307, $R_{int} = 0.0844$, observed data ($I > 2\sigma(I)$) = 7669, $R = 0.0719$, $R_w = 0.1785$, GOF = 1.037.

For **2**, atoms C4, C8, and F10 were refined isotropically. For **3**, atoms C4, F24, O9, and O10 were found in the final stage, and thus their atom positions were isotropically refined under rigid condition. For **4**, atoms N1, N5, N10, C16, C19, and C20 were refined isotropically. CCDC-265911 (**2**), CCDC-265912 (**3**), and CCDC-265913 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

UV/Vis reflection spectra were recorded on a Shimadzu UV-3101PC spectrophotometer over the range from 400 to 800 nm at room temperature. IR spectra were recorded on a JEOL WINSPEC-50 spectrometer with the samples prepared as KBr pellets. X-band EPR spectra were recorded on a JEOL JES-PX1060 spectrometer at 77 K. Magnetic susceptibility measurements were carried out in the temperature range 2–250 K with a magnetometer MPMS-7 (Quantum Design) equipped with a SQUID sensor.

A DNA–Protein Nanoengine for "On-Demand" Release and Precise Delivery of Molecules**

*Razvan Nutiu and Yingfu Li**

We demonstrate that artificial DNA probes can be merged with natural biological processes to create highly active nanomechanical devices by developing a DNA–enzyme hybrid nanoengine that is triggered by a small molecule as the input to cyclically dispatch and retrieve a DNA strand as the output. Moreover, the movement of the output can be accurately directed between two specific DNA destinations. Joint exploration of small molecules, nucleic acids, and enzymes may eventually lead to the engineering of bionanodevices that can both detect a biological malfunction and send out a messenger to initiate a repair mechanism.

Nucleic acids encode "smart" molecular recognition properties that commend their exploitation in bionanotechnology.[1,2] It has been proven that DNA or RNA can be used as structural material for building complex self-assembled objects,[3–7] computational devices,[8–13] or active machines and motors.[14–22] In the latter case, DNA also represents the "fuel" that triggers the function of the DNA machine. However, the

need of artificial DNA molecules for the manipulation of DNA-based devices limits their potential for biological applications. Herein we show that an artificial DNA-aptamer nanoswitch can be coupled to an enzymatic reaction to create a hybrid DNA–enzyme nanoengine capable of transporting an antisense DNA molecule between two specific destinations under the control of a small-molecule input.

DNA aptamers are highly structured single strands of DNA that are capable of binding a ligand with great affinity and specificity. The nature of these aptamers makes them inherently capable of recognizing two different molecules: the cognate non-nucleic acid target for which the aptamer is created and an antisense DNA molecule through Watson–Crick base pairing. It has been shown that the addition of a target to a solution containing the properly engineered aptamer/antisense duplex can trigger rapid structure switching from the aptamer/antisense duplex to the aptamer/target complex.[23] The dual binding capability of DNA aptamers and the reversibility of the duplex–complex switching process are the two key elements exploited in the design of the DNA nanoswitch presented herein.

The molecular model of the DNA nanoswitch is illustrated in Figure 1 A. The nanoswitch has three components: a modified version of a previously described adenosine-binding DNA aptamer (black line),[24] a short complimentary DNA strand as the output (gray line), and adenosine as the input (red star). In the absence of adenosine, the system is in the "off" state, as the output molecule is docked onto the DNA aptamer through Watson–Crick base pairing. Upon addition of adenosine, the system is switched to the "on" state, as adenosine displaces the output from the aptamer. Therefore, the presence of one biological entity is transduced into the release of another.

The evidence for the output displacement by the input was obtained by using agarose gel electrophoresis (Figure 1 B). For this experiment, the output DNA strand was labeled with fluorescein at the 3′ end (green circle in Figure 1 A). DNA strands of 11 and 12 nucleotides in length (named "output 11" and "output 12") were studied as the output molecules at two concentrations. Figure 1 C plots the percentage release of the output versus the concentration of the input for each gel. In each case, a clear dependence of the output release on the input concentration was observed. The experiments with 20 nM output 12 and 100 nM output 11 gave higher release percentages at all tested concentrations than those with 100 nM output 12 and 500 nM output 11. It is important to note that, by using different concentrations of the nanoswitch, the absolute amount of the output to be released can be controlled independently of the concentration of the input. For example, 1 mM adenosine can cause the release of the output in four different amounts: 10.4 nM (52% of 20 nM output 12), 16 nM (16% of 100 nM output 12), 50 nM (50% of 100 nM output 11), or 80 nM (16% of 500 nM output 11). This suggests the possibility that a certain amount of input can be accurately transduced into a desired amount of output by utilizing different sizes of the DNA output along with different concentrations of the DNA nanoswitch.

As only physical interactions are involved in the function of the nanoswitch, the release of the output is a reversible

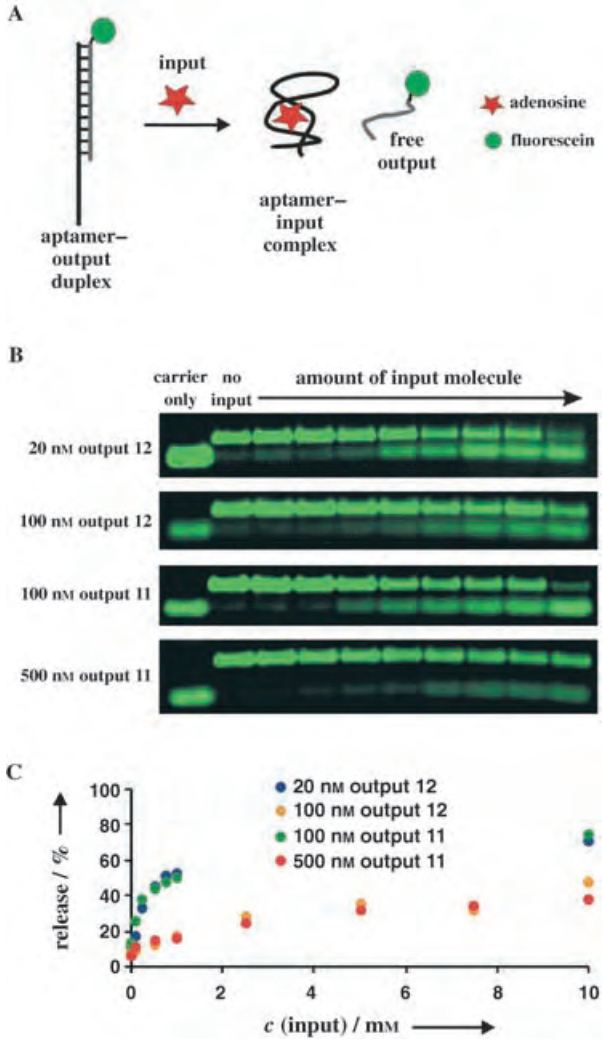

Figure 1. A DNA nanoswitch (see text). A) The working principle. B) Gel evidence for output release. Lanes 3–10 show the response of the nanoswitch to gradually increasing concentrations of the input (10^{-3}–10 mM). C) The dependence of output release on input concentration and overall concentration of the nanoswitch.

process. Therefore, the nanoswitch can be programmed to work cyclically when it is coupled to adenosine deaminase (ADA, blue oval in Figure 2 A)—an enzyme that converts adenosine (red star) into inosine (red pentagon), for which the aptamer has no affinity.[24] ADA is expected to convert free adenosine into inosine and this process should cause more and more aptamer–adenosine complexes to dissociate. Thus, freed aptamer molecules will then engage the output DNA molecules to reform the aptamer–output duplex. The inclusion of ADA in the system therefore converts the DNA nanoswitch into a two-stroke DNA nanoengine. The first stroke, triggered by the addition of adenosine, is represented by the release of the output; the second stroke, driven by the transformation of adenosine into inosine, is the return of the output to the aptamer.

A fluorescence quenching/dequenching experiment was performed to provide a physical readout of the cyclic function of the DNA nanoengine (Figure 2 B). First, the aptamer was

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

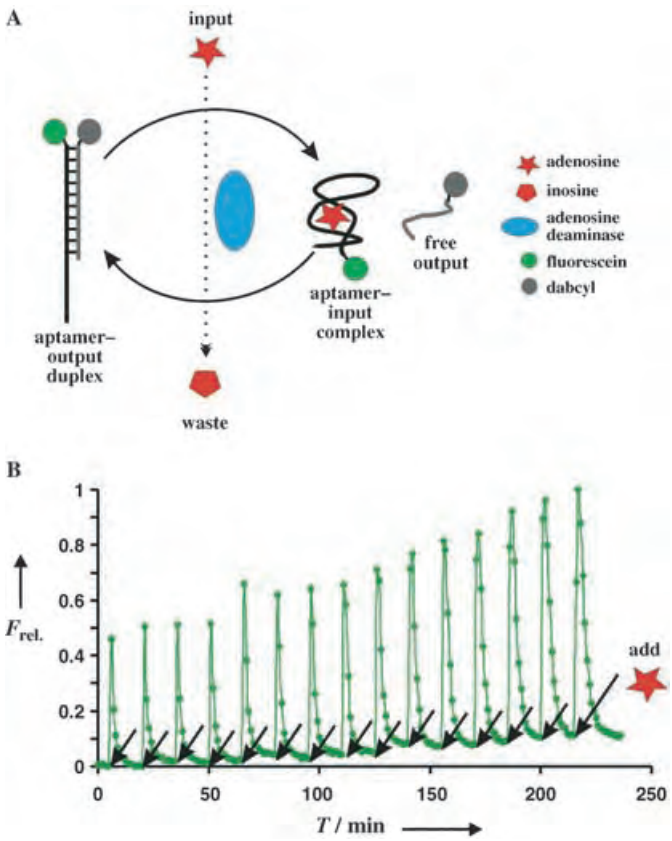

Figure 2. Transformation of the nanoswitch into a two-stroke DNA–enzyme nanoengine (see text). A) Cycling the nanoengine. B) A fluorescence quenching/dequenching experiment illustrates the working of the nanoengine. The figure presents the first 15 cycles of the nanoengine, where every cycle is initiated by the addition of fresh adenosine (black arrows).

labeled with fluorescein (green circle in Figure 2A) at its 5′ end and the output was labeled with 4-(4-(dimethylamino)-phenylazo)benzoic acid (dabcyl, a universal fluorescence quencher, gray circle) at its 3′ end. The fluorophore-labeled aptamer and the quencher-labeled output were then mixed with ADA and the fluorescence of the system was recorded over time. Prior to adenosine addition, the output was docked onto the aptamer, thereby bringing the quencher into close proximity with the fluorophore for efficient fluorescence quenching; therefore the system had a low fluorescence reading. The addition of adenosine after 5 min (the first black arrow in Figure 2B) elicited a rapid increase of the fluorescence intensity of the system, a result reflecting the fast release of the output (the first stroke of the engine). Slowly but gradually, ADA converted adenosine into inosine, thereby prompting the reannealing of the output onto the aptamer (the second stroke), which was indicated by the progressive decrease of the fluorescence intensity of the system.

A full cycle of the engine, under our experimental conditions, took about 15 min to complete. However, this interval could be easily altered by increasing or decreasing the amount of ADA in the system. Although only 15 cycles are shown in Figure 2B, each one triggered by the addition of fresh adenosine (black arrows), in theory the nanoengine should work for an indefinite period of time. However, in practice, the lack of an exhaust system will result in an accumulation of inosine and ammonia that will inhibit ADA[25] and will eventually arrest the engine. This may explain the gradual increase of the fluorescence intensity of the system as well as the steady peak widening observed in Figure 2B.

The above nanoengine could also be designed to include a defined destination for the output molecules upon their release. Two extra strands of DNA were introduced into the system to create two different destinations for the output: a mutagenized version of the aptamer as the desired destination and a control DNA strand as the unwanted destination. The mutant aptamer contained three mutations: A7→T7, G15→T15, and G27→T27. The first mutation, introduced into the output-binding site, caused the mutant aptamer to have a decreased affinity for the output, whereas the other two mutations, introduced into the adenosine-binding site, abolished the adenosine-binding ability. The control DNA had a sequence completely unrelated to that of the original aptamer. The active aptamer, the mutant aptamer, and the control DNA were labeled with Cy3, fluorescein, and Cy3.5, respectively, while the output was still labeled with the dabcyl quencher. Therefore, the arrival of the output at a given destination would be transduced into a decrease in the fluorescence intensity of the corresponding fluorophore.

When all the DNAs were mixed with ADA in the absence of adenosine, the high level of fluorescence of the mutant aptamer and the control DNA as well as the low level of fluorescence of the aptamer (Figure 3B) indicated that the output was docked onto the aptamer as planned. However, when adenosine was introduced, the rapid fluorescence increase of the active aptamer, coupled with the rapid fluorescence decrease of the mutant aptamer, confirmed the prearranged direction of movement of the output (Figure 3A). Importantly, the fluorescence of the control DNA remained unchanged, thereby demonstrating that the movement was indeed driven by specific molecular recognition. The action of ADA promoted the reverse movement of the output from the mutant aptamer to the active aptamer, reflected in the decrease of the fluorescence of the active aptamer and the increase of the fluorescence of the mutant aptamer. The dependence of the pattern of the fluorescence signal on the DNA sequence was verified by permutating the three fluorophores on the three DNA sequences (data not shown).

We have demonstrated above that a small molecule, an aptamer, an antisense DNA, and an enzyme can be configured into a two-stroke DNA nanoengine that can function in a cyclic fashion. The input-removing enzyme ADA is an essential component of our nanoengine. However, ADA functions independently of the output. A more desirable feature, particularly for real-world applications, that has yet to be demonstrated is the intricate linking of the enzyme activity with the freed output. Such a system can first detect a specific problem (input) and then dispatch a signal (output) for activating a rescuing protein or pathway (equivalent to ADA) for the correction of the problem. The completion of the final

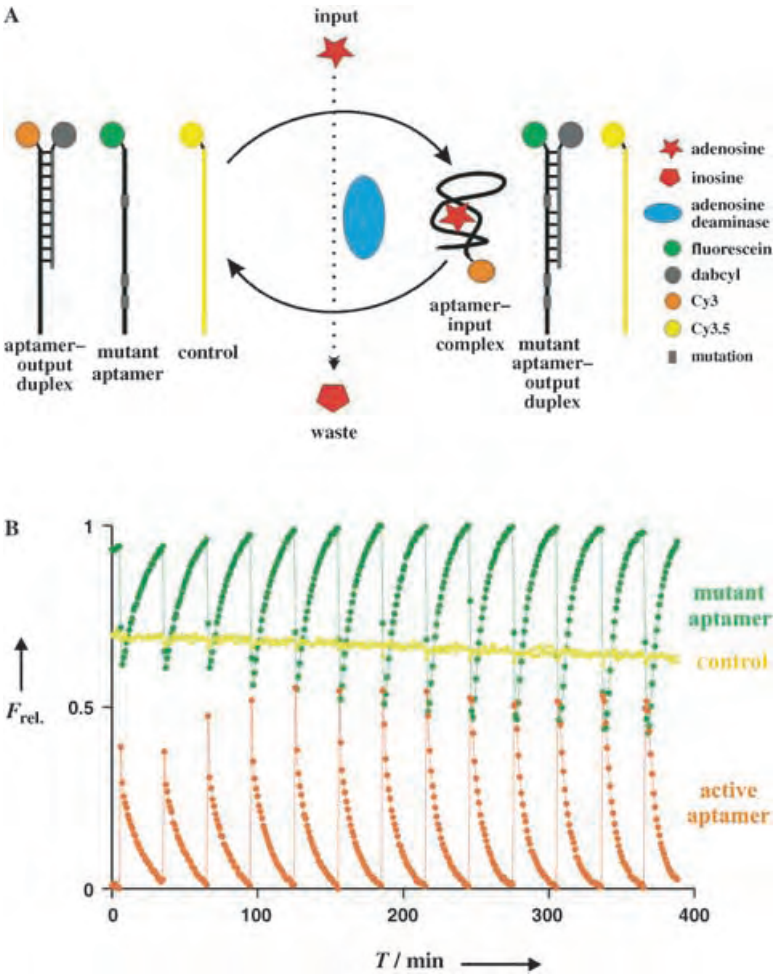

Figure 3. Precise delivery of the output (see text). A) Schematic representation. One cycle of the nanoengine is represented by the travel of the output from the aptamer to the mutant and back. B) A three-color fluorescence quenching/dequenching experiment.

step will deliver the output back to the aptamer, which resets the nanoengine for a new round of action, if necessary. Our nanoengine prototype does not offer a solution to this practical problem and can only dispatch a DNA strand as the output in response to a relatively high concentration of the small-molecule input. However, on the basis of the functional versatility of natural enzymes and the ease of in vitro selection with which diverse aptamers can be identified for virtually any target,[26,27] we speculate that highly practical nanoengines of a similar nature with a better input sensitivity and the ability to dispatch a desirable output will be created in the future for different input/output systems and that these nanoengines will offer new ways for the delivery of a drug or the regulation of a disease-causing biological process.

On the Importance of Leaving Group Ability in Reactions of Ammonium, Oxonium, Phosphonium, and Sulfonium Ylides**

Varinder K. Aggarwal, Jeremy N. Harvey,* and Raphaël Robiette*

Dedicated to Professor Steven Ley on the occasion of his 60th birthday

Ammonium, phosphonium, and sulfonium ylides are powerful and versatile reagents in organic chemistry, which undergo three important types of reaction: olefination, cyclization to a three-membered ring, and rearrangement.[1] The reactivity and selectivity of the ylides in these reactions depend on the nature of the central heteroatom. The nucleophilicity of the carbon centre of the ylides is one important aspect of their reactivity, which is affected by the degree to which the onium group stabilizes the adjacent negative charge. It has been shown that stabilization increases in the order O < N ≪ P < S.[2] However, this feature alone does not explain all the observed reactivity. We present comparative computational data which suggest that the differences are mainly due to the differing leaving group ability of the respective onium groups. The calculations[3] are carried out using the accurate B3LYP density functional, which is known to describe trends of the kind studied here accurately.[4,5] We also include a continuum solvent model in all calculations as the gas-phase potential energy surfaces are qualitatively inaccurate for some of these very polar species.[5]

In the reaction with organoboranes, sulfonium ylides give homologation products at low temperature[6] while the more nucleophilic ammonium ylides react only at reflux of THF,[7] and phosphonium ylides require temperatures above 130 °C.[8] The energy profile[3] for the reaction of BMe_3 with ylides **1** involves barrierless addition to form ate complex **2**, followed by rate-determining 1,2-migration (Figure 1). The first step is most exothermic for the ammonium and oxonium ylides while the barrier for migration is smallest with the oxonium ylide and largest with the phosphonium derivative. Nucleophilicity of the onium ylides is clearly irrelevant for this process, with the key factor being instead the leaving group ability of the onium group, which decreases in the order O > S > N > P.

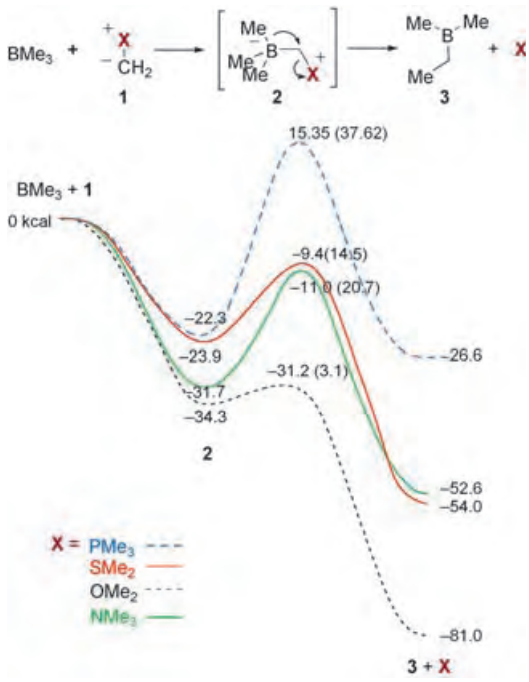

Figure 1. Calculated[3] energy surface (in kcal mol^{-1}) for reaction of BMe_3 with **1**. Values in parentheses are relative to **2**.

For epoxidation, observed reactivity does not correlate with carbon nucleophilicity either. Sulfonium ylides react with aldehydes at temperatures as low as −78 °C,[9] whilst room temperature is required using ammonium ylides.[10] This is consistent with the energy profile[3] for the reaction of the ylides **1** with benzaldehyde, and again, the higher reactivity of the sulfur-based species is due to a lower barrier in the intramolecular substitution step (Figure 2). In this reaction, the initial addition step is barrierless with the more nucleophilic ammonium ylide, and hence more favorable than with the sulfonium ylide, where a small barrier is observed. In the latter case, though, addition is the only demanding (and rate-limiting) step, whereas with nitrogen, betaine formation is followed by slower decomposition over a 15 kcal mol^{-1} barrier. This is consistent with the experimental observation that β-hydroxy ammonium salts are isolated upon work-up of the reaction of ammonium ylides at low temperature.[11] Wittig reaction leading to alkenes is the main pathway with phosphonium ylides. This difference in reaction behavior compared to sulfonium ylides has a number of reasons,[12] such as the fact that oxathietanes are not formed in the sulfur reaction.[5] One important effect is clearly leaving group ability: our calculations show that *trans* betaines can be formed from phosphorus ylides over a low barrier, but nucleophilic displacement of the phosphine involves a very significant barrier. Cyclization to the oxaphosphetane (see Figure S1, Supporting Information), or indeed facile direct formation of the latter, and subsequent phosphine oxide loss, therefore compete very effectively. As with the borane reaction, calculations suggest that the reaction with oxonium ylides would be very favorable, although no examples are

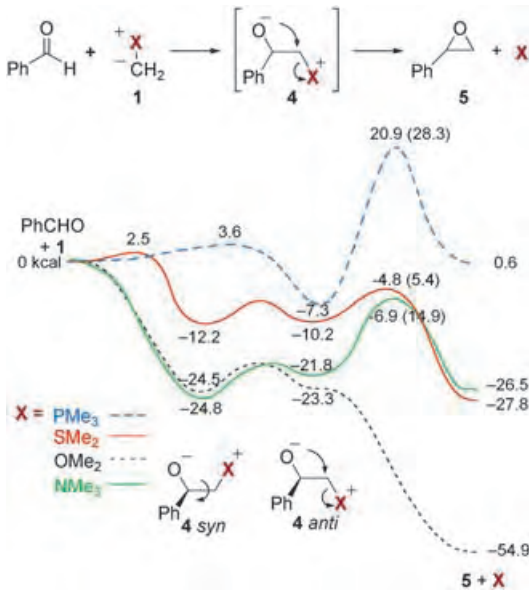

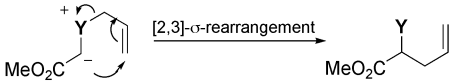

Figure 2. Computed[3] potential energy surface (in kcal mol^{-1}) for styrene oxide formation from **1**. Values in parentheses are relative to **4** *anti*.

reported in the literature. Overall, leaving group ability plays an extremely important role in determining reactivity and the nature of products formed in this set of reactions.

[2,3]-σ-Rearrangement is known for ammonium, oxonium, and sulfonium ylides[1] but only one low-yielding example has been reported for phosphonium ylides.[13] This process can in principle involve radical intermediates (Stevens rearrangement), but experimental evidence suggests a concerted pathway in most cases.[11,14] For the latter, the rate could be expected to depend both on nucleophilicity of the ylide carbon atom (which decreases in the order O > N > P > S) and on the leaving group ability of the corresponding onium (which should decrease as O > S > N > P, as in the other two reactions). Experimentally, the rearrangement is very facile even at low temperature for all but the phosphonium ylides. Our calculations[3] (Table 1) show that the barrier height follows the order O < S < N ≪ P, indicating that leaving group ability is the dominant effect in this case also. The magnitude of the barriers for the O, N, and S ylides confirms that their rearrangement should be rapid, while the high activation energy for phosphonium ylides accounts for the dearth of examples in this latter case. Considering the similarity in nucleophilicity of phosphonium and sulfonium ylides, the very different activation barriers for rearrangement emphasizes the dominant effect of leaving group ability.

Table 1: Computed[3] activation energies ($\Delta E^{\neq}$) and reaction energies (ΔE) of [2,3]-σ-rearrangements (in kcal mol^{-1}).

Y	$\Delta E^{\neq}$	ΔE
NMe_2	12.18	−27.29
OMe	2.94	−60.44
PMe_2	35.13	−4.71
SMe	7.83	−33.45

The consistent order of leaving group ability of the four onium groups in these three reactions is intriguing. Which factors cause ether and thioether groups to be excellent leaving groups, amines to be somewhat less good, and phosphines to be so poor? Nucleophilic substitution is one of the most important reactions in organic chemistry,[15] and extensive efforts have been made to develop a quantitative description of nucleophilicity,[16] and, to a lesser extent, the complementary kinetic property of leaving group ability.[17] It is generally recognized that both intrinsic factors and thermochemistry contribute to the barrier height. The combined impact of these two effects can be treated quantitatively using Marcus theory,[18] which has been applied successfully to group transfer reactions[19] and in particular to S_N2 reactions.[15,20] The intrinsic nucleophilicity of a given species is the same as its intrinsic leaving group ability, and can be measured by the rate or barrier height for the identity S_N2 reaction $X + CH_3X^+ \rightleftarrows X^+CH_3 + X$. The calculated[3] energy barriers for these reactions give a reactivity order similar to that found above, with O > S > N ≫ P (Table 2).[21,22]

Table 2: Intrinsic barrier heights (in kcal mol^{-1})[3] for the identity reaction $X + CH_3X^+ \rightleftarrows X^+CH_3 + X$; forward and reverse barrier heights and exothermicity for the reaction $H_2O + CH_3X^+ \rightleftarrows H_2O^+CH_3 + X$.

X =	OMe_2	SMe_2	NMe_3	PMe_3
		$X + CH_3X^+ \rightleftarrows X^+CH_3 + X$		
$\Delta E^{\neq}$	15.5	22.5	26.3	40.1
		$H_2O + CH_3X^+ \rightleftarrows H_2O^+CH_3 + X$		
$\Delta E^{\neq}$ forward	13.2	25.6	38.9	50.7
$\Delta E^{\neq}$ backward	10.6	9.4	2.1	4.8
ΔE	2.6	16.3	36.8	45.9

These intrinsic reaction barriers have been discussed for other nucleophiles previously, and depend on the strength of the C–X bond but also on the balance between bond-making and bond-breaking at the exchange transition state.[23] All other factors being equal, then, ether oxygens are (intrinsically) the best nucleophiles (and leaving groups), followed by sulfides and amines, with phosphines being poor for both types of reaction.

However, all factors are not equal: the thermodynamics of substitution vary considerably due to differences in the carbon–element bond strength, which decreases in the order P > N > S > O.[24] In trying to understand the trend in leaving group ability in reactions with a common nucleophile—the topic of the present study—these differences in bond energies need to be taken into account as well as the intrinsic reactivity, as the resulting changes in thermodynamics have an indirect impact on barrier heights. Assuming a constant intrinsic reaction barrier, leaving group ability would increase with decreasing bond energy, in the order P < N < S < O. In fact, the intrinsic barriers are not identical (Table 2), and indeed follow the same order of increased reactivity going from P to O, so that the two factors combine synergistically to yield an overall hierarchy of leaving group ability P < N < S < O.[25]

This is shown for three different nucleophiles: an alkyl group in Figure 1, an alkoxide anion in Figure 2, and water in Table 2. To take another better known example, this trend explains the stability of alkyl phosphonium and ammonium salts in the presence of halide counterions, and the instability of the corresponding sulfonium salts.[26] A nucleophilic halide counterion can displace a good leaving group (sulfide), but not a poor one (amine, phosphine). It also accounts for why nature, with ready access to compounds containing N, O, S and P, has chosen a sulfonium salt (*S*-adenosyl methionine, SAM) for methyl group transfer.[27] Unlike oxonium salts, such species are stable enough to be formed without reacting instantaneously with water, yet have a higher alkylating reactivity than ammonium salts.

Although the focus of the present work is on leaving group ability, it is useful to note that the same two factors of intrinsic reactivity and thermochemistry account for the relative nucleophilicity of the different groups also. For example, phosphines are usually quite good nucleophiles despite their low intrinsic reactivity, because the strong C–P bond means that substitution is usually quite strongly exothermic. Calculated barriers for the reaction $X + CH_3OH_2^+ \rightarrow CH_3X^+ + H_2O$ are shown in Table 2. Because the exothermicity increases in the order ether < sulfide < amine < phosphine, the calculated nucleophilicity follows the well known[28] order $R_3N > R_3P > R_2S > R_2O$. The intrinsically weakest nucleophile, R_3P, has the second lowest barrier to reaction due to forming the most stable products. The ether group, on the other hand, is intrinsically reactive but the reaction is near thermoneutral and hence has a significant barrier.

In summary, the reactivity of sulfonium, ammonium, phosphonium, and oxonium ylides in a range of reactions is to a large part determined by the leaving group ability of the corresponding onium group, and this decreases for both intrinsic and thermochemical reasons in the order O > S > N > P. This means that when comparing reactions of, for example, ammonium and sulfonium ylides, the rate-limiting and selectivity-determining steps in a multistep mechanism may well be different. This insight should be of considerable use in designing new stereoselective synthetic transformations.

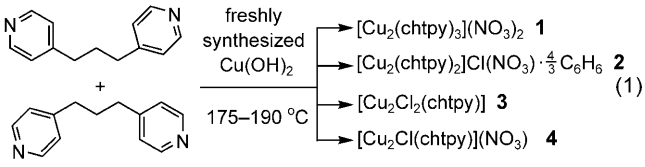
Cu^{2+}-Mediated Dehydrogenative Coupling and Hydroxylation of an N-Heterocyclic Ligand: From Generation of a New Tetratopic Ligand to the Designed Assembly of Three-Dimensional Copper(I) Coordination Polymers**

Sheng Hu, Jing-Cai Chen, Ming-Liang Tong, Bo Wang, Yun-Xin Yan, and Stuart R. Batten*



Great interest has been focused on the rapidly expanding field of crystal engineering of two- (2D) and three-dimensional (3D) coordination polymers due to their structural and topological diversity as well as their potential application as functional materials.[1] The main strategy popularly used in this area is a building-block approach,[2] and much effort has been made towards the connection of suitable, predetermined building blocks into networks in order to obtain the desired materials. In this regard, the development of new multitopic building blocks is one of the central tasks. Recently, we have been investigating a few in situ metal/organic reactions such as ligand oxidative coupling, hydrolysis, and substitution by hydrothermal methods,[3] which provide an intriguing pathway for generating new, functional building blocks and coordination polymers. In particular, we have isolated and structurally characterized covalent hydrates of N-heterocyclic ligands in delocalized mixed-valence Cu^{I}–Cu^{II} complexes, which are not only an important bridge between coordination chemistry and organic heterocyclic chemistry, but can also be successfully applied to the assembly of functional molecular solids.[3a,b] Following our recent report on the in situ metal/ligand redox reaction, in this communication we report a new Cu^{2+}-mediated dehydrogenative coupling and hydroxylation of an N-heterocyclic ligand (chtpy) in four Cu^{I} coordination

chtpy

polymers, namely $[Cu_2(chtpy)_3](NO_3)_2$ (**1**), $[Cu_2(chtpy)_2]Cl(NO_3)\cdot{}^4/_3\,C_6H_6$ (**2**), $[Cu_2Cl_2(chtpy)]$ (**3**), and $[Cu_2Cl(chtpy)](NO_3)$ (**4**; chtpy = *a*,*a*-1,4-dihydroxy-*e*,*e*,*e*,*e*-1,2,4,5-tetra(4-pyridyl)cyclohexane). This is the first time that simultaneous dehydrogenative coupling and hydroxylation of an N-heterocyclic ligand has been observed to generate a new, potentially tetratopic, coplanar ligand in situ.

Pale-yellow or reddish crystals of **1**–**4** (ca. 18–35 % yield) were obtained from the in situ hydrothermal treatment of $Cu(OH)_2$ (freshly synthesized from $Cu(NO_3)_2\cdot 3H_2O$ and NaOH) with 1,3-bis(4-pyridyl)propane (bpp), 1,4-cyclohexanedicarboxylic acid, and water in dilute HCl at 175–190 °C [Equation (1)]. The component diversification of the result-

(1)

ing Cu^{I}–chtpy nets can be controlled simply by tuning the molar ratio of the starting materials. Elemental analysis and PXRD (Figure S1 in the Supporting Information) confirmed the phase purity of the bulk materials. Compounds **1**–**4** are air-stable and insoluble in water and most organic solvents.

One of the most intriguing features regarding the synthesis is the direct observation of dehydrogenative coupling and hydroxylation of 1,3-bis(4-pyridyl)propane mediated by Cu^{2+}. It has been reported previously that dehydrogenative coupling of phenanthroline and 2,2′-bipyridine under hydrothermal conditions leads to two functional tetradentate ligands—biphenanthroline and quaterpyridine, respectively—that are difficult to obtain by common organic reactions.[4] Moreover, hydroxylation of N-heterocyclic ligands such as phenanthroline and 2,2′-bipyridine is now well understood and can be easily carried out under hydrothermal conditions.[3a,b] However, to the best of our knowl-

edge, the simultaneous dehydrogenative coupling and hydroxylation of an N-heterocyclic ligand is unprecedented.[5] The cyclohexane analogue having both hydroxyl and pyridyl substituent groups that is generated in situ may act as an important organic intermediate. Other interesting cases concerning tetradentate ligands generated in situ have been found in the reaction of silver(I) with 1,2-di(4-pyridyl)ethene,[6a] a template-directed solid-state [2+2] photodimerization of 4-chlororesorcinol with *trans*-1-(2-pyridyl)-2-(4-pyridyl)-ethylene,[6b] and the hydrothermal reaction of $Cd_{10}S_4(SPh)_{12}$ with 4,4′-trimethylenedipyridine and Na_2SO_4.[6c]

An X-ray crystallographic study[7] revealed unequivocally that a six-membered ring is formed by C–C coupling between four of the carbon atoms of each pair of bpp ligands in **1**–**4**. The six C–C bond distances of the ring fall in the range 1.503(8)–1.562(8) Å for **1**, 1.542(7)–1.552(5) Å for **2**, 1.491(9)–1.517(10) Å for **3**, and 1.536(3)–1.553(6) Å for **4**, characteristic of C–C single bonds.[8] Moreover, two hydroxy groups are also formed at the carbon atoms linking the pyridyl groups, with C–O bond lengths of 1.441(9)–1.458(8) Å for **1**, 1.437(11) Å for **2**, 1.466(10)–1.451(10) Å for **3**, and 1.423(4) Å for **4**, which are typical of a C–O single bond. Each cyclohexyl ring of the chtpy ligands in **1**–**4** adopts a chair conformation, with the four pyridyl groups located at the equatorial positions and the two hydroxy groups at the axial positions.

The structure of $[Cu_2(chtpy)_3](NO_3)_2$ (**1**) contains one crystallographically unique tetrahedral Cu^I atom, which lies on a general position, three unique L ligands, all of which lie across inversion centers, and one unique, uncoordinated nitrate counteranion. Two of the unique L ligands act as bidentate bridges between the copper atoms (Cu–N = 2.037(4) and 2.077(5) Å) by coordinating through their pyridyl groups *trans* to each other across the central six-membered ring; the other pyridyl groups are not coordinated. The third type of ligand acts as a tetradentate bridge (Cu–N = 2.050(5) and 2.054(4) Å) and coordinates through all four pyridyl groups (Figure 1a).

The ligands bridge the copper atoms to form three identical, interpenetrating 3D networks. The network topology can be simplified by considering just the tetrahedral copper atoms and the tetradentate ligands (represented by a square-planar node); the bidentate ligands can be represented simply as links between the copper nodes. The resulting net is shown in Figure 1b, and has the moganite topology,[9] which is a rare four-connected net with tetrahedral and square-planar nodes in the ratio 2:1. A topological analysis of this net was performed with OLEX.[10] The long topological (O'Keeffe) vertex symbol is $4.8_6.6.6.6.6$ for the Cu node, and $4.4.6_2.6_2.8_2.8_2$ for the chtpy node, which gives the short vertex symbol $(4^2.6^2.8^2)(4.6^4.8)_2$. The three interpenetrating networks are shown in Figure 1c. We are aware of only three examples of coordination polymers with this topology: the structures of $Cd(CN)_2(H_2O)_{2/3}\cdot t$BuOH and $[Cu_3(pytac)_6]\cdot 14H_2O$ (pytac = 2-(4-pyridyl)thiazole-4-carboxylate) contain a single moganite network,[11a,b] while the structure of $[Cu_2(TCNB)_3](PF_6)_2$ (TCNB = 1,2,4,5-tetracyanobenzene) contains two interpenetrating moganite nets.[11c] This structure is particularly relevant as, like the structure of **1**, it contains tetrahedral Cu^I atoms bridged by potential tetradentate ligands, only one-third of which are actually tetradentate and act as square-planar nodes, while the other two-thirds are simply bidentate.

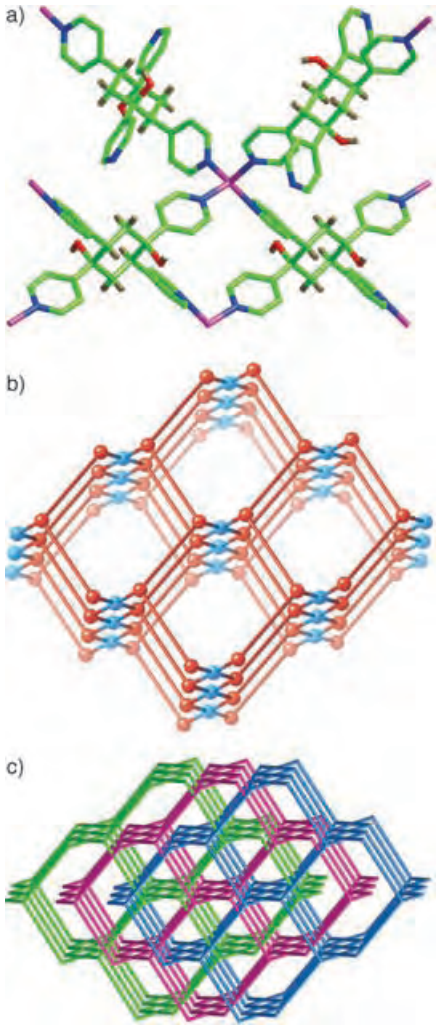

Figure 1. a) Local geometry in the structure of **1**. Each Cu^I center bonds to two crystallographically distinct bidentate ligands (top) and two symmetry-related tetradentate ligands (bottom). For clarity, pyridyl hydrogen atoms and nitrate counterions are not shown; pink Cu, blue N, red O, green C, gray H. b) The moganite topology of the 3D, four-connected nets in the structure of **1**. The red spheres represent copper atoms, while the blue spheres represent the tetradentate ligands. The bidentate ligands are represented by Cu···Cu links. c) The three interpenetrating moganite nets in the structure of **1**.

The nitrate anions, although uncoordinated, actually link the three interpenetrating networks together by hydrogen-bonding interactions between one of their oxygen atoms (O5) and the three different types of ligand hydroxide groups—one from each net for each nitrate anion ((O)H···O5 = 1.635(4), 1.871(5), and 1.865(6) Å, respectively). One of the hydroxide groups in fact participates in a bifurcated hydrogen bond and interacts with a second oxygen on the same nitrate anion ((O3)H3A···O6 = 2.140(5) Å).

The structure of **2** reveals an interesting porous 3D framework with the asymmetric unit consisting of one crystallographically unique tetrahedral Cu^I atom, which lies

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

on a special position, one-quarter of a chtpy ligand with the hydroxy groups showing twofold disorder, one-sixth of a benzene guest molecule, and disordered uncoordinated nitrate and Cl^- counteranions, each with one-eighth occupancy. Each chtpy ligand acts as a tetradentate bridge (Cu–N = 2.025(3) Å) and coordinates through all four pyridyl groups (Figure 2a).

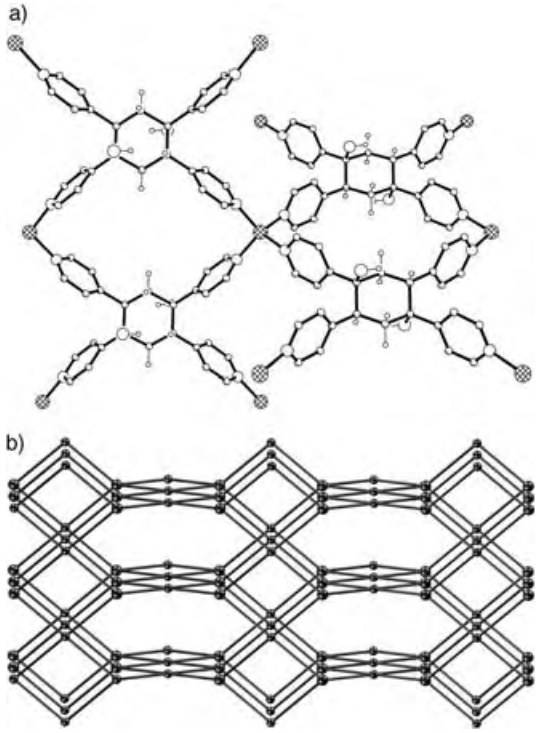

Figure 2. a) Local geometry in the structure of **2**. For clarity, pyridyl hydrogen atoms and counterions are not shown. b) The PtS topology of the 3D, four-connected, noninterpenetrating net in the structure of **2**.

The planar tetratopic chtpy ligands bridge the copper atoms into a noninterpenetrating 3D network. By considering just the copper atoms and the tetradentate ligands as tetrahedral and square-planar nodes, respectively, **2** can be defined as a rare four-connected net with tetrahedral and square-planar nodes in the ratio 1:1. The long topological (O'Keeffe) vertex symbol is $4.4.8_7.8_7.8_7.8_7$ for the Cu node and $4.4.8_2.8_2.8_8.8_8$ for the chtpy node, thus giving a short vertex symbol $4^2.8^4$, which is that of the PtS topology,[9] as shown in Figure 2b. It is worth noting that there are 3D channels running along the *a*-, *b*-, and *c*-axes in the cationic net structure of **2**, as shown in Figure 2b. An analysis using PLATON[12] suggested that the channels occupy 58.2% of the crystal volume. The guest benzene molecules and disordered NO_3^- and Cl^- counteranions are located within these channels. The calculated crystal density (in the presence of guest and the disordered counterions) of 0.914 g cm^{-3} is comparable to those found for some porous metal–polycarboxylate coordination materials.[1c]

Compound **3** consists of 2D coordination polymer sheets with the asymmetric unit containing one crystallographically unique Cu^I atom, which lies on a general position, one unique chtpy ligand, which lies across an inversion center, and one unique Cl^- counteranion. Each Cu atom is coordinated in a trigonal geometry by two pyridyl N atoms and one Cl atom (Cu–N = 1.978(5) and 1.993(5) Å; Cu–Cl = 2.167(2) Å; N–Cu–N/Cl = 113.9(2)–125.30(16)°). Each chtpy ligand acts as a tetradentate bridge to connect the CuCl motifs into a 2D (4,4) net (Figure 3). Adjacent (4,4) nets are each twofold interpenetrating in a diagonal/diagonal inclined fashion.[13]

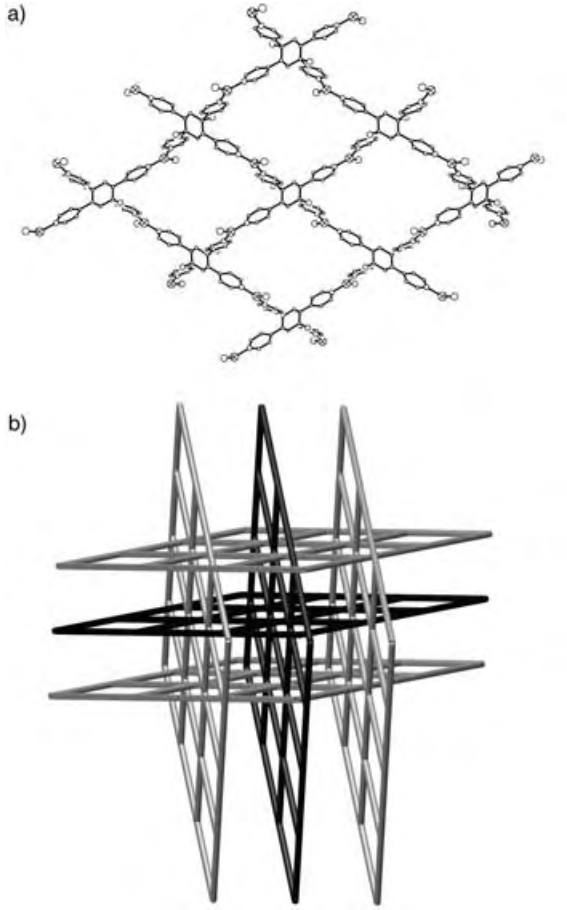

Figure 3. a) The 2D (4,4) coordination layer in the structure of **3**. b) The twofold interpenetrating 2D (4,4) nets in the structure of **3**.

Compound **4** is a 3D coordination network with the asymmetric unit consisting of one crystallographically unique tetrahedral Cu^I atom, which lies on a special position, one unique chtpy ligand, which lies across a fourfold axis, and one unique Cl^- atom and an uncoordinated nitrate, both of which lie on special positions. Similar to those in **3**, each Cu atom is coordinated in a Y-shaped geometry by two pyridyl N atoms and one Cl atom (Cu–N = 1.917(2) Å; Cu–Cl = 2.4802(7) Å; N–Cu–N/Cl = 101.99(8) and 156.01(17)°). Each chtpy ligand acts as a tetradentate bridge to connect the CuCl motifs into a 2D coordination layer of a (4,4) net (Figure 4a). The most interesting structural feature is that adjacent (4,4) nets are covalently connected by sharing the linear μ_2-Cl bridges, thereby generating two identical, interpenetrating 3D networks. The network topology can be simplified by considering

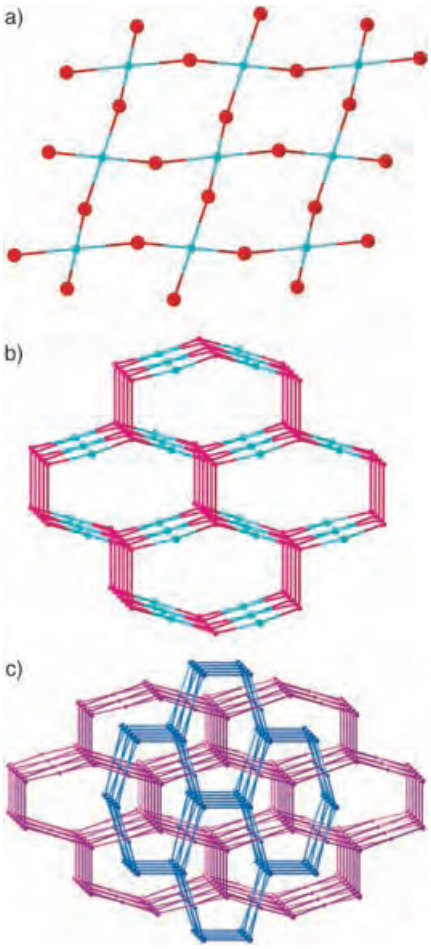

Figure 4. a) The 2D (4,4) coordination subnet motif in the structure of **4**; red Cu, cyan ligand. b) The 3D (3,4)-connected topological net constructed from the 2D (4,4) subnets. c) The two interpenetrating nets in the structure of **4**.

just the three-connected copper atoms and the tetradentate ligands as trigonal nodes and square-planar nodes; the bidentate μ_2-Cl bridges can be represented simply as links between the copper nodes. The resulting net is shown in Figure 4b, and is a rare (3,4)-connected net[14] with trigonal and square-planar nodes in the ratio 2:1. The long topological (O'Keeffe) vertex symbol is $6.6.8_2$ for the Cu node, and $6.6.8.8.10_2.10_2$ for the chtpy node, which gives the short vertex symbol $(6^2.8^2.10^2)(6^2.8)_2$. The twofold interpenetrating networks are shown in Figure 4c.

In order to obtain the newly generated multitopic building block, which will be of further use for the assembly of functional molecular solids, we separated the chtpy ligand from the metal center by treating **1** with $Na_2(H_2edta)$. An X-ray crystallographic study[7] clearly showed that the free chtpy molecule also adopts a chair conformation, with the four pyridyl groups located at the equatorial positions and the two hydroxy groups at the axial positions. Each unique chtpy molecule lies across a twofold axis (Figure 5). The six C–C bond distances of the cyclohexyl ring fall in the range 1.536(4)–1.543(4) Å, in agreement with those found in **1**–**4**

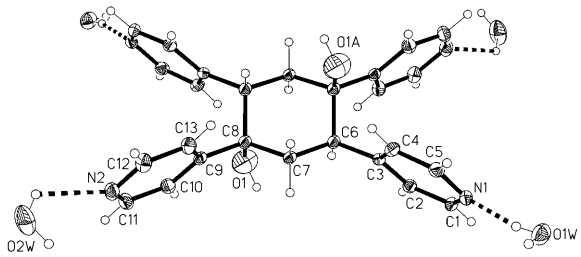

Figure 5. Crystal structure of chtpy·4 H_2O.

and characteristic of C–C single bonds.[8] The C–O bond length of 1.440(6) Å is indicative of a single-bond character.

In summary, we have prepared and characterized four new examples of copper(I) coordination networks with a new planar tetratopic ligand generated in situ and isolated this tetratopic ligand.[15] Extension of this functional, four-connected ligand to other metal salts and a further systematic investigation of their network connectivity and function is in progress.

Experimental Section

1: A mixture of $Cu(NO_3)_2{\cdot}3H_2O$ (0.061 g, 0.25 mmol), NaOH (0.02 g, 0.5 mmol), 1,4-cyclohexanedicarboxylic acid (0.086 g, 0.5 mmol), bpp (0.198 g, 1.0 mmol), and H_2O (9 mL) was placed in a Parr Teflon-lined, stainless-steel vessel and heated at 175 °C for 3 d to yield fine, pale-yellow crystals (yield ca. 25% based on Cu^{2+}). $C_{39}H_{36}CuN_7O_6$: calcd. C 61.45, H 4.76, N 12.86; found C 61.09, H 4.62 N 12.71.

2: A mixture of $Cu(NO_3)_2{\cdot}3H_2O$ (0.121 g, 0.5 mmol), NaOH (0.04 g, 1.0 mmol), 1,4-cyclohexanedicarboxylic acid (0.172 g, 1.0 mmol), bpp (0.198 g, 1.0 mmol), benzene (0.5 mmol), and H_2O (9 mL) was placed in a Parr Teflon-lined, stainless-steel vessel, acidified with HCl (0.25 mmol), then heated at 180 or 190 °C for 3 d to yield fine, pale-yellow crystals (yield 20–30%). $C_{60}H_{52}ClCu_2N_9O_7$: calcd. C 61.40, H 4.47, N 10.74; found C 61.14, H 4.36, N 10.65.

3: A mixture of $Cu(NO_3)_2{\cdot}3H_2O$ (0.484 g, 2.0 mmol), NaOH (0.08 g, 2.0 mmol), 1,4-cyclohexanedicarboxylic acid (0.172 g, 1.0 mmol), bpp (0.198 g, 1.0 mmol), and H_2O (9 mL) was placed in a Parr Teflon-lined stainless-steel vessel, acidified with HCl (0.25 mmol), then heated at 175 °C for 3 d to yield fine, primrose-yellow crystals (yield 18–22% based on bpp). $C_{26}H_{22}Cl_2Cu_2N_4O_2$: calcd. C 50.33, H 3.57, N 9.03; found C 50.10, H 3.42, N 8.95.

4: Compound **4** was prepared by a similar experimental procedure to that for **3** except for the molar ratio of HCl (0.5 mmol). Yield: 30–35% based on bpp. $C_{26}H_{22}ClCu_2N_5O_5$: calcd. C 48.26, H 3.43, N 10.82; found C 47.95, H 3.35, N 10.91.

chtpy: A solution of $Na_2(H_2edta)$ (0.149 g, 0.4 mmol) in water (10 mL) was added dropwise to a stirred suspension of **1** (0.145 g) in a mixture of dichloromethane (30 mL) and water (10 mL) at room temperature, followed by stirring for 48 h under nitrogen. The organic phase was then separated from the reaction mixture and the aqueous layers were extracted with dichloromethane (3 × 60 mL). The combined organic phase was concentrated in vacuo. The residue was dissolved in dichloromethane, purified by column chromatography, and dried with anhydrous Na_2SO_4 to give chtpy as a pale-yellow powder. Yield: 0.095 g (78%). (ESI-MS): $m/z = 425$, 213; ^{1}H NMR (300 MHz, $(CD_3)_2SO$): $\delta = 1.27$ (m, 4H, C7-H7a, C7-H7b), 2.18 (t, $J =$ 3.3 Hz, 2H, C6-H6), 7.14 (d, $J = 5.1$ Hz, 4H, C2-H2, C4-H4), 7.54 (d, $J = 5.4$ Hz, 4H, C10-H10, C13-H13), 8.56 ppm (d, $J = 3.6$ Hz, 8H, C1-H1, C5-H5, C11-H11, C12-H12); ^{13}C NMR (75 MHz, $(CD_3)_2SO$): $\delta =$ 30.9 (C-7), 34.6 (C-6), 79.9 (C-8), 121.9 (C-9), 124.5 (C-2), 150.1 (C-1), 151.1 ppm (C-3). $C_{26}H_{24}N_4O_2$: calcd. C 73.57, H 5.70, N 13.20; found C

73.26, H 5.62, N 13.09. IR (KBr disk): $\tilde{\nu}=3228$ (m, OH), 1596, 1545 cm^{-1} (s, py). Colorless crystals of chtpy·4 H_2O were obtained by dissolution of the powder in acetonitrile at ambient temperature in air. $C_{26}H_{24}N_4O_2\cdot 4H_2O$: calcd. C 62.89, H 6.50, N 11.28; found C 62.71, H 6.62, N 11.03.

Mimicking the Function of Eggshell Matrix Proteins: The Role of Multiplets of Charged Amino Acid Residues and Self-Assembly of Peptides in Biomineralization**

*Parayil Kumaran Ajikumar, Subramanian Vivekanandan, Rajamani Lakshminarayanan, Seetharama D. S. Jois, R. Manjunatha Kini, and Suresh Valiyaveettil**

The molecular-level understanding and rationalization of nature's clues on how to produce complex, organized structures such as bone, teeth, and seashells at ambient temperature and in aqueous environments has resulted in the design and synthesis of novel materials.[1,2] The properties of the crystals such as size, shape, stability, polymorph selectivity, and crystallographic orientation are controlled by biomacromolecules, which are classified as "framework macromolecules" and "control macromolecules".[2,3] The complexities of the natural biomineralization process have resulted in research efforts being focused on "tailor-made" low-molecular-weight compounds and macromolecular additives for structure–function investigations by in vitro mineralization experiments.[4] So far, research efforts have been focused on auxiliary oligopeptides to probe the role of functional motifs in the kinetics, habit modifications, and polymorph selectivity during the crystal growth process.[5,6]

The structure–function sequence analysis of eggshell-specific proteins revealed that the presence of multiplets of charged amino acid residues and characteristic self-aggregation in solution influence the formation of biominerals.[7,8] We anticipate that the design and testing of peptides with multiplets of charged residues could mimic the functions of such proteins during in vitro experiments.[6c] Thus, to investigate the role of self-assembly and multiplets of charged amino acids in calcium carbonate mineralization, we designed a series of peptides (Table 1) and studied their structure–activity relationships. The first two groups (I, II) of peptides have an ordered arrangement of doublets of charged residues which resembles the primary structure of avian eggshell matrix proteins (a full sequence comparison is given in the Supporting Information).[7] The significant structural differences between the peptides involve replacing the arginine residue with lysine—a basic flexible residue with a primary amino group and hydrophobic side chain—and the incorporation of a proline residue in the middle of the peptides in group II. The proline residue is expected to limit the conformational flexibility,[6c] and organisms use such domains to form three-dimensional supramolecular structures of proteins.[2a,8,9] Among the three peptides in group III, $K_2E_2W_2D_2G$-17 and $K_2AE_2AW_2AD_2P$-23 have an ordered arrangement of doublets of charged residues. However, the incorporation of one glycine residue in the former and six alanine residues in the latter peptide is expected to disrupt the ordered, stable secondary structure of the peptides and impart flexibility to the peptide backbone. The peptide $(KE)_2(WD)_2$-16, with alternate acidic and basic residues, is designed as a control peptide for confirming the perceived critical role of multiplets of charged residues.

To understand the role of these designed peptides in calcite growth and habit modification, we carried out in vitro mineralization of calcium carbonate by slow diffusion of CO_2 and NH_3 gas to the peptide dissolved in $CaCl_2$ solution (7.5 mM).[10] The first two groups of peptides showed significant influence on the calcite crystal morphology and aggregation as compared with the group III peptides (compare images 2–5 with images 6–8 in Figure 1 and Supporting Information).

The $CaCO_3$ crystals formed in presence of group I and II peptides showed—similarly to those formed in the presence of ansocalcin[8]—concentration-dependent changes in crystal morphology (Figure 1 and Supporting Information). Polycrystalline aggregates of calcite crystals were formed as the concentration was increased to 2 mg mL^{-1}, and the size of the crystal aggregates obtained with $K_2E_2W_2D_2$-16 ($\approx$41 μm) and $K_2E_2W_2D_2P$-17 ($\approx$35 μm) was almost double that of crystals obtained with $R_2E_2W_2D_2$-16 ($\approx$20 μm) and $R_2E_2W_2D_2P$-17 ($\approx$21 μm). The observed superstructures are composed of smaller rudimentary calcite crystals assembled into spherical structures. The crystal lattice was further characterized by X-ray diffraction studies. In addition, the nucleation density (that is, the number of crystals per unit area) also increased with an increase in the peptide concentration. Group III peptides did not show significant influence on the calcite crystal nucleation, growth, or morphology. This finding indicates that not only the primary structural characteristics but also control of the spatial disposition of the functional sites on the peptide is important for the nucleation of crystal aggregates. Thus, the designed peptides $R_2E_2W_2D_2$-16, $R_2E_2W_2D_2P$-17, $K_2E_2W_2D_2$-16, and $K_2E_2W_2D_2P$-17 (2 mg mL^{-1}, $\approx$0.8 μM) induce the nucleation and formation

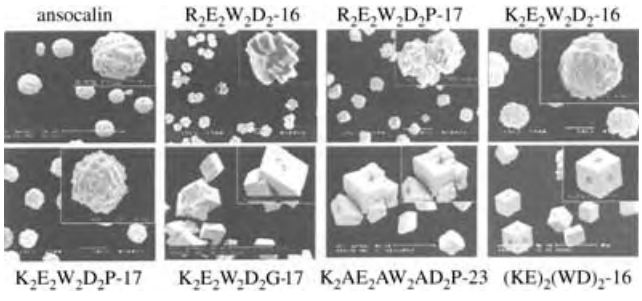

Figure 1. Crystal habit modification in the presence of the protein ansocalcin (500 μg mL^{-1}) and designed peptides (2 mg mL^{-1}). The scale bars represent 50 μm. Magnified images are given in the insets.

of polycrystalline calcite crystal aggregates similar to the parent protein ansocalcin.

For a detailed investigation of the structure–activity relationship, we investigated the self-assembly of the peptides in solution by dynamic light scattering (DLS), tryptophan fluorescence, circular dichroism (CD), NMR spectroscopy, and molecular modeling studies. The DLS and fluorescence analysis showed a concentration-dependent aggregation of group I and II peptides in $CaCl_2$ solution (Figure 2). The observed hydrodynamic radii of the group I peptides ($\langle R_H \rangle =$ 3.3 and 4.1 nm) are smaller than those of the corresponding proline-incorporated group II peptides ($\langle R_H \rangle = 6.4$ and 8.1 nm). However, a fourfold reduction in the size of the aggregate was observed when proline in $K_2E_2W_2D_2$P-17 (**IV**, 8.1 nm) was replaced with glycine in $K_2E_2W_2D_2$G-17 (**V**, 2.2 nm). These results highlight the expected role of proline toward decreasing the conformational flexibility and enhancing the oligomerization of peptides into large aggregates. The observed particle sizes for the group III peptides K_2AE_2-AW_2AD_2P-23 (**VI**, 2.2 nm) and $(KE)_2(WD)_2$-16 (**VII**, 1.8 nm) were low. Interestingly, alterations of the peptide sequences result in the enhancement of the mean diffusion coefficient ($\langle D \rangle$, Figure 2). In addition, the observed mean diffusion coefficient for the group I and II peptides is almost comparable to that of monomeric forms of ansocalcin and lithostathine.[8,11]

The study of the microenvironment around the tryptophan residues gives an insight into the self-aggregation tendency of the peptides. All the peptides showed distinct emission characteristics (see Supporting Information) and changes in intensity of the emission maximum with change in peptide concentration. The lysine-incorporated peptides $K_2E_2W_2D_2$-16 and $K_2E_2W_2D_2$P-17 showed weaker emission intensities than the peptides $R_2E_2W_2D_2$-16 and $R_2E_2W_2D_2$P-17. Notably, the intensity increased linearly with concentration up to 0.25 mg mL^{-1}, followed by an approximately 85% decrease in intensity for groups I and II peptides at a concentration of 2 mg mL^{-1}. This result might be a consequence of the quenching of the tryptophan fluorescence by the polar functional groups (CO_2H), which are brought into close proximity through aggregation of the peptide molecules.[12] However, in the case of the group III peptides, the emission intensity increased linearly with concentration up to 1 mg mL^{-1} followed by a small intensity drop at 2 mg mL^{-1}.

The CD spectra of the peptides were recorded in a concentration range of 0.05 to 2 mg mL^{-1} at 25 °C in $CaCl_2$ solution (Figure 3 and Supporting Information). It is clear that the secondary structure of the peptides $R_2E_2W_2D_2$-16 and $K_2E_2W_2D_2$-16 in solution is an extended β-sheet conformation

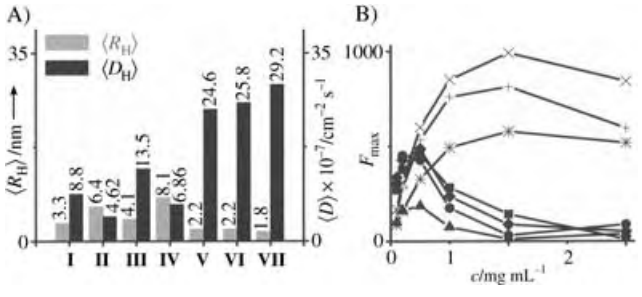

Figure 2. A) Mean hydrodynamic radius ($\langle R_H \rangle$) and diffusion coefficient ($\langle D \rangle$) of synthetic peptides **I**–**VII**. The *y* axis represents the $\langle R_H \rangle$ in nanometers or $\langle D \rangle \times 10^{-7}$ in cm^2 s^{-1}. B) Intensity (F_{max}) versus concentration profile of fluorescence emission of synthetic peptides **I** (◆), **II** (■), **III** (▲), **IV** (●), **V** (*), **VI** (+), and **VII** (×) in $CaCl_2$ solution (7.5 mM).

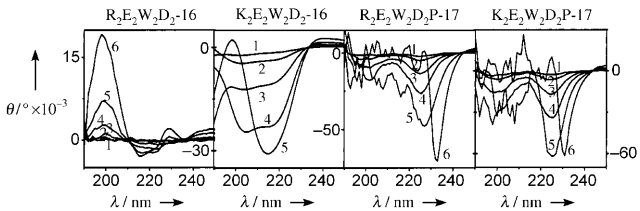

Figure 3. Circular dichroism spectra of group I and II peptides in $CaCl_2$ (7.5 mM) at various concentrations: 1) 50 μg mL^{-1}, 2) 100 μg mL^{-1}, 3) 250 μg mL^{-1}, 4) 500 μg mL^{-1}, 5) 1 mg mL^{-1}, and 6) 2 mg mL^{-1}. The instrument settings used were: scan range, 190 to 260 nm; scan rate, 50 nm min^{-1}; sensitivity, 10 millidegrees; response time, 1 s.

at high peptide concentrations (2 mg mL^{-1}). However, the incorporation of the proline in the middle of the sequences ($R_2E_2W_2D_2$P-17 and $K_2E_2W_2D_2$P-17) disrupts the extended β-sheet structure. The CD spectra showed the appearance of an amide n–π* negative-transition band at 225 and 227 nm for the peptides, which corresponds to a β-turn conformation.[13] The replacement of proline with glycine in $K_2E_2W_2D_2$G-17 resulted in an unordered structure with turns (negative minimum at 201 and 223 nm).[14] Similarly, the CD spectra of the peptides $K_2AE_2AW_2AD_2$P-23 (negative minimum at 199 and 224 nm) and $(KE)_2(WD)_2$-16 (negative minimum at 199 nm and a weak positive maximum at 216 nm) also indicated unordered structures in solution.

The results obtained from CD spectrometry are supported by data from NMR experiments. The 1D NMR spectra of $R_2E_2W_2D_2$-16 and $K_2E_2W_2D_2$-16 showed a significant peak broadening (Figure 4A) as a result of the formation of an

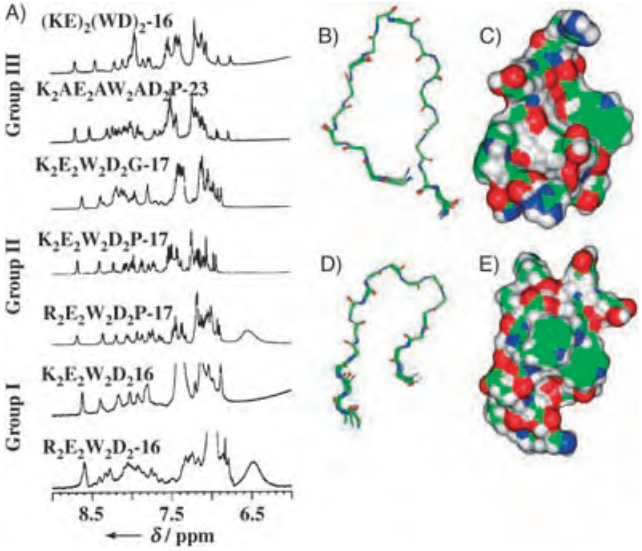

Figure 4. A) 1D pulsed-field gradient ^{1}H NMR spectra of the NH region of the model peptides; 300 K, in 90% H_2O/10% D_2O, pH 3.0. Proton chemical shifts are referenced from internal [2,2,3,3-D_4]TSP. B)–E) Conformational ensembles and surface structures obtained from molecular dynamics simulations of the peptides $R_2E_2W_2D_2$P-17 (B, C) and $K_2E_2W_2D_2$P-17 (D, E).

extended β-sheet conformation in solution. In contrast, the 1D NMR spectra of the peptides $R_2E_2W_2D_2$P-17 and $K_2E_2W_2D_2$P-17 showed sharp NH peaks within the range of $\Delta\delta = 1.3$ ppm, which indicates an ordered structure in solution. The NMR spectrum of $K_2E_2W_2D_2$G-17 showed a strong overlap of amide protons, thus indicating an unordered structure. Similarly, the peptides $(KE)_2(WD)_2$-16 and $K_2AE_2AW_2AD_2$P-23 also showed an extensive chemical shift overlap, which indicated an unordered structure in solution. The calculated proton chemical shift difference measured with TSP references (TSP = 3-(trimethylsilyl)propionate) showed deviation from the random coil values for the $R_2E_2W_2D_2$P-17 and $K_2E_2W_2D_2$P-17 peptides (see Supporting Information).[15]

The calculated δ values for residues E4-D7 and R/K10-D17 in the group II peptides are greater than random coil values by 0.1 ppm, which indicates that both peptides adopt a similar nonextended conformation with a turn structure for the backbone. The calculated ratio of $d_{\alpha N}(i,i+1)$:$d_{NN}(i,i+1)$ is greater than 1.4, which suggests an ordered peptide conformation. A long-range NOE cross-relaxation transfer ($d_{\alpha N}(i,i+2)$) was observed between the residues P9/R11 and E12/W14 for $R_2E_2W_2D_2$P-17 and D8/K10, P9/K11, and E12/W14 for $K_2E_2W_2D_2$P-17 (see Supporting Information). However, in the case of the glycine-containing peptide ($K_2E_2W_2D_2$G-17), no $d_{NN}(i,i+1)$ NOE connectivities were observed. Thus, from the above observations we conclude that the peptides $R_2E_2W_2D_2$P-17 and $K_2E_2W_2D_2$P-17 adopt a nonextended structure with a turn or kink on the backbone.

By using the available NMR restraints, the conformations of the peptides were calculated with the help of molecular-dynamics-simulated annealing/minimization experiments to determine a plausible lowest-energy conformational ensemble (ten structures) that fits the target NMR data set. The conformers with the fewest NOE violations were used to represent the structure. Figures 4B, D show the backbones of ten overlapped, energy-minimized structures of the peptides $R_2E_2W_2D_2$P-17 and $K_2E_2W_2D_2$P-17, whereas the surface structures (Figure 4C, E) represent the distribution of functional groups. Analysis of the ϕ,ψ distribution obtained for the ten conformational ensembles revealed that the dihedral pairs near proline consistently centered within the ϕ,ψ regions associated with a turn structure in polypeptides. Comparison of the dihedral angles shows a type II turn structure near P9-R10 residues of the peptide $R_2E_2W_2D_2$P-17 and a type I turn structure in the region of P9-R10 and E12 to E13 of $K_2E_2W_2D_2$P-17.

The observations from the CD and NMR spectra and molecular modeling studies are well-correlated and consistent. The peptides $R_2E_2W_2D_2$P-17 and $K_2E_2W_2D_2$P-17 exhibit a β-sheet-type structure with a turn near the proline residue. Such an unfolded conformation would minimize the electrostatic side-chain charge repulsion, orient the charged residues (D, E, R, and K), and make them accessible for complexation with calcium ions in solution.[16]

The observed extensive overlap of the NMR signals in the amide region of group III peptides indicates the presence of an unordered open structure with rapid conformational exchanges. In addition, the low hydrodynamic radius ($\langle R_H \rangle$) and high value of the mean diffusion coefficient ($\langle D \rangle$) obtained from the DLS experiments also corroborate the findings from the CD and NMR studies. Moreover, the fluorescence studies revealed the absence of concentration-dependent self-assembly of group III peptides in solution. The results from conformational studies of the peptides are consistent with the observed mineralization behavior in solution. Thus, in the nonaggregated form, the random movement of the peptides resulted in a nonspecific interaction with the $CaCO_3$ crystals, thereby inducing pits and truncation of the calcite crystal surfaces.

In conclusion, seven peptides were designed and fully characterized to mimic the function of the goose eggshell matrix protein, ansocalcin. The ordered arrangement of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

doublets of charged residues and the self-assembling characteristics of the group I and II peptides generated a functional-group-segregated surface which facilitates the nucleation, growth, and aggregation of calcium carbonate crystal nuclei to form polycrystalline calcite crystal aggregates. The group III peptides showed an unordered structure in solution and no activity toward mineralization. This finding is supported by evidence from DLS, NMR, CD, and fluorescence spectroscopy investigations.

Label-Free Detection of Protein–Protein Interactions on Biochips**

*Woon-Seok Yeo, Dal-Hee Min, Robert W. Hsieh, Geoffrey L. Greene, and Milan Mrksich**

The recent introduction of protein microarrays is now providing tools for the global profiling of biochemical activities.[1] Snyder and co-workers, for example, used yeast protein chips to identify kinase substrates and lipid-binding proteins.[2] Labaer and co-workers reported self-assembling protein microarrays to map pairwise interactions among 29 human DNA replication proteins.[3] Any application of a protein chip must involve a suitable labeling strategy that will permit the observation of activities. Common strategies include the use of radioisotopes to follow phosphorylation reactions[4] and fluorescent tags to identify protein–protein interactions.[5] The use of labels has limitations, including the need for additional steps in an assay, the difficulty in detecting certain biochemical activities, and the inability to identify unanticipated activities. These limitations have motivated the development of label-free formats for identifying the full range of biochemical activities on protein chips. Herein, we demonstrate that MALDI-TOF MS can be used to identify protein–ligand and protein–protein interactions on biochips that are prepared from self-assembled monolayers (SAMs) on gold. This work is significant because it extends the capacity of the SAMDI (self-assembled monolayers for MALDI) method from observation of low-molecular-weight species to proteins that are 50 kDa in size.

Our approach begins with a SAM of alkanethiolates on gold that presents maleimide groups amongst a background of tri(ethylene glycol) groups in a ratio of 1:20. The maleimide groups serve as a handle to immobilize thiol-derivatized small molecules,[6] and the tri(ethylene glycol) group ensures that the monolayers are inert to nonspecific protein adsorption.[7] Two model systems were used in the examples that follow: the binding of carbonic anhydrase (CA) to a benzenesulfonamide ligand and the binding of glutathione S-transferase (GST)-tagged protein complexes to a glutathione ligand (Scheme 1).

Scheme 1. Strategy for the label-free detection of protein–ligand (top) and protein–protein interactions (bottom) using MALDI-TOF MS on SAMs presenting capture ligands.

To immobilize the small molecules, monolayers were treated with either glutathione thiol (1 mM in tris(hydroxymethyl)-aminomethane (Tris) buffer, pH 7.5) or benzenesulfonamide thiol (2.5 mM in phosphate-buffered saline (PBS) containing 10% methanol, pH 7.4) (Figure 1a).[8] MS analysis of these monolayers showed peaks corresponding to the immobilized ligands and confirmed that the reactions proceeded in high yield (Figure 1b).[9]

Herein, we report several examples that establish the use of SAMDI for the direct observation of proteins bound to surface-immobilized ligands. A monolayer presenting glutathione groups was treated with GST (10 μM in Tris buffer containing 1 mM dithiothreitol (DTT), pH 7.5) for 1 hr, rinsed with distilled water, and dried under a stream of nitrogen. MS analysis of this monolayer showed two major peaks corresponding to the singly and doubly charged protein at m/z 28.0 kDa ($[M+H]^+$) and m/z 14.0 kDa ($[M+2H]^{2+}$), respectively (Figure 2a). A control experiment showed that the addition of soluble glutathione (1 mM in Tris buffer, pH 7.5) to the solution containing GST prevented binding of the protein to the monolayer. Indeed, MS data from the monolayer showed no major peaks, verifying the effectiveness of the monolayer in preventing nonspecific interactions (Figure 2b). Furthermore, no protein peaks were observed when a maleimide-presenting monolayer was treated with a cysteine-containing hexapeptide (CGRGDS) followed by incubation with GST (data not shown).

This experiment was repeated with several fusion proteins. A fusion between GST and a focal adhesion targeting domain (GST–FAT) bound to the monolayer, as evidenced by two major peaks corresponding to singly and doubly charged

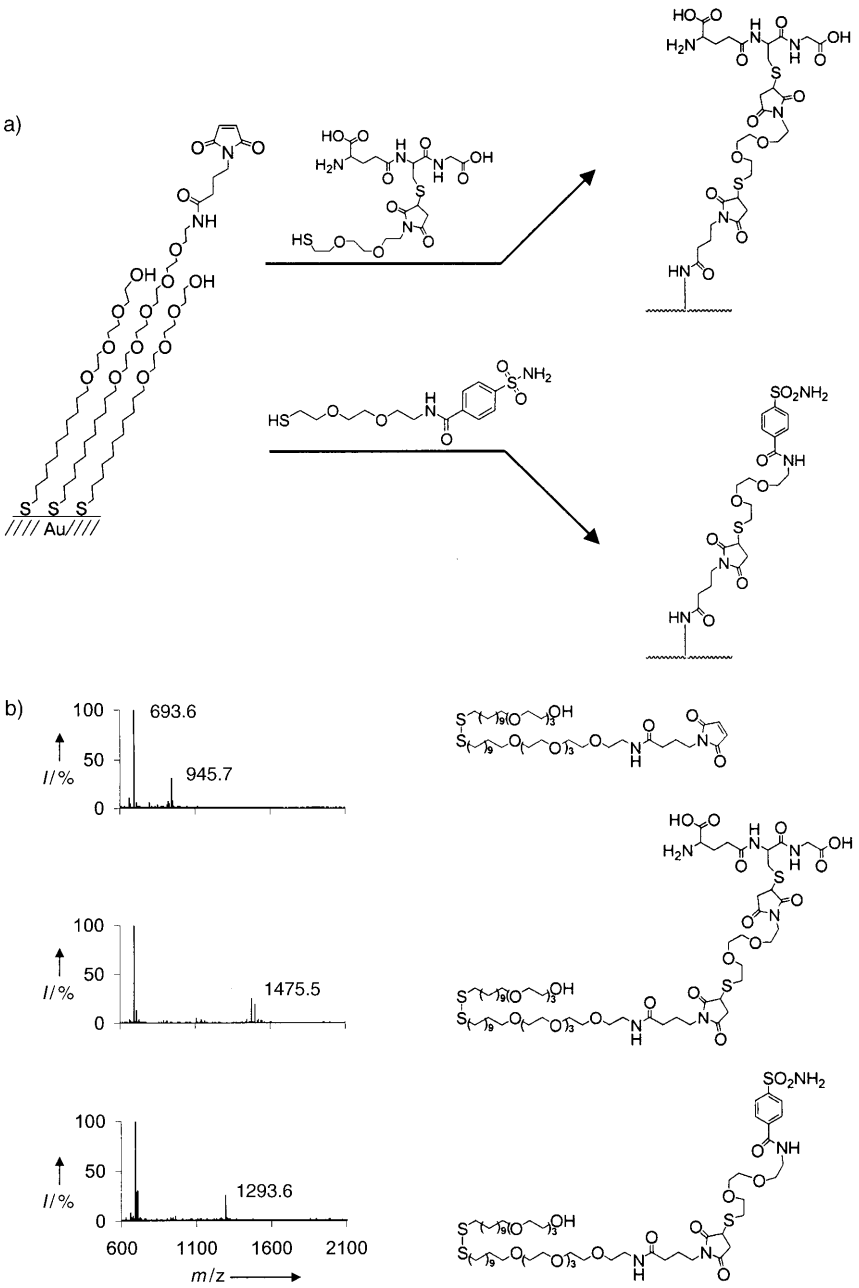

Figure 1. a) Protein-capture ligands were immobilized onto a maleimide-terminated SAM by reaction of the thiol-tagged ligands. b) MS data for the initial monolayer (top) displayed a peak at *m*/*z* 945.7, which corresponds to the mixed disulfide derived from a maleimide-terminated alkanethiolate and a tri(ethylene glycol)-terminated alkanethiolate. After treatment with ligands, the original peak disappeared and gave rise to a new peak at *m*/*z* 1475.5, which corresponds to the glutathione-conjugated product (middle) or at *m*/*z* 1293.6, which corresponds to the benzenesulfonamide-conjugated product (bottom).

bound GST–FAT at *m*/*z* 44.2 kDa ($[M+H]^+$) and *m*/*z* 22.1 kDa ($[M+2H]^{2+}$), respectively (Figure 2c).[10] We also found that a monolayer treated with a crude lysate of *E. coli* that had been transformed with the GST–FAT plasmid gave major peaks identical to those obtained from a purified GST–FAT protein (Figure 2d). This result gives further evidence that the immobilization of GST proteins is specific, and that the monolayer is inert to the nonspecific adsorption of proteins. In a separate experiment, a monolayer presenting the benzenesulfonamide ligand was treated with CA (5 μM in Tris buffer, pH 7.5). MS analysis of this monolayer revealed peaks corresponding to the bound protein, including a doubly charged monomer ($[M+2H]^{2+}$, *m*/*z* 14.5 kDa), a singly charged monomer ($[M+H]^+$, *m*/*z* 28.9 kDa), and a singly charged dimer ($[2M+H]^+$, *m*/*z* 57.9 kDa) (Figure 2e). Pre-incubation of CA with soluble benzenesulfonamide (500 μM) inhibited the binding of protein to the monolayer (data not shown). This latter example is significant because it suggests that SAMDI can be applied to the use of small-molecule arrays to identify inhibitors of target proteins.[11] Indeed, small arrays of carbohydrate ligands have been prepared on SAMs[12] and chemistries have been demonstrated for the immobilization of small molecules that have amine or thiol functional groups.[6,13]

This method is also well-suited for characterizing protein–protein interactions on biochips. We demonstrate this application with the interaction between estrogen receptor (ER) and steroid receptor coactivator (SRC).[14,15] ER serves as a molecular switch; its binding to SRC requires a small-molecule agonist.[16] The MALDI MS spectrum of a glutathione-presenting monolayer that was exposed to GST–SRC gave peaks corresponding to the singly and doubly charged fusion protein at *m*/*z* 44.7 kDa ($[M+H]^+$) and *m*/*z* 22.4 kDa ($[M+2H]^{2+}$), respectively (Figure 3a).[17] A solution containing GST–SRC (10 μM), ER (10 μM), and estradiol (E2, agonist, 50 μM) was applied to the monolayer and analyzed by MS. The analysis revealed peaks derived from both GST–SRC ($[M+H]^+$ at *m*/*z* 44.7 kDa, $[M+2H]^{2+}$ at *m*/*z* 22.4 kDa) and ER ($[M+H]^+$ at *m*/*z* 30.4 kDa, $[M+2H]^{2+}$ at *m*/*z* 15.2 kDa) (Figure 3b). However, a repeat of this experiment in which the E2 agonist was replaced with an antagonist (4-hydroxytamoxifen, OHT, 50 μM) that disrupts the protein–protein interaction, resulted in major MS peaks derived from GST–SRC and only minor peaks derived from ER (Figure 3c). As expected, the presence of the antagonist significantly diminished the recruitment of ER. These results indicate that the combination of SAMs presenting capture ligands and MALDI-TOF MS allows the detection of protein complexes without any

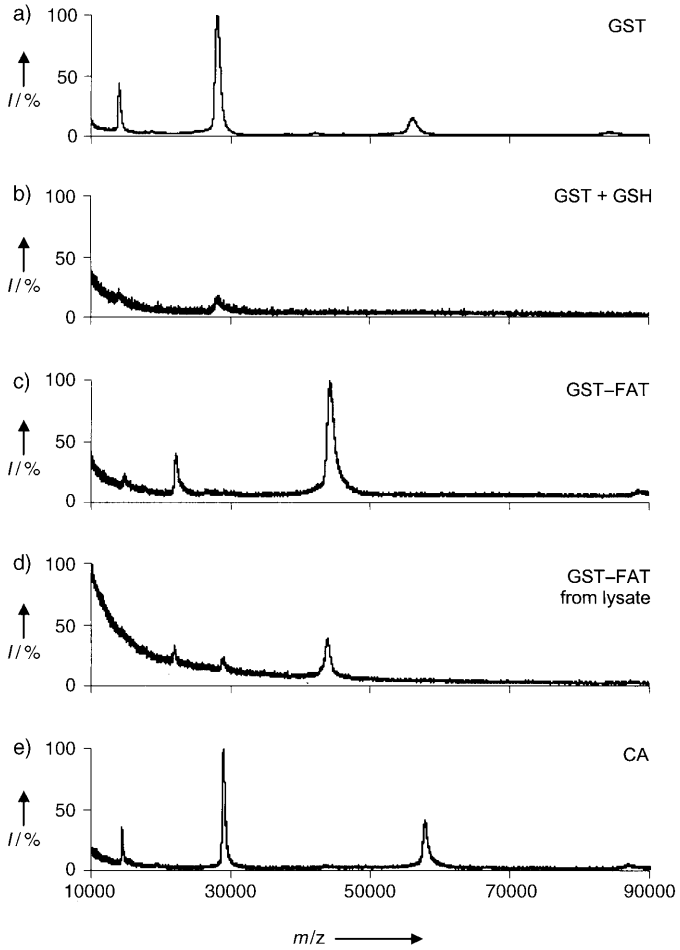

Figure 2. MS analysis of the binding of target proteins to monolayers presenting capture ligands. a) A monolayer presenting glutathione was treated with GST; the data show two major peaks corresponding to GST ions at m/z 28.0 kDa ($[M+H]^+$) and m/z 14.0 kDa ($[M+2H]^{2+}$), respectively. b) Pre-incubation of GST with soluble glutathione gave rise to no major peaks. c) An identical experiment was performed with GST–FAT, and the data show two major peaks corresponding to GST–FAT ions at m/z 44.2 kDa ($[M+H]^+$) and m/z 22.1 kDa ($[M+2H]^{2+}$), respectively. d) The monolayer was treated with a crude lysate from *E. coli* transformed with the GST–FAT plasmid and analyzed. The MS data show major peaks identical to those obtained from purified GST–FAT. e) A benzenesulfonamide-presenting monolayer was treated with CA; the resulting peaks correspond to the CA ions at m/z 14.5 kDa ($[M+2H]^{2+}$), m/z 28.9 kDa ($[M+H]^+$), and m/z 57.9 kDa ($[2M+H]^+$).

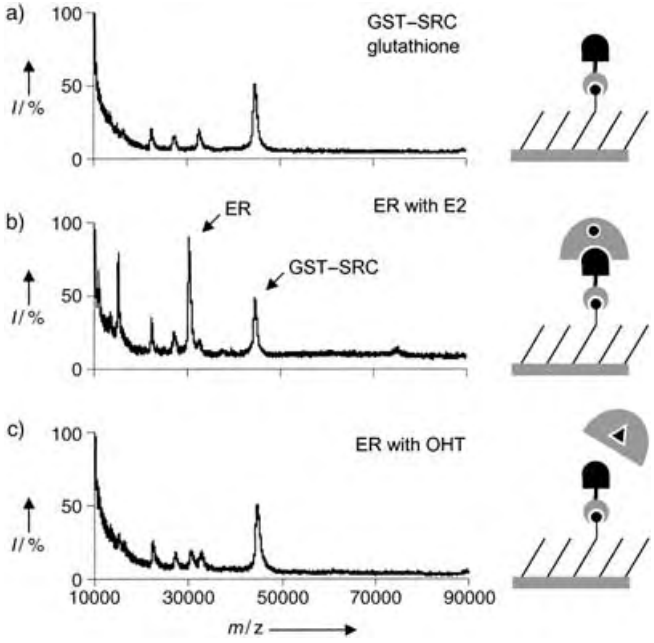

Figure 3. SAMDI analysis of protein- protein interactions on biochips. a) MS data from a glutathione-presenting monolayer treated with GST–SRC show peaks that correspond to bound-protein ions at m/z 44.7 kDa ($[M+H]^+$) and at m/z 22.4 kDa ($[M+2H]^{2+}$). b) A solution containing GST–SRC, ER, and E2 (agonist) was applied to a glutathione-presenting monolayer; the observed peaks derived from both GST–SRC ($[M+H]^+$ at m/z 44.7 kDa, $[M+2H]^{2+}$ at m/z 22.4 kDa) and ER ($[M+H]^+$ at m/z 30.4 kDa, $[M+2H]^{2+}$ at m/z 15.2 kDa). c) MS analysis of an identical experiment with OHT (antagonist) instead of E2 gave major peaks derived from GST–SRC and only minor peaks derived from ER.

labels. Furthermore, it differentiates agonist-induced and antagonist-blocked protein–protein interactions.

The combination of biochips and MALDI-TOF MS offers a powerful and flexible method for identifying protein–protein interactions on biochips and should be extendible to arrays. Importantly, the performance of this method is directly related to the use of self-assembled monolayers of alkanethiolates on gold as the substrate. The structural regularity and synthetic flexibility that are intrinsic to monolayer surface chemistries allow the properties of the interface to be optimized for biochip applications. In particular, the use of oligo(ethylene glycol)-terminated alkanethiols is very effective at controlling unwanted protein adsorption at the interface. This reduces false-positive signals and eliminates the need for usual blocking procedures.[7] Furthermore, a range of immobilization chemistries gives good control over the orientation, density, and activity of small molecules and proteins that are presented on the surface.[18] These factors make monolayers useful for quantitative assays of biochemical activities.[4b] The monolayers are also well-suited to analysis by MALDI-TOF MS. The gold substrate facilitates the release of alkanethiolates and bound proteins, and gives clean spectra that are readily interpreted. Whereas alternate methods based on porous silicon substrates share some of these properties,[19] only SAMDI allows MS detection of the interaction of both low-molecular-weight molecules (as in the case of immobilized peptides that report enzyme activities) and high-molecular-weight proteins, and is based on surface chemistries that are tailored for biochip applications.[20]

The work described herein offers a new opportunity for applying protein arrays to identify biomolecular interactions. The ability to identify protein–protein interactions without the need for labels will be particularly relevant for the observation of unanticipated activities. The SAMDI format also allows different classes of protein–protein (and enzyme–protein) interactions to be studied with a single array. Current methods, by contrast, often use labeling strategies that allow only a specific class of activity to be identified. These characteristics also suggest that SAMDI will be useful for

The "Noncoordinating" Anion Tf_2N^- Coordinates to Yb^{2+}: A Structurally Characterized Tf_2N^- Complex from the Ionic Liquid [mppyr][Tf_2N]**

Anja-Verena Mudring, Arash Babai, Sven Arenz, and Ralf Giernoth*

Crystal structures of bis(trifluoromethanesulfonyl)amide (Tf_2N^-) complexes of transition or f elements are unknown to date. This is surprising, since a variety of bis(trifluoromethanesulfonyl)amide compounds have been identified to be excellent Lewis acid catalysts. The Tf_2N^- ion is the conjugate base of an extremely strong Brønsted acid and has the power to strengthen the Lewis acidity of a metal center when acting as a ligand.[1] Lanthanide bis(trifluoromethanesulfonyl)amide compounds are, for example, used as Lewis acid catalysts for Diels–Alder reactions, Friedel–Crafts acylations, Fries transpositions, and Baeyer–Villinger oxidations.[2] Much effort (although to no avail) has been put into the crystallization of lanthanide bis(trifluoromethanesulfonyl)amides, but so far the structural identity of these catalysts remains uncertain.[3] Attempts to crystallize an ytterbium–Tf_2N^- complex from *N*,*N*′-dimethylpropyleneurea (dmpu)/ethyl acetate yielded a crystal structure with Yb^{III} ions surrounded octahedrally by six dmpu ligands. The Tf_2N^- ion was, however, only incorporated into this structure as a noncoordinating anion.[4] It is, therefore, not surprising that the Tf_2N^- ion has often been considered as weakly or even noncoordinating. The Tf_2N^- ion shows the feature that is essential for an ion to have a low tendency to coordinate: delocalization of negative charge over an extended area of functional groups.[5] The extremely strong acidity of the corresponding acid Tf_2NH has been attributed to extensive electron delocalization. As a consequence, the term "gas-phase superacid" has been coined for Tf_2NH.[6]

The Tf_2N^- ion has recently gained much attention in the ongoing search for new room-temperature ionic liquids (RTILs), since it has become clear that anions with diffuse charges and negligible possibility to form hydrogen-bonding interactions have the highest potential to produce ionic compounds that are liquid at room temperature and below.[7] RTILs have attracted wide attention as "green" solvents for catalysis, chemical synthesis, and separations. They have many favorable properties that are tuneable through the choice of the cation/anion pair, such as negligible volatility, high chemical, thermal and (electro)chemical stability, viscosity, density, hydrophobicity. The Tf_2N^- ion has been found to frequently produce salts with low melting points that have high fluidity and high ionic conductivity.[8] Ionic liquids based on the Tf_2N^- ion have gained special attention as they improve the performance of lithium batteries and fuel cells.[9] Indeed, most crystal structures of ionic liquids with the Tf_2N^- ion reveal no substantial hydrogen bonding between the cation and anion.[10] Displacement factors and sometimes the tendency to disorder show that the anion is conformationally highly flexibile, which might be the reason for the low number of structure determinations containing the Tf_2N^- ion.[11]

In our ongoing studies to explore the reactivity of rare-earth compounds as reagents for organic synthesis and catalysis in ionic liquids we were able to structurally characterize the first ytterbium–Tf_2N^- complex. Here, we present the first homoleptic Tf_2N^- complex obtained by interaction of YbI_2 with the ionic liquid [mppyr][Tf_2N] (mppyr = 1-methyl-1-propylpyrrolidinium).[12]

The complex crystallizes in the monoclinic space group $P2_1/n$ with four formula units in the unit cell. The asymmetric unit of the crystal structure shows Yb^{II} being coordinated by four Tf_2N^- ions through their oxygen atoms (Figure 1), with two cations of the ionic liquid to balance the charge.[13] To our knowledge, this is the first structure showing the Tf_2N^- ion coordinating in a η^2-bidentate manner to a metal center to form discrete anionic molecules. The Yb atom is surrounded

aryloxo–ytterbium complexes, while Yb–O bond lengths in bridging aryloxo ligands lie in the range 224–234 pm.[14] Yb–O bond lengths of 238–239 pm are reported for $[Yb(thf)_6]^{2+}$ with neutral tetrahydrofuran as a ligand.[15] Unfortunately there are no structural data for Yb^{II}–1,3-diketone complexes available for comparison. Considering that the ionic radius of an eightfold coordinate Yb^{2+} ion corresponds to the one for an eightfold coordinate La^{3+} ion, it might be possible to compare the average Yb–O bond length of 246.1 pm in $[mppyr]_2[Yb(Tf_2N)_4]$ to d(La-O) of 247 found for $[La(acac)_3(H_2O)_2]$ (acac = acetylacetonate).[16]

Surprisingly, all the ligands show a *cisoid* conformation with respect to the CF_3 groups, which fixes the $[Yb(Tf_2N)_4]^{2-}$ antiprisms along the crystallographic *b*-axis (Figure 2). The free acid Tf_2NH crystallizes with the CF_3 groups being oriented in a *transoid* banner to each other.[17] The Tf_2N ion also prefers the *transoid* conformation in the absence of suitable coordination centers.[10,11] This observation is backed by theoretical calculations (*transoid* Tf_2NH is about 8 kJ mol^{-1} more stable than *cisoid* Tf_2NH, and *transoid* Tf_2N^- about 4 kJ mol^{-1} more stable than *cisoid* Tf_2N^-).[18] It can thus be concluded that the *cisoid* conformation of the Tf_2N^- ion in [mppyr][Tf_2N] results from by Yb–Tf_2N^- interactions. The very weak interaction between the metal center and the oxygen atoms results in the average S–O bond lengths [144.3 pm (coordinating oxygen atoms) and 141.6 pm (non-coordinating oxygen atoms)] being only slightly affected by coordination to the Yb^{2+} ion, even when compared to the neutral amine (d(S-O) = 140.1 pm and 141.7 pm).[17]

The question that arises is: why does the Tf_2N^- ion coordinate through its oxygen atoms and not through the deprotonated nitrogen center? In this context, the often-cited

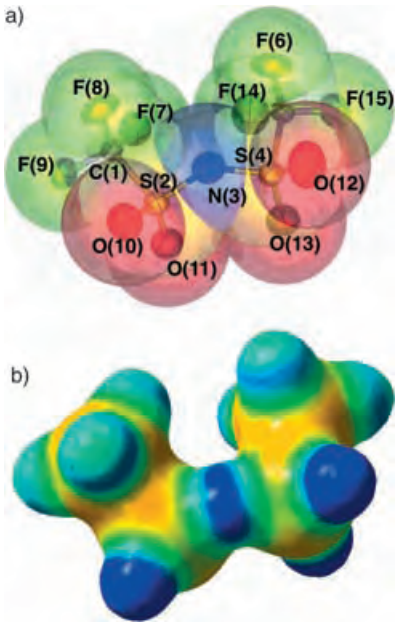

Figure 2. a) Space filling model of Tf_2N^- as found in $[mppyr]_2[Yb(Tf_2N)_4]$. b) Calculated electrostatic potential of *cisoid* Tf_2N^-.

Cruickshank model predicts that charge delocalization in these systems only occurs between the nitrogen and sulfur atoms.[19] In contrast, Mulliken charges as well as natural charges obtained from NBO analysis indicate that high partial charges occur not only at the nitrogen center but also at the oxygen atoms of the Tf_2N^- ion (Table 2). This charge

Table 2: Mulliken charges and natural charges for *cisoid* Tf_2N^- at the MP2 and B3LYP level of theory.

distribution is further backed by a plot of the electrostatic potential (Figure 2a).[20] Thus, electrostatic (high negative charge on the oxygen atoms, more favorable coordination to two sulfur atoms than to one nitrogen atom) and steric reasons (the nitrogen center is well shielded by its surroundings, Figure 2b) are the origin of the observed coordination mode of the Tf_2N^- ion.

These observations show that ionic liquids containing the bis(trifluoromethanesulfonyl)amide anion (Tf_2N^-) are not as "innocent" or "noncoordinating" as they are often believed to be. In the absence of any stronger coordinating ligand, even the weak bis(trifluoromethanesulfonyl)amide anion coordinates to a metal cation present in solution. This observation is important, as many reactions in these solvents may be crucially influenced by complexation. Furthermore, our observation helps to understand the solvation process of inorganic salts in ionic liquids, since we are able to show that the metal cation, in our case Yb^{2+}, dissolves under complexation. The discovery of $[mppyr]_2[Yb(Tf_2N)_4]$ shows not only the high potential of ionic liquids for the synthesis of complex compounds with weakly coordinating anions but also the versatility of ionic liquids as solvents for highly reducing species as divalent rare-earth iodides.

[12] Synthesis: YbI_2 was prepared by reduction of YbI_3 with Yb metal in a sealed tantalum container jacketed with an evacuated silica tube. YbI_3 was prepared from ytterbium (chips, Chempur, 99.5%) and iodine (Riedel de Häen, 99.8%) according to the procedure described in: G. Meyer, *Chem. Rev.* **1988**, *88*, 93]. [mppyr][Tf_2N] was prepared according to the procedure in D. R. Mac Farlane, P. Meakin, J. Sun, N. Amini, M. Forsyth, *J. Phys. Chem. B* **1999**, *103*, 4164. Storage and manipulation of the starting materials and products were handled under dry-box conditions under dry argon (MBraun, Garching, Germany).
$YbI_2 + 4[mppyr][Tf_2N] \rightarrow [mppyr]_2[Yb(Tf_2N)_4] + 2[mppyr][I]$
The reaction of YbI_2 (0.2 mmol, 87 mg) with [mppyr][Tf_2N] (4.8 mmol, 1 g) was carried out in a evacuated and sealed silica tube at 393 K for 48 h. Colorless single crystals of $[mppyr]_2[Yb(Tf_2N)_4]$ formed as the single, insoluble product after subsequent cooling (2 K min^{-1}) of the mixture to room temperature. The product was separated by filtration. Estimated yield: 66%; m.p. 107 °C; IR (KBr): $\tilde{\nu}$ = 1473 (s), 1433 (s), 1352 (vs), 1331 (vs), 1231 (vs), 1197 (vs), 1144 (vs), 1058 (vs), 972 (w), 940 (w), 797 (m), 763 (w), 742 (m), 652 (s), 618 (s), 608 (s), 599 (s), 574 (s), 515 cm^{-1} (s).

[13] Crystal data: A suitable single crystal (0.3 × 0.2 × 0.2 mm) was mounted in a glass capillary. Intensity data were collected on an IPDS diffractometer (Stoe, Darmstadt, Germany) at 120(2) K. 120 K: monoclinic, space group $P2_1/n$; a = 1122.01(4), b = 2260.21(9), c = 2188.47(9) pm, β = 102.209(3)°, V = 5.4244(4) nm^3; Z = 4; ρ_{calcd} = 1.8978 g cm^{-3}; $1.80 < \theta < 27.19°$; IPDS II, $Mo_{K\alpha}$ radiation (λ = 71.073 pm); T = 120(2) K; $F(000)$ = 3056; μ = 2.177 mm^{-1}; 56375 reflections were measured, of which 11822 were unique. R_1 = 0.0436 and wR_2 = 0.1109 for [$I_0 > 2\sigma(I_0)$]. The data were processed with the program systems SHELX-97 [G. M. Sheldrick, SHELX-97, Universität Göttingen, **1997**] and X-Seed [L. J. Barbour, *J. Supramol. Chem.* **2001**, *1*, 189]. Numerical absorption correction after crystal shape optimization was performed by using the programs XRED and XSHAPE [Stoe, XRED 1.01 and XSHAPE 1.01, Darmstadt, **1996**]. CCDC-268479 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Hierarchically Structured Carbon: Synthesis of Carbon Nanofibers Nested inside or Immobilized onto Modified Activated Carbon

Dang Sheng Su, Xiaowei Chen, Gisela Weinberg, Achim Klein-Hofmann, Olaf Timpe, Sharifah Bee Abd. Hamid, and Robert Schlögl*

The rapidly expanding knowledge about the physical and chemical properties of carbon nanotubes and nanofibers (CNTs and CNFs) has led to a range of potential applications in nanotechnology[1–5] including field-effect transistors, one-dimensional quantum wires, field emitters, and hydrogen-storage devices. Most applications of CNTs/CNFs either use individual objects (in nanoelectronics) or embed the fibers into a host matrix. The outer surface of CNTs/CNFs can be tailored to display the desired chemical properties ranging from metallic (graphite layers parallel to the tube or fiber axis) and to acidic–basic (all prism faces are exposed along the fiber axis and saturated with hydroxy groups).[6,7] The selective chemisorption of undesired species from drinking water (Mn, As, Hg, Fe), the modification of the properties of polymers (heat conduction, electrical conduction, mechanical reenforcement), and the use of CNTs/CNFs as catalysts or catalyst supports are only some of the applications of chemical nanotechnology.[8–19] These applications require, however, large amounts of CNTs and CNFs with well-defined surface-chemical and mechanical properties. In addition, the nanocarbon particles must be formed into larger objects to optimize the hydrodynamic properties and allow effective contact with reacting matrices. Loose CNTs/CNFs are unsuitable as their suprastructural properties cannot be controlled, and operations of compaction can destroy or at least inhibit the access of the reactant medium to the nanostructures. On the molecular level it is potentially useful to grow dendritic structures of CNTs/CNFs onto each other to maximize the surface area exposed and to provide molecular roughness for entanglement of, for instance, polymer strands.

A hierarchical organization of the nanocarbon units on itself to form small objects and on a robust carrier structure on larger dimensions is therefore highly desirable. For chemical applications it is essential that only one chemical element is

used for the construction and that the combination of nanocarbon with the non-carbon support structures is avoided as the resulting discontinuities in transport and in chemical properties would lead to deterioration of the overall compound properties and chemical instability.

An ideal substrate is activated carbon from natural sources. Such bioinorganic polymers containing typically lignins and silicates are strong, well-structured in several dimensions, accessible for chemical modifications, and available in large amounts.[20] Natural precursors to activated carbons[21] utilize the biological cell structure to preset the disposition of the macropore network, and they benefit from inorganic additives as anchoring sites for the catalyst and therefore for the nanocarbon. It is essential that the chemical interaction between the nanocarbon and the activated carbon carrier is strong and inert to preserve the hierarchical structure during extended operation.

The present paper describes ways to modify the activated carbon obtained from the biowaste of palm oil production to serve as the support for the growth of nanocarbon. We obtained a family of immobilized CNFs in various modifications. Nanostructured carbon can be obtained on the outer surface of the activated carbon yielding a useful geometry for binder–filler applications. Alternatively, burning large pores into the bulk structure of the activated carbon and subsequently filling the pores with carbon nanostructures leads to hierarchically structured carbon materials with nested CNFs inside the activated carbon which are highly suitable for sorption and catalytic applications.

The concept behind the production of these hierarchically structured carbon materials is illustrated in Scheme 1. On the macroscopic level, bulk activated carbon aggregates are transformed into a macroporous scaffold by selectively removing the "soft" parts of the biopolymer. This is achieved by catalytic burning during or after carbonization. The catalyst particles are then deliberately embedded in the carbon matrix by transforming the oxidic form of the catalyst used for creating porosity into a metallic form. The metal particles gasify the support locally under a reducing atomosphere. This form is then used for growing nanocarbon by chemical vapor decomposition (CVD) of organic molecules in one or several generations; if needed additional catalyst is embedded. The resulting immobilized nanocarbon-activated carbon composite (NAC) can then be assembled into larger solid aggregates by growing nanocarbon on the outside of the activated carbon grains to bind NAC particles firmly to each other. The transport of matrix media can be well controlled by changing the density of the nanostructures and by varying the filling factor of the porous carbon support. A final stage of chemical surface modification that may be necessary is not shown in Scheme 1. The preferential location of catalyst deposition inside or outside of the activated carbon scaffold can be varied by changing the deposition conditions of the catalytic precursor from ion exchange to homogeneous precipitation.

Scheme 1. The synthesis of hierarchically structured carbon materials by modifying activated carbon with nanocarbon.

By varying the unit operations—1) impregnation with the catalyst, 2) calcinations of the support carbon, 3) reduction of the catalyst and growth of nanocarbon—a family of nested or immobilized CNTs/CNFs can be obtained. We use the CVD method for growing the CNTs/CNFs as it has several advantages over electric-arc discharge and laser ablation. For example, the CVD method leads not only to single-walled or multiwalled CNTs but also to aligned CNTs when different hydrocarbons are used. Carbon growth on inner surfaces is possible, large amounts of CNTs/CNFs can be synthesized at moderate temperatures and with low cost, and structure can be controlled by regulating the growth parameters. The CVD method is the most promising method for the large-scale synthesis of CNTs/CNFs.[1,22–26] A suitable choice for the catalyst system is iron, as it catalyzes both the oxidation of carbon and nanocarbon growth.

A typical carbonized precursor obtained from palm kernel shell exhibits a BET surface area of 1081 $m^2 g^{-1}$; the pore volume is 0.365 $cm^3 g^{-1}$. A scanning electron micrograph (SEM) of this activated carbon is displayed in Figure 1a. To prepare the host for the designed hierarchical structure, the as-obtained AC was oxidized under mild conditions at 400 °C in air for 4 h. The activated carbon suffered a weight loss of about 5.2 %. Figure 1b shows a SEM image of activated carbon after the mild oxidation. Oxidation at this temperature removes also carbon debris from the surface and cleans the pores of activated carbon. Furthermore the oxidation increases the pose size as is apparent by comparison of the electron micrographs in Figure 1a and 1b.

The SEM image in Figure 1c shows the iron catalyst particles observed on the surface of the AC catalyst after impregnation, oxidation, and reduction of the catalyst (see the Experimental Section). The specific BET surface area of the Fe/AC catalyst is 1490 $m^2 g^{-1}$, and the pore volume increases to 0.551 $cm^3 g^{-1}$. The plot of BJH pore-size distribution in Figure 2 shows that the volume of mesopores in the Fe/AC catalyst is substantially greater than that of the parent material. In parallel to the formation of mesopores, the micropores are also enlarged as evident in the BJH plot at a pore size of about 2 nm (Figure 2). After catalytic decomposition of a mixture of C_2H_4 and H_2 at 700 °C on the Fe/AC catalyst, carbon nanofibers form and cover the activated

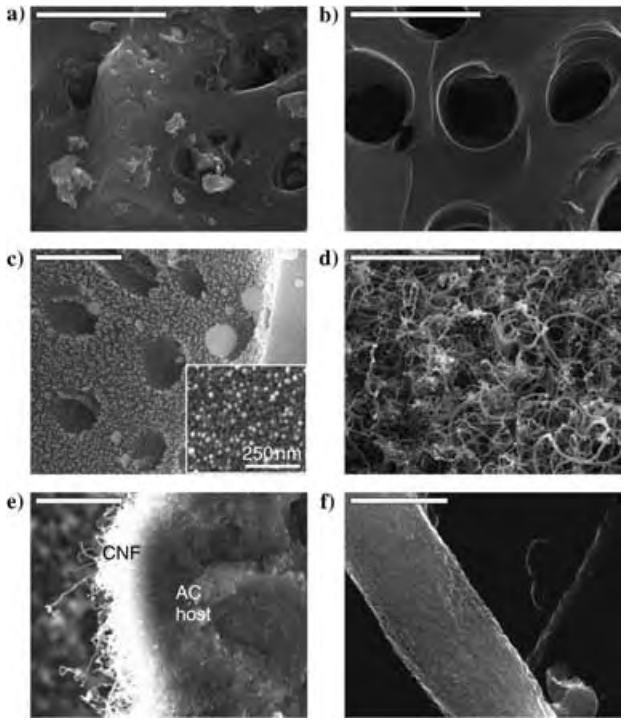

Figure 1. SEM images of a) activated carbon (AC); b) activated carbon calcined at 400 °C; c) 1 wt % Fe/activated carbon, the inset is a enlarged image of the catalyst particles; d) carbon nanofibers on activated carbon; e) a cross section of CNFs on the outer surface of activated carbon; f) a single CNF showing the rough surface morphology. Scale bars: 2 μm (a–c), 20 μm (d), 10 μm (e), and 500 nm (f).

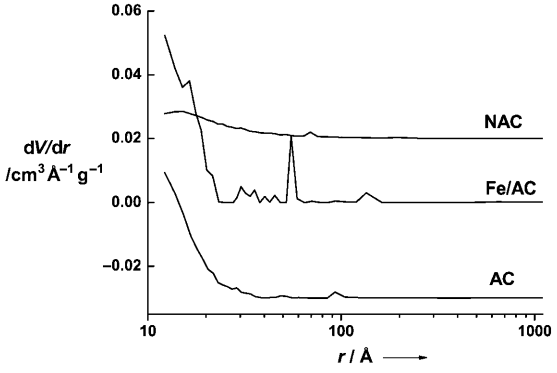

Figure 2. Pore-size distribution (determined by BJH adsorption) of the activated carbon, Fe/AC, and activated carbon with CNFs grown inside and outside. For distinction the plot of NAC is offset by 0.02 units; the plot of AD is offset −0.03 units.

carbon (as shown in Figure 1 d). They orient randomly and are entangled. The diameters of the fibers are widely distributed from 20 to 300 nm. The cross-section SEM image in Figure 1 e confirms that the CNFs are grown on the outer surface of the AC. The SEM image of a single CNF in Figure 1 f reveals the considerable roughness of the outer surface of the CNFs. Such a morphology is beneficial for the hydrodynamics of sorption processes from the liquid phase and provides mechanical and chemical anchoring sites when it is used as additive in polymer materials.

The yield of carbon nanofibers on an Fe/AC host reaches ca. 105 g of C per g of Fe. The growth mechanism is the same as that known for the CVD preparation of CNTs/CNFs, which consists of the dissolution, diffusion, and precipitation of carbon atoms on the catalyst particle.[27] Secondary electron and backscattered electron images of carbon nanofibers on the activated carbon are presented in Figures 3 a and 3 b,

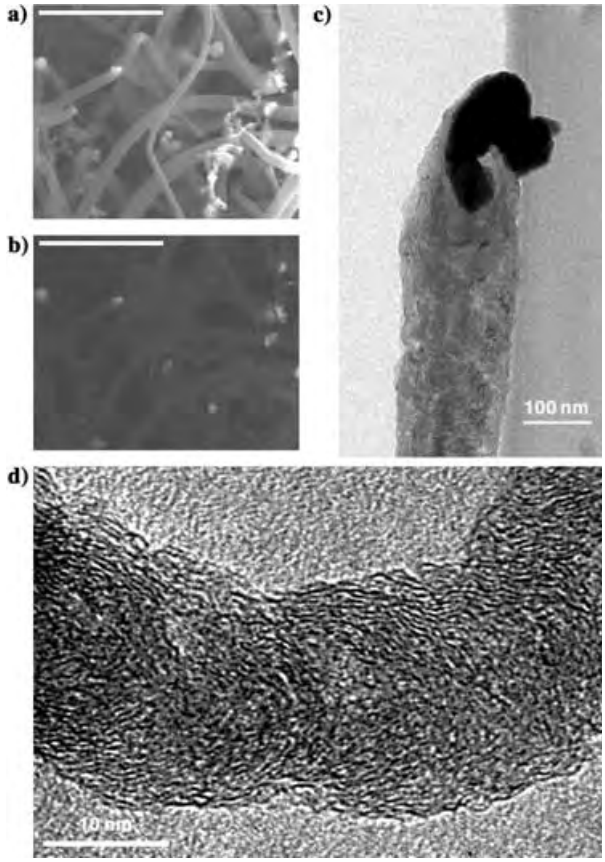

Figure 3. a, b) SEM images of immobilized CNFs with the Fe catalyst: a) SE mode, b) BSE mode; light spots correspond to Fe particles; c) TEM image of an immobilized CNF with a Fe particle on the tip; d) high-resolution TEM image showing the herringbone structure of a CNF. Scale bars: 5 μm (a, b).

respectively. From a comparison of the contrasts, the iron catalyst particles can be located as bright objects in the backscattered electron micrograph. The growth of CNFs follows the "tip-growing" model:[5,28] most of the iron catalyst particles are found on the tips of the CNFs (transmission electron micrograph (TEM) in Figure 3 c), although in few cases the iron particles are found not only at the tip but also in the middle of carbon nanofiber.

The high-resolution TEM image (Figure 3 d) of the carbon nanofibers reveals that the carbon nanofibers are of the herringbone type, which explains the origin of the surface roughness seen in SEM (Figure 1 f). Keeping in mind the intended applications, we wanted to expose as many prismatic faces as possible on the surface of the nanocarbon without losing mechanical stability. The shape and the size of the metal catalyst control the nanocarbon morphology.[29] Baker

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

et al. reported that nanofibers are obtained from large Fe particles (>20 nm), while nanotubes were formed from smaller particles (<20 nm).[30,31] The high loading and the activation conditions caused the catalyst particles to aggregate (see Figure 3c) and form the desired rough surface of the CNFs.

Figure 4a presents a cross-section SEM image though an AC particle with a large pore in it after the CNF growth. Hair or microbrush structures are found inside the pore (cf. the SEM image Figure 1b). The enlarged SEM image in Figure 4b reveals that the dentritic structure results from entangled CNFs created during the CVD process. The cross-section TEM image of the pore in Figure 4c proves convincingly that CNFs were grown on the inner wall of the pore. Moreover, the distribution of diameters of CNFs in the pores is quite narrow, in the range of 20–50 nm. In addition, the CNFs grown inside the pores are shorter than those grown on the surface of the activated carbon. This could be a result of the limited transport of ethylene into the pores. The microstructure of the CNFs in the pores is revealed by high-resolution TEM (Figure 4d).

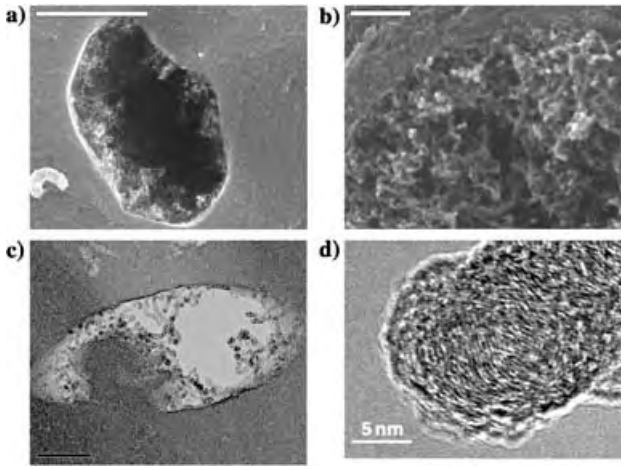

Figure 4. a) SEM image of cross section of CNFs on activated carbon, b) enlarged image of a; c) TEM image of cross section of CNFs on activated carbon; d) high-resolution image of a CNF in (c). Scale bars: 2 μm in a, 200 nm in b–c.

The microscopic data were confirmed by the specific BET surface area of activated carbon with CNFs inside which decreases to 305 $m^2 g^{-1}$ and is much smaller than that of activated carbon and of the Fe/AC catalyst. The pore volume decreases to 0.289 $cm^3 g^{-1}$. This is attributed to the partial filling of the pores in the matrix by CNFs. The pore-size distribution (Figure 2) changes drastically with a broad distribution of nanometer-sized pores being attributed to the desired voids between the entangled CNF fillers.

The surface of the freshly prepared CNFs should be poor in acidic oxygen functional groups due to the reductive reaction atmosphere of their growth. Chemisorption by ion exchange with OH groups should thus be negligible. On the other hand, the nanostructured voids between the entangled CNFs and their rough surfaces should support the agglomeration of condensable species and should thus allow the filtering of difficult-to-adsorb species, for example, the oxo anions of transition metals.

We tested this in a demonstration experiment comparing the adsorption of noncondensable chromate in basic solution and condensable heteropolymolybdate $H_3[PMo_{12}O_{40}]$ in solution. In Table 1 the adsorption capacities per unit mass and unit surface area are listed. The activated carbon adsorbs chromate by means of ion exchange with the acidic surface hydroxy groups. After treatment and growth of the CNFs these surface hydroxy groups are absent, depriving the material of its adsorption function. On the other hand, the polyoxomolybdate is poorly anchored to the hydroxy groups owing to its unfavorable charge-to-surface ratio. Sites for polycondensation of the anions into oxyhydroxide polymers are created by changing the surface texture of the activated carbon, and even better by introducing the CNF filling into the pore system. The absorption capacity of the activated carbon increases a factor of 5 when it is mildly oxidized at 400 °C, but by a factor of 27 when CNFs are grown on and inside the activated carbon (Table 1).

In summary, we have prepared hierarchically structured carbon with CNFs nested inside or immobilized onto modified activated carbon by means of chemical vapor decomposition of ethylene. The activated carbon is obtained from the biowaste of palm oil production, pretreated by mild oxidation, and impregnated with an iron catalyst. The method is cheap and can be scaled up. The preliminary results of adsorption experiments prove that the deliberate nanostructuring of a carbon surface can result in novel adsorbant properties. It is expected that the polymerization of metallic polyanions can be optimized by changing the pore-size distribution, adjusting roughness of the CNFs, and adding special surface functional groups.

Table 1: Adsorption of chromate and heteropolymolybdate in aqueous solution by activated carbon (AC), activated carbon calcined at 400 °C (AC-400), and nanocarbon-activated carbon composite (NAC).

[a] Estimated from absorption at $\lambda = 420$ nm. [b] Values are based on difference to blank. [c] [PMo] = $[PMo_{12}O_{40}]^{3-}$. [d] The concentration after the experiment is identical to that of the blank. [e] In all solutions the absorption ($\lambda = 325$ nm) after the experiment was enhanced; adsorption of [PMo] for blank is used as the reference.

Experimental Section

The activated carbon used as the support was supplied by COMBI-CAT research center, University of Malaya (Malaysia). It was made from palm kernel shells, a waste product from palm oil production.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Beside carbon, it contains substantial amounts of silicate and traces of iron as iron silicate after the activation. Palm kernel shells were carbonized in N_2 at 350 °C and activated in steam at 600 °C. The support activated carbon was calcined at 400 °C for 4 h in air. The Fe/AC precursor (1 wt % Fe) was prepared by impregnation with a 0.09 M aqueous solution of $Fe(NO_3)_3$ and activated carbon calcined at 400 °C with a loading of 1 % iron oxide onto dry carbon. A drying step at 60 °C overnight was followed by the autogeneous pore formation through calcination at 500 °C in N_2 for 4 h. The Fe-impregnated sample was reduced with H_2 at 700 °C for 4 h. The Fe/AC catalyst (100 mg, 1 wt % Fe) was put into the vertical quartz reactor and flushed with He overnight. The carbon nanofibers were grown by treating the Fe/AC catalyst at 700 °C in flowing 60 % C_2H_4/H_2 (125 mL min^{-1}) at atmospheric pressure for 2 h. The obtained sample was cooled to room temperature in a stream of He.

For the adsorption experiments, 10 mg of activated carbon or the NAC sample were suspended in 1.5 mL of aqueous $H_3PMo_{12}O_{40}$ or K_2CrO_4 (1 mM). The suspensions were stirred for 1 h at room temperature. The concentration of $[PMo_{12}O_{40}]^{3-}$ was measured by photometry ($\lambda = 325$ nm). The adsorption test was performed in an Eppendorf cap (Volume 2.0 mL, material is PE). The pH was not adjusted (with additional buffer); the pH calculated for heteropolymolybdate solution is around 3.0, for chromate solution around 8.5. SEM investigations were performed on a Hitachi S-4000 FEG in secondary-electron (SE) mode and backscattered-electron (BSE) mode at 15-kV accelerating voltage. TEM studies were performed on a Philips CM 200 LaB_6 operating at 200 kV.

Solid-State Structure and Enantioselective Reactions of a Complex of a 1-Thio-Substituted Propargyllithium and (−)-Sparteine**

*Ralf Otte, Roland Fröhlich, Birgit Wibbeling, and Dieter Hoppe**

Organolithium (−)-sparteine complexes have become valuable tools in enantioselective synthesis.[1] Nevertheless, only few X-ray crystal structure analyses of lithium (−)-sparteine complexes with either chiral[2] or achiral carbanions[3] are known. Among these, there are no examples of an α-thio-

substituted carbanion complex.[4,5] Chiral α-thioalkyllithium and -benzyllithium complexes were found to racemize rapidly;[6–9] this is attributed to only a weak interaction between the cation and the anion in the ion pair.[10] In contrast, for α-carbamoylthio-substituted alkyllithium,[11] benzyllithium,[12] and cyclic allyllithium compounds,[13] a remarkably high configurational stability is recorded, presumably resulting from efficient chelation by the *S*-(*N*,*N*-dialkylcarbamoyl) group. The asymmetric deprotonation and substitution of thio-substituted compounds have been described recently in several publications.[14]

We investigated the (−)-sparteine-assisted lithiation of thiocarbamate **1** (Scheme 1).[15] In pentane at temperatures below −30 °C, a precipitate of complex (*S*)-**3**·**2** was formed, which provided suitable crystals for an X-ray analysis with anomalous dispersion (Figure 1).[16,17] Trapping the precipitate with trimethylsilyl triflate (TMSOTf) yielded the propargylsilane (*S*)-**4a** in 83 % yield with ≥95 % *ee*.[18] Similarly, the reaction with *tert*-butyldimethylsilyl triflate (TBSOTf) resulted in the crystalline silane (*S*)-**4b** (69 % yield, ≥95 % *ee*).[18] An X-ray crystal structure analysis with anomalous dispersion revealed the *S* configuration of **4b** (Figure 2).[17,19]

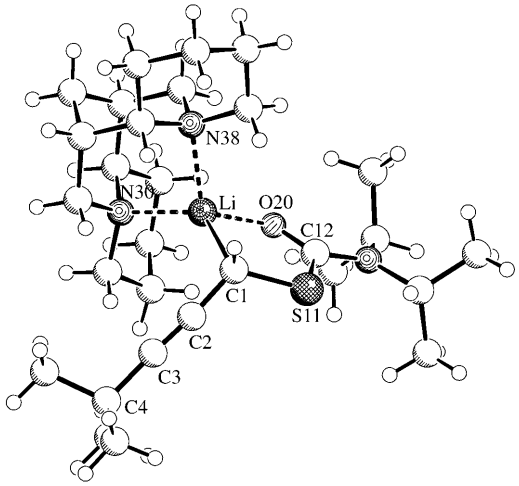

Figure 1. Molecular structure of (*S*)-**3**·**2** in the crystal. Selected bond lengths [pm] and angles [°]: Li–C1 217.3(10), Li–N30 203.8(9), Li–N38 205.0(9), Li–O20 189.7(9), C1–C2 141.7(7), C2–C3 119.8(7), C3–C4 149.5(8), C1–S11 176.1(5); N30-Li-N38 90.2(4), N30-Li-C1 127.8(4), N30-Li-O20 121.8(5), N38-Li-C1 115.1(4), N38-Li-O20 112.5(4), C1-Li-O20 91.0(4), Li-C1-S11 104.3(3), Li-C1-C2 103.3(4), S11-C1-C2 115.9(4), C1-C2-C3 175.2(5), C2-C3-C4 176.3(6), Li-C1-S11-C12 −1.9(4).

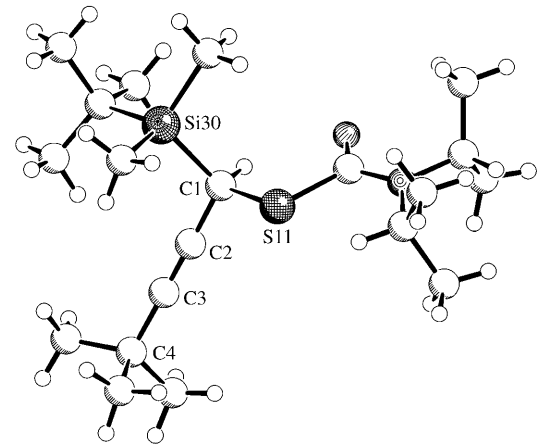

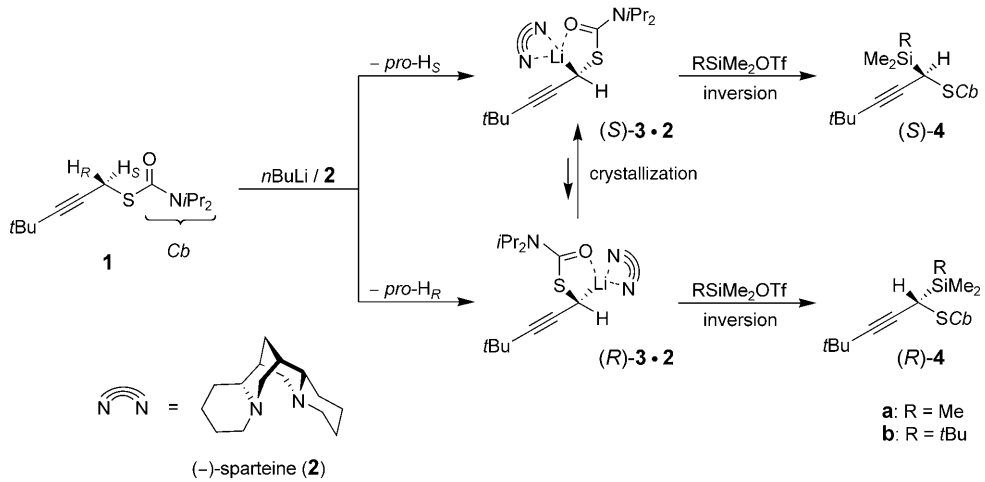

Figure 2. Molecular structure of (*S*)-**4b** in the crystal. Selected bond lengths [pm] and angles [°]: C1–C2 144.5(3), C1–S11 183.5(2), C1–Si30 190.6(2), C2–C3 120.3(3), C3–C4 147.1(3); C2-C1-S11 107.7(2), C2-C1-Si30 109.8(1), C3-C2-C1 176.2(3), C2-C3-C4 179.5(3).

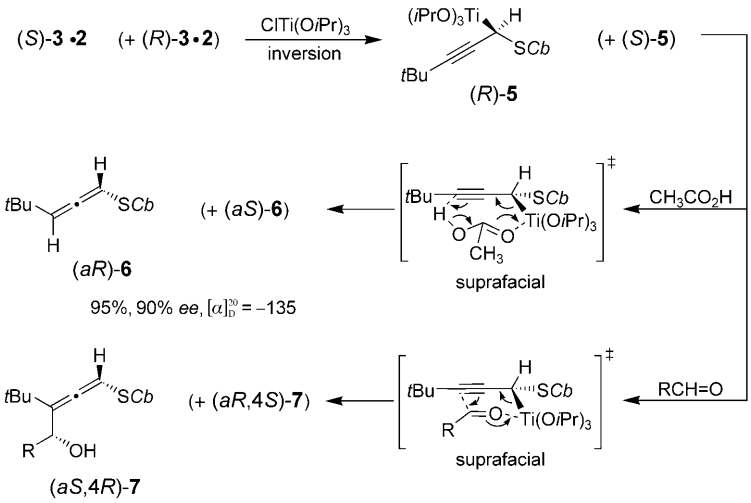
As observed for all silylations of thio-substituted mesomerically stabilized carbanion/lithium–sparteine complexes the silylation proceeds with stereoinversion.[12,9]

Compound (*S*)-**3**·**2** crystallizes as a monomeric chelate complex with a tetragonally coordinated lithium cation, which is attached to the carbanionic center, the oxo group, and both nitrogen atoms of (−)-sparteine (Figure 1). The carbanionic center at C1 is *S*-configurated, and the stereogenic lithium cation has *S* configuration, as was also found for an allyllithium (−)-sparteine complex.[2b] Surprisingly, C1 is sp^3-hybridized: the sum of angles Li-C1-S11, Li-C1-C2, and S11-C1-C2 amounts to 323.5(11)° (the ideal values for sp^3



Scheme 1. Asymmetric deprotonation and silylation of **1**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

hybridization are 328.4°, for sp^2 hybridization, 300.0°). This, in combination with the bond lengths for C1–C2 (141.7(7) pm) and C2–C3 (119.8(7) pm), leads us to the conclusion that mesomeric stabilization of the negative charge plays only a minor role. The lengths and angles in the vicinity of C1 to C3 are surprisingly similar for the lithium compound (*S*)-**3·2** and silane (*S*)-**4b** (Figure 2), which supports the lack of mesomeric stabilization in (*S*)-**3·2**.

The Li–C1 bond (217.3(10) pm) is relatively long and, consequently, the bonds to (−)-sparteine, $d_{\text{Li-N30}} = 203.8(9)$ pm and $d_{\text{Li-N38}} = 205.0(9)$ pm, are shorter than those in lithiated alkenyl carbamates.[20] Theoretical calculation on α-thio-substituted organolithium complexes[4c,14b,21] predict an antiperiplanar relationship between the bonds C1–Li and S–C12 for the conformation of lowest energy. In the cyclic complex (*S*)-**3·2** the dihedral angle Li-C1-S11-C12 is forced into synperiplanarity (−1.9(4)°).

Solid (*S*)-**3·2** undergoes transmetalation with $ClTi(OiPr)_3$ with stereoinversion to form the propargyltitanium intermediate (*R*)-**5**. This was the conclusion from some suprafacial reactions explored during the investigation of the *O*-carbamates analogous to **1**.[22] Quenching **5** with a solution of acetic acid in ether at −78 °C gave the allene (*aR*)-**6** in 95 % yield and 90 % *ee*[23] (Scheme 2). The absolute configuration of

7	R =	Yield [%]	d.r.	% *ee*	$[\alpha]_D^{20}$
a	2-naphthyl	79	≥ 98:2	96	−558
b	phenyl	82	≥ 98:2	98	−466
c	cyclohexyl	71	≥ 98:2	98	−77
d	2-propyl	66	≥ 98:2	97	−27

Scheme 2. Synthesis of enantioenriched 1-thio-substituted allenes **6** and **7**.

(*aR*)-**6** was elucidated by an X-ray crystal structure analysis,[17,24] again with anomalous dispersion (see Figure 3 in the Supporting Information).

At −78 °C the titanium intermediate **5** readily added to aldehydes and formed diastereomerically pure, highly enantioenriched 1-thio-substituted 4-hydroxy-1,2-alkadienes **7** with an (*aS*,4*R*) configuration, which arise from a Zimmerman–Traxler-type transition state (Scheme 2).[25] The reaction with naphthalene-2-carbaldehyde furnished the allene (*aS*,4*R*)-**7a** in 79 % yield and 96 % *ee*;[26] its absolute configuration was concluded from an X-ray crystal structure analysis (see Figure 4 in the Supporting Information).[27,17]

What is the mechanism resulting in enantiomeric enrichment?[28] When **1** was lithiated by *n*BuLi/**2** in toluene at −78 °C without crystallization and the soluble complexes **3·2** were trapped after 1 min with TMSOTf, (*S*)- and (*R*)-**4a** were formed in a ratio of 68:32 (36 % *ee*) and a yield of 84 %. The ratio shifted only slightly (71:29, 42 % *ee*) after 10 h of stirring at −78 °C. The precipitate of (*S*)-**3·2** formed by crystallization at −30 °C was dissolved in toluene and the solution kept for 6 h at −78 °C; the solution was treated with TMSOTf, and no decrease in the enantiomeric ratio of the silylated product (*S*)- and (*R*)-**4a** was observed (≤ 97.5:2.5, ≤ 95 % *ee*). These experiments demonstrate that there is only little preference for abstraction of *pro*-H_S under kinetically controlled conditions and essentially complete configurational stability. When the dissolved precipitate was stirred for 2 h at −30 °C, a ratio of 71:29 (42 % *ee*) was recorded, which is assumed to be close to the thermodynamically controlled ratio of (*S*)- and (*R*)-**3·2**. At −30 °C, epimerization is rapid enough so that the selection occurs by selective and complete crystallization of the major diastereomer (*S*)-**3·2** ("dynamic thermodynamic resolution").[29,30]

The reported results not only give deep insight into structural features of chiral substituted propargyllithium ion pairs and the stereochemistry of their reactions,[31,32] but also offer an efficient access to highly enantioenriched allenes.[33,34]

Experimental Section

The preparation of single crystals of (*S*)-**3·2** was performed under an argon atmosphere in a flame-dried Schlenk flask. A clear solution of **1** (0.128 g, 0.50 mmol, 1.00 equiv) and **2** (0.123 g, 0.53 mmol, 1.05 equiv) in dry pentane (8 mL) was prepared at room temperature. The reaction mixture was then cooled to −30 °C, and *n*BuLi (0.34 mL, 0.55 mmol, 1.1 equiv; 1.6 M in *n*-hexane) was added slowly over 5 min. Moderate stirring was stopped immediately when the addition was complete. The slightly yellow homogenous solution was kept undisturbed under argon at −30 °C for 1 h, and the first tiny crystals formed. These were allowed to grow by gradual evaporation of the solvent under vacuum (approx. 50 mbar). Under these conditions colorless crystals of suitable size formed over 4 h. The flask was back-filled with argon, and the remaining supernatant solution was removed carefully. The obtained crystals are stable below 0 °C under argon; at room temperature they decompose within hours. In solution, decomposition occurs much faster.

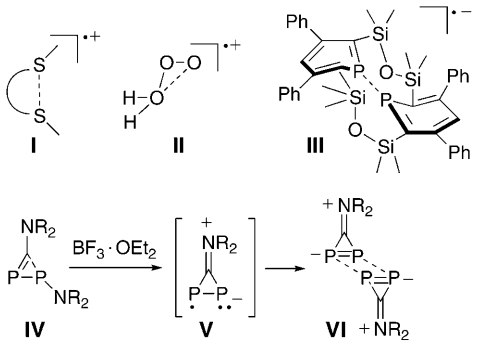
Odd-Electron Bonds

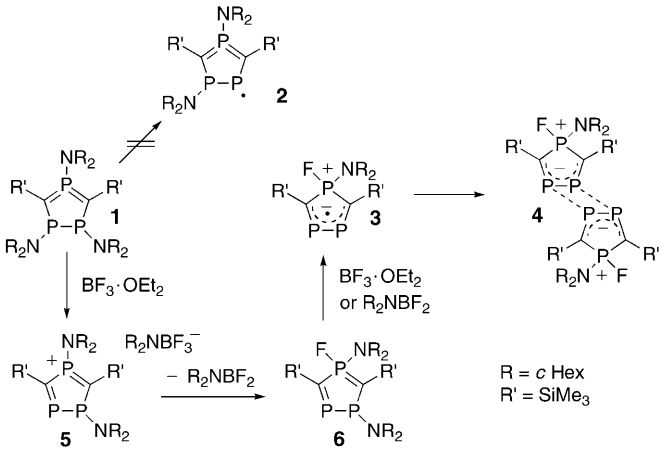


DOI: 10.1002/anie.200501369

Dimerization of a Cyclo-1σ⁴,3σ²,4σ²-Triphosphapentadienyl Radical: Evidence for Phosphorus–Phosphorus Odd-Electron Bonds**

*Tsuyoshi Kato, Heinz Gornitzka, Wolfgang W. Schoeller, Antoine Baceiredo, and Guy Bertrand**

Dedicated to Professor Herbert Roesky on the occasion of his 70th birthday



In hydrocarbon chemistry, carbon-centered radicals are rather short-lived intermediates and usually dimerize to give classical two-electron bonds.[1] If main group elements are involved, however, the situation is more diverse;[2] as predicted as early as 1931 by Pauling,[3] odd-electron bonds are sometimes formed. For Group 16 elements, the intensely studied radical cations of type **I**[4] are a good illustration of compounds that feature a two-center, three-electron bond, in which two electrons occupy a σ bonding orbital, and one electron occupies a σ* antibonding orbital (Scheme 1). Three-center, one-electron bonds have also been evoked to rationalize the formation of radical cation **II**;[5] in this case, the singly occupied π* orbital of O_2^+ interacts with an electron lone-pair orbital on water.

Scheme 1. Some examples of compounds that feature odd-electron bonds, and the synthetic route from **IV** to **VI**.

In phosphorus chemistry, only two examples of compounds that feature odd-electron bonds are known. Le Floch and co-workers[6] prepared the macrocyclic derivative **III**, which features a two-center, one-electron P–P bond in which the single electron is mainly located in a P–P σ bonding orbital. In 1998, we isolated derivative **VI**, which features a P_4 framework, which is best described as a four-center, six-π-electron system.[7] Four π electrons are present in the π orbitals of the two P=P bonds within each CP_2 ring, and the remaining two π electrons are used to join the two CP_2 units by two two-center, one-electron bonds. This description is consistent with the observation that the intra-ring P–P bonds are quite short (2.205 Å), whereas the inter-ring P–P bonds are very long (2.634 Å). Derivative **VI** resulted from the π*-π* dimerization[8] of diphosphirenyl radical **V**. Indeed, according to calculations, the unpaired electron of **V** is equally distributed over both phosphorus atoms and is localized in the π* orbital of the P=P bond.

In an attempt to prepare radical **2**, in which the unpaired electron would be distributed over a more extended π-conjugated framework, cyclic bis(methylene)phosphorane **1**[9] was treated with $BF_3{\cdot}OEt_2$ in a method used to homolytically cleave the P–N bond of diphosphirene **IV**. After removal of all the volatiles under vacuum and extraction with pentane, a new compound **4** was obtained in 40% yield as an air-sensitive purple solid (Scheme 2). Surprisingly, the ^{31}P NMR spectrum

Scheme 2. The synthesis of derivative **4**. *c*Hex = cyclohexyl.

showed a doublet of triplets at $\delta = 89$ ppm ($J_{P,F} = 938$ Hz and $J_{P,P} = 18$ Hz), characteristic of tetracoordinate phosphorus bearing a fluorine atom. It also had a very broad signal around 300 ppm in the region of phosphaalkene moieties. ^{19}F NMR spectroscopy gave a signal at $\delta = 23$ ppm as a doublet of triplets ($J_{F,P} = 938$ Hz and $J_{F,P} = 7$ Hz). The large P–F coupling constant confirms the direct P–F bond, and the triplet multiplicity of the signal is in good agreement with the presence of a P–P fragment. In solution at room temperature, no trace of paramagnetic species was detected by ESR spectroscopy.

Dissolving **4** in hot toluene (≈60 °C) followed by slow cooling of the solution gave deep-red crystals suitable for a single-crystal X-ray diffraction study (Figure 1).[10] Compound **4** is organized around an inversion center located in the middle of the parallelogram described by four phosphorus atoms (P–P–P angles: 97.2° and 82.7°). The plane of the parallelogram is almost perpendicular (109 and 112°) to the two planar five-membered rings. All C–P bond lengths in the latter are equal (1.70 Å) and only slightly longer than C=P double bonds. The distance between the two five-membered rings of **4** is 2.427 Å, which is much longer than a classical P–P single bond,[11] but almost 0.2 Å shorter than that of the diphosphirenyl radical dimer **VI** (2.635 Å). In contrast, the P2–P3 bond length is short (2.157 Å), in fact even shorter than the analogous bond in **VI** (2.205 Å).

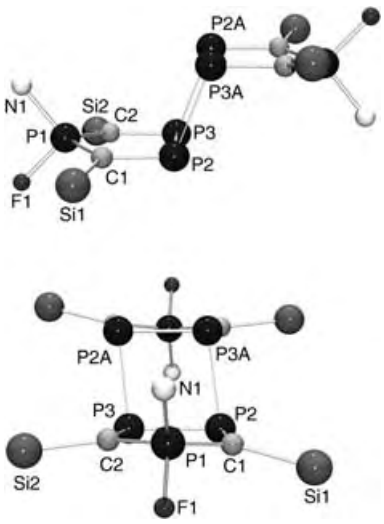

Figure 1. Simplified molecular views of **4** in the solid state. Selected bond lengths [Å] and angles [°]: P2–P3A 2.427(3), P1–C1 1.700(7), P1–C2 1.693(7), C1–P2 1.698(7), C2–P3 1.700(7), P2–P3 2.157(3), P1–N1 1.656(6), P1–F1 1.562(4), C1–Si1 1.851(7), C2–Si2 1.864(3); ∢C1-P1-C2 107.7(3), ∢P1-C1-P2 115.1(4), ∢P1-C2-P3 116.4(4), ∢C1-P2-P3 100.8(3), ∢C2-P3-P2 98.9(3), ∢P1-C1-Si1 128.6(4), ∢P2-C1-Si1 116.2(4), ∢P2-P3-P2A 82.7(11), ∢P3-P2-P3A 97.2(11), $\sphericalangle_{tors}$C1-P2-P3-P2A 109.1, $\sphericalangle_{tors}$C2-P3-P2-P3A 112.4.

Before performing a detailed investigation of the electronic structure of **4**, we studied the reaction leading to this unexpected compound. ^{31}P and ^{19}F NMR spectroscopy indicated that a small amount of cyclic ylide **6** was formed (Scheme 2). This compound was isolated by crystallization in THF, and its structure was unambiguously established by a single-crystal X-ray diffraction study (Figure 2).[10] Hence, it is reasonable to postulate that instead of the expected homolytic cleavage of a P–N bond, which would have led to **2**, heterolytic cleavage occurs to generate a cyclic methylenephosphonium salt **5**, as already observed by Grützmacher and Pritzkow in their work with analogous acyclic compounds.[12] The highly electrophilic cation **5** then abstracts a fluorine anion from the $R_2NBF_3^-$ counteranion to give the isolated cyclic ylide **6**. Finally, BF_3-catalyzed homolytic cleavage of the remaining σ^3-P–N bond leads to the transient cyclotriphosphapentadienyl radical **3**, which dimerizes to give **4**. Therefore, although we have not generated the desired radical **2**, we have, by serendipity, formed the radical **3** in which the unpaired electron is distributed over an extended π-conjugated framework, which was our primary aim.

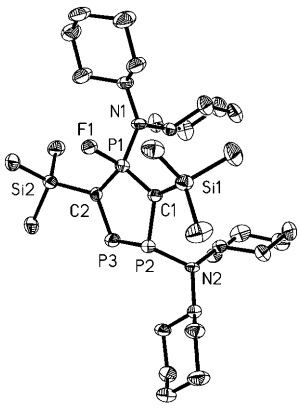

Figure 2. Molecular view of **6** in the solid state. Selected bond lengths [Å] and angles [°]: P1–C1 1.686(4), P1–C2 1.764(4), P2–C1 1.772(4), P3–C2 1.708(4), P2–P3 2.159(2), P1–N1 1.657(3), P1–F1 1.508(2), P2–N2 1.685(3), C1–Si1 1.854(4); ∢C1-P1-C2 109.0(2), ∢P1-C1-P2 111.5(2), ∢P2-P3-C2 97.2(1), ∢P1-C2-P3 116.0(2).

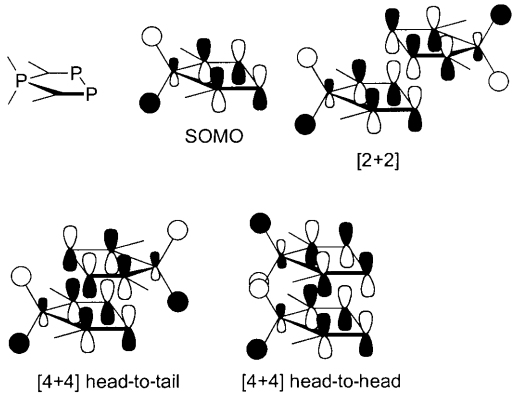
The single occupied molecular orbital (SOMO) of radicals of type **3** is, upon first estimate, the π_3 molecular orbital of a *cis*-oriented pentadiene unit with small contributions from the PR_2 fragment (Figure 3). Among the three symmetry-allowed dimerization processes that could occur from SOMO–SOMO (π_3–π_3) interactions, the [2+2] pathway clearly leads to the least sterically hindered and minimally strained product, namely **4**. In terms of canonical structures, radicals **3** can be represented as follows: the unpaired electron can reside at the carbon positions, as in **A**, or at the phosphorus atoms, as indicated in **B** (Scheme 3). As a consequence, a double bond is present between either the two phosphorus atoms (in **A**), or a phosphorus and a carbon atom (in **B**). From **A**, dimerization refers to a [π^2+π^2] reaction of two P=P double bonds and would result in a cyclotetraphosphane ring system with four



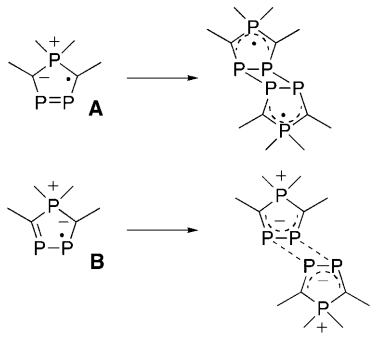


Figure 3. Representation of the SOMO for radical **3** and possible SOMO–SOMO interactions.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 3. Canonical structures **A** and **B** for radical **3** and the respective canonical structures for the product dimer **4**.

P–P single bonds.[13] However, for the dimerization from **B**, only one unpaired electron is supplied from each radical unit. This results in an electron deficit for the resulting inter-ring P–P bonds, as only two electrons are available for forming two P–P bonds. The presence of the resonance form **A** in competition with **B** easily explains the differences observed in the P–P bond lengths between the four-membered-ring framework of dimers **VI** and **4**, and especially why the "long" P–P bond is shorter in **4**.

Another consequence of these two alternative resonance structures would be the ability to vary the P–P bond lengths in dimers of type **4** by changing the substituents attached to the carbon atoms. To substantiate these qualitative considerations, we performed quantum chemical calculations (Table 1). Various computational levels[14] were tested for the parent compound ($R^1 = R^2 = H$). Given the same DFT level (BP86) and increasing the quality of the basis set in the order SVP, TZVP causes only a slight shortening of the long P–P bonds. On the other hand, changing the electron correlation level from BP86 to MP2 exerts a stronger shrinking of the P–P bonds. The CBS-Q method (complete basis set method), considered to be a much better computational level,[14b] yields, for the parent dimer, a long inter-ring P–P distance of 2.592 Å and a concomitant dimerization energy of $-19.6\ kcal\,mol^{-1}$ (0 K). The effects of the different substituents were investigated with the less costly computational level (RI-BP86/SVP). Not surprisingly, the substituents at the carbon atoms which stabilize the canonical structure **A** and the electronegative substituents at phosphorus, shorten the inter-ring P–P distance. A drastic shortening is observed with an added exchange of substituents that can simultaneously stabilize a negative charge and an unpaired electron ($R^1 = NO_2$, SiH_3; $R^2 = F$). In contrast, strong electron-donating substituents at the carbon atoms, such as amino groups, elongate the inter-ring P–P distance. In all cases, a rhombic distortion of the central P_4 ring is observed. For the experimentally observed derivative ($R^1 = TMS$; $R^2 = F$ or $N(c\text{Hex})_2$), the calculated inter-ring P–P distance (2.599 Å) is still too large to agree well with the experimentally determined value of 2.427 Å; this probably means that DFT methods are not able to take weak bonds into account properly.[15]

A series of radical dimers of type **4** that feature different substituents at phosphorus and carbon positions are under current investigation. The possibility of finely tuning the interaction between such radicals might have implications in material sciences.[16]

Table 1: Substituent effects on P–P bond lengths and P-P-P bond angles for dimers of type **4** at the RI-BP86/SVP level.

Experimental Section

All manipulations were performed under an inert atmosphere of argon by using standard Schlenk techniques. Dry, oxygen-free solvents were employed. ^1H, ^{13}C, ^{19}F and ^{31}P NMR spectra were recorded on Bruker AC80, AC200, WM250 or AMX400 spectrometers.

4: $BF_3{\cdot}Et_2O$ (0.24 g, 1.30 mmol) was added at room temperature to a solution of **1** (0.45 g, 0.62 mmol) in toluene. The solution was heated at 30 °C for 2 days in the absence of light, and the reaction monitored by multinuclear NMR spectroscopy. When the starting materials were consumed, the volatiles were removed under vacuum and the product was extracted with toluene. After evaporation of toluene, the residue was recrystallized from hot toluene as deep-red crystals (0.12 g, 42 %); m.p. = 115 °C (decomp); $^{31}P\{^1H\}$ NMR (C_6D_6): $\delta = 88.9$ (dt, $^2J(P,P) = 15.3$ Hz, $^1J(P,F) = 939.8$ Hz, 1 P), 280 ppm (br, 2 P); ^1H NMR (C_6D_6): $\delta = 0.78$ (s, 36 H, $SiCH_3$), 1.2–2.2 (m, 20 H, CH_2), 3.04 (br, 4 H, CHN), 3.65 ppm (broad d, $^2J(P,H) = 13.8$ Hz, 4 H, CHN); $^{13}C\{^1H\}$ NMR (C_6D_6): $\delta = 3.9$ (s, $SiCH_3$), 25.5, 25.8, 26.7, 27.1 (s, CH_2), 34.3 (br, CH_2), 35.1 (d, $^2J(C,P) = 1.3$ Hz, CH_2), 57.4 (broad, NCH), 58.2 ppm (d, $^2J(C,P) = 5.1$ Hz, NCH), PCP (not observed); $^{19}F\{^1H\}$ NMR (C_6D_6): $\delta = 20.1$ ppm (dt, $^3J(F,P) = 60.0$ Hz, $^1J(F,P) = 939.8$ Hz). Computational procedures: quantum chemical calculations were performed with the Gaussian suite[14a] of programs as well as the Turbomole[14b] program systems. Various computational levels were studied. In general, RHF and B3LYP calculations yielded intermolecular bond lengths that were too large, whereas the BP86 density functional level yielded more satisfactory geometries, albeit with some P–P bond lengths too large for intermolecular bond formation between two radicals. At the MP2 level, shorter P–P bonds

were observed, but this methodology is restricted to the study of the parent compound.

[15] The diamagnetic coupling of two radicals through π*–π* interactions usually leads to weak bonds. Consequently, the bond lengths in these dimers easily fluctuate. This is well-documented for the N_2O_2 dimer. For example, the N–N interatomic distance in the gas phase[15a] is 2.24 Å, whereas it is 2.18 Å in the solid state.[15b] a) S. G. Kukolich, *J. Am. Chem. Alzheimer's Disease Related Copper(II)-β-Amyloid Peptide Exhibits Phenol Monooxygenase and Catechol Oxidase Activities**

*Giordano F. Z. da Silva and Li-June Ming**

Over the past few years an enormous effort has been directed toward the investigation of the metal-dependent mechanisms that lead to the neuropathology of Alzheimer's disease (AD).[1] The self-assembled metallo-β-amyloid (Aβ) peptide fibrils are the hallmark of this disease[2] and have been attributed to Fe^{III}- and Cu^{II}-centered generation of H_2O_2 under reducing conditions. The latter, H_2O_2, has been postulated to be of significant importance in connection with neuropathy in AD.[3,4] However, an area of oversight has been the detailed chemical processes associated with the neuropathology of AD, besides the generally acclaimed assault by ROS (reactive oxygen species; e.g. H_2O_2).[5] Hence, a better understanding of metal-centered redox chemistry and the mechanism for the generation of ROS and their fate can provide insight into potential strategies for the prevention and treatment of AD.

Several examples of redox chemistry in biological systems are known to be associated with di- or multinuclear "Type-3" Cu oxidases,[6] which may be related to the redox activity of $Cu^{II}A\beta$.[1–4] A number of chemical model systems that target Type-3 copper centers have successfully been demonstrated to contain highly active isoelectronic copper–dioxygen species (i.e. Cu_2^{II}-μ-η^1:η^1-peroxo, Cu_2^{II}-μ-η^2:η^2-peroxo, and Cu_2^{III}-bis-μ-oxo), which are responsible for copper-dependent oxidation and hydroxylation reactions.[6–9] Despite extensive modeling studies, peptide mimics of these enzymes have apparently been excluded from the studies. $Cu^{II}A\beta$ seems to fill the gap as it is a naturally occurring Cu–peptide complex demonstrated to exhibit oxygen-associated redox chemistry,[1–4] although details about its oxygen binding and activation mechanisms are lacking. Herein, we present results which bring together two distinct fields of research: Alzheimer's disease and Type-3 copper centers. The results elucidate that the Cu^{II} complex ($CuA\beta_{1-20}$) of the icosapeptidyl metal-binding domain of Aβ ($DAEFR^5HDSGY^{10}EVHHN^{15}$-$KLVFF^{20}$) exhibits metal-centered redox chemistry that is consistent with the mechanisms of the Type-3 copper enzymes, namely, phenol monooxygenase (e.g. tyrosinase) and catechol oxidase.

The metal-centered redox chemistry of $CuA\beta_{1-20}$ was probed using catechol and the more-inert phenol as substrates.[10,11] The oxidation of catechol under aerobic conditions reached a plateau at low mM concentrations, and the saturation profile fits well to pre-equilibrium kinetics [Eqs. (1) and (2)][12] to afford the rate constant $k_{cat} = 0.154\ s^{-1}$, the dissociation constant $K'_{app} = 0.35$ mM (Figure 1a), and a significant second-order rate constant $k_{cat}/K'_{app} = 440\ M^{-1}s^{-1}$ (cat = catalytic, app = apparent). As the formation of quinone from catechol is a two-electron oxidative process, the reaction is expected to follow the two-electron dinuclear reaction pathway for catechol oxidase,[13] wherein the binding of catechol to the active-site dicopper(II) center results in the reduction of the center to yield dicopper(I) with concomitant production of *o*-quinone. The reduced dicopper(I) center can bind dioxygen to afford the active peroxo-bridged dicopper(II) center, which can further oxidize a subsequently bound substrate. H_2O_2 can also be generated in this reaction pathway from the peroxo-bridged dicopper(II) center in the presence of a reducing agent such as the substrate itself. This pathway for the production of H_2O_2 under reducing conditions is consistent with previous observations in AD studies.[3] The catechol oxidase like mechanism has also been observed in kinetic studies of several chemical model systems[14] and in the oxidation of polyphenols by $CuA\beta_{1-20}$.[15] Note that a recent study based on density functional theory (DFT) pointed to mixed-valence Cu^{II}–Cu^{I} transition states,[16] which support the suggested reduction pathway for the Cu center.

We previously determined the $Cu^{II}/A\beta_{1-20}$ stoichiometry as 1:1 for oxidative activity with three N_ε-coordinated imidazole histidine rings as metal-binding ligands.[15] As activity is an excellent probe for determining stoichiometry, gradual replacement of Cu^{II} centers in $CuA\beta_{1-20}$ with redox-inactive Zn^{II} centers can serve as a practical method for addressing the nature of the active metal center by virtually "silencing" the active sites through dilution with Zn^{II}. A quadratic correlation between the activity and the extent of Zn^{II} dilution should be observed for simple 1:1 metal binding if there is no cooperativity and/or interactions between the Cu^{II} centers at the active site with different Aβ strands. Conversely, a sigmoidal activity profile was observed as a function of the mole fraction of Cu^{II} in $A\beta_{1-20}$ toward the oxidation of the catechol derivative 3,5-di-*tert*-butyl catechol (DTC, $k_{cat} = 0.411\ s^{-1}$ and $K'_{app} = 0.781$ mM) which can be fitted well to the Hill equation [Eq. (3)][17] with a Hill coefficient of $\theta = 2.40$ and $r^2 = 0.99$ (Figure 2a, solid line). The data clearly cannot be fitted well to a quadratic equation for 1:1 noncooperative binding mode ($r^2 = 0.91$; dashed line, Figure 2a). These results imply the possible presence of a cooperative dinuclear active Cu^{II} center during the catalytic

oxidation of catechol by $CuA\beta_{1-20}$, consistent with the catalytic cycle of catechol oxidase.[13]

The presence of the reactive oxygen species H_2O_2 (25 mM) significantly enhances the turnover and catalytic efficiency of $CuA\beta_{1-20}$ toward catechol oxidation, yielding $k_{cat} = 0.531\ s^{-1}$ and $K'_{app} = 0.342$ mM, and a significant second-order rate constant $k_{cat}/K' = 1.51 \times 10^3\ M^{-1} s^{-1}$ from the Hanes plot [Eq. (4) and Figure 1e][18,19] for a random two-substrate reaction, in which the binding of the two substrates H_2O_2 and catechol are independent of each other. Note, the second-order rate constant for catechol oxidation is only about 20 times lower than that for catechol oxidase extracted from gypsywort.[20] This pathway is consistent with the so-called peroxide shunt in the action of catechol oxidase in the presence of H_2O_2 for which a Cu^{II}_2-μ-η^2:η^2-peroxo intermediate is proposed to be the active species.[6] The oxidation of catechol to form *o*-quinone in the absence and presence of H_2O_2 exhibits remarkable rate accelerations (3.25×10^5 and 1.12×10^6 fold, respectively) in terms of the first-order rate constant k_{cat} relative to that for aerobic autooxidation of catechol in the absence of $CuA\beta_{1-20}$ ($k_o = 4.74 \times 10^{-7}\ s^{-1}$).

Owing to their inertness, metal-centered hydroxylation of phenol and its derivatives, particularly polychlorophenols, poses some challenging tasks in chemical synthesis and environmental detoxification and remediation[21] and may provide further insight into the action of those metalloenzymes for the monooxygenation of arenes.[8,22] Besides the oxidation of catechol described above, phenol was hydroxylated and oxidized by $CuA\beta_{1-20}$ in the presence of a saturating amount of H_2O_2 (> 50.0 mM). The formation of *o*-quinone exhibited rate and dissociation constants of $k_{cat} = 0.213\ s^{-1}$ and $K'_{app} = 1.31$ mM, respectively, and $k_{cat}/K' = 457\ M^{-1} s^{-1}$ from the Hanes plot (Figure 1a and d). This result represents a remarkable 4.6×10^6-fold rate acceleration for the hydroxylation/oxidation of phenol to form *o*-quinone in terms of k_{cat} relative to that for aerobic autooxidation of phenol ($k_0 = 4.6 \times 10^{-8}\ s^{-1}$). This reaction is expected to take place according to a dinuclear mechanism similar to the hydroxylation and oxidation of tyrosine by the dicopper enzyme tyrosinase, in which the active center is believed to contain dinuclear μ-η^2:η^2-peroxo-Cu^{II}_2 species on the basis of spectroscopic studies.[8,16]

Cooperativity of H_2O_2 in the oxidation of both catechol and phenol in terms of k_{cat} is observed upon titration of H_2O_2 and is reflected in the sigmoidal activity profile with respect to the concentration of H_2O_2 (Figure 1b). The data from the oxidation of catechol and phenol by H_2O_2 fit well to the Hill

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

equation [Eq. (3)], yielding Hill coefficients of $\theta = 2.23$ and 1.78, respectively. Moreover, fitting of the rates to a random two-substrate reaction mechanism yields corrected K' values of 2.07 and 2.10 for phenol and catechol, respectively, and a cooperativity index based on the ratio K'_{app}/K' of 1.70 for H_2O_2 in both phenol and catechol oxidation reactions. These values suggest a small cooperativity of H_2O_2 and the independent binding of H_2O_2 and phenol or catechol to the active center.

Of particular interest is the observation of a scarcely reported process, namely, aerobic Cu^{II}-centered hydroxylation and oxidation of phenol in the absence of H_2O_2.[23] The production of *o*-quinone from phenol catalyzed by $CuA\beta_{1-20}$ follows pre-equilibrium kinetics, yielding $k_{cat} = 3.90 \times 10^{-3}\ s^{-1}$ and $K'_{app} = 1.23$ mM (Figure 1a) that represent an 8.67×10^4-fold first-order rate acceleration with respect to aerobic autooxidation of phenol. The k_{cat} value is lower than that for catechol oxidation and indicates that the hydroxylation step here must be the rate-limiting step. Otherwise, these two reactions would have similar k_{cat} values attributed to the oxidation of a bound catechol upon hydroxylation of a bound phenol. Moreover, the use of deuterated phenol as substrate reveals a significant kinetic isotope effect (KIE); k_{cat} values of 1.12×10^{-3} and $0.0442\ s^{-1}$ are obtained in the absence and presence, respectively, of H_2O_2 (100 mM) and represent KIE values of 3.46 and 4.77, respectively. The results indicate that hydroxylation and cleavage of the *o*-C–H bond of phenol is the rate-limiting step, which is followed by a faster step to form *o*-quinone. The different KIE values for the hydroxylation of phenol in the presence and absence of H_2O_2 suggest that the rate-determining step in these two cases may be different and/or possibly involve additional pathways. The K'_{app} values are not significantly different between phenol and deuterated phenol (1.31 and 1.23 mM for the latter in the presence and absence of H_2O_2, respectively) which suggests that k_{cat} does not significantly contribute to the magnitude of K'_{app} and that the two substrates may have a similar binding mode. The mechanistic reasoning for the conversion of phenol to *o*-quinone may be attributed to the fact that the Cu^{II}/Cu^{I} redox equilibrium can be achieved upon phenol binding, followed by electron transfer to afford a Cu^{I}–phenol radical, which is thought to be stabilized through resonance structures with delocalization of the free radical at the *ortho* and *para* positions[23a] (Figure 3, step a). This intermediate is then attacked by dioxygen and followed by electron transfer to possibly form a Cu^{II} superoxide center which may be further stabilized by a dinuclear center (step b). It was proposed previously that the free radical was attached directly by triplet dioxygen[23a] which, however, is not symmetrically favorable. Coupling of the superoxide radical to the bound phenol radical at an *ortho* position is then expected to be a favorable step (step c), which is followed by transfer of electrons and an oxygen atom to afford the final quinone product (step d). Involvement of a dinuclear center for the catalysis is possible as discussed below.

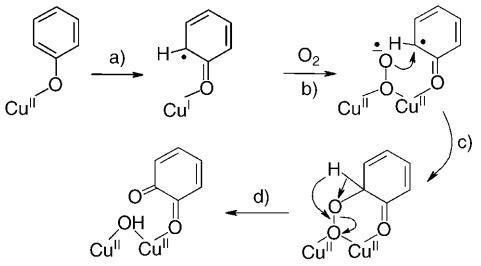

Figure 3. Proposed mechanism for aerobic hydroxylation and oxidation of phenol in the absence of H_2O_2, with the binding of phenol and reduction of the metal center as the key step (a). The binding of dioxygen and formation of superoxide (b) is proposed to be assisted by a dinuclear center. See text for details.

As the hydroxylation and oxidation of phenol is a multi-electron-transfer process, the involvement of two metal centers is suspected. The activity profile for phenol oxidation is similar to that for the Zn^{II} dilution experiment for catechol oxidation. The data can be fitted equally well to the Hill equation [Eq. (3)] to afford $\theta = 1.80$ ($r^2 = 0.98$) and a quadratic equation for single-metal binding ($r^2 = 0.98$), consistent with either a mononuclear oxidation[23] or a cooperative mechanism involving a dinuclear center,[16] or a combination of both pathways.

To monitor substrate binding, a "slow" substrate, 4,5-dichlorocatechol (DCC), which is approximately 200 times slower than catechol in terms of k_{cat}, was titrated into a solution of $CuA\beta_{1-20}$ (0.2 mM) in the presence or absence of H_2O_2 (100 mM) and monitored by UV/Vis spectroscopy at 25 °C at pH 7.0 (Figure 4). Similar spectra were obtained through the course of the titration, indicating that H_2O_2 was not involved in the binding of DCC to $Cu^{II}A\beta$ under the experimental conditions. The absorption at 437 nm increased upon addition of DCC to $(Cu^{II}A\beta)_2$ and reached saturation at more than 1.2 equivalents of DCC, and the data were fitted to a single-substrate binding model to yield a dissociation constant of 0.24 mM. The result provides direct evidence for catechol binding to a dicopper(II) center, consistent with the

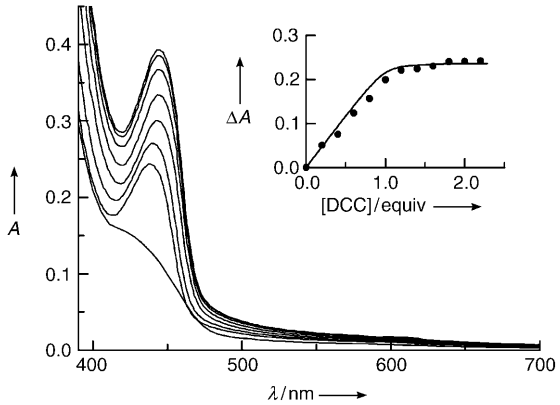

Figure 4. Titration of DCC to CuAβ (0.2 mM) in the presence of H_2O_2 (100 mM) in HEPES buffer (100 mM) at pH 7.0 monitored by UV/Vis spectroscopy. Analogous spectra were obtained in the absence of H_2O_2. The inset shows the change in absorbance at $\lambda = 437$ nm as a function of the number of equivalents of DCC added with respect to $(Cu^{II}A\beta)_2$, consistent with the formation of a 1:1 DCC–$(Cu^{II}A\beta)_2$ adduct.

observations with a chemical model[24] and the mechanism proposed above.

In conclusion, we have established the catalytic activities of $CuA\beta_{1-20}$ toward the relatively inactive species (according to their k_0 values) catechol and phenol in the presence and absence of H_2O_2 in aqueous solutions at near-physiological conditions. The reaction patterns are consistent with the mechanisms carried out by Type-3 copper centers as observed with catechol oxidase and tyrosinase and their dinuclear model systems.[8,22] So far these results are unique in metal-centered redox chemistry related to Alzheimer's disease and are expected to offer further insight into the neuropathology of this disease, as it is suspected to be linked with, besides many other factors, the oxidation of mono- and diphenol-containing neurotransmitters such as dopamine, epinephrine, norepinephrine, and serotonin.[25,26] Furthermore, the association of this highly reactive Cu–oxygen chemistry with Alzheimer's disease can better define the role of metallo-β-amyloids in the neuropathology of this disease and possibly lead to different treatment strategies toward this disease.

[10] Phenol hydroxylation/oxidation and catechol oxidation were performed as previously reported[11] with minor changes to suit the current studies. The same molar concentrations of phenol or catechol and 3-methyl-2-benzothiazolinone hydrazone (MBTH, an indicator of *o*-quinone) were mixed in HEPES buffer (100 mM) at pH 7.00 in the presence of $CuA\beta_{1-20}$ at 5.0 μM (phenol hydroxylation/oxidation) or 0.50 μM (catechol oxidation). The red adduct of the *o*-quinone product was monitored at 500 nm ($\varepsilon = 32{,}500\ M^{-1}cm^{-1}$; see Figure 1c). The autooxidation of phenol and catechol were determined under the same conditions in the absence of $CuA\beta_{1-20}$. The 1–20 fragment of Aβ was synthesized at the Peptide Center of the University of South Florida. The identity of the peptide was confirmed with a Bruker MALDI-TOF mass spectrometer.

Electrografting of Poly(ethylene glycol) Acrylate: A One-Step Strategy for the Synthesis of Protein-Repellent Surfaces**

*Sabine Gabriel, Peter Dubruel, Etienne Schacht, Alain M. Jonas, Bernard Gilbert, Robert Jérôme, and Christine Jérôme**

Nowadays, the availability of biocompatible surfaces is a key issue in the design and production of medical devices and implants to be used in contact with blood. Poly(ethylene glycol) (PEG) has the unique capacity to reduce protein adsorption and cell adhesion on a variety of hydrophobic substrates,[1] which explains the continuing efforts to develop new methods for the deposition of strongly adhering PEG coatings on gold[2] from thiols and disulfides, on silicon[3] and glass[4] from silanes or a poly(glycidyl methacrylate) primer,[5] and on metal oxides from poly(L-lysine)-g-poly(ethylene glycol)[6] or by plasma treatment.[7] In addition to these techniques, electrografting is often used for the chemisorption of poly(meth)acrylate chains onto electrically conductive substrates whatever their shape (plates, stents, fibers, powders,…).[8–11] Compared to the chemical methods, electrografting has the advantage of being applicable to a large variety of substrates, including metals and alloys, semiconductors, ITO-glass, and carbon. Although originally reported for acrylonitrile,[11] electrografting has been extended to a large variety of (meth)acrylates, thereby allowing the surface properties to be tuned by the appropriate choice of the ester substituent. For example, reactive, hydrophobic, and electroactive coatings have been deposited by the electrografting of various acrylates bearing *N*-succinimidyl,[12] norbornenyl,[13] and pyrrolyl[14] moieties, respectively. To the best of our knowledge, the one-step electrografting of highly hydrophilic coatings has not yet been reported.

Herein, we want to report the direct electrografting of acrylic end-capped PEG (macromonomers). In the following, A-PEG and A-PEG-A will be used as abbreviations for the number of polymerizable end-groups A (one or two, respectively; Scheme 1). The electropolymerization of PEG macromonomers was conducted by voltammetry in DMF containing a conducting salt (tetraethylammonium perchlorate, TEAP). As is usually observed for the cathodic polymerization of (meth)acrylates, two reduction phenomena can be distinguished[9] in solvents of a high donor number,[8] (Figure 1 A,

curve a). At the less-cathodic potential (peak I), a species is formed which is responsible for both the initiation of the macromonomer polymerization and the chemisorption of the growing chains,[11] whereas at a more-cathodic potential (Figure 1 A, signal II), the initiating species are also formed by electron transfer from the cathode to the monomer; however, the chains now propagate in solution and are no longer chemisorbed onto the cathode surface. Whenever the cathodic potential equals the maximum of peak I, the electrode is passivated within a few seconds as the result of the grafting of an insulating polyacrylate film. This polymer grafting was also confirmed by the extremely low current intensity observed during a second potential scan on the same electrode (curve 2 in the inset of Figure 1 A).

In a second part of the work, the macromonomer concentration was varied and the intensity of the passivation peak I (Ip1) was determined from the voltammograms, as exemplified in Figure 1 for A-PEG-A. As previously reported for ethyl acrylate electrografting,[8] the data summarized in Table 1 confirm that an increase in monomer concentration

Table 1: Current intensity at the potential of peak I in relation to the A-PEG-A concentration.[a]

[A-PEG-A]	0.1 M	0.5 M	1 M
Ip1 for A-PEG-A (M_n = 700) [mA]	−1.67	−1.28	−0.70
Ip1 for A-PEG-A (M_n = 258) [mA]	−0.66	−0.50	−0.40

[a] In a DMF solution of TEAP (0.05 M) at 20 mV s^{-1}.

results in a smaller Ip1 at a constant scan rate (20 mV s^{-1}). Indeed, only the polymerization initiation is an electrochemical process, in which only the adsorbed monomer participates. The kinetics of this step are thus weakly dependent on the monomer concentration. In contrast, chain propagation, and thus the increase of the degree of polymerization (DP) of the insulating brushes, is a chemical process which is fast when the monomer concentration is high. Therefore, passivation occurs rapidly when the chain propagation is fast and Ip1 decreases accordingly. In the case of the monoacrylate macromonomer, the voltammetric peaks I and II overlap and the passivation of the electrode is less efficient, as shown by the current intensity, which decreases more slowly when the potential scan is repeated (Figure 1 B, inset). These observations are consistent with a less-effective adsorption of the A-PEG macromonomer at the surface. The overlap of peaks I and II is indeed known to be extensive when the monomer concentration is low.[8] The lower efficiency of the electrografting of A-PEG also has a direct influence on the electrode passivation. As a rule, these electrochemical observations are observed irrespective of the substrate (glassy carbon, stainless steel, and gold).

Grafting of poly(ethylene glycol) was confirmed by ATR-FTIR analysis of the electrode surface after intensive washing with DMF, which is a good solvent for PEG; the three main absorptions at 2861, 1732, and 1106 cm^{-1} are characteristic of the CH_2, C=O, and C–O–C vibrations of poly(A-PEG), respectively (Figure 2). Moreover, a careful analysis of the spectra for all the electrografted films (PEG bands) shows

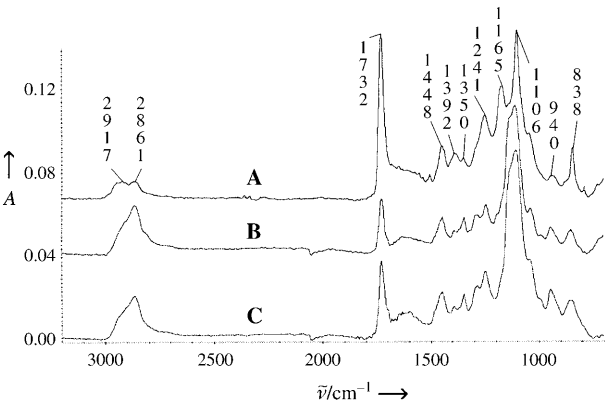

Figure 2. ATR-FTIR spectra for A-PEG-A (M_n = 258, 0.5 M) (A), A-PEG (M_n = 454, 1 M) (B), and A-PEG-A (M_n = 700, 0.1 M) (C) electrografted onto stainless steel.

that the CH_2 scissoring mode at 1448 cm^{-1} and the CH_2 twisting mode at 1241 cm^{-1} dominate the CH_2 wagging mode at 1350 cm^{-1}, which indicates that the PEG side chains are oriented parallel to the surface, as has been reported elsewhere.[6] Figure 3 illustrates this preferential

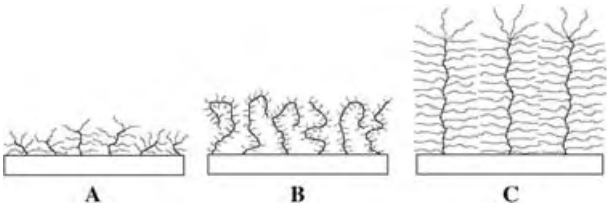

Figure 3. Expected architecture and conformation of poly(A-PEG) (A) and poly(A-PEG-A) (B and C) electrografted from A-PEG (M_n = 454, DP_{EG} = 7; A), A-PEG-A (M_n = 258, DP_{EG} = 3; B), and A-PEG-A (M_n = 700, DP_{EG} = 13; C). PEG side chains are in gray and the polyacrylic backbone in black.

orientation of the PEG teeth of the comb-like architectures. Interestingly, Raman analysis of the diacrylate PEG films showed that the electrografted coatings still contain unreacted acrylic functions. Indeed, although the intensity ratio of the C=C band at 1632 cm^{-1} to the C=O band at 1730 cm^{-1} has decreased, the C=C band does not disappear completely (Figure 4), which could offer a unique opportunity for further functionalization of the coating, for example by the Michael addition of nucleophiles.[15]

The film thickness was measured by ellipsometry at five distinct spots on the surface of films electrografted on stainless steel and glassy carbon (Table 2). The dispersion of the five data points for each film is lower than 10% error, which is a strong indication of the homogeneity of the films. Although the film thickness is systematically smaller when the substrate is stainless steel rather than glassy carbon (the difference being significant only for the A-PEG macromonomer), this characteristic feature depends more on the monomer concentration, as illustrated in Figure 5 for the glassy carbon substrate. The film thickness increases with the macromonomer concentration at a rate which is, however,

	Contact angle [°]	43 ± 2	31 ± 3	25 ± 3	43 ± 3	48 ± 4	< 10	< 10
Stainless steel	Thickness [nm]	9 ± 1	18 ± 2	39 ± 4	11 ± 4	202 ± 31	98 ± 22	437 ± 39
	Contact angle [°]	45 ± 4	37 ± 4	29 ± 3	42 ± 4	50 ± 3	< 10	< 10

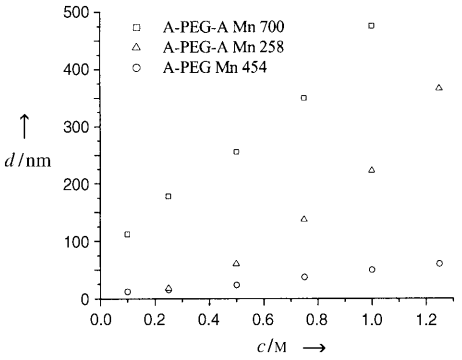

Figure 5. Dependence of the film thickness d on the macromonomer concentration c on polished glassy carbon.

much faster for the bifunctional than for the monofunctional macromonomer of comparable molecular weight. A greater thickness for the films formed by the bifunctional macromonomer was expected because the concentration of the polymerizable acrylic moieties is doubled in this case, thus making the propagation of the tethered chains much faster and, consequently, the DP and thickness greater, as illustrated in Figure 3 (A and B).

In the case of PEG monoacrylate films, a maximum thickness of 50 nm was observed for a coating prepared at high concentration (1M). This thickness is in agreement with the values previously measured for films synthesized starting from a monoacrylic monomer.[10,16] For example, for poly(ethyl acrylate)[10] or poly(acrylonitrile)[16] films, the thickness never exceeds 100 nm for a monomer concentration of 1M. In the case of PEG diacrylate, an increase in macromonomer concentration and molecular weight makes the coating thickness grow very rapidly such that a thickness of up to 500 nm can be reached when a macromonomer of $M_n = 700$ is used at a concentration of 1M.

This drastic evolution of the coating thickness can be explained by the peculiar architecture of the polymer chains that are formed by electrografting, namely a comblike polymer consisting of an acrylic backbone with PEG side chains grafted onto each acrylic unit. The conformation of such poly(acrylic) comblike polymers depends on the length of the macromonomer, i.e., on the size of the PEG side chain. As shown by Fredrickson,[17] the repulsive interaction between the side chains induces the rigidity of the comb polymer: the greater the length of the side chains, the higher the persistence length of the main chain. In other words, we can assume that when the M_n of the PEG side chains is increased, the stretching of the tethered chains is responsible for the rapid increase of the coating thickness (B and C in Figure 3). It should be emphasized that Figure 3 (B and C) does not consider the possible reaction of the second acrylic function of the macromonomer. However, this reaction most probably occurs and leads to additional branching of the brushes, cross-linking, loops, and/or network formation. All these additional reactions are also expected to increase the film thickness. These reactions have been neglected in Figure 3 for reasons of clarity as the extent of these reactions is limited, as already mentioned in the description of the Raman spectrum (Figure 4).

The water contact angles measured for the different PEG films are in good agreement with the thickness measurements. Table 2 shows that in the case of PEG diacrylate (thick films) the contact angles do not depend on the macromonomer concentration. These films fully cover the underlying substrate such that the contact angle only depends on the macromonomer composition and not on the macromonomer concentration, i.e., for A-PEG-A ($M_n = 258$), the DP of PEG is only 3, which makes the hydrophobic acrylic content quite high, and the contact angle levels at around 45°. When the M_n of the macromonomer is increased (from $M_n = 258$ to $M_n = 700$) very hydrophilic films are obtained (< 10°). As far as the monoacrylate PEG is concerned, the film thickness is low and concentration-dependent. As observed in Table 2, the contact angle decreases with increasing film thickness from 45 to 25°. When the films prepared with this hydrophilic macromonomer (A-PEG) are thin, the underlying hydrophobic substrate has an effect on the contact angle of water (Table 2), probably due to a weak tendency of these hydrophilic chains to spread out on the hydrophobic surface. For the thicker films, the contact angle reaches 25°, which is a value already lower than that usually reported for PEG monolayers 5–6 nm thick (30–35°).

The comblike architecture of the films obtained in this one-step process would be particularly interesting in cases where protein adsorption has to be avoided. Indeed, branched PEG chains, like PEG stars, have recently been shown to be more efficient at preventing unspecific protein adsorption

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

than linear chains[3a,18] because they combine both high grafting density and high PEG segment mobility.

Based on contact angle and ellipsometry data, films of monoacrylate PEG prepared at a 1M concentration combine high hydrophilicity and low thickness, which are two key criteria for reliable measurements of protein adsorption by surface plasmon resonance (SPR). The poly(A-PEG-A) films were disregarded because of the possible Michael addition of the proteins to unreacted acrylate groups. Liedberg and coworkers, the pioneers in the SPR field, have demonstrated the utility of this practical and commonly used technique for the characterization of bio-interfaces.[19] SPR substrates (glass slides coated on one side by a thin gold film) were electrografted by ethyl acrylate (0.1M; reference sample) and PEG monoacrylate (1M) in a DMF solution containing TEAP (5×10^{-2}M). The sensorgrams showing the proteins' adsorption with time were compared for the hydrophobic poly(ethyl acrylate) (PEA) and hydrophilic poly(A-PEG) coatings. Figure 6 illustrates the adsorption of bovine serum albumin

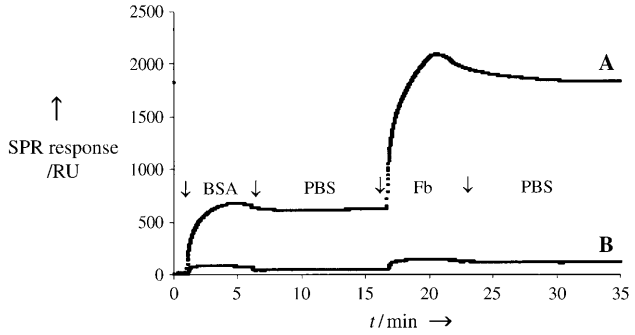

Figure 6. SPR adsorption profiles for bovine serum albumin (BSA; 0.5 mg mL^{-1}) and fibrinogen (Fb; 0.1 mg mL^{-1}) in a phosphate buffer (PBS; 10 mM, pH 7.4) on: A) electrografted PEA (0.1 M)[10] and B) electrografted A-PEG (M_n = 454, 1 M). Flow rate: 20 μL min^{-1}. Substrate: gold.

(BSA) (first injection) and fibrinogen (Fb) (second injection) on the two types of electrografted films. Curve B in Figure 6 is convincing evidence that electrografted PEG is very efficient in preventing protein adsorption. The electrografted PEG film decreases both the BSA and fibrinogen adsorption relative to the grafted PEA film: BSA adsorption is reduced by 93% (±3%), whereas fibrinogen adsorption is reduced by 92% (±2%). These results are highly reproducible, further indicating the homogeneous and reproducible coating process when using electrografting.

The one-step electrografting of PEG macromonomers is a technique that is very well suited for coating conductive substrates homogeneously with a strongly adhering hydrophilic coating. These electrografted chains, which have a comb-like architecture, have proven to be very efficient in preventing the adsorption of proteins. This very simple technique is thus highly promising in the field of coatings of biomedical devices and biosensors. In addition, the unreacted acrylic functions remaining in the PEG diacrylate films offer the opportunity of straightforward derivatization, for instance by Michael addition, with a variety of molecules of interest such as proteins. This opens the way to the easy elaboration of surfaces for the specific recognition of proteins or with sensor capabilities.

Experimental Section

PEG macromonomers (M_n = 258, 454, and 700; Aldrich) were dried by three azeotropic distillations with toluene. DMF and tetraethylammonium perchlorate (TEAP) were dried before use.[10] Electrochemical experiments were carried out in a three-compartment cell equipped with a Pt pseudo-reference electrode, a Pt counter-electrode, and a working electrode (1 cm^2) with a PAR EG&G potentiostat (Model 273A). All electrochemical experiments were carried out in a glovebox under a dry and inert atmosphere (N_2). All the electrografted films of PEG diacrylate and monoacrylate were prepared by, respectively, two or three scans of the potential between the initial potential of the open circuit and the potential at the top of the first peak, where it is kept for 5 s. The electrografted PEA films were prepared in the same way from ethyl acrylate (EA; 0.1M) solution in DMF/5×10^{-2}M TEAP, as reported previously.[10] This EA concentration was chosen such that the film thickness was similar to that prepared with the A-PEG macromonomer (1M). ATR-FTIR, Raman, and contact-angle measurements were carried out on the modified surface after rinsing with DMF to remove the monomer and the nongrafted polymer, and in acetonitrile to dry the coating. Ellipsometry was carried out with an Ellisel ellipsometer (Jobin-Yvon/Sofie instrument) operating at a wavelength of 632.8 nm. The film thickness was measured at 70.67° (incidence angle with respect to the normal of the substrate). At least five measurements were taken for each sample at different locations; the error in the thickness was about 10%. The refractive index for PEG was 1.506.[20] For thicker films (< 200 nm), the thickness was measured with a Sentech, SE 800 spectroscopic ellipsometer. SPR experiments were performed with a Biacore-X instrument equipped with an internal injection system (Hamilton syringe, 200 μL). The experiments were carried out with a phosphate buffer (10 mM, pH 7.4) at a flow rate of 20 μL min^{-1}. The concentration of the protein solutions was 0.5 mg mL^{-1} for bovine serum albumin (Sigma, Fraction V, 95%) and 0.1 mg mL^{-1} for fibrinogen (bovine, Sigma, Fraction I, 86%) rather than physiological protein concentrations. These low protein concentrations were chosen in order to avoid poisoning of the SPR signal by protein exchange phenomena. However, similar results were obtained for higher concentrations of fibrinogen (1 mg mL^{-1}). After each protein injection the SPR substrate was washed with a phosphate buffer (PBS). The percentage of absorbed protein was calculated based on the plateau levels after the PBS cleaning.

Formation of an Unsymmetrical Dinuclear Ruthenium Complex with μ-H, μ-OH, and μ-κ^2-CO_2 Bridges and Multiple Reactive Sites**

*Yasuhiro Arikawa, Shuichi Nagae, Jun-ichi Morishita, Katsuma Hiraki, and Masayoshi Onishi**

Hydrido ruthenium species and their organometallic derivatives play important roles as chemically active intermediates in the key steps of numerous catalytic reactions.[1] Judicious design and syntheses of model compounds for these processes have contributed to the rapid development of organoruthenium chemistry. We have exploited some versatile hydrido (phosphine) transition-metal compounds to obtain useful highly reactive catalysts[1,2] and to investigate the structural characteristics and chemical reactivities of organometallic intermediates derived from them through the incorporation of organic substrates, such as alkenes, alkynes, nitriles, and allylic compounds.[3] In the course of these studies, we treated ethanol solutions of some chloro(carbonyl)(phosphine) ruthenium(II) complexes $[RuCl_2(CO)_n(PR_3)_m]$ with a large excess of concentrated aqueous KOH solution, and from the reactions of the PMe_3 complexes, we succeeded in isolating and characterizing of an unprecedented dinuclear ruthenium complex with μ-H, μ-OH, and μ-κ^2-CO_2 bridges.[4] In contrast to this result, Lavigne and co-workers have described that reactions of the halo(carbonyl)ruthenium(II) complex $[RuCl_2(CO)_3(thf)]$ with methanolic solutions of KOH result in the formation of a hydroxycarbonyl species $[RuCl_2(CO)_2\{C(O)OH\}]^-$, and that subsequent thermal decarboxylation gives a transient hydride "$[RuCl_2(H)(CO)_2]^-$".[5] Our isolated dinuclear species is bridged not only by hydrido but also by hydroxo and κ^2-*O*,*C*- carbon dioxide ligands. Herein we report the synthesis of this complex and its chemical reactivity towards neutral monodentate donor molecules (i.e. Lewis bases), protic acids, and molecular iodine.

Treatment of *cis*,*cis*,*trans*-$[RuCl_2(CO)_2(PMe_3)_2]$ with 100 equivalents of KOH (10 M aqueous solution) in refluxing ethanol was found to afford $[\{Ru(CO)(PMe_3)_2\}_2(\mu\text{-}H)(\mu\text{-}OH)\{\mu\text{-}\kappa^2\text{-}C(O)O\}]$ (**1**) as yellow brown powder in 59% yield (Scheme 1). The structural assignment of **1** was performed by an X-ray diffraction study of single crystals grown from benzene/hexane (Figure 1).[6]

Scheme 1. Synthesis of **1**.

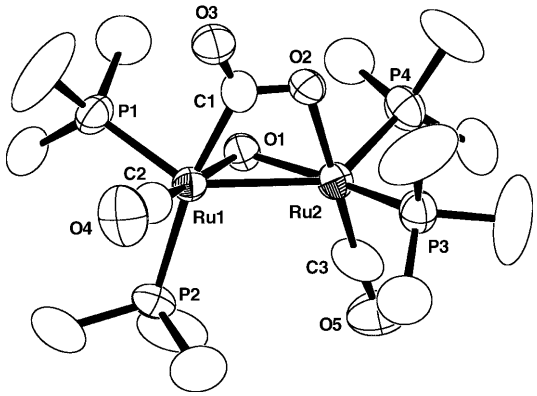

Figure 1. ORTEP diagram of complex **1** (thermal ellipsoids set at 50% probability). Selected bond lengths [Å] and angles [°]: Ru1-Ru2 2.788(1), Ru1-P1 2.282(2), Ru1-P2 2.402(2), Ru2-P3 2.273(3), Ru2-P4 2.312(3), Ru1-O1 2.089(5), Ru2-O1 2.089(5), Ru1-C1 2.089(9), Ru2-O2 2.105(5), O2-C1 1.320(10), O3-C1 1.248(10); O2-C1-O3 119.3(8).

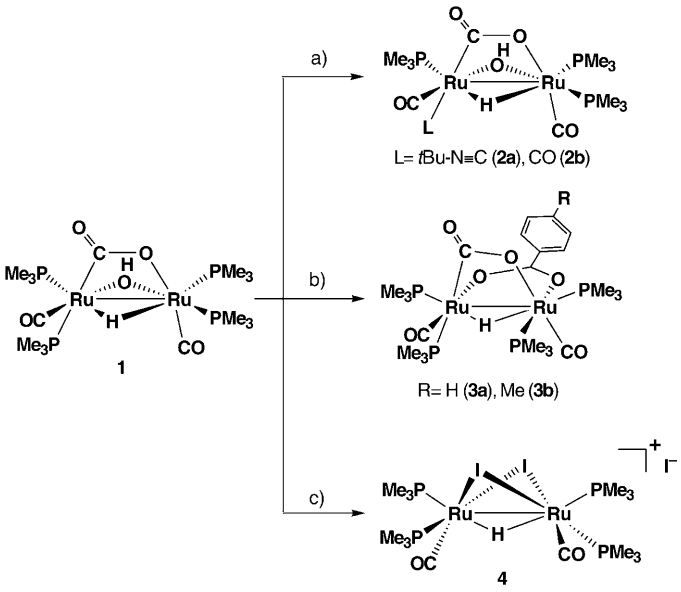

The molecule consists of two $[Ru(CO)(PMe_3)_2]$ units bridged by hydrido, hydroxo, and additionally κ^2-*O*,*C*-carbon dioxide ligands, resulting in an asymmetric dinuclear structure. Although some other dinuclear complexes containing CO_2 in a similar unsymmetrical bridging mode have been reported,[7] such a triply bridged dinuclear species is unprecedented. The geometry around each ruthenium atom is approximately octahedral. The coordinated carbon and oxygen atoms in the κ^2-*O*,*C*-CO_2 ligand are *trans* to a PMe_3 ligand (P2 of Ru1) and the CO ligand (of Ru2), respectively. The CO ligand of Ru1 and the PMe_3 (P3) ligand of Ru2 conform to the "A-frame" structure imposed by the bridging hydroxo group. Moreover, two positions *trans* to the bridging hydrido group are occupied by two PMe_3 ligands. Compound **1** has 34 cluster valence electrons with a typical Ru–Ru single bond of 2.788(1) Å.[8] The hydrido atom was located in a difference electron density map, but unfortunately its position was not refined. Bond lengths between the bridging hydroxo oxygen atom and two ruthenium atoms (Ru1-O1 2.089(5), Ru2-O1 2.089(5)) fall within the range of normal hydroxo bridge bonds in dinuclear complexes.[9] Whereas the Ru1-C1 bond length (2.089(9) Å) is comparable to that found in the only other structurally characterized metallacyclic CO_2-bridged diruthenium complex $[\{Ru(CO)_2\}_2\{\mu\text{-}\kappa^2\text{-}C(O)O\}\{\mu\text{-}(i\text{PrO})_2\text{PN(Et)P(O}i\text{Pr)}_2\}_2]$,[7a] but the Ru2-O2 bond (2.105(5) Å) of **1** is shorter. The C–O bond length of 1.248(10) Å for the noncoordinated carboxyl oxygen atom (O3), that is, the carbonyl oxygen, is shorter than the other C–O bond (C1–O2 1.320(10) Å) in the CO_2 ligand. The Ru1-P2 bond (2.402(2) Å) is the longest of the Ru–P bonds in **1**. The O···O separation of 2.758(8) Å between the hydroxo oxygen (O1)and neighboring non-coordinated carbonyl oxygen (O3) atoms indicates the presence of intermolecular hydrogen bonding.

The IR spectrum of **1** shows two ν(CO) bands at 1920 and 1906 cm^{-1}, together with a broad ν(OH) band near 3390 cm^{-1} which arises from the intermolecular hydrogen-bonding. The $^{31}P\{^1H\}$ NMR spectrum displays four non-equivalent signals at $\delta = 16.1$, 3.81, 0.21, and -18.4 ppm with multiple mutual couplings. In the ^1H NMR spectrum, a diagnostically split signal for the bridging hydrido atom which couples with these phosphorus atoms is observed at $\delta = -11.2$ ppm, in addition to a broad signal ($\delta = -0.61$ ppm) for the hydroxo proton. The latter signal diminished on addition of D_2O to the NMR sample. In the $^{13}C\{^1H\}$ NMR spectrum, the bridging CO_2 carbon atom resonated at $\delta = 205$ ppm and shows a large *trans*-phosphine coupling, in addition the spectrum also shows two lowfield resonances for the CO ligands. The FAB-MS spectrum supported the formulation of **1**.

While a similar reaction of the isomeric *trans*,*trans*,*trans*-$[RuCl_2(CO)_2(PMe_3)_2]$ failed to afford **1**, the use of another related ruthenium complex *trans*-$[RuCl_2(CO)(PMe_3)_3]$ gave rise to **1** in a low yield (4%). Thus, employment of *cis*,*cis*,*trans*-$[RuCl_2(CO)_2(PMe_3)_2]$ was essential for the successful isolation of the triply bridged diruthenium complex **1**, as the use of *cis*,*cis*,*trans*-stereoisomers with other phosphines PR_3 did not yield similar dinuclear complexes with the exception of $R_3 = Me_2Ph$, where formation of the corresponding dinuclear compound was detected in the solution, but it could not be isolated owing to its high instability. Use of a large excess of highly concentrated aqueous KOH solution was also a crucial factor in the successful formation of **1**. A reasonable mechanistic rationalization for the formation of **1** would involve initial generation of the five-coordinated hydroxycarbonyl species $[RuCl\{C(O)OH\}(CO)(PMe_3)_2]$, followed by its intermolecular unsymmetrical association as a dimer through two hydroxycarbonyl groups. Decarboxylation of one group and deprotonation of the other group would afford the μ-H and asymmetric μ-κ^2-*O*,*C*-CO_2 bridges, respectively.[10] A similar formation mechanism has been suggested by Lavigne and co-workers in the reaction of $[RuCl_2(CO)_3(thf)]$ with Et_4NOH to form polymeric carbonyl- and chloride-bridged diruthenium polyanions.[5b]

To examine the chemistry of the reactive sites in **1**, its reactivities toward neutral monodentate donor molecules were tested (Scheme 2). Treatment of **1** with excess *t*BuNC or CO in benzene gave rise to $[\{Ru_2(CO)_2(PMe_3)_3(L)\}(\mu\text{-}H)(\mu\text{-}OH)\{\mu\text{-}\kappa^2\text{-}C(O)O\}]$ (L = *t*BuNC (**2a**) and CO (**2b**)), respectively. Both $^{31}P\{^1H\}$ NMR spectra of **2a** and **2b** show a disappearance of the highest-field signal ($\delta = -18.4$ ppm) of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 2. Reactions of **1** with various reagents. a) *t*BuNC or CO, b) benzoic acid or *p*-toluic acid, c) I_2.

the four observed for **1**, and in the ^{1}H NMR spectrum the resonances of the hydrido ligands were detected as doublet of doublet of doublet signals ($\delta = -11.0$ (**2a**), -10.9 ppm (**2b**)). Furthermore, the IR spectra of **2a** and **2b** show additional strong bands arising from ν(CN) at 2148 and ν(CO) at 2018 cm^{-1}.

Yellow crystals of **2a** were obtained and the molecular structure was determined by single-crystal X-ray structural analysis.[11] Complex **2a** has a similar framework to **1**, despite the use of excess *t*BuNC only the PMe_3 ligand situated *trans* to the bridging CO_2 carbon atom is selectively displaced by a *t*BuNC ligand. In contrast to this result, some hydrido-bridged dinuclear complexes have been reported to react with *t*BuNC to give μ-formimidoyl derivatives.[12] Moreover, it is noted that treatment of **1** with CO gas also resulted in displacement of the PMe_3 ligand at the same position (based on the ^{31}P{^{1}H} and ^{1}H NMR spectra) to give **2b**.

The reaction of **1** with benzoic acid as a protic acid was carried out to give [{Ru(CO)(PMe_3)$_2$}$_2$(μ-H)(μ-κ^2-O_2CPh){μ-κ^2-C(O)O}] (**3a**) in 49% yield (Scheme 2). The ^{31}P{^{1}H} NMR spectrum shows similar signal pattern arising from four non-equivalent phosphorus atoms, indicating the framework of **3a** is analogous to that of **1**. In the ^{1}H NMR spectrum, the aryl protons, the methyl protons of the PMe_3 groups, and the hydride are detected but there is no signal from the hydroxo proton. The *p*-toluic derivative [{Ru(CO)(PMe_3)$_2$}$_2$(μ-H)(μ-κ^2-O_2CC$_6$H$_4$Me){μ-κ^2-C(O)O}] (**3b**) was also isolated in 77% yield from reaction with *p*-toluic acid under the same conditions, and the molecular structure of the monohydrate of **3b** was revealed by X-ray crystallographic analysis.[13] Complex **3b** consists of two [Ru(CO)(PMe_3)$_2$] units connected by hydrido, κ^2-*O*,*C*-CO_2, and a new arylcarboxylato bridge. During this reaction, the configuration of the dinuclear structure remains intact. The bond lengths of **3b** are comparable to those of **1**, except for the elongation of the Ru–Ru bond to 3.0160(5) Å, which is still within the range of typical Ru–Ru single bonds.[8] FAB-MS and elemental analyses confirm the formulation.

When **1** was treated with HBAr$^F_4$ (Ar$^F_4$ = 3,5-C$_6$H$_3$(CF$_3$)$_2$) at -78 °C, four new signals were detected in the ^{31}P{^{1}H} NMR spectrum, these are at $\delta = 17.1$, 5.36–4.39 ppm (overlap of two signals), and $\delta = -14.0$ ppm, and the ^{1}H NMR spectrum showed the multiplet hydride signal at $\delta = -11.4$ ppm along with methyl protons of PMe_3 and aryl protons of BAr$^F_4$. The ESI-MS spectrum exhibited a parent peak at *m*/*z* 626 ascribed to [**1**+H]$^+$. Although complete purification of this product was unsuccessful due to its low stability in solution, these data probably indicate generation of an H_2O-bridged species [{Ru(CO)(PMe_3)$_2$}$_2$(μ-H)(μ-OH$_2$){μ-κ^2-C(O)O}]BAr$^F_4$ (**3′**), which would be the intermediate leading to **3a** and **3b**. Unfortunately, the μ-OH$_2$ protons were not detectable even at -60 °C in the ^{1}H NMR spectrum.

Treatment of **1** with I_2 at room temperature for 23 h afforded [{Ru(CO)(PMe_3)$_2$}$_2$(μ-H)(μ-I)$_2$]I (**4**) in 66% yield (Scheme 2). The ^{31}P{^{1}H} NMR spectrum exhibited only two multiplet signals, indicating a higher symmetry in **4** than **1**. A triplet of triplet signal of the hydrido ligand of **4** supports the presence of two pairs of PMe_3 ligands. Cooling the acetone solution of **4** afforded yellow crystals suitable for X-ray diffraction analysis.

The crystal structure of **4** (Figure 2)[14] which has a crystallographic two-fold axis verified the presence of two {Ru(CO)(PMe_3)$_2$} units symmetrically bridged by two iodide

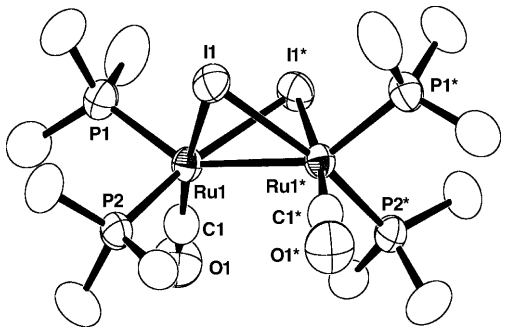

Figure 2. ORTEP diagram of complex **4** (thermal ellipsoids set at 50% probability). Selected bond lengths [Å]: Ru1-Ru1* 2.8955(8), Ru1-I1 2.7644(5), Ru1*-I1 2.7817(5), Ru1-P1 2.338(2), Ru1-P2 2.293(2).

and one hydrido ligands, accompanied by a counterion I$^-$. The hydrido atom was located in a difference electron density map, but unfortunately its position was not refined, however its presence was confirmed by the ^{1}H NMR spectrum (see Supporting Information). The Ru1–Ru1* distance of 2.8955(8) Å,which clearly indicates the presence of a metal–metal single bond,[8] is slightly longer than that of similar complex [{Ru(CO)(PPh_3)$_2$}$_2$(μ-H)(μ-Cl)$_2$]BF$_4$ (2.842(1) Å).[15] The cationic structure of [{Ru(CO)(PMe_3)$_2$}$_2$(μ-H)(μ-I)$_2$]$^+$ was also confirmed by the observation of the parent ion [*M*−1]$^+$ at *m*/*z* 817 in the positive ESI mass spectrum (acetone).

Interestingly, when **1** was treated with molecular iodine I_2 in dilute acetone solutions for only 30 min, the intermediate [{Ru(CO)(PMe_3)$_2$}$_2$(μ-H)(μ-OH)(μ-I)]I (**4′**) was detected

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

with a small amount of **4** on the basis of NMR spectroscopy and ESI mass spectra. This result indicates that the mechanism of formation in the initial I_2 oxidation involves the release of CO_2 in **1** and coordination of I^- to the resulting vacant site generating the intermediate **4′**. Further reaction of the bridging OH group of **4′** with another mole of I_2 would proceed to produce **4**. However, isolation of **4′** failed owing to its facile conversion into **4** during the separation procedures.

In conclusion, we have isolated the novel dinuclear species **1** that is bridged by hydrido, hydroxo, and κ^2-*O*,*C*-CO_2, and which has multiple reactive sites. With *t*BuNC and CO **1** undergoes simple ligand replacement of one PMe_3 molecule to give **2a** and **2b**, respectively. The reactions with protic acids (benzoic and *p*-toluic acid) afford arylcarboxylato bridging complexes (**3a** and **3b**) in reactions that proceed through the selective protonation on the hydroxo ligand. A similar result was also observed in the reaction with $HBAr^F{}_4$. On the other hand, for the reaction of **1** with I_2, oxidative addition occurred to afford the decarboxylated complex **4** via the intermediate **4′**. Further investigations on other chemical reactivities of **1** are underway.

Experimental Section

Details on the syntheses as well as full spectroscopic characterization of **1**–**4** are given in the Supporting Information.

1: An aqueous 10 M KOH solution (76 mL, 760 mmol) was added to an ethanol solution (230 mL) of *cis*,*cis*,*trans*-$[RuCl_2(CO)_2(PMe_3)_2]$ (2.9 g, 7.6 mmol). The mixture was heated under reflux for 24 h and the resulting red brown solution was concentrated to one-third of its original volume to produce red brown oil. The supernatant colorless solution was then removed and the oily product was dried in vacuo. The residue was extracted with benzene and addition of hexane precipitated a yellow brown powder of **1** (1.4 g, 59%). ^{1}H NMR (C_6D_6, 400 MHz): $\delta = 1.51$ (d, $J = 9.4$ Hz, PMe_3), 1.30 (d, $J = 9.9$ Hz, PMe_3), 1.26 (d, $J = 9.8$ Hz, PMe_3), 1.15 (d, $J = 6.0$ Hz, PMe_3), −0.61 (s, μ-OH), −11.2 ppm (m, μ-H); ^{31}P{^{1}H} NMR (C_6D_6; 162 MHz): $\delta =$ 16.1 (d, $J = 26$ Hz, PMe_3), 3.81 (dd, $J = 11$, 41 Hz, PMe_3), 0.21 (dd, $J =$ 26, 41 Hz, PMe_3), −18.4 ppm (d, $J = 11$ Hz, PMe_3); ^{13}C{^{1}H} NMR (C_6D_6; 100 MHz): $\delta = 207$ (dd, $J = 7.9$, 16 Hz, CO), 205 (br, d, $J =$ 102 Hz, CO_2), 204 (t, $J = 14$ Hz, CO), 20.3 (d, $J = 31$ Hz, PMe_3), 19.4 (d, $J = 27$ Hz, PMe_3), 18.9 (d, $J = 16$ Hz, PMe_3), 15.8 ppm (d, $J =$ 27 Hz, PMe_3). Highly Sensitive MRI Chemical Exchange Saturation Transfer Agents Using Liposomes**

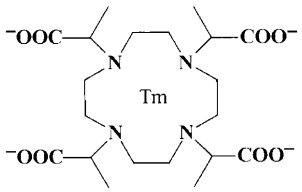
Silvio Aime, Daniela Delli Castelli, and Enzo Terreno*



Chemical exchange saturation transfer (CEST) agents represent an emerging class of magnetic resonance imaging (MRI) contrast media that has huge potential. They act as negative agents by reducing the signal intensity of the water protons through a saturation transfer mediated by chemical exchange.[1] Saturation transfer occurs through selective irradiation at the absorption frequency of the exchanging protons of the agent. The great potential of CEST agents lies in the possibility of switching the contrast "on" and "off" at will, since each response is uniquely related to the specific absorption frequency of their mobile protons, thus making it possible to detect several agents in the same sample.[2] Basically, the saturation transfer efficiency is proportional to the exchange rate (k_{ex}) and to the number of mobile protons in the CEST agent. However, the value of k_{ex} must be smaller than the frequency separation ($\Delta\omega$) between the resonances of bulk water and the exchanging protons of the agent if the mobile protons are to be selectively irradiated. For this reason, it might be possible to find efficient CEST agents in the class of paramagnetic metal complexes (the so-called PARACEST agents),[3] in which the presence of unpaired electrons induce large $\Delta\omega$ values. However, the sensitivity of a PARACEST agent is still below that of the conventional relaxing agents based on the Gd^{III} ion, even when k_{ex} and $\Delta\omega$ are optimized.

[**] Financial support from Bracco Imaging S.p.A., MIUR, NoE-EMIL, and DIMI are gratefully acknowledged. This work was carried out under the framework of the EU-COST D 18 action.

It has been suggested that an improved sensitivity may be obtained by increasing the number of exchangeable protons. Van Zijl and co-workers suggested the use of polymers, such as polyamino acids, polyamidoamine-based (PAMAM-based) dendrimers, and single-stranded RNA, containing a large number of labile amide protons.[4,5] We have further extended this approach by designing supramolecular adducts between a paramagnetic shift reagent and a substrate containing many, fast-exchanging protons.[6] The latter approach appears promising, but it bears the drawback of showing a severe broadening of the absorption corresponding to the exchangeable protons that, in turn, results in the need to apply a much more intense B_1 field to maximize their saturation.

To design a system with a well-defined paramagnetically shifted resonance that corresponds to a high number of exchangeable protons, we considered the use of liposomes containing a paramagnetic shift reagent for water protons in the aqueous inner cavities. In such systems, which we call LIPOCEST agents, the resonance of the water protons inside the liposomes is shifted from that of the external water to an extent that depends upon the structure and the concentration of the shift reagent entrapped within the liposomes. Thus, the ^1H NMR spectrum of such a suspension will display two signals for water that correspond to water confined in the liposome cavity and to the external solvent. The exchange of water molecules across the liposome membrane is usually slow and can be controlled, to some extent, by varying the composition of the lipidic bilayer. Suitable candidates for the shift reagent should be found among paramagnetic metal complexes containing at least one highly shifted and fast-exchanging water molecule. In principle, several macrocyclic lanthanide(III) chelates derived from 1,4,7,10-tetraaza-1,4,7,10-tetrakis(carboxymethyl)cyclododecane (DOTA), α,α′,α″,α‴-tetramethyl-1,4,7,10-tetraacetic acid (DOTMA), and related ligands display an axially coordinated water that nicely fulfills the latter requirement.[7] Herein we report the results obtained with the $[Tm(dotma)]^-$ complex, which has recently been proposed as a non-invasive MR probe for in vivo thermometry.[8]

[Tm(dotma)]⁻

$[Tm(dotma)]^-$ has been entrapped within a liposome formed from a blend of unsaturated/saturated phospholipids and cholesterol (palmitoyloleoylphosphatidylcholine (POPC)/dipalmitoylphosphatidylglycerol) sodium salt (DPPG)/cholesterol, 55:5:40 w/w/w). Previous studies on Gd(III) chelates entrapped within liposomes have shown that a mixture of cholesterol and unsaturated phospholipids results in a faster exchange of water across the liposome membrane relative to systems based only on saturated phospholipids.[9–11] When the preparation of the liposomes

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim InterScience

was carried out in the presence of 0.19 M [Tm(dotma)]$^-$, the water signal in the inner compartment resonated (at 312 K) at $\Delta\delta = 3.1$ ppm downfield of the signal of bulk water (Figure 1, top).

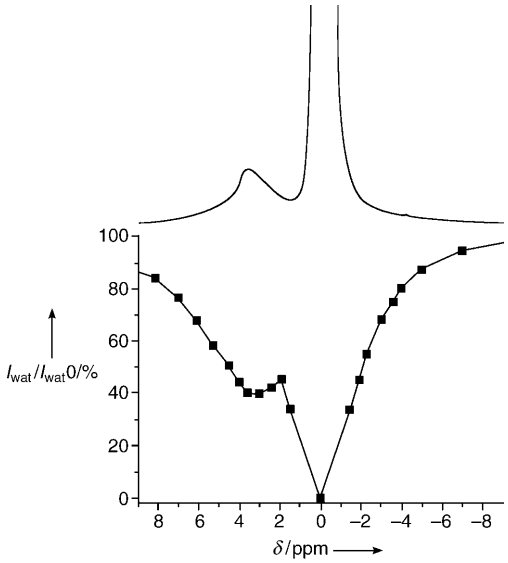

Figure 1. Top: ^{1}H NMR spectrum, recorded at 14.1 T and 312 K, of a suspension of the LIPOCEST agent entrapping [Tm(dotma)]$^-$. The signal at $\delta = 3.1$ ppm from the bulk water (off-scale signal at 0 ppm) corresponds to the water protons entrapped within the liposomes containing 0.1 M paramagnetic shift reagent, as demonstrated by the Z-spectrum (lower) obtained at 7 T and 312 K (liposome concentration 2.88 nM, B_1 field intensity 12 μT, irradiation time 3 s).

The difference in the chemical shift between the water resonances allows the actual concentration of the shift reagent in the liposome's inner cavity to be assessed, once the dependence of the paramagnetic shift of the bulk water resonance on the concentration of [Tm(dotma)]$^-$ has been determined by an independent experiment.[12] On this basis, it has been possible to determine that the experimental procedure used for the preparation of the liposomes led to an effective intraliposome [Tm(dotma)]$^-$ concentration of 0.1M. These liposomes showed a mean diameter of 270 ± 2.5 nm (polydispersity index 0.32) which gives a volume of the inner cavity of about 9.2×10^{-18} L. The ratio between the total concentration of the shift reagent in a given liposome suspension and its effective concentration inside the liposomes corresponds to the ratio between the volumes of the two compartments.

In this way the number of liposomes in the suspension, and thus their concentration, can be calculated by the ratio between the inner volume of a single liposome and the total volume of the compartment. The concentration of [Tm(dotma)]$^-$ in the the stock suspension of liposomes entrapping 0.1M shift reagent was 1.3 mM and the corresponding liposome concentration was 2.8 nM.

The Z-spectrum (7 T, 312 K, B_1 intensity 12 μT, irradiation time 3 s) of such a suspension is reported in Figure 1 (bottom). The profile confirms that the resonance $\Delta\delta =$ 3.1 ppm downfield from the bulk water protons corresponds to the pool of mobile water protons encapsulated within the liposomes.

Figure 2 shows the results of the saturation transfer (ST) experiments carried out at 7 T and 312 K upon irradiating the intraliposome water signal as a function of the liposome concentration. The data show the typical pseudohyperbolic

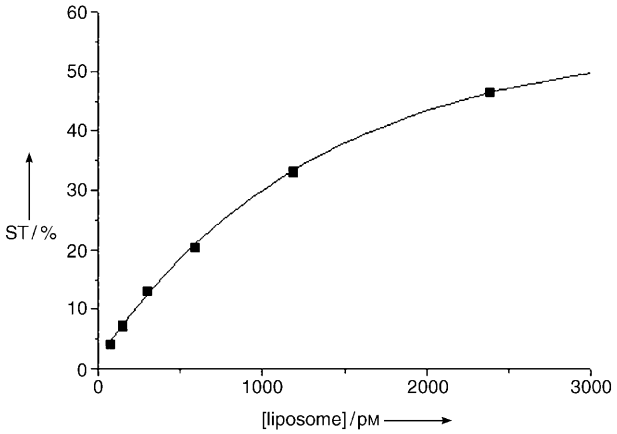

Figure 2. Saturation transfer assessment as a function of the liposome concentration for the LIPOCEST agent entrapping [Tm(dotma)]$^-$. Experimental conditions: 7 T, 312 K, irradiation pulse: train of 120 sinc3 pulses (25 ms each, B_1 field intensity 12 μT); the irradiation frequency was set at 930 Hz from the bulk water. The data points were fitted by using a simple hyperbolic function.

behavior[13] that leads to detectable ST effects down to picomolar concentrations of the LIPOCEST agent. If the threshold of the detectable saturation transfer is set at 5%, in analogy to previous works,[6,13] the agent reported herein can be detected down to about 90 pM!

As has been recently pointed out,[14,15] the intensity of the applied B_1 saturation field for attaining the maximum ST effect is directly related to the k_{ex} values of the mobile protons of the CEST agent. It is thus expected that the B_1 field necessary for transferring saturation in LIPOCEST agents is much lower than in other paramagnetic CEST probes containing fast-exchanging protons. In fact, the B_1 field used for liposomes entrapping [Tm(dotma)]$^-$ is about 20 times smaller than that used to saturate the metal-bound water protons in paramagnetic [Ln(dotamGly)]$^-$ complexes (dotam = 1,4,7,10-tetrakis(carbamoylmethyl)-1,4,7,10-tetraazacyclododecane).[13,16]

Figure 3 shows a difference (on/off) CEST image (see the Experimental Section) of a phantom made of eight capillaries containing different liposome concentrations to illustrate the dependence of the saturation transfer efficiency on the liposome concentration. The image clearly indicates that, for this agent, it is still possible to detect contrast at a liposome concentration of about 90 pM. The difference CEST images were acquired in about two minutes (with a total irradiation time of 3 s) by using a modified RARE pulse sequence.

In summary, the results reported here show that LIPOCEST agents represent an innovative class of MR imaging probes of outstanding sensitivity (per liposome). Moreover,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

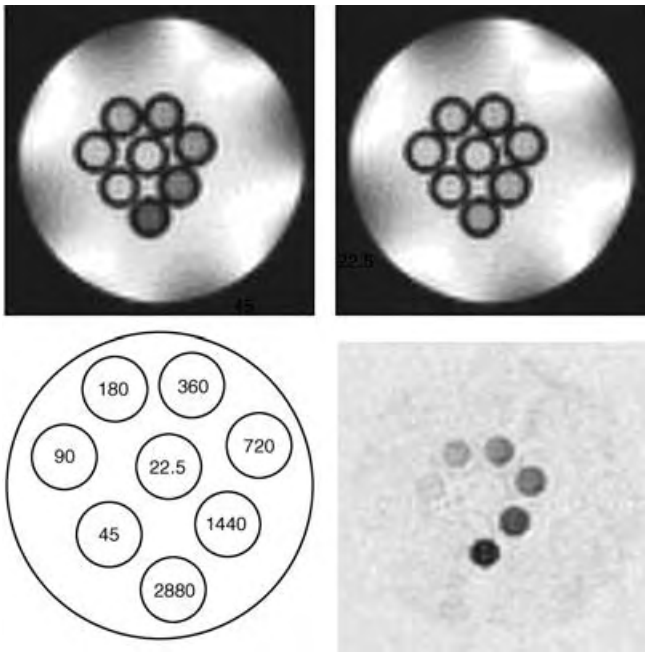

Figure 3. MRI-CEST images (matrix 64×64) of a phantom consisting of eight capillaries containing suspensions of the LIPOCEST agent entrapping $[Tm(dotma)]^-$ in the concentration range 22.5–2880 μM (see bottom left). Experimental conditions: 7 T, 312 K, RARE sequence: TR/TE/NE = 9 s/3.3 ms/1, rare factor = 8, irradiation pulse: train of 120 sinc3 pulses (25 ms each, B_1 field intensity 12 μT). Top left: On-image: irradiation frequency +930 Hz from bulk water. Top right: Off-image: irradiation frequency −930 Hz from bulk water. Bottom right: difference on/off image.

as the chemical shift of water entrapped within the liposomes depends upon the nature and concentration of the shift reagent as well as on the permeability of the liposome membrane, one may envisage facile access to a number of LIPOCEST agents with different absorption frequencies. This approach will allow a dramatic extension of the experiments that can be carried out by having the possibility of irradiating the various LIPOCEST agents present in the same sample specifically.

Experimental Section

The dotma ligand was provided by Bracco Imaging (Milano, Italy) and the corresponding Tm^{III} complex was prepared according to the published procedure, and characterized by ^1H NMR spectroscopy.[7] DPPG, POPC, and cholesterol were purchased from Sigma-Aldrich.

The liposomes were prepared according to the thin-film hydration method.[17]

The size of the liposomes were determined by photon correlation spectroscopy using a 90 Plus instrument (Brookheven, New York, USA) at a fixed scattering angle of 90° and 25 °C.

The total concentration of the Tm^{III} complex in the liposome suspension was determined by using the "bulk magnetic susceptibility" method (*tert*-butyl alcohol was used as the inert reference).[18]

Saturation transfer efficiency (ST%) was calculated by using Equation (1), where I_S and I_0 refer to the intensities of the bulk water signal when the irradiation pulse is set at the resonance frequency of the water protons entrapped within the liposomes (I_S) or on a frequency equally spaced with respect to the bulk water, but in the opposite direction (I_0).[6]

$$ST\% = (1-\frac{I_S}{I_0})100 \quad (1)$$

ST% values and the MR images were obtained on a Bruker Avance300 instrument operating at 7 T and equipped with a micro-imaging probe (inner diameter 10 mm). The image reported in Figure 3 (bottom right) is the difference between two images (top) obtained by irradiating the resonance frequency of the water protons inside the liposome (on-image, 930 Hz from bulk water) and acquired under off-resonance conditions (off-image, −930 Hz from water protons), respectively. Both images (matrix 64 × 64) were obtained by using a conventional RARE sequence (TR/TE/NE = 9 s/3.3 ms/1, RARE factor 8) preceded by a train of sinc3 pulses (120 pulses, 25 ms each, irradiation B_1 field 12 μT). The total acquisition time for each image was about 1 minutes.

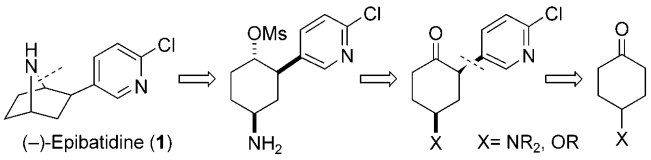
Enantioselective α-Arylation of Cyclohexanones with Diaryl Iodonium Salts: Application to the Synthesis of (−)-Epibatidine**

Varinder K. Aggarwal and Berit Olofsson*

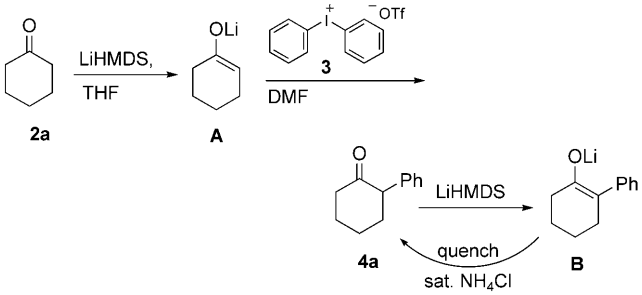
The enantioselective introduction of electrophiles α to carbonyl groups is a central topic in asymmetric synthesis. Although asymmetric α-alkylations have been well developed, high enantioselectivity in α-arylation of ketones has only been achieved in a very limited number of cases. These involve arylation of trisubstituted enolates using binap–Pd complexes which gives non-epimerizable, tetrasubstituted ketones.[1,2] However, this strategy cannot be used in the desymmetrization/arylation of cyclic ketones, since even if the enolate was generated enantioselectively, the ketone product would racemize the starting enolate (through proton transfer) at the high temperatures required for arylation.



An alternative strategy involves α-arylation of β-ketoesters with aryl lead reagents (Scheme 1).[3] This strategy can be

Scheme 1. Possible asymmetric routes toward 2-aryl cyclohexanones.

rendered asymmetric through 1) desymmetrization/β-ketoester formation,[4] 2) arylation,[3] and 3) decarboxylation and subsequent equilibration.



However, a direct asymmetric arylation of cyclohexanones would clearly be superior. If this could be achieved, we envisaged that this strategy could be applied to a short asymmetric synthesis of the alkaloid (−)-epibatidine (**1**) (Scheme 2). Herein, we describe our success in achieving these goals.

Scheme 2. Retrosynthesis of (−)-epibatidine.

As possible electrophilic sources of aryl reagents, we considered diaryl iodonium(III) salts since scattered reports existed of couplings with silyl enol ethers,[5] ketones,[6] and malonates,[7] albeit with varying yields. The scope and limitations of these couplings had not been investigated, and no successful asymmetric reactions have been reported.[8] Indeed, the dearth of examples of enolate arylations with diaryl iodonium(III) salts encouraged us to explore this area further.

The coupling conditions were optimized with cyclohexanone (**2a**) and the commercially available diphenyl iodonium salt **3** (Scheme 3).[9] Under optimized conditions arylation of cyclohexanone (**2a**) gave **4a** in 83% yield (entry 1, Table 1). It should be noted that 2 equivalents of base are required; the second equivalent is used to deprotonate the product ketone.[10] Despite the fact that part way through the reaction enolates **A** and **B** are both present, no bis-arylated product was observed under our optimized conditions (Scheme 3).[11]

Scheme 3. α-Arylation of cyclohexanone (**2a**); HDMS = hexamethyldisilazide.

When applied to 4-substituted cyclohexanones **2b–d**, the coupling reaction afforded 2,4-disubstituted products **4b–d** in high yields and with high diastereoselectivities (Table 1).[12] As expected, arylation of *tert*-butyl ketone **2b** resulted in **4b** with high *cis* selectivity (entry 2), whilst ketone **2c** yielded a 5:1 *cis*/*trans* mixture (entry 3). In contrast, reaction of the 4-silyloxy ketone **2d** led to **4d** with high *trans* selectivity, the 4-OTBDMS occupying the axial position (entry 4). It has been suggested that an attractive electrostatic interaction and/or an n,π* orbital overlap between the silyloxy group and the carbonyl carbon favors the axial orientation of 4-alkoxy substituents and so the *trans* isomer is likely to be the

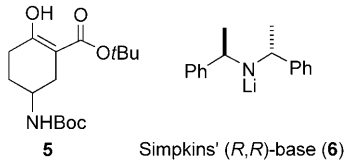
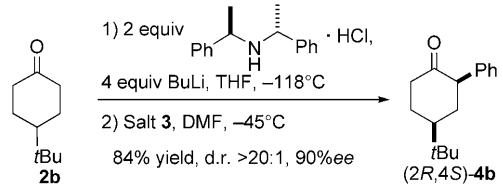
Table 1: Couplings of ketones **2** and diphenyl iodonium salt **3**.[a]



2a–f **4a–f**

Entry	Ketone (R)	Base	Yield of **4** [%][b]	*cis*/*trans*
1	**2a** (H)	LHMDS	83	–
2	**2b** (*t*Bu)	LDA	69	>20:1
3	**2c** (Ph)	LDA	76	5:1
4	**2d** (OTBDMS)	LDA	70	1:15
5	**2e** ($NBoc_2$)	LHMDS	18[c]	>20:1
6	**2f** (NHBoc)	LDA	31[d]	10:1

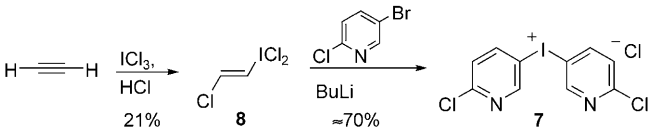
[a] Conditions: The ketone was treated with LHMDS or LDA at −78 °C in THF. Salt **3** was added in DMF and the reaction was stirred at −45 °C for 4–5 h. LDA = lithium diisopropylamide, TBDMS = *tert*-butyldimethylsilyl, Boc = *tert*-butoxycarbonyl. [b] Yields of isolated products. [c] The major product was Boc-transfer product **5**, see text. [d] 2,2-Diphenyl-4-NHBoc ketone (38%) and **2f** (30%) were also isolated.



thermodynamically more stable product.[13,14] Application of this methodology to 4-aminoketone **2e**[15] was complicated by an unexpected intramolecular Boc-transfer reaction, yielding enol ester **5** as the major product (37%) (entry 5 and Scheme 4).[16] The Boc-transfer could be avoided by employing ketone **2f**, but the yield of **4f** was moderate due to competitive deprotonation of the carbamate nitrogen.[17] This entry shows that enolate **B** (Scheme 3) can indeed react to give disubstituted product when enolate **A** is absent, as the major product in this case was the corresponding diphenyl compound (38%).

5 Simpkins' (*R*,*R*)-base (**6**)

Scheme 4. Boc-transfer product **5** and chiral base **6** used in asymmetric reactions.

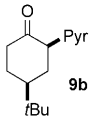


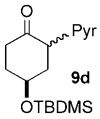
Employing Simpkins' (*R*,*R*)-base (**6**; Scheme 4) instead of LDA or LHMDS, we found that *tert*-butylcyclohexanone (**2b**) gave the arylated product (2*R*,4*S*)-**4b** in 84% yield and 90% enantiomeric excess (Scheme 5).[18] The enantioselectivity was in the range typical for this class of desymmetrization,[19,20] which clearly indicates that proton transfer between the product and the starting enolate was not occurring. Had this occurred, lower enantioselectivity would have been expected because the second equivalent of base would have deprotonated the ketone at −45 °C instead of −118 °C. Evidently, the second equivalent of base acted to directly deprotonate the arylated ketone.

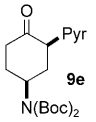
Scheme 5. Asymmetric coupling with Simpkins' base.

Having established the asymmetric methodology for the α-arylation of cyclic ketones, we sought to apply it to a short enantioselective synthesis of epibatidine (**1**; Scheme 2). This alkaloid, which was isolated from the Ecuadorian poison frog *Epipedobates tricolor* in 1993, is 400 times more potent than morphine as an analgesic, and is also an extremely potent agonist of the nicotinic acetylcholine receptor.[21] Numerous syntheses of epibatidine have since been published, most of which are racemic.[22] One commonly employed strategy to introduce the pyridyl group involves an organometallic coupling with a 2-halosustituted cyclohexanone,[23,24] a reaction that cannot be rendered asymmetric (since the starting material is already chiral). As depicted in our retrosynthesis (Scheme 2), the direct coupling of a 4-substituted cyclohexanone with a pyridyl iodonium salt not only shortens the synthetic pathway but also renders the synthesis asymmetric.

Our strategy required a pyridyl iodonium salt that had not been previously prepared. After some experimentation, pyridyl salt **7** was synthesized in good yield from compound **8** and commercially available 2-chloro-5-bromopyridine (Scheme 6).[25]







Scheme 6. Synthesis of pyridyl iodonium salt **7**.

Various cyclohexanones were treated with chiral base **6** and coupled with salt **7**, leading to the corresponding arylated ketones with high enantioselectivities and moderate to good yields (Table 2).[22,26] The pyridyl group on the iodonium salt had a negative impact on the yield of the coupling of ketones **2a** and **2b**. Whilst the diphenyl iodonium salt **3** gave **4a** in 83% yield, the pyridyl iodonium salt **7** only gave a 51% yield of coupling product **9a** (entry 1, Tables 1 and 2 respectively). Fortunately ketones **2d** and **2e**, both possible precursors to epibatidine, proved to be better substrates in the coupling reaction with the pyridyl iodonium salt **7**. Ketone **2d** has been previously employed in asymmetric desymmetrization reactions.[19,27] When this substrate was treated with base **6** and coupled with iodonium salt **7**, 2-pyridyl ketones **9d** were obtained in good yield and high enantioselectivity (entry 3). Interestingly, whilst the 2-phenyl ketone **4d** was formed with high *trans* diastereoselectivity (Table 1, entry 4), the 2-pyridyl ketone **9d** was produced with modest *cis* selectivity.[28]

Although asymmetric desymmetrization of ketone **2e** had not been previously reported, we expected that the steric bulk provided by the $N(Boc)_2$ moiety would lock the conformation of the cyclohexanone ring and thus lead to good asymmetric induction. Indeed, enantioselective deprotonation with base **6** and subsequent coupling afforded pyridyl ketone **9e** in 41%

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

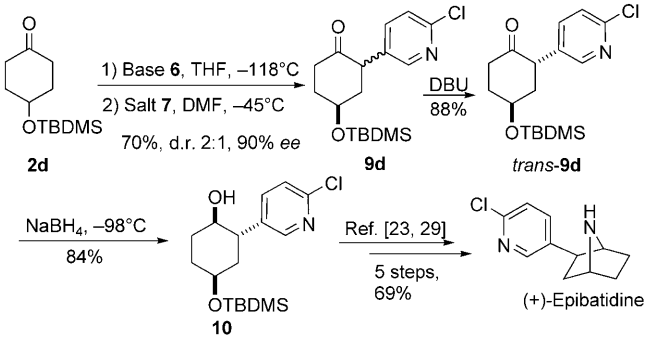


Table 2: Asymmetric couplings with pyridyl iodonium salt **7**.[a]

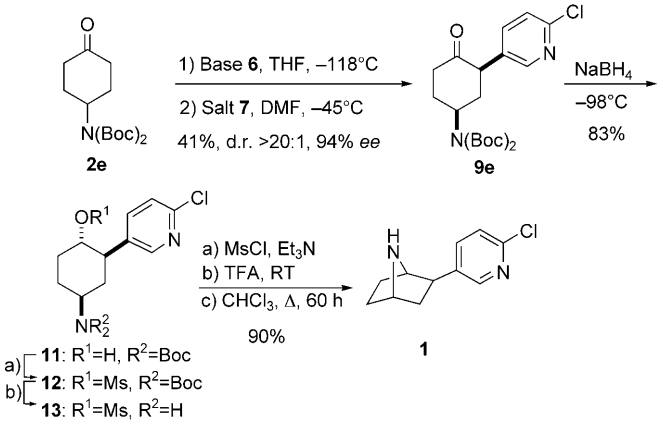
Entry	Ketone	Product[b]	Yield [%][c]	*ee* [%]
1	**2a**	 **9a**	51	–
2	**2b**	 **9b**	51	90
3	**2d**	 **9d**	70[d]	90
4	**2e**	 **9e**	41[e]	86 (94)[f]

[a] Conditions: The ketone was treated with base **6** at −118 °C in THF (entry 1: LHMDS at −78 °C). A solution of salt **7** in DMF was added and the reaction was stirred at −45 °C for 4 h. [b] Pyr = 5-(2-chloropyridyl). [c] Yields of isolated products. [d] *cis*/*trans* 2:1, 13% recovered **2d**. [e] Compound **5** isolated in 14% yield. [f] After recrystallization.

yield and 86% *ee* with complete *cis* selectivity (entry 4). Furthermore, a single recrystallization enhanced the enantiomeric excess of **9e** to 94%. This result indicates that salt **7** is more reactive than the diphenyl salt **3**, as much less of the Boc-transfer product was observed in this reaction.



Having established the asymmetric α-arylation reaction we proceeded to complete the synthesis of epibatidine with ketones **2d** and **2e**. Commercially available ketone **2d** was employed in a formal synthesis of (+)-epibatidine (Scheme 7). As discussed above, the asymmetric iodonium

Scheme 7. Formal synthesis of (+)-epibatidine.

coupling afforded 2-pyridyl ketone **9d** as a kinetically formed 2:1 *cis*/*trans* mixture, which was equilibrated with DBU (1,8-diazabicyclo[5.4.0]undec-7-ene) to afford a separable 1:4 mixture with *trans*-**9d** as the major diastereomer. Ketone *trans*-**9d** was subsequently reduced with sodium borohydride to give the corresponding equatorial alcohol **10** in 84% isolated yield (d.r. 10:1 in crude). Alcohol **10** has previously been transformed into epibatidine in a further five steps,[23,29] thus providing a short and high-yielding formal synthesis of (+)-epibatidine. The optical rotation of **10** revealed that although the 4-OTBDMS group in **2d** prefers the axial conformation, it must be the *equatorial* conformation that becomes deprotonated by the chiral base.[30]

Alternatively, transformation of ketone **2e** to naturally occurring (−)-epibatidine could be performed in five straightforward steps (Scheme 8). 2-Pyridyl ketone **9e** was formed

Scheme 8. Synthesis of (−)-epibatidine. Ms = methanesulfonyl, TFA = trifluoroacetic acid.

with high enantiomeric excess, as discussed above, and reduced to alcohol **11** using sodium borohydride at low temperature with high diastereoselectivity (d.r. 7:1 in crude). Compound **11** was converted into (−)-epibatidine ($[\alpha]_D^{20} = -6.2$ ($c = 0.21$, CH_2Cl_2); literature value:[22b] $[\alpha]_D^{25} = -6.7$ ($c = 0.21$, CH_2Cl_2)) by sequential mesylation, deprotection and ring-closure in 90% yield over the three steps.[31] The total synthesis was thus accomplished in six steps and 31% overall yield from commercially available **2f** with essentially complete control of diastereoselectivity, thus providing the shortest and most efficient asymmetric route to this important compound to date.[32]

In summary, a direct asymmetric α-arylation of cyclohexanones has been developed. The method employs Simpkins' base to desymmetrize 4-substituted cyclohexanones by asymmetric enolization followed by coupling with diaryl iodonium salts, leading to 2-aryl ketones in moderate to good yields and high enantioselectivities. The method expands the scope of the desymmetrization strategy pioneered by Simpkins and Koga, and highlights the utility of iodonium salts for aryl transfer reactions in synthesis. This approach has been applied in a short and efficient total synthesis of (−)-epibatidine and a formal synthesis of (+)-epibatidine.

Highly Efficient $NaNO_2$-Catalyzed Destruction of Trichlorophenol Using Molecular Oxygen**

Xinmiao Liang, Dongmei Fu, Renhua Liu,* Qing Zhang, Tony Y. Zhang, and Xinquan Hu**

Polychlorinated phenols (PCPs) are a class of compounds once widely used as wood preservatives, pesticides, insecticides, and defoliants. Moreover, an alarming amount of these compounds are produced by the pulp industry as a result of lignin chlorination by chlorine-based bleaching processes. The remarkable resistance of these compounds toward degradation led to their substantial release into the environment, even in treated pulp waste streams.[1,2] Their numerous and abundant points of entry, inherent toxicity, persistence, and their presence in significant quantities in the environment have resulted in chlorophenols becoming one of the worst offenders in the environment, and are listed by the US Environmental Protection Agency as priority pollutants.[3]

Eradication of these persisting pollutants from the environment has attracted much attention from academia, industry, and governmental agencies. However, for a number of reasons, decades of efforts aimed at the treatment of PCPs have met with a limited degree of success with regard to efficiency, complexity, and industrial viability. While biological methods for the treatment of PCPs have been intensively investigated,[4–6] progress in this field to date has been hampered by the inherent toxicity of PCPs against the organisms used. Adding to the frustration is the finding of the tendency of some microorganism to convert some PCPs into even more toxic and more persistent pollutants such as polychlorinated dibenzo-*p*-dioxins.[7] As a result of these limitations on bioremediation, environmental chemists have turned their attention to chemical methods for destroying these pollutants. Catalytic reductive dechlorination (CRD) has been extensively investigated as a direct method to decrease the level of PCPs, and high efficiency has been achieved.[8,9] A major drawback to this method is its inability to reduce the overall chemical oxygen demand (COD) in the waste, thus necessitating a secondary treatment of the waste stream after reductive dechlorination. In addition, catalysts for CRD are usually noble metals, which could be deactivated by complex pollutants. On the other hand, advanced oxidation processes (AOPs), which are designed to destroy the environmental pollutants and reduced COD level, are emerging as a versatile strategy to achieve this goal.[10–12] A representive example of an AOP highlighted by Meunier and co-workers is the H_2O_2-based oxidative degradation method.[2,13] In this process a degradation of 99% of trichlorophenol (TCP) was obtained with release of 70% chlorine and 14% carbon mineralization by using iron phthalocyanines as a catalyst, 30% H_2O_2 (5 equiv) as an oxidant, and acetonitrile as a cosolvent in a buffered solution. Lenoir, Collins, et al. have further demonstrated the effectiveness of this homogeneous oxidation pathway for PCPs.[14] They have demonstrated a degradation of 99% TCP by using an iron complex of a tetraamidomacrocyclic ligand (Fe-taml) with 100-fold excess of H_2O_2 at 25°C. In that process, 35% carbon mineralization was achieved, together with 46.5% conversion to low-molecular-weight acids and 83% of the chlorine atoms being released as free chloride. In light of these ground-breaking results, we sought to discover and develop innovative and economically feasible technologies that would be intrinsically easy to industrialize. Specifically, we focused our efforts on finding a catalytic system that uses inexpensive and easily available oxidants/catalysts, and are operationally economical in an industrial setting. As such, one key criterion is the use of minimum quantities or total elimination of transition metals, organic solvents, and hazardous oxidants. Herein we reported our preliminary results toward achieving these goals.

Recently we reported a highly efficient catalytic aerobic oxidation system for alcohols that did not necessitate a transition-metal catalyst.[15,16] Key to the newly developed oxidation process is the ability of a nitrite salt to activate molecular oxygen as well as the suitability of the system towards an aqueous environment. It was intriguing to see if this $NaNO_2$/molecular oxygen method could be adopted for the destruction of the environmental pollutants such as PCPs. Thus, we started our research with TCP as the prototypical PCP substrate in high dilution (thus mimicking the environmental contaminant level) with $NaNO_2$ under pressurized oxygen. After systematic investigation and optimization of the reaction conditions (temperature, oxygen pressure, and amount of $NaNO_2$), we developed an efficient and simple oxidative degradation method for TCP.

Several features of this simple yet robust system are worth noting. First, the catalytic system results in fairly efficient removal of TCP at a moderate reaction temperature (Table 1 entries 1–4). As the reaction temperature increases, the rate of TCP destruction increased correspondingly and the color of the reaction mixture underwent the anticipated changes: from colorless to pink, then to yellow, and finally to colorless,

[d] The trace of dioxin in the TCP raw material was decreased by more than 80% under the above conditions. –: not determined. TCP: trichlorophenol; COD: chemical oxygen demand; TOC: total organic carbon.

as observed in previous research studies.[13,14] We were pleased to find that at a relatively mild reaction temperature (150 °C) with a stoichiometric amount of $NaNO_2$, 99% TCP was removed and 91% of the chlorine atoms of the TCP were released as innocuous inorganic chloride (entry 4). With a catalytic amount (1 mol%) of $NaNO_2$, 25% TCP degradation and 11% chlorine mineralization was observed (entry 5). This result clearly implicated the role of $NaNO_2$ as an active catalyst. Furthermore, a control experiment indicated that the oxidative destruction of TCP was totally ineffective in the absence of $NaNO_2$. This catalytic system also shows the degradation rate of TCP is rapid, for example, within only 1 hour, 92% TCP was removed and 68% chloride was released from the TCP (entry 8). Increasing the reaction time led to a slow increase in the removal of TCP, but a much greater extent of COD reduction. It is noteworthy that with 100 mol% $NaNO_2$, (which is within the feasible range given the relatively low environmental concentration of PCPs) under 0.5 MPa of O_2 and at 150 °C, more than 99% TCP was destroyed with 96% dechlorination and 72% COD reduction after 8 h (entry 10). The oxygen pressure had no significant influence on the reaction efficiency of the current catalytic system (entries 11–14). When air was used in place of pure oxygen, no apparent difference was observed (entry 15 versus entry 13). Finally, to demonstrate the viability of this new aerobic TCP degradation method for potential industrial applications, a scale-up experiment was carried out in a 5-L Hastelloy autoclave (entry 16). We observed a slightly lower degradation at this larger scale compared with the reaction in the small autoclave (entry 16 versus entry 4), which can be attributed to better agitation efficiency in the smaller vessel and can be easily compensated by a modest increase in temperature (entries 17–20). Overall, when all the facets of this new oxidation system is considered, the use of inexpensive $NaNO_2$ and air as reagents rendered it very attractive for potential application at an industrial scale for the treatment of these persistant environmental pollutants.

The extent of mineralization is also one of the critical factors for the evaluation of a new oxidative degradation system. Toward this end, we determined both the inorganic chloride released and the residual total organic carbon (TOC). The amount of chloride ions generated was measured by ion chromatography. As shown in Table 1, chlorine mineralization is up to 96% after 8 h at 150 °C (entry 10). TOC measurements indicated that 77% of the carbon in TCP was mineralized (entry 20). These analyses demonstrate that TCP was nearly completely destroyed and a considerable amount was mineralized; only a fraction of the TCP was converted into lower organic products (Scheme 1). The mass balance was determined by reduction of the TOC and some

Scheme 1. Products formed after TCP degradation by $NaNO_2$-catalyzed oxidation.

measurable reaction products such as acetic acid (**1**), formic acid (**2**), pyruvic acid (**3**), succinic acid (**4**), and oxalic acid (**5**) were identified and quantified with known standards by ion chromatography (Figure 1). The fate of 90% of the carbon atoms is accounted for (Table 2, entry 19). Gas chromatography/mass spectrometry (GC-MS) was used to identify residual organic compounds in the reaction mixture (Table 1, entry 18) and the results show that the major product is succinic acid (**4**), a fairly innocuous compound with a short environmental half-life. Other detectable minor

components from the degraded mixture include levulinic acid (**6**), fumaric acid (**7**), 2-methylsuccinic acid (**8**), glutaric acid (**9**), and 3-carboxypentanedioic acid (**10**, Figure 2). Interestingly, the GC-MS results indicated that most detectable degradation products do not contain chlorine atoms, which is consistent with the extent of mineralization of the chlorine atoms. To the best of our knowledge, this is the first demonstration of $NaNO_2$, a simple, inexpensive and biodegradable inorganic compound, as a catalyst to activate molecular oxygen for the destruction of PCPs. Its remarkable effectiveness at attacking substances with low reduction potentials such as polychlorinated aromatic compounds has not been reported previously. However, several reports on biologically mediated systems[17–22] have provided useful insights for understanding the current oxidative degradation process. We postulate that peroxynitrite, which possesses activity similar to a hydroxyl radical, is most likely to be involved in the present catalytic system and acts as the veritable active oxidant for the degradation of TCP. Elucidation of the detailed mechanistic pathway will undoubtedly shed light on the pathway and allow further optimization of this aerobic oxidative degradation system.

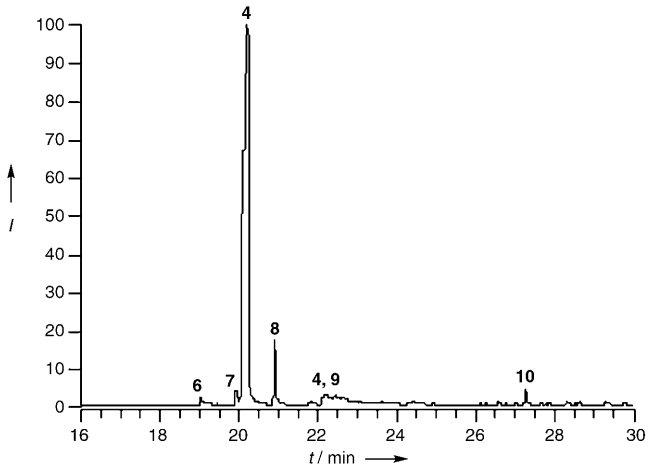

Figure 2. Products of TCP degradation detected by GC-MS after esterification.

The $NaNO_2/O_2$ system efficiently oxidizes the recalcitrant TCP into CO_2 and/or CO and a small fraction of biodegradable organic products with a high conversion rate. To the best of our knowledge, such a high extent of mineralization has not been reported previously without resorting to the extreme measure of high-temperature combustion. In addition, this system is intrinsically devoid of complications caused by other components found in industrial effluents, which tend to deactivate metal catalysts and render metal-based aerobic oxidation of pollutants ineffective. This non-transition-metal system is also free of the risk of secondary pollution during treatment as the catalyst, $NaNO_2$, was oxidized to $NaNO_3$. Therefore, this practical, inexpensive and efficient catalytic system represents a significant step forward in the fight against recalcitrant chlorinated organic pollutant and displays considerable promise for its practical application in an industrial setting.

Experimental Section

The catalytic oxidation of trichlorophenol (TCP) was carried out in a 50-mL teflon-lined stainless-steel autoclave. The reaction temperature was measured using a thermocouple and controlled by a PID regulator. TCP solution (20 mL, 1 mM) and $NaNO_2$ (20 μL, 1M) were added to the autoclave with a magnetic stirrer, thus, the mole ratio of TCP/$NaNO_2$ was 1:1. The autoclave was then closed and charged with pure oxygen to 0.5 MPa and then heated to the desired temperature. The stirring speed was set at 500 rpm. After reaction (heating time included), the autoclave was cooled to room temperature with a water bath, carefully depressurized, and sampled to perform further analysis. For scale-up experiments, TCP (395 mg, 1 equiv) and $NaNO_2$ (27.6 mg, 1 equiv) were added to the 5-L Hastelloy autoclave containing pure water (2 L, Millipore). The stirrer speed was set at 600 rpm. The rest of the procedure was similar to that described for the small-scale reaction.

Asymmetric Photocycloaddition in Solution of a Chiral Crystallized Naphthamide**

Masami Sakamoto, Atsushi Unosawa, Shuichiro Kobaru, Ayako Saito, Takashi Mino, and Tsutomu Fujita*

Asymmetric synthesis starting from an achiral material and in the absence of any external chiral agent has long been an intriguing challenge to chemists[1] and is also central to the origin of optical activity in Nature.[2] Stereospecific solid-state chemical reactions of chiral crystals formed by spontaneous crystallization of achiral materials are defined as "absolute" asymmetric synthesis, and most of the successful examples of such transformations involve photochemical reactions.[1,3] If the molecular chirality generated by chiral crystallization is retained even after the crystals are dissolved in a solvent, the "frozen" chirality is effectively transferred to the optically active products by various types of asymmetric reactions, besides the solid-state photochemical reaction.[4,5] Herein, we provide the first example of an asymmetric intermolecular photochemical reaction in solution through transfer of the chirality generated by chiral crystallization of an achiral naphthamide.

2-Alkoxy-1-naphthamides **1** were chosen to perform this asymmetric synthesis because the bond rotation between the naphthalene ring and the C=O(NR^1R^2) group corresponds to enantiomerization of **1**, and the rate is considerably affected by the substituents on both the naphthalene ring and the amide group (Scheme 1).[6] Naphthamides comprising a bulky

group such as *N*,*N*-diisopropylamide have stable axial chirality, which is used to advantage in many asymmetric synthesis methods.[7] Therefore, achiral naphthamides **1a** and **1b** that contain a relatively compact amide group derived from piperidine were prepared. X-ray crystallographic analysis of single crystals of **1a** and **1b** revealed that both amides adopt similar molecular conformations and, remarkably, that the carbonyl group in each is twisted such that it lies almost orthogonal to the naphthalene plane.

It was important that the achiral materials crystallized to yield chiral precursors for the proposed asymmetric synthesis. Fortunately, **1a** crystallized in a chiral space group, $P2_12_12_1$, and the constituent molecules adopted a chiral and helical conformation in the crystal lattice. On the other hand, ethoxy derivative **1b** formed a racemic crystalline system, $P2_1/c$.[8]

Recrystallization of **1a** from a mixed solvent system of hexane/chloroform gave colorless cubic crystals. X-ray analysis revealed that each single crystal was chiral and composed of one enantiomer. Circular dichroism (CD) spectra were measured to ascertain whether the chiral conformation was retained after the crystals were dissolved in an organic solvent. When a single crystal selected randomly was dissolved in THF at 5 °C using a cryostat apparatus, a strong Cotton effect was observed at below $\lambda = 350$ nm (Figure 1).

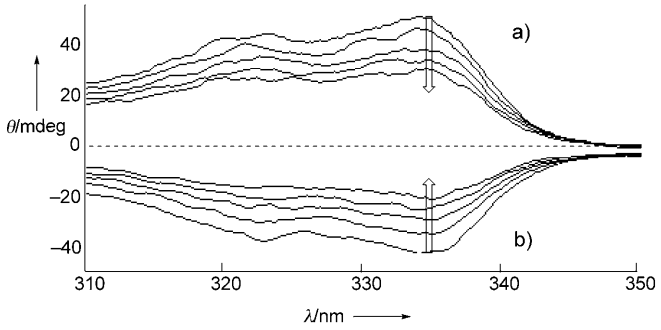

Figure 1. CD spectra of enantiomorphic crystals of **1a** in THF recorded at 5 °C using a cryostat apparatus: a) CD spectra of a solution of crystal (+)-**1a** measured every 10 minutes; b) CD spectra of a solution of a crystal (−)-**1a** measured every 12 minutes.

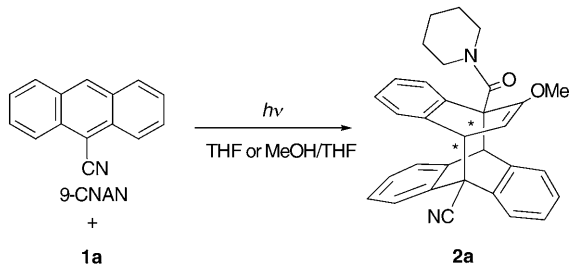

As expected, crystals of both enantiomers, which showed mirror-image CD curves, were easily obtained by crystallization from the solvent. One showed a positive Cotton effect (Figure 1 a), and the other showed a negative Cotton effect at the same wavelengths (Figure 1 b). Furthermore, the Cotton effect gradually decreased with racemization as a result of the rotation about the naphthalene–C(=O) bond.

To study how long naphthamide **1a** retained its molecular chirality after dissolving the crystals in a solvent, we measured the rate of racemization according to the changes in the CD spectra and calculated both the Gibbs free energy of activation ($\Delta G^{\neq}$) and the half-life of enantiomerization ($t_{1/2}$). The half-life was 11.8 minutes when the crystals were dissolved in THF at 15 °C, and the value increased upon lowering the temperature; $t_{1/2}$ values of 19.4 and 36.7 min were determined at 10 °C and 5 °C, respectively (Table 1). The free energy of activation was calculated as $\Delta G^{\neq} = 21.1$–21.2 kcal mol^{-1} from the temperature dependence of the kinetic constant, k (5 °C: $k = 4.90 \times 10^{-4}$; 10 °C: $k = 2.98 \times 10^{-4}$; 15 °C: $k = 1.58 \times 10^{-4}$). The rate of enantiomerization slowed considerably in a mixed solvent system of MeOH/THF. The half-life was 128.3 min at 15 °C and 21.2 min at 25 °C. In MeOH, naphthamide **1a** freezes its molecular conformation and maintains the molecular chirality derived from the crystal over a long period as result of the hydrogen-bonding interaction between the carbonyl group and methanol and also through the rather strong zwitterionic character of the amide group in a polar solvent. These facts indicate that achiral amide **1a** can retain the axial chirality induced in the crystal lattice after the crystallinity is lost and that the lifetime is long enough for application of **1a** in asymmetric synthesis.

Table 1: Kinetic parameters for enantiomerization of naphthamide **1a**.

Solvent	T [°C]	$t_{1/2}$ [min]	$\Delta G^{\neq}$ [kcal mol^{-1}]	$\Delta H^{\neq}$ [kcal mol^{-1}]	$\Delta S^{\neq}$ [cal mol^{-1} K^{-1}]
THF	5	36.7	21.08	17.53	−12.77
	10	19.4	21.11	17.52	−12.69
	15	11.8	21.21	17.51	−12.84
MeOH/	15	128.3	22.58	30.13	26.19
THF	20	62.6	22.46	30.12	26.11
(1:1)	25	21.2	22.32	30.11	26.13

To the best of our knowledge, there are no examples of photocycloaddition reactions of naphthamides with anthracene derivatives,[9,10] so the photocycloaddition of **1a** with 9-cyanoanthracene (9-CNAN) was first examined at room temperature. When a solution of naphthamide **1a** and 9-CNAN (0.05 M each) in THF was irradiated with a high-pressure mercury lamp under argon at room temperature, photocycloaddition occurred effectively and the [4+4] cycloadduct **2a** was obtained in quantitative yield (Scheme 2). The structure of the adduct **2a** was unequivocally established by X-ray crystallographic analysis.[11]

Scheme 2. Photochemical cycloaddition reaction of **1a** in the presence of 9-cyanoanthracene (9-CNAN).

Next, we attempted the asymmetric photocycloaddition using the frozen chirality. A number of chiral crystals of (+)-**1a** were dissolved in a cooled solution of 9-CNAN in THF (−20 °C), and the solution was irradiated with an ultrahigh-pressure mercury lamp for 30 minutes. Only one cycloadduct, (+)-**2a**, was obtained in 100 % yield with 95 % *ee* (Table 2,

Table 2: Asymmetric photochemical cycloaddition reaction of (+)-**1a** with 9-cyanoanthracene (9-CNAN) using the frozen axial chirality.

Entry	Solvent	T [°C][a]	Conc. [M][b]	Conv. [%][c]	*ee* of (+)-**2a** [%][d]
1	THF	−20	0.05	52	95
2	THF	20	0.05	45	29
3	MeOH/THF[e]	−20	0.025	54	94
4	MeOH/THF[e]	20	0.025	40	88

[a] A solution of 9-CNAN was cooled to the cited temperature, and then powdered chiral crystals of (+)-**1a** were added. [b] Concentration of both **1a** and 9-cyanoanthracene. [c] Determined on the basis of the amount of **1a**. [d] *ee* value was determined by HPLC using a CHIRALCEL-ADH column. [e] A 1:1 mixture of MeOH/THF was used.

entry 1). When a mixed solvent system of MeOH and THF was used, a similar enantioselectivity was obtained (94% *ee*; entry 3). Even at 20°C, at which temperature the enantiomerization of **1a** occurs competitively with the photocycloaddition, the adduct from the reaction in THF was obtained with 29% *ee* (entry 2). The rate of enantiomerization is suppressed in MeOH/THF ($t_{1/2} = 62.6$ min at 20°C; Table 1) relative to pure THF, and, surprisingly, the cycloaddition product from the mixed solvent system was obtained with 88% *ee* at 20°C (Table 2, entry 4).

As the rate of racemization of naphthamide **1a** is slow, a high enantiomeric excess of the bulk crystals could not be obtained by recrystallization from a mixed solvent of hexane/chloroform. Therefore, crystals of **1a** used for the asymmetric photoreaction were prepared by stirred crystallization at high temperature,[12] by which the completely melted sample of **1a** at 120°C (m.p.: 110–112°C) was cooled and solidified by lowering the temperature to 100°C with stirring. Five independent crystallization experiments followed by photocycloaddition reactions with 9-CNAN were performed, and the photoadduct **2a** was obtained with enantioselectivities of 92, 97, 96, 94, and 97% *ee*. A high level of reproducibility of both chiral crystallization and asymmetric photoreaction was achieved by this method.

In many cases, the initially generated enantiomorphic crystal works in situ as a seed in the crystallization step such that all the subsequent crystals in the batch have the same absolute configuration.[12] The use of crystals generated in this fashion in the photocycloaddition reaction can lead to isolation of either of the enantiomers of the cycloadduct. For instance, from three independent experiments, (+)-**2a** was obtained on one occasion while (−)-**2a** was afforded in the other two reactions. Of course, the desired crystals of **1a** could be selectively prepared in large quantities by the addition of a corresponding seed crystal during the crystallization process.[13]

In conclusion, we have demonstrated asymmetric intermolecular photocycloadditions with high enantiomeric excess using the "frozen chirality" generated by spontaneous crystallization. The crystallization of achiral molecules in chiral space groups, while rare and unpredictable, is well documented.[1] Extension of spontaneous chiral crystallization to a variety of new systems is possible, and we believe that this methodology can be applied to the development of new absolute asymmetric syntheses.

[13] Seeding was carried out as follows: the melted sample of **1a** at 120 °C was gradually cooled, and a powdered single crystal (about 0.5 mm size) was added at below the melting point of 110–112 °C. The presence of the seed crystal induces the same conformation in the subsequent crystallization such that all the crystals in the batch have the same optical rotation.

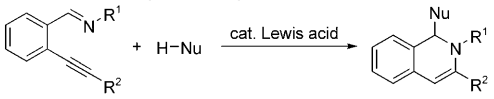
Direct Mannich and Nitro-Mannich Reactions with Non-Activated Imines: AgOTf-Catalyzed Addition of Pronucleophiles to *ortho*-Alkynylaryl Aldimines Leading to 1,2-Dihydroisoquinolines



Naoki Asao, Salprima Yudha S., Tsutomu Nogami, and Yoshinori Yamamoto*

The Lewis acid and/or transition-metal-catalyzed addition of carbon nucleophiles to imines is one of the most important methods for the preparation of nitrogen-containing organic compounds.[1] In particular, the direct addition of carbon pronucleophiles to imines in the presence of catalysts is highly desirable as it represents an atom-economical approach. Previously, we reported the first example of the transition-metal-catalyzed direct addition of malononitrile derivatives and simple ketones, such as acetone, to activated imines [Eq. (1)].[2]

This transformation is useful for synthesizing amines and amino acid derivatives. However, activated imines that bear an electron-withdrawing group on the imine nitrogen atom have to be used as a substrate to induce the addition of pronucleophiles. Although direct Mannich-type reactions of activated ketones and malonates[3] and direct nitro-Mannich (aza-Henry) reactions catalyzed by metals and Brønsted acids were reported recently,[4] activated imines were also required in these cases. Herein, we report new direct Mannich and nitro-Mannich reactions of non-activated imines; AgOTf-catalyzed addition of carbon pronucleophiles to *ortho*-alkynylaryl aldimines **1** produces 1,2-dihydroisoquinoline derivatives **2** in good to high yields (Table 1).[5] Treatment of **1a** ($R^1 = R^2 = Ph$) with nitromethane (2 equiv) in the presence of AgOTf (3 mol%) in $(CH_2Cl)_2$ at 80°C for 1.5 h gave 1-nitromethyl-2,3-diphenyl-1,2-dihydro-isoquinoline (**2a**) in 85% yield (Table 1, entry 1). On the other hand, the reaction of benzylidene phenylamine, which bears no alkynyl group at the proximal position, under similar conditions did not give the corresponding addition product, and the starting material was recovered in 81% yield. This result clearly showed that the *ortho*-alkynyl group of **1a** is essential for the present direct addition of nitromethane to the imine moiety. Besides AgOTf, $Cu(OTf)_2$ was a suitable catalyst for the present reaction while the AuCl-catalyzed reaction gave **2a** in only 1% yield (Table 1, entries 2–3). Other starting materials **1b–e** were suitable for this reaction, and the corresponding

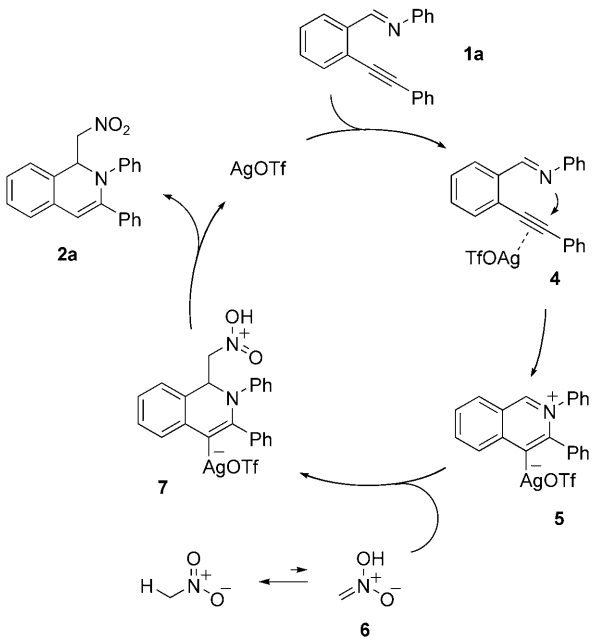
products **2b–e** were obtained in moderate to high yields (Table 1, entries 4–7). The reaction of **1a** with nitroethane gave **2f** as a mixture of diastereomers (d.r. 84:16, stereochemistry not determined; Table 1, entry 8). The reaction of **1a** with other pronucleophiles that bear activated methylene groups proceeded smoothly, and the corresponding dihydroisoquinoline derivatives **2g–i** were obtained in moderate to high yields (Table 1, entries 9–11). The reaction of **1a** with acetone (2 equiv) gave **2j** in a low yield. However, when acetone was used as the solvent, the direct addition proceeded smoothly, and **2j** was obtained in 80% yield (Table 1, entry 12). The reaction with CH_3CN proceeded in a low yield, even when the reaction was carried out in CH_3CN; however, when $[Rh(cod)(PPh_3)_2PF_6]$ was used as catalyst instead of AgOTf, the corresponding product **2k** was obtained in 61% yield (Table 1, entry 13).

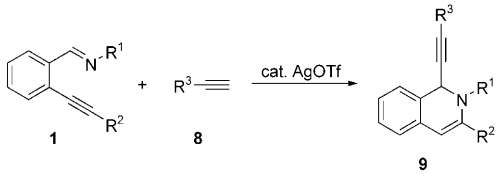
Interestingly, the direct pronucleophile addition could also be applied to the pyridine derivative **1f**; treatment with nitromethane gave the naphthyridine derivative **2l** in 75% yield [Eq. (2)].

(2)



To clarify the mechanism of the process, we examined the reaction of **1a** with AgOTf in the absence of any pronucleophiles. Treatment of **1a** with AgOTf (1 equiv) in CH_2Cl_2, followed by addition of TfOH gave a crude material, which was recrystallized from a mixture of hexane and EtOH to give isoquinolinium salt **3** in 86% yield [Eq. (3)].[6]

(3)

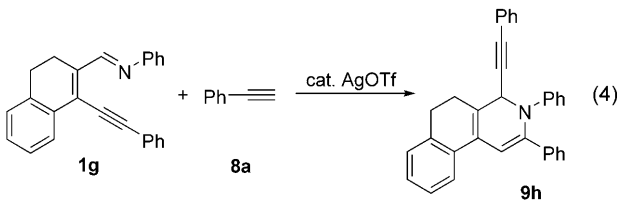


This result clearly indicates that at the beginning of the cyclization the triple bond coordinates to the Lewis acid, as shown in **4** (Scheme 1). Subsequent attack of the nitrogen atom at the electron-deficient triple bond leads to the isoquinolinium intermediate **5**. The addition of aci-nitromethane **6**, which is derived from nitromethane, gives the product **2** via **7**. As shown in Table 1, the AuCl-catalyzed reaction gave **2a** in a very low yield. Indeed, when **1a** was treated with AuCl (1 equiv) under similar reaction conditions as shown in Equation (3), the isoquinolinium salt **3** was obtained in 10% yield, which indicates that the formation of the isoquinolinium intermediate **5** is a key step in the present reaction.

Because the 1,2-dihydroisoquinoline derivatives **2** were produced unexpectedly easily from **1**, we were interested in whether the terminal alkynes **8** could be used as a pronucleophile. The results are summarized in Table 2. The reaction of **1a** with phenylacetylene **8a** under the similar reaction conditions as those given in Table 1 afforded 1-phenylethynyl-1,2-dihydroisoquinoline derivative **9a** in 93% yield. Analogously, the reaction proceeded smoothly with aliphatic

Scheme 1. Proposed mechanism for the AgOTf-catalyzed direct addition of nitromethane to **1a**.

Table 2: Direct addition of terminal alkynes **8** to **1**.[a]



Entry	**1**	R^1	R^2	**8**	R^3	**9**	Yield [%][b]
1	**1a**	Ph	Ph	**8a**	Ph	**9a**	93
2	**1a**	Ph	Ph	**8b**	C_4H_9	**9b**	90
3	**1a**	Ph	Ph	**8c**	CO_2Et	**9c**	86
4	**1b**	C_4H_9	Ph	**8a**	Ph	**9d**	42
5	**1c**	$PhCH_2$	Ph	**8a**	Ph	**9e**	70
6	**1f**	Allyl	Ph	**8a**	Ph	**9f**	70
7	**1d**	Ph	C_4H_9	**8a**	Ph	**9g**	58

[a] The reaction was carried out with **1** (1 equiv) and terminal alkynes **8** (1.2 equiv) in the presence of AgOTf (3 mol%) in $(CH_2Cl)_2$ at 80°C within 6 h. [b] Yields of isolated products.

alkynes, such as hexyne (**8b**), and even with ethyl propanoate (**8c**), and the products **9b** and **9c**, respectively, were obtained in high yields (Table 2, entries 2 and 3). Not only **1a** but also the other substrates **1b**,**c**, and **f**, which have alkyl groups on the nitrogen atom of the imine moiety, were suitable for the present reaction (Table 2, entries 4–6). The reaction of **1d**, which has a butyl group at the end of the alkynyl group, with **8a** also gave **9g** in 58% yield (Table 2, entry 7). Interestingly, the reaction of **1g** with phenylacetylene (**8a**) gave the 3,4,5,6-tetrahydrobenzo[*f*]isoquinoline derivative **9h** in 62% yield [Eq. (4)]. Several methods for direct addition of terminal alkynes to imine compounds have been reported.[7–8] However, the direct addition of alkynes to benzylidene phenylamine, which bears no alkynyl group at the proximal position, did not proceed at all under the present reaction conditions.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

This result again indicates that the presence of an *ortho*-alkynyl group is essential for the imine addition, and the formation of the isoquinolinium intermediate **5** is a key step.

We are now in a position to synthesize functionalized 1,2-dihydroisoquinoline skeletons through the direct addition of various carbon pronucleophiles to *ortho*-alkynylaryl aldimines. Even without the use of the usual activated imines that bear an electron-withdrawing group, the addition to imines proceeded well, probably due to the formation of the reactive isoquinolinium intermediates **5** in situ. In general, the 1,2-dihydroisoquinoline framework can be constructed by nucleophilic addition to isoquinolinium salts, which are derived from the corresponding isoquinolines by acylation or alkylation.[9] Evidently, the present reaction proceeded without such activation, and the current transformation provides an alternative method for the construction of 1,2-dihydroisoquinolines.[10] Further studies to elucidate the precise mechanism of this reaction and to extend the scope of its synthetic utility are in progress in our laboratory.[11]

[10] Recently, we developed a synthetic method for 1,2-dihydroisoquinoline derivatives in the presence of a bis-π-allylpalladium catalyst: M. Ohtaka, H. Nakamura, Y. Yamamoto, *Tetrahedron Lett.* **2004**, *45*, 7339–7341.

[11] The asymmetric version of the present reaction was investigated briefly. The reaction of **1** with nitromethane was carried out in the following catalytic systems; $Cu(OTf_2)$–(*R*)-(+)-2,2′-isopropylidenebis-(4-phenyl-2-oxazoline), $Cu(OTf_2)$–2,2′-isopropylidenebis[(4S)-4-*tert*-butyl-2-oxazoline], $Cu(OTf_2)$–2,6-bis[(4*S*)-(−)-isopropyl-2-oxazolin-2-yl]pyridine, and AgOTf–(*R*)-(+)-2,2′-bis(diphenylphosphanyl)-1,1′-binaphthalene. The reaction gave **2** in good yields, but the enantioselectivities were very low (≈1% *ee*).

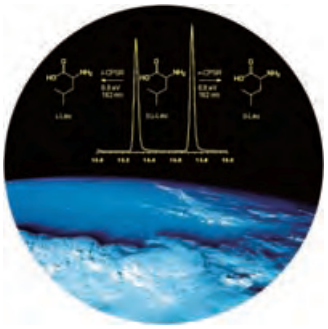
Cover Picture

Holger Braunschweig,* Krzysztof Radacki, Daniela Rais, and David Scheschkewitz



Cationic T-shaped platinum complexes are obtained because of the high *trans* influence of the ferrocenyl(bromo)boryl ligand. Addition of 4-methylpyridine to the platinum(II) boryl complex (as shown in the cover picture) causes displacement of the bromide ion at boron, leading to a cationic platinum complex with a 4-methylpyridine-stabilized borylene ligand (bottom right). For more information on this approach, see the Communication by H. Braunschweig et al. on page 5651 ff.

Mesocrystals
The formation and morphogenesis of mesocrystals apparently contradict the classical textbook knowledge on crystallization. This new type of colloidal crystals is discussed by H. Cölfen and M. Antonietti in their Review on page 5576 ff.

Organic Nanomaterials
One of the central roles of current materials research is a technology based on functional single molecules or small ensembles of molecules. The latest research is described by K. Müllen and A. C. Grimsdale in their Review on page 5592 ff.

Homochirality
U. Meierhenrich, L. Nahon et al. show in their Communication on page 5630 ff. that irradiation of solid D,L-leucine probes with right circularly polarized synchrotron radiation results in an enantiomeric excess of D-leucine.

Who Is Going To Read all This?

DOI: 10.1002/anie.200502730

Samuel Taylor Coleridge (the 18th century poet, critic, philosopher, and opium abuser) is said to have been the last man "to have read everything". Today it is no longer possible for scientists to even read everything (carefully) that is published in their own field, let alone in their discipline. As a result the questions of quality and selection of information become ever more pressing, and electronic search machines can only help a little. When we read a newspaper or watch a news program we want to be sure that the most important information is given quickly and reliably, it is no use finding out later which news was important and which was not. And it would be no help to put the news media to one side and to go directly to the vast amount of information that is made available by the news agencies, we would drown in information and in most cases we would lack the competence to differentiate important and right from unimportant and false.

The same situation exists in science. Today it is certainly possible to make all the research results (including all the raw data) of all scientists available without further selection or improvement as soon as the author has placed the last full stop. In chemistry alone this approach would give far in excess of the approximately 700000 articles currently covered per year by *Chemical Abstracts*[1] because, without barriers and filters, the manuscript output would increase unabated. Even using electronic search engines with stringently selected criteria would still deliver an immense amount of information, you would still have to sort and select yourself. And if, for the sake of curiosity, you wanted to inform yourself about developments in neighboring disciplines, you would be helplessly lost in an ocean of information.

The possibility of having a genuine and uncensored view of all information is one of the basic pillars of a democratic, enlightened society and in this point scientists see themselves as the avant-garde of such a society. However practicalities can not be ignored: Selection is necessary, more than ever! The main burden of responsibility lies with the authors, then with the publishers and editors, and finally, but also very importantly with the referees. The authors are the source of scientific information, and the others decide what information readers can find where; of course, scientists can be authors, editors, and referees all at the same time, but naturally all these roles can not be assumed for the same manuscript.

Selection is necessary, more than ever!

Authors: Their number has increased dramatically again in recent years because with China a new scientific giant has emerged onto the stage. In addition, the productivity of scientists has increased remarkably in the last two decades. Twenty years ago an X-ray structure analysis could take months, today it is usually a matter of hours. A similar trend is true across the whole breadth of instrumental analysis, and the productivity of computer chemists has without doubt risen at an even faster rate. Today, the rate-limiting step in chemistry seems no longer to be obtaining new scientific results, or their publication, but the writing of manuscripts. The high scientific productivity, which is not to be confused with an increase in knowledge, leads to an enormous pressure to publish. This pressure is increased further through the competition for positions, funding, and prizes. Today, authors must publish frequently and publish in respected journals. The quality of a journal is currently all to often reduced to "one with a high impact factor". The pressure of publishing lots has led to the search for the "Lowest Publishable Unit" (LPU) with a consequence that journals are flooded with "low-content/low-quality manuscripts". The hankering after the high impact factor has resulted in many authors giving up a healthy amount of self criticism and sending their manuscript first to a journal in which it has no chance of being accepted. This ideology is already producing fruit as can be seen

... Our manuscript was evaluated by three referees.

Referee 1 finds the work is important and recommends publication to Angewandte Chemie (**IF = 9.16**) after minor revision.

Referee 2 finds the scope of the work is directed to a journal such as Crystal growth and design (**IF = 2.74**)

Referee 3 finds the work of high quality and complements the authors, and feels that it would be a pity not to publish in its actual form. He or she recommends publication in Inorganic Chemistry. (**IF = 3.38**).

We were pleased to read that you spoke with Dr. Karen Hindson and recommended our paper for publication. However I would like to draw your attention that if you add up the values of the IF's of the three journals cited above and then divide by three you will obtain a value of **IF = 5.09**. The closet journal to this value would be *Chemistry A. European Journal*. (**IF = 4.517**). I therefore gently ask you to accept our paper in *Chemistry A. European Journal*, since you are the Editor in Chief...

in the following: An author had a manuscript rejected from *Angewandte Chemie* after the assessment of three scientists. Deputy Editor Neville Compton recommended publication in the *European Journal of Inorganic Chemistry* (the editor of which is Karen J. Hindson) and shortly afterwards received a letter containing the passage reproduced on the previous page.

Clearly not only science administrators but also more and more scientists themselves are taking a completely uncritical view of impact factors. Naturally, journal impact factors can give a general impression about the importance of a journal and its articles, but very little about the quality of an individual article.

Angewandte Chemie
Impact Factor 2004: 9.161
Immediacy Index 2004: 1.966

How often an article is cited depends on many factors: Most important, is the number of researchers currently working on that topic; articles on unfashionable or highly specialized topics, which can certainly be or become very important, are naturally less cited than articles on current, main-stream research. *Angewandte Chemie* publishes articles from the full spectrum of chemistry and thus highly cited articles and less cited articles can stand side by side. The journal's very high impact factor, which increased still further in 2004 (Figure 1), should certainly not be interpreted as indicating that all the articles in *Angewandte Chemie* have the same "impact" or even the same quality—the most cited are perhaps not the most important. Authors should however use the high impact factor to decide, before they submit a manuscript, if their manuscript complies with the high expectations of the journal and its readers. In 2005, *Angewandte Chemie* once again has to cope with a huge increase in the number of manuscripts submitted. In the first six months alone we received 2069 Communications, which is nearly 30% more than in the first six months of 2004. This growth in submissions comes not only from China, but from almost all regions

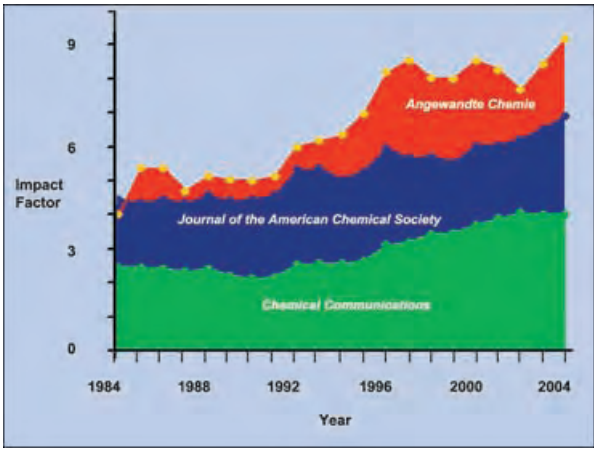

Figure 1. Impact factors of three important chemistry journals. The impact factors are determined by the Institute of Scientific Information (ISI); see http://www.isiknowledge.com

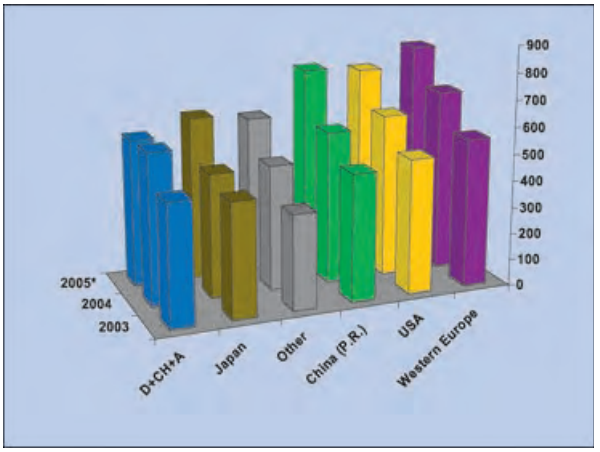

Figure 2. Country or region of origin for Communications submitted to *Angewandte Chemie* in 2003–2005. The values for 2005 are extrapolated on the basis of the first six months.

of the world (see Figure 2). The land of origin for the submitted Communications in 2004 is shown in Figure 3. Currently, nearly 70% of submitted Communications are rejected, though the rejection rate for manuscripts from individual countries varies from 40% to 90%. We would be delighted if the high impact factor led to better journal selection by the authors.

Publishers and Editors (and their advisors from Editorial Boards etc.) are in the front line in dealing with the manuscript flood, and for most journals the selection occurs in several stages: At *Angewandte Chemie* around 10% of manuscripts are rejected immediately (and this figure is increasing), all the others are selected after refereeing. Controlling the manuscript flood requires ever more skilled and trained personnel. The fate of manuscripts and the selection of referees is determined by me, the two Deputy Editors, Neville Compton (Inorganic Chemistry) and Haymo Ross (Organic Chemistry), and four Senior Associate Editors, Frank Maass (Inorganic Chemistry), José Oliveira (Organic Chemistry), Guy Richardson (Inorganic Chemistry), and Diane Smith (Supramolecular Chemistry). All these editors have Doctorates in their specialist areas and in most cases postdoctoral research experience as well as many years experience as full-time editors. We select manuscripts in the interests of our readers—when our readers open an issue or look at Early View articles on the computer screen they should have the guarantee that they are reading something important and not wasting any time. "You've got to feel the heat when you read a journal" Peter Dervan, a member of the International Advisory Board of *Angewandte Chemie* once remarked.

Editors can make mistakes, and in the eyes of authors, almost every rejection is a mistake. However, a rebuttal should only follow if the decisive referee comments are inaccurate or wrong. When it is "only" a difference of opinion on the importance of an article then a rebuttal is usually rejected immediately. The decisions of editors are not based just on the simple mathematics of addition, that is, the receipt of one positive and one negative report does not mean that a third referee must be consulted. Not all referee reports are equally good. After reading the manuscript and the reports (or the only report in some cases) the editors in most cases are quite capable of deciding on the fate of a manuscript. In any case the decision has always to be justified if a member of the Editorial Board or the International Advisory Board asks for this.

Referees are naturally extremely important in the selection process. Working together, editors and referees are able to avoid making unjust and incorrect decisions. In the refereeing phase the system is placed under further pressure: Not only the pressure to publish lots in respected journals, but also the demand to publish quickly. Authors want to see their manuscripts published as fast as possible, even if the collection of the results took years and there is no competition on the horizon. Journals want to be the fastest, "instant publishing" seems to be desired. Referees complain that they have too many manuscripts to assess, and teaching, lectures, and administration can not wait. After the LPU comes the MRR (minimalistic referee report). Many reports for *Angewandte Chemie* demonstrate the expertise of the referees and the desire to help the authors even if the manuscript is recommended for publication in another journal. Regretfully, however, many of these manuscripts are then sent on to the next best journal without improvements—and the same referees might see it again and react accordingly. The refereeing load for *Angewandte Chemie* was carried by over 2000 scientists in the first half of 2005, although of these, round a half gave only one report in the six months. However, in this time 27 referees also had over 10 manuscripts to review (see Table 1). I would like to thank all our referees for their continued support and advice.

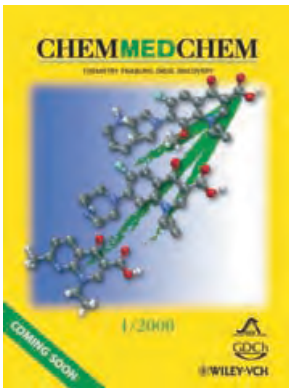
Table 1: Number of reports per referee for *Angewandte Chemie* in the first six months of 2005.

Referees	Reports
1	≥20
2	19–15
24	14–10
176	9–5
148	4
243	3
436	2

Several years ago, the then Editor in Chief of the *Journal of the American Chemical Society*, Allen J. Bard wrote that "quality should never be sacrificed for speed". There is no reason to change this view today. That in the first six months of 2005 we have been able to reduce publication times from first receipt to online publication for *Angewandte Chemie* from, on average 150 days to 110 days, has been made possible through the enormous efforts of the editorial staff and the decision that all manuscripts should be published online in the Early View mode as soon

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

as the corrections from the galley proofs have been incorporated. Many Communications are published (after critical refereeing and careful editing) within three months of submission, and when "danger is looming" in the form of competition, then manuscripts of high-enough quality can even be published in days. Instant publishing is not magic, with current technology any publisher can do it, it is the quality of the manuscript that makes the difference. Through fast publication (and high impact factors) most people forget that what is actually important is that the manuscript is promptly read by many and that its content is used rapidly and productively. A high immediacy index indicates these tendencies; its development from 2003 to 2004 is shown in Figure 4.



Chemistry creates new structures
Angewandte Chemie ***recognizes new structures***

"Chemistry creates new structures" is the motto of the Annual Conference of the Gesellschaft Deutscher Chemiker (German Chemical Society, GDCh) which takes place this year, September 11–14 in Düsseldorf. The excellent program helps, just like every issue of *Angewandte Chemie*, to recognize new structures. To help our readers see the trees *and* the wood, to ensure they do not miss important work in their own field, *and* to help them recognize the big discoveries in Chemistry, is what we aim to do.

Dr. Peter Gölitz

PS: As occasionally in the past, there is a new journal to introduce, which, with the help of *Angewandte Chemie*, should have a successful start. Following on from *ChemBioChem* (www.chembiochem.org) and *ChemPhysChem* (chemphyschem.org) comes *ChemMedChem* (www.chemmedchem.org). The Societá Chimica Italiana (SCI) will close its journal *Il Farmaco* at the end of the year and, from 2006, in conjunction with the GDCh and the publishers Wiley-VCH, will launch *ChemMedChem*.

The new journal, which will offer a European forum for articles from the whole world, will be dedicated to all aspects of drug discovery, with medicinal chemistry in the foreground. From bioinformatics and relevant chemical biology and molecular biology through to combinatorial chemistry, drug targeting, and toxicology a broad pallet of relevant articles (reviews and original research articles) will be presented. High quality is assured by the Editorial Board and the International Advisory Board which are headed by Professors R. Metternich (Schering, Berlin) and G. Tarzia (Università degli Studi di Urbino, Italy)

Horror scenarios have been conjured up, but how harmful, really, are the hormone-like compounds with which we come into contact daily in food, medications, and sunscreens? A xenobiotic can compete with a hormone at the hormone receptor and even block its action, as the picture shows for the estrogen receptor. To cause an observable effect, however, the potency and concentration of the xenobiotic must be sufficiently high, which fortunately is rarely the case.

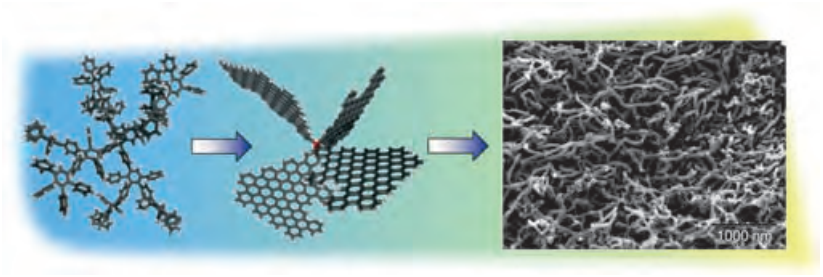
Reviews



Nonclassical Crystallization: Mesocrystals are superstructures of well-aligned nanoparticles, which exhibit common outer faces on the mm or μm scale (see picture, right: SEM image of DL-alanine). They are usually built up from nonspherical nanoparticles which allows for further degrees of orientational freedom so that only very little is known about mesocrystal formation. Mesocrystals are examples of nonclassical crystallization, which were only recently discovered.

Mesocrystals: Inorganic Superstructures Made by Highly Parallel Crystallization and Controlled Alignment

Smaller and better: Thanks to recent progress in organic nanomaterials, functional building blocks based on single molecules or small ensembles of molecules are no longer just the realm of science fiction, but are a realistically attainable goal. The picture shows the different organization steps of functional molecules, from a dendrimer, to a "nanopropeller", to nanotubes.

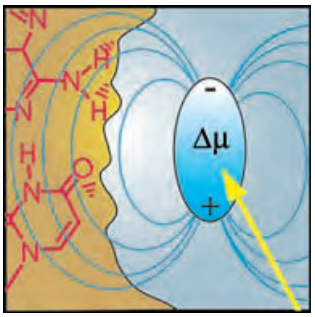
Homochirality

U. J. Meierhenrich,* L. Nahon,* C. Alcaraz, J. H. Bredehöft, S. V. Hoffmann, B. Barbier, A. Brack _____ 5630 – 5634

Asymmetric Vacuum UV Photolysis of the Amino Acid Leucine in the Solid State



One hand clapping: Based on solid-state circular dichroism data, the leucine (π^*, π_1)-electronic transition is excited with right circularly polarized synchrotron radiation (*r*-CPSR) at 182 nm (see scheme). This treatment induced an enantiomeric excess of 2.6% of D-leucine. The results support the assumption that interstellar asymmetric photoreactions are capable of inducing significant enantiomeric enrichments in solid-state amino acids.

Femtosecond Spectroscopy

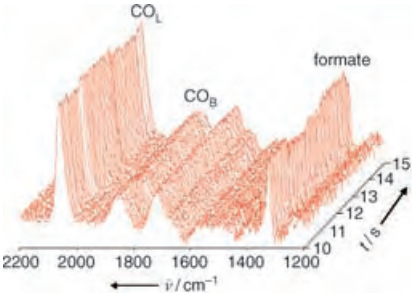
Phosphates

M. Nazaraly, G. Wallez, C. Chanéac, E. Tronc, F. Ribot,* M. Quarton, J.-P. Jolivet ——— **5691 – 5694**

The First Structure of a Cerium(IV) Phosphate: Ab Initio Rietveld Analysis of $Ce^{IV}(PO_4)(HPO_4)_{0.5}(H_2O)_{0.5}$

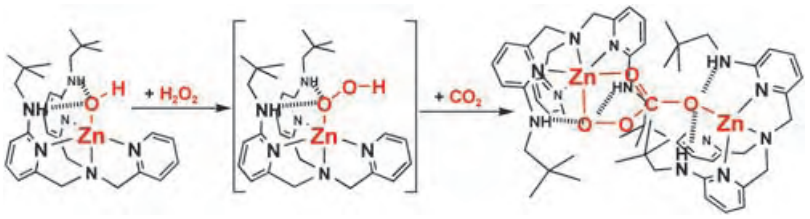
Layer apparent: Crystalline cerium(IV) phosphates have been studied for a long time as ion exchangers, but their structures have remained unknown. The structure of a cerium(IV) phosphate has been determined (see picture: tetrahedra PO_4, yellow Ce, blue O (water)) and clearly explains a notable feature of this compound, its inability to intercalate amines. The X-ray study is supported by solid-state NMR spectroscopy investigations.



Electrochemical Oscillations

G. Samjeské, M. Osawa* ——— **5694 – 5698**

Current Oscillations during Formic Acid Oxidation on a Pt Electrode: Insight into the Mechanism by Time-Resolved IR Spectroscopy

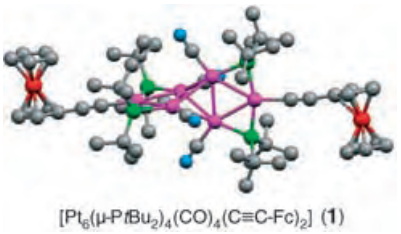


Revised model: Current oscillations in the electrooxidation of formic acid at a fixed potential can be observed by time-resolved surface-enhanced infrared absorption spectroscopy (see picture). Real-time probing of the reaction dynamics on the electrode surface provides new insight into the oscillations that are not accessible by conventional techniques. The reaction mechanism involves adsorbed formate as a reactive intermediate.

Bioinorganic Chemistry

A. Wada, S. Yamaguchi, K. Jitsukawa, H. Masuda* ——— **5698 – 5701**

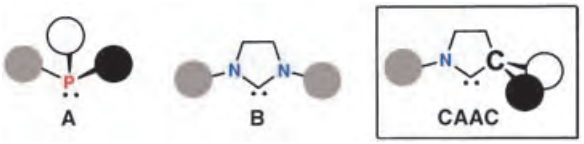
Preparation of a Hydroperoxo Zinc(II) Intermediate



Three legs and four teeth: The tripodal tetradentate ligand bis[(6-neopentylamino-2-pyridyl)methyl][(2-pyridyl)methyl]amine (H_2bnpa) was used to prepare a novel {Zn—OOH} species. The intermediate of the reaction of $[Zn(H_2bnpa)(OH)]^+$ with H_2O_2 (see scheme) was characterized by a combination of ^{1}H NMR spectroscopy and ESI mass spectrometry; further treatment with CO_2 gave $[\{Zn^{2+}(H_2bnpa)\}_2(CO_4^{2-})](ClO_4)_2$.

Electron Transfer

A. Albinati, F. Fabrizi de Biani, P. Leoni,* L. Marchetti, M. Pasquali, S. Rizzato, P. Zanello* ——— **5701 – 5705**

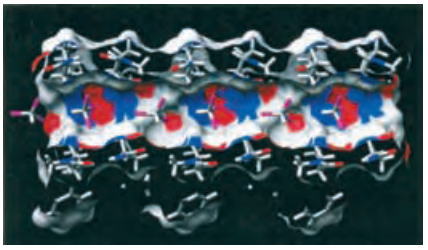


Redox Control of Light-Induced Platinum-Cluster-to-Iron Charge Transfer in a Bis(ferrocenylethynyl)-Substituted Hexanuclear Platinum Derivative

$[Pt_6(\mu\text{-}PtBu_2)_4(CO)_4(C{\equiv}C\text{-}Fc)_2]$ (**1**)

Give and take: Compound **1** (see structure: purple Pt, red Fe, green P, blue O; Fc = [(η-C_5H_5)Fe(η-C_5H_4)]) is prepared in good yields by the CuI-catalyzed coupling of two equivalents of ethynylferrocene with the hexanuclear cluster $[Pt_6(\mu\text{-}PtBu_2)_4(CO)_4Cl_2]$. Electrochemical and spectroelectrochemical data show the presence of photoelectrochemically triggered electron transfer from the $\{Pt_6\}$ core to the peripheral ferrocenyl subunits.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Like NHCs? Not quite: Cyclic (alkyl)(amino)carbenes (CAACs) are strong σ-donors and have steric environments that differ dramatically from those of bulky, electron-rich phosphines (**A**) and cyclic diaminocarbenes (**B**). These readily available carbenes are desirable ligands for catalysis, as illustrated by the first palladium-mediated α-arylation of ketones and aldehydes with non-activated aryl chlorides at ambient temperature.

Homogeneous Catalysis

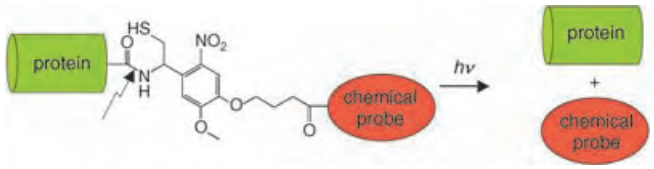
Stable Cyclic (Alkyl)(Amino)Carbenes as Rigid or Flexible, Bulky, Electron-Rich Ligands for Transition-Metal Catalysts: A Quaternary Carbon Atom Makes the Difference



Cyclic peptides can dimerize through β-sheet-like hydrogen bonding. Heterodimerization is favored over homodimerization, which creates interesting combinatorial possibilities without detriment to the functionalization of amino acid side chains. These dimers represent a new class of self-assembling peptide nanotubes in which the hydrophobicity of the internal cavity (see picture) can be controlled.

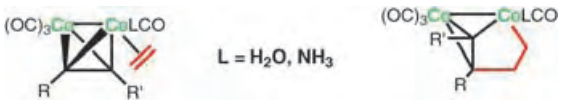
Methyl-Blocked Dimeric α,γ-Peptide Nanotube Segments: Formation of a Peptide Heterodimer through Backbone–Backbone Interactions



Design and light: A photocleavable synthetic moiety is ligated to the C terminus of a recombinant protein. In the ligated state, the chemical and protein components influence the properties of one another. Upon irradiation with light, both elements are released and their respective function is recovered. In this way a protein can be delivered into living cells and activated by UV irradiation at a desired time or location.

Awarded...

During its annual meeting between September 11 and 14, 2005 in Düsseldorf, the German Chemical Society (GDCh) will present numerous awards.

The Adolf von Baeyer Medal for A. de Meijere

Armin de Meijere (University of Göttingen, Germany) will be awarded the Adolf von Baeyer Medal. He will be recognized for his work with strained rings such as cyclopropane, for which he has become known as the "Lord of the Small Rings". His comprehensive chemistry with these strained compounds has led to the development of active agents and novel catalytic procedures. In *Chemistry—A European Journal*, for which he is a member of the editorial board, he recently reported the production of [D_{3d}]-octahedrane, the most stable $(CH)_{12}$ hydrocarbon.[1] De Meijere has literary versatility and is especially active in his capacity as an editor; his two-volume handbook of metal-catalyzed cross-coupling reactions, co-edited with F. Diederich, was published last year by Wiley-VCH.

A. de Meijere

De Meijere studied Chemistry at the Universities of Freiburg and Göttingen, and received his PhD in 1967 under the direction of W. Lüttke. He subsequently worked as a postdoc in the research group of K. B. Wiberg at Yale University in New Haven, Connecticut, USA. He returned to the University of Göttingen in 1969, where he obtained a habilitation in 1971. In 1974, he was named extraordinary professor and in 1977, he accepted a professorship at the University of Hamburg. He returned again to the University of Göttingen in 1989.

Bredereck Prize Goes to H.-A. Wagenknecht

The GDCh awards organic and bioorganic chemists working in the areas of hydrocarbons, heterocycles, nucleotides, and proteins with the Hellmuth Bredereck Endowment. This year, Hans-Achim Wagenknecht (Technical University of Munich, Germany) was honored for his research on charge-transfer mechanisms, the electronic properties of DNA, and the interactions of fluorescent probes in DNA. He recently reported in *Angewandte Chemie* the real-time spectroscopy and chemical probing of reductive electron transfer in DNA.[2]

H.-A. Wagenknecht

Wagenknecht studied Chemistry in Freiburg. He earned his PhD in 1998 in the group of W.-D. Woggon at the University of Basel from research with enzyme models and intermediates of the chloroperoxidase cycle. Over the following two years, he worked with J. K. Barton at the California Institute of Technology (Pasadena, USA). Since 2000 he has led a research group at the Institute for Organic Chemistry at the Technical University of Munich, where he obtained his habilitation in 2004 for his work on charge-transfer processes in DNA.

H. Vahrenkamp Receives Wilhelm Klemm Award

The GDCh gives out the Wilhelm Klemm Award for outstanding contributions to the field of inorganic chemistry. This year it went to Heinrich Vahrenkamp (University of Freiburg, Germany), in recognition of his work in organometallic chemistry. His past research interests dealt with electron transfer in multinuclear complexes, multinuclear carbonyl complexes, and in the potential application of coordination compounds as sensors and catalysts. His research group has focused more recently on the coordination chemistry and biological roles of zinc. Vahrenkamp recently reported on zinc thiolate complexes with tridentate ligands as models for thiolate alkylating enzymes.[3]

Vahrenkamp earned his PhD in 1967 on work with H. Nöth at the University of Munich, Germany, and worked as a postdoc with L. F. Dahl at the University of Wisconsin in Madison, USA. He received his 'habilitation' at the University of Munich in 1972. Since 1973 he has worked as a professor of inorganic chemistry at the University of Freiburg. From 1990 to 1997 he was co-editor of *Chemische Berichte*, one of the predecessors of the *European Journal of Inorganic Chemistry*.

H. Vahrenkamp

The Karl Ziegler Prize for M. Reetz

The Karl Ziegler Prize from the endowment of the same name is awarded by the GDCh in recognition of excellence in the field of inorganic and organic chemistry of catalysts and polymers. Manfred T. Reetz (Max Planck Institute for Coal Research in Mülheim/Ruhr) will receive the award for his work in test-tube evolution as a method for the generation of enantioselective biocatalysts and the development of new methods in asymmetric transition-metal catalysis. His recent report about a new method for expanding the substrate acceptance of

M. Reetz

enzymes through a combinatorial active-site saturation test appears in *Angewandte Chemie*.[4]

Reetz studied at Washington University in St. Louis and the University of Michigan in Ann Arbor, USA. He received his PhD in 1969 at the University of Göttingen under the direction of U. Schöllkopf. He did his postdoctoral research with R. W. Hoffmann at the University of Marburg, where he earned his habilitation in 1974. In 1978, he accepted a position at the University of Bonn, and in 1980 he returned to the University of Marburg. He became a director at the Max Planck Institute for Coal Research in 1991. Reetz is a member of the academic advisory board for *Advanced Synthesis & Catalysis* and has served on the editorial board of *Angewandte Chemie* since 2002.

August Wilhelm von Hofmann Medal Awarded to R. H. Grubbs and R. R. Schrock

Every two years, the GDCh honors foreign chemists and German nonchemist-scientists with the August Wilhelm von-Hofmann Medal. This year, the honor went to Robert H. Grubbs (California Institute of Technology, Pasadena, USA) and Richard R. Schrock (Massachusetts Institute of Technology, Cambridge, USA). Both have made outstanding contributions to the field of organometallic chemistry through organic and polymer synthesis. Grubbs is famous for the development of a range of ruthenium-containing catalysts of olefin metathesis;[5] Schrock's name is associated with alkylidene complexes and ring-opening-metathesis polymerization.[6]

R. R. Schrock

Grubbs received his PhD in 1968 at Columbia University in New York under the direction of R. Breslow. In 1968 and 1969 he worked as a postdoc in the research group of J. P. Collman (Stanford University), and then as assistant and associate professor at Michigan State University in East Lansing. Since 1978 he has held a position as professor at the California Institute of Technology in Pasadena. He is the editor of the 2003 "Handbook of Metathesis" published by Wiley-VCH.

R. H. Grubbs

Schrock earned his PhD in 1971 at Harvard University with J. A. Osborn. He subsequently worked for a year at Cambridge University, and for three years at DuPont de Nemours. He has been active at the Massachusetts Institute of Technology since 1975, and as professor, since 1980. Both Grubbs and Schrock are members of the academic advisory board for *Advanced Synthesis & Catalysis*.

Arfvedson–Schlenk Prize Goes to D. Stalke

The GDCh awards excellence in lithium chemistry with the Arfvedson–Schlenk Prize. This year the honor goes to Dietmar Stalke (University of Göttingen). Stalke completed his PhD studies in chemistry at this university in 1987 with U. Klingebiel. He did his postdoctoral research with P. von R. Schleyer (University of Erlangen-Nürnberg) and at Cambridge University with R. Snaith and P. R. Raithby. In 1993 he obtained his habilitation in the research group of G. M. Sheldrick at the University of Göttingen and accepted a position at the University of Würzburg in 1995. In April of this year, he returned to the University of Göttingen.

Stalke's research is concentrated on the determination of electron densities through multipole refinement, sulfur–nitrogen chemistry, ligand design with N-heteroarenes, and low-temperature investigations of crystals. The award comes particularly for his development of cryotechniques that have enabled the elucidation of principles in structure and reactivity in the field of organolithium chemistry, among other things, of *n*- and *tert*-butyllithium. He recently reported on metal coordination to the formal P=N bond of an iminophosphorane.[7]

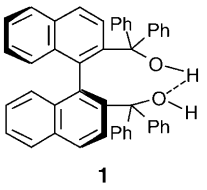
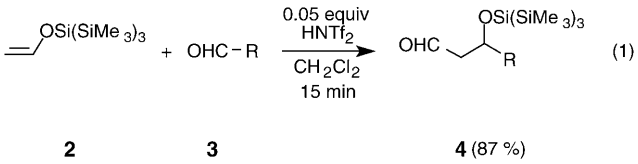
Organometallics at Lake Geneva**

Holger Butenschön*



Between July 17 and 21, 2005 the 13th IUPAC International Symposium on Organometallic Chemistry Directed Towards Organic Synthesis (OMCOS-13) was held in Geneva. This biennial conference, organized this year by Peter Kündig and Alexandre Alexakis, was a success; OMCOS-13 was proven particularly attractive, as it gathered about 1200 participants from all over the world. Organometallic chemistry directed towards organic synthesis has been a rapidly developing area of high relevance, with asymmetric transition-metal catalysis still dominating the field.

L. Hegedus (Fort Collins, USA) won the audience over with his contribution in which he gave a nice review of OMCOS-1, which was held with his cooperation in Fort Collins in 1981. The list of speakers from OMCOS-1 shows how forward-looking the foundation of this series of conferences was: Posner, Noyori, Tsuji, Larock, Negishi, Semmelhack, Pearson, Heimbach, Chiusoli, Trost, Rosenblum, Nicholas, Murahashi, and others—the list reads like a Who's Who in Organometallic Chemistry! As has been the case for preceding OMCOS conferences, the organizers this year succeeded in acquiring a number of highly attractive speakers. In addition to 23 plenary lectures and one award lecture, 22 short communications were presented. The diversity of organometallic chemistry was represented by more than 620 poster presentations.



The conference was given a brilliant start by A. Fürstner (Mülheim an der Ruhr, Germany) with a plenary lecture on *Catalysis for Total Synthesis*. He presented the application of iron compounds as catalysts for coupling reactions as a current development. In the presence of iron(III) acetylacetonate, alkyl Grignard reagents can be coupled with aryl chlorides, bromides, or tosylates with high selectivity as was impressively demonstrated by Fürstner in the synthesis of amphidinolide X.[1] Interestingly, the process can be switched around to allow the coupling of secondary alkyl bromides with aryl Grignard reagents.

Catalytic enantioselective C–C bond-formation reactions based on chiral sulfoximines were presented by C. Bolm (Aachen, Germany). In particular, C_2-symmetric bissulfoximines and C_1-symmetric sulfoximines were used, a large variety of which are accessible through a building-block system. The potential of these catalysts was verified among others in Mukaiyama aldol and in carbonyl-ene reactions. Bidentate ligands with a chiral sulfoximine and a phosphane, phosphite, or amine co-ligand were successfully applied in iridium-catalyzed enantioselective reductions of imines to give enantiomeric excesses of up to 98%, thereby setting a new standard.

M. Murakami (Kyoto) impressed with a highly detailed study on the torquoselectivity of thermal conrotatory electrocyclic ring-opening reactions of silyl- and boryl-substituted cyclobutenes, which, in contrast to alkyl-substituted systems, prefer an inward opening. J. Maddaluno (Rouen) reported on chiral lithium amides and their application in asymmetric synthesis, whereby important aggregates were characterized by ^{6}Li NMR spectroscopy. H. Yamamoto (Chicago) introduced "designer acid catalysts", which are combinations of Lewis (L) and Brønsted (B) acids (A). The possible combinations BLA, LBA, LLA, and BBA lead to various kinds of activation. For example, diol **1** of the BBA type allows enantiomeric excesses up to 98% in hetero-Diels–Alder reactions.[2] Particularly interesting was the application in the enantioselective nitroso-aldol addition for the formation of 2-hydroxyketones. A remarkable increase in the nucleophilicity of silyl enol ethers was achieved with the tris(trimethylsilyl) (TTMSS) group, as shown by the Mukaiyama-aldol addition of **2** and **3** to **4** [Eq. (1); R = alkyl, Tf = trifluoromethanesulfonyl]. The silyl migration allows successive repetition similar to a cascade Mukaiyama aldol reaction, which proceeds with high *syn* selectivity.

1

2 **3** **4** (87%) (1)

Akin to preceding conferences, palladium-catalyzed reactions held a prominent position at OMCOS-13. G. Balme (Lyon) opened this field with a lecture on palladium-catalyzed multicomponent reactions for the construction of such heterocycles as furans, γ-lactones, and heterocyclic natural products. A true fireworks display of palladium-catalyzed reactions was then presented by this year's winner of the OMCOS award, S. Ma (Shanghai), who lectured on transition-metal-catalyzed reactions of allenes.[3] The carbometallation of allenes either leads to π-allyl complexes or to alkenyl metal compounds. A subsequent β-hydride elimination leads to new allenes. Ma also reported on multicomponent reactions. A special bonus at the end of his impressive lecture was a rhodium-catalyzed synthesis of steroid **6** from bisallene **5**, which was carried

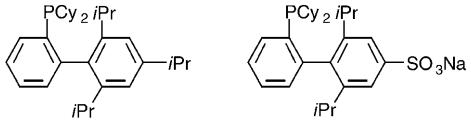
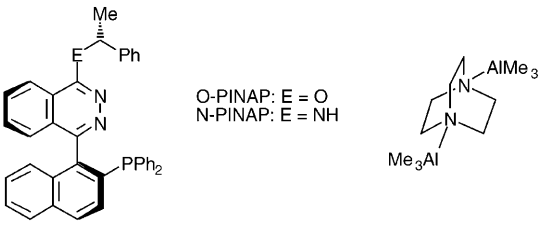
out in 74% yield [Eq. (2)]. If the central $C(CO_2Me)_2$ unit in **5** is replaced by NTs (Ts = toluene-4-sulfonyl), diazasteroid **7** forms in 57% yield.



S. L. Buchwald (Cambridge, USA) presented a large number of special biphenyl-derived phosphanes such as **8**, which allow important palladium-catalyzed aminations and Suzuki–Miyaura coupling reactions, even with sterically hindered aryl chlorides. Interestingly, the similar phosphane **9** has recently proven valuable for Sonogashira coupling reactions in the aqueous phase.

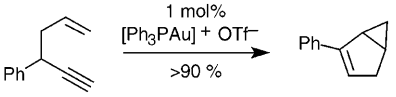
10 **11** **13** **12** (75 %, d.r. 5:1, 99% *ee*) (3)

5 **6** (74 %) (2) **7** (57 %)



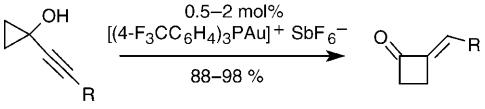
8 **9**

K. Oshima (Kyoto) reported on some interesting, cobalt-catalyzed reactions based on single-electron transfers, in which $[CoCl_2(dppe)]$ (dppe = ethane-l,2-diylbis(diphenylphosphane)) proved particularly successful. Cobalt Schiff-base complexes were the focus of the lecture by E. N. Jacobson (Cambridge, USA), who presented a large number of natural product syntheses. For example, the dynamic kinetic resolution for the hetero-Diels–Alder cycloaddition in the synthesis of the membrenone C building block **12** from **10** and **11** requires use of **13** as the hexafluoroantimonate [Eq. (3)].



New ligands for the control of asymmetric catalysis were the central topic of the lecture by E. M. Carreira (Zürich). Chiral diene ligands have proven particularly useful in asymmetric rhodium-catalyzed Michael additions with 98% *ee*,[4] and Carreira gave proper credit to related work by Hayashi (Kyoto). For a number of other asymmetric catalyses such as hydroboration and dipolar addition reactions with azomethyne ylides, the group of PINAP ligands **14** were useful. S. Woodward convinced the audience with a very clear presentation on applications of aluminum reagents. For example, the 1,4-diazabicyclo[2.2.2]octane (DABCO) adduct DABAL (**15**) in the presence of chiral phosphane ligands of the Feringa type facilitates the stereoselective methylation of aldehydes.

Despite the dominant role of palladium among the catalytically important metals, there are frequent reports on remarkable catalyses by less-prominent metals. N. Chatani (Osaka) reported on gallium trichloride catalyzed cycloadditions of isocyanides, and F. D. Toste (Berkeley) presented a brilliant array of gold(I)-catalyzed reactions. The incentive for this research was the development of air-stable transition-metal catalysts. Next to $[(Ph_3PAu)_2O]$, which had been introduced by Schmidbaur, triphenylphosphane gold(I) triflate was used to facilitate the isomerization of enyne **16** to bicyclo[3.1.0]hexane **17** in greater than 90% yield [Eq. (4)]. Especially interesting is the isomerization of alkynylcyclopropanol **18** to 2-methylenecyclobutanone **19** (88–98%) with $[(4\text{-}F_3CC_6H_4)_3PAu]^+$ SbF_6^- (0.5–2.0 mol%) as catalyst [Eq. (5)]. The reaction was explained by a mechanism via a gold carbene intermediate.[5,6]



M. Sodeoka (Sendai, Japan) held the Chemical Communications 40th Anniversary Lecture on acid–base catalysis with chiral palladium catalysts. As in many other talks the 2,2′-bis(diphenylphosphanyl)-1,1′-binaphthyl (binap) ligand was featured prominently. The binap bis(aqua) complex of palladium shows Brønsted acidity at the aqua

14 **15**

ligands and Lewis acidity at the palladium atom. This allows an interaction that results in asymmetrically catalyzed aldol and Mannich reactions, and Michael additions with excellent yields and stereoselectivities. Remarkably, Michael additions are also possible with α,β-unsaturated aldehydes. Also notable is the catalytic enantioselective α-fluorination of α-monosubstituted β-dicarbonyl compounds and β-ketophosphonates with $(PhSO_2)_2NF$ with up to 97% yield and 96% *ee*, in which enolization and racemization are avoided. After a lecture by H. Lebel (Montréal) about nitrenes and their use in metal-catalyzed aziridinations, B. Lipshutz (Santa Barbara, USA) impressed the audience not only by the scientific content of his lecture but also by the enthusiastic style of his presentation. The focus of his talk was catalysis with the readily affordable nickel in charcoal and in graphite. Negishi coupling reactions, aminations of the Buchwald–Hartwig type, and Suzuki–Miyaura coupling reactions give high yields. These reactions can be accelerated remarkably upon microwave irradiation. The important aspect of planar chiral compounds was put forward by J. C. Carretero (Madrid), who investigated sulphenylphosphinylferrocenes as catalysts for asymmetric C–C bond formation and their use as catalysts for hetero-Diels–Alder cycloadditions.

A. S. C. Chan (Hong Kong) gave a lecture about "smart ligands" for C–C coupling reactions, in which chiral ligands are combined in such a way that the resulting synergism produces better results than is possible with single ligands only. Palladium catalysis was the focus of the talk given by M. Lautens (Toronto), who presented an interesting indole synthesis by a tandem coupling reaction of geminal dibromoalkanes and a vinylogous Mukaiyama–Mannich reaction. The direct α-alkylation or α-alkenylation of carbonyl compounds by treatment with ethene or ethyne was the target of N. Nakamura (Tokyo). This was finally successful by treatment of the respective imines with LDA, $ZnCl_2$, and butyl lithium followed by ethene via the zinc enolates. For the ethenylation of β-dicarbonyl compounds by treatment with ethyne, indium(III) triflate proved superior to the zinc salt. K. Ding (Shanghai) described his success in devising a way to decrease the amount of catalyst typically applied from 1–5 mol% to 0.1–0.05 mol%. He exploited the asymmetric activation of achiral ligands. His "self-supported ligands" are coordination polymers such as **23** that consist of two different chiral building blocks **20** and **22**, and the metal **21** [Eq. (6)][7] which combine the advantages of heterogeneous and homogeneous catalysis. The enantioselective epoxidation of enones, for example, gave 99% yield with 97.6% *ee*.

20, **22**: chiral, bidendate ligands
21: metal atom

After the lecture of C. Genari (Milan) about rhodium-catalyzed asymmetric hydrogenation reactions with monodentate phosphorous amidates, V. Aggarwal (Bristol, UK) completed the wide spectrum of organometallic chemistry by illustrating some possible uses for sulfur ylides which include asymmetric epoxidation and its application to the synthesis of natural products.

Next to the mostly excellent plenary lectures a number of short communications also had their place, among which were the impressive presentations by B. Breit (Freiburg, Germany) and J. Takacs (Lincoln, USA). Each described an approach to the field of self-organized bidentate ligands, yet from different starting ideas. The presentation of J. Williams (Bath, UK) about *Borrowing Hydrogen Using Transition Metal Catalysis* outlined a rather creative concept: a primary alcohol is oxidized to an aldehyde, which in turn is subjected to a Wittig olefination with formation of the respective alkene, which is finally reduced to the alkane—in summary, a primary alcohol has been alkylated. Interesting talks were also given by P. Chiu (Hong Kong) about copper-catalyzed (Stryker reagent: $[(Ph_3PCuH)_6]$) hydrostannylations of activated alkanes and the application of secondary phosphane oxides according to Li in titanium- and palladium-catalyzed amination reactions, which were the subjects of the communication of L. Ackermann (Munich).

Overall, it can be said that the application of organometallic chemistry to organic synthesis is still highly attractive. Various facets of asymmetric catalysis and cross-coupling reactions dominated many lectures. In addition to the frequently used palladium, other metals such as ruthenium or rhodium are playing an increasingly important role. The issue of practicability in catalysis was the topic of some contributions, in which the use of affordable metals (such as Ni and Fe) or heterogeneous catalysts without air exclusion were emphasized. The program was superbly arranged; the large number of poster contributions, which were presented at a great poster party and which were on display throughout the conference, inspired a highly communicative atmosphere. In summary, OMCOS-13 was a great success, and expectations are high for OMCOS-14 (August 2–6, 2007, in Nara, Japan).

Organocopper for the Craftsman Cunning at His Trade**

*Simon Woodward**

Keywords:
aluminum · copper · Grignard reactions · nucleophilic substitution · zinc

Although modern organocopper chemistry emerged from the use of CuCl as a catalyst to promote 1,4-additions of Grignard reagents to enones by Kharasch and Tawney in 1941,[1] such reactivity has until recently remained the poorer cousin of stoichiometric cuprate reactivity, as exemplified by the use of Gilman's cuprate, $LiCuMe_2$, which recently celebrated its 50th birthday.[2] However, in the last twelve months an influx of papers that describe copper-catalyzed asymmetric reactions of organozinc, aluminum, and especially Grignard reagents has provided new, highly enabling methodologies. The exceptional utility of these reactions promises to displace stoichiometric cuprates from their preferred position as the reagents of choice for conjugate addition and S_N2' displacement reactions of allylic electrophiles.

The synthetic potential of general asymmetric 1,4-additions of RMgX species to enones has been recognized since the earliest days of organometallic chemistry. However, a near-enantiospecific catalyst for such reactions was considered viable "only in dreams", even as recently as 1997.[3e] Despite the screening of a wide range of ligands, including thiolates, phosphanes, and imines, the *R*/*S* selectivity in even the simple test reaction of 2-cyclohexenone and *n*BuMgX remained moderate for over a decade (Figure 1), and *ee* values remained persistently in the range 60–80%.[3] The benchmark result of

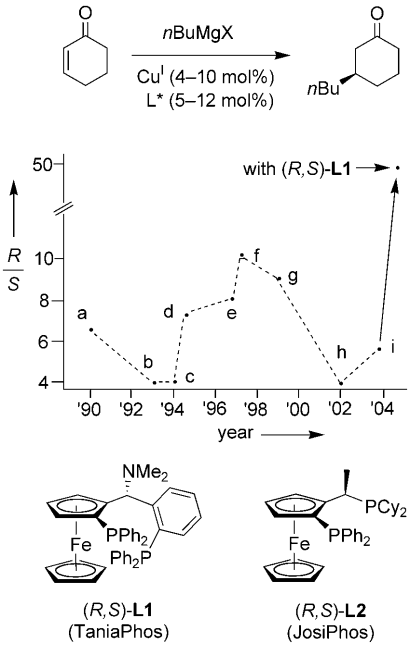

Figure 1. Selected maximum *ee* values for catalytic additions of BuMgX to 2-cyclohexenone, except (d), which involves addition of MeMgI to benzylideneacetone (< 10 mol% Cu^I; < 12 mol% chiral ligand, L*). Data points a–i correspond to References [3a–i], respectively. Cy = cyclohexyl.

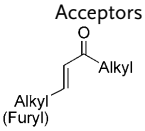
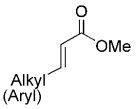
van Koten and co-workers in this area on benzylideneacetone (76% *ee*) in 1994[3d] has also been included in Figure 1 for comparison. However, a huge improvement in *R*/*S* selectivity has very recently (2004–2005) been reported in a series of three publications by the group of Feringa.[4–6] Use of the key ferrocenyl ligands TaniaPhos (**L1**) and JosiPhos (**L2**) allows a wide range of Grignard 1,4-additions to cyclic and acyclic enones as well as α,β-unsaturated esters, with *R*/*S* selectivities that are 5–10 times higher than those seen with all previous catalysts. These ligands typically afford 85–95% *ee* for a wide range of substrates. The very high rate efficiency of the catalyst minimizes, or eliminates, the direct 1,2-addition of the Grignard reagent to the carbonyl group. Of additional note is the forgiving nature of these reactions with respect to their tolerance of traces of water and oxygen and that they can operate at very low catalyst loadings (down to 0.2 mol% in one case). Further synthetic simplicity in the form of an air-stable precatalyst prepared from **L2** and $CuBr{\cdot}SMe_2$ lead to near-optimal reaction conditions. The currently tolerated combinations of preferred ligands per substrate type are summarized in Table 1.





The current limitations of this system are few but are worth summarizing for those who are interested in using the reaction in target synthesis. 1) The presence of α branching in the Grignard component often leads to a catastrophic loss in enantioselectivity; 2) highly hindered enones, such as RCH=CHC(O)-*t*Bu (R = alkyl), lead to a poor selectivity (≈40% *ee*); 3) for the less-reactive α,β-unsaturated esters, the rate of addition of MeMgBr is slow (high *ee* values were still observed, but at low chemical yields); and 4) the presence of a double bond in the Grignard reagent leads to approximately 10% lower enantioselectivity than that observed for the parent hydrocarbon. These minor limitations represent goals for the future design of catalysts. However, the new methodology of Feringa and co-workers offers one last important advantage: as a result of the inherently high reactivity of the magnesium enolate formed in these reactions, great opportunities exist for

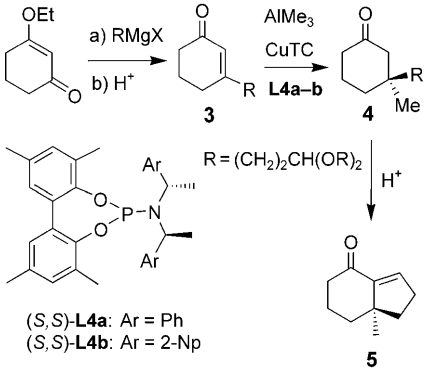
one-pot consecutive trapping reactions and these will undoubtedly be realized in the near future.



The use of Grignard nucleophiles has also allowed remarkable recent progress in S_N2' displacement reactions of allylic halides, as demonstrated by the group of Alexakis (Scheme 1).[7] Such reactions are mechanistically akin to 1,4-enone additions except that, in this case, the two-electron shift is accommodated by loss of "X^-" rather than its storage at the carbonyl oxygen atom.[8] The asymmetric transition state for ligand-promoted additions of organometallic reagents to (*E*)-RCH=$CHCH_2X$ species is presently not well understood and appears rather fragile. Despite intensive efforts in the last five years, catalytic systems have been able to afford stereoselectivities of over 90% only in special cases. However, the use of a combination of a Grignard reagent and a key chiral ligand has again led to a general strategy for this reaction. For a range of allylic chlorides and Grignard reagents, the α-chiral alkenes **1** are isolated in good yield and with outstanding enantioselectivity. The presence of the methoxy group in **L3** is crucial, but whether this unit can act as a bridging ligand to magnesium can only be speculated on at present. Direct exposure of the reaction mixture to ethyl acrylate and 5 mol% of the Grubbs II catalyst allows direct formation of the unsaturated esters **2** in moderate to good yield. Esters **2** would be excellent substrates for Josiphos (**L2**)-promoted addition of a further Grignard reagent using Feringa's system. The potential for creating one-pot multiple cascades that lead to two or three contiguous stereocenters is indeed very high.

Scheme 1. Preparation of chiral esters. R^1 = Ph, 4-Me-C_6H_4, Cy; R^2 = Et, 3-butenyl, 4-pentenyl; CuTC = copper(I) thiophene-2-carboxylate; Mes = 2,4,6-trimethylphenyl.

Unfortunately, the zinc analogues of Grignard reagents, RZnX, often lack sufficient reactivity to be useful in catalytic asymmetric 1,4- or S_N2' additions. Recently, we demonstrated a method to overcome this difficulty: By promoting the reverse Schlenk equilibrium, RZnCl can be transformed back into R_2Zn and $ZnCl_2$.[9] As the resultant diorganozinc reagent is of higher reactivity it could be utilized in copper-catalyzed S_N2' reactions of (*Z*)-ArCH=$C(CH_2Cl)CO_2Me$ to afford $ArCHRC(=CH_2)CO_2Me$ with good enantioselectivity (80–90% *ee*) in the presence of simple chiral amines. (Normally *Z*-allylic halides give far lower *ee* values in S_N2' chemistry, and to improve this remains a significant challenge in this area). The key trick in this chemistry of RZnCl is to add methylaluminoxane $[MeAlO]_n$ to the reaction mixture to scavenge $ZnCl_2$ and give ZnR_2 rather than the usual, highly thermodynamically favored RZnCl species. The formation of strong Al–Cl bonds probably accounts for the thermodynamic driving force. Thus, although this reaction does not use zinc Grignard reagents as such, the success of the approach is clearly related.

As a last example from this influx of organocopper-based methodology, Alexakis and co-workers have also exploited the strong Lewis acidity and oxophilicity of organoaluminum reagents to conquer another demanding class of substrates in classical organocuparate chemistry: β-disubstituted enones (Scheme 2).[10] Traditionally, the additional steric hindrance afforded by enones of type **3** leads to very poor reactivity. However, by using $AlMe_3$ and as little as 4 mol% of chiral ligands **L4a–b**, highly efficient catalytic syntheses of species **4** (91–95% *ee*), which contains a quaternary center, were reported. Interestingly, in this chemistry the presence of acetal groups is tolerated and allows rapid access to bicyclic structures such as **5**.

Scheme 2. Preparation of stereogenic quaternary centers with high enantiopurity by conjugate addition of $AlMe_3$. R = Et, *i*Bu, $(CH_2)_nCH{=}CH_2$ (n = 2,3), $(CH_2)_2CH(OR)_2$; Np = naphthyl.

All of the strategies described above have been attained with loadings of

copper(I) salts of 5 mol% or less. It is clear that the nature of asymmetric copper-promoted reactivity is changing rapidly from a situation in which chiral stoichiometric reagents of low general utility (often targeting just a single substrate) were the norm to more-powerful, general catalytic asymmetric procedures. While some problematic combinations of organometallic reagents and substrates still exist in both conjugate addition and S_N2' chemistry, we can be confident that in the near future ligand structures will be identified to overcome these difficulties and an essentially complete set of synthetic methodologies in this area will be available.

A Revolution in Electron Microscopy**

*John Meurig Thomas**

Keywords:
electron diffraction · electron microscopy · femtochemistry · protein structures · structural dynamics

A paper on four-dimensional ultrafast electron microscopy published recently[1] reports breakthroughs and preliminary results that are of great potential significance to physical, materials, and biological scientists. A. H. Zewail and co-workers have described how to unite the time domain with the spatial domain in such a manner as to achieve unprecedented real-time and real-space capabilities. Adding the fourth dimension, time, to the three spatial ones that are retrievable by high-resolution electron microscopy opens up new vistas and applications by using timed, single-electron packets.

All this is achieved through coherent electron packets, which are liberated from a photocathode with femtosecond laser pulses, are accelerated at 120 keV, and contain as little as one electron per pulse. Such design ensures that no space–charge broadening of the electron beam occurs and that electron trajectories can be brought into sharp focus. The photocathode is illuminated with very weak ($E \approx 500$ pJ) femtosecond pulses—which constitute a high-frequency train (12.5 ns or longer separation)—such that the ultrafast electron microscope (UEM) provides, in principle, the ability to benefit from multiple pulsing with single-shot time resolution. For example, with a periodic sample, each electron pulse could, by dextrous manipulation, be applied to a different but equivalent region. Moreover, by lengthening the interval between pulses any reversible damage inflicted by an electron pulse on samples such as metals or other inorganic objects (e.g. Si, Ge, GaAs) may be allowed to self-heal prior to further repeated investigations. By obtaining diffraction patterns Zewail and co-workers[1] have reached atomic resolution, and by microscopy they have already obtained images that are resolved on the nanometer scale.

The conceptual design of the UEM, in which a femtosecond optical system is integrated with a high-resolution electron microscope, is depicted in Figure 1. The laser system consists of a diode-pumped mode-locked Ti:sapphire laser oscillator which generates sub-100-fs pulses at 800 nm with a repetition rate

of 80 MHz and an average power of 1 W. Part of the beam may be used to heat or excite the sample and to define the zero of time, while the remainder is frequency-doubled in a nonlinear crystal to yield 400-nm femtosecond pulses for generating the train of electron pulses. Single-electron detection is achieved by using a phosphor scintillator in conjunction with a charge-coupled device camera. Since 1990, the use of pulsed photoelectrons has been at the heart of the development of ultrafast gas-phase diffraction and ultrafast crystallography by Zewail and co-workers.

This approach is to be contrasted with the pioneering use of intense single pulses of nanosecond duration, also using photoelectrons, pursued by Bostanjoglo and co-workers[2–4] for the studies of texture of thin metallic films. In this case, the single pulse contains approximately 10^8 electrons, which is detrimental to time resolution because of Coulombic repulsion. It also limits spatial resolution to the micron level and to studies of, for example, melting and ablation. It differs also from the seminal work of Gai and Boyes,[5] who used continuous beams in a specially constructed microscope that could record high-resolution images of the migration of supported metal catalysts on oxide supports at elevated temperatures with millisecond resolution in an environmental cell. With their setup, Zewail and co-workers[1] demonstrated the versatility of their designated 4D UEM by recording images and diffraction patterns of amorphous carbon, polycrystalline aluminum, and single-crystal gold. They also obtained images of stained biological cells with an electron dose of around two electrons per $Å^2$.

In light of this major breakthrough and particularly the 4D capabilities, it is instructive to consider, along with some other recent advances, future possible implications for dynamic structural analyses of inorganic, organic, and biological materials. In the past, especially with regard to the determination of structures that are of interest to macromolecular biochemists and biophysicists, far greater use has been made of X-ray diffraction than electron diffraction and microscopy. Indeed, the structures determined were static ones, but, even so, they have sometimes conveyed deep insight into mechanism and function, and two outstanding examples are the structure of DNA and that of lysozyme. On the basis of the latter, Phillips and co-workers proposed a plausible (and still largely valid) mechanism for the mode of action of the proteolytic enzyme.[31] Equally, there have been many instances in which the detailed static structure deduced from X-ray studies gave no immediate clues as to the mechanism of its action—a noteworthy example is hemoglobin. As Max Perutz remarked when he solved the structure of this protein, the structure itself gave no suggestion as to how it functioned, and well-meaning friends to whom he proudly showed his model of hemoglobin hinted that the molecule that had yielded to his prolonged X-ray study might be that of an inconsequential impurity! With the ultrafast diffraction[6] and microscopy techniques introduced by Zewail and co-workers, dynamical evolution of structure and the concomitant charting of energy landscapes may be directly mapped so that there is reason to believe that greater appreciation of biological function may be gained by the application of 4D UEM.

With regards to sensitivity, X-rays are inferior to electrons as probing beams. Electron-scattering cross-sections are higher than those of X-ray scattering from molecules by some five to six orders of magnitude. Moreover, electrons are less damaging to specimens, per useful scattering event, than X-rays are.[7] In synchrotron studies that use intense X-ray beams, the question of beam damage of the specimen is often critical. Even so, synchrotron radiation readily permits time-resolved studies by means of the von Laue method of recording diffraction data. However, very few synchrotron sources are, as yet, capable of offering the timescale necessary to investigate the breaking and making of chemical bonds or the tracking of torsional and vibrational amplitudes, or of adaptation to enable direct, real-space imaging. Pulses of X-rays of 1 ps may be created with a laser-induced plasma, which generates a burst of X-rays from a tiny metal target, and these have recently been used[8] to such good effect in the study of multiple quantum wells that it has led to the possibility of making "X-ray movies of wiggling crystals".[9] Following simulations which indicated that the onset of radiation damage on the atomic scale in a typical protein occurs about 10 to 20 fs after significant diffraction has occurred, it has been suggested by Neutze et al.[10] that X-ray diffraction patterns could be collected from successive randomly oriented protein molecules in a stream that crosses an X-ray beam in synchrony with the X-ray pulses. This difficult experiment has not yet been carried out.

Ever since the landmark achievements of Klug,[11] who devised a way to deduce the structure of biological macromolecules by transmission electron microscopy, considerable use has been made of his general approach, notably by Henderson,[12] Unwin,[13] and others, to determine the structures of membranes and related materials. A recent triumph was the determination of the structure of the nicotinic acetylcholine receptor (at 4 Å resolution).[13] Spence et al.[14,15] have made the ingenious suggestion that electron-diffraction patterns from aligned molecular beams could be used to solve the structure of proteins, especially of those that are difficult to crystallize. Their arrangement consists of continuous, orthogonal, intersecting electron, molecular, and laser beams. This approach, which shows considerable promise, would greatly simplify the data-collection procedures over similar femtosecond-pulsed X-ray schemes proposed by Neutze et al.[10] To determine the structure of an enzyme such as lysozyme in this way, it has been estimated[15] that up to 1 kW of continuous-wave near-infrared laser power together with cooling to liquid N_2 temperatures may be needed to produce sufficiently accurate alignment for the direct observation of the secondary structure of the enzyme.

If—and this is the quintessential point—the suppression of electron-beam damage to be expected from the multiple and controlled pulsing, single-shot approach outlined above permits the collection of diffraction data at higher dose, one cannot but speculate that Zewail and co-worker's 4D UEM method will not only reveal new insight into the dynamics of biophysically relevant processes but also open up the possibility of arriving at structures of even higher resolutions than those re-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cently obtained by utilizing cryogenic procedures.[16,17]

Prior to their development of 4D UEM, Zewail and co-workers had already reached atomic-scale resolutions in time and space by using ultrafast electron diffraction, which they applied to the study of different phases from gases and crystals to interfaces.[6,18–20] In a recent report, they completed a study of the atomic-scale dynamical structures of a fatty acid bilayer by using ultrafast electron crystallography. Apart from determining the structure of the two-dimensional assembly, they mapped structural dynamics by recording the diffraction frames every picosecond following a femtosecond temperature jump and found that coherent anisotropic expansion took place along the aliphatic chains of the bilayer, which itself is a 2D crystal (50 Å thick).

This level of resolution and sensitivity of electrons as probing beams coupled with the fact that, unlike X-rays, they may be readily focused makes 4D UEM unique as an investigative technique. Electron microscopy has often been able to reveal structural detail of great chemical interest when it is not possible to carry out single-crystal X-ray diffraction studies. The precise nanoporous nature of the key aluminosilicate, zeolitic (molecular sieve) catalyst, ZSM-5, for example, was determined[21] by electron microscopy long before a single-crystal structure was determined by X-ray studies. Moreover, because some 10^{15} unit cells need to be spatially averaged, in X-ray crystal structure determinations certain key microstructural details go undetected—they are obliterated by the process of spatial averaging. By using high-resolution microscopy, the number of unit cells explored is seldom more than 10^5 (and often much less) and a real-space picture of the local structure is recorded. In this way recurrent intergrowths of ZSM-5 and its symmetry-related analogue, ZSM-11, were first detected,[22] and many new structures, including such exotic samples as infinitely adaptive structures (where a fully ordered mixed oxide structure may be formed for every possible nonstoichiometric composition[23]), that remained unobserved by X-ray diffraction were subsequently discovered. Moreover, the structures of highly ordered mesoporous materials cannot be solved from X-ray patterns alone because of the paucity of reflections and their widths. Electron microscopy is the only reliable tool for the determination of such structures.[24]

In principle, the kind of experiment now rendered feasible by the inauguration of 4D UEM should enable unprecedented detail to be retrieved in the study of inorganic, organic, and biological materials. For example, the femtosecond-scale heating (or photoexciting) pulse opens up the possibility of the direct study of a wide range of phase transitions including such phenomena as martensitic transformations, the dynamics of which have hitherto proved inordinately difficult to record directly by other experimental means. For solid-state and materials chemists, the phenomenon of diffusionless reactions[25,26] (such as photostimulated dimerizations and polymerizations) in organic molecular crystals, with its related strategy of crystal engineering, should be a rich pasture to explore. Likewise, the investigation of redox metalloenzymes by dynamic electron microscopy should shed new light on the mechanisms of action of cytochrome P450, manganese oxidase, the hydrogenases, and many other enzymes because it will be possible to record electron-energy-loss spectra[27] (and to reveal oxidation states of the metal ions at active centers, even though the measurements may be complicated by the reducing environment created by the secondary electrons within the sample). Also, with open-structure, single-site heterogeneous catalysts[28,29] the "breathing" of nanopores and nanocages and the amplitudes of atomic motion of the active center grafted onto them, which are crucial determinants in catalytic performance, should be directly recordable. Because of the high sensitivity of 4D UEM it should also be possible to uncover new facts about the enigmatic catalytic activity of nanoparticle gold (supported on certain oxides). Bulk gold is catalytically inactive, but nanoparticles of the metal (diameter ≈ 5 nm) supported on TiO_2 catalytically oxidize[30] carbon monoxide in air at below room temperature. What are the structural dynamics of the terrace, step, and kink sites of this remarkable material? And what are the ultrastructural characteristics of macromolecular assemblies, nanocomposites, grain boundaries, and quantum dots?

The development at Caltech of 4D diffraction, crystallography, and microscopy is indeed revolutionary. The door is now open for myriad explorations in the physical and biological sciences.

Chemicals with Endocrine-Disrupting Potential: A Threat to Human Health?**

*Helmut Greim**

Keywords:
endocrine system · environmental chemistry · hormones · toxicology

1. Introduction

In 1996 the book "Our Stolen Future: Are We Threatening Our Fertility, Intelligence, and Survival?" by Colborn, Dumanoski, and Myers was published.[1] Thereafter, reports of decreased human sperm counts and increased incidences of testicular cancer in males and breast tumors in females aroused intense discussions in the public and the scientific community. Previously, Carlsen et al.[2] had evaluated a total of 61 studies on sperm count and had established that there was a decrease from 113 million to 66 million sperm per milliliter of semen between 1938 and 1990. This led Sharpe and Skakkebaek[3] to present the hypothesis that the dysfunctions and diseases of the male sex organs (such as testicular cancer, malformations of the urethra, and cryptorchidism), which have been observed with increasing frequency in the course of the last three to five decades, could be associated with chemicals that mimic the action of estrogen. In particular, medications that mimic the action of estrogen, phytoestrogens, estrogens in cows' milk, and certain industrial chemicals have been considered. This assumption is supported by observations in wild animals. DDT, for example, accumulates in the bodies of birds of prey, which are at the end of the food chain, and leads to reproductive disorders. Colborn et al.[4] described smaller penises in alligators and unfertilized eggs that had been laid as the result of an industrial accident in Florida. In this case, large quantities of the insecticide Dicofol had been discharged into a lake. In other regions, more female than male offspring had been counted for several species of fish and the gulls that ate these fish. These observations and hypotheses resulted in a multitude of studies to identify hormonally active chemicals and to explain their mechanism of action and their significance for humans and the environment.

The different effects have been described and discussed by various authors and committees[5–14] as well as the consequences for appropriate testing.[15,16] In a continuous flow of reports, the chemical exposure of children is linked to hormone-related disorders. These include

- birth defects,
- developmental disorders,
- declining proportion of male newborns,
- mental deficiencies in families of pesticide workers,[17,18]
- testicular dysgenesis syndrome as a result of the disruption of embryonal programming and gonadal development during fetal life by adverse environmental influences,[19]
- insufficient androgen action in the male fetus with subsequent undervirilization and hypospadias in the newborn as a result of intrauterine exposure to environmental hormonal disruptors.[20]

However, except for obvious associations such as the Yusho disease after high exposure to polychlorinated biphenyls, dibenzodioxins, and dibenzofurans,[21,22] none of these suggested associations demonstrated a sufficiently robust correlation between exposure and effects so that increasingly other causes for the observed effects have been discussed like sociodemographic characteristics[23] and combinations of more than one problem.[19]

It is impossible to review all of the available information and add to the detailed reports of the different review panels. Therefore, in this Essay the possible mechanisms and criteria to evaluate the plausibility of a correlation between adverse effects in children and exposure to endocrine-disrupting chemicals will be described. Possible effects of endocrine disruptors in the environment have been discussed recently by Lintelmann et al.[24]

2. Substances Mimicking the Action of Hormones

An "endocrine disrupter" is defined as an exogenous substance or mixture that alters function(s) of the endocrine system and consequently causes adverse health effects in an intact organism, or its progeny, or (sub-) populations.[7,25] Interaction with endogenous hormones may occur by different mechanisms. Xenobiotics can influence hormone synthesis and the release, transport, effect, metabolism, and excretion of hormones. A further group of natural and synthetic substances interferes with the hormones at receptors. Phytoestrogens such as coumestrol, daidzein, and genistein,

medications such as diethylstilbestrol, ethinyl estradiol, and tamoxifen, and industrial chemicals such as DDT, 4-nonylphenol, and bisphenol A belong to this group. They bind to the estrogen receptor and interact with the binding of the hormone. A third group of substances, for example, the DDT metabolite *p,p′*-DDE and vinclozoline metabolites, interact with the androgen receptors, that is, the receptors for the male hormone testosterone. Speculations that xenoestrogens may act through unique cellular receptors that do not bind endogenous endocrine modulators lack support.

Compounds that interact with a receptor trigger a cascade of events, which are regulated by the receptor. Substances that compete with the physiological ligand such as a hormone at the receptor and imitate its effect are called agonists, those which block the receptor are antagonists. The kinetics of interactions of xenobiotics with an endogenous compound at a receptor are well understood and are the basis for the evaluation of drug effects via a receptor (see textbooks of pharmacology). The interaction of a ligand with a receptor is described by Equation (1) (see also Figure 1)

$$\text{Ligand} + \text{Receptor} \rightleftharpoons \text{Ligand} - \text{Receptor Complex} \quad (1)$$

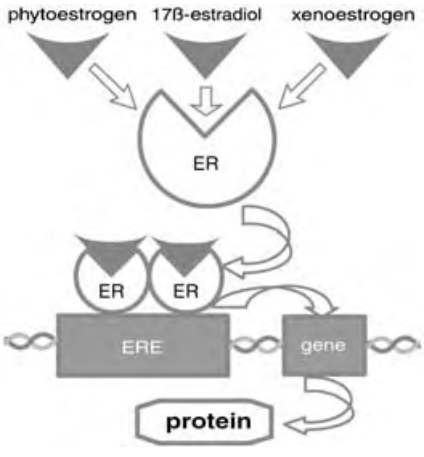

Figure 1. Competition of xenoestrogens and phytoestrogens with 17β-estradiol at an estrogen receptor (ER). The ligand–receptor complex interacts with the estrogen responsive element (ERE), which activates the response gene that in turn triggers the estrogen-dependent production of proteins.

Replacement of a physiological ligand such as an estrogen from the receptor by a competitor such as a xenoestrogen depends on its relative affinity to the receptor and its concentration. For example, replacement of the physiological ligand from the receptor by a compound of 1000-fold lower affinity requires a 1000-fold higher concentration. Although this oversimplifies the competitive interaction of compounds at a receptor, it demonstrates that information on the relative binding affinities of the compounds in question and their concentration in the organism are major criteria to evaluate possible effects of endocrine-disrupting compounds.

The Scientific Committee on Toxicology, Ecotoxicology and the Environment (CSTEE)[7] of the European Commission has compared the potency of xenoestrogen concentrations detected in human blood as a surrogate for concentrations at the receptor with the potency of estradiol concentrations in blood. It appears that the relative potency of *o,p′*-DDT, 4-nonylphenol, and bisphenol A are about millionfold lower than that of estradiol. Only the phytoestrogen genistein showed a potency exceeding that of estradiol. From this it was concluded that an interaction of the compounds at the receptor with physiological consequences is unlikely.

In addition to the reproductive organs, the liver, kidneys, adrenal glands, central nervous system, immune system, cardiovascular system, and bones are target tissues of the effect of steroid hormones; the corresponding receptors have been identified in these tissues. Moreover, there are indications of a concentration-dependent stimulation (low concentrations) and inhibition (high concentrations) of tumor growth by steroid hormones.[10,26,27] For example, xenoestrogens stimulate mitotic activity by interacting with specific receptors of cells in the female genital tract. Many chemicals that humans ingest with their diet have estrogen-like effects, which have been identified in a multitude of test systems.[28] Among these are industrial chemicals such as certain herbicides, fungicides, organochlorine insecticides, nematocides, organophosphates, pyrethroids, heavy metals, polychlorinated biphenyls, and phthalates. Colborn et al.[4] compiled a list of 45 chemicals, including the polychlorinated biphenyls, dibenzodioxins, dibenzofurans, and DDT, to which they attribute an influence on the reproductive system in humans. Also included are the phytoestrogens, that is, naturally occurring plant substances.

3. Test Systems for Identifying Endocrine-Disrupting Chemicals

A great variety of test systems are being used with different experimental modifications, and it is difficult to directly compare the results.[28,15] In most cases standardization is required. The in vitro tests are suitable for identifying the intrinsic hormone-like potential (hazard identification) of a chemical and its relative potency. However, they do not include toxicokinetics of the chemical and its metabolites so that results have to be verified by in vivo testing. Some of the tests are briefly described in this section.

3.1. In Vitro Test Systems

The recombinant yeast estrogen assay uses yeast cells that are transfected with the human estrogen receptor α gene, together with expression plasmids (estrogen-responsive elements and the *lac*-Z reporter gene encoding β-galactosidase). The cells are incubated with the test compound and a chromogenic compound. Active ligands that bind to the receptor induce the expression of β-galactosidase, changing the chromogen to yellow, which is quantified by a spectrophotometer.[29]

In the E-SCREEN test the human MCF-7 breast cancer cell line is incubated with the test compound for several days to allow proliferation. Thereafter the number of cells is quantified, for example, by measuring optical density.[30]

In the estrogen-R(α) competitor screening test the human estrogen receptor is fixed to the 96 wells of a microtiter plate. The test compound and fluorescein-labeled 17β-estradiol are added. After incubation and washing, the fluorescence of 17β-estradiol attached to the receptor is measured.[31]

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The placental aromatase assay utilizes aromatase cytochrome P450 mediated conversion of C19 androgens to aromatic C18 estrogens. Androgens have been shown to inhibit this reaction.[32]

The androgen binding or reporter gene assay and the thyroid receptor binding assay determine the affinity of androgen-like and thyroid hormone-like compounds, respectively, to the specific receptors relative to that of the endogenous hormones.

It has to be stressed that these and other in vitro tests are screening tests for the determination of relative potencies of the test chemicals, which must be verified by appropriate studies in animals.[33]

3.2. In Vivo Test Systems

The traditional Hershberger test was originally designed to differentiate between anabolic and androgenic effects of drugs by determining the weights of the *musculus levator ani* and seminal vesicles in mice after treatment for several weeks. Other workers have used a wide range of treatment regimens to determine the androgenic potential of chemicals in intact and castrated laboratory animals. The endpoints used are, for example, prostatic weight, seminal vesical weight, and DNA/RNA contents of male reproductive organs.[34]

In the uterotrophic assay juvenile female rats are treated with the test compound, and uterine growth is monitored after several days of treatment. Since several experimental designs are used, the test requires standardization.[35]

The OECD 407 Test is a repeated-exposure test in rats over 28 days in which histopathological alterations in the gonads can be observed. To better detect endocrine effects of the test chemicals, the OECD 421/422 Screening Tests can be performed to determine the weight and histopathology of hormone-regulated organs and analyze epididymal sperms, the estrous cycle, and a battery of hormones.

The OECD 416 reproductive test in rodents permits an in-depth study of the growth, development, and sexual functionality of the F_1 generation and includes the monitoring of the subsequent F_2 generation through to weaning. The recently revised protocol is considered to include parameters like weights and pathological examinations of the reproductive organs, and detailed spermatogenesis and sperm investigations of the parental generation and their offspring. Evaluation of physical, sexual, and behavioral development and the learning and memory abilities of the offspring is also included.

4. The Relative Potency of Xenoestrogenic Effects

The intensity of the effect of substances, particularly in comparison to the endogenous hormones or natural hormone-like chemicals, is critical for an evaluation. Sonnenschein et al.[36] studied the proliferative effect in estrogen-sensitive cells and found that the estrogenic potency of chemicals such as 4-octylphenol and bisphenol A was considerably less than that of endogenous estradiol by a factors of 3000 and 30000, respectively (Table 1). In view of the low amounts of these chemicals found in the organism, the resulting intensity of effect is very low. Safe[37] calculated the estrogenic and antiestrogenic potencies of xenoestrogens that may be ingested daily relative to 17β-estradiol. A woman taking a birth control pill ingests about 17000 equivalents per day, during postmenopausal estrogen therapy 3300 equivalents. In contrast, ingestion of estrogenic flavonoids in food amounts to 102 equivalents and of environmental organochlorine estrogens 2.5×10^{-6} equivalents. Similar data have been obtained with antiestrogens.

Table 1: Estrogenic potency in the E-SCREEN assay. Proliferation of breast cancer cells MCF-7.[36,51]

Substance	Concn[a] [nmol L^{-1}]	Potency [%][b]
estradiol	0.03	100
4-octylphenol	100	0.03
4-nonylphenol	1000	0.003
bisphenol A	1000	0.003
bisphenol A dimethacrylate	1000	0.003
benzyl butyl phthalate	10000	0.0003
tert-butylhydroxyanisole	50000	0.00006

[a] Lowest concentration that elicits maximal proliferation. [b] Relative proliferative potency ($concn_{estradiol}$/$concn_{test\ substance}$) × 100.

Bolt et al.[33] compared the potencies of the estimated daily intake of 4-nonylphenol and bisphenol A (each 1 μg kg^{-1} body weight) with that of the phytoestrogen daidzein (1 mg kg^{-1} body weight) and ethinyl estradiol (0.5 μg kg^{-1} body weight), which was ingested daily as a low-dosage contraceptive pill. The estrogenic potencies of nonylphenol and bisphenol A were 125–250 and 1000 times lower, respectively, than the daidzein intake, whereas that of ethinyl estradiol was 20 times higher. Daidzein penetrates the placenta.[38] Since soy is the major source of phytoestrogens in human food, which can amount up to 8 mg kg^{-1} body weight in babies fed with soy-based infant formula,[39] the consequences of these exposures carry far more weight than the exposure to xenoestrogens.

The CSTEE[7] in its opinion on endocrine-disrupting chemicals calculated the relative estrogenic potencies of several compounds in humans. Based on their concentration in human serum and their estrogenic potencies as determined in the recombinant yeast estrogen assay, the potencies were shown to be several orders of magnitude lower than that of estradiol (Table 2).

Specific low-dosage effects indicated by experiments reported by the group of vom Saal[40,41] on bisphenol A and nonylphenol could not be verified.[16,42] Attempts to demonstrate the potentiation of low-dosage effects by the presence of several compounds also failed. McLachlan's research group[43] reported that in an in vitro system with yeast cells the effect of two separate, weakly active estrogens was 1000 times higher in combination. Other research groups were not able to repeat these results.[44] Finally McLachlan et al. officially retracted the results and any inferences drawn from them.[45]

Considering this, a toxicologically relevant effect on the prenatal or post-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Table 2: Estrogenic potency of endocrine modulators detected in the recombinant yeast estrogen assay.[7]

Substance	$Concn_{effect.}$ [mol L^{-1}][a]	$Concn_{hs}$ [ng L^{-1}][b]	Rel. potency
estradiol	2.25×10^{-10}	187	1.0
testosterone	5.09×10^{-5}	6	1.3×10^{-4}
o,p'-DDT	1.80×10^{-3}	0.006	3.0×10^{-9}
4-nonylphenol	1.00×10^{-6}	< 1	1.5×10^{-6}
bisphenol A	3.40×10^{-6}	< 1	4.0×10^{-7}

[a] Effective concentration. [b] Concentration in human serum.

natal phase from synthetic chemicals is not plausible or likely. However, the potential beneficial or adverse effects of phytoestrogens and other natural compounds with hormone-like effects must be considered in the toxicological evaluation.

5. Phytoestrogens in the Human Diet

Phytoestrogens occur naturally in plants. Common classes comprise isoflavones, lignans, coumestans, and resorcylic acid lactones; they are structurally similar to the mammalian estrogen and have a weak estrogenic potency ranging from 500 to 1000 times less than that of 17β-estradiol. A major phytoestrogen source in the human diet is soybean-derived products, which contain the isoflavones daidzein and genistein. As a result of great differences in the consumption of such products, adults in the UK and the USA ingest about 1 mg of isoflavons per day, whereas Asians ingest 50–100 mg daily.[46] Infants who are fed soy-based formula as a sole source of nutrition ingest 22 to 45 mg per day.[47]

The beneficial effects of phytoestrogens in women have been investigated in several studies.[46,48] These indicate that phytoestrogens in the diet have a beneficial effect with respect to breast cancer most likely by prolonging the menstrual cycle. Mean cycle length in Western countries with high breast cancer risk is 28 to 29 days. In Japan it is 32 days, and breast cancer risk is four times lower. Since the division rate of breast cells is four times slower during the follicular phase of the cycle, the authors hypothesize that longer menstrual cycles result in longer follicular phases with reduced cell division during the premenopausal years. Other beneficial effects reported may be reduced serum cholesterol levels, low rates of cardiovascular disease, cancer, and, especially in postmenopausal women, conservation of bone mass.[49]

In newborns fed a soy-based formula during the first three to six months no clinical effects such as feminization have been reported so far. Essex[50] assumes that in babies the hypothalamic–pituitary–gonadal axis (Figure 2) is more active than in older children and adults, which compensates the estrogenic effects of the high intake of isoflavons. However, the author concludes that breast-feeding obviously is best for babies.

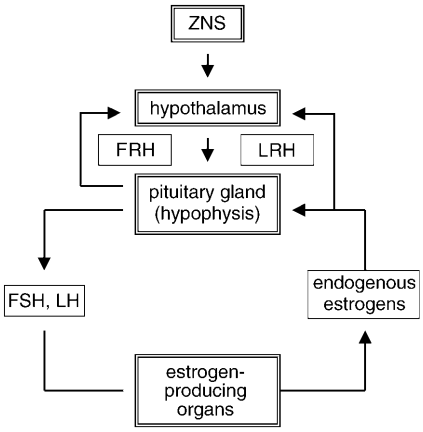

Figure 2. Representation of the hypothalamic–pituitary–gonadal axis. CNS: central nervous system; FSHRH: follicle stimulating hormone releasing hormone; LHRH: lutinizing hormone releasing hormone; FSH: follicle stimulating hormone; LH: lutinizing hormone.

6. Questionable Correlation between Diseases and Endocrine-Disrupting Chemicals

Several well-respected institutions have evaluated the evidence for adverse health effects resulting from human exposure to endocrine disruptors.[7,51,52] They conclude that analysis of the human data so far has failed to provide firm evidence of direct causal association between low-level exposure of endocrine disruptors measured in the general population and adverse health effects. The specific conclusions of the CSTEE[7] and the IPCS[52] are:

- Temporal increases in the frequency of developmental abnormalities of the male reproductive tract, particularly cryptorchidism and hypospadias have been reported, but no causative role for endocrine-disrupting chemicals has been determined. The data on temporal trends in the incidence of hypospadias and cryptorchism should be interpreted with considerable caution, given the lack of longitudinal studies and the consequent difficulties in comparing data from separate studies, in which definition, ascertainment, and registration of these defects may have differed substantially.
- The reports on the declining proportion of male newborns during the last decades remain unexplained.
- Concerns have been raised about the influence of endocrine-disrupting chemicals on the timing of puberty, but the possible mechanisms of action and role of other factors such as nutrition need to be clarified.
- High accidental exposure of pregnant women to certain organochlorine compounds, for example, polychlorinated biphenyls, has led to delays in the physical and mental development of the offspring. Some of these effects appear to result from altered thyroid or neurotransmitter function, but in most instances endocrine mechanisms have not been demonstrated.
- A number of studies report a decline (since 1939) in human sperm quality in several countries. Several re-analyses of these data has indicated possible bias and confounding, and have reached different conclusions with respect to sperm quality, depending on the methodology used. Recent, well-designed studies have shown large regional differences in overall sperm quality and time trends, both within and between countries. Even if semen quality

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

has deteriorated, this would not necessarily be due to endocrine disruption.

- Temporal increases in the incidence of testicular cancer have been reported in certain countries, but rates vary considerably among countries. The underlying reason(s) for the increased incidences has not been determined. However, exposure data on endocrine-disrupting chemicals for critical periods are lacking.
- Exposure to certain pesticides and organochlorine compounds has been linked to increases in the incidence of prostate cancer in a few limited studies, but most studies have found no association and the mechanism is unknown.
- There has been a steady increase in breast cancer incidence rates over the last decades (in Europe). The available data associating breast cancer development with exposure to organochlorine compounds do not support a causal relationship. Adult women currently at risk may have been exposed to endocrine-disrupting chemicals in utero or during infancy, childhood, and adolescence in the mid-twentieth century, when contaminant levels of these compounds were higher.

7. Ongoing Evaluation by the European Commission

In June 2000 the Commission established a first priority list of 553 substances. Evidence of endocrine disruption or potential endocrine disruption was found for 118 of these substances. However, when the CSTEE evaluated the list, it concluded that the source of the material, the methodology, and the selection criteria used to establish the list were not scientifically adequate.[53,54] In particular, the omission of dose–response/potency and exposure considerations have been criticized as well as the fact that synthetic hormones released into the environment were not considered. Several suggestions for improving the current approach have been made, including a stepwise approach for the selection of substances for further evaluation and prioritization.

Thereafter, the Commission initiated an in-depth evaluation of a group of 12 candidate substances consisting of 9 industrial compounds and 3 natural/synthetic hormones. At the same time information was gathered on the persistence, production volume, and legal status of another 435 substances for which there was insufficient data to decide on their potential for endocrine disruption. The two studies were presented to the CSTEE for a determination of scientific soundness.

For the first group of 12 substances the CSTEE reached the following conclusions:

- BADGE, carbon disufide, 4-chloro-3-methylphenol, 2,4-dichlorophenol, 4-nitrotoluene, and 2-phenylphenol do not appear to cause critical endocrine-disrupting effects in humans and wildlife.
- 4-(5,5-Dimethylhexyl)phenol and resorcinol do not appear to cause critical endocrine-disrupting effects in humans, but there is a potential risk to aquatic organisms near discharge points.
- The data for 4-chloro-3-methylphenol, 2,4-dichlorophenol, 2-phenylphenol, 4-nitrotoluene, and 4-(5,5-dimethylhexyl)phenol were quite limited, especially regarding environment impact.
- Further testing for potential endocrine-disrupting effects is needed for resorcinol, both on human health and the environment.
- Since the control of 2,2′,4,4′-tetrabromodiphenyl ether (tetra-BDE) can be extracted from the control of penta-BDE (particularly given that tetra-BDE is not produced commercially), it was not considered necessary to review this substance in further detail.
- As expected, the hormones estrone, 17β-estradiol, and ethinyl estradiol cause critical endocrine-disrupting effects in the environment.

The report on the 435 substances now adequately applies selection criteria such as exposure and persistency data, and missing data such as environmental impact have been identified. A preliminary evaluation indicates that of the 435 compounds, 30 are listed in Category 1 (at least one positive in vivo study); of these, 2,3,7,8-TBDD shows a higher endocrine-disrupting potency, whereas the others show 50- to 1000000-fold lower potencies. Of the 57 listed in Category 3, 19 did not show scientific basis for inclusion (3a), the others were classified as having "no data" (3b). Since the report now evaluates reproduction toxicity as part of other systemic toxic effects, further evaluation of the data will allow a comparison of the relative sensitivity of the endocrine system to a compound as compared to other toxic effects. Again, information on wildlife generally is insufficient, and no final conclusion on the impact of endocrine-disrupting chemicals to wildlife populations can be drawn at present.

From both of these reports it can be concluded that although many chemicals have the intrinsic potential for endocrine-disrupting effects, a more detailed evaluation reveals that the NOELs (no observed effect levels) of these effects are usually higher than those of the effects on other organs. Thus, environmental control levels and occupational exposure levels that are based on other endpoints protect humans from endocrine disruption. Because of insufficient information on environmental effects, this conclusion cannot be drawn about possible endocrine-disrupting effects on the environment.

8. Estrogenicity of Sunscreens

Recently Schlumpf et al.[55] investigated a number of compounds that are used as UV absorbers in sunscreen formulations in vitro in the E-SCREEN assay in MCF-7 breast cancer cells and the uterotrophic assay using immature Long Evans rats in vivo. As shown in Table 3 five out of six chemicals indicated estrogenic effects[55] in vitro, whereas three of the six compounds were positive in the uterotrophic assay. However, in the uterotrophic assay the estrogenic potency of benzophenone-3 (Bp-3) was 1500000 times lower than that of ethinyl estradiol, that of 4-methylbenzylidene camphor (4-MBC) 300000 times lower, and of octylmethoxycinnamate (OMC) 1000000 times lower.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Table 3: Estrogenic activity of compounds in sunscreens (UV-screens).[55]

	BP-3	HMS	4-MBC	OMC	OD-PABA	B-MDM	EE_2
E-SCREEN assay *MCF-7* cells	+	+	+	+	+	negative	+
uterotr. assay [ED_{50}]	1.525 mg kg^{-1}	negative	309 mg kg^{-1}	935 mg kg^{-1}	negative	negative	0.8 μg kg^{-1}
Rel. Potency [ED_{50} EE_2/ED_{50} UV-screen]	1:1.5×10^{-6}	negative	1:0.3×10^{-6}	1:1×10^{-6}	negative	negative	1

[a] BP-3: benzophenone-3 (2-hydroxy-4-methoxybenzophenone); HMS: homosalate (3,3,5-trimethylcyclohexyl 2-hydroxybenzoate); 4-MBC: 4-methylbenzylidene camphor; OMC:octyl methoxycinnamate; PABA: 4-aminobenzoic acid; OD-PABA: octyl-dimethyl-PABA; B-MDM: butylmethoxydibenzoylmethane; EE_2: ethinyl estradiol

However, in the in vitro test the potency of the compounds was similar to that of other industrial chemicals and thus low relative to endogenous estrogens. Bolt et al.[33] criticized these findings since a nonstandardized and non-GLP (good laboratory practice) protocol and uncommon rat strains (Long Evans and Nu rats) had been used. When these authors repeated the work using standardized and GLP protocols, they did not see estrogenic effects for 4-MBC, Bp-3, and OMC in the uterotrophic assay.

Moreover, Nakagawa and Suzuki[31] generally questioned the in vitro test systems used to determine the estrogenic potency of chemicals. In an investigation of 2-hydroxy-4-methoxybenzophenone (HMB) in metabolically competent rat hepatocytes, HMB was hydroxylated to 2,4-dihydroxy-4-methoxybenzophenone (DHMB) and the hydroxylated intermediate, which was tentatively identified as an isomer of 2,2′-dihydroxy-4-methoxybenzophenone (DHP). Both metabolites and the parent compound were rapidly conjugated to glucuronic acid. The metabolites had higher estrogenic activities than the starting HMB in MCF-7 cells (HMB (no activity) < DHMB (weak) < DHP). These findings further indicate that in vitro tests do not mirror the complexity of the intact organism, and that any results must be verified by in vivo testing before any conclusion can be drawn.

9. Conclusion

A great number of endocrine-disrupting chemicals have been identified by in vitro test systems. Since toxicokinetics and metabolism, which are not or insufficiently represented in these tests, affect the toxic potency of a substance, the results from in vitro test systems must be verified by in vivo studies. With such test systems like the improved 28-day toxicity test in rodents (OECD 407), the screening tests on reproduction (OECD 421/422), and the two-generation reproduction toxicity test (OECD 416), endocrine disrupters either showed no effects or the effects appeared only at very high doses exceeding those of other toxic endpoints.

Considering the relative low exposure of humans to endocrine-disrupting chemicals, it is not plausible that low-affinity compounds can displace high-affinity compounds from a receptor unless they reach sufficiently high concentrations. Such high exposure in humans has occurred only after industrial accidents. Thus, the assumption that the binding of a compound to a receptor per se has biological consequences is not acceptable.

There is overwhelming experience from the therapeutic use of very potent synthetic estrogens during pregnancy in order to prevent spontaneous abortion, for contraception, and to treat menopausal or postmenopausal disorders. All of these treatments require sufficiently high therapeutic doses to modulate the endocrine system. No one would expect that a dose more than 1000 times less than the therapeutic dose would be effective.

Overall, the science-based knowledge on the robustness of the endocrine system, the well-understood principles of substrate—receptor interactions, and the generally low exposure of humans to potentially endocrine-disrupting chemicals make it unlikely that the latter play a causative role in diseases and abnormalities observed in children and in the human population in general.

The array of in vitro test systems that covers relevant endpoints of endocrine disrupters is useful for mechanistic studies and helps in setting priorities for further testing. Since these tests do not evaluate the toxicokinetics of the chemical and its metabolites, they may generate false-negative as well as false-positive effects, so that the results must be verified by in vivo studies. Therefore, instead of supporting the further development of in vitro screening tests, it is recommended to improve available long-term in vivo tests like the enhanced OECD 407 28-day test and the OECD 416 two-generation study. These tests are considered relevant for the detection of hormone-like effects of chemicals. They usually demonstrate that endocrine-disrupting effects of chemicals are weaker than other effects like hepatotoxicity and neurotoxicity. Due to insufficient information on environmental effects, such conclusions cannot be drawn about possible endocrine-disrupting effects on wildlife populations.

10. Glossary

Explanation of some biological and medical terms:

- Cryptorchidism: failure of the testes to descend into the scrotum.
- Hypospadias: developmental anomaly in which the urethra opens on the underside of the penis or the peritoneum.
- Testicular dysgenesis syndrome: syndrome that encompasses low sperm quality, hypospadias, cryptorchidism, and testicular cancer.
- Hypothalamic–pituitary–gonadal axis: different feedback mechanisms between CNS (hypothalamus) and the hormone system (pituitary gland, gonads) for the regulation of endogenous sexual hormones; for example, a decrease in blood levels of estrogens stimulates their production in the ovary while an increase

Controlled self-organization of nanoparticles can lead to new materials. The colloidal crystallization of non-spherical nanocrystals is a reaction channel in many crystallization reactions. With additives, self-organization can be stopped at an intermediary step—a mesocrystal—in which the primary units can still be identified. Mesocrystals were observed for various systems as kinetically metastable species or as intermediates in a crystallization reaction leading to single crystals with typical defects and inclusions. The control forces and mechanism of mesocrystal formation are largely unknown, but several mesocrystal properties are known. Mesocrystals are exiting examples of nonclassical crystallization, which does not proceed through ion-by-ion attachment, but by a modular nanobuilding-block route. This path makes crystallization more independent of ion products or molecular solubility, it occurs without pH or osmotic pressure changes, and opens new strategies for crystal morphogenesis.

1. Introduction

Alignment of nanoparticle building blocks into ordered superstructures by bottom-up approaches is one of the key topics of modern colloid and materials chemistry.[1] In this area, much can be learned from the processes of biomineralization, which lead to well defined organic–inorganic hybrid materials with superior materials properties, complex morphologies. and hierarchical order.[2–4] Biominerals are often single crystals with amazingly complex morphologies such as the hammer-shaped building units of coccoliths[5] or the skeletal plates of sea urchins.[6] Although it is known that organic scaffolds, as in the case of coccoliths, play an important role,[5] the actual crystallization mechanism of the inorganic phase remains largely unexplored. Recently, increasing evidence was found that biomineralization takes place through amorphous precursor particles, for example, as reported for sea urchin spines.[7] In this way large amounts of material can be stored in metastable precursor particles, which are readily available to a crystallization event in a confined reaction environment. Further advantages of this crystallization pathway are highly efficient mass fluxes that are independent of solubility-products, the coupled high crystallization speeds, and crystallization without change of the pH value and the osmotic pressure. These are key features for mineralization especially in biological systems. This pathway is in stark contrast to the classical crystallization, which postulates an ion-by-ion or single-molecule attachment to a critical crystal nucleus and is therefore bound to solubility products and diffusion limitations. Mesoscale transformation processes towards crystalline phases were recently reviewed.[8]

By mesoscale transformation, not only single crystals with complex morphologies but also superstructures made up of nanoparticles interspaced by organic additives can be formed. The fusion of the building blocks leads to single-crystalline structures with included organic additives as defects. Support for this view comes from biomineral examples, which, although single crystalline, often contain minor amounts of included biopolymers. This inclusion is not understandable from the viewpoint of an ion-mediated crystallization process, as additives are generally considered to adsorb at edges and kinks of the developing crystal surface stopping it from further growth.[9]

Mesocrystal formation and the process of mesoscale transformation seem, however, not to be limited only to biominerals. It looks like nature only employs this advantageous physico-chemical construction principle, gaining speed and flexibility of construction. For example, similar to biomineralization, inclusions of additives up to 30 wt % are observed in synthetically grown crystals, too.[10,11] Revisiting the existing literature shows indeed that comparable observations have been made in synthetic inorganic chemistry much earlier, even in the absence of additives,[12,13] and the question can be raised if precursor particles and their superstructures also play a role—at least as intermediates—in crystallization in a much broader context.

In this Review we revisit the existing literature and examine it from the viewpoint of nonclassical, nanoparticle-mediated crystallization. A mesocrystal in this context is defined as a superstructure of crystalline nanoparticles with external crystal faces on the scale of some hundred nanometers to micrometers (Figure 1).

Mesocrystal intermediates can also lead by fusion to the formation of single crystals with included organic additives, sometimes allowing the observation of highly oriented nanoparticle-based intermediates. This scenario is shown in Figure 1.

It has to be noted that the term "mesocrystal" has already been used in the literature, but in the less restricted sense of a mutual three-dimensional translational order of various nanocrystals. As templates, pore systems of the MCM-41

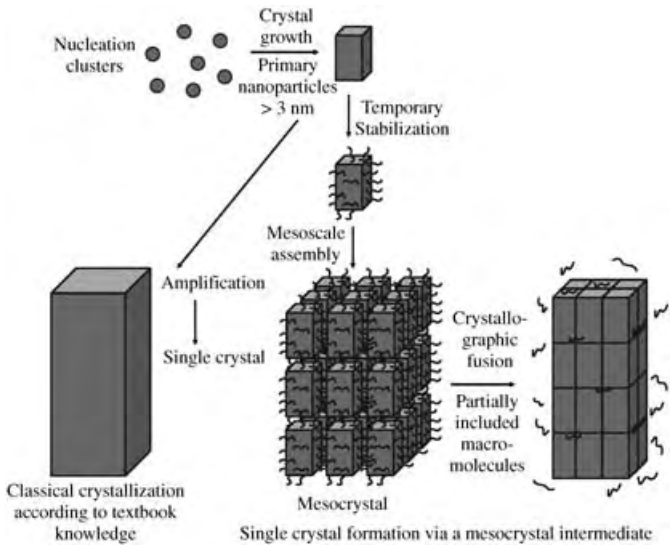

Figure 1. Classical crystallization (left) by ion-by-ion addition versus single-crystal formation by a mesocrystal intermediate formed by nanoparticle self-assembly. Image based upon ref. [8]

type were used for the deposition of size-quantized $BaTiO_3$[14–16] or $SrBi_2Ta_2O_9$.[15,17] Our definition is more restricted as it also involves orientational order (vectorial alignment) and the self assembly to facetted microstructures.

Mesocrystals are a special case of colloidal crystals. The latter have received considerable attention in recent years, as they result from the formal substitution of atoms or molecules in a classical crystallization event by defined and monodisperse nanoparticles this leads to superlattices with new and desirable properties such as photonic band gaps[18] or altered electronic and optical properties as in the case of semiconductors.[19] In addition to colloidal crystals made from SiO_2 which are a convenient model case, semiconductor and metal nanoparticles have been intensively investigated, owing to their electronic and optical applications.[20–24] Usually, the nanoparticle building blocks can be regarded as spherical core–shell nanoparticles with an inorganic core and an organic surfactant/ligand shell, both of which play a role for the crystallographic symmetry of the superlattice. Even colloidal crystals from two different nanocrystal systems could be prepared.[24] If inorganic and slightly prolate building units such as CdSe were used, an almost perfect crystallographic alignment of the nanocrystals was detected[19]—a feature which is also observed in mesocrystals as will be discussed later. Nevertheless, colloidal crystals were so far only self-assembled from spherical nanoparticles or by covalent linkage of clusters,[25] although it is clear that nonspherical nanoparticle building units should provide additional opportunities for self-assembly. Concepts to design such colloidal crystals, for example by orientation of nonspherical nanoparticles through magnetic fields are just being developed, and have to date not been experimentally verified.[26] It is important to remember that the mesocrystals described below already manifest the applicability of such concepts as they consist of highly oriented nonspherical building units and are formed through a pure self-assembly approach.

2. Early Reports on Mesocrystals

Although particle aggregates have been observed since the advent of crystallization experiments, particle aggregates with defined morphology and size were much less reported. For a Review by one of the pioneers in this field, see ref. [27]. One of the very first indications of mesocrystal intermediates was deduced from the porous internal structure of $BaSO_4$[28] which—according to the classical crystallization theory—should crystallize to a defect-free single crystal.

First indications of mesocrystals, although without perfectly flat external faces, were reported by Matijevic et al. in a synthetic study on various Ce^{IV} compounds in absence of any organic additives.[13] Figure 2 shows some of these rod-like particles of Ce^{IV} minerals.

These structures are clearly nanoparticle aggregates but without a well facetted external morphology. Nevertheless, the single rodlike or platelike nanoparticles mutually align with high positional and vectorial precision to give a reproducible superstructure.

Another example is reported for the same components[13] as well as for CuO, depicted in Figure 3 (right).[29] For CuO, the aggregation from primary nanoparticles could be revealed in a kinetic study which already indicated the general self-assembly mechanism for mesocrystals, although a faceting of the nanocrystal aggregates is generally lacking (Figure 3,

Helmut Cölfen studied Chemistry at the university Duisburg and completed his PhD in 1993 supervised by Werner Borchard. After a Postdoc at the NCMH Nottingham with Stephen Harding, he joined the Max Planck Institute of Colloids and Interfaces in 1995 and finished his Habilitation on "Biomimetic Mineralization" in 2001 with Markus Antonietti. He is now a lecturer at the University of Potsdam and head of the analytical service in the colloid chemistry department of the MPI. His current research is focused on the synthesis and analysis of double hydrophilic block copolymers, biomimetic mineralization, and nonclassical crystallization. In his spare time he plays music in a band.

Markus Antonietti studied Chemistry in Mainz and did his doctorate with Hans Sillescu. His habilitation about nanostructured polymergels in 1990 filled him with enthusiasm for complex materials. After his professorship for Chemistry at the University of Marburg he was appointed director for the department of Colloid Chemistry at the Max Planck Institute of Colloids and Interfaces in 1993. His main academic interest is in the creativity in research. He loves to share and impart this passion. He likes cooking with his family and loud music.

right). For CeO_2, a two-dimensional hexagonal platelet is formed from not very homogeneous and not very well-defined spherical nanoparticles (Figure 3, left). Clearly, the mutual interaction forces drive the single nanoparticles to form a hexagonal superstructure. It is remarkable that CeO_2 possesses a primitive triclinic unit cell, that is, it has especially no hexagonal symmetry axis. It will be shown below that mesocrystals very often have a higher symmetry than their constituting tectons. This occurrence is speculatively assigned to multiple twinning of primitive units and the resulting symmetry average on the mesoscale.[30] In these early experiments, the hexagon superstructure however just represented a minor part of the precipitates and its formation mechanism remained as unclear as for the rods shown in Figure 1. Nevertheless, it was an early observation of crystalline superstructures with an external structure and symmetry differing from that of the nanoparticle building units, but with a not too well ordered nanoparticle interior. For the sake of completeness, it should be mentioned that very similar observations on the oriented aggregation of CuO were just recently published,[31] however with a more precise view of the relevant phenomena.

As early as 1986, mesocrystals with even higher definition were reported for $CaCO_3$ made in silica gels.[32] In this case, fibers built from a set of cleaved calcite rhombohedra arranged along their *c*-axis were reported. Although each fiber was an aggregate of crystalline subunits, the observed behavior by polarization microscopy was that of a single crystal indicating the high orientational alignment of the subunits in this one-dimensional mesocrystal.[32] Interestingly, these mesocrystal fibers were only an outer part of a hierarchical structure, the so called "sheaf of wheat" morphology.[32] From different sheaves, mesocrystal fibers with a very different morphology radially splayed out from the sheaf center. Again, the mesocrystals behaved like single crystals in polarization microscopy and exhibited a complicated morphology (Figure 4). The reason for this unusual aggregate morphology remained unexplained, although the morphogenesis process was assumed to be of importance.

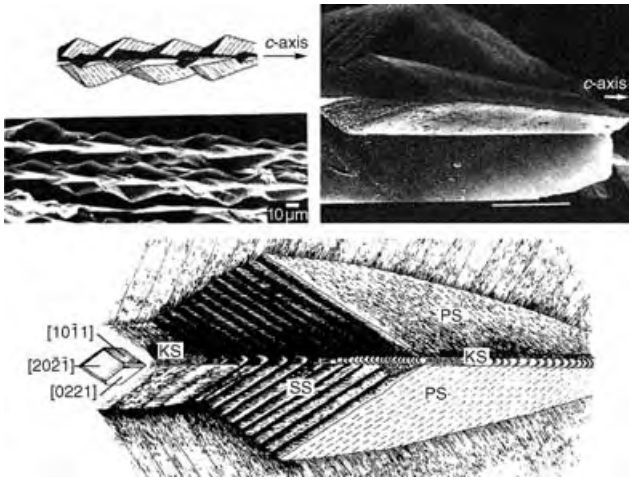

Figure 4. $CaCO_3$ formed in a silica gel. Top left: SEM view of a set of serrated fibers and a diagram of one fiber. Top right: Enlarged view of the left SEM image showing a morphological unit form by two domes (scale bar = 10 μm. Such work has stimulated experiments where otherwise stable nanoparticles of anatase were destabilized in a controlled fashion, either by hydrothermal treatment[33] or by the addition of face-specific organic molecules called "assemblers".[34,35] Indeed, a few years ago, the first nanoparticle-based structuration mechanism was identified.[33] In this so called "oriented attachment", nanoparticles fuse together with their high-energy surfaces under crystallographic fusion and elimination of the high-energy faces under energy gain, thus creating extended structures.[33] Addition of assembler throughout this process even improves the control

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

over the aggregation process;[34,35] similar levels of control were also found with polymeric additives.[36–39] Such an oriented attachment mechanism was then suggested also to hold true for iron hydroxide biomineralization products.[40]

3. One- and Two-Dimensional Mesocrystals

One- and two dimensional particle arrays such as those shown above were also reported by Mann and co-workers but in a difference to the previous studies, they used a surfactant microemulsion-mediated approach. In this case, presumably a combined action of nanoparticle crystallization and surfactant interactions led to the self assembly of these remarkable low-dimensional structures, and a surfactant-mediated aggregation mechanism was suggested for the growth of these structures, as shown in Figure 5.[41]

The structures shown in Figure 5 quite nicely illustrate some of the building principles of mesocrystals (shown as a sketch in Figure 1) in one or two dimensions: the primary crystalline building blocks are mutually aligned, following common crystallographic coordinates. The structure in itself is not exactly crystalline, as minor differences in length or size are tolerated and taken up in the structure. It is a mutual self-organization principle, which can tolerate lattice defects.

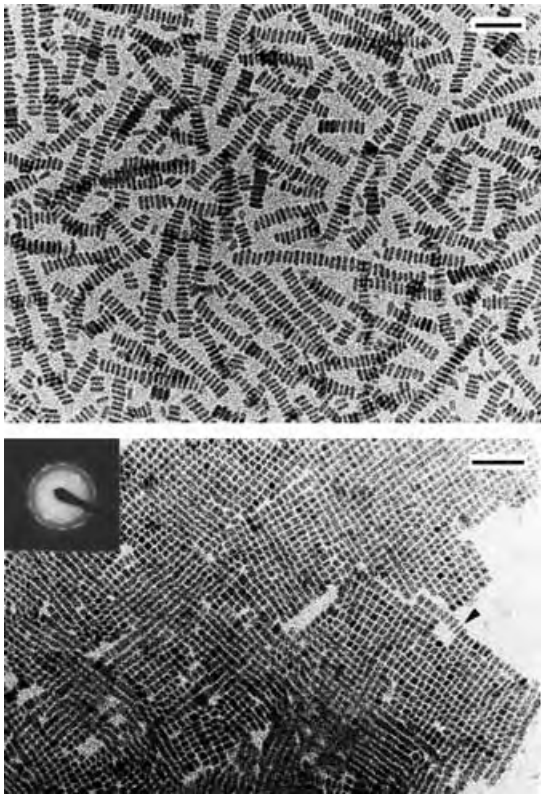

Figure 5. TEM images showing top: ordered chains of prismatic $BaCrO_4$ nanoparticles and bottom: rectangular superlattice of $BaCrO_4$ nanoparticles[41] prepared in a reverse microemulsion. Scale bars = 50 nm . The arrow indicates dislodged particles revealing the prismatic morphology of individual crystallites. Inset: The electron diffraction pattern gives the superimposition of reflections from zone axes approximately parallel to the [100] direction. Reproduced from ref. [41] with kind permission of Nature Publishing Group.

4. Three-Dimensional Mesocrystals

Examinations on defined particle aggregation by hydrophilic molecules[42] or double hydrophilic block copolymers (DHBCs) as especially powerful surface-active agents to control crystallization and superstructure formation of inorganic compounds,[43] have subsequently multiplied the reported observations of diverse mesocrystal systems. Herein, it will be shown that the restrictions on additive design for mesocrystal formation are not too strict, as even just a preferential attachment to specific surfaces of the primary crystals can lead to strongly anisotropic mutual interactions. Among these interactions, dipole fields were first suggested by Busch, Kniep, et al. to be of importance for the structuration process of inorganic matter.[44,45]

The formation mechanisms of three dimensional mesocrystals are largely unexplored. One of the difficulties maybe the high lattice energy of inorganic crystals, which in many cases leads to the crystallographic fusion of the oriented nanocrystal building units to a single crystal (Figure 1) through the three-dimensional oriented attachment mechanism.[33] Another difficulty maybe the homogeneous aqueous environment, where it is difficult to predict how hydrophilic nanoparticles can be arranged to defined three-dimensional mesocrystals. Herein we will try to reveal a general mesocrystal formation mechanism, that is clearly distinguishable from the default case of uncontrolled primary particle aggregation.

One of the first three-dimensional mesocrystals and probably the most perfect to date was reported by Busch and Kniep in form of an elongated, hexagonal-prismatic fluoroapatite seed crystal formed in a double diffusion experiment at ambient temperature in a gelatine gel (Figure 6).[44–46] The hexagonal seed crystal was not directly recognizable as a mesocrystal, as it showed a well-facetted, single-crystal-like morphology (Figure 6). Even X-ray diffraction showed features of a fluorapatite single crystal oriented along the *c*-axis,[47,48] because of the very high vectorial order of its nanoparticulate building units. Although the hexagonal crystals contain approximately 2 wt-% intracrystalline gelatine, the polymer does not modulate the crystal structure, so it was concluded that the gelatine adapts to the fluoroapatite structure.[47]

Kniep et al. were able to reveal the radial inner structure of this seed crystal by a hexagonal cross section perpendicular to the seed axis, thus disproving the existence of a classical single crystal.[45] It was concluded that the hexagonal seed crystal with single-crystalline appearance and scattering behavior is a hierarchically ordered inorganic–organic composite superstructure with periodic orientation of hexagonal primary apatite nanocrystals,[49] or, in our words, a mesocrystal (see also Figure 1).

In a more recent study, the internal nature of the hexagonal seed crystals (Figure 7, left) was investigated in more detail.[50] Figure 7 (right) shows the growth model for the observed radial outgrowth. It agrees with the mesocrystal scheme presented in Figure 1 but modified for the case of hexagonal building units.[50]

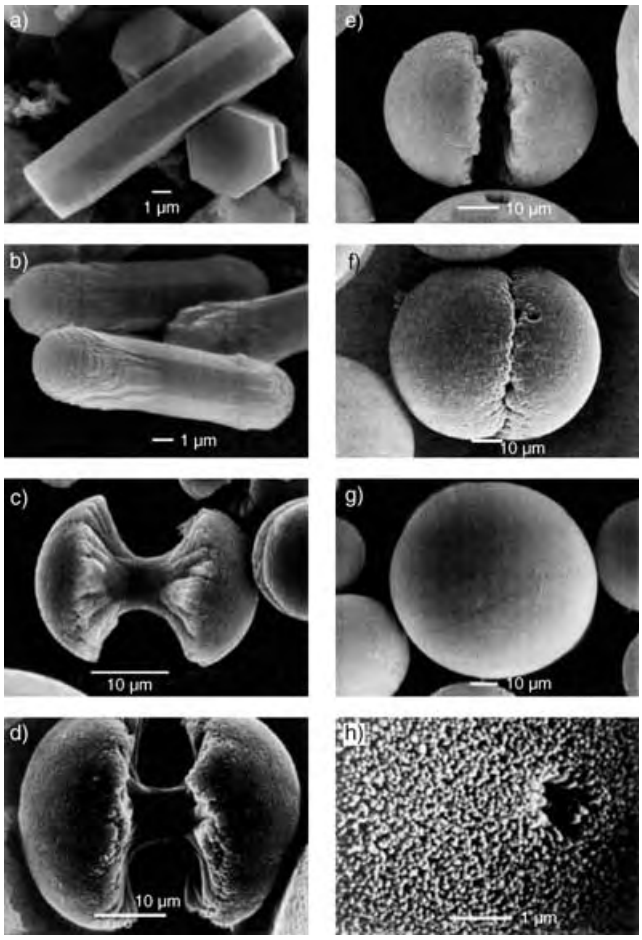

Figure 6. Selected sequence of SEM images of progressive stages of self-assembled (hierarchical) growth of fluorapatite aggregates in a gelatin gel (morphogenesis): from an elongated hexagonal-prismatic seed (a) through dumbbell shapes (c–f) to spheres (g); the surface of a just closed sphere also consists of needlelike units (h) following the general principles of self-similarity. Intrinsic electric fields were suggested control factor for the rod–dumbbell–sphere fractal growth. Picture reproduced from ref. [45].

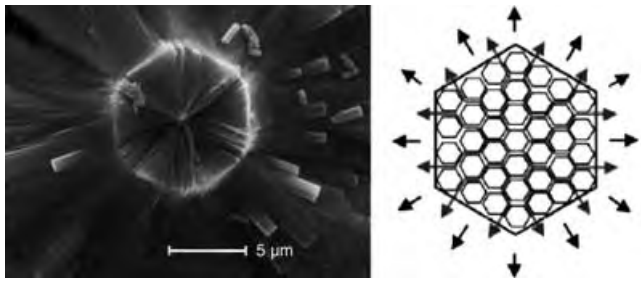

Figure 7. Left: SEM image of the fracture area of a central seed of a fractal composite aggregate. The fracture surface is dominated by a radial pattern. SEM (vacuum) was used instead of "environmental SEM" (freezing of sample) because areas of structural weakness are made visible more clearly by shrinking effects during evacuation (drying). Right: Idealized two-dimensional arrangement of hexagonal nanoparticles forming a hexagonal nanoensemble (nanosuperstructure). The organic component inside and between the crystalline building units is omitted for clarity. The inner lines in the right Figure indicate possible directions of preferred cleavage, the outer arrows show the radial structure of the cleavage. Reprinted from ref. [50] with permission of the Royal Society of Chemistry.

The hexagonal pattern, already known from X-ray diffraction studies,[47,48] was also found in high-resolution micrographs with subsequent fast Fourier transform (FFT) analysis (Figure 8, top). Electronic filtering and enhancement of this image revealed structural defects, which were attributed to a collagen triple-helix strand (white circle Figure 8, bottom),[50] the memory of the former grain boundaries that are stabilized by organic material.

In addition, a superstructure periodicity of 10 nm was revealed, in good agreement with a tecton or primary nanoparticle size of about 10 nm.[50] Furthermore, TEM of a focused ion beam milled sample showed pores and channels at the grain boundaries containing an amorphous phase,[51] giving final evidence for the mesocrystalline nature of the well facetted hexagonal superstructure (see also Figure 1).

Reactions in gels appear to be well suited for the generation of mesocrystals as crystal growth in gels takes place under very high supersaturation[52] leading to increased nucleation of small clusters—the building units for the mesocrystals. Simultaneously, convection or turbulence throughout crystallization can be suppressed, thus allowing the interaction potentials between the particles to dominate the mutual alignment of the particles. This process explains why many of the most defined mesocrystals are observed in gels.

Whereas gelatine gels can be considered to interact with inorganic crystals, at least through their charged groups, polyacrylamide gels can be considered to be essentially inert. The growth of $CaCO_3$ in polyacrylamide gels led to remarkable pseudo-octahedral calcite mesocrystal morphologies built up of rhombohedral primary nanocrystallites (Figure 9).[53,54] The external faces of the superstructure could even be indexed and a growth model based on hierarchical aggregation of rhombohedral subunits was proposed.[53] As already found for the fluorapatite hexagonal seeds, the crystallographic orientation of the subcrystallites is almost perfect, and the organic matrix appears to be interspaced between individual crystallites (Figure 9).[53] However, whereas the fluoroapatite diffraction pattern was that of a single crystal,[47] the calcite mesocrystals indicated a slight orientational distortion of the diffraction spots (Figure 9) corresponding to an average mosaic spread of 3.9 ± 1.1 degrees. This result nevertheless still confirms a high orientational order of the subunits in the mesocrystal.[53] We attribute this difference to the fact that the calcite system contains many vacancies and is potentially twinned (to allow construction of an octahedra from rhombohedra), whereas the particles from Kniep et al. have a higher symmetry and are clearly rather tightly packed.

Varying the polyacrylamide hydrogels by copolymerization with charged acrylamidopropanesulfonate (AMPS) to give polyacrylamide-co-acrylamidopropanesulfonate (PAAm-co-PAMPS), the morphology of the calcite mesocrystals could be tuned from the pseudo-octahedral[53] towards a cubooctahedral morphology with increasing

amounts of the charged AMPS in the copolymer gel (Figure 10).[55] The substructure of the mesocrystals from aligned smaller crystals could be nicely visualized (Figure 10c,d).

One important conclusion of this study was that the alteration of the functional groups in the hydrogel changed not the mesocrystal formation as such, but the morphogenesis process, shedding some light onto the question why mesocrystals exhibit defined outer faces and how they can be influenced.[55]

Mesocrystals can not only be formed in gel matrices with their special slow transport conditions, they can also form

directly in solution. Among the first reported three-dimensional mesocrystals was a pseudocubic hematite (α-Fe_2O_3) particle.[56–59] For this crystal, the typical but remarkable high orientational alignment of the nanoparticle subunits as well as the iso-aligned nanoparticle building units was clear even from electron-diffraction images (Figure 11).[59] However the result were interpreted as being from single-crystal particles with internal discontinuities.[59] According to this interpretation, it was noted that the reported monodisperse polycrystalline hematite particles grow through a dissolution–recrystallization mechanism and not through an aggregation-based mechanism, although a "characteristic internal structure" of the pseudocubic particles was suggested. Furthermore, it was noted that the adsorption of anions plays an important role for the morphology and internal structure control where Cl^- ions were suggested to remain in the mesocrystal interior.[59] In our opinion, these nice results could also be explained by the controlled aggregation of primary nanoparticles and mesocrystal formation, analogous to the other cases. The experimental results however clearly reveal the nanocrystalline substructure as well as the radial alignment of elongated subcrystals (Figure 12) resulting in different crystal orientations according to their position.

Another example for mesocrystals formed directly from solution without any additive is $(NH_4)_3PW_{12}O_{40}$.[60–64] In these crystals, nanocrystals were unidirectionally aligned and epitaxially connected to form dodecahedral aggregates, and the analogy of the mesocrystal aggregate to a single crystal in terms of diffraction analysis was underlined. In addition, the mesocrystals were found to be porous.[62] Comparison of the cesium and ammonium salts which precipitated at different temperatures allowed a variation of the degree of order in the mesocrystals. [65] The solubility of the salts was considered to be responsible for the control of the microstructure morphology with the higher solubility favoring the regular polyhedral shape.[65] This result is qualitatively in agreement with the finding that the mesocrystal morphogenesis in gels is influenced by the functional groups of the gel, which in turn determines the gel–crystal surface interaction and therefore the surface conditions of the mesocrystal.

Mesocrystal formation was also observed for Zeolites.[66,67] In these experiments, the zeolite first forms "nanoslabs" containing 2, 6, 12, or 48 zeolithic unit cells, which then vectorially align to larger structures. TEM however clearly revealed that those bigger units are composed of the smaller building blocks, with all the textures and defects typical for mesocrystals.

A very detailed study on mesocrystal formation directly in solution and subsequent fusion to iso-oriented crystals was reported for copper oxalate.[68,69] In this case, nanoparticles

were found to arrange almost perfectly to a mesocrystal, which could be influenced in terms of morphology by hydroxymethylpropylcellulose (HPMC, Figure 13). It was found that the polymer influences nucleation, nanocrystal growth, and aggregation by selective interaction of the polymer with the more hydrophobic lateral (110)/(1$\bar{1}$1) ε-faces of an [001] elongated nanocrystal as compared to the hydrophilic (001) α-face.[69]

Increasing polymer concentration led to the formation of more but smaller crystal nuclei as a result of the decrease of the interfacial tension between nuclei and solution. The specific HPMC adsorption to the lateral ε-surfaces of the growing nanocrystals, once a sufficient HPMC concentration was reached, led to the formation of anisotropic shapes. Upon aggregation of these nanocrystals, a mesocrystal is formed as intermediate but is apparently not stable because of the low repulsive electrostatic and steric forces. Depletion flocculation of the weakly adsorbed polymer layers was suggested to be the reason for the depletion of the polymer from the inner mesocrystal surfaces to the outer mesocrystal faces resulting in attraction of the nanoparticles with subsequent nanoparticle fusion to give an iso-oriented crystal.[69] Nevertheless, this iso-oriented crystal was shown to be not single crystalline, as line width analysis in wide-angle X-ray scattering (WAXS)

reveals the nanometer size of the primary building units, which get smaller with increasing HPMC concentration. As typical for mesocrystals, electron diffraction indicated a minor, but detectable orientational disorder, in this case along the [001] direction, which also supports the nanoparticle-aggregation-based mechanism of mesocrystal formation (Figure 14).

The whole mesocrystal formation process originally proposed is illustrated in Figure 15. In this case, the role of the polymeric additive on nucleation, growth, and organized aggregation to a mesocrystal is shown, and a coding of the mesocrystal morphology by tuning the surface energies of the nanocrystal building units and thus the nanocrystal morphology is suggested (that is, the morphology of the nanocrystal is a major influence on the shape of the resulting mesocrystal). In this particular case, the mesocrystal appears to adopt the same morphology as the nanoparticles. It is remarkable to note that the copper oxalate mesocrystals retain their morphology and nanometric substructure throughout decomposition into copper oxide.[70]

In a later and more detailed study on the copper oxalate system,[71,72] the "brick-by-brick" aggregation mechanism could be revealed in a time-dependent study.[71] However, the mesocrystal core parallel to the [110] direction showed poor organization with increasing order towards the particle surface and with increasing nanoparticle size. The particle density was higher at the hydrophobic ε-surfaces than the hydrophilic α-surface. Kinetic studies revealed a fast nucleation, growth, and agglomeration onset of primary mesocrystals leading to the relatively unordered particle core. This step is followed by a much slower growth stage with controlled aggregation as the predominant growth mechanism, which amplifies the mesocrystal morphology. Secondary particle nucleation was found as a competing event. Upon extended ripening, likely by dissolution–recrystallization, high-energy surfaces were eliminated.[71] This study implies that a mesocrystal is more a kinetic, metastable intermediate than a thermodynamically stable product.

The studies were extended onto the related cobalt oxalate dihydrate.[73] As was found for copper oxalate, WAXS showed the crystals were composed from nanometer building units. Atomic force microscopy (AFM) revealed strings of nanodomains oriented along the principal axis of the particle (Figure 16) and that the lateral and basal faces of the precipitate are composed of stacked nanoparticle layers with a thickness between 5–7 nm.

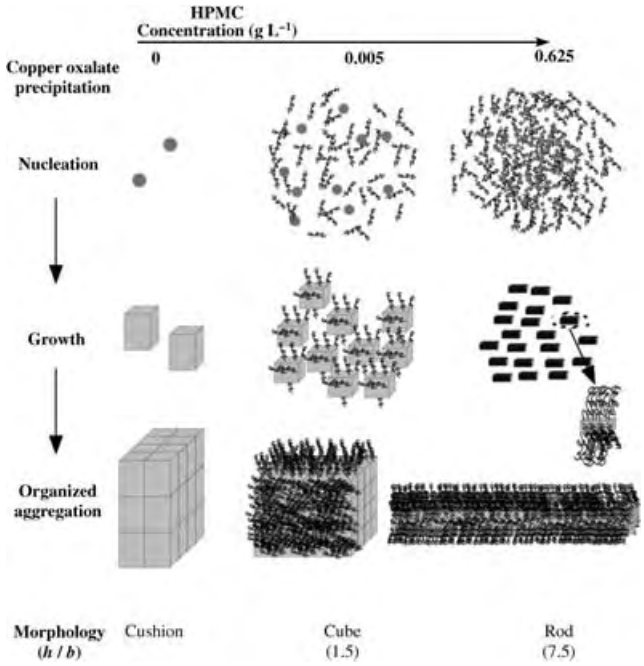

Figure 15. Schematic representation copper oxalate precipitation showing the influence of HPMC on the three major steps of particle formation (h = height, b = breadth). Figure reproduced from ref. [69] with permission of Academic Press.

A time resolved HRSEM study revealed the formation mechanism of the mesocrystal (Figure 16).[73] Poorly crystalline primary particles (10 nm) first aggregate to form secondary particles (23 nm). The latter subsequently aggregate to form polydisperse elongated particles (Figure 16, middle). These elongated particles also aggregate at the end and center of a growing particle (Figure 16, bottom) building the mesocrystal. Afterwards, there is a layer-by-layer growth by aggregation of primary particles onto the lateral external faces. Thus the mesocrystal is a core–shell particle or core–shell mesocrystal, where the core is quite disordered owing to the polydispersity of the nanoparticle building units.[73] The presence of steps and kinks on the external faces is reminiscent of classical crystallization models—except that the atoms or molecules are replaced by nanoparticles. The changes in supersaturation and thus ionic strength, which is closely associated to colloidal stability of nanoparticles, were suggested to play a major role in the process of ordering the nanocrystals into a mesocrystal because the ordered mesocrystal shells were formed at a lower supersaturation than the disordered cores. However, the ordering of nanoparticles to a mesocrystal can certainly not be reduced to the nanoparticle colloidal stability issue alone. An example are $CaCO_3$ mesocrystals, which are formed by the selective adsorption of poly(styrene sulfonate) PSS onto the highly polar calcite (001) nanoparticle faces.[74] If the nanocrystal is considered as a dielectric, adsorption of PSS onto one (001) face results in repulsion of negative ions from the opposite (001) face so that a dipole field is built up. It was argued that this situation can lead to a controlled arrangement of the nanoparticle subunits to give mesocrystals (Figure 17). These mesocrystals are

highly porous but show their common mutual high orientation by a rather perfect tensorial birefringence under crossed polarizers. Note that calcite is highly birefringent except when observed from the [001] direction (white plane in the Cerius model, Figure 17).

Variation of the $CaCO_3$/PSS ratio resulted in very systematic variations of the mesocrystal morphology, including a whole family of highly defined rounded structures (for one case with six elliptic faces, see Figure 17). Higher PSS concentrations lead to increasing exposition of the highly polar (001) face, finally resulting in a multicurved convex–concave structure with broken symmetry along the [001] direction at high Ca^{2+} and PSS concentrations. This result shows the importance of dipole fields as ordering forces for mesocrystal formation.[74]

Interestingly, there is evidence that some biominerals are also mesocrystals. For example, sea urchin calcite skeletal elements scatter like single crystals but have a nearly isotropic fracture behavior, which is untypical for single-crystalline calcite. Indeed, in a very recent study, an AFM investigation of a fracture pattern of sea urchin skeletal elements revealed a rough, clusterlike pattern without any preferred plane orientation.[75] The detected subunit size was in the range of 30–50 nm. In the same study, a synthetic calcite mesocrystal was reported, which was grown from an amorphous precursor in presence of polyaspartic acid. This calcite crystal consisted of uniformly shaped, oriented, and interlocked planar triangular growth domains with a length of 80–150 nm, width 40–100 nm, and a thickness of 3–6 nm.

Mesocrystals can not only be obtained for inorganic but also for organic crystals. An advantage of using organic nanocrystals is that these are molecular crystals, where a dipole moment as well as an anisotropic polarizability can be encoded in the molecule. Such mesocrystals are particularly well suited to learn about the mechanism of mesocrystal formation. For example, alanin is dipolar, and thus mesocrystals can be formed using a block-copolymer additive that has an anionic polyelectrolyte block which selectively adsorbs onto the positive (001) face of DL-alanine. This process creates platelets with a dipole moment along the *c*-axis (Figure 18).[30] The dipole moment along the [001] axis leads to the observed stacking of the nanocrystal platelets forming the mesocrystal where the individual building units are interspaced by the adsorbed polymer on (001).

A model example for a mesocrystal formed by anisotropic van der Waals attraction was reported by Taden et al. for dyes with an anisotropic polarizability.[76] Amorphous particle precursors were made in a size-controlled fashion by cooling the liquid nanodroplets of a miniemulsion. Spontaneous

Figure 17. $CaCO_3$ mesocrystals formed in presence of PSS ($Ca^{2+} = 2.5$ mM, PSS = 1 g L^{-1}) a) SEM micrograph of a single mesocrystal. b) Cerius^2 calculated morphology of a $CaCO_3$ single crystal with the mesocrystal morphology (gray = (104), white = (001)). c) higher magnification clearly indicating the alignment of primary particles and the porous nature of the mesocrystal. d) lowering the PSS concentration ($Ca^{2+} = 2.5$ mM, PSS = 0.5 g L^{-1}) results in a curving of the (001) planes. The former (104) planes are now six ellipses, illustrating that mesocrystals can easily exhibit highly defined curved morphologies.

Figure reproduced from ref. [30].

rearrangement of many nanodroplets towards well-defined linear mesocrystal aggregates was observed, which was accompanied by significant color changes of the dye superstructures. These rodike particles could be ripened to larger three-dimensional mesocrystals that retained the almost perfect molecular orientation found in the nanoparticle aggregate. This orientation could be demonstrated on turning the ripened mesocrystals under crossed polarizers (Figure 19, bottom).

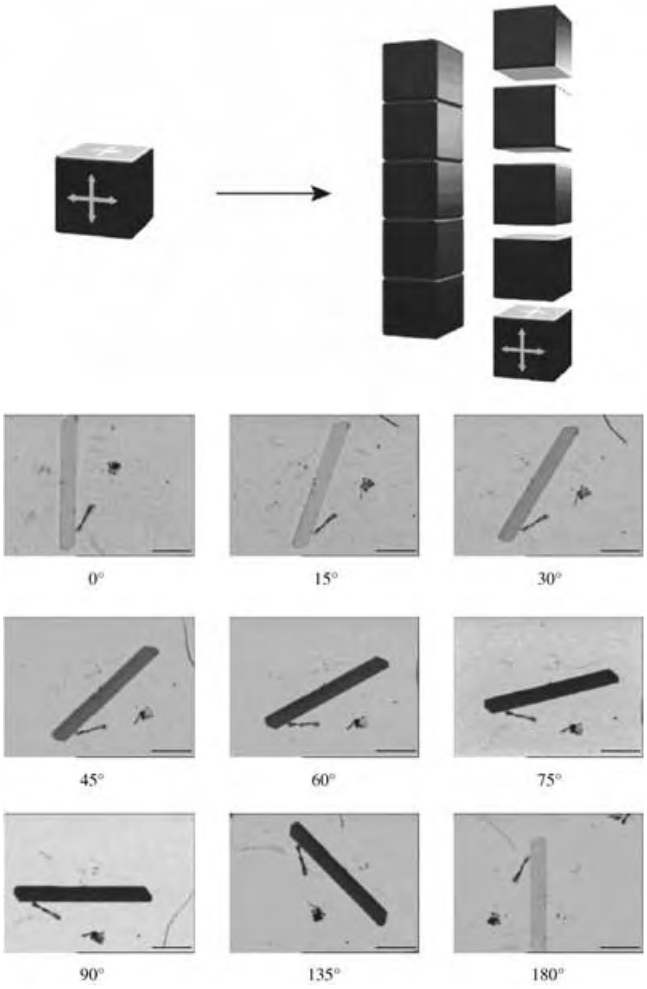

Figure 19. Top: Scheme to illustrate the directed mesoscale aggregation of dye nanoparticles. Because of the symmetry of the unit cell the primary nanocrystals formed show different polarizabilities along different planes. As is typical for van der Waals forces, similar polarizabilities attract each other optimally ("attraction of the same"). In this representation the light faces with the highest polarizability give the strongest van der Waals force. As a result, aggregation and mesocrystal formation occurs only in this direction. Bottom: series of polarization tilts of a selected large crystal of oil blue (scale bar = 20 mm). Figure reproduced from ref. [76] with permission of the American Chemical Society.

The fact that the dipole moment of such dyes is along the molecular axis and coupled to the maximum color allows the difference between polarizability and dipole moment as the driving force for organization to be studied. A high polarizability will lead to a high van der Waals attraction (light

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

faces in Figure 19, top), a dipole moment will lead to an attraction of different dipoles. As the dye molecules are perfectly aligned perpendicular to the main axis of the mesocrystal, these experiments revealed tensorial differences in the polarizability of various nanocrystal faces to be the driving force for the formation of mesocrystals with the observed high orientational order. Whether or not the nanocrystalline building units in the mesocrystals fused together by oriented attachment[33] to form a single crystal was not revealed.

In addition to the above examples, where mesocrystals are sufficiently long-lived to be isolated at least as kinetically stable intermediates, there are also examples where mesocrystals can only be postulated as short-lived intermediates by indirect evidence in a "classical crystallization" event,[77] which is usually expected to occur by molecule or ion-by-ion attachment.

In most cases, however, the speed of crystallization events makes the classical molecule- or ion-mediated crystallization picture unrealistic. For example, Rieger et al. have demonstrated that the particle formation from highly supersaturated boehmite solutions is determined by the mixing process, which is orders of magnitude too fast to be covered by classical nucleation and growth theories.[78] Even in the crystallization process of a mineral such as $BaSO_4$, which has been intensively studied in the past and which was assumed as a model case for ion-mediated crystallization, strong experimental evidence was found that crystallization also progresses by organized mesoscale aggregation and alignment. Judat and Kind analyzed the additive-free crystallization of $BaSO_4$ for various supersaturation conditions[77] and found clear evidence for a nanoparticle-mediated crystallization mechanism contradicting the classical ion-mediated mechanism. Electron microscopy and diffraction revealed a polycrystalline, but almost perfectly oriented mesocrystalline superstructure of primary $BaSO_4$ nanocrystal subunits with the typical slight orientational distortions of the superstructure (data not shown; similar to Figure 8, right). It was proposed that a mesocrystal formed as an intermediate on the way to a porous $BaSO_4$ crystal and various evidence for the absence of the classical crystallization pathway for this example was collected.[77] However, in other regions of supersaturation, crystallization according to the classical mechanism was also observed.

These examples indicate that the evidence for mesoscale aggregation and organization towards mesocrystals should increase dramatically in the next few years as mesocrystals also appear to be regular intermediates in ordinary crystallization reactions, which to date were assumed to be ion mediated. Typical areas in the parameter space to expect mesocrystals are high supersaturation ratios or corresponding low solubilities or ion products.

5. Conclusions

In summary, mesocrystals are oriented superstructures of nanocrystals with common outer faces, and are a new type of colloidal crystals formed from nonspherical, crystalline building units. Both the formation as well as the morphogenesis of mesocrystals apparently contradict the classical textbook knowledge on crystallization, where growth of shapes is based on the integration of atomic or molecular building blocks into energetically favorable sites on a growing crystal face.[79,80] The adsorption of ions or molecules onto the crystal face is followed by subsequent diffusion across the surface to steps and kink sites[81] which leads to a plane-by-plane growth of a single crystal. The relevant parameters for classical crystallization are molecular solubility (defining the speed of crystallization) and crystal-face-specific interface tensions (defining growth rates, relative exposure, and therefore the morphology of the crystal).

This type of crystallization is clearly not observed for mesocrystals, which are built from nanoparticle building units, where speed of crystallization and morphology of the superstructure are only encoded in colloidal stabilization and vectorial long-ranged interaction potentials. This principle delivers new tools and possibilities into the hands of chemists, as it is now possible to generate crystalline nano- and mesostructures in a much broader and potentially useful way. The universal applicability of the classical crystallization picture was already questioned for a few years,[82] partly as a result of the careful observation of biominerals.

In addition, mesocrystal formation processes may even be a common crystallization pathway in the formation of single crystals, especially in systems with very low molecular solubilities or high supersaturations. As a result of the progress in instrumentation, direct evidence for such mesocrystals was recently discovered, which appear to be valid over a wide parameter space. The reason for the remarkable, almost perfect order of the nanocrystalline subunits which results in diffraction patterns similar to single crystals is still unknown, but tensorial polarization forces and dipole fields are discussed.[45,74] Indeed, theoretical studies suggest that a nonspherical charged object in an electrolyte creates a screened electrostatic potential that is anisotropic at any distance[83] so that mutual ordering can be induced.

There are however some criteria by which the presence of a mesocrystal either as an intermediate or as the final product can be identified. Even if the nanoparticle orientational order is almost perfect, the porosity in mesocrystals can be quite high as a result of nanoparticle polydispersity and stacking defects during mesocrystal formation. These defects are transformed into pores with organic or foreign-ion inclusions upon ripening to a single connected crystal.[77] Organized grain defects or amorphous interlayers can occur in the same way.

The reasons for the formation of the external mesocrystal faces are still unknown. In the most simple case, they maybe simply the reflection of the nanocrystal morphology[69] but in the majority of cases, mesocrystals exhibit external morphologies not related to the primary crystal symmetry, sometimes they have the typical rough faces, but a higher symmetry than the primary units, sometimes they even have curved, parabolic, or elliptic faces, as shown in Section 4.

In an extreme case, a mesocrystal can, although vectorially quite perfectly aligned, completely loose any macroscopic crystalline appearance and can exhibit morphologies

like the $BaCO_3$ helices shown in Figure 20, which were formed after selective encoding of special faces of the orthorhombic primary nanoparticle building units by additive adsorption.[84] Not only the high alignment of elongated nanoparticles in these helices is remarkable, also the apparent "communication" between the two helices is. Identical morphologies and irregular helix pitch strongly indicate the presence of ordering electric fields in addition to the constraints exerted by the face-selective polymer adsorption. Helices from twisted twin subunits were also reported for triclinic $K_2Cr_2O_7$ and H_3BO_3, formed in a diffusion field created around a growing crystal in poly(acrylic acid) or poly(vinyl alcohol) gels[85] or orthorhombic K_2SO_4 in a viscous poly(acrylic acid) solution (PAA).[86] In the latter case, the crystal habit was modified by selective PAA adsorption leading to tilted platelike crystals. This effect is in addition to the diffusion-limited growth condition, which controls the assembly of the tilted subunits. Even the direction of the helical turn could be influenced for $K_2Cr_2O_7$ in a gel medium by molecular recognition of the enantiomeric triclinic subunit surfaces by glutamic acid enantiomers.[87]

Nanoparticle surface interactions appear to be of importance for the formation of a mesocrystal and possibly are also responsible for the formation of external faces, which can be indexed like those of a single crystal. Mesocrystals are a new type of nanostructured matter with potentially exciting applications, either in construction materials (as exploited by nature for biominerals) or as functional ceramics (e.g. with color or magnetic properties). However, there is still much to be learned about the forces guiding mesocrystal assembly and the exact formation mechanisms.

The development of nanotechnology using organic materials is one of the most intellectually and commercially exciting stories of our times. Advances in synthetic chemistry and in methods for the investigation and manipulation of individual molecules and small ensembles of molecules have produced major advances in the field of organic nanomaterials. The new insights into the optical and electronic properties of molecules obtained by means of single-molecule spectroscopy and scanning probe microscopy have spurred chemists to conceive and make novel molecular and supramolecular designs. Methods have also been sought to exploit the properties of these materials in optoelectronic devices, and prototypes and models for new nanoscale devices have been demonstrated. This Review aims to show how the interaction between synthetic chemistry and spectroscopy has driven the field of organic nanomaterials forward towards the ultimate goal of new technology.

1. Introduction

1.1. Nanomaterials, Nanotechnology, and Nanoscience

Nanomaterials are functional materials comprised of objects with at least one dimension below 100 nm. These objects may be either nanoparticles (small ensembles of molecules) or even individual molecules. Functional nanoparticles have an ancient pedigree. Soot, which contains nanosized (< 1 μm) carbon particles, was used as a colorant by the earliest humans, while colloidal gold particles have served as a pigment, for example, for ruby-colored stained glass, since the middle ages.[1] Nanoobjects, such as polymer latices or pigment particles and technology dependent upon the unique properties of nanomaterials, have today acquired great economic importance. However, it is something of a paradox that nanotechnology, which we define as technology that is dependent upon the unique properties of nanomaterials, is seen as an ultramodern technology even though, from a chemistry point of view, these materials are anything but new.

One of the most exciting aspects of nanoobjects is that their properties may differ very significantly from those of the corresponding bulk materials, for example, silver nanoparticles show biological (antimicrobial) activity whereas silver metal does not.[2] Similarly the conductivity of metal particles undergoes a marked change as their size decreases,[1] and the optical and electronic properties of inorganic semiconductor nanoparticles are known to depend upon the particle size.[3] It is therefore justified to assert that the study of the properties and manipulation of individual nanoobjects constitutes a scientific discipline (nanoscience) in its own right. It should be noted that while there is an accepted standard definition for a nanomaterial as given above, there is as yet no consensus as to the exact meaning of the terms nanoscience and nanotechnology, as clearly shown by the varying definitions given in two recent overviews by leading figures in their development;[4,5] the above descriptions are our personal attempts at defining them. Nanotechnology and nanoscience, however they may be defined, must also include more complex functions of nanoobjects, such as the development of devices with dimensions of less than 100 nm. It is this aspect that has captured the public imagination, and spurred funding agencies all over the world to launch programs for both fundamental and industrial research. As a result "nano" is one of the current buzzwords driving investment in research and development. (As an aside it should be noted that "nano-" is the form used by physical scientists, whereas the biological sciences use the prefix "nanno-", for example, in nannoplankton.[6]) Public excitement, and also concern about the environmental and other aspects of the development of nanotechnology, has led to the publication of major reports by the Royal Society in London,[7] and the Academies of Science and Technology in Paris,[8] into the social and other impacts of these emerging technologies. There have also been a number of general reviews and books on nanoscience and nanotechnology, as well as on various aspects and applications of

them ranging from catalysis to food science.[9–23] The excitement about the construction of nanosized devices, and especially those using single molecules,[24] stems in part from the fact that they represent the logical endpoint for the ongoing miniaturization of devices, for example, of the integrated circuits in computers, which underlies the whole electronics revolution that has changed the face of our world. As Richard Feynman famously pointed out,[25] if 100 atoms were sufficient to store one bit (binary digit) of information then all the books ever written could be stored in a cube with edges 6 mm long, so the potential impact of nanotechnology on information storage and processing is hard to overstate. Another exciting point is that if nanoelectronic devices can be made by chemical synthesis and processing, then more devices could be made in a single day than have ever been made by lithographic methods!

Given that the definition of nanoobjects by size is somewhat diffuse—and also embraces materials with only one dimension in the nanometer range, such as functional self-assembled monolayers[26,27]—much nanoscience therefore focuses on the properties of *single* molecules or particles rather than the properties of the ensembles, but it must always be borne in mind that nanoobjects also include supramolecular aggregates held together by intermolecular forces. The study of single molecules is a special challenge which has become possible through the development of new physical methods for probing their electronic and optical properties, in particular single-molecule spectroscopy (SMS) and scanning tunnelling microscopy (STM). These technical developments have prompted chemists to investigate ways to efficiently and reproducibly synthesize materials which perform optimally at the single-molecule level, or which can self-assemble to form well-defined functional nanostructures; indeed to a chemist the design and synthesis of the latter is one of the key aspects of nanoscience. The further advancement of nanoscience and nanotechnology will thus require an integrated combination of synthesis and physical methods.

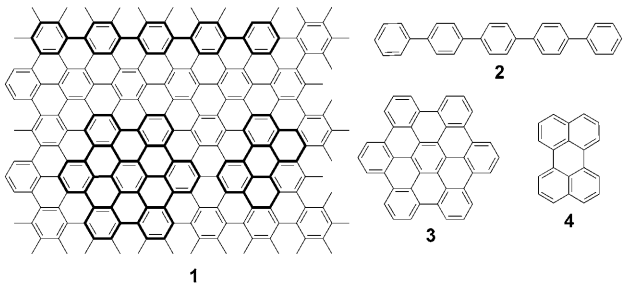
1.2. Scope of the Review

In this Review we present an overview of our recent work towards the development of organic nanomaterials. In particular we want to show how an integrated approach combining many fields of structural chemistry (conjugated polymers, polycyclic aromatic hydrocarbons, dyestuffs, dendrimers, and biomaterials) can lead to significant advances. Of equal importance is the close collaboration between our synthetic efforts and the development of means for visualizing, manipulating, and addressing molecules and small aggregates of molecules. When one considers how many publications have appeared in the last decade reporting SMS and STM studies of the commercially available perylene tetracarboxydiimides and dianhydrides, and reflects that these molecules have been chosen in large part simply because they are available, one can immediately see the tremendous scope for synthetic chemists to advance nanoscience.

There are three issues that must be considered in designing and synthesizing a new compound that will act as a nanomaterial. First there are the properties of individual molecules (or even of individual functional groups within multifunctional molecules); these correspond to those of isolated molecules either in a dilute solution, in a matrix, or upon a surface. Second the interactions between these molecules (or functional groups) and how they affect the properties of discrete ensembles of the molecules must be considered. Finally the interface with the outside world must be designed, that is, how the input of the energy or charge is going to be achieved, and how an output is going to be received or detected. In principle the properties of a single molecule (or functional group) are much simpler to predict and control than those of a group of molecules, as in the latter case it has to be considered how the individual molecules interact, which in turn may depend in subtle ways upon the size and shape of the molecule. Thus, the design of a nanomaterial involves both the optimization of the functional units and the control of their supramolecular order. The ultimate aim is to produce hierarchies of structures with different types of order on different length scales,[28,29] as are seen in living organisms.

Light and/or charge can be used as potential interface mechanisms as these are highly controllable and are detectable even at the very low levels associated with the output from individual molecules or nanoparticles. Our approach therefore involves the combination of new functional and

Klaus Müllen received his Diploma in 1969 from the University of Cologne for work with Prof. E. Vogel, and in 1972 he completed his PhD with Prof. F. Gerson at the University of Basel, Switzerland for research on EPR spectroscopy. He pursued postdoctoral research on dynamic NMR spectroscopy and electrochemistry with Prof. J. F. M. Oth at the ETH, Zurich, and in 1977 completed his habilitation there. In 1979 he became a Professor of Organic Chemistry in Cologne, and in 1983 he accepted a chair in Organic Chemistry at the University of Mainz. In 1989 he became one of the directors of the Max-Planck Institute for Polymer Research. His research interests focus on synthetic macromolecular chemistry and materials science.



Andrew Grimsdale was born in Waiouru, New Zealand, and graduated from the University of Auckland. He completed his PhD there in 1990 with Prof. R. C. Cambie for work on the synthesis of analogues of biologically active drimane sesquiterpenes. After postdoctoral work on photochromic and electroactive materials with Prof. A. Pelter at the University of Wales in Swansea, and on electroluminescent polymers with Prof. A. B. Holmes at the University of Cambridge, in 1999 he joined Prof. Müllen at the Max-Planck Institute for Polymer Research at Mainz. In 2005 he rejoined Prof. Holmes, now at the University of Melbourne. His research involves the synthesis of polyphenylene-based materials for optoelectronic applications.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

structural units into new compounds and materials in which the supramolecular order of the functional elements is engineered to maximize beneficial and minimize undesirable interactions.

We begin by briefly introducing the methods by which the optical, mechanical, and electronic properties of materials can be probed at the nanolevel: SMS, STM, and atomic force microscopy (AFM). Then we survey each of the main classes of building units which we have used for making nanomaterials: rigid-rod phenylene-based conjugated polymers and oligomers (1-D polyphenylenes), planar polycyclic aromatic hydrocarbons (PAHs), and rylene-based dyes. An emphasis has been placed on their materials properties at the nanoscale. An interesting feature of these classes of materials is that many of the compounds involved can be thought of as molecular subunits of graphite (Scheme 1). Thus, examination of a single sheet of graphite (a graphene sheet; **1**) enables one to readily pick out subunits such as the 1-D oligophenylene quinquephenyl (**2**) or a an all-benzenoid (classification according to E. Clar)[382] PAH ("2-D polyphenylene"; see Section 4.1) such as hexabenzocoronene (HBC, **3**), or a subunit not belonging to this type such as perylene (**4**). As graphite is a conductor and strongly absorbs light, it is not surprising that its molecular subunits often have notable optoelectronic properties.

Scheme 1. One- and two-dimensional polyphenylenes and rylenes as subunits of graphite

By contrast in the next class of materials, polyphenylene dendrimers (3-D polyphenylenes), the benzene rings are nearly nonconjugated (see Figures 7 and 9). Thus, whereas the previous materials are all functional units, dendrimers are used more as structural elements in nanomaterials.

We then move on to various combinations of these building blocks: dye-substituted dendrimers, polymers and discs as nanoemissive materials, and then molecules containing combinations of one-, two-, and three-dimensional polyphenylene nanostructures with controllable sizes and shapes. As a logical extension of the research into carbon-rich fibers and columnar superstructures we finally discuss our new methods for making carbon nanoparticles. The key aim here was to obtain better control over the morphology of the products by pyrolysis of polyphenylenes in ordered mesophases or confined geometries.

In this Review we show not only how we can optimize each of the potential components of nanomaterials (graphenes, dyestuffs, dendrimers etc.), but also how we can combine them to optimize the properties of the final materials. In particular we will illustrate the value of collaborative research with physicists that utilize the most up-to-date SMS, STM, and other techniques to probe the optical and electronic properties of these materials.

2. Probing, Visualizing, and Manipulating Single Molecules by Single-Molecule Spectroscopy and Scanning Probe Microscopy

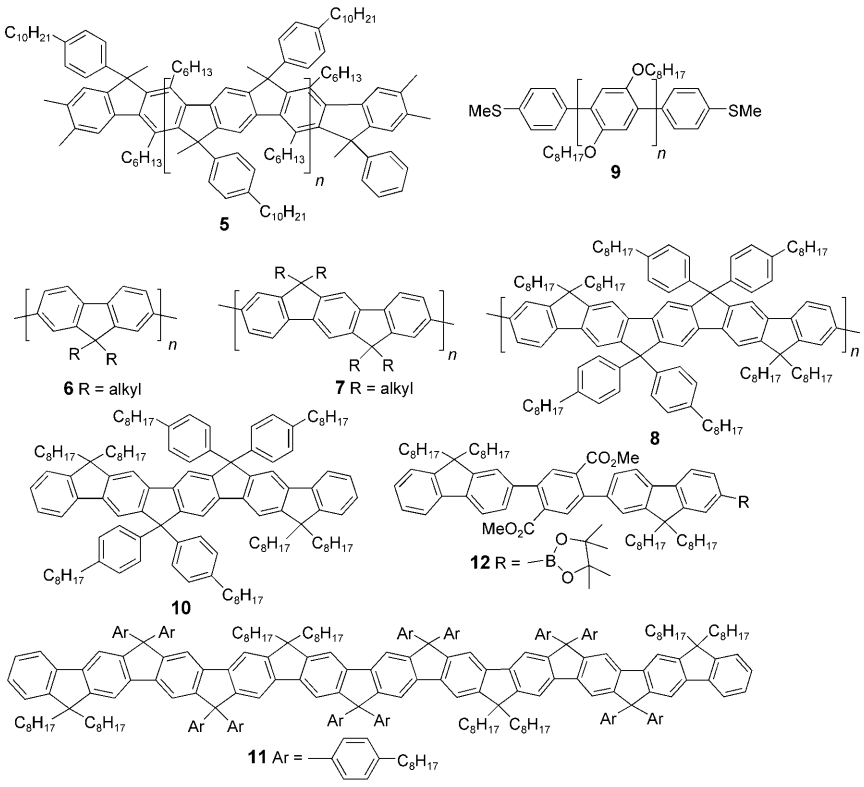
An SMS experiment[30,31] requires the emissive molecules to be isolated. This is usually achieved by dispersing them highly diluted ($< 10^{-10}$ M) in a solid transparent matrix, for example, polystyrene. SMS measurements can also be performed in very dilute liquid solutions, but this presents problems arising from the Brownian motion of the molecules, especially at room temperature. The absorption and emission of the chromophores are then probed, often at low temperature, by excitation with short pulses of laser light. Whereas an averaged result for the absorption and emission of the chromophores is typically recorded in bulk measurements, spectra for each individual species are observed in SMS experiments; the species may even display distinct blinking[383] as individual chromophores "switch" on and off. SMS experiments are generally performed on a number of individual molecules and histograms of the results are compiled, which can provide information about the distribution of states not obtainable from the bulk data. Furthermore the broadening of the signals in the bulk spectra produced by disorder is absent so that individual spectral features may be more clearly resolved. Time-resolved measurements may provide insights into the nature of excitation energy transfer that may not be available from studies of the bulk materials; for example, it has been possible to observe quantum jumps between singlet and triplet states of terrylene directly by SMS.[32] SMS is thus of great importance for investigating multichromophoric species, in particular the kinetics of interchromophore interactions can be determined. Attachment of fluorescent tags to biologically active molecules also enables biological processes to be studied by SMS. For example, the infection pathway of fluorescently labeled virus particles into a cell has been monitored in this way.[33,34]

Scanning probe microscopy[35] can be used to visualize single molecules in real space and to investigate their chemical and electronic properties. It is possible to scan across molecules deposited on a surface with resolutions down to the sub-nanometer range, and to manipulate individual nanoobjects. The breakthrough in investigating the electronic properties of individual molecules or particles came with the invention of scanning tunneling microscopy (STM).[36,37] An STM experiment involves scanning a sharp tip across a sample on a conducting substrate, for example, highly ordered pyrolytic graphite (HOPG), while determining at each point the probability that electrons can tunnel between the tip and the substrate, and so gain insight into the local electronic density of states.

The visualization of individual molecules by STM is performed after their immobilization on a surface, often as

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

part of an ordered monomolecular layer. The combination of scanning tunneling microscopy with scanning tunneling spectroscopy offers the possiblity of recording current–potential curves for individual molecules or even parts of molecules.[35,38] The STM tip has also been used to manipulate nanoobjects, for example, metal atoms or organic molecules, and even to perform nanochemistry by making and breaking individual chemical bonds,[35] or initiating a polymerization.[39] STM is also an important tool for investigating supramolecular self-assembly of molecules within monolayers and epitaxial growth of double and multilayers[40] and has even been used to study photoinduced chemical reactions within monolayers.[39,41,42]



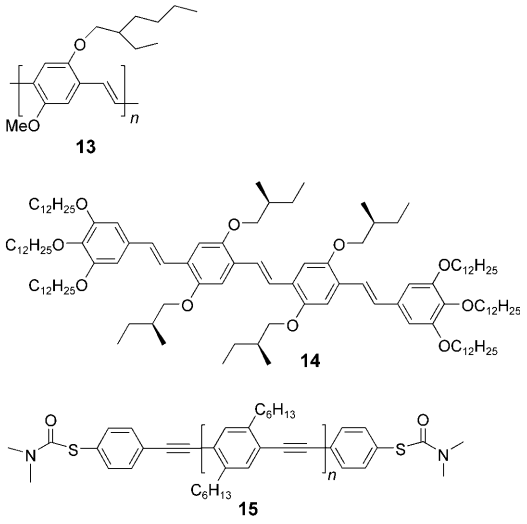
Another scanning technique that is used to investigate nanostructures is atomic force microscopy (AFM)[43]—sometimes also called scanning force microscopy (SFM). In an AFM experiment the contact force between a tip and the surface is measured at each point as the surface is scanned. The advantage of AFM over STM is that it can be used to study the surfaces of insulating substrate materials, whereas STM requires the surface being examined to be electrically conductive. The AFM tip can also be used for manipulating nanoobjects, for example, polymer chains,[35] or be chemically modified to measure the strengths of bonds, for example, the rupture forces of ruthenium complexes linked to both an AFM tip and a substrate have been measured.[44] AFM has also been used to estimate directly the molecular weight of polymer chains within a Langmuir–Blodgett film.[45] It should be kept in mind, however, that scanning probe methods do not replace, but complement classical techniques, such as electron microscopy or various spectroscopy techniques, in an integrated approach toward the investigation of nanomaterials.

3. Rigid-Rod Polymer Chains as Nanoobjects

Conjugated polymers have attracted attention in recent years as organic semiconductors for use in devices such as light-emitting diodes (LEDs),[46] solar cells,[47] and field-effect transistors (FETs).[48] There has also been interest in monodisperse conjugated oligomers, both as active materials and as models for polymers.[49,50] Since these materials are well-defined molecular species, reliable structure–property relationships can more easily be obtained from them than from the corresponding polydisperse polymers. A desirable feature for the conjugated materials to be useful is that they can self-assemble into well-defined nanostructures. A number of approaches have been adopted to direct the assembly of conjugated polymers and oligomers. For example, hydrogen bonding can be used to induce self-assembly of oligo(phenylenevinylene)s to form polymers, including chiral helical polymers,[51] and such materials have served as active components in a photovoltaic device.[52] Rod-coil or coil-rod-coil block copolymers offer another way to control assembly processes through variation of the number, nature, and size of the coil units.[53–65] A wide range of topologies, including sheets of mushroomlike aggregates;[56,64] spherical, vesicular, cyclindrical, and lamellar aggregates;[58–61,66] and porous membranes,[53,62,63] have been obtained in this way.

3.1. One-Dimensional Polyphenylenes and Poly(phenyleneethynylene)s

One-dimensional polyphenylenes are generally rodlike materials, whose degree of rigidity depends upon their structure. The rigidity has been controlled by linking of some or all adjacent benzene rings through methine bridges introduced by intramolecular Friedel–Crafts alkylations. Thus ladder-type poly(*para*-phenylene)s such as Me-LPPP (**5**, Scheme 2) in which the bridges are formed in a polymer-analogous Friedel–Crafts reaction,[67] are rigid linear ribbon-like molecules, whereas the partially bridged polyfluorenes (PFs, **6**)[68] can form coils because of their nonlinear monomer units. Other partially bridged structures such as polyindenofluorenes (PIFs, **7**)[69,70] or poly(ladder-type pentaphenylenes) (**8**)[71] have linear monomers and so are rigidly linear. The rigidity of these materials has been confirmed by dynamic light scattering experiments which have shown them to



Scheme 2. One-dimensional polyphenylenes and oligomers.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

possess persistence lengths ranging from 8 nm for PFs (**6**) up to 25 nm for the pentaphenylene-based polymer **8**.[72] These polymers can be prepared by nickel(0)-mediated coupling of dihaloarenes,[73] or by Suzuki polycondensation of dihaloarenes with diboronates,[74] with very high ($>100000\,g\,mol^{-1}$) molar masses and have lengths of ten to several hundreds of nanometers. Methods have been established by which functional groups can be attached to the ends of the polymer chains by adding suitable endcapping reagents to the polymerization reactions.[75–78] Such groups can be used to help bind the chain end to a surface, for example, the thiol endgroups in compound **9** assist in its attachment to gold electrodes. These endcapping procedures also offer a way in which to control the molecular mass and thus chain length of the polymer and to synthesize rod-coil block copolymers.[75,76,78]

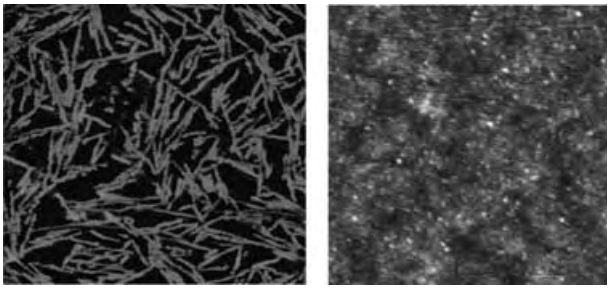
Oligomers of fluorene up to hexadecamers are known,[79,80] but the nonlinearity of the fluorene monomer means that these are not rigidly linear species. The ladder-type pentaphenylene (**10**)[71] is also readily available, This oligomer is already a 2-nm long linear rigid rod, and can be difunctionalized to permit attachment of other building units such as dyes. The largest ladder-type oligophenylene made to date is the undecamer **11**,[81] which is 4.5 nm long and with 11 benzene rings is of comparable size to the estimated effective conjugation length of polymer **5**.[82] The key intermediate was a pentaphenylene monoboronate **12** which was treated with a dibromoterephthalate to produce an undecaphenylene, which was converted into **11** by addition of several equivalents of an aryllithium and a subsequent Friedel–Crafts ring closure. The synthesis and purification of asymmetrically substituted intermediates such as **12** are the main challenges in the synthesis of larger bridged oligomers.

Phenylenevinylene polymers, such as MEH-PPV (**13**), and oligomers, such as the chiral OPV **14** (Scheme 3), are not rotationally restricted about the C–C bonds, and so the polymers can form coils, whereas the alkyne linkages in poly(phenyleneethynylene)s (PPEs)[83] are linear so that these polymers are rigid rods. Endcapping with functional groups has also been accomplished, for example, in polymer **15**,[84,85] and suitable endgroups have been used to make rod-coil block copolymers.[86]

Scheme 3. Polymers and oligomers from phenylenevinylene and phenyleneethynylene.

3.2. Studying the Self-Asembly of Polymers and Oligomers by AFM and STM

The microscopic surface morphology of polymer films can best be investigated by tapping-mode AFM. This method is unable to distinguish individual molecules or polymer chains, and so molecular modeling studies also need to be done to understand the supramolecular organization producing the observed morphology. The self-assembly of conjugated phenylene-based homopolymers and rod-coil copolymers has been probed in such a combined AFM/molecular modeling approach.[87] The most commonly observed organized structures in drop-cast films of these polymers are nanoribbons or nanofibres produced by π stacking of the chains. For example, poly(dioctylfluorene) (**6**, R = *n*-octyl) displays a fibrillar morphology (Figure 1, left) with straight fibrils.[87] These



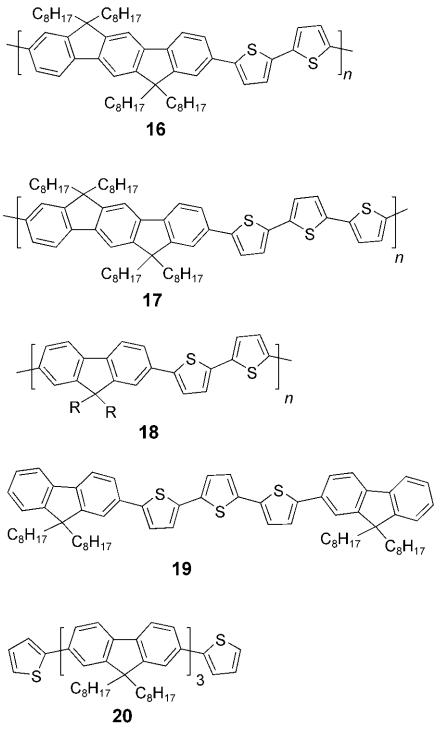


Figure 1. Morphologies of thin films of poly(dioctylfluorene) (**6**, left), poly(tetra(2-ethylhexyl)indenofluorene) (**7**, right) as revealed by AFM.

fibrils typically have heights of only a few nm and widths of tens of nm, which is equivalent to the lengths of individual chains, thus indicating that the chains are oriented perpendicular to the main axis of the fibers. A similar morphology is observed for the corresponding polyindenofluorene (**7**, R = *n*-octyl), whereas the polyindenofluorene with a branched alkyl substituent (**7**, R = 2-ethylhexyl) displays a smooth featureless morphology (Figure 1, right).[88,89] These differences can readily be explained by modeling studies, which show that the bulkier branched alkyl or aryl substituents hinder π stacking of the chains.[87,89,90] Another effect of the substituents is in controlling the thermotropic phase forming properties of these polymers. Thus PFs and PIFs with *n*-alkyl substituents typically form two nematic liquid-crystalline (LC) phases, while ethylhexyl-substituted polymers exhibit only a single nematic phase.[69,91–93] Annealing films of PFs on rubbing-aligned polyimide alignment layers has been used to obtain aligned films which exhibit polarized luminescence.[94]

Such differences have significance for the bulk optoelectronic properties of conjugated polymers: close packing enhances exciton diffusion to defect sites, which can suppress

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

fluorescence or cause the dominant emission to arise from emissive defects. As a result the amount of green emissions arising from defects in films of PIFs (**7**) correlates with the degree of π stacking as evidenced by a fibrillar morphology in AFM studies.[88] Thus, hindering interchain interactions is clearly desirable to achieve stable blue emission from materials such as PIFs. By contrast, strong π stacking is beneficial if efficient charge transport is desired. It has been demonstrated that a fibrillar morphology correlates to a relatively high charge-carrier mobility in copolymers of fluorene and indenofluorene with oligothiophenes such as **16**, **17**, and **18** (Scheme 4).[95–97] Modeling studies on the

Scheme 4. Copolymers of oligothiophenes with indenofluorene and fluorene.

polymer chain packing show that whereas the chains in polymers **17** and **18** have extended linear conformations and can undergo face-to-face packing between the oligothiophene and oligophenylene units to form closely packing ensembles (Figure 2), polymer **16** has a bent lowest energy chain conformation and cannot close-pack in this way.[98] The terthienyl oligomer **19** forms ordered striplike nanostructures when dropcast on glass, mica, or graphite. The height of these stripes (ca. 3 nm) matches the length of the molecules, thus indicating that they were aligned perpendicular to the surfaces. In contrast, the terfluorenyl oligomer **20** produced only disordered structures.[99]

Layers formed upon physisorption of PPE **15** from solution showed an interesting feature: polymer chains of similar sizes formed clusters.[84,100,101] This observed fractionation is attributed to formation of such clusters in solution,

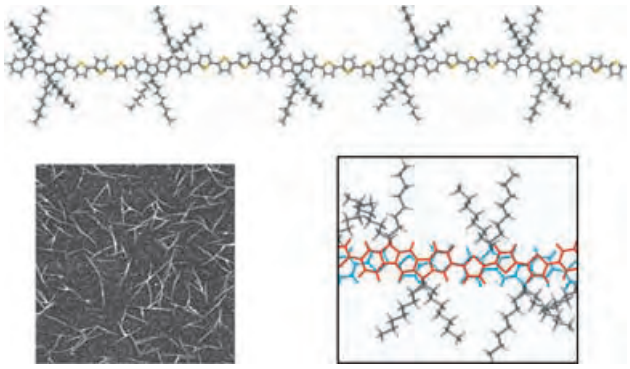

Figure 2. AFM image of a deposit of **17** from THF on mica, as well as simulations of the chain conformation and packing of **17**.

followed by their adsorption, and later exchange between adsorbed and non-adsorbed molecules at the solid–liquid interface which favors larger molecules being adsorbed where permitted sterically. The size and shape of the ribbons was independent of the substrate, thus indicating that the growth of the architectures from solution was largely governed by intermolecular interactions. The rod-coil block copolymers with polyphenylene or PPE blocks show fibrillar morphologies when deposited from solvents that are good for the conjugated blocks, but deposition of a polyphenylene–poly(ethylene oxide) (PPP-PEO) block copolymer from methanol, which solubilizes the coil but not the rod, produces apparently hollow, round-shaped deposits.[87] This result again confirms that the fibrillar morphology is a clear sign of π stacking of conjugated units. Self-assembly of chiral oligo(phenylenevinylene)s and oligothiophene-oligo(ethylene oxide) block copolymers on silicon produces chiral helical fibrils.[90,102,103]

STM has also been used to investigate conjugated phenylene-based oligomers and polymers at the single-molecule level. Chiral oligo(phenylenevinylene)s, such as **14**, were found to form ordered monolayers in which the packing in **14** was directed by the alkyl chains so as to induce an end-to-end arrangement, whereas in longer oligomers the conjugated backbones were the dominant influence and produced a closely packed columnar phase.[104] A similar close packing was seen for polymer **15**.[84] Trimeric phenyleneethynylenes, which were used as model systems, were synthesized by stepwise Hagihara–Sonogashira coupling and both their 2D and 3D solid-state structures determined.[84] The formation of tightly packed 2D crystals grown epitaxially on the basal plane of graphite was visualized by STM. The stiffness of the backbone and the conformational mobility of hexyl side chains were key structure-forming parameters. Two kinds of defects were recorded on the nanometer and subnanometer scale: missing molecules within a crystallite and domain boundaries surrounding such crystallites. Both defects turned out to be dynamic and Ostwald ripening occurred. This packing information is important since it helps to tune interchain distances and thus interchain hopping processes. STM studies on less rigid materials such as polythiophenes show a lamellar close-packing of the long linear segments that are linked together by hairpinlike folds

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of the polymer chain, thus suggesting that π-π interactions are the dominant force in their packing also.[105]

3.3. Nanostructured Devices

The next step required is to utilize the nanomaterials described above to make nanostructured devices. For example, field-effect transistors (FETs) could be fabricated either by aligning the structures between predeposited electrodes or by attaching electrodes to prealigned structures. Three methods for such alignment are available: 1) Cooling a liquid-crystalline material from the ordered mesophase has been used to align bulk materials, for example, PF-T2 (**18**), in FETs. This approach requires that the material be liquid-crystalline at a temperature significantly above room temperature, but not so high as to damage the other components of the device. 2) Oxidative nanolithography of silicon has been used to create a silicon dioxide array of parallel lines of width 30–50 nm and lengths of several micrometers. This array then acted as a template for the growth of a monolayer of an oligothiophene.[106] 3) The final approach uses lithographically controlled wetting, in which a stamp is placed in contact with a liquid thin film. Capillary forces cause the liquid to distribute itself only under the protrusions of the stamp, so that the solute forms patterns with the same length scale as the stamp upon evaporation of the solvent. In this approach a stamp with sub-micrometer features produces nanostructures with dimensions of several 10s of nanometers.[107,108] This method has been utilized to construct an FET using stripes of the oligomer **19**.[109] It must be noted that while self-assembled nanostructures can be made with dimensions considerably smaller than the smallest currently accessable devices, the devices discussed above are no smaller than those obtained using conventional materials, because of the need to fabricate stamps and/or deposit electrodes by conventional methods. Further advances in minaturization will thus require new methods for deposition of electrodes, for example, by advances in microcontact printing.

3.4. Optical and Electrical Measurements on Isolated Polymer Chains

Single-molecule spectroscopy gives fundamental insights into the photophysics of multichromophoric species. For example, the emission from individual chromophore subunits of Me-LPPP (**5**) can be resolved at low temperature and the interactions between them investigated.[110] The spectral diffusion dynamics of individual chromophores in Me-LPPP and the totally different conjugated polymer MEH-PPV (**13**) appears to be identical, but emission from multiple chromophores is possible only from the latter, which indicates that the major differences in the bulk behaviour of the polymers can be ascribed to morphological differences in the chain, and thus that structure–property relationships in conjugated polymers are extrinsic to the nature of the chromophores.[111] Comparison of the oligomer **10** with the polymer **5** by SMS shows that while there are individual chromophores of the same size on the polymer as on the oligomer (as shown by their emission maxima), their fluorescence intensity is much higher, and their line widths are narrower. The fluorescence dynamics of the oligomer and polymer are different in ensemble measurements, with the polymer showing appreciably shorter lifetimes of the excited state. These important differences between the oligomer and polymer chromophores are attributed to the excited states on the polymer having excitonic character, while the oligomer exhibits a molecular excitation.[81]

A new direction for single-molecule studies is the application of SMS on single chains of a conjugated polymer in a LED structure under a controllably varied electrical bias to probe the oxidation/reduction processes that occur in these devices.[112,113] Such techniques may lead to the optimization of LEDs by providing greater understanding of the mechanisms for their operation and breakdown.

Since the first proposal that rectifiers could be constructed using individual molecules linking two electrodes,[114] there has been interest in utilizing conjugated molecules, and even biomolecules, as so-called "molecular wires".[115–119] In such a case, charge-carrier transport would occur along a conjugated chain and not along their π-stacked aggregates as discussed above. The methods that have been used to measure the electrical characteristics of individual or small ensembles of molecules have recently been reviewed.[120] In most studies the molecules are tested as a self-assembled monolayer (SAM), for example, by scanning a self-assembled monolayer (SAM) on a gold electrode or other conductive surfaces with an STM or conducting AFM tip. Groups such as isonitriles or thiols are used as so-called "alligator clips" to attach the molecules to the conductive surface, and the position of these anchoring groups on the molecule has been shown to affect the detected electric current.[121] The reproducibility of results from single-molecule measurements is limited, so that statistical analysis of a number of individual measurements provides the best means for comparing the electronic properties of single molecules of different substances.[122] The thiol endgroups on polymers **9** and **11** enable them to bind to gold electrodes. It is possible to measure the electrical properties of individual polymer chains by using them to bridge two electrodes. The thiol-endcapped poly(*para*-phenylene) (PPP, **9**) with an average length of about 8 nm has been deposited between two electrodes in a transistor structure. Weak transistor behavior was observed upon altering the gate voltage, thus showing that in principle isolated conjugated polymer chains can be used in single-molecule FETs, although the transistor properties will need considerable improvement.[123]

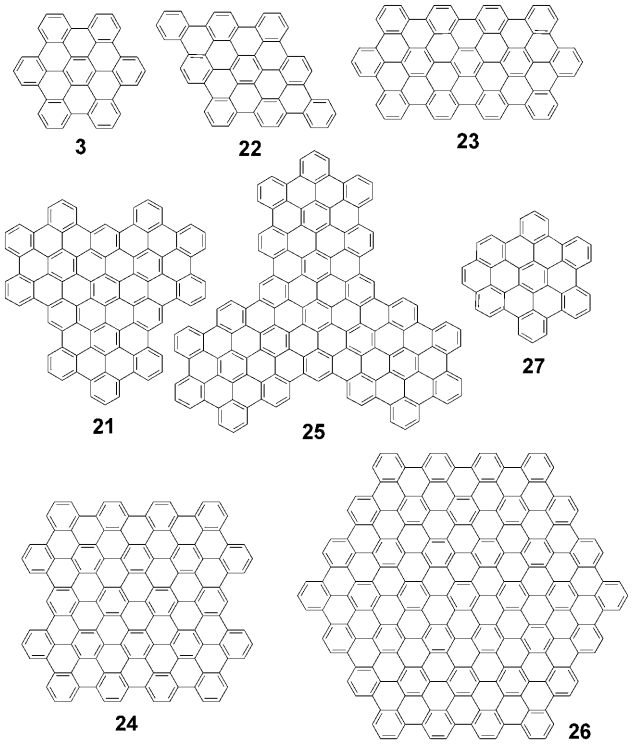
3.5. Conjugated Polymers for Chemical Sensors

An important emerging area of nanotechnology is the use of sensors based on self-assembled monolayers.[26] As shown above, conjugated polymers can form ordered monolayers, and chemical sensors utilizing conjugated polymers may show greater sensitivity than small molecules.[124–126] The principle behind most of this work is that interactions between the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

analyte and the polymer induce a change in the conformation of the polymer chain which in turn affects its electrical and optical properties. These interactions are detected as changes in the conductivity, redox behavior (measured by cyclic voltammetry), absorption, or fluorescence of the polymer. The materials that can be detected by such methods include halide ions,[127,128] chemical warfare agents,[129] proteins,[130,131] nucleic acids,[132–135] and even bacteria.[136] The sensitivity of these methods is such that as few as 220 DNA molecules in 180 μL (2.4×10^{-18} M) can be detected.[134] Another DNA-sensing approach uses a polycationic fluorene–phenylene copolymer and a peptide nucleic acid (PNA) strand bearing a chromophore dye.[137] The PNA can hybridize with a strand of complementary DNA to form a polyanion which is then electrostatically attracted to the copolymer. In this case energy transfer can occur form the polymer to the dye and lead to intense fluorescence from the dye, whereas in the presence of noncomplementary DNA such complexation and energy transfer cannot occur. A third approach to DNA sensing is to attach two identical sequences of single-stranded DNA to a conjugated rigid rod.[138] Hybridization with the complementary sequences induces a marked augmentation in the fluorescence from the conjugated moiety. Even single nucleotide polymorphisms can be detected efficiently.

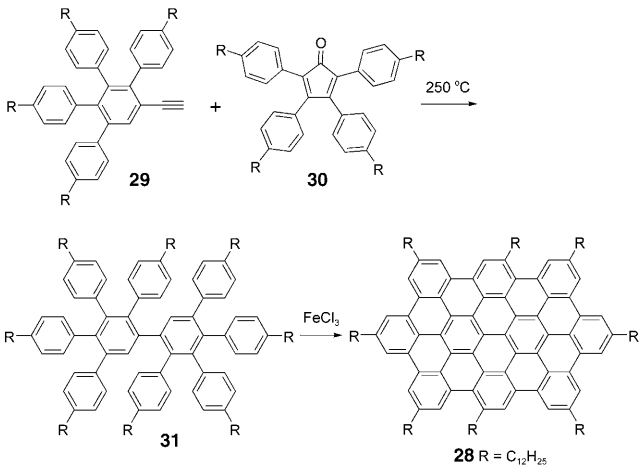
It can be seen from these results that rigid-rod one-dimensional conjugated materials will play a considerable future role as the active components in nanoelectronic devices such as FETs. Transistors with channel lengths of 100 nm or below are conceivable (compared with the multi-micrometer channel lengths seen in conventional devices). A key feature of these compounds as nanomaterials is their self-assembly behavior which arises from the π-π interactions of the "hard" aromatic backbone, but is heavily influenced by attachment of "soft" alkyl substituents or ethylene oxide coils. This combination of a hard aromatic core whose self-assembly through π stacking is controlled by a soft alkyl shell is seen in more extreme form in the case of "two-dimensional polyphenylenes", which will be considered in the next section.



4. "Two-Dimensional Polyphenylenes": Graphene Molecules as Nanosized Semiconductors

4.1. PAHs as Molecular Subunits of Graphite

Planar polycyclic aromatic hydrocarbons (PAHs)[139] can be regarded as molecular subunits of graphite that consist of fused benzene rings. Such molecules have long played an important role as models in molecular orbital theory and, more recently, have become important objects in the visualization of single molecules by STM.[35] PAHs can be divided into two types according to the model of Clar, in which the π electrons are distributed among the benzene rings so as to form the greatest possible number of "full" rings, that is, π-electron sextets.[140] In all-benzenoid PAHs all the π electrons in the PAH can be distributed so that each benzene ring contains either 6 or 0 π electrons (which means such molecules must have a number of ring carbon atoms divisible by 6). All-benzenoid PAH molecules are more stable, less reactive, and have larger HOMO–LUMO gaps than isomeric compounds that do not satisfy this criterion.[139]



Efficient routes have been developed to a large variety of graphene molecules with different molecular topologies (Scheme 5; substituents are not shown). The diameters of these molecules range from 1.4 nm (**3**) to 3.5 nm (**26**). Of the skeletons shown, C_{42} (HBC, **3**),[141] C_{96} "superphenalene" (**21**),[142] C_{54} (**22**),[143] C_{78} (**23**),[143] C_{132} (**24**),[143] C_{150} (**25**),[144] and C_{222} (**26**)[145] are all-benzenoid, whereas C_{44} (**25**)[146] is not. The PAHs are all made in good yield by oxidative cyclodehydrogenation of a soluble three-dimensional polyphenylene dendrimer precursor, as illustrated in Scheme 6 for the substituted C_{60} molecule **28**.[147] The branched oligophenylene precursor **31** was synthesized by Diels–Alder addition between tetraphenylcyclopentadienone (**30**) and the monoethynyl-substituted pentaphene **29**. Oxidative cyclodehydrogenation of this precursor by treatment with iron(III) chloride then afforded the planar C_{60} molecule **28** in nearly quantitative yield.[147] This simple and efficient route is suitable for the large-scale synthesis of all-benzenoid PAHs, which are now obtained as structurally perfect nanosized 2D π systems. PAHs bearing solubilizing groups such as alkyl groups can be processed in solution. Large unsubstituted PAHs such as **22** are insoluble but thin films can be obtained by ultrahigh vacuum deposition at high temperature (550–650 °C) because of their excellent thermal stability.

As would be expected, the size and shape of the PAHs have major effects upon their optoelectronic properties.

Scheme 5. Graphene molecules.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 6. Synthesis of a disc-type C_{60}-molecule **28**.

Increasing size leads to greater delocalization of the π electrons and a decrease in the bandgap as reflected in the UV/Vis spectra. A linear relationship is seen between the absorption maximum of the α band and the number of "full" aromatic rings.[139,148] As illustrated in Figure 3, this change is also

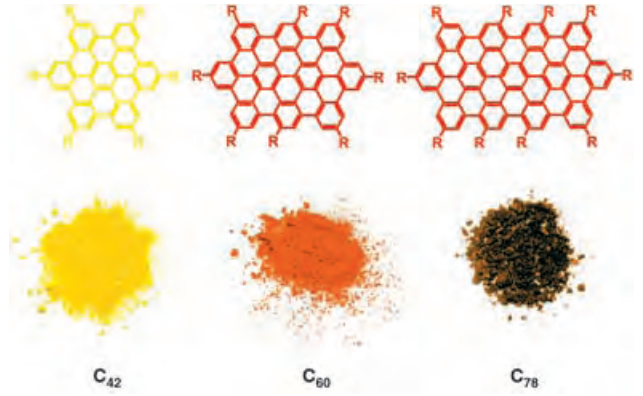


Figure 3. Examples of PAHs showing the bathochromic shift in the spectra with increasing size of the molecule.

readily visible in the color of the materials. Thus C_{42} (HBC) is a yellow powder, while C_{132} **24** possesses a red color in solution,and the parent compound C_{222} **26** is a black powder with a broad absorption band extending up to 1200 nm. The introduction of extra π center—such as in **25**—produces a strong perturbation of the π-electron cloud, so that additional bands are seen in the UV/Vis spectrum and the intensity of the lowest band of the α transition is greatly enhanced as a result of the loss of symmetry.[146] The Raman spectra of PAHs reflect both the size and shape of the molecules,[149,150] and have been used as models for simulating and interpreting the spectra of complex carbon materials, for example, amorphous carbon and graphite.[149,151,152] An important question concerns the relation between the size of the PAHs and the charge-carrier mobility within their columnar superstructures (see Section 4.2.2).[148]

4.2. Liquid-Crystalline Graphite Molecules as Building Blocks for Nanostructured Arrays

Soluble discotic graphite molecules such as alkyl-substituted HBCs **32** (Figure 4) can form thermotropic liquid-crystalline phases, in which the molecules align into ordered

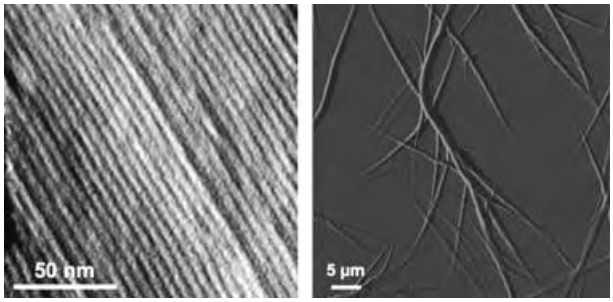

Figure 4. Zone-cast films (left) and microfibres (right) of HBCs cast from THF solution onto glass substrates.

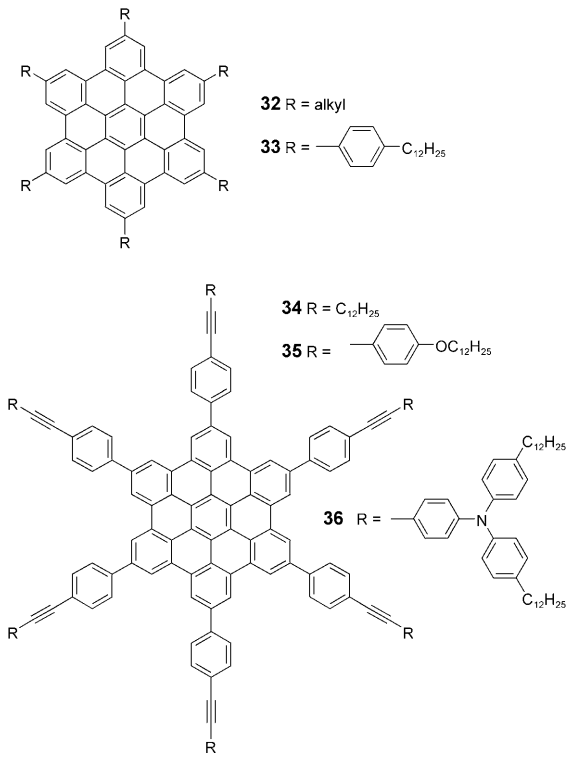
nanosized columns.[153] While the π interaction of the aromatic cores leads to self-assembly into columnar structures, the side chains are partially organized at the core periphery and produce nanophase-separated arrays. The supramolecular order is strongly dependent on the thermal behavior of the compound. Thus, the aromatic cores of the discs have reduced molecular dynamics in the crystalline state and arrange in a herringbone structure which is characterized by a molecular tilting with respect to the columnar axis. Heating to the liquid-crystalline phase results in the molecular arrangement changing to an orthogonal intracolumnar packing. Longitudinal and lateral displacements of the molecules are possible within the stacks as a result of a high side-chain mobility and the increase in their steric requirements. The self-organized molecules are typically about 0.35 nm apart, which allows for efficient overlap of the π orbitals on adjacent discs and the generation of high charge-carrier mobility along the axis of the column.[148,153–155] This arrangement means that a column of HBCs acts like a nanowire with a conductive core and an insulating shell of alkyl substituents. As a result, the highest efficiencies will be attained in electronic devices when the columns are aligned perpendicular to the electrodes; in FETs this means the discs are edge-on to the substrate (heterotropic alignment) and for a solar cell they are face-on (homeotropic alignment). Whereas the former is the favored orientation for discs deposited from solution, it has been shown that the latter can be achieved by cooling an HBC layer from the isotropic phase between two substrates.[153,156] Here again the size of the molecules plays an important role. Although discotic mesophases have been obtained for a large number of disc-type molecules[153] it is the size of the PAHs which leads to anistropic LC phases that are stable over a broad temperature range as well as to increased charge-carrier mobilities.

Two methods have been used for producing aligned films of HBCs. In the first the material is spin-cast upon a pre-aligned polytetrafluoroethylene (PTFE) layer,[157] while the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



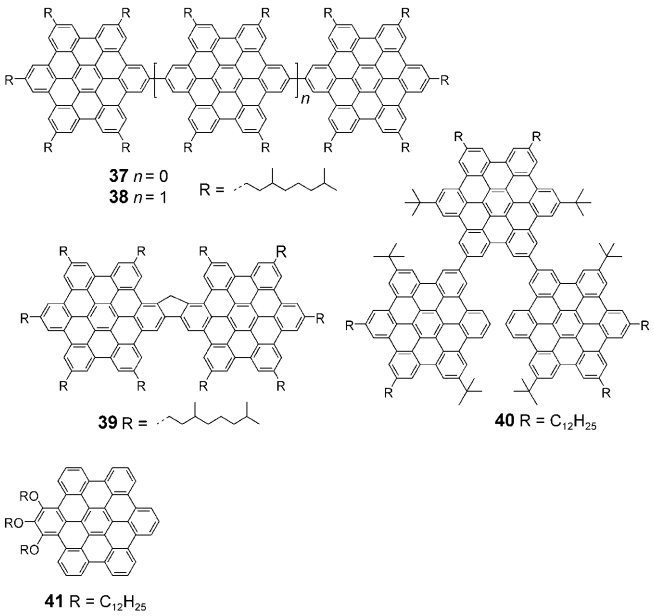
second utilizes zone-casting from solution.[158] In this simple procedure, a solution is deposited through a nozzle onto a moving substrate, with both nozzle and substrate being thermally stabilized. The concentration and temperature gradients suffice to uniaxially align the columnar nanostructures along the deposition direction. The casting conditions can be varied to obtain either continuous films with a "quasi-single-crystalline", long-range ordered surface layer (Figure 4, left) or highly oriented microfibres (right). Zone crystallization from the melt has also been used to obtain highly aligned films.[159]

Both methods have been used to construct efficient FETs using films of HBCs **32** which have been aligned between the electrodes (method for the pre-alignment PTFE layer: $\mu = 10^{-3}$ cm^2 Vs^{-1};[157] zone-casting: $\mu = 10^{-2}$ cm^2 Vs^{-1}).[160] A blend of the aryl-substituted HBC **33** with an electron-accepting perylenediimide dye showed high efficiency in a photovoltaic device with an external quantum efficiency (EQE) of 34% being seen at 460 nm.[161] The partial phase separation of the two components to provide separate percolation pathways for holes and electrons seems to be the main reason for the good efficiency. Thus, optimizing the performance of FETs and photovoltaic cells with PAHs as the active components requires increasingly complex supramolecular hierarchies.

The parent HBC could be sublimed under ultrahigh vacuum and the thin films deposited on MoS_2, HOPG, Au(111), and copper surfaces. The films produced displayed epitaxial order with the HBC normal perpendicular to the surface.[162] Highly ordered, several nanometers thick films of alkylated discs could also be grown on a MoS_2 surface by solution processing.[163] These films exhibited a two-dimensional lateral arrangement of columns standing on the surface. The planar arrangement of the first layer might be the reason for the observed epitixal growth. Angle-resolved photoelectron spectra revealed a highly anisotropic quasi-one-directional electronic structure with an extended π-electronic wave function. An intermolecular dispersion of the highest occupied band of at least 0.15 eV along the stacking direction has been measured.

The charge transport in columns of HBCs can be optimized by attaining the maximum degree of intracolumnar order and thus the best overlap of orbitals. One way of increasing the order of the columns is to replace the alkyl substituents in **32** with (di)arylethyne units, as in **34**–**35** (Scheme 7).[164] Compound **35** displays helical stacking with each successive disc rotated by 15° about the columnar axis. Very high charge-carrier mobility is also achieved by attaching hole-accepting triarylamine units, as in **36**.[165] Here the HBC cores and triarylamine units provide two coaxial pathways for the charges to move along.

AFM studies on spin-cast films of **34** revealed individual columns of discs as stripes with widths of about 3.4 nm (corresponding to the intercolumnar distance seen from X-ray diffraction measurements on the bulk material) and lengths of up to several hundred nanometers within larger ordered domains.[164] The height of these objects also conformed to the calculated diameter of the HBC units, thus suggesting that they were comprised of individual columns with the column axis approximately parallel to the substrate

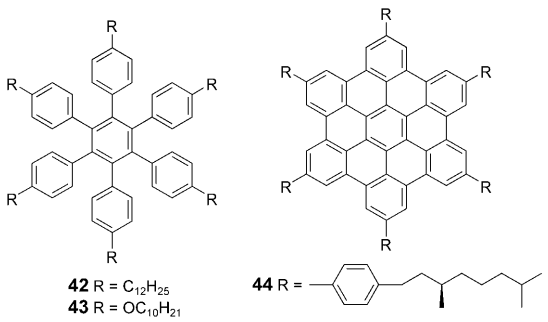


Scheme 7. Discotic liquid-crystalline HBCs.

surface. Drop-casting films of **35** produced nanoribbons several micrometers in length, with widths of about 21 nm and heights of about 4 nm, which we interpret as being arrays of 5–6 columns. Similar self-assembled fibres have been seen for dendrimers and dendronized polymers (see Section 6.5). The next problem to be solved is to align individual HBC fibres or columns between two electrodes and so fabricate a nano-FET. The lithographically controlled wetting technique described in Section 3.3 offers one way to achieve this.

The above materials illustrate how we can optimize intracolumnar order in HBCs, but the control of intercolumnar order is equally important if more than a single column is to be used in a device. One method to achieve this is to combine one- and two-dimensional structural motifs by preparing HBCs with rigid conjugated linkers which might be blended with other HBCs and thus link together the columns in which they are incorporated. These conjugated links might also allow charge to be transferred between columns, thus by-passing any defects in the columns. To this end the HBC dimer **37** and linear "*para*-trimer" **38**, the "superfluorene" **39**, and the nonlinear "*ortho*-trimer" **40** (Scheme 8) have been prepared and their phase-forming behavior investigated.[166] Compounds **37**–**39** self-assemble into ordered columnar mesophases as shown by X-ray diffraction experiments. By contrast the nonlinear trimer **40** does not form an ordered columnar array, presumably because the HBCs in this material are twisted even more out-of-plane by steric interactions than the rings in the other materials. An "unwrapped" HBC molecule **41** was also synthesized which displays a stable columnar liquid-crystalline phase with a low isotropization temperature (190 °C).[167]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 8. Oligomers of HBC and "unwrapped" HBC **41**.

In addition, it possesses a good solubility in common solvents and can be used as active components in field-effect transistors. Thus, the interactions between unsubsituted aromatic cores should allow for better intercolumnar charge transport.

4.3. Scanning Tuneling Microscopy on Monolayers of Polycyclic Aromatic Hydrocarbons

The STM visualization of individual molecules in real space is performed after their immobilization, often as part of an ordered monomolecular layer.[35] The formation of the monolayer (a so-called 2D crystal) is a sensitive function of the size and shape of the molecule, and is controlled by the symmetries of both the adsorbate and substrate. Such layers are obtainable either by ultrahigh vacuum (UHV) deposition[168] or by physisorption from solution. Since the formation of monolayers competes with the occurrence of double and multilayers, complex problems of epitaxial growth arise both for single and for multicomponent deposition.[168] The interactions between molecules can be probed by STM of the resulting films to determine how the molecules stack within the layers. Thus STM has established that the chiral PAH heptahelicene forms SAMs consisting of chiral molecular clusters when deposited under UHV conditions.[169] In the deposition of alkyl-substituted PAHs upon HOPG it was determined that π interactions between the adsorbate and substrate, as well as the adhesion of the alkyl chains to the surface play a role. It is interesting that the alkyl chains can easily change their conformation upon adsorption so as to obtain the best packing arrangement. An ordered monolayer of **32** ($R = C_{12}H_{25}$) has even been created by depositing the hexaphenylbenzene (HPB) precursor **42** (Scheme 9) on

Scheme 9. PAH precursors and PAHs visualized by STM.

HOPG, and then converting it into the HBC with iron(III) chloride.[170] In this case STM could not be used to monitor the reaction because of the presence of the metal ions, but the similarity in the unit cells of **42** and **32** suggested that it proceeded at the surface. Thus, this technique might be useful for depositing ordered films of larger, less soluble, PAHs through conversion of their soluble precursors.

STM was also used to confirm the thermally induced cyclodehydrogenation of the hexadecyloxy HPB **43** on a copper surface at 550–710 K.[171] The cyclodehydrogenation was accompanied by loss of the alkyl groups, and the molecules became anchored to the surface through the oxygen atoms of the ether groups during the course of the reaction. Very large PAHs are formed upon copper surfaces by heating diphenylacetylene or HPB to 550–700 K.[172] STM visualization has been used to prove the rhomoboidal shape of the C_{54} molecule **22**,[143,173] which was difficult by conventional spectroscopic means, and the biaryl nature of a "superbiphenylene" (**36**, $R = C_{12}H_{25}$).[174] The contrast within the STM images of the C_{60} molecule **28** appears to reflect the nodal properties of the frontier orbitals and so enables the π bonding within the molecule to be described as a combination of three weakly coupled terphenyl and quaterphenyl chains.[147] The "thickness" of the PAH monolayers can be controlled by the branching within the alkyl chains and the presence of additional (twisted) phenyl rings. Thus, deposition of the HBC **44** creates a staircase pattern in which each molecule can adopt one of three different heights (that is, different positions between the substrate and the tip).[175] Each molecule thus has a different position within the pattern and gives a different tunneling current. Such a site-specific contrast becomes even more important since some of the positions within the pattern remain vacant which allow the displacement of molecules between positions with different currents, thus creating a kind of register.

While the visualization and manipulation of nanometer-sized molecules in real space described above are fascinating experiments, it is important to go one step further and utilize the electronic function of single molecules. Graphene molecules have played an important role in this key step towards molecular electronics. By combining STM with STS it has become possible to record current–potential curves for single PAH molecules.[35,38] These curves displayed a typical diode-like asymmetry when the tip was passed over the aromatic

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

cores, whereas the aliphatic chains produced a symmetrical curve.[38] The shapes of the curves vary in going from C_{42} to C_{60} and C_{78} to C_{114}, and indicates how the increased core size changes the frontier orbitals.[176]

Current–potential curves were recorded separately for the donor and acceptor components of molecule **45**—with an HBC core as the electron donor surrounded by six alkyl chains bearing electron-accepting anthraquinone (AQ) groups (Figure 5). The curves showed characteristic differences in their slope, thus indicating that the tunneling currents were strongly influenced by the resonant enhancement of the HBC HOMO and the quinone LUMO. Remarkably, transistor activity has been demonstrated for a single molecule of **45** on a surface, in which the HBC and anthraquinone both lie flat on the surface. The addition of 9,10-dimethoxyanthracene (DMA, **46**) resulted in the formation of a charge-transfer complex with the anthraquinone, whose dipole changed the substrate work function by about 120 meV, and so induced a detectable change in the I/V characteristics of the HBC core as measured by a STM tip. In this way a chemical gate effect[177] was produced with a nanometer-sized gate. In this system the dipole was parallel to the channel direction of the transistor, and thus perpendicular to the surface. Attachment of a dipole to the HBC with its direction parallel to the surface had no effect on the HBC I/V behavior.[178] Although it is certainly a fascinating experiment to demonstrate a FET function on a nanometer scale, the currents involved are much too small to be of practical value in a real FET.

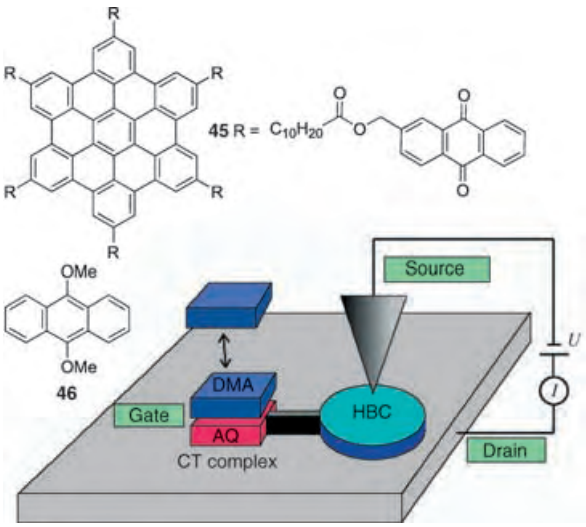


Figure 5. A single-molecule chemical FET.

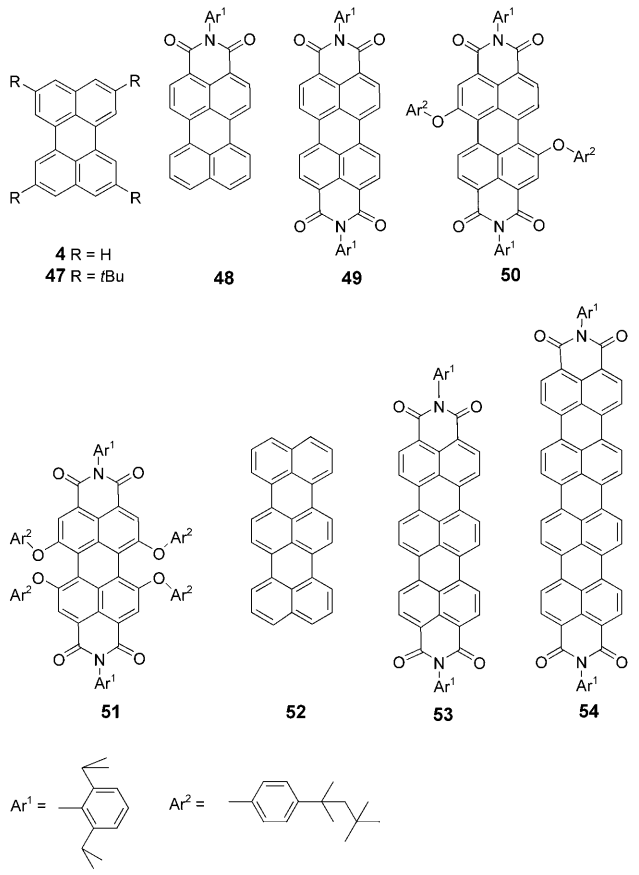
In this section we have considered the behavior of PAHs with various molecular topologies. The effects of different topologies upon properties are even more clearly seen with rylenes, a class of not all-benzenoid graphite subunits which display excellent performance as colorants, particularly when substituted with auxochromic anhydride and imide groups.

5. Rylene Dyes for Single-Molecule Spectroscopy



Soluble (dyes) or insoluble (pigments) colorants may be used to add color to materials. The insolubility of pigments means they are generally employed as dispersions of particles (most commonly micrometer sized) within the material they are coloring. Smaller particles give a more even distribution of color and so, as mentioned in the Introduction, colored nanoparticles have long been used as pigments. In recent years there has been much industrial interest in developing pigment nanoparticles and particularly nanocrystals as colorants.[179] A second point of interest beyond the colorant aspect is the use of "functional dyes" as active components for xerography,[180] optical switches,[181] laser-dyes,[182] photovoltaic cells,[161] optical recording,[183] light-emitting diodes,[184] or as tracers in fluorescence analytical assays.[185]

A third, more recent, research field arises from the idea of using light as a way to address single molecules. Our ability to control light is now so developed that even single photons can be detected and manipulated reliably, either as an input or output; thus optical addressing of nanomaterials in devices is an attractive option. In parallel with this came the development of single-molecule spectroscopy (SMS) as a powerful tool for the investigation of the photophysics of materials, particularly in conjunction with confocal microscopy. The necessary requirements for this technique are chromophores, whether molecular or polymeric, which show strong absorption and/or emission in appropriate regions of the electromagnetic spectrum. Other requirements are good photo- and chemical stability, and for some applications, for example, bioassays, water solubility and anchoring to a biologically active moiety may also be needed. The issue of stability is particularly vital for chromophores for use in nanomaterials. In bulk materials there are many "surplus" molecules present to compensate for any which fail, and so the failure of a certain amount of the material may not have an immediate effect on the overall properties of the materials. In nanomaterials, where there are only a limited number of molecules present, every molecule matters. Molecules or assemblies with multiple chromophores, in which there is thus a certain amount of "back-up" functionality, might therefore be more desirable for nanoapplications than single-chromophore compounds. Such molecules will also show more absorption and emission per molecule, thus increasing the detection sensitivity and making them better for studies by SMS. Before we investigate the SMS of dyes, we must first take a detour into classical dyestuff chemistry whose origins go back to the early 20th century.[186] The class of dyes examined are rylenes, which perfectly satisfy the above-mentioned criteria and additionally can be readily functionalized by simple, high-yielding procedures to enhance their solubility and to permit them to be attached to various other chemical or biological systems.

5.1. Tuning the Properties of Rylenes

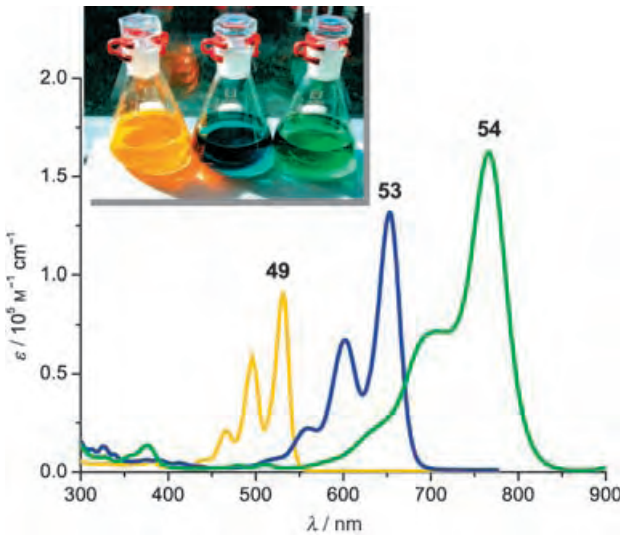
Rylene dyes have a backbone consisting of *peri*-linked naphthalene units (Scheme 10). The emission color of these

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 10. Representative rylene dyes.

dyes can be tuned from blue through to the NIR by varying the number of naphthalene units and/or the number, type, and pattern of the substituents. Thus, of the compounds with two naphthalene units, the parent compound perylene (**4**)[187] and the tetra-*tert*-butyl derivative **47** are blue-green and blue emitters, respectively.[187] Substitution with imide units produces a red-shift so that perylenemonoimide (PMI, **48**) is a yellow emitter with an emission maximum at 506 nm, while the diimide (PDI, **49**) is an orange emitter ($\lambda_{max} = 526$ nm). Attachment of substituents in the bay positions also induces a bathochromic shift in the absorption and emission maxima, as well as markedly improving the solubility of the dyes. The diphenoxylated PDI **50** and tetraphenoxylated PDI **51** are thus orange ($\lambda_{max} = 575$ nm) and red emitters ($\lambda_{max} = 610$ nm) respectively.[188]

Higher rylenes are made by aryl–aryl coupling of naphthalene or perylene units followed by a ring closure of the bisaryl precursors to the ladder-type rylene structure. Homocoupling of bromoperylenes with nickel(0) provides an efficient route to bisperylenes,[189] while Stille or Suzuki coupling are the optimal methods for the heterocoupling of naphthalene or perylene units.[190,191] The synthesis of the boronate or stannyl intermediates is a crucial step in these routes. Since functional groups such as the imide structure are sensitive towards organolithium compounds the synthesis of boronic acids or esters with organolithium reagents are not applicable here. Therefore, mild palladium-catalyzed methods have to be used to form a boronate[192] or organostannane.[193] Base-promoted cyclizations in the presence of strong electron-withdrawing groups, such as imides, provide the rylenes in nearly quantitative yields,[189,191,194] while for materials without such groups oxidative cyclodehydrogenation of the coupled biaryls to the rylenes can be efficiently performed with aluminum trichloride or iron(III) chloride.[195,196] Increasing the number of rylene units produces a red-shift in the emission so that terrylene (**52**) is a green emitter ($\lambda_{max} = 573$ nm)[195] and the emission maxima for the terrylenediimide (TDI, **53**)[190] and quaterrylene (QDI, **54**)[189,197] are at 650 and 760 nm, respectively (Figure 6). However, while the emission quantum yields for PDI and TDI are close to unity, that for QDIis only 5%.[197] This low quantum yield is attributed to the increased possibility of nonradiative loss of energy by means of vibrationally induced torsion between adjacent rylene units.



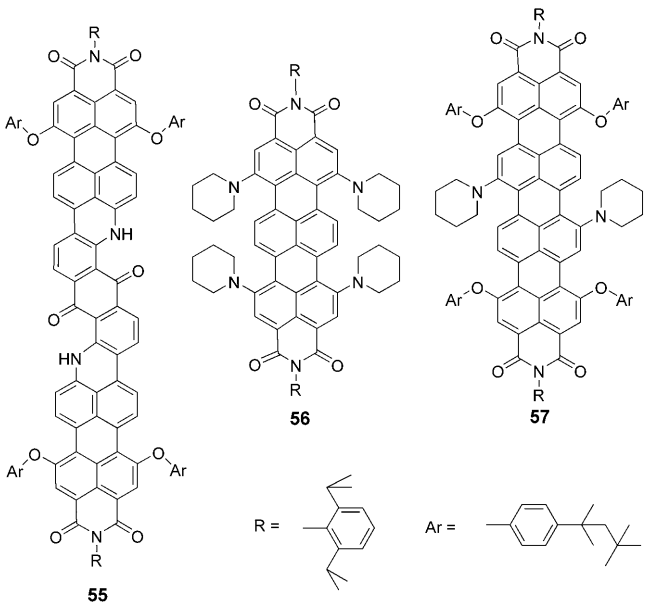


Figure 6. UV/Vis absorption spectra of PDI, TDI, and QDI.

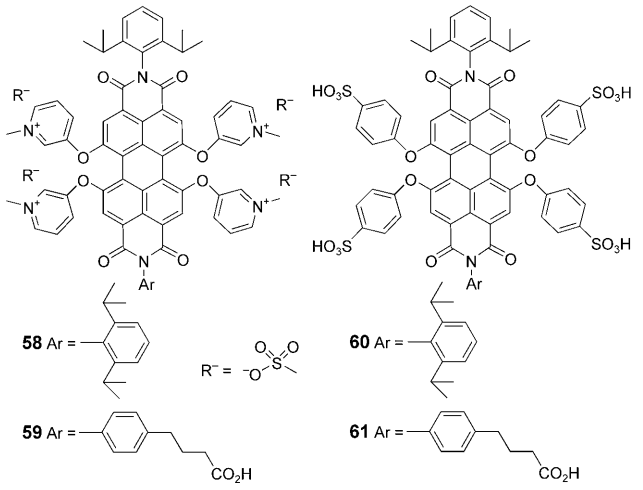
The even greater bathochromic shifts needed to obtain absorption in the NIR have been achieved by other means. Aryl amination of two equivalents of a bromo-substituted PMI with a diaminoanthraquinone followed by oxidative ring closure produced compound **55**, which possesses an absorption maximum at 1000 nm with a shoulder at 1106 nm (Scheme 11).[194] Introduction of piperidine substituents in the bay positions of TDI and QDI has been used to make the dyes **56** and **57** which possess absorption maxima at 765 and 910 nm, respectively.[198]



The next question to be addressed is that of water solubility (with retention of high fluorescence efficiency), which is necessary if the dyes are to be used in bioapplications. The excellent efficiency and stability (and also the nontoxicity) of PDI were utilized in the development of water-soluble PDI-based chromophores by introduction of highly hydrophilic units into the bay position of PDI (by phenoxylation of tetrachloro-PDIs). Aromatic nucleophilic substitution with 3-pyridinol followed by quaternization with

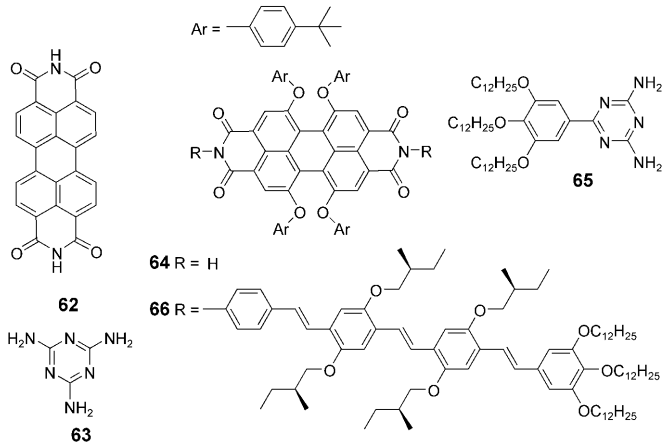
iodomethane gave the positively charged dyes **58** and **59** (Scheme 12), while phenoxylation followed by sulfonation gave the tetrasulfonates **60** and **61**.[199] All of these possessed

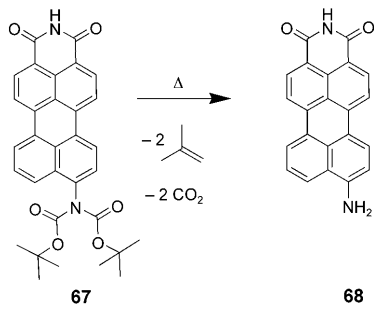
Scheme 12. Water-soluble perylenediimide dyes.

good solubilty in water and the photoluminescence quantum yields in aqueous solution varied from 0.66 for **58** to 0.49 for **61**. The biological applicability of these materials was demonstrated with cardiac cell cultures. After staining, the cells were intensely fluorescent and no sign of a structural degradation could be observed. Furthermore, the cells continued to proliferate, thus underlining the nontoxicity of the label. Fluorescence intensity remained for a long period of time after contact with cell cultures, and demonstrates the suitability of perylene dyes as labels in biological studies.[200]



Another way to introduce charges around the perylenediimide chromophore and achieve water solubility is the attachment of oligonucleotides as polyanions. In general, DNA allows the formation of well-defined supramolecular aggregates of small organic molecules by base pairing.[201–204] Structurally defined chromophore dimers, trimers, tetramers, and pentamers with equidistant spacing of the dyes were realized by introducing two identical oligonucleotide sequences into the imide structures. Two of these biological–organic hybrid structures with complementary sequences form linear assemblies by hybridization.[205] These arrays containing only one type of chromophore are the first step towards the rational bottom-up approach of DNA-based supramolecular structures for controlled excitation energy transfer.

Water-soluble PDIs can also be obtained by coupling with polypeptide chains which can be achieved by functionalization of the phenoxy groups in the bay and subsequent "grafting-from" reactions of the peptide fragments.[206,207]



5.2. Self-Assembly Using Perylenediimides

Self-assembly of chromophores is of great interest because such assemblies are models for natural light-harvesting systems,[208–210] and because they have potential application in solar cells.[211] Perylene is a planar molecule and so in the absence of bulky substituents PDIs will readily aggregate through π stacking. The introduction of phenoxy substituents, such as in **50**—**51**, thus markedly improves their solubility by suppressing this aggregation. Attaching suitable functionality at the imide positions enables the PDI derivatives to be used as building units for supramolecular architectures held together by noncovalent forces such as hydrogen bonding, ionic interactions, or metal–ligand coordination.[212] The folding of copolymers of perylenediimides with flexible chains, including nucleotides, can be controlled by means of the temperature-dependent stacking of the dye units.[213] The thermally induced folding can be reversed by DNA hybridization, thus offering a new approach towards biosensors based on color change. PDIs with a thiol substituent have been shown by AFM to self-assemble on gold surfaces.[214] The fluorescence from these aggregates was much stronger on patterned than on unpatterned surfaces which enabled the structure of gold surfaces to be probed by simple fluorescence methods. The self-assembly of monolayers (both vacuum deposited and from solution) of PDIs has been studied by STM. While PDI **62** (Scheme 13) forms an array with quasihexagonal symmetry,[215] co-deposition with melamine (**63**) produces an extended hydrogen-bonded hexagonal network.[216] A mixture of the substituted PDI **64** with the triazine **65** gives a partially ordered monolayer containing local domains of linear complexes of the two components that coexist with uncomplexed dimers of **65**.[217] The two conjugated systems in the OPV-perylene compound **66** could be distinguished by their bias-dependent tunneling currents, which are higher for the OPV group at negative bias and for the PDI unit at positive bias as a result of resonant enhancement by the HOMO of the OPV and the LUMO of the PDI.[218]

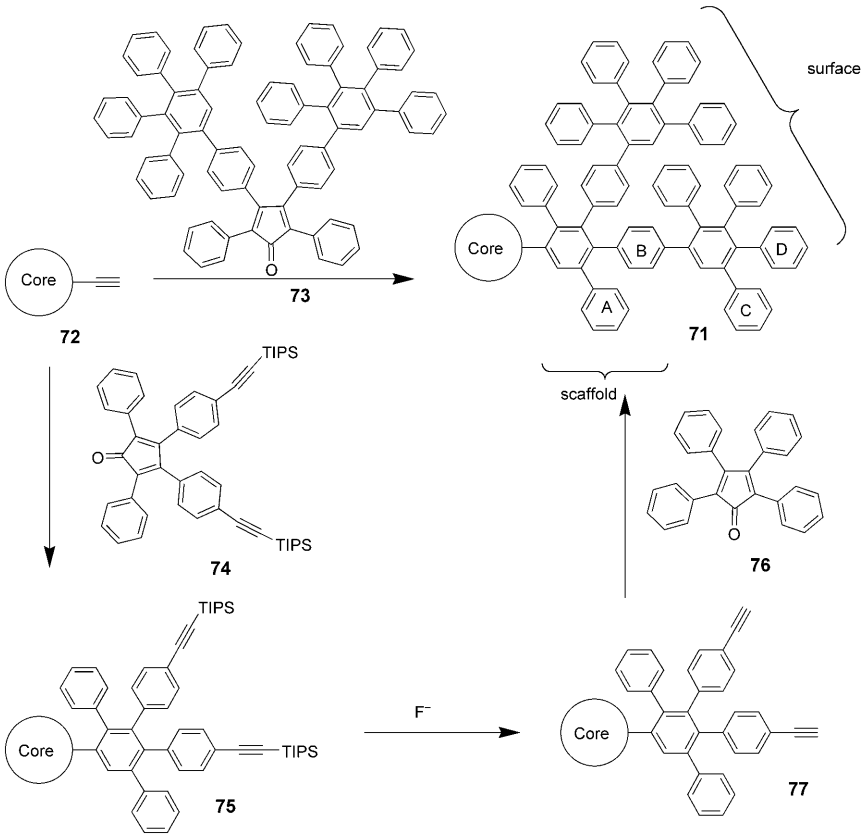
5.3. SMS on Rylene-Based Chromophores

Rylenes possess most of the properties desired for SMS—including strong absorption, high fluorescence efficiency, low photobleaching efficiency—and so have been the object of much attention. There were several early SMS studies on terrrylene (**52**),[219–223] including, as mentioned in the Introduction, the direct observation of quantum jumps between singlet and triplet states.[32] Isolated molecules of TDI **53** have been studied by frequency-selective high-resolution laser spectroscopy at liquid helium temperatures and by confocal fluorescence microscopy between 100 K and room temperature, and their spectral dynamics determined.[224–226] Most of the molecules showed several (up to 10^7) on-off-on (blinking) transitions before permanent bleaching occurred. From the point of view of photostability, the main advantage of TDI **53** is its low-lying triplet state. SMS studies on the tetraphenoxy-PDI **51** have been used to investigate its conformational changes[227] and by comparing these in different environments to probe the local free space inside various polymer glasses.[228,229] The water-soluble PDI **60** could be imaged inside living cells by one-photon confocal microscopy and fluorescence lifetime microscopy with two-photon excitation. A good example of how SMS can be used to obtain information not derivable from ensemble measurements is presented by the dyes **48**, **67**, and **68**.[230–232] The spectra of solutions of **48** and **67** are almost indistinguishable but they can be clearly distinguished by SMS. Even different conformations of **68** can be detected by single-molecule fluorescence measurements. Since **67** undergoes a thermally induced fragmentation to give **68** (Scheme 14), the course of this reaction can be monitored at a single-molecule level, and information derived about the nature of intermediates.

A logical extension of SMS studies of individual rylene chromophores is to include bischromophores made up from identical dyes. This theme will be extended in Section 6 to the study of vectorial Förster-type energy transfer in bis- and multichromophores and in Section 7 to the SMS study of linear oligophenylenes by using dyes as labels. The first such system to be studied was compound **69** (Scheme 15) in which two perylenemonoimides are attached to the *para* positions of a benzil spacer. Collective off-times of both chromophores could be seen in SMS studies as a result of single–triplet annihilation, and the probability of coincident emission of two photons vanished because of singlet–singlet annihilation.[233]



Single bischromophores (as a first approximation to collective effects) allow the distribution of cooperative radiative decay rates in bis- and multichromophoric aggregates to be studied. Coherent energy transport has been a matter of dispute in J-aggregates,[234] light-harvesting complexes,[235] and polymers.[236] SMS succeeded in identifying molecules of bisperylenylmonoimide **70** with the excitation either delocalized (superradiant emission) or localized. Transitions between both states could be seen for a single molecule of **70** under the influence of structural fluctuations of the guest matrix system, another phenomenon which would not be detectable in the ensemble.[237]

The above results confirm that rylene-based chromophores are particularly suitable for use as emissive groups in nanomaterials and for SMS studies. A question remaining to be resolved is the suppression of interchromophore interactions in the aggregated state. This problem has stimulated the concept of shielding the dyes by encapsulating them within a dendrimeric polyphenylene structure. Before we can discuss the perfect site definition of single fluorophores we must first consider the synthesis and properties of functional polyphenylene dendrimers.

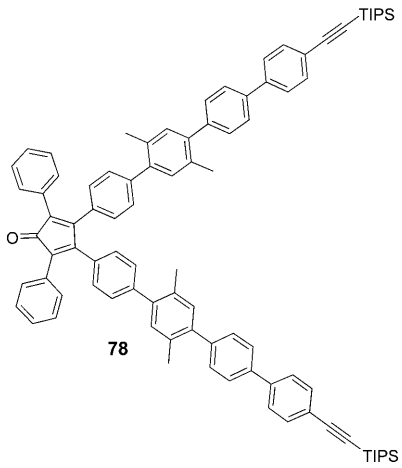
6. Dendrimers as Vessels for Chemistry, Physics, and Biology

Dendrimers,[238–240] unlike hyperbranched polymers are regular macromolecules with well-defined structures, and have served as functional objects in nanotechnology and nanoscience,[241–243] including as vehicles for drug delivery[244,245] and as light-harvesting materials.[246] Most types of dendrimers possess flexible branches which are easily deformed by external stimuli, and can even bend back towards the center of the molecule. As a result of this backbending they are usually denser at the center than on the periphery.[247,248] By contrast polyphenylene dendrimers[249] are rigid, shape-persistent compounds which can be visualized as discrete nanoobjects by AFM (see Section 6.5).[250,251] Neutron diffraction experiments have shown that they are denser at the periphery than at the core.[252] As a result of this rigidity any two groups within the dendrimer or upon its surface are in well-defined spatial relationships to each other, which is of great importance for controlling their electronic interactions, particularly the transfer of excitation energy between them. It also means that the shape of the empty space between groups in the interior of the dendrimer is well-defined and, as a consequence of the limited mobility of the benzene rings within the structure, relatively invariant, which offers the possibility of manipulating this space by synthetic design so as to produce great selectivity for guest molecules. This specificity in host–guest interactions could then be used for sensing, for example, by selective incorporation of molecules, or to create a nanoreactor in which reactions could occur selectively, similar to the use of pores in inorganic materials such as zeolites to induce chemo- or regioselectivity in reactions.

Scheme 16. Convergent (top) and divergent approaches to second-generation polyphenylene dendrimers.



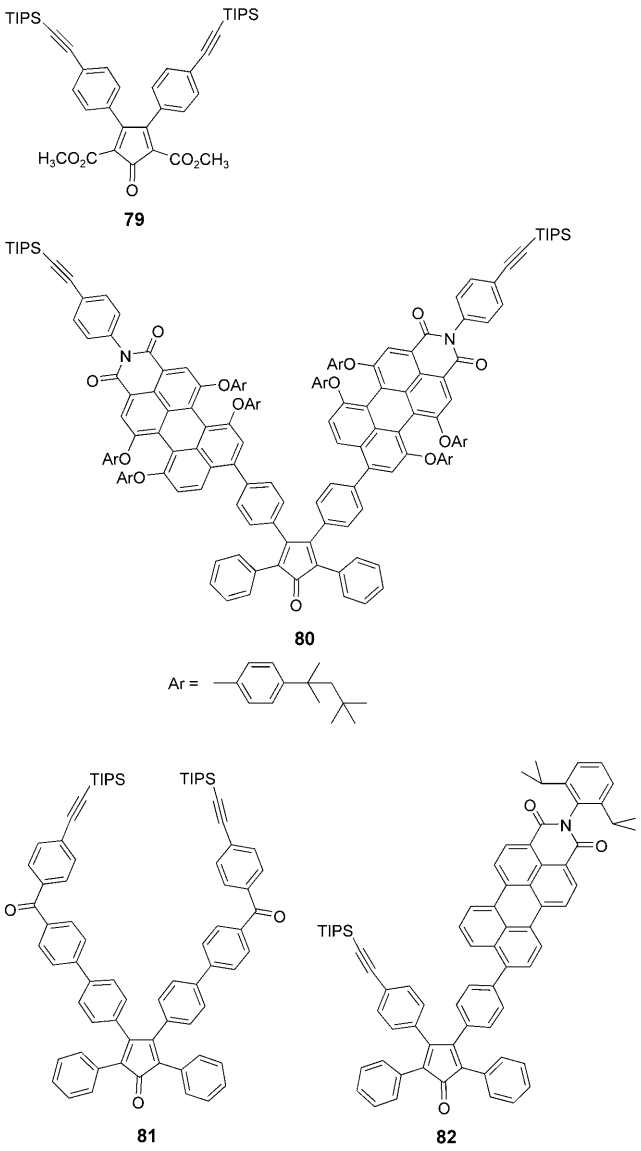
6.1. Synthesis of Polyphenylene Dendrimers

The two basic approaches to the synthesis of polyphenylene dendrimers[249] are shown in Scheme 16 for a second-generation dendrimer **71**. Both routes utilize Diels–Alder cycloadditions of cyclopentadienones to alkynes. In the convergent approach the ethynyl-substituted core **72** is treated with a cyclopentadienone **73** substituted with dendrons to make **71** directly. In the divergent approach the dendrons are grown outwards from the core in an iterative manner by addition of a cyclopentadienone **74** with silyl-protected ethynyl functionality to **72** to make **75**, followed by deprotection and addition of a second cyclopentadienone **76** to the resulting ethynyl-substituted first-generation dendrimer **77**. It must again be emphasized that the inherent stiffness of the structure means that these macromolecules are well-defined shape-persistent nanoobjects. Molecular modeling studies[253] predict sizes of 7 nm for the fourth-generation dendrimers, which have been confirmed by light-scattering, TEM, and AFM measurements.[250,251] A spectacular increase in the size of these nanoobjects is obtained by employment of the branching unit **78** (Scheme 17), in which a rigid spacer is inserted between the cyclopentadienone and the ethynyl groups on **74** to increase the distance between successive layers of the dendrimer. Dendrimers with a complete fifth generation can now be made as spherical monodisperse objects with diameters up to 22 nm by using **78**.[254]

As can be seen from Scheme 16, functionality can be introduced into the dendrimer at three places: at the core, in the scaffold (rings A and B in **62**), and at the surface (rings C and D in **62**). Functionalization of the core requires synthesis of a ethynyl-substituted core molecule on which the dendrons can be constructed. Functionalization of the scaffold and surface requires suitably functionalized cyclopentadienones.

Functionalization of the scaffold enables multiple functional groups to be built into the dendrimer in well-defined relationships to each other and to whatever groups are at the core and the surface. This approach requires modification of the ethynylcyclopentadienone **74** used to build the higher

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

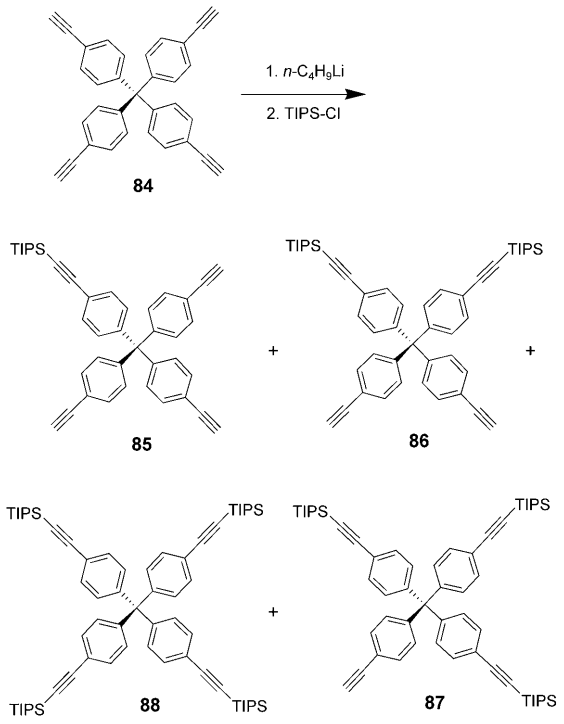


Scheme 17. Expanded dendrimers can be synthesized by incorporating a cyclopentadienone.

generation dendrimers. There are two ways in which this can be achieved (Scheme 18): 1) Functional groups can be added into **74** either at the α-positions by replacement or substitution of the phenyl rings (for example, in **79**),[255] or by inserting them between the β phenyl rings and the ethyne bonds (for example, in **80** or **81**);[256] 2) **74** can be desymmetrized by replacing one of the ethynyl groups with a functional group, for example **82** with one perylene monomimide dye.[257] This is achieved by using a Knoevenagel condensation of diphenylacetone with an assymmetrically functionalized benzil.

The effect of the substituents in **79** and **80** is to introduce functionality within the scaffold which may affect the internal density of the dendrimer and the chemical properties of the cavities without affecting the possible number of branches or the number of potential functional groups at the surface. Thus, ester groups can be incorporated within a dendrimer by using the reagent **79** which can then be hydrolyzed to carboxylates, thus producing charged cavities of defined sizes which could be used to form complexes with cationic species within the dendrimers.[258] The perylenediimide groups in **80** not only introduce functionality, but also act to extend the space between the adjacent layers, which has the effect of reducing the peripheral density of the molecules. In this way the total number of chromophores in the dendrimers can be significantly increased and thus the intensity of their overall absorption or emission increased. The effect of using desymmetrized reagents such as **82** is to introduce bulky functional groups into a layer of the scaffold without increasing the space between the layers.

The introduction of many functional groups also provides a way of ensuring efficient energy or charge transfer occurs between the core and the surface in larger dendrimers. Furthermore, the ketone groups on **81** are sites for subsequent chemistry, for example, conversion to trityl radicals which would enable radical interactions within a nanosized dendrimer cage to be studied.

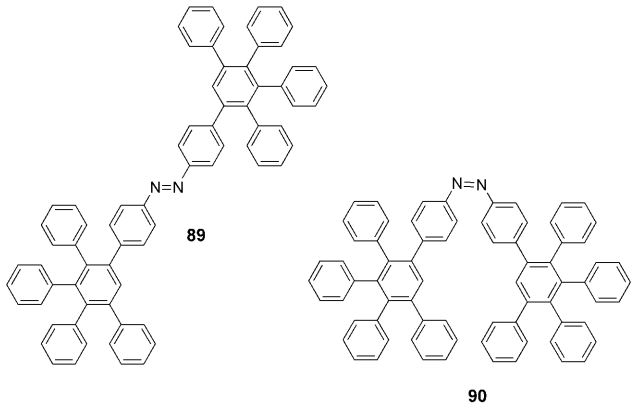


Scheme 18. Modified cyclopentadienones for introduction of functionality into scaffold.

6.2. Desymmetrized Dendrimers

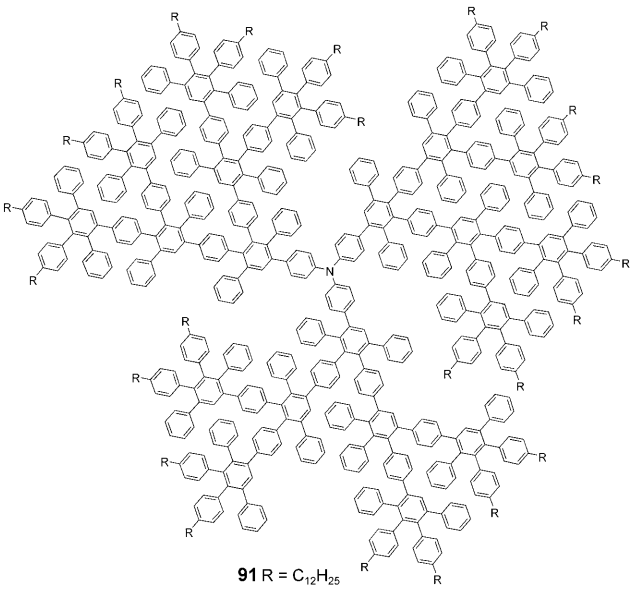
An exciting possibility for tailoring the properties of functional dendrimers is desymmetrization, that is, to have different functional groups on different regions of the nanoparticle surface.[259] For example, a dendrimer with part of its surface substituted with groups capable of binding to a biologically active material, while other parts bear chromophores has applications in bioassays. To prepare such dendrimers one requires a desymmetrized core. Treatment, for example, of tetra(4-ethynylphenyl)methane (**84**) with less than four equivalents of *n*-butyllithium followed by an excess of triisopropyl chloride (TIPS-Cl) gives a statistical mixture of the readily separable mono- (**85**), di- (**86**), tri- (**87**), and tetrasilylated (**88**; this is unreactive and so is converted back into **84**) cores (Scheme 19).[260] The free ethyne groups can

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 19. Synthesis of desymmetrized dendrimer cores.

now be used to create dendrons, and then the protected ethynes can be deprotected and used to build other dendrons, thus leading to a range of new molecular topologies.[260]

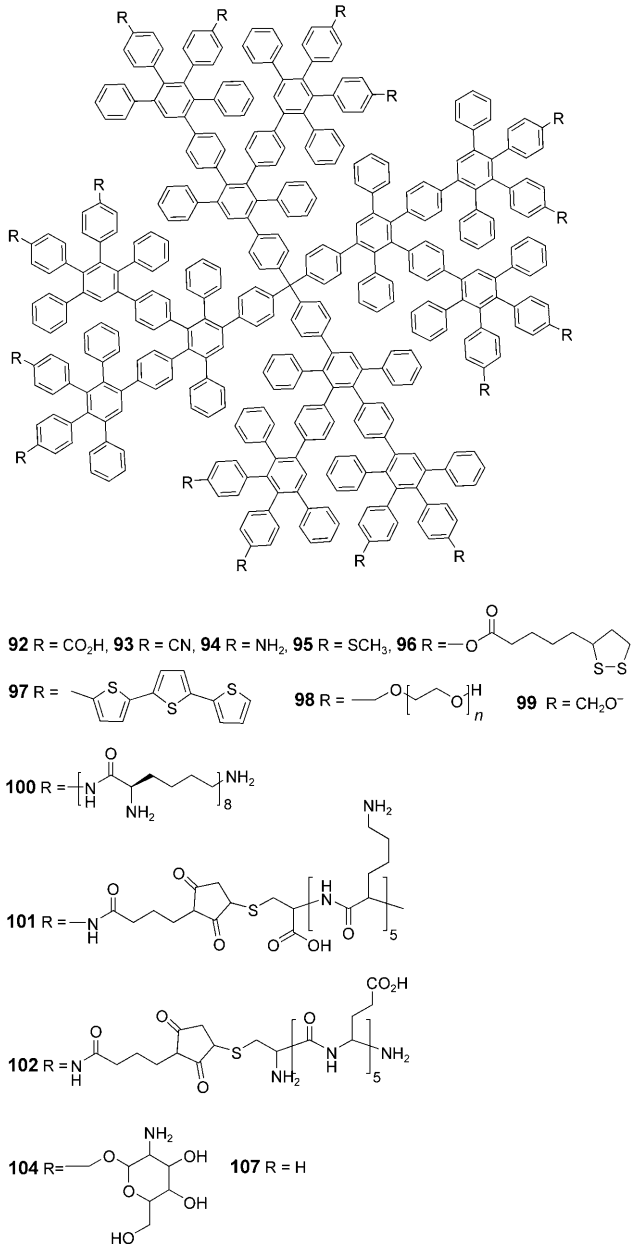


6.3. Polyphenylene Dendrimers with Functional Cores

An example of a dendrimer with a functional core is a first-generation dendrimer **89**/**90** (Scheme 20) with a photochromic azobenzene core, which isomerises from the *trans* to the *cis* form upon irradiation with ultraviolet light.[261] It can be clearly seen that the *trans* form **89** and *cis* form **90** have markedly different volumes. Gel permeation chromotography (GPC) measurements show an increased retention time of the *cis* isomer **90** on the column because of its markedly decreased (24–38%) hydrodynamic volume. These dendrimers thus represent an example of a nanosized so-called "smart material", in that they show a clear reproducible response to an external stimulus (in this case light). The rate of light-induced *trans–cis* isomerization and the proportion of the *cis* isomer in the photostationary state decrease with increasing generation or increasing branching of the dendrimer, while the rate of the thermally induced reverse isomerization increases. Dendrimers with azobenzene cores have also been prepared by other research groups,[261] but the flexibility of their dendrons results in their photoisomerization not causing a marked, well-defined change in the dendrimer shape.

Scheme 20. First-generation azobenzene-cored dendrimers showing the marked change in volume of the nanoobject upon *trans–cis* isomerization.

The dendrons are not expected to be good charge transporters because of the twists between adjacent benzene rings. This has been confirmed by cyclic voltammetry (CV) studies; for example, dendrimer **91** with a triphenylamine core (Scheme 21)[262,263] showed an increase in the potential of the anodic peak in the oxidation cycle in going from the first- to the third-generation dendrimer together with a two-thirds reduction in the peak current.[262] This observation shows that the effect of the dendrons is to hinder electron transfer from the hole-accepting triphenylamine core. Thus, the shell should not be made too large when encapsulating an electrically active unit within a dendrimer.



Scheme 21. Third-generation dendrimer with a triphenylamine core.

6.4. Dendrimers with Functionalized Surfaces and Scaffolds

Dendrimers have been prepared bearing a variety of polar groups, for example, carboxylic acids (**92**), nitriles (**93**), amines (**94**), and thiols (**95**, **96**; Scheme 22).[249] Such substituents can be used to confer water solubility (**92**) or to assist in binding to substrates, for example, the thiol-substituted dendrimers **95** and **96** bind to gold. Dendrimers **92–94**

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 22. Second-generation dendrimers with peripheral substituents.

selectively include volatile organic molecules within their internal free space, so that layers of these dendrimers on a quartz microbalance act as chemical vapor sensors, with sensitivities as high as 5 ppm for some analytes.[264] Dendrimer **95** with thiomethyl substituents serves as a template for the formation of gold nanoparticles.[265] Electron microscopy studies reveal that all the particles are spherical with average diameters of about4 nm. The particles self-assemble to form porous nanocomposites in which the randomly arranged gold nanoparticles are separated by dendrimer "nanolinkers". Similar nanocomposites have been made by layer-by-layer deposition of gold nanopartcles (ca. 4 nm in diameter) and the dithiane-substituted dendrimer **96**.[266] The electrical resistance of films of these porous nanocomposites was found to increase dramatically and reproducibly upon exposure to organic vapors. Much greater sensitivity was observed for nonpolar solvents because of their much greater sorption onto the hydrophobic dendrimers.[266,267]

Conjugated rods can also be attached to the surface of dendrimers. Such functionalized dendrimers could assemble to form three-dimensional networks of conjugated rods. As an example, dendrimers such as **97** with terthiophene subtituents have been prepared (Figure 7).[268] Two processes occur during electrochemical oxidation of **97**: coupling of the terthiophene chains to sexithiophene bridges with formation of an oligothiophene–dendrimer 3D network and, at higher potential, partial cyclodehydrogenation of the dendrimers to furnish a unique polythiophene–graphite hybrid. In situ conductivity measurements of the resulting nanocomposites revealed two well-separated electrical conductivity processes which correspond to the different electroactive components of the network. Both processes can be addressed by applying the correct electrical charge to the material.

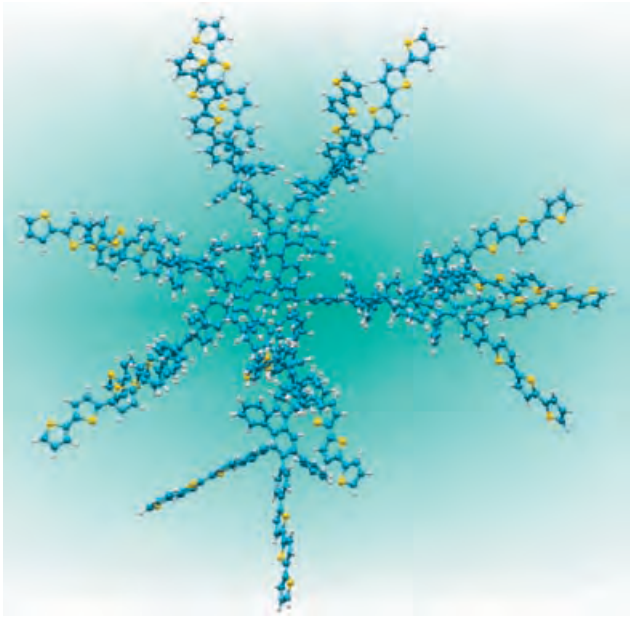


Figure 7. Molecular model of the terthienyl-substituted dendrimer **97**.

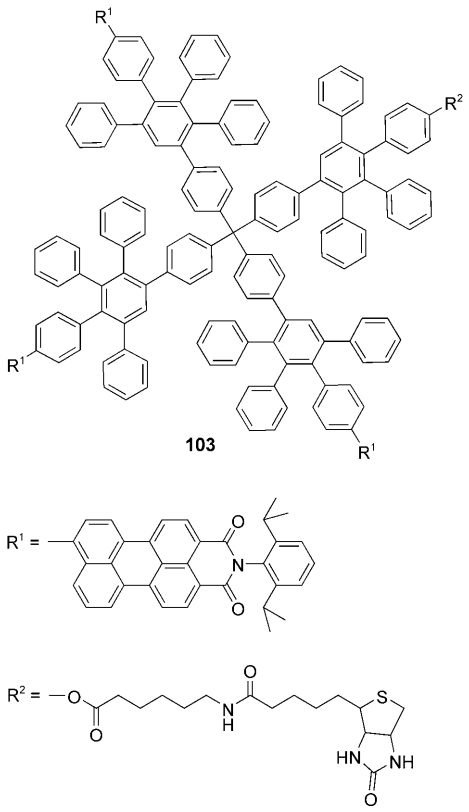
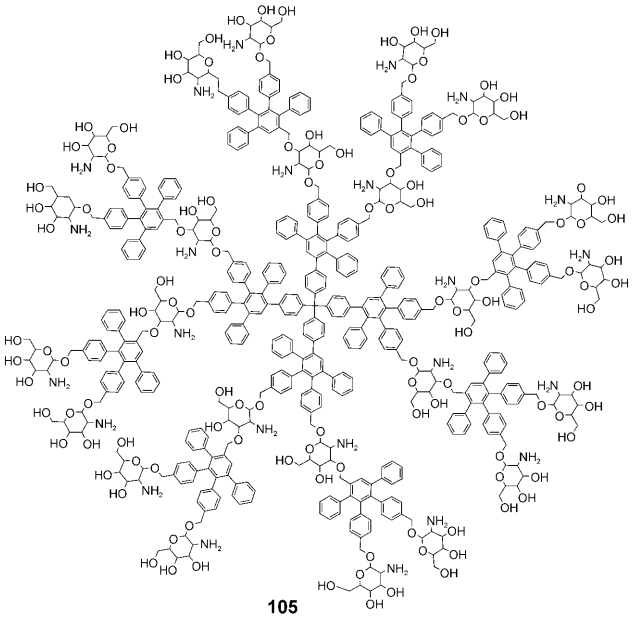
Solid-supported metallocenes have great industrial importance as catalysts for the polymerization of olefins.[269] The product morphology is controlled by immobilizing the metal catalyst on the surface of a support by use of latex particles (typically 80–100 nm in diameter) with poly(ethylene oxide) (PEO) chains on their surface.[270] These form secondary particles as a result of interactions with methylalumoxane which bind the catalyst. A key concern in making high quality polyolefins is that the solid support must fragment during the course of the polymerization to make catalyst sites accessible for the monomer.



As polyphenylene dendrimers are small discrete particles (less than 10 nm in diameter) they are attractive models for carriers of metallocene systems, and we have shown that zirconocene catalysts for olefin polymerization can be

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

attached to the surface of a polyphenylene dendrimer.[249] Dendrimer-based core-shell systems, for example, **98**, with a rigid polyphenylene core surrounded by a PEO shell have been prepared by both a "grafting-from" approach using **99** as a macroinitiator for anionic polymerization of ethylene oxide and a "grafting-onto" approach in which the ethylene oxide chains are attached to a substituted dendrimer.[271] These dendrimer models can then be compared with the latex versions.



Dendrimers have been the subject of much interest as possible delivery agents for drugs or DNA.[244,245] Polyphenylene dendrimers are particularly suitable substrates for biological applications as they are biologically inert and thus nontoxic, but can be readily and controllably functionalized. Dendrimers bearing oligopeptide chains have been prepared either by using peptide-substituted cyclopentadienones (for example, dendrimer **100**) or by functionalizing an amino-substituted dendrimer such as **94** with an *N*-alkyl maleimide followed by a Michael reaction with a thiol-endcapped peptide (for example, dendrimers **101** and **102**).[272] Such dendrimers are being used as model compounds for studying DNA complexation, and as agents for the introduction of RNA into cells (transfection).[273]

By utilizing the desymmetrization method discussed in Section 6.2 dendrimers can be made bearing both a biologically active functionality and an optically or electrically active functional group in a nanosized array. In the resulting bioassay the former group binds to a target biological moiety and the latter group is used for visualization. The rigidity and shape-persistence of the dendrimers are important as they maintain the biologically active moieties in fixed, well-defined relationships to each other and to the other active substituents. For example, the asymmetrically functionalized dendrimer **103** (Scheme 23) bears one biotin unit which binds strongly with the protein streptavidin, and three dye units which act as fluorescent markers.[274] The dendrimer has to be mixed with a non-ionic detergent to obtain water solubility. The solubilized dendrimer binds strongly to streptavidin in aqueous media to create a highly fluorescent complex, which remains intact in the presence of proteins, thus demonstrating the potential of this approach for bioassay applications.

Scheme 23. Biotin-substituted dendrimer for applications in bioassays.

It is possible to incorporate sugar groups not only on the periphery of a polyphenylene dendrimer (as in **104**, Scheme 22), but also within the dendrimer scaffold (as in **105** (Scheme 24).[275] The role of the peripheral sugar groups is to impart water solubility to the dendrimer. Fluorescence probe experiments show that the interior sugar groups in **105** are encased within a hydrophobic environment of the nanosized molecule, reminiscent of an active center situated within a hydrophobic pocket, as seen in enzymes. It is anticipated that these interior sugar groups can form stable hydrogen bonds to a guest and so lead to molecular recognition.

Scheme 24. Glycodendrimers with sugar groups at the periphery and in the scaffold.

6.5. AFM Studies and Self-Assembly of Dendrimers

As mentioned, above, polyphenylene dendrimers can be visualized as discrete nanoobjects by AFM (Figure 8).[250,251] Unlike other flexible dendrimers, the height of these objects matches that calculated by molecular modeling studies,[253] which confirms their rigidity (the height of "soft" objects is usually underestimated by AFM because of deformation). Their stiffness was further confirmed by pulsed-force mode AFM experiments. Just as flexible dendritic structures have

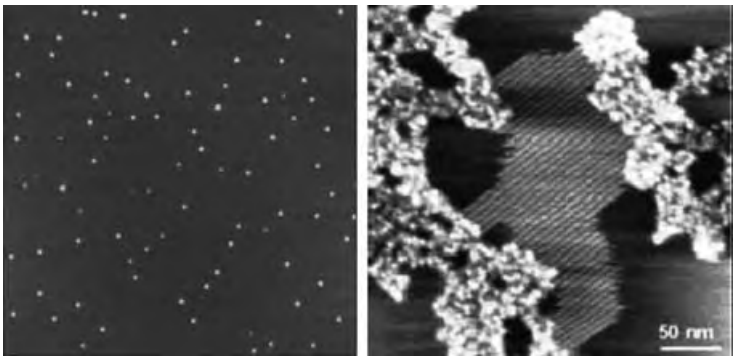

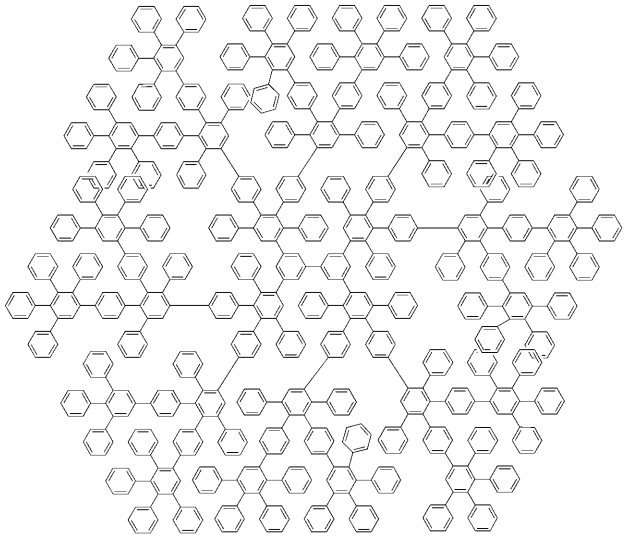

Figure 8. AFM images of: single third-generation unsubstituted dendrimers with a tetrahedral core (left) and nanorods of second-generation dendrimers with tetrahedral cores and alkyl substituents (right).

been demonstrated to form self-assembled monolayers and a variety of complex structures,[276] polyphenylene dendrimers can also self-assemble to form more complex architectures. The dumbbell-shaped third-generation dendrimer **106** with a biphenyl core (Scheme 25) forms globular clusters on mica with heights of about 6 nm when spin-cast and about 47 nm

106

Scheme 25. Dendrimer with a biphenyl core that forms globular aggregates on mica and fibers on HOPG.

when drop-cast.[277] In contrast spin-casting produced monolayers on HOPG or silanized mica surfaces, while drop-casting resulted in the formation of nanofibres with widths of up to several hundred nanometers, heights of up to 100 nm, and lengths of up to 400 μm. Similar micrometer-sized fibers have also been reported from the self-assembly of nonrigid dendrimers.[278] Stable, pinhole-free monolayers are also formed from alkyl-substited dendrimers on graphite surfaces.[263,279,280] Dendrimers up to the fourth generation with biphenyl (for example, **106**) or *trans*-azobenzene (for example, **89**) cores have also been shown to give rise to such globular cluster or nanofibers.[281,282] The formation of nanofibers was found to be favored by lower dendrimer generations and more-separated dendrimer branches. The major driving forces for aggregation are π interactions between the dendrimers as a result of interdigitation of the branches.

The dendrimer **92** substituted with carboxylic acid groups also forms aggregates, as shown by light-scattering experiments. AFM analysis of thin deposits from very dilute solutions reveal objects with heights corresponding to three to eight dendrimer layers.[250] Ionized molecules of **92** have been visualized by AFM after adsorption onto a SAM terminated with carboxylic acid groups through linkage with copper(II) ions.[283] Deformation of the SAM and a decrease in the measured height of the dendrimer ions compared to the calculated dimensions of the dendrimer were observed as a result of the strong interactions between the ions and the SAM. This dendrimer also undergo Decher-style layer-by-layer self-assembly[284] with poly(allylamine) which can be followed by surface plasmon spectroscopy.[285] A similar self-assembly process has been seen with the lysine-substituted dendrimer **101**,[258] while the glutamate-substituted dendrimer **102** forms complexes with cationic polyionenes.[286] The size and shape of larger polyphenylene dendrimers can also be determined by transmission electron microscopy. Single-molecule detection is possible, but size determination depends upon how the macromolecules are lying upon the substrate surface.[251]

6.6. SMS Studies on Dendrimer–Dye Host–Guest Systems

The torsions between adjacent phenylene units in polyphenylene dendrimers means that they have only limited conjugation and so such dendrimers fluoresce in the near ultraviolet with maxima around 365 nm.[287] Increases in the quantum efficiency of the emission are observed with increasing generation number as well as increased crowding and rigidity of the structure which reduce nonradiative decay pathways. SMS studies on host–guest systems in which cyanine dyes are incorporated within dendrimer **92** substituted with carboxylic acid groups[288,289] show that the absorption band of the dyes are red-shifted upon incorporation into the dendrimer as a result of the change in the polarizability of the environment. The incorporation of two different dyes enabled the energy transfer between to be studied. The energy-transfer efficiency was observed to fluctuate with time, which could be interpreted as arising from changes in the free volume within the host, or to variation in the transfer modes possible at the single-molecule level.

Now that we have introduced the properties of both perylene dyes and poylphenylene dendrimers we will examine the benefits of combining these classes of materials.

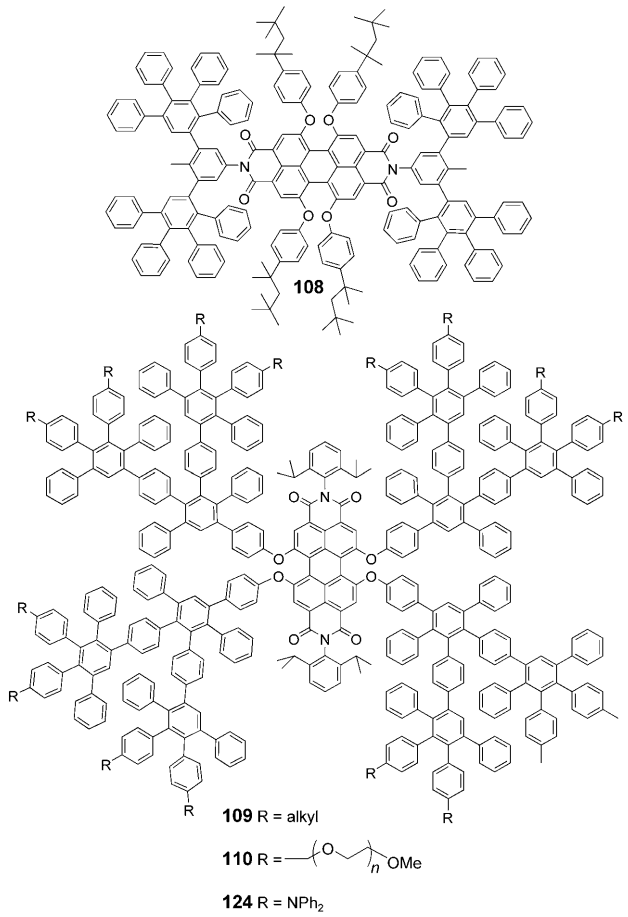
7. Dye-Loaded Dendrimers: Emissive Nanoparticles

Attaching dyes to polyphenylene dendrimers results in the formation of emissive nanoparticles. Such nanoparticles are of interest for a number of present and putative applications. An example of the former is that the attachment of dyes to the nanoparticles described in Section 6.4 generates supports for metallocene catalysts in polyolefin synthesis. Here the fragmentation of the catalyst particles within the product can be monitored by confocal fluorescence spectroscopy[290] to gain insight into the polymerization process.



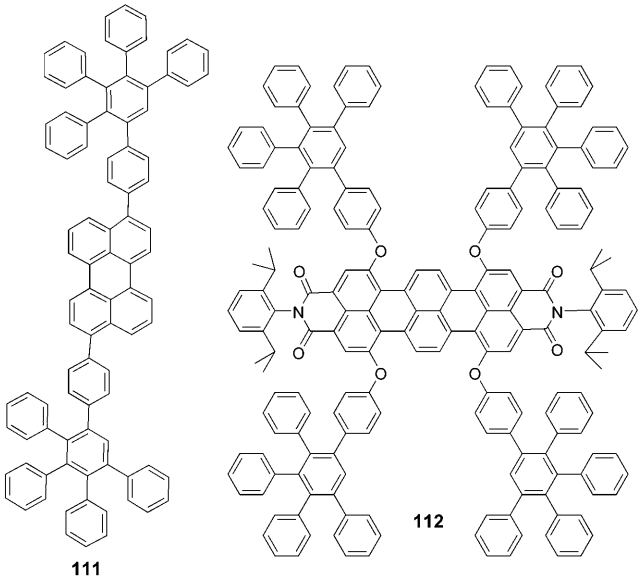
A possible future application is the use of light emission from single molecules in molecular electronics. The aim here is to manipulate excited states to encode or transmit information. For example, if a degenerate and vectorial energy-transfer process is considered, then allowing or not-allowing energy transfer between two dyes of a multichromophore would allow a read-out to be controlled at the molecular level. Two key problems of the approach are 1) the limited time before irreversible photobleaching occurs and 2) the limited excursion to the triplet state which renders the molecule dark for extended periods of time. The former aspect suggests that the lifetime of the multichromophores needs to be increased upon laser irradiation, for example, by rigorously excluding oxygen. The latter problem explains why control of the spin statistics have recently attracted the most interest in the optimization of molecular light systems.[291]

The combination of dyes with rigid dendrimers in host–guest systems has several potential advantages: 1) the dendrimer can be used as a shield around an emissive core to prevent chromophore interactions, which are well-known to lead to quenching of photoluminescence or to red-shifting in absorption or emission spectra as a result of the formation of aggregates or excimers.[292] 2) Multiple dyes can be attached in the scaffold and/or at the surface to produce materials with very high absorption and luminance. 3) Different dyes can be attached at different parts of the dendrimer, and/or the dyes can be combined with other functionality. 4) All the chromophores are in well-defined positions with respect to each other and to other substituents. Since energy (or charge) transfer between two chromophores is heavily dependent upon their distance and relative orientation, interactions between them can be finely controlled.

As single photon sources, multichromophoric dendrimers would, despite limited lifetimes, have distinct advantages over the existing materials: 1) the absorption cross-section can be increased by increasing the number of identical dye units. This means that 2) every laser pulse should result in at least one excited state being generated on the dendrimer, and that 3) the geometric conditions for energy transfer can be tuned. This last point is important since singlet–singlet annihilation processes need to be efficient to ensure only one photon is emitted.

7.1. Dendronised Dyes: Isolated Chromophores

Dendrimers with rylene dyes as cores have been made (Scheme 26) to demonstrate the efficient suppression of chromophore interactions by dendronization. Emissive PDI cores have been used with dendrons of increasing size attached to either the imide moieties[293] or in the bay positions.[294] Molecular models of the nanosized emitters such as **108** (Figure 9) and **109** clearly show that the dendrons in these materials shield the perylene core to hinder aggregation of the chromophores. The shielding is more effective for the materials with the dendrons in the bay positions. The dendrimer **110** bearing poly(ethylene oxide) chains has been used as a support for metallocene catalysts in polyolefin synthesis. The emissive core enables the fragmentation of the catalyst particles inside the polyolefin to be studied by confocal fluorescence microscopy.[295]

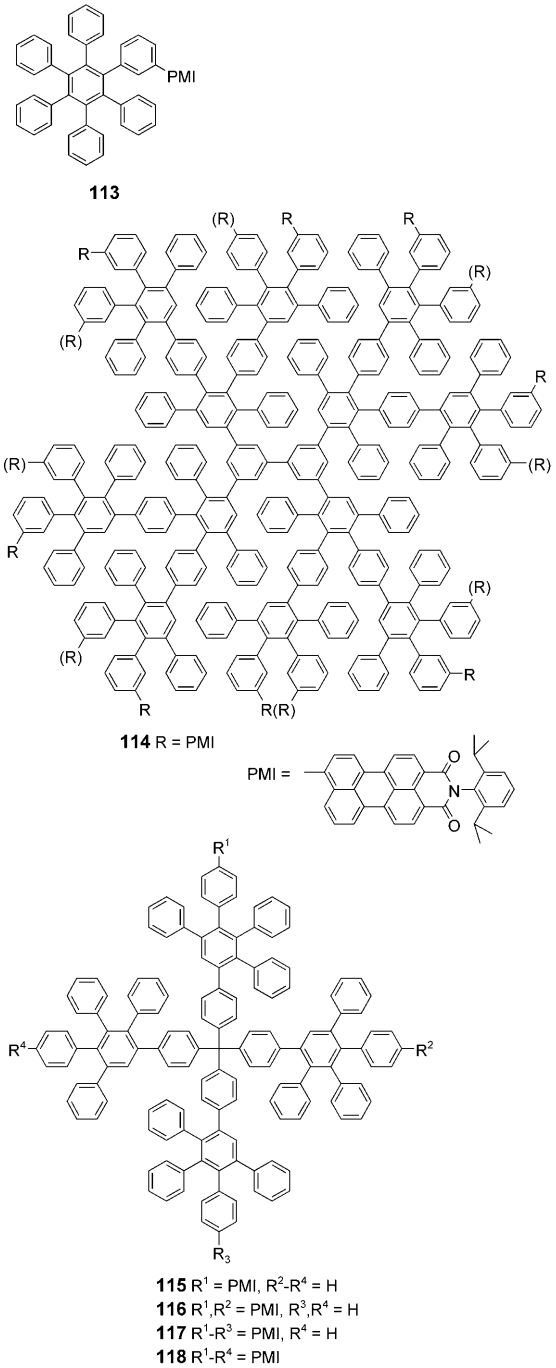


Scheme 26. Representative first- and second-generation dendrimers with PDI cores.

Figure 9. Molecular models of **108** (left) and its second- (middle) and third-generation (right) analogues.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

In both cases the effect of the dendronization is to produce a blue-shift in the solid-state absorption and emission spectra relative to an undendronized perylenediimide, thus showing that the chromophores have been prevented from aggregating.[293,296] The photoluminescence quantum yield of the dyes dendronized at the imide decrease with increasing dendrimer generation. This observation is attributed to the opening up of new nonradiative deactivation pathways by the dendrons.[293] It has also been shown that excitation of the dendrons stimulates emission from the PDI core as a result of efficient energy transfer between them; the calculated Förster radius is about 2.4 nm.[287] Light-emitting diodes (LEDs) have been prepared using these dendronized dyes[296,297] but show low efficiencies, especially for the higher-generation dendrimers, which is attributed to poor charge transport through the dendrimer shell. Blending the imide-dendronized dyes such as **108** with polyfluorenes improves the electroluminescence yield because of better charge injection and transport.[297] Blends of dyes dendronized at the bay position, for example, **109** in a poly(*N*-vinylcarbinol) (PVK) matrix show a more intense electroluminescence because of the charge-transporting properties of PVK.[296] A similar suppression of interchromphore effects occurs for other dendrimers with perylene (for example, **111**)[298] or TDI cores (for example, **112**,[299] Scheme 27; only first generation dendrimers shown).

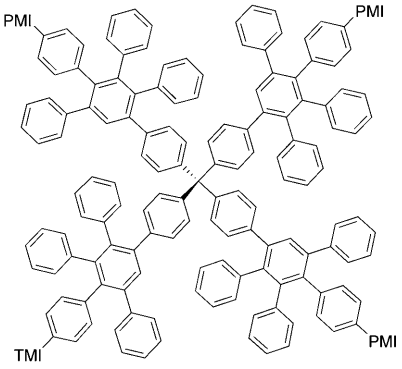


Scheme 27. Examples of first-generation dendrimers with rylene dyes as cores.

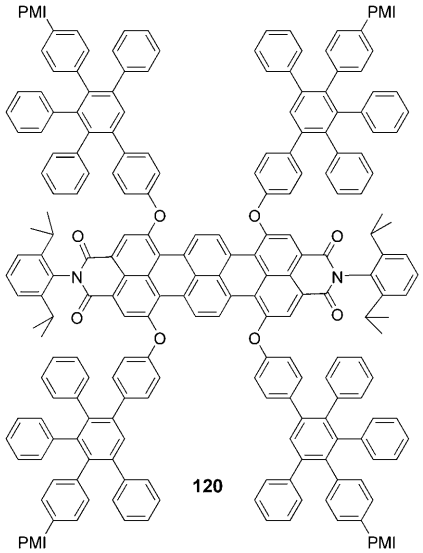
7.2. Dendrimers with Dyes on the Surface and/or in the Scaffold

Polyphenylene dendrimers can have multiple chromophores attached at their peripheries, thus producing strongly emissive nanoparticles. The well-defined spatial positions and orientations of the attached chromophores makes these materials particularly suitable subjects for single-molecule spectroscopy (SMS) studies on the intramolecular interactions between chromophores. Studying such chromophore interactions is essential for the understanding of the photophysical processes that occur in solid-state optical systems and in multichromophore systems such as the light-harvesting systems involved in photosynthesis.

A broad range of dendrimers with perylenemonoimide (PMI) chromophores have been used in SMS studies—from the isomeric hexaphenylbenzene model compound **113** with one PMI group to the second-generation dendrimer **114** with a biphenyl core bearing eight PMI chromophores (Scheme 28).[300] The dessymmetrization procedures discussed in Section 6.2 can be used to prepare dendrimers with dyes on only part of the surface, such as in dendrimers **115**–**118**.[260]

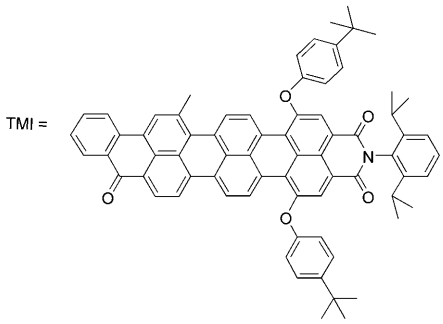


Scheme 28. Dendrimers with PMI chromophores on the periphery.

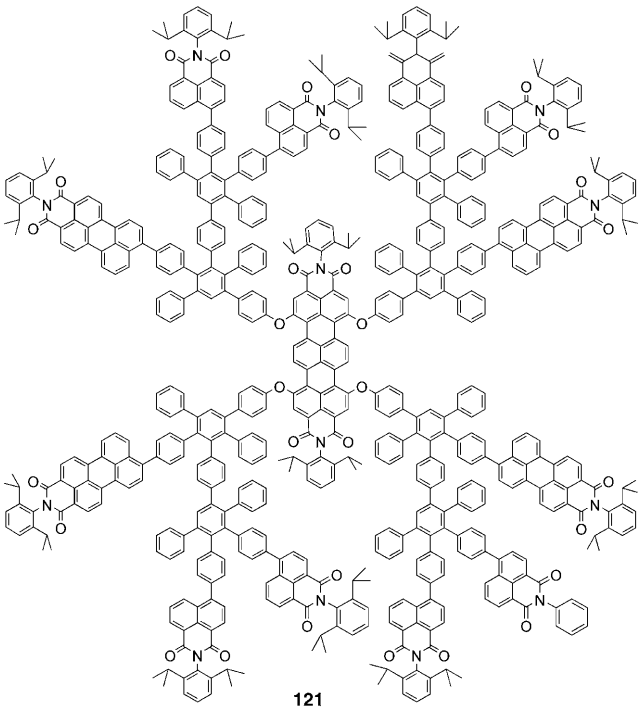


© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Better models for light-harvesting systems are dendrimers containing both donor and acceptor chromophores for energy transfer. Both dyes can be attached to a dessymmetrized surface or each can be incorporated separately in different layers, that is, as the core, in the scaffold, or at the surface. Both approaches have been used successfully, as exemplified by the dessymmetrized dendrimer **119**,[260] and the dyad **120** (Scheme 29).[301]



The most sophisticated example of this approach is the triad **121**, which incorporates three different dyes at the core, in the scaffold, and at the periphery (Scheme 30).[257] The

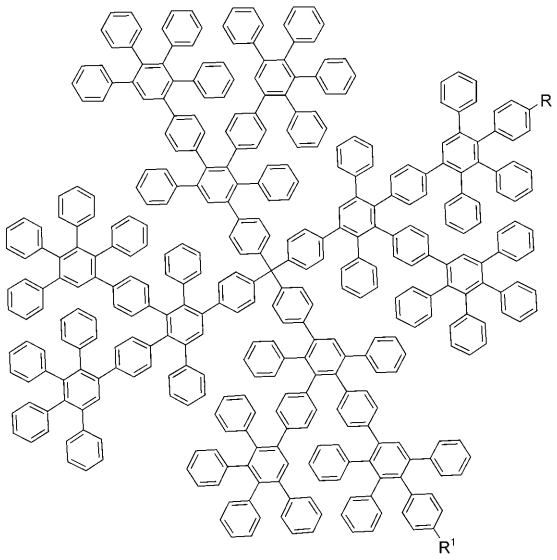


119

120

Scheme 29. Dendrimers with both perylene and terrylene chromophores.

121



Scheme 30. Triad system with an energy-harvesting unit.

overlap between the emission spectrum of the chromophore in each layer with the absorption spectrum of the chromophore in the next layer towards the core is designed to promote efficient energy transfer from the periphery to the core in **121**. This triad is made by first adding the desymmetrized cyclopentadienone **82** bearing a perylenecarboxydiimide dye unit (Scheme 18) to a terrylenetetracarboxdiimide core, then deprotecting with fluoride ions, and finally treating the deprotected alkynes with a cyclopentadienone bearing naphthalimide dye units. Highly efficient intramolecular energy transfer is demonstrated in all three molecules **119**, **120**, and **121**, with the photoluminescence emission coming almost exclusively from the terrylenediimide units. A blend of the triad (5 wt %) in charge-transporting violet-emitting PVK matrix produces red electroluminescence, which shows that efficient energy transfer can also occur under electrical stimulation, and thus leads to the possibility of building a single-molecule LED.[302]

7.3. Self-Assembly of Fluorescent Dendrimers

As mentioned in Section 6.5, polyphenylene dendrimers can self-assemble to form fibers (Figure 8). Long fluorescent nanofibers have been obtained from such an assembly of the third-generation dendrimer analogue of **116** and the second-generation dendrimer **122** bearing one PMI unit.[282] The emission from **122** is red-shifted relative to that of the solution and indicates that aggregation of the chromophores is occurring. In contrast, the dendrimer **123** with two dye units (Scheme 31) does not form such nanofibers, only nanorods.

122 R = PMI, R^1 = H
123 R, R^1 = PMI

Scheme 31. Dye-loaded dendrimers that form fluorescent nanofibres.

Mixtures of **123** with the nonfluorescent dendrimer **107**, however, do form nanofibers. The emission from nanofibers containing mixtures of **107** and **122** or **123** is blue-shifted as the dye content decreases. No polarization of the emission is seen from any of the nanofibers, thus indicating that the chromophores are randomly oriented.

7.4. SMS Studies on Emissive Dendrimers

SMS measurements of the chromophores in the nanoemitters described in the previous section allow detailed investigations of processes such as energy or electron transfer.[303,304] SMS can provide important insights even for the model compound **113**. Single molecules of **113** show a reversible on-off "blinking" effect with two different time scales.[305] The shorter off-times of 10–100 μs are ascribed to formation of non-emissive triplet states, while the longer times of 100 ms to tens of seconds may arise from formation of radical anions or cations by electron tunneling. Energy hopping and transfer to the chromophore with the lowest singlet state is observed in studies of the multichromophoric systems such as **114**[300,306–311] and **115**–**118**[312–323]. Multichromophoric dendrimers such as **115** can be shown by their Mandel parameter to act as a single-photon emitters with sub-Poissonian characteristics when embedded in a polymer matrix and subjected to coincidence measurements.[324] These dendrimers (like the bischromophores mentioned in Section 5.3) behave as single photon sources, as efficient singlet–singlet annihilation means only one photon is emitted at a time even when more than one chromophore is excited simultaneously.[317,321,323,324] Both singlet–singlet and singlet–triplet annihilation have been detected in these systems by SMS, but only the former can be visualized in studies on the ensemble.[301,303,304,310]

Single-photon emission, in which light pulses each consisting of a single photon are produced at a user-determined time is a particularly exciting concept in modern electronics. Quantum dots[325,326] and color centers in diamond single crystals[327] have been used as single-photon sources. Quantum logic gates based upon single photons[328] and a sort of quantum cryptography based on the polarization of a single photon[329] are examples of the potential utility of such sources. Multichromophoric dendrimers meet some of the requirements for a single-photon cryptography source, but future research needs to address, besides the issue of stability, additional challenges, such as controlling the polarization of single photons and sending an encryption key with the photons emitted from the single dendrimer.

One unexpected result was that dendrimer **114**, in which the chromophores are only weakly coupled, showed collective on/off fluorescence, which is usually seen only in strongly coupled systems. This result has been attributed to energy transfer between the chromophores on **114**, with the collective off periods arising from a triplet state on one of the chromophores acting as a nonradiative trap.[310] This concept has been used as a model for understanding the energy-transfer processes seen in natural light-harvesting systems.[310] Regioisomerism in dendrimers such as **114** means that there are a range of interchromophore distances and orientations which leads to a loss of structure in the fluorescence spectra from **114**, and the appearance of extra components in time-resolved spectra. The spectra of two isomers of a first-generation dendrimer **117** bearing only three chromophores have been distinguished in SMS experiments.[312]

There are a wider variety of interchromophore relationships available for study in systems containing different chromophores, as not only can degenerate energy transfer between identical chromophores, but also Förster or Dexter transfer between the different chromophores can occur. Both ensemble and SMS measurements have been used to probe the photophysics of systems such as **119**[260,330] and **120**[301,331–335] that contain both perylene and terrylene units. Efficient (95%) energy transfer from the perylenes (donor) to the terrylene (acceptor) chromophore has been demonstrated in both cases.[330,332–335] For the dendrimers with a terrylene core, such as **120**, two independent energy-transfer processes were identified, whose rates correlated with the size of the dendrimers: 4 and 25 ps for the first-generation (**120**) to 22 and 68 ps for the corresponding second-generation dendrimer.[331] Singlet–singlet annihilation was found to compete with energy transfer at low excitation powers so that emission was only seen from the terrylene core. At high excitation powers, an exciton blockade was observed in which several perylene units were simultaneously excited and not all underwent singlet–singlet annihilation so that emission from both donor and acceptor chromophores was seen.[333] Frequency-selective excitation in SMS measurements of **120** at low temperature enables the addressing of individual perylene donors and the terrylene acceptor and thus allows the energy-transfer times for each donor to be defined. The interrogation of both the energy donors and energy acceptors

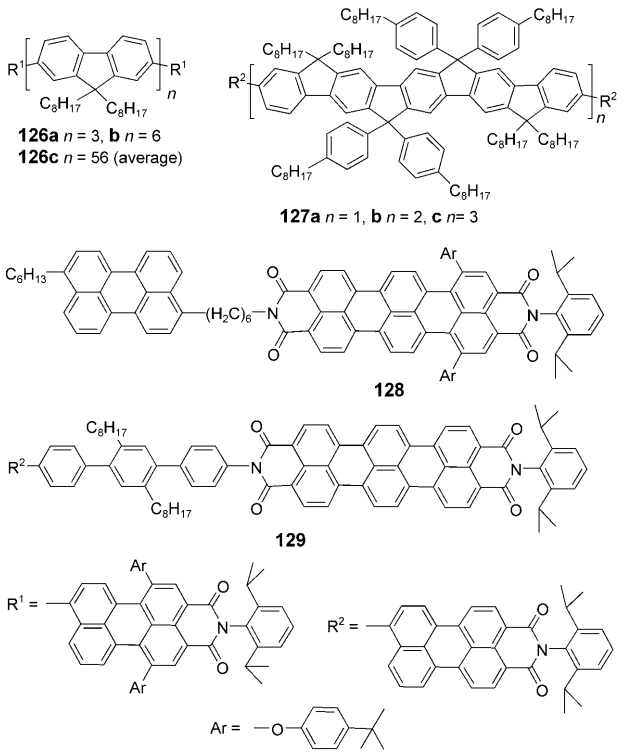
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

should allow fluctuations in the transfer rate caused by spectral shifts in the emissions from either type of chromopore to be detected.[331] SMS studies of the triad **121** show that energy transfer between the naphthalene and terrylene chromophores may proceed by either a direct or a cascade route.[336]

7.5. Electron Transfer in Emissive Dendrimers containing Triarylamine Units

Perylenecarboxydiimide chromophores are good electron acceptors, and both energy and electron transfer from the amines to the dye have been seen in ensemble and SMS studies in dendrimers, such as **124** (Scheme 26), with peripheral electron-donating triphenylamine units.[294,337,338] As would be expected from the distance-dependence, the electron transfer is more favorable in first- than in second-generation dendrimers, as well as in more polar solvents. Similarly, ensemble and SMS measurements on dendrimer **125** (Scheme 32) with an electron-donating triarylamine core and a dye on the periphery show that reversible electron transfer occurs between the core and the dyes.[339–341] The single-molecule emission spectra of the two isomers resulting from the Diels–Alder addition are again resolvable: the electron-transfer processes have different kinetics because of the different distances between donor and acceptor in the isomers (1.5 and 1.7 nm for the *meta* and *para* isomers, respectively).

Understanding the kinetics of such electron-transfer processes is important in the study of photosynthesis and other natural processes involving charge transfer between active units. One futuristic concept that has yet to be realized is to use donor–acceptor molecules as single-molecule photovoltaic devices. The major hurdle to be overcome is collecting the charges in dendrimers with one of the active units at the core, as any charges at a totally enclosed active core would be inaccessible. Dessymmetrized dendrimers with donors on one dendron and acceptors on another, or with only a partially enclosed core are promising solutions to the problem.



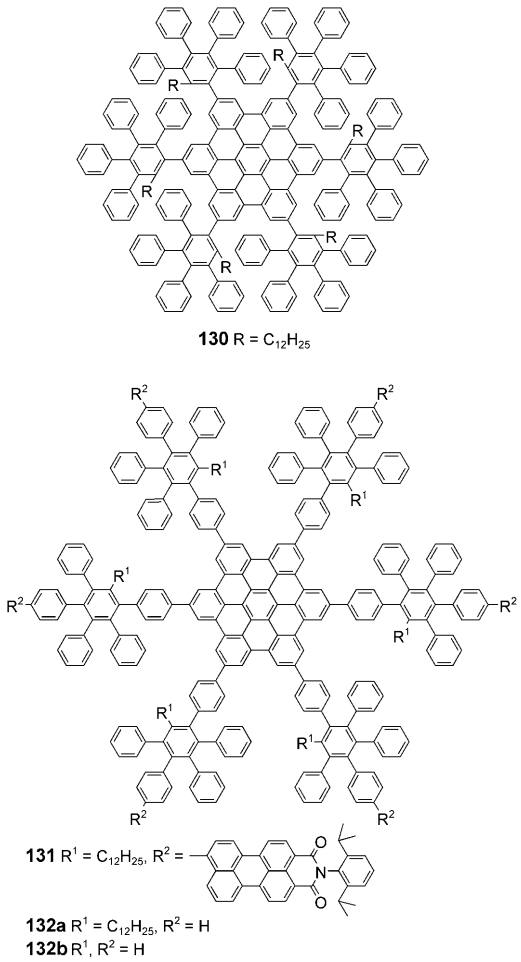
Scheme 32. Dendrimer with a triarylamine core and a perylene chromophore at the periphery.

7.6. Combining Dyes with One- and Two-Dimensional Polyphenylenes

We showed in the previous section that perylene dyes can be combined with three-dimensional polyphenylene dendrimers to make strongly emissive compounds. They can also be combined with polyphenylenes of lower dimensionality to make emissive materials with different topologies. One-dimensional oligo- and polyphenylenes are rigid rods and thus they are clearly suitable scaffolds to which chromophores can be attached to produce nanoemitters.

One-dimensional polyphenylenes are wide-bandgap materials which emit in the violet, blue, or blue-green regions of the spectrum, and so can transfer excitation energy to a smaller bandgap chromophore such as a rylene dye. Thus, perylene dyes can be incorporated into polyfluorenes as random co-monomers within the chain, on side-chains, or at the termini of the chains.[188] In all three cases efficient Förster energy transfer between the blue-emitting polyfluorene and the dyes results in emission coming from the latter. This principle has enabled the fabrication of efficient polyfluorene-based LEDs whose emission color can be tuned across the visible spectrum. The energy transfer is much more efficient in the solid state, and occurs in thin films even when the mole fraction of dye is only 1%. Unlike the emissive dendrimers described above, these emissive polymers do not possess multiple chromophores in well-defined positions with respect to each other. The polymers with dyes at the chain ends are polydispserse and so the distances between the two dye units are also random. Therefore, oligofluorenes **126a**,**b** have been prepared with dyes at the ends so as to have materials with well-defined interchromophore distances (Scheme 33). Both compounds were studied at the ensemble and single-molecule levels and compared with the dye-endcapped polymer **126c**.[342,343] Energy hopping, and singlet–singlet and singlet–triplet annihilation processes could all be detected in the oligomers. In contrast, only some chains showed singlet–singlet annihilation in the dye-endcapped polymer, presumably because the chain length was too short or the chain conformations were such that the two dye units

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Scheme 33. Oligophenylenes with a rylene chromophore at each end.

were brought close to each other; polyfluorenes are not rigidly linear and can adopt coiled conformations.

SMS studies on the trimer **126a** in a zeonex matrix showed that the angle between the dipoles of the chromophore was 70°, thus indicating it had a bent conformation. This arrangement is attributed to the lipophobicity of the matrix inducing aggregation of the alkyl side chains.[344] This determination of the conformation of an isolated molecule illustrates the power of SMS techniques. Whereas oligofluorenes can adopt nonlinear conformations, which makes the interchromophore distances difficult to predict, the oligomers **127** based on ladder-type pentaphenylenes are rigidly linear. Here the distance between the dyes can be tuned from 2.2 nm (**127a**)[71] to 6.7 nm (**127c**)[345] by varying the number of pentaphenylene units. An SMS study on **127a** in a poly(methylmethacrylate) (PMMA) matrix revealed that 44% of molecules switched between the locally excited state and an emissive charge-transfer state by a reversible electron transfer from the pentaphenylene to the dye. The same switching ratio was detectable in ensemble experiments performed in polar solvents.[346]

SMS studies have been performed on systems such as **128**[347] and **129**[348] that contain a perylene and a terrylene chromophore separated by short spacers. Förster energy transfer was observed in both cases, with a calculated Förster radius of 3.3 nm for **128**. Somewhat unexpectedly the dipoles of the two chromophores were found not to be colinear (maximum in the distribution of deviation angles observed at 22°). This observation was tentatively attributed to the transition dipole not being aligned with the long molecular axes of the chromophores. The key advantage of bichromophores such as **129** is that the distance and relative orientation of the donor and acceptor dyes can be controlled. These dyads then serve as important models for complex multichromophores such as the dye–dendrimer hybrids described above. The aim of further studies is to increase the length of the oligophenyl spacer and to introduce a kink by incorporating in *meta*-phenylene units.[349]

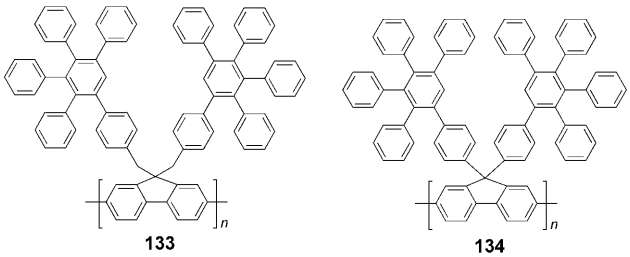
Two-dimensional polyphenylenes offer a wider range of topologies than the rodlike one-dimensional conjugated polymers and can also have more positions to which dye units can be attached. Such a multichromophore combining a disc-type PAH with perylene-based dyes is the hexa-*peri*-hexabenzocoronene (HBC) derivative **131** (Scheme 34) in

Scheme 34. HBCs with dye-loaded dendron substituents.

which the chromophores are attached to six dendron substituents. HBCs are good hole-accepting units and perylene imides are good electron acceptors and so efficient electron transfer from the HBC core to the dyes is seen.[350] An important motivation for the development of HBC–perylenemide hybrids is the combination of light-induced charge separation with charge-carrier transport in supramolecular architectures.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Compound **131** combines phenylene nanostructures of two different dimensionalities, in this case a two-dimensional disc and a three-dimensional dendrimer. As shown in the next section, this combination approach furnishes increasingly complex nanoarchitectures.



8. Combining One-, Two-, and Three-Dimensional Polyphenylene Nanostructures

A combination of one-dimensional and two-dimensional structural motifs has already been shown in the HBC oligomers **32**–**35** in Section 4.2 above. We have also demonstrated that dendronization of rylene dyes offers a way to prevent interchromophore interactions in the solid state. An extension of this concept is to use dendronization of conjugated polymers and of PAHs to control their packing. Also, since lithium ions can intercalate between,[351] and hydrogen molecules can adsorb to, graphene sheets[352,353] materials containing well-defined three-dimensional arrays of such sheets might have applications in lithium batteries or hydrogen storage.

8.1. Controlling the Stacking of HBCs and Conjugated Polymers by Dendronization

As was discussed in Section 4, optimizing the mobilities of electrons and electron defects by the intra- and intercolumnar order of HBCs is a major research goal. However, if bulky groups are attached to an HBC then the stacking of the discs can be restricted (Scheme 34). Such compounds cannot be used in existing electronic devices but exemplify how the self-assembly of molecules is controllable by means of varying the substituents.The dendronized HBC **130** cannot stack and so exists as isolated discs. Attaching the dendrons through an intermediate phenylene ring reduces the steric hindrance to stacking so that **131** forms stable dimers, while **132a** displays an equilibrium between the monomer and dimer which can be studied by NMR spectroscopy.[354]

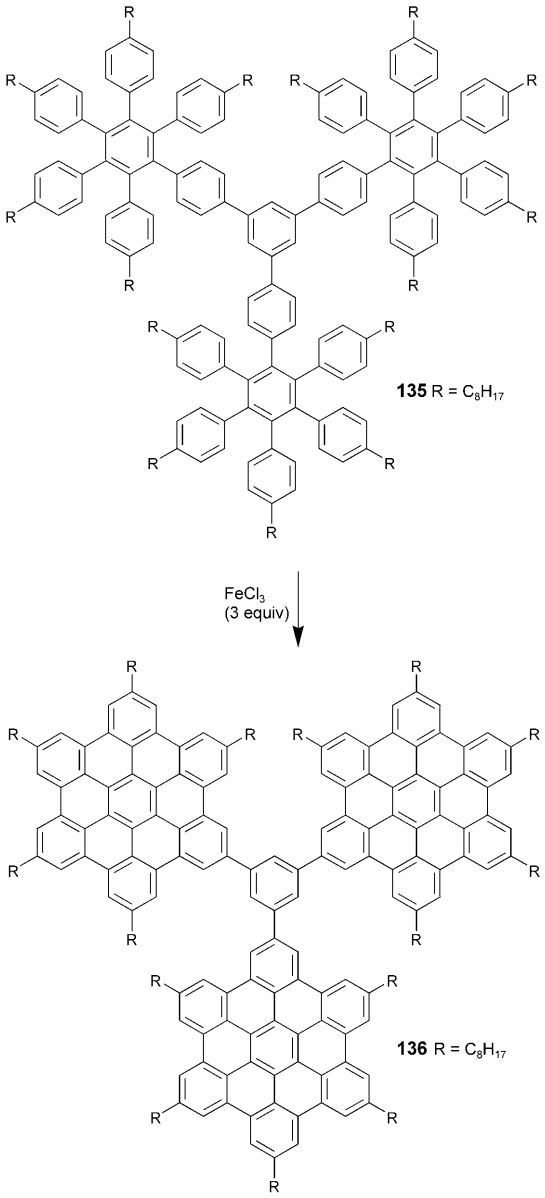
Whereas the most important properties of discotic molecules such as HBCs are associated with assemblies of molecules, those of emissive conjugated polymers arise from individual molecules so that restricting their stacking has fewer negative ramifications and is likely to be beneficial as it can suppress undesirable interchain interactions such as those leading to excimer emission or to enhancement of non-radiative decay pathways. The aim of wrapping conjugated polymers in polyphenylene dendrimers is to have the polymers encased within a protective shell so that the polymer chains are electronically isolated but without preventing the charge hopping from chain to chain necessary for obtaining electroluminescence. Polyfluorenes in which first-generation dendrons are attached to the bridgehead carbon atoms either by a benzyl linker (**133**) or directly (**134**; Scheme 35)[355,356] exhibit much stabler blue emission from LEDs than corresponding nondendronized PFs.[355,357] This effect is attributed to the reduction in exciton migration as a result of defects and the greater resistance of the arylated bridgeheads in **134** towards oxidation to form emissive defects. The dendrons have been shown to alter the exciton dynamics in the polymers,[358] and in particular to increase the triplet lifetimes[359] and reduce triplet migration.[360]

133 134

Scheme 35. Polyfluorenes with phenylene dendrimer side chains.

The dendronized polymers described here are highly rigid and, similar to polyphenylene dendrimers, can assemble to form nanofibers.[361] This assembly does not result from π stacking as seen for alkylfluorene polymers, and so should not affect the electronic properties of the individual chains.

8.2. Nanopropeller Molecules with Three-Dimensional Arrays of Graphene Sheets



Another class of molecules in which polyphenylene nanostructures of different dimensionalities are combined are "propeller" molecules in which a number of 2D polyphenylene units (graphene sheets) are linked through a nonplanar core.[362] These molecules are made by the partial dehydrogenation of polyphenylene dendrimers, as illustrated in Scheme 36 for the preparation of a soluble model compound **136** from the dendrimer **135**. The three HBC units In **136** are not coplanar as shown by the fact that Raman and UV/Vis spectra closely match those for individual HBCs (Figure 10). Propellers **139** and **140** with larger blades have been made from their dendrimer precursors **137** and **138** (Figure 11). However, these materials are insoluble and have been characterized only by solid-state UV/Vis and Raman spectroscopy, as well as by mass spectrometry. Thus, the cyclodehydrogenation must be conducted in such a way as to restrict the planarization to the separate dendron arms. Separation of the enantiomers of propeller **137** (4.5 nm diameter) was not possible because of its insolubility.

As can be seen from these results, the combination of polyphenylene nanostructures of various dimensionalities opens up a whole new range of molecular architectures, but there remains one class of carbon-rich materials we have not yet addressed, that is, carbon nanotubes.

9. From Discotic Mesophases to Carbon Nano- and Microstructures

Carbon nanotubes (CNTs)[363] are discrete particles that belong to a broad family of carbonaceous materials which have a long history and have proven of great industrial importance. CNTs may comprise either a single graphite

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 36. Partial cyclodehydrogenation of a C_{132} dendrimer **136** to a model "propeller" molecule **135**.

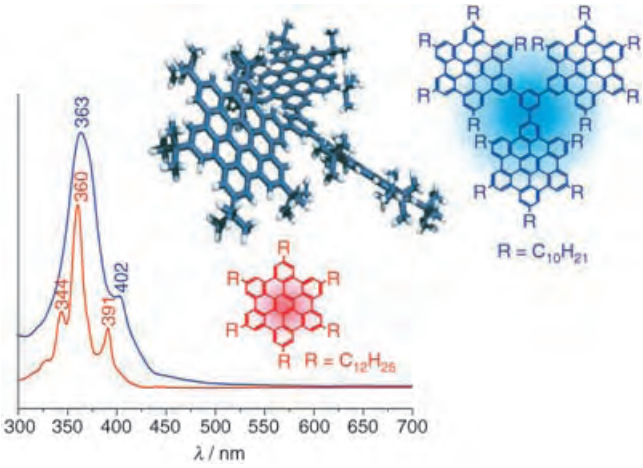


Figure 10. UV/Vis spectra of model propeller compound **135** (blue) compared with an alkylated HBC (red).

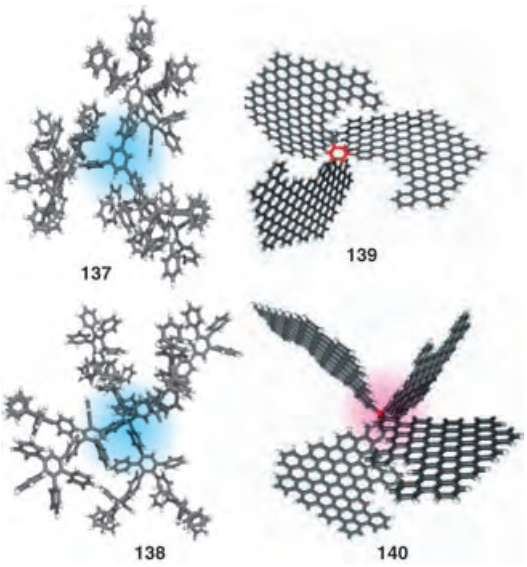

Figure 11. Formation of larger nanopropellers from dendrimer precursors.

sheet (single walled nanotubes, SWNTs) or an array of such nanotubes concentrically nested in a similar way as the rings in a tree trunk (multiwalled nanotubes, MWNT).[364] CNTs (and the related fullerenes) have become of intense academic and industrial interest recently because of their outstanding electronic (they can be either metallic or semiconducting) and physical (high tensile strength) characteristics, and potential use in electronic devices, or as chemical sensors, but there remain difficulties in obtaining these materials, particularly the SWNTs in both high yield and purity.[353,365–372] The standard methods for preparing carbon nanotubes and fullerenes typically involve high temperatures or pressures, for example, electric arc discharge of graphite electrodes[363] or laser ablation of graphite.[373] The chemical vapor deposition method is particularly attractive for the synthesis of aligned CNTs from the gas phase.

A new milder method has now been developed for preparing carbon nanoparticles by a two-stage pyrolysis of an alkyl-HBC (**32** $R = C_{12}H_{25}$).[374] The first stage of the pyrolysis occurs at 400 °C—a temperature at which the HBCs are still in an ordered liquid-crystalline mesophase (a carbomesophase). This results in the formation of large PAH intermediates (detected by MALDI-TOF) which preserve some mesomorphic order as shown by polarizing optical microscopy studies. In the second step, pyrolysis at 800 °C results in mild graphitization to produce carbon nano- and microparticles with graphitic nanostructures, including fibers and rods (Figure 12).[375]

Pyrolysis on mica afforded a mixture of films coated on the surface and discrete nanoparticles, whose preferred shape appeared to be a hexagonally symmetric zigzag, for example, large microobjects with cross-sections of 1–10 mm, and lengths in the micrometer range (Figure 11, bottom left), and rootlike microobjects with cross-sections of 400 nm–1 μm and lengths of > 30 μm (Figure 12, bottom right).

Metal particles are known to catalyze the formation of the aryl–aryl bonds in CNTs, and thus an organometallic complex

can serve as both a carbon source and a catalyst precursor in a pyrolysis. The solid-state pyrolysis of organometallic compounds such as metallo-dehydro[*n*]annulenes has emerged as a new method for making CNTs (primarily MWNTs).[376–379] The pyrolysis of an HBC–cobalt complex **141** in the solid-state produces carbon nanotubes (Figure 13).[380] Nearly quantitative yields of either "bamboo-shaped" or straight nanotubes are obtained. The shape and yield of the carbon nanostructures can be finely controlled by regulation of the heating process. The precursor **141** contains both a graphite carbon source (HBC) and a catalyst precursor, and at high temperatures the graphite islands form tubelike graphene structures on the cobalt catalyst units.

The next progression is to use the ordering of graphene molecules such as HBC to induce order in the nanotube pyrolysis products. Thus, a well-controlled pyrolysis of HBC molecules has been performed in a porous alumina membrane which acts as a template.[381] The HBC molecules were introduced to the nanochannnels within the alumina template by a simple wetting process, whereby it is important that the HBC discs adopt an edge-on arrangement of the template surface. Pyrolysis then furnishes carbon nanotubes. After dissolution of the template, high-resolution TEM studies (Figure 14) showed that the carbon nanotubes were formed with graphite layers perpendicular to the nanotube axis, that is, matching the alignment of the original HBCs. It was found

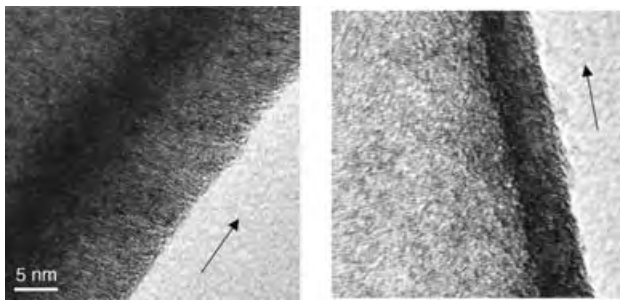

Figure 14. TEM pictures of the nanotubes showing the aligned graphene layers.

that the ordered preorganization of the liquid-crystalline HBC molecules on the surface of the membrane played a key role in obtaining carbon nanotubes with controlled orientation of the graphene layer. This special alignment of the graphene sheets is expected to induce significantly different properties in these nanotubes compared with those made by the previously known methods.

Further development of these concepts aims to produce nanotubes with controllable size, morphology, and electronic properties. For example, pyrolysis of materials containing heteroatoms could be used to selectively produce n- or p-type semiconductors.

10. Summary and Outlook

Though the emergence of a technology based on nanometer-sized devices still lies some time in the future, useful progress has been made. Hand-in-hand with the development of new methods for visualizing and manipulating matter at the nanoscale has come progress in the chemistry of nanomaterials—that is, in the design, synthesis, processing, and characterization of materials capable of performing as func-

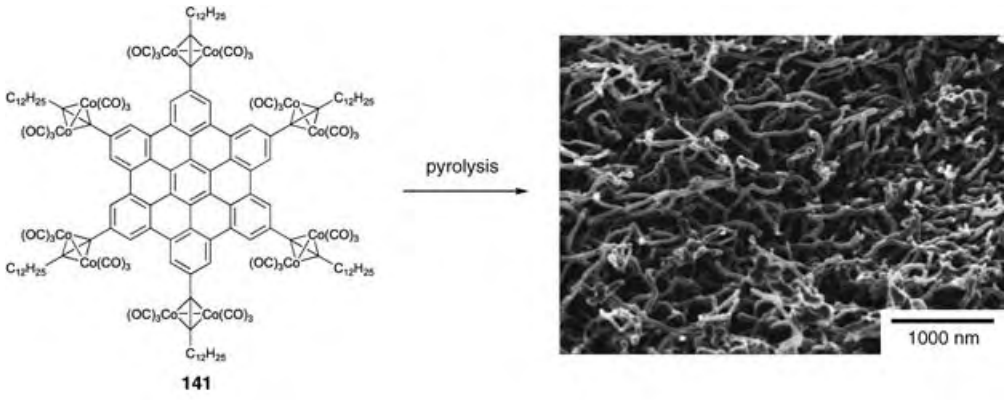

Figure 13. High-yielding synthesis of carbon nanotubes by pyrolysis of an HBC–cobalt complex in the solid state.

tional elements in putative nanodevices. In this Review we have presented our work on the development of such materials within the context of the wider ongoing research into the nanosciences.

Thus, we have shown how the optical, electronic, and phase-forming properties of rigid-rod one-dimensional polyphenylenes, discotic polycyclic aromatic hydrocarbons, rylene dyes, and polyphenylene dendrimers as well as of molecules containing various combinations of these structural elements can be manipulated by synthetic means. Crucial feedback for the synthetic design has been obtained by our research colleagues who have visualized individual molecules or small ensembles of these materials and probed their optical and electronic properties by means of single-molecule spectroscopy and scanning probe microscopy techniques. In this way, valuable insights have been gained into the fundamental processes of charge transport as well as of energy and charge transfer within and between molecules. This knowledge not only permits the design of improved nanomaterials but also provides valuable information about the behavior of the wonderfully sophisticated light-harvesting and other systems found within living organisms. It should not be forgotten that, in addition to the development of nanosized devices, there is still considerable scope for improvement in bulk organic electronic devices through investigation and optimization of the behavior of their component materials at the nanoscale. For example, the design of organic solar cells requires a control not only of the electronic properties of components absorbing light and acting as electron donors and acceptors, but also of phase-separated morphologies, preferably at the nanoscale, for charge transport.

Some initial steps have also been taken towards proving the viability of advanced nanotechnology. For example, a chemically gated transistor has been demonstrated for individual molecules of a substituted hexa-*peri*-hexabenzocoronene. On a more immediately practical level, fibers consisting of small bundles of columns of HBCs have been obtained which might plausibly be used in a nanosized FET. Polyphenylene dendrimers have been developed as highly stable shape-persistent nanoobjects which can be functionalized at the core, in the scaffold, and/or at the surface with a range of groups. This diversity offers the possibility of making functional nanoparticles with a wide range of possible applications including as nanoemitters, chemical sensors, drug-delivery systems, bioassays, and supports for catalysts.

New stable dyes with very efficient absorption and/or emission across the whole visible range and into the near infrared region have been developed which are both of great practical importance and are suitable for study by single-molecule spectroscopy techniques. These dyes can be combined with polyphenylenes of various dimensionalities to make highly emissive materials. In particular, they can be combined with polyphenylene dendrimers to make materials which act as single-photon sources and meet some of the requirements for single-photon cryptography.

An area that holds great promise for the development of complex nanostructures containing novel molecular topologies is the combination of one-, two-, and three-dimensional polyphenylene nanostructures. We have demonstrated that attaching dedrimers to one- and two-dimensional polyphenylenes can be used to control their assembly and thus their electronic properties. Finally we have shown that pyrolysis of ordered mesophases of HBCs is a practical way to make novel carbon nanoparticles with well-defined, synthetically controlled properties.

All of these results suggest that functional devices using individual molecules or small ensembles of molecules should no longer be regarded as the stuff of science fiction but as a realistically attainable goal. Further advances in techniques for the manipulation of matter at the nanoscale are needed, and the issue of electronically addressing nanoparticles or single molecules must be solved. However, if progress continues at the current rate and driven by the fruitful interaction between chemists and physicists, we may soon be rewarded with an advanced nanotechnology.

We thank all the many people who performed the work we have presented. First we thank all our co-workers, past and present, at Mainz. Second we cannot acknowledge too deeply the invaluable contributions from our distinguished collaborators, in particular Thomas Basché, Steven De Feyter, Frans De Schryver, Richard Friend, Johan Hofkens, Roberto Lazzaroni, Emil List, John Lupton, Jürgen Rabe, and Paolo Samori. The assistance and advice of Roland Bauer, Andreas Herrmann, Lileta Gherghel, Marcel Kasker, Markus Klapper, Christopher Kohl, Wojciech Pisula, and Jishan Wu in the preparation of this manuscript is also gratefully acknowldeged. Financial support for this research from the Max Planck Society for the Advancement of Science, the European Commission, the Bundesministerium für Bildung und Forschung, the Deutsche Forschungsgemeinschaft, the Volkswagen Stiftung, BASF, Merck, SONY, Roche and DuPont Displays is also gratefully acknowledged.

Communications

DOI: 10.1002/anie.200501311

The origin of biomolecular asymmetry could be found in asymmetric photochemistry in interstellar regions. It is assumed that the amino acids were formed in these regions. The irradiation of solid D,L-leucine probes with right circularly polarized synchrotron radiation at 182 nm produced an enantiomeric excess of the D enantiomer of 2.6%. For more details see the Communication by Meierhenrich, Nahon et al. on the following pages. The image was taken in June 1998 on the space shuttle Discovery.

Asymmetric Vacuum UV photolysis of the Amino Acid Leucine in the Solid State**

Uwe J. Meierhenrich, Laurent Nahon,* Christian Alcaraz, Jan Hendrik Bredehöft, Søren V. Hoffmann, Bernard Barbier, and André Brack*

The origin of biomolecular asymmetry, the fact that biological molecules such as amino acids show the same chirality, still requires an explanation and might be traced back to interstellar low-temperature processes.[1–6] Under interstellar conditions, chiral solid-state amino acids might have been subjected to circularly polarized vacuum ultraviolet (VUV) electromagnetic radiation before and during their space journey to Earth. However, to date, experimental data on chiroptical properties of amino acids were limited to aqueous solutions, which is not relevant in terms of astrophysical conditions.

Amino acids, the chiral building blocks of proteins, probably played a key role in both the appearance of life on Earth and the emergence of biomolecular asymmetry. Some of these amino acids were discovered in carbonaceous meteorites,[1,2] with enantiomeric excesses (*ee* values) and isotopic composition[3] indicating an extraterrestrial origin of biomolecular asymmetry. Amino acids have also been synthesized in the laboratory by simulating interstellar/circumstellar ice photochemistry.[4,5] Proteins are exclusively based on L-amino acid monomer units. The use of homochiral monomers is generally considered as advantageous for the prebiotic construction of their structure.[7–9] Interestingly, even small *ee* values can be amplified by autocatalytic reactions leading to near homochirality.[10,11]

Numerous asymmetric mechanisms have been suggested and tested experimentally, including the influence of circularly polarized light (CPL) as an external chiral force.[12–14] Astronomical sources of CPL,[15,16] which might produce enantiomeric selection in interstellar organic molecules, were observed in the IR range.[17] Electromagnetic radiation from magnetic white dwarfs and white-dwarf binaries (Polars) can be circularly polarized up to 12% and 50%, respectively.[18] CPL might also be produced by dust grains aligned by a magnetic field in the reflection nebulae in star-formation regions.

Since the pioneering work of Kuhn et al. who studied the enantioselective photodecomposition of ethyl-α-bromopropionate and *N*,*N*-dimethyl-α-azidopropionamide via electronically excited states,[19,20] asymmetric photolysis experiments on several chiral compounds have been reported.[21,22] In 1977, the amino acids alanine[23] and leucine[24] were decomposed enantioselectively in aqueous solution by excitation of the (π^*,n)-transition at 213 nm, and gave *ee* values of 2.5%.[24] The corresponding photolysis mechanism was recently examined.[25,26] To date, no higher *ee* value has been generated in amino acids.

So far, experiments using CPL have been performed in solution, which is less relevant with respect to astrophysical conditions. Because of the solvent absorption below 200 nm, such studies have been restricted to excitations of the (π^*,n)-electronic transition (213 nm on leucine), so that only part of the UV/VUV absorption spectrum was accessible. This situation is unfortunate since in general amino acids exhibit stronger absorption cross-sections for the (π^*,π_1)-electronic transitions, which are therefore interesting to investigate. It is noteworthy that Inoue et al.[27] irradiated pentane solutions of racemic (*E*)-cyclooctene with left circular polarized synchrotron radiation (*l*-CPSR) or right-CPSR (*r*-CPSR) at 190 nm and observed an enantioselective photoisomerization effect. Herein we report on chiroptical properties and asymmetric photolysis of D,L-leucine that was exposed, for the first time in the solid state, to VUV *l*-CPSR and *r*-CPSR at 170 nm and 182 nm, inducing asymmetric photochemistry via (π^*,π_1)-electronic transitions.

The amino acid leucine was chosen for the study of solid-state asymmetric photodecomposition experiments for the following reasons: 1) The photochemistry of the (π^*,n)-electronic transition is well-known. 2) Leucine shows the largest anisotropy factor g ($g = \Delta\varepsilon/\varepsilon$) among proteinaceous amino acids.[24] It has been established that the gain in *ee* value achievable during photolysis of a racemate is a function of the magnitude of g and of the extent of reaction.[22] 3) Enantiomeric separation techniques provide a high separation factor α and a high resolution R_S. 4) Leucine has a slow racemization rate compared to other amino acids.[28]

To establish the most suitable conditions for the enantioselective photodecomposition of solid-state leucine, electronic transitions and circular dichroism (CD) features were studied in the VUV photon energy range. VUV absorption spectra of solid films of leucine (1 μm film thickness deposited on an MgF_2 window) were recorded between 110 and 220 nm by synchrotron radiation (SR) absorption spectroscopy on beamline SA-61 of the Super-ACO storage ring of LURE in Orsay (France). A weak (π^*,n)-transition of leucine was detected at 211 nm, and a strong (π^*,π_1)-transition at 183 nm, about five-times more intense. Additional electronic transitions were determined below 150 nm.

A VUV CD spectrum of L-leucine in solution in 1,1,1,3,3,3-hexafluoroisopropanol has been reported.[29] It shows a positive (π^*,n)-electronic transition at 194 nm and a negative (π^*,π_1)-electronic transition at 168 nm. As part of our study VUV-CD spectra of solid-state D-leucine films, with estimated thickness ranging from 0.2 to 1 μm deposited on MgF_2 windows, were run below 200 nm at the Institute for Storage Ring Facilities, University of Aarhus (Denmark) using the synchrotron beamline UV1-ASTRID. The obtained CD spectrum is given in Figure 1 (top). It shows a negative band at 207 nm and a positive band at 191 nm, noticeably different from the spectrum recorded in solution. Comparing the CD data with the absorption spectrum, we conclude that the (π^*,π_1)-electronic transition splits into three CD bands, a negative band above 200 nm which overlaps with the negative (π^*,n)-band, and two positive bands, at 191 nm and at 175 nm.

The CD band splitting is assumed to arise from an excitation coupling based on coupling processes between leucine molecules in the solid state. We deduce from the CD data that the (π^*,n)-electronic transition of D-leucine is induced preferentially by right-handed circularly polarized light (*r*-CPL) and the two positive (π^*,π_1)-electronic transitions of D-leucine are preferentially excited by *l*-CPL. Since VUV electronic excitations lead to leucine photolysis, mainly by decarboxylation, irradiation of D,L-leucine with *r*-CPL at the (π^*,n)-electronic transition should theoretically produce an enantiomeric excess of L-leucine. Conversely, irradiation at the positive (π^*,π_1)-electronic transitions with *r*-CPL should lead to an enantiomeric excess of D-leucine by photodecomposition of the L-leucine. Opposite enantioenrichments are expected when using the opposite photon helicity *l*-CPL.

To achieve VUV asymmetric photodecomposition of solid state D,L-leucine, intense and quasi-perfect CPSR (Figure 2) as emitted by the OPHELIE Undulator[30] of the VUV SU5 beamline[31] was used to irradiate the samples. The photon energy was first set at 6.8 eV (182 nm; see Figure 1 bottom) and then at 7.3 eV (170 nm), so that information about the energy-dependence of the process could be gained. The first energy closely matches the middle of the two CD positive bands of the (π^*,π_1)-electronic transitions, while the second

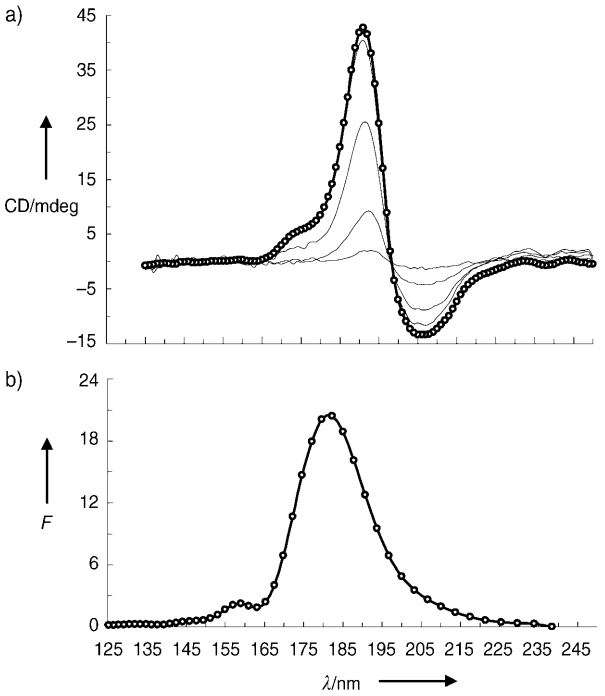

Figure 1. Spectral dependence of leucine CD and SR-irradiation. a) VUV CD spectrum of solid-state D-leucine recorded at the Synchrotron Facility ISA, University of Aarhus (Denmark). High-resolution measurement of D-leucine, film thickness 1 μm (bold line); low-resolution measurements of D-leucine, film thickness 0.2, 0.4, 0.6, and 0.8 μm (thin line); leucine films were immobilized on MgF_2. b) Spectral flux (F) of the OPHELIE undulator of the SU5 beamline at LURE (Orsay, France) in arbitrary units used for irradiation with CPSR centered at 6.8 eV (182 nm).

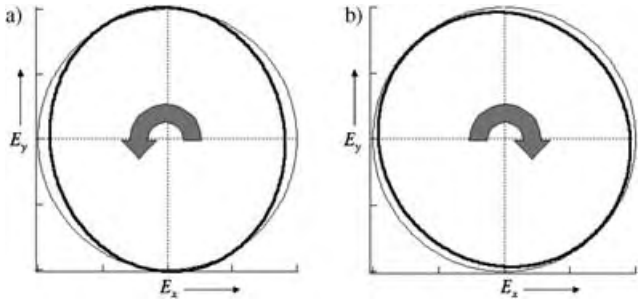

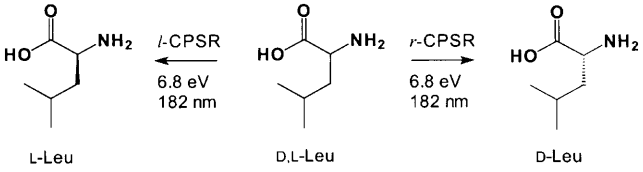

Figure 2. Measured polarization ellipses (thick lines) at the sample location. They were measured for a SR centered at 6.8 eV (182 nm), for a) *l*-CPSR and b) *r*-CPSR, as produced by the OPHELIE undulator of the SU5 beamline. Absolute circular polarization rates are of 91% for *r*-CPSR and 94% for *l*-CPSR. Thin lines are guide to the eye illustrating the perfect CP light case and the dashed lines indicate the normal ellipse axes corresponding to the two components (E_x, E_y) of the electric field associated with the light. The curved arrows indicate the helicity of the photons as seen by an observer facing the beam coming out of the plane of the Figure.

corresponds to the almost absent CD contribution on the short-wavelength side. Solid films of D,L-leucine were irradiated with *r*-CPSR and with *l*-CPSR in separate experiments. After photodecomposition, the remaining leucine was extracted and analyzed by enantioselective CG-MS. As summarized in Table 1, five samples were used: sample 1 was not irradiated and was used as a normalization sample, while the other samples were irradiated with different photon energies and CPL helicities. Sample numbers 1, 3, and 4 were analyzed six times in parallel, sample number 2 was analyzed three times, and sample number 5 was analyzed four times (see Table S1 in the Supporting Information). Overlaid chromatograms of the irradiated and separated leucine enantiomers are presented in Figure 3. No decomposition products of leucine could be identified with the GC-MS technique used, the expected volatile decomposition products, CO_2 and primary amines, would be evacuated in the high-vacuum synchrotron beamline and avoid detection.

Table 1: Enantiomeric excesses (averaged over three to six samples for the same irradiation conditions) obtained after irradiation of D,L-leucine with *l*-CPSR and *r*-CPSR.[a]

Sample	E_{photon} [eV]/λ [nm]	Irradiation	*ee* (D-leucine) [%]	CI_{95}[b]
1[c]	–	–	0.00	0.38
2	6.8/182	*l*-CPSR	−0.88	0.28
3	6.8/182	*r*-CPSR	2.60	0.16
4	7.3/170	*r*-CPSR	0.75	0.36
5	7.3/170	*l*-CPSR	0.53	0.48

[a] Complete set of data in the Supporting Information. [b] CI_{95} = confidence interval at 95% determined by multiple analyses of each sample. [c] Not irradiated, control sample.

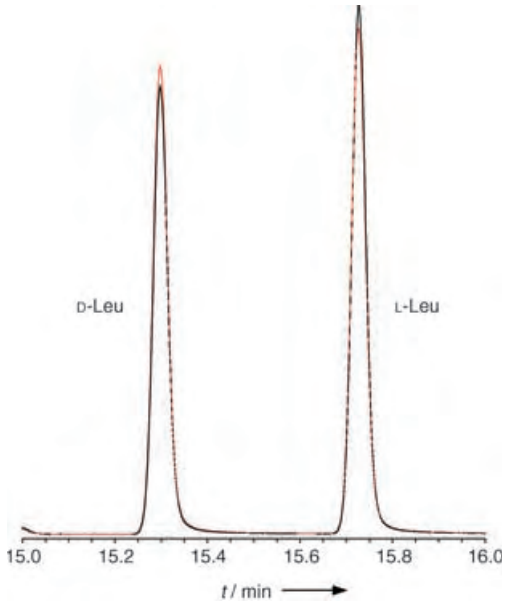

Figure 3. Overlaid gas chromatograms of irradiated D,L-leucine depicting the separated enantiomers after irradiation at 6.8 eV (182 nm) with *l*-CPSR (black line) and *r*-CPSR (red line) on the SU5 beamline at the Synchrotron Facility LURE, Orsay (France). The first eluting enantiomer is D-leucine. D,L-Leucine irradiated with *r*-CPSR, shows a marked enantioselective photodecomposition of L-leucine, the *ee* value for D-leucine being 2.60%. Chromatograms were measured in the single-ion monitoring mode at *m/z* 158 amu. For chromatographic overlay, the area of the sample irradiated with *r*-CPSR was multiplied by a factor of 1.61. *t* = retention time.

The highest gain in *ee* value was found to be +2.6% in D-leucine when irradiating with *r*-CPSR at 6.8 eV (182 nm), that is, near the two positive (π^*,π_1)-electronic transitions. Irradiation with *l*-CPSR at 6.8 eV resulted in an *ee* value of +0.88% in L-leucine. Samples were irradiated for 3 h each with a decreasing photon flux, owing to the decrease of the electron current in the Super-ACO storage ring. The photon flux was measured during the irradiation by monitoring the photoemission current from a highly transparent gold mesh inserted in the SR beam just upstream of the samples. From this measurement, we can determine that the total dose of irradiation (flux × duration) received by sample 2 is about 25% lower than for sample 3. This result explains parts of the observed difference between the absolute *ee* value for the two light helicities. The remaining part could be explained by a likely difference in the spatial transverse flux density and pointing between *r*-CPSR and *l*-CPSR owing to non-perfect symmetry of the OPHELIE undulator.[32] The result of these effects being that irradiation would not have the same efficiency for the different helicities. Beside this, tiny inhomogeneities of the solid-state leucine samples 2 and 3 resulting in a nonsymmetrical alignment within the synchrotron beamline may account for some of the differences.

The results demonstrate that a significant enantiomeric enrichment can be induced in solid-state D,L-amino acids by irradiation with energies closely matching the positive (π^*,π_1)-electronic transitions. Irradiation of solid-state D,L-leucine with CPSR at a higher energy, 7.3 eV (170 nm), did induce a minor *ee* value, which in addition does not change sign by switching photon helicity. This observation is coherent with the fact that the CD signal of leucine (see Figure 1) at 170 nm is vanishing.

In conclusion, enantiomeric excesses were induced in samples of leucine by VUV asymmetric photochemical reactions, such as enantioselective photolysis, under realistic interstellar/circumstellar conditions. These experimental data support the assumption that tiny interstellar/circumstellar ice grains can experience asymmetric reactions when irradiated by circularly polarized ultraviolet light. Various families of amino acids have been identified in carbonaceous meteorites,[1,2,33] with *ee* values and isotopic composition[3] indicating an extra-terrestrial origin of biomolecular asymmetry. A systematic study of asymmetric VUV photolysis in the solid state for different amino acids would help us to better understand the processes leading to their asymmetric formation and their role in prebiotic chemistry. Based on the present data, it is possible to conclude that asymmetric interstellar/circumstellar solid-state photochemical processes

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

in the VUV might have triggered the appearance of biomolecular asymmetry and thus could have assisted the start of life.

Experimental Section

Information on VUV circularly polarized synchrotron radiation and enantioselective GC-MS analyses are given in the Supporting Information. For the preparation of the solid-state leucine sample D,L-leucine (space group $P\bar{1}$, triclinic; 600 μg) were lyophilized and suspended in *m*-xylene (1,3-dimethylbenzene; 200 μL). A 2.5-μL sample of the suspension was introduced into a 1×5 mm cavity carved out at the surface of a VUV-transparent MgF_2 window. The samples were dried in a desiccator filled with P_2O_5 at ambient pressure. By this technique, a homogeneous film of leucine was deposited on the surface of the MgF_2 window.

VUV CPSR was produced by the recently developed electromagnetic polarizing undulator OPHELIE[30] installed on the Super-ACO storage ring of LURE in Orsay (France), feeding the VUV high resolution variable polarization SU5 beamline,[31] whose monochromator was set to deliver only the zeroth order diffraction of its gratings. Under these conditions, the spectrum of the synchrotron radiation (SR) impinging on the sample, as depicted in Figure 1 (bottom), corresponds to a peak centered on the tunable central photon energy ε_c with a 11% relative bandwidth ($\Delta\lambda/\lambda_c$) proving an integrated flux in the range of 10^{14} photon per second as derived from a VUV photodiode signal. Absolute circular polarization rates, measured at the sample location with a dedicated VUV polarimeter, vary from 90 to 100% over the 6 to 28 eV range.[32] For both photon energies, 6.8 eV and 7.3 eV, corresponding to two different undulator settings, they reach 91% for *r*-CPSR and 94% for *l*-CPSR. The corresponding polarization ellipses are shown in Figure 2.

After CPSR irradiation the remaining leucine was extracted from the MgF_2 window cavity with 0.1M hydrochloric acid (3×20 μL). The extract was transferred into a reaction vial (1 mL volume) and an ethanol–pyridine mixture (3:1, v/v; 30 μL) was added. To this solution, ethyl chloroformate (6 μL) was added, the vial was capped tightly, and shaken vigorously for 10 s to form *N*-ethoxycarbonyl leucine ethyl esters (leucine-ECEE).[34,35] Chloroform (18 μL) was added and the vial was shaken again for extraction of the leucine-ECEE into the (lower) organic layer. Finally, 1 μL of the organic phase was withdrawn by a microliter syringe and injected directly into the gas chromatographic Agilent 6890/5973 GC-MSD system equipped with a 25 m chiral stationary Chirasil-L-Val phase.

Ultrafast Solvation of *N*-Methyl-6-quinolone Probes Local IR Spectrum**

*J. Luis Pérez Lustres, Sergey A. Kovalenko, Manuel Mosquera, Tamara Senyushkina, Wolfgang Flasche, and Nikolaus P. Ernsting**

Solvation is a matter of central interest in chemistry. It influences the energetics of chemical reactivity because the reactants, transition state, and products may be stabilized differently by the solvent, and it creates frictional forces for the dynamics. Here we consider charge-transfer reactions in polar media. Usually the polarity of the environment is in equilibrium with the charge distribution along the reaction path. But ultrafast reactions may even "leave the solvent behind", the polarity can no longer stay adjusted, and the energy barrier is crossed in a nonequilibrated environment.[1] The time behavior of adjustment, or "polar solvation dynamics",[2–10] is a key to understanding many reactions in the condensed phase. In liquids at room temperature, individual solvent molecules respond to charge redistribution on a timescale of 10–100 femtoseconds (fs). The collective answer comes slower, and restructuring of solvent shells may take picoseconds or longer.

Measurements of polar solvation dynamics aim to observe the process directly, independent of reactive motion, and for this purpose one needs a suitable molecular probe. Usually these are solvatochromic dye molecules whose color depends strongly on the surrounding because the ground and excited electronic states interact differently with it. Using the novel probe *N*-methyl-6-quinolone (**MQ**), we show that its solvation in water and methanol is reproduced quantitatively, both in magnitude and time behavior, by the bulk dielectric dispersion $\varepsilon(\nu)$ of the liquid, the connection being continuum theory.[11–16] The surprising ability of a simple model to describe the dynamics was already noted.[8,11,13] It is now substantiated with the detection of solvent oscillations which modulate the emission frequency.

MQ

The match of observed, time-resolved solvation with prediction from continuum theory is at once puzzling and a chance. For one, the solvation process is microscopic by its very nature, as shown by numerous molecular dynamics simulations. The solute disturbs the liquid structure, and liquid dynamics around the probe is therefore expected to deviate from the bulk. It is far from trivial to relate the solvation response of a chromophore to solvent properties such as $\varepsilon(\nu)$, and this problem has been addressed by statistical theories.[17,18] Deviations from continuum theory are termed "molecularity of solvation".[14] The new dye does not exhibit molecularity towards collective solvent motion at the accuracy of present experiments, and this could lead to specific applications in characterizing water dynamics in restricted or biological environments on molecular dimensions. For this purpose **MQ** has several advantages over other probes. It is not charged, hence does not polarize the surrounding more than is needed for measurement. The solvent polarity couples mainly through dipole moment change, allowing straightforward evaluation of experiments. Most importantly, there is no interfering solute motion at frequencies relevant for aqueous solvation. Finally, the molecule is small enough to replace natural bases in nucleic acids or tryptophan in proteins. If continuum theory holds in such environments, femtosecond solvation measurements will provide the local IR spectrum.

Water and methanol are used here as benchmark solvents. Water deserves attention owing to its unique features. It can stabilize polar reactants within 100 fs and thus is the "fastest" solvent known. The interest in water extends from the properties of the pure solvent to its behaviour in complex environments[19–21] and especially to biopolymers where "biological water"[21] is expected to be involved in important primary reaction steps. Methanol is interesting because of its amphiphilic character. For both solvents, $\varepsilon(\nu)$ is known to high accuracy, and conclusions about the ability of continuum theory to describe **MQ** solvation can be drawn.

Femtosecond solvation experiments are explained in Figure 1. The molecule is suddenly promoted into the S_1 state by a short laser pulse. The ensuing relaxation of the excited state in terms of the free energy gap $\Delta E(t) = E_1(t) - E_0(t)$ is central to optical spectroscopy in the condensed phase. How $\Delta E(t)$ is accessed by time-resolved interaction of femtosecond optical pulses depends on the nonlinear optical signal that is detected. The fluorescence band provides probably the most direct view of relaxation in the excited state. Its time-resolved dynamic Stokes shift is a linear image of the solvation process, provided that intramolecular reorganization is either absent because the molecular structures in S_1 and S_0 are the same, or else avoided by excitation into S_1 without excess energy. Here we monitor stimulated emission which is strictly related to spontaneous fluorescence.

The continuum theory of polar solvation is also sketched in Figure 1. Consider first the pure liquid in an external electric field (not shown) which partially orients the solvent molecules, generally represented by their dipole moments (arrows). Continuum theory replaces the microscopic liquid

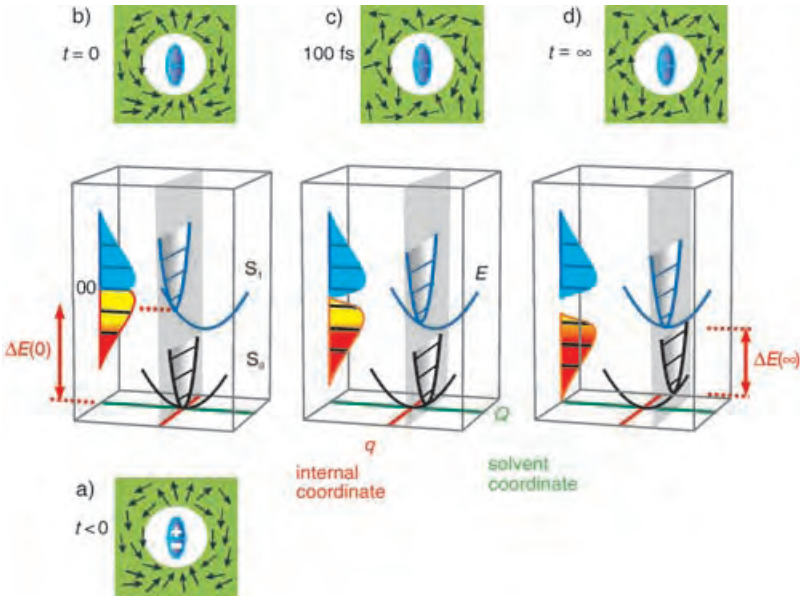

Figure 1. The dynamic Stokes shift of fluorescence (yellow–red band) images the relaxation of the surrounding solvent in the S_1 state of the solute. Solvent coordinate Q represents the configurational state of the environment and is treated classically. High-frequency motion along internal coordinate q for bond lengths and angles is quantized in vibrational states. Before femtosecond excitation (a) the solute is in the equilibrated ground state S_0 and the (blue) absorption band extends over a Franck–Condon progression for upward optical transitions. Immediately after excitation (b) the emission overlaps the absorption band at the electronic absorption origin 00. Partially relaxed $E_1(Q)$ (c) corresponds to solvent configurations that have raised $E_0(Q)$. The fluorescence therefore changes from yellow to red as solvation proceeds. After several picoseconds (d) a new equilibrium is reached for the S_1 state. A point dipole in a spherical polarizable cavity represents the solute, while a continuum with dielectric dispersion $\varepsilon(\nu)$ represents the surrounding liquid.

structure with an average, smooth, dipole density—the polarization P. The latter responds to changes in the field, and from such measurements at frequencies ν in the microwave, far-infrared, and infrared spectral regions one obtains the polarization susceptibility $\chi(\nu)=\varepsilon(\nu)-1$, where $\varepsilon(\nu)$ is the dielectric dispersion. For solvation, the field is instead derived from the charge distribution of the chromophore (Figure 1 a). It polarizes the surrounding medium, which in turn creates a reaction field R which stabilizes the solute. Analogous to the previous consideration, R responds to changes in the solute charge distribution at frequency ν. Equivalently the charge distribution may be switched from one form into another by femtosecond excitation $S_1 \leftarrow S_0$, and the solvent configuration and R are thus driven towards a new equilibrium.

Altogether the free energy of solvation can be calculated. In continuum theory a cavity is carved out of the solution, with the solute charge distribution inside and a homogeneous medium characterized by $\varepsilon(\nu)$ outside. A simple version is obtained when the cavity is taken to be spherical with radius r and the solute charge distribution is approximated by its dipole moment μ at the center. In this case the susceptibility of the reaction field to changes in the dipole moment[11,12] is given by Equation (1).

$$\chi_{\mathrm{dip}}(\nu)=\frac{2(n_{\mathrm{cav}}^2+2)}{3r^3}\left(\frac{\varepsilon(\nu)-1}{2\varepsilon(\nu)+n_{\mathrm{cav}}^2}-\frac{n^2-1}{2n^2+n_{\mathrm{cav}}^2}\right) \quad (1)$$

Here n and n_{cav} are the refractive indices of the solvent and the cavity, respectively, due to electronic response at optical frequencies. The latter is related to the polarizability α_1 of the solute in the S_1 state through the Clausius–Mosotti equation [Eq. (2)]

$$\frac{\alpha_1}{r^3}=\frac{n_{\mathrm{cav}}^2-1}{n_{\mathrm{cav}}^2+2} \quad (2)$$

Equation (1) is needed below to calculate the time-dependent Stokes shift.

The absorption and stationary stimulated emission spectra of **MQ** in water are shown in Figure 2 a. Femtosecond transient absorption was measured with the pump—supercontinuum–probe technique. Typical transient spectra are shown in Figure 2 b. They have three contributions: excited-state absorption ($S_n \leftarrow S_1$, ESA), stimulated emission ($S_1 \rightarrow S_0$, SE), and negative absorption due to the ground-state hole ($S_1 \leftarrow S_0$, bleach). The time-dependent red shift of the SE band is easily recognized together with a blue shift of the ESA band at 350 nm.

The stimulated emission band at delay time t is extracted from the corresponding transient absorption spectrum, and the peak frequency $\nu(t)$ is adopted as a measure of the free-energy gap. $\nu(t)$ is the desired time-resolved Stokes shift. The experiment thus provides a normalized relaxation function [Eq. (3)]

$$S_\nu(t)\equiv\frac{\nu(t)-\nu(\infty)}{\nu(0)-\nu(\infty)} \quad (3)$$

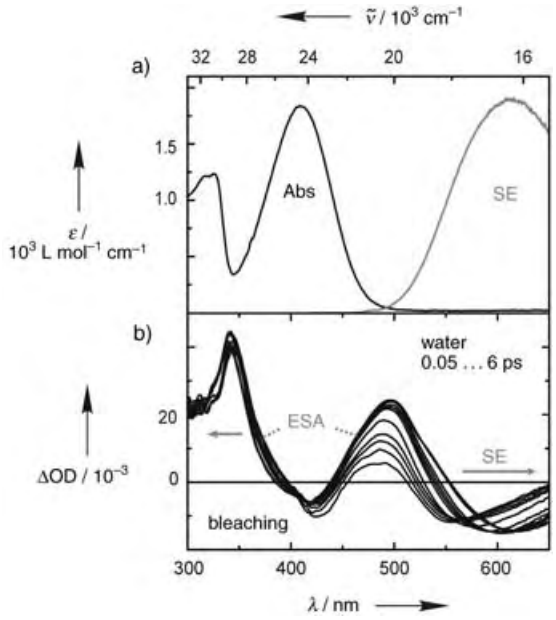

Figure 2. Optical spectra of **MQ** in water (pH 9). a) Stationary absorption (Abs) and stimulated emission (SE). b) Femtosecond transient absorption recorded with a time resolution of 30 fs after excitation at 430 nm. Induced change of optical density $\Delta OD < 0$ indicates stimulated emission in the fluorescence region and bleach in the absorption region where excited-state absorption (ESA) dominates. Transient spectra between 0.05 and 1 ps are shown in 0.1-ps steps and between 1 and 6 ps in 1-ps steps.

Here $\nu(0)$ is the peak emission frequency immediately after excitation and $\nu(\infty)$ the frequency at a later time; the full Stokes shift is $\Delta\nu = \nu(0) - \nu(\infty)$.

To calculate the time-dependent Stokes shift from dielectric dispersion we consider the energy gap $\Delta E_{dip}(t)$ of an ideal dipolar chromophore in a cavity (Figure 1a). Equilibrium solvent motion causes fluctuations $\delta\Delta E_{dip}$ of the energy gap, and the classical correlation function is given by Equation (4)

$$S_{dip}(t) \equiv \frac{\langle \delta\Delta E_{dip}(0)\, \delta\Delta E_{dip}(t)\rangle}{\langle \delta\Delta E_{dip}(0)\, \delta\Delta E_{dip}(0)\rangle} \tag{4}$$

where $\langle\rangle$ is the ensemble average. The same time behavior is expected, essentially, for the nonequilibrium relaxation of $\Delta E_{dip}(t)$. The full spectral density of the correlation function for the energy gap is accessible through the fluctuation–dissipation theorem [Eq. (5)] (see the Supporting Information):

$$C_{dip}(\nu) = \left\{1 + \coth\left(\frac{h\nu}{2\,k_B\,T}\right)\right\}\chi''_{dip}(\nu) \tag{5}$$

Finally, the quantity defined in Equation (4) is given a theoretical curve [Eq. (6)]

$$S_{dip}(t) \propto \int_{-\infty}^{+\infty} d\nu\, C_{dip}(\nu)\cos(2\pi\nu t) \tag{6}$$

which can be compared to experimental $S_\nu(t)$.

The procedure is illustrated for water in Figure 3.[11,22,23] Our main observation is that the measured relaxation of **MQ** in water is identical, within measurement error, with the calculated dipole solvation relaxation. For the moment let us treat this as an hypothesis and replace $S_\nu(t)$ in Equation (3) by $S_{dip}(t)$ to obtain Equation (7)

$$\nu(t) = \Delta\nu\, S_{dip}(t) + \nu(\infty) \tag{7}$$

where the full Stokes shift is given by Equation (8)

$$\Delta\nu = \chi_{dip}(0)\mu_1(\mu_1 - \mu_0)/h\,c \tag{8}$$

(in wavenumbers, with c speed of light, h Planck's constant, and molecular dipole moments μ_i of **MQ**). In order to prove the hypothesis the theoretical curve [red line, Eq. (7)] is mapped onto the measured curves (gray dots, blue, green, and black lines) in Figure 4, where we summarize our results. For example, Figure 4a shows several measurements in water. The peak emission frequency sweeps precipitously from ca. 19400 cm^{-1} at $t = 0$ to 18200 cm^{-1} at $t = 100$ fs and further to equilibrium with $\nu(\infty) = 16340$ cm^{-1}. Optimal values for the cavity index and Stokes shift are found by simultaneous fit of all measurements, and they are consistent with the molecular properties of the probe (see the Supporting Information). The red curve shows the calculation with $n_{cav} = 2.3$ and $\Delta\nu =$

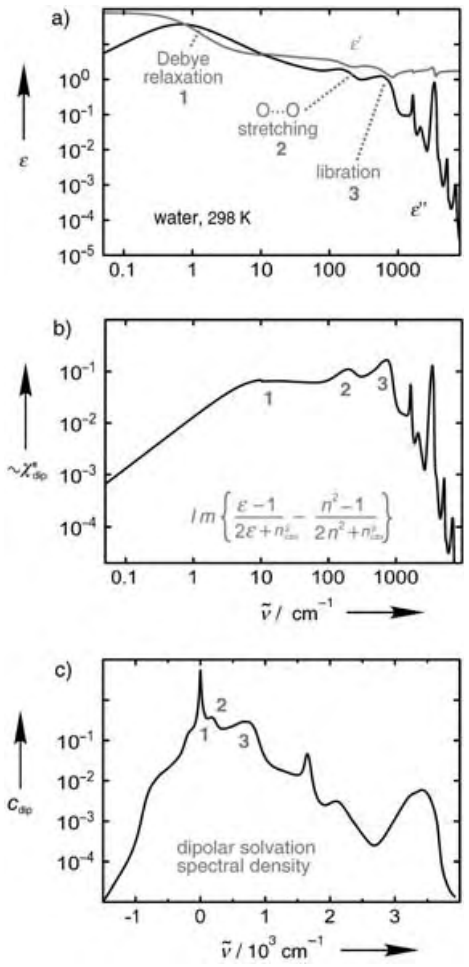

Figure 3. Calculations for the solvation of a molecular dipole by dielectric continuum theory. a) Real (ε') and imaginary (ε'') parts of water dielectric dispersion. Sharp structure results from intramolecular IR activity and broad bands 1–3 are caused by collective motion. b) Susceptibility χ''_{dip} of solute stabilization to solvent motion. The transformation from ε enhances high-frequency contributions and reduces low-frequency contributions. c) The spectral density for dipole solvation $C_{dip}(\nu)$ is constructed from the susceptibility. From here the theoretical relaxation function $S_{dip}(t)$ is reached by Fourier transformation.

3050 cm^{-1}. Increasing solute polarizability slows down the relaxation as already noted from molecular dynamics simulations.[24–26]

The initial relaxation dynamics in water is particularly interesting. The dynamic Stokes shift across this range is best seen in the insert of Figure 4a. Oscillations during the first picoseconds come from vibrational modes in the excited chromophore. But around 170 fs a shoulder can be discerned underneath. Dipolar solvation predicts a weakly underdamped relaxation feature at precisely the same time and with the same relative amplitude. Indeed, if the intramolecular vibrations are removed by spectral filtering, an underlying relaxation curve emerges that exactly matches the predicted one. (Deviations before $t = 100$ fs are caused by a coherent contribution to transient absorption during pump-and-probe overlap in time[27]). It follows that the oscillation feature around 170 fs is due to coherent nuclear motion in the solvent shell. The motion can be traced to a broad band in the

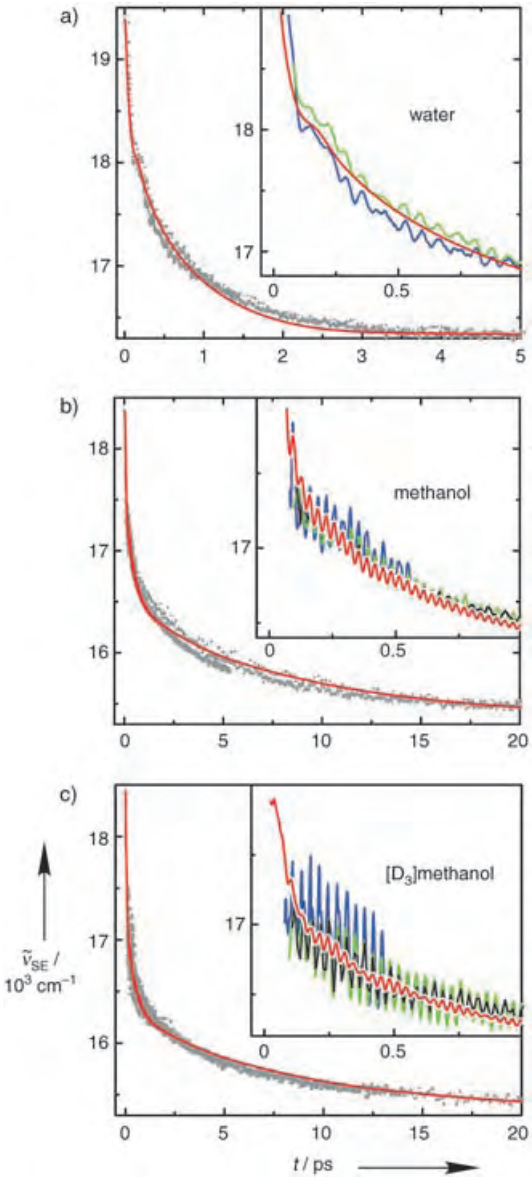

Figure 4. The time-dependent, measured peak position of the stimulated emission band (gray points, blue, green, and black lines) is well described by continuum theory (red). a) **MQ** in water. Here high-frequency oscillations correspond to intramolecular modes at 460 and 580 cm^{-1}. If they are removed by spectral filtering, an underlying relaxation curve emerges that matches the (red) predicted curve exactly. An oscillation hump at ≈170 fs marks the coherent O···O stretching period in the water shell. b, c) **MQ** in methanol and [D_3]methanol after excitation at 540 nm. Fast frequency modulation is caused by coherent C–O stretching motion of solvent molecules (1100 and 930 cm^{-1}, respectively). A hump at ≈0.25 ps indicates the period for collective libration.

dielectric dispersion of water, around 200 cm^{-1}, from intermolecular O···O stretching of the hydrogen-bonded network.[28,29]

Measurements for **MQ** in methanol and [D_3]methanol are analyzed in Figure 4b and c. In this case the excitation was tuned to the very red absorption edge to avoid creating *intra*molecular wavepackets. The emission peak relaxes from 18450 (fitted) to 17320 cm^{-1} (measured) during the first 100 fs. A slower stage with strong oscillations—that is, frequency modulation of the emission band—follows up to 2 ps. As with water, simple continuum theory describes quantitatively the shape of the relaxation curve.[30] Strong oscillations correspond to the IR band from C–O stretching in methanol at 1030 cm^{-1}, or at 980 cm^{-1} in [D_3]methanol (Figure 4c).

We conclude: 1) ultrafast excitation of **MQ** launches and reports coherent solvent motion in the surrounding liquid, and 2) solvation dynamics is well described by dipolar change $\Delta\mu$ in a sphere of radius r and refractive index n_{cav} surrounded by a dielectric continuum. Eventually the dynamic Stokes shift may be inverted into the dielectric dispersion $\varepsilon(\nu)$ in the vicinity of the probe, and the imaginary part will give the local IR spectrum $\nu\varepsilon''(\nu)$.

Energetics and Mechanism of a Room-Temperature Catalytic Process for Ammonia Synthesis (Schrock Cycle): Comparison with Biological Nitrogen Fixation**

*Felix Studt and Felix Tuczek**

A room temperature catalytic process for ammonia synthesis analogous to biological nitrogen fixation has for a long time presented a challenge of fundamental chemical importance.[1–4] The recent discovery by Schrock et al. of the first truly catalytic system for ammonia synthesis working under ambient conditions and involving well-defined intermediates marks a historic breakthrough in this respect.[5–10] It is based on the molybdenum complex $[Mo(hiptN_3N)]$ (**I**) with the specially designed triamidoamine ligand $hiptN_3N$ (tris(hexaisopropylterphenyl)triamidoamine) which provides the metal center with a sterically shielded site for dinitrogen bonding and reactivity (Scheme 1). This system has allowed the catalytic generation of ammonia from N_2 at room temperature and atmospheric pressure using $(LutH)BAr'_4$ (Lut = 2,6-dimethylpyridine, Ar'_4 = 3,5-bis(trifluoromethyl)-phenyl) as a proton source and decamethylchromocene ($[Cp^*_2Cr]$, $Cp^* = C_5Me_5$) as reductant. To date six catalytic turnovers have been achieved. Apart from establishing the physicochemical conditions under which the room-temperature catalytic synthesis of ammonia is feasible, the molybdenum triamidoamine system also allows insight into the mechanism of this process at the molecular level. This aspect is of particular interest for a comparison with the mechanistic pathway of the enzyme nitrogenase (which converts N_2 into NH_3) on which important information has been obtained by theoretical calculations recently.[11,12]

A number of intermediates relevant to the molybdenum triamidoamine catalytic cycle have been isolated and characterized: $[Mo(hiptN_3N)N_2]$, $[Mo(hiptN_3N)NNH]$, $[Mo(hiptN_3N)NNH_2]^+$, $[Mo(hiptN_3N)N]$, $[Mo(hiptN_3N)NH]^+$, $[Mo(hiptN_3N)NH_3]^+$, and $[Mo(hiptN_3N)NH_3]$.[7,9] Based on the available experimental information, a mechanism has been proposed (Schrock cycle).[6,9] Herein we present density functional theory (DFT) calculations on all the possible intermediates that can appear in the catalytic transformation of N_2 to ammonia mediated by the molybdenum triamidoamine complex **I**, including those invoked by Schrock et al. On the basis of these calculations the detailed mechanistic pathway and the free energy profile of the entire cycle are determined. The calculations are performed on complexes **1**–**14** where the hipt groups have been replaced by hydrogen atoms (Figure 1). Applying this simplification and the model chemistry described in reference [13], the observed structural and spectroscopic data have been reproduced.[14] A comparison of calculated and measured vibrational frequencies is given in the Supporting Information, structural parameters of the optimized model complexes (some of which are shown in Figure 1, lower left) are collected and compared to available X-ray data in the Supporting Information). Energies for reduction and protonation steps are explicitly calculated relative to the processes $[Cp^*_2Cr] \rightarrow [Cp^*_2Cr]^+$ and $LutH^+ \rightarrow$ Lut, respectively, which have been theoretically treated without any simplification of the molecules involved. All the energies are evaluated at the B3LYP/TZVP level and are zero-point energy (ZPE), thermal, as well as solvent corrected (see Supporting Information);[13] corresponding standard free enthalpies have been determined and are plotted in Figure 1 against the reaction coordinate ρ.

The starting complex $[(N_3N)Mo]$ (**1**; $(N_3N)^{3-} = [(HNCH_2CH_2)_3N]^{3-}$) gives rise to $S = 1/2$ and $S = 3/2$ states

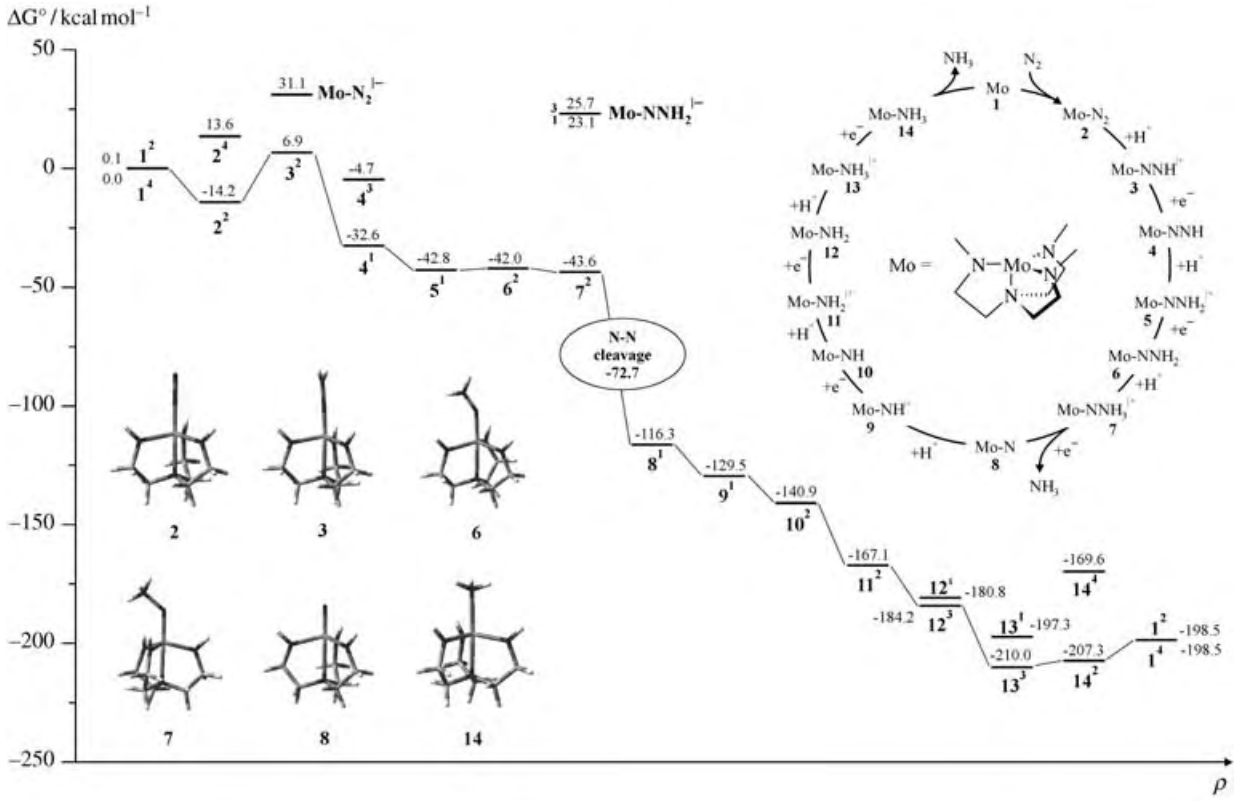

Figure 1. Catalytic cycle (upper right) and energy profile (center) of the reduction of N_2 to ammonia in the molybdenum triamidoamine system. All energies correspond to standard free enthalpies and are in kcal mol^{-1}. Lower left: optimized structures of selected intermediates.

which are about isoenergetic (calculated energy splitting between $\mathbf{1}^{\mathbf{2}}$ and $\mathbf{1}^{\mathbf{4}}$ 0.1 kcal mol^{-1}). Addition of dinitrogen to **1** leads to $[(N_3N)Mo^{III}–N_2]$ (**2**) which is found to have an $S = 1/2$ ground state; the $S = 3/2$ state is 27.8 kcal mol^{-1} higher in energy. The coordination of dinitrogen is calculated to be exergonic by 14.2 kcal mol^{-1}, which is in agreement with the observation that **2** is thermally stable towards loss of N_2.[5] The next step in the catalytic cycle is the protonation of **2** to $[(N_3N)Mo^{V}–NNH]^+$ (**3**) which is endergonic by 21.1 kcal mol^{-1}, reflecting a "moderate" activation of **2** towards protonation.[15] Subsequent reduction of **3** in an exergonic reaction gives the neutral molybdenum(IV) species $[(N_3N)Mo–NNH]$ (**4**) which exhibits an $S = 0$ ground state; the $S = 1$ state is found to be 27.9 kcal mol^{-1} higher in energy. The next two steps (protonation and reduction of **4**) are about thermoneutral, leading to complexes $[(N_3N)Mo–NNH_2]^+$ (**5**) and $[(N_3N)Mo–NNH_2]$ (**6**).

Complex **6** is susceptible to further protonation, as evident from the weakly exergonic character of the reaction **6**→$[(N_3N)Mo^{V}–NNH_3]^+$ (**7**). Direct reduction of **6** to the anionic molybdenum(IV) complex $[(N_3N)Mo–NNH_2]^-$ can be discounted based on the highly endergonic character of this reaction. Judging from its very large N–N distance of 1.57 Å, complex **7** has a highly activated N–N bond (see Supporting Information), this activated bond initiates N–N cleavage which is the next step in the reaction sequence. In fact, geometry optimization of **7** after addition of one electron spontaneously leads to splitting of the N–N bond under generation of the nitrido complex $[(N_3N)Mo^{VI}–N]$ (**8**) and the first equivalent of ammonia. This process is calculated to be highly exergonic (72.7 kcal mol^{-1}) and is predicted to occur without an activation barrier, in analogy to molybdenum–NNH_3 systems with phosphine ligands.[14]

The next protonation and reduction steps are exergonic as well. Thus, protonation of the nitrido complex **8** leads to the molybdenum(VI) complex $[(N_3N)Mo–NH]^+$ (**9**). Reduction of **9** and protonation of the resulting neutral molybdenum(V) imido complex $[(N_3N)Mo–NH]$ (**10**) generates $[(N_3N)Mo–NH_2]^+$ (**11**) which is reduced to the neutral molybdenum(IV) amido complex $[(N_3N)Mo–NH_2]$ (**12**). The two d-electrons of **12** give rise to an $S = 0$ and an $S = 1$ state, the latter being found at 3.4 kcal mol^{-1} lower energy. Protonation of **12** generates the Mo^{IV} complex $[(N_3N)Mo–NH_3]^+$ (**13**) which also exhibits an $S = 1$ ground state; in this case the $S = 0$ state is calculated to be 12.7 kcal mol^{-1} higher in energy. Complete reduction of **13** was experimentally determined to require the presence of $[Cp^*_2Cr]$ whereas all other reductions could be performed by the weaker reductant $[Cp_2Co]$ ($Cp = C_5H_5$) as well.[5,8] Even for $[Cp^*_2Cr]$ this step is calculated to be slightly endergonic (+2.7 kcal mol^{-1}). If less-strongly reducing agents are employed the endergonic character of this reaction concomitantly increases (e.g. $\Delta G° = +27.9$ kcal mol^{-1} if $[Cp_2Co]$ is used), eventually causing the total suppression of the reaction. The resulting molybdenum(III) ammine complex

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$[(N_3N)Mo–NH_3]$ (**14**) exhibits an $S = 1/2$ ground state with the $S = 3/2$ state being 37.7 kcal mol^{-1} higher in energy. At this stage, the dinitrogen complex **2** has been reduced by six $[Cp^*_2Cr]$ molecules and protonated by six molecules of $LutH^+$. To close the catalytic cycle the NH_3 ligand of **14** has to be replaced by N_2. Dissociation of **14** under formation of **1** and ammonia is endergonic by 8.8 kcal mol^{-1}. Subsequent bonding of N_2 under formation of the dinitrogen complex **2**, however, is exergonic ($\Delta G° = -14.2$ kcal mol^{-1}, see above), rendering the overall substitution of NH_3 by N_2 exergonic by 5.4 kcal mol^{-1}.

Thus, the catalytic cycle consists of a sequence of strictly alternating protonation and reduction steps. This agrees with the mechanism proposed by Schrock et al.,[6,9] except for the conversion of the dinitrogen complex **2** into the neutral NNH complex **4** (see below). All the relevant intermediates therefore are either neutral or positively charged and the formation of negative species appears to be excluded. Moreover, most reactions are exergonic. By far the most exergonic step is the cleavage of the N–N bond which in addition is predicted to proceed spontaneously. Only three steps (**2**→**3**, **13**→**14**, and **14**→**1**) of the cycle are endergonic. The transformation of **13** to **14** is found to be the most difficult of all the reduction steps, in agreement with the experiment (see above). The endergonic dissociation of **14** to **1** + ammonia is part of the exchange of NH_3 for N_2 on complex **1** that is calculated to be weakly exergonic overall. Experimentally this exchange reaction is found to be about thermoneutral.[9] Energetically the most demanding of all reactions of the cycle is the protonation of the dinitrogen complex **2** to the cationic intermediate **3** ($\Delta G° = +21.1$ kcal mol^{-1}). The subsequent reduction of **3**, however, is strongly exergonic, providing the driving force for the net conversion of **2** into **4**. Schrock et al., in contrast, have postulated a primary reduction of **2** to the complex $[(N_3N)Mo–N_2]^-$ followed by protonation to **4**.[9] Based on the much higher energy of the negatively charged intermediate in comparison to **3**, this scenario appears less likely.[16]

The exergonic character of most of the elementary reactions involved in the Schrock cycle is also evident from the fact that the total free reaction enthalpy $\Delta G°_R$ of one turnover corresponding to the reaction in Equation (1) is strongly negative (−198.5 kcal mol^{-1}; see Figure 1 from left to right and Figure 2a). Formally the six reduced $[Cp^*_2Cr]$ and six protonated $LutH^+$ molecules needed in Equation (1) can be considered to result from the reaction in Equation (2) for which the calculation gives a $\Delta G°$ value of +186.2 kcal mol^{-1} (in heptane).

$$N_2 + 6\,[Cp^*_2Cr] + 6\,LutH^+ \rightarrow 2\,NH_3 + 6\,[Cp^*_2Cr]^+ + 6\,Lut \quad (1)$$

$$3\,H_2 + 6\,[Cp^*_2Cr]^+ + 6\,Lut \rightarrow 6\,[Cp^*_2Cr] + 6\,LutH^+ \quad (2)$$

Equations (1) and (2) combine to give the net reaction in Equation (3) for which the calculation gives a standard free enthalpy change $\Delta G°_f$ of −12.3 kcal mol^{-1} (in heptane).[17]

$$N_2 + 3\,H_2 \rightarrow 2\,NH_3 \quad (3)$$

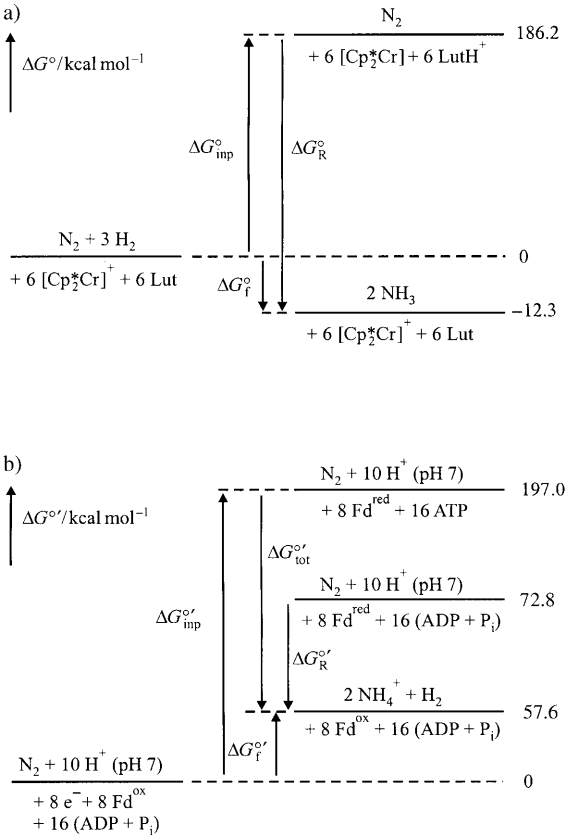

Figure 2. Free enthalpies for the formation of ammonia from N_2 at room temperature and normal pressure in the molybdenum triamidoamine system (a) and nitrogenase (b). Energies not to scale.

The synthetic system thus is calculated to require a standard free enthalpy input $\Delta G°_{inp}$ of +186.2 kcal per mol N_2 to generate ammonia at room temperature and normal pressure (Figure 2a). This energy expenditure is very large, but is also required in nitrogen fixation mediated by the enzyme nitrogenase. In the biological system, ammonia is produced along with H_2 according to Equation (4) where Fd = Ferredoxin.[18–21]

$$N_2 + 10\,H^+ + 8\,Fd^{red} \rightarrow 2\,NH_4^+ + H_2 + 8\,Fd^{ox} \quad (4)$$

Under standard conditions this reaction is associated with a free enthalpy change $\Delta G°_R$ of −110.8 kcal mol^{-1};[22] changing to pH 7 yields a transformed standard free reaction enthalpy $\Delta G°'_R$ of −15.2 kcal mol^{-1} (Figure 2b).[23] Moreover, the biological process requires the hydrolysis of two molecules of ATP per transferred electron such that the total reaction [Eq. (5)] is associated with a reaction enthalpy $\Delta G°'_{tot}$ of −139.4 kcal mol^{-1} at pH 7.[24]

$$N_2 + 10\,H^+(pH\,7) + 8\,Fd^{red} + 16\,ATP \rightarrow 2\,NH_4^+ + H_2 + 8\,Fd^{ox} + 16\,(ADP + P_i) \quad (5)$$

Under this condition the free enthalpy change for the formation of NH_4^+ and H_2 according to Equation (6) is

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

positive ($\Delta G_f^{\circ\prime} = 57.6\ \text{kcal mol}^{-1}$).[23]

$$N_2 + 10\,H^+(pH\,7) + 8\,e^- \rightarrow 2\,NH_4^+ + H_2 \quad (6)$$

In order to make the overall reaction in Equation (5) exergonic by 139.4 kcal mol^{-1}, a free energy input $\Delta G_{inp}^{\circ\prime}$ of +197.0 kcal is needed which is associated with the reaction in Equation (7).

$$8\,e^- + 8\,Fd^{ox} + 16\,(ADP + P_i) \rightarrow 8\,Fd^{red} + 16\,ATP \quad (7)$$

This value is close to that of the artificial system.[25] In both cases the (free) energy input of approximately 190 kcal per mol N_2 is used for the generation of the respective reduction equivalents; the hydrolysis of 16 ATP molecules in nitrogenase thereby acts to lower the reduction potential of the iron protein.[19] The energy profile presented in Figure 1 shows that the strongly negative reduction potential is primarily necessary to activate N_2 towards protonation; once the first protonation of N_2 has been achieved, most of the following steps are exergonic. This situation is similar to that calculated for the conversion of N_2 into NH_3 at the iron–molybdenum cofactor (FeMoco) of nitrogenase in which, however, combined protonation–reduction steps corresponding to hydrogenation reactions were considered.[11,12] Moreover, the N–N cleavage reaction in this process is exothermic and activationless, in agreement with the same reaction in the molybdenum triamidoamine system.

In summary, the energy profile of the first room-temperature catalytic process for ammonia synthesis from N_2 proceeding via well-defined intermediates has been determined, and a theoretically founded mechanism for this reaction established. Salient features of the calculated reaction course correctly reproduce experimental observations. The reaction pathway exhibits strong similarities to that obtained theoretically for nitrogenase. Importantly, the energy input of approximately 190 kcal calculated to be involved in the conversion of 1 mol N_2 into 2 mol NH_3 is found to be very near to that obtained empirically for biological nitrogen fixation, underlining the significance of the molybdenum triamidoamine system as a functional model of nitrogenase.

Studying the Solvothermal Formation of MoO_3 Fibers by Complementary In Situ EXAFS/EDXRD Techniques**

*Alexej Michailovski, Jan-Dierk Grunwaldt, Alfons Baiker, Ragnar Kiebach, Wolfgang Bensch, and Greta R. Patzke**

The reliable and straightforward fabrication of nanoparticles is essential for developing future nanotechnology.[1–5] Nanoscale transition-metal oxides provide a wide spectrum of important properties,[6,7] and their functionalization and alignment is greatly facilitated by anisotropic morphologies.[8] Among the transition-metal oxides, MoO_3 is the focus of much attention owing to its numerous applications, for example, in catalysis[9–11] or sensor technology.[12,13] We have recently developed a solvothermal procedure that provides a convenient access to highly anisotropic nanoscale MoO_3 fibers.[14,15]

The solvothermal process[16] is famous for its unique control facilities regarding the particle size of the material produced.[17,18] Its major drawback, however, is that the predictive and rational preparation of a desired solid remains a major preparative challenge—especially if the morphology of the product is to be tuned as well. This problem is because of the tremendous impact of the synthetic parameters on the course of the reaction. Thus, the development of solvothermal nanomaterials syntheses may require considerable "trial and error" work. The elucidation of solvothermal reaction mechanisms is therefore vital for devising more predictive strategies so that the resulting materials can be optimized for commercial purposes. As solvothermal reactions are usually performed in thick-walled reaction containers, sophisticated in situ techniques employing high-intensity synchrotron radiation are required for their direct monitoring.[19–22] Generally, the development of high-pressure, in situ spectroscopic approaches is a challenging topic of chemistry and materials science.[23] Orientating kinetic studies may also be performed by quenching hydrothermal reactions, but this information is only valid if the recovered material is not affected by any irreversible changes upon cooling and isolation. Among the multitude of solvothermally generated materials, special emphasis has been placed upon the in situ study of zeolites,[24–26] open-framework compounds,[27,28] silicate minerals,[29,30] and sulfide-based systems.[22,31] For the transition-metal oxides, the main focus has been on ternary compounds of industrial interest (e.g. bismuth molybdates[32] or $BaTiO_3$[33]), whereas considerably fewer binary oxides (such as ZrO_2[34]) have been investigated by solvothermal in situ methods. Very little mechanistic information is available on their solvothermal transformation into nanomaterials.

Herein, we report the first comprehensive in situ study on the growth of MoO_3 fibers by complementary EDXRD (energy dispersive X-ray diffraction) and XANES/EXAFS (X-ray absorption near edge structure/extended X-ray absorption fine structure) techniques. While XRD allows the long-range order to be monitored, XANES/EXAFS provides information on the short-range order.[35–37] This information is indispensable for describing the solvothermal crystallization of nanostructured matter, because amorphous solids and small particles (typically below 50 Å) cannot be detected by Bragg diffraction. Moreover, the simultaneous observation of both the solid and the liquid phase during the reaction is vital for proposing a reaction pathway. For this purpose, a special in situ-EXAFS cell was used (see Supporting Information).[38] The EXAFS technique is ideally suited to monitor both crystalline and amorphous solid intermediates as well as species in solution, whereas all crystalline components can be fully characterized in terms of the complementary EDXRD method.

The solvothermal access to MoO_3 nanorods is quite straightforward: yellow molybdic acid, $MoO_3 \cdot 2H_2O$, is quantitatively transformed into the fibrous product after a few hours of autoclave treatment at 180–220 °C in water or acetic acid.[14] The fibers often display high aspect ratios with lengths above 10 μm and diameters between 100 and 150 nm. Although the parameters (e.g. time, acid concentration, or temperature) can be varied quite widely, the presence of $MoO_3 \cdot 2H_2O$ is a prerequisite for the formation of MoO_3 fibers.[14] MoO_3 and $MoO_3 \cdot 2H_2O$ both have layered crystal structures that are topotactically related by a stepwise dehydration proceeding via β-$MoO_3 \cdot H_2O$.[39] Preliminary experiments covering the formation of MoO_3 fibers in various media point to a different formation pathway under solvothermal conditions.[14]

The temperature interval for the onset of MoO_3 rod formation from $MoO_3 \cdot 2H_2O$ in acetic acid was evaluated with

ex situ quenching experiments between 80 °C and 180 °C (Experimental Section). The reaction can be monitored visually because the bright yellow starting material is converted into a gray-blue product by a partial reduction of MoO_3 (the amount of product falls below the detection limit of standard analytical techniques). At 80 °C, the yellow color was maintained, whereas a sharp color change was observed after 12 min of treatment at 100 °C. When the reaction temperature was raised, this time interval further decreased to 6 min (120 °C) and 2 min (180 °C). These observations are supported by the corresponding scanning electron micrograph (SEM) images and powder diffraction patterns (Figure 1 I): at 80 °C, $MoO_3{\cdot}2H_2O$ (JCPDS 39–363; $P2_1/n$, $a = 10.618(5)$, $b = 13.825(7)$, $c = 10.482(5)$ Å, $\beta = 91.61(4)°$) undergoes no significant structural (Figure 1 Ia, bottom) or morphological (Figure 1 Ia, top) changes. However, at 100 °C, the dehydration to MoO_3 is finished (Figure 1 Ib, bottom) and the formation of a fibrous material sets in (Figure 1 Ib, top). Between 100 °C and 180 °C both the fibrous morphology (Figure 1 Ic, d, top) and the crystallinity (compare the (061), (002) and (112) reflections in Figure 1 Ic,d, bottom) improve further. The analogous quenching series in water proceeded on a similar timescale and led to the quantitative formation of MoO_3 nanorods at 150 °C within 3–4 min. (Figure 1 IId, top/bottom). The powder diffraction patterns of the flat, fibrous products display intensities different from the literature data (JCPDS 35–609; *Pbnm*, $a = 3.963$, $b = 13.856$, $c = 3.697$ Å). This deviation may be due to the presence of stacking faults in the [001] growth direction[40] together with a preferred orientation of the MoO_3 rods on the flat sample holder.

The presence of stacking faults in the as-synthesized rods grown after 20 min of ex situ treatment was confirmed by TEM investigations and may account for the broadened reflections occurring in the powder diffraction patterns (Figure 1). Figure 2 demonstrates that separated rods with

well-defined edges and tips are accessible after prolonged solvothermal treatments (16–24 h at 180 °C). Even at 100 °C, only few residual microcrystals of $MoO_3 \cdot 2H_2O$ are still present (see powder XRD pattern (Figure 1 II b, bottom) and SEM images (Figure 1-II b, top)).

The temperature-dependent formation of MoO_3 rods was studied with in situ X-ray absorption spectroscopy. Our novel autoclave cell allows the study of the liquid phase and the solid/liquid interface. The cell can be positioned so that the X-ray beam probes either the liquid phase or the solid/liquid interface (see Supporting Information). In the present case, the monitoring of the liquid phase is essential to distinguish a strictly topotactic dehydration from alternative dissolution–precipitation mechanisms. XANES spectra at the molybdenum K edge of the reaction of $MoO_3 \cdot 2H_2O$ in water were taken both at the bottom of the cell (mainly solid part, Figure 3 a,b) and the middle of the cell (liquid part, Figure 3 c) between 25 °C and 150 °C. Up to 50 °C no molybdenum-containing species were observed in solution (Figure 3 c) and the solid phase displayed the XANES spectrum of pure $MoO_3 \cdot 2H_2O$. The first slight changes were observed at 90 °C, and the reaction sets in around 99 °C (Figure 3 a,b). The XANES and Fourier transformed EXAFS spectra (Figure 3 a,b) demonstrate the continuous transformation of $MoO_3 \cdot 2H_2O$ into MoO_3 nanorods at 99 °C and do not indicate the presence of any intermediates (for reference spectra see the Supporting Information). Furthermore, the concentration of water-soluble species increases significantly at around 95 °C and rises continuously up to 150 °C. Note that the separation into individual MoO_3 nanorods proceeds at these elevated temperatures (cf. Figure 1-I/II d, top). The reaction starts as soon as the first soluble Mo species are detected and it accelerates at higher temperature so that the concentration of Mo species in solution increases. Furthermore, the rod formation is diffusion limited, as shown by the reaction being slower when performed in glass wool (see Experimental Section). All these observations strongly support a solution-based mechanism rather than a topotactic transformation of $MoO_3 \cdot 2H_2O$ into MoO_3.

In situ-EDXRD techniques were employed to study the time-resolved formation of MoO_3 rods from $MoO_3 \cdot 2H_2O$. A typical result of the time-dependent evolution of the diffraction patterns at 120 °C in acetic acid is shown in Figure 4 a. The Mo signals and the characteristic reflections of $MoO_3 \cdot 2H_2O$ (Figure 4 a, inset) are visible from the start. After a temperature-dependent induction time (in this case: 8 min) during which the signals of the starting material vanish, the first reflections of the product are observed and the product starts to form without the occurrence of a crystalline intermediate. All the reflections of the material grow simultaneously. The reaction is complete after another 7–8 min. The crystallization curve ($\alpha(t)$ vs. time) has a sigmoidal shape (Figure 4 b) which is typical for the kinetics of many solid-state reactions. Compared to other solid-state reactions, the velocity of the MoO_3 rod formation is very high. Therefore, a further evaluation of the observed kinetic data was not possible.

In summary, the formation of MoO_3 rods is a rapid process that is finished within minutes at temperatures well below 180 °C. All the experimental results point to a quick dissolution–precipitation mechanism without a crystalline intermediate phase. Thus, the high anisotropy of the MoO_3

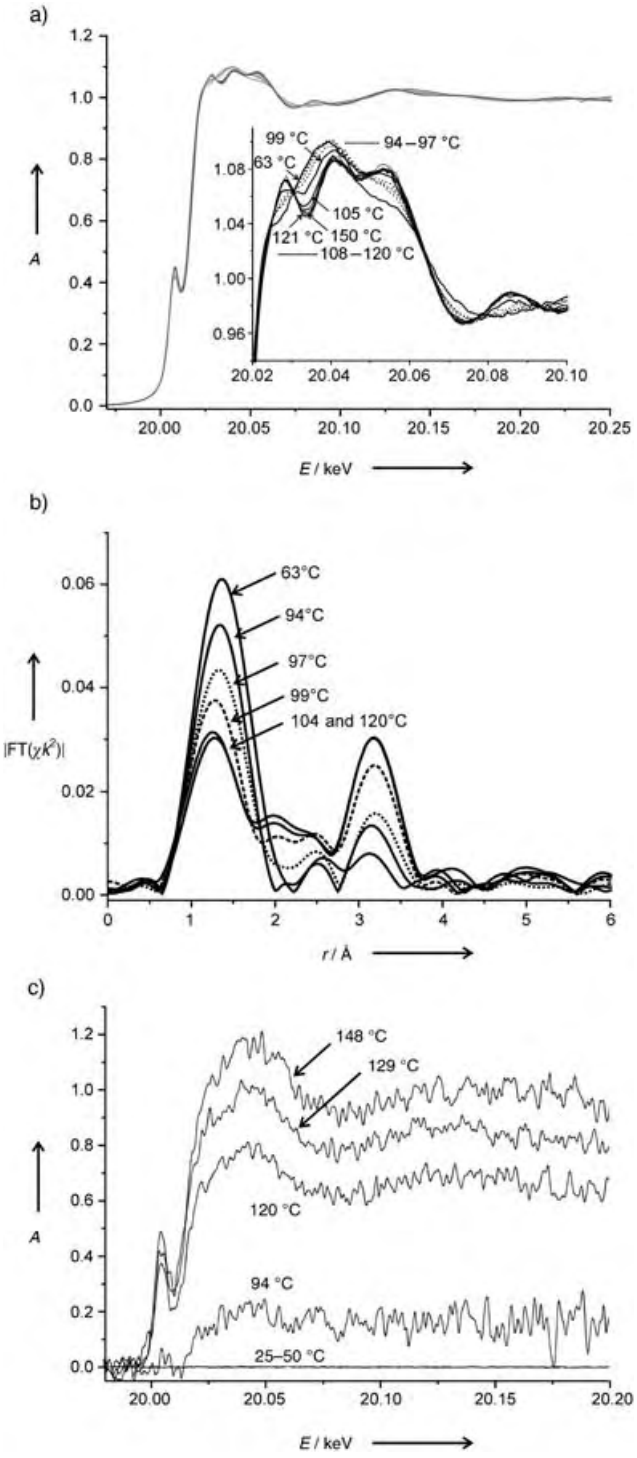

Figure 3. a) Molybdenum K-edge X-ray absorption near edge spectra during the hydrothermal reaction of $MoO_3 \cdot 2H_2O$ to MoO_3 fibers (solid phase), inset: expansion of the 20.02–20.1 region, b) Fourier transforms of the EXAFS spectra, c) molybdenum K-edge XANES spectra of the liquid phase during the reaction. Figure 4. a) Time-resolved, background-corrected powder patterns recorded at 120 °C. The indices of the starting material (*), the product, and the Mo fluorescences are marked (the inset shows a magnification of the first spectrum), b) time dependence of the extent of reaction α for reflection (021) at 120 °C. The crystallization curve has a sigmoidal fit.

fibers presumably arises from the higher growth velocity of the [001] crystal direction in the orthorhombic α-MoO_3 lattice cell (*Pbnm*, $a = 3.9630$, $b = 13.856$, $c = 3.6966$ Å).[41,42] Our approach provides a versatile strategy towards understanding solvothermal reactions. After a series of orientating ex situ quenching experiments, the temperature-dependent solid–liquid equilibria of a given reaction can be monitored with a newly developed autoclave suitable for in situ-EXAFS spectroscopy. A kinetic study based on in situ-EDXRD provides the essential complementary information. In this way, the solvothermal mechanisms and the role of the precursor material are analyzed from different perspectives. Such insights are essential for optimizing syntheses for industrial scale-up processes. In conclusion, the presented approach is a step towards the rational solvothermal design of nanomaterials and of syntheses proceeding by amorphous and/or liquid phases in general.

Experimental Section

For the quenching experiments, $MoO_3 \cdot 2H_2O$ (180 mg, 1 mmol), glacial acetic acid (0.5 mL), and water (1.5 mL) were added to a glass ampoule (volume 23 mL) that was sealed under atmospheric pressure. The ampoules were heated for 20 min at 80, 100, 120, or 180 °C and subsequently quenched at −8 °C in a NaCl/ice mixture. The products were centrifuged several times in water, ethanol, and acetone and then subjected to scanning electron microscopy (SEM, LEO 1530 (FEG) microscope with 1 kV electrons) and to X-ray powder analysis (STOE STADI-P2 diffractometer, flat sample holders, $Cu_{K\alpha}$ radiation).

The in situ EXAFS and XANES experiments were performed at the beamline X1 at HASYLAB (DESY, Hamburg, Germany). $MoO_3 \cdot 2H_2O$ (50 mg) was embedded between glass wool plugs to fix the solid phase and were loaded together with water (3 mL) into a newly designed spectroscopic cell (see Supporting Information). The EXAFS scans around the molybdenum K edge were recorded between 19850 and 21200 eV under stationary conditions (liquid solution and solid phase) and were calibrated with a Mo reference foil. Faster spectra during the change of the reaction conditions were recorded in the QEXAFS mode between 19950 and 20450 eV (110 s/spectrum). The following procedure was applied: Heating to 150 °C in 1.5 °C min^{-1} steps from RT to 50, 94, 120, and 150 °C. The raw data were energy-calibrated with the according reference foil, background corrected and normalized (WINXAS 3.0 software[43]). Fourier transformation for EXAFS data during dynamic changes was applied to the k^3-weighted functions in the interval $k = 3.5$–9.3 $Å^{-1}$.

MoO_3 nanorods were obtained during the in situ EDXRD experiments (HASYLAB beamline F3, Hamburg, Germany) from (230.0 mg, 1.27 mmol) $MoO_3 \cdot 2H_2O$ in a solution of glacial acetic acid (0.4 mL) and H_2O (1.1 mL). The reaction was carried out under autogeneous pressure and isothermal conditions in sealable glass tubes as inserts for autoclaves (see Supporting Information).[22,31] The reaction vessel was transferred into the autoclave, and the reaction time was started after a delay time of approximately 1 min. The reaction temperatures were then reached after about 30 s, and X-ray powder patterns were recorded with acquisition times of 120 s. The spectra were evaluated with EDXPow.[44] The reflection profiles were modeled with a Gaussian peak shape, and the intensities of the product reflections were normalized against the peak intensities of the $Mo_{K\alpha}$ resonance.

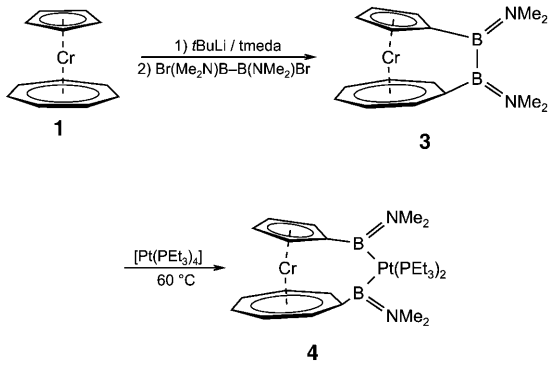
Synthesis of *ansa*-[2]Boracyclopentadienylcycloheptatrienylchromium and Its Reaction to the *ansa*-Platinabis(boryl) Complex by Oxidative Addition of the Boron–Boron Bond**

Holger Braunschweig, Matthias Lutz, and Krzysztof Radacki*

Metalation reactions are of great importance in metallocene chemistry since they provide access to a wide variety of functionalized sandwich complexes. Among those, the dilithiation of ferrocene[1] and related compounds such as bis(benzene)chromium,[2] for which an alkyllithium base is employed in the presence of a chelating amine (typically *N*,*N*,*N*′,*N*′-tetramethylethylenediamine = tmeda), are the most prominent examples to accomplish this goal. Recently, Mulvey and co-workers reported the selective tetrametalation of ferrocene[3] and monometalation of bis(benzene)chromium[4] by the use of mixed alkali-metal–magnesium amide bases.



Our interest focused on cyclopentadienylcycloheptatrienylchromium $[(\eta^5\text{-}C_5H_5)Cr(\eta^7\text{-}C_7H_7)]$ (trochrocene **1**),[5] which is isoelectronic to bis(benzene)chromium and was intensively studied by Fischer and co-workers.[6,7] Although the metalation of trochrocene was the subject of a series of studies, in which either *n*-amylsodium[7] or mixtures comprising *n*BuLi/tmeda[8] were employed, there is no precedence for the metalation of both the Cp and the Cht ring. We achieved the double lithiation of trochrocene by using a *t*BuLi/tmeda mixture, which resulted in the formation of the base-stabilized compound $[(\eta^5\text{-}C_5H_4Li)Cr(\eta^7\text{-}C_7H_6Li)]\cdot$tmeda (**2**) in yields of up to 80%. The ^{1}H NMR spectrum of **2** is in agreement with an overall C_S-symmetric compound in solution and features two signals for the Cp ligand ($\delta = 3.51$ and 3.86 ppm) and two signals for the Cht ring ($\delta = 5.23$–5.30 and 5.70 ppm) with a relative intensity of 2:2:4:2. However, the ^{13}C NMR spectrum exhibits only five resonances for the aromatic carbon atoms; the *ipso*-carbon atoms are undetectable at room temperature, a fact which is probably due to the quadrupolar moment of the Li atom.[9]

Dilithiotrocrocene (**2**) was subsequently treated with stoichiometric amounts of $Br(NMe_2)B{-}B(NMe_2)Br$ to afford the [2]boratrochrocenophane **3**, which was isolated from pentane solutions at −30 °C as green crystals in 35–45% yields (Scheme 1). The most noteworthy feature in the ^{1}H NMR spectrum of **3** is the splitting of the Cp resonances

Scheme 1. Synthesis of the [2]boratrochrocenophane **3** and Pt^0-mediated oxidative cleavage of the boron–boron bond.

into two apparent triplets ($\delta = 3.90$ and 4.05 ppm) and of the Cht resonances into three multiplets ($\delta = 5.51$–5.52, 5.57–5.60 and 5.78–5.79 ppm), which are significantly lowfield shifted compared to the corresponding resonances in trochrocene ($\delta = 3.66$ ppm, C_5H_5, 5.45 ppm, C_7H_7). Owing to chemical inequivalence and hindered rotation, four resonances are detected for the aminomethyl groups of **3** in the ^{1}H and ^{13}C NMR spectra. As for the dilithio compound **2**, there are only five resonances detectable for the aromatic carbon atoms between $\delta = 77.58$ and 93.06 ppm. Moreover, the two expected ^{11}B NMR resonances were detected at $\delta = 45.05$ and 48.90 ppm.[10]

To gain more detailed insight into the structural properties of **3**, the compound was subjected to a single-crystal X-ray diffraction analysis (Figure 1).[11] In accord with the molecular geometry of $[(\eta^5\text{-}C_5H_5)Cr(\eta^7\text{-}C_7H_7)]$,[12] the metal–carbon distances to the seven-membered ring (2.1370(18)–2.1683(20) Å) are not markedly different from those to the five-membered ring (2.1616(20)–2.2056(18) Å). In contrast, the corresponding nonbridged titanium and vanadium congeners display a metal–(η^7-C_7H_7) separation that is markedly smaller than the metal–(η^5-C_5H_5) distance.[12] Since a decrease of the interatomic metal–carbon distance greatly increases the overlap of the e_2 orbital of the ligand with the $d_{x^2-y^2}$ orbitals of the metal, these findings emphasize the importance of the δ bonding in the Ti–(η^7-C_7H_7) moiety, which is more pronounced than in the case of Cr.[8,13] The incorporation of the [2]bora bridge into the framework of trochrocene imposes moderate molecular strain, which is manifested in the tilt angle $\alpha = 8.9°$. This value is comparable to that for previously reported [2]boraarenophanes[14] but significantly smaller than that for highly strained [1]boraferrocenophanes.[15]

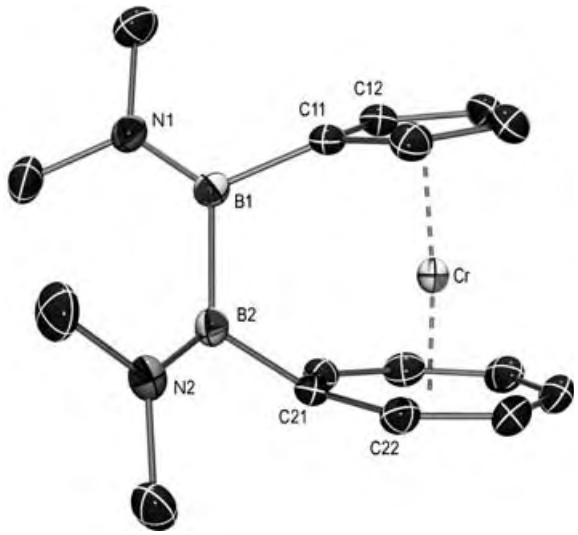

Figure 1. Molecular structure of **3**.[11] Selected bond lengths [Å] and angles [°]: Cr-C11 2.1806(18), Cr-C12 2.1932(18), Cr-C13 2.2056(18), Cr-C14 2.1939(20), Cr-C15 2.1616(20), Cr-C21 2.1370(18), Cr-C22 2.1683(20), Cr-C23 2.1597(19), Cr-C24 2.1676(19), Cr-C25 2.1649(19), Cr-C26 2.1559(18), Cr-C27 2.1386(17), B1-B2 1.7260(29), B1-C11 1.5957(27), B2-C21 1.6062(27), B1-N1 1.3902(26), B2-N2 1.3837(27), Cr-X_{Cp} 1.823, Cr-X_{Cht} 1.416; X_{Cp}-Cr-X_{Cht} 173.1, C21-B2-B1-C11 −40.5 (X = centroid).

Especially in the case of Si-bridged *ansa* complexes, the oxidative addition of the bridging Si–C bond to late transition metals has led to very interesting heterodinuclear complexes, which are key intermediates of the metal-catalyzed ring-opening polymerization (ROP) of such metallocenophanes.[16] Extending this reactivity pattern to B-bridged metallocenophanes would be highly desirable, for example, to provide an alternative to the commonly applied thermally induced ROP, which unfortunately fails in the case of thermally labile complexes.[14,15] The corresponding oxidative addition of a [1]borametallocenophane, however, is precluded by the strength of the B–C bond, which significantly exceeds that of a Si–C linkage.[17] Moreover, the reversed reaction, that is, the reductive elimination of B–C bonds from late transition-metal centers, is thermodynamically favorable and is known to be a key step in metal-catalyzed hydroboration.[18]

B–B bonds, however, are prone to undergo facile oxidative addition reactions with a variety of low-valent transition-metal complexes[18d,19] with concomitant formation of bisboryl–metal species $M(BR_2)_2$.[20] Hence, diboranes(4) have been very successfully applied to the transition-metal-catalyzed diboration of alkenes,[21] alkynes,[22] and 1,3-dienes.[23]

These findings have prompted us to further investigate [2]boratrochrocenophane **3** as a suitable candidate for a boron–boron bond cleavage. To this end, treatment of **3** with stoichiometric amounts of $[Pt(PEt_3)_4]$ in benzene at elevated temperature for two days afforded the oxidative addition product **4** as a green, crystalline solid in 85 % yield. The NMR spectroscopic data of **4** are in full agreement with the formulation of a C_1-symmetric compound. Interestingly, the ^{31}P NMR spectrum exhibits two singlets at $\delta = 10.69$ and 11.76 ppm with a peak widths at half height of about 70 Hz, which are flanked by characteristic ^{31}P–^{195}Pt satellites with coupling constants of $J_{P,Pt} = 1139.45$ Hz and $J_{P,Pt} = 1186.22$ Hz, respectively. However, no coupling between the nonequivalent phosphorus atoms could be observed. Previously, $^2J_{P,P}$ couplings of 19 Hz have been reported for a [2]platinasilaferrocenophane bearing an unsymmetrically substituted *cis*-$\{Pt(PEt_2)_2\}$ moiety.[24] The absence of ^{31}P–^{31}P couplings in the ^{31}P NMR spectrum between the two chemically nonequivalent ^{31}P atoms in **4** is presumably attributable to the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

quadrupolar moment imposed by the ^{11}B nuclei.[20b] Two ^{11}B resonances ($\delta = 60.63$ and 66.95 ppm) are recorded on a high-field NMR spectrometer.[10]

To confirm the structural details of **4** in the solid state, a single-crystal structure analysis was carried out (Figure 2).[11] As to be expected the incorporation of the $Pt(PEt_3)_2$ subunit

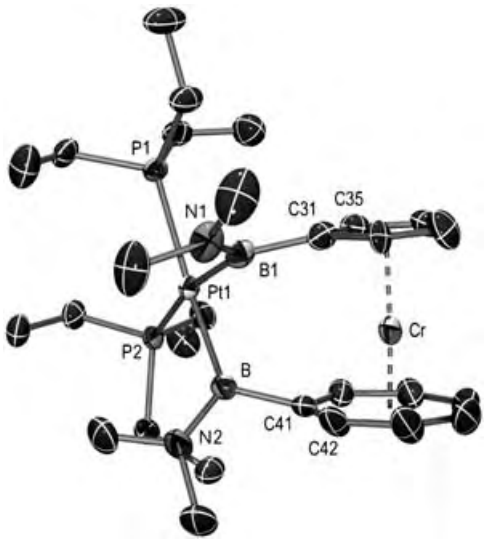

Figure 2. Molecular structure of **4**.[11] Selected bond lengths [Å] and angles [°]: Cr-C31 2.181, Cr-C32 2.181, Cr-C33 2.173, Cr-C34 2.174, Cr-C35 2.152, Cr-C41 2.178, Cr-C42 2.158, Cr-C43 2.156, Cr-C44 2.157, Cr-C45 2.158, Cr-C46 2.144, Cr-C47 2.130, B1-C31 1.5956(41), B2-C41 1.6029(39), B1-Pt1 2.1081(28), B2-Pt1 2.0963(28), B1-N1 1.4187(40), B2-N2 1.4246(36), Pt1-P1 2.3463(7), Pt1-P2 2.3399(6); B1-Pt1-P1 90.27(8), B2-Pt1-P2 94.53(8), B1-Pt1-B2 76.42(12), P1-Pt1-P2 99.18(2), B2-Pt1-P1 165.98(9), B1-Pt1-P2 168.92(9), Cr-X_{Cp} 1.800, Cr-X_{Cht} 1.422, X_{Cp}-Cr-X_{Cht} 176.91 (X = centroid).

leads to a drastic release of molecular strain, as illustrated by the tilt angle $\alpha = 3.48(0.15)°$, thus allowing the arene ligands in **4** to be in an almost parallel arrangement. Notable pertinent metric parameters around the platinum center, which displays a distorted square-planar environment, include the Pt–B bond lengths (Pt1–B1 2.108(3), Pt1–B2 2.096(3) Å), the Pt–P distances (Pt1–P1 2.3463(7), Pt1–P2 2.3399(6) Å), the B-Pt-B angle (76.42(12)°), and the P-Pt-P bond angle (99.18(2)°) all of which lie within previously reported ranges.[19c,20a,20b,22c,22e]

Herein, we have reported the synthesis and structural characterization of the first [2]boratrochrocenophane **3** and its reaction with the low-valent species $[Pt(PEt_3)_4]$, which yields the [3]boraplatinatrochrocenophane **4** by oxidative addition of the boron–boron bond. This reaction is of particular interest, since **4** has the potential for subsequent diboration reactions of alkynes, thus leading to polymers bearing the trochrocene moiety in its backbone. Corresponding studies are currently ongoing in our laboratories and will be reported elsewhere.

Experimental Section

2: A solution of *t*BuLi in pentane (12.42 mL, 1.7 M) was added slowly at 0 °C to a suspension of **1** (2.00 g, 9.60 mmol) in pentane (50 mL) and tetramethylethylenediamine (tmeda) (2.45 g, 3.15 mL, 21.1 mmol). The yellow suspension was allowed to warm up to ambient temperature and stirred overnight. The green-yellow precipitate was filtered off, washed with pentane (2 × 20 mL), and dried in vacuo (2.54 g, yield 79 %). ^1H NMR (500 MHz, [D$_8$]THF, 297 K): $\delta = 2.08$ (s, 12 H; $((CH_3)_2NCH_2)_2$), 2.23 (s, 4 H; $((CH_3)_2NCH_2)_2$), 3.51 (s, 2 H; C_5H_4), 3.86 (s, 2 H; C_5H_4), 5.23–5.30 (m, 4 H; C_7H_6), 5.70 ppm (m, 2 H; C_7H_6); $^7Li\{^1H\}$ NMR (117 MHz, [D$_8$]THF, 297 K): $\delta =$ 2.39 ppm (br. s); $^{13}C\{^1H\}$ NMR (126 MHz, [D$_8$]THF, 297 K)): $\delta =$ 46.30 ($(CH_3)_2NCH_2)_2$), 58.69 ($(CH_3)_2NCH_2)_2$), 78.82 (C_5H_4), 85.75 (C_7H_6), 86.33 (C_5H_4), 91.48 (C_7H_6), 97.77 ppm (C_7H_6).

3: A solution of $B_2Br_2(NMe_2)_2$ (1.70 g, 5.95 mmol) in pentane (20 mL) at −78 °C was added dropwise over a period of 30 min to a suspension of **2** (2.00 g, 5.95 mmol) in pentane (50 mL). After complete addition, the reaction mixture was stirred for 2 h at −78 °C and subsequently allowed to warm up to ambient temperature over a period of 6 h, during which time the color of the suspension changed from pale yellow to dark green. The suspension was filtered through Celite, and **3** was isolated by crystallization at −30 °C as a dark green solid (846 mg, 45 %). ^1H NMR (500.13 MHz, C_6D_6, 297 K): $\delta = 2.67$ (s, 3 H; $N(CH_3)_2$), 2.88 (s, 3 H; $N(CH_3)_2$), 2.91 (s, 3 H; $N(CH_3)_2$), 3.12 (s, 3 H; $N(CH_3)_2$), 3.90 (m, 2 H; C_5H_4), 4.05 (m, 2 H; C_5H_4), 5.51–5.52 (m, 2 H; C_7H_6), 5.57–5.60 (m, 2 H; C_7H_6), 5.78–5.79 ppm (m, 2 H; C_7H_6); $^{11}B\{^1H\}$ NMR (161 MHz, C_6D_6, 297 K): $\delta =$ 45.05, 48.90 ppm; $^{13}C\{^1H\}$ NMR (126 MHz, C_6D_6, 297 K): $\delta = 40.31$ ($N(CH_3)_2$), 40.98 ($N(CH_3)_2$), 43.66 ($N(CH_3)_2$), 43.94 ($N(CH_3)_2$), 77.58 (C_5H_4), 81.70 (C_5H_4), 86.70 (C_7H_6), 92.04 (C_7H_6), 93.06 ppm (C_7H_6); elemental analysis (%) calcd for $C_{16}H_{22}B_2CrN_2$ (315.98): C 60.82, H 7.02, N 8.87; found: C 61.07, H 6.84, N 9.03.

4: A resealable bulb was charged with $[Pt(PEt_3)_4]$ (235 mg, 0.352 mmol) and heated for 20 min at 60 °C under vacuum. Compound **3** (100 mg, 0.352 mmol) and benzene (2 mL) were added to the resulting red oil. The mixture was heated at 60 °C for two days and subsequently dried in vacuo. The residue was taken up in heptane (20 mL) and filtered through a short pad of Celite. The solution was concentrated to about 3 mL and then cooled to −78 °C. The greenish crystals that separated were decanted from the mother liquid, washed with pentane (2 × 3 mL), and dried in vacuum. Yield 200 mg (0.268 mmol, 85 %). ^1H NMR (500.13 MHz, C_6D_6, 297 K): $\delta = 0.90$ (dt, $J = 13.85$, 7.60 Hz, 9 H; $P(CH_2CH_3)_3$), 1.13 (dt, $J = 14.15$, 7.60 Hz, 9 H; $P(CH_2CH_3)_3$), 1.52 (m, 6 H; $P(CH_2CH_3)_3$), 1.79 (m, 6 H; $P(CH_2CH_3)_3$), 2.94 (d, $^5J_{P,H} = 1.60$ Hz, 3 H; $N(CH_3)_2$), 3.12 (d, $^5J_{P,H} =$ 1.55 Hz, 3 H; $N(CH_3)_2$), 3.32 (s, $^4J_{Pt,H} = 4.45$ Hz, 3 H; $N(CH_3)_2$), 3.41 (s, $^4J_{Pt,H} = 5.05$ Hz, 3 H; $N(CH_3)_2$), 4.04 (m, 1 H; C_5H_4), 4.06 (m, 1 H; C_5H_4), 4.26 (m, 1 H; C_5H_4), 4.58 (m, 1 H; C_5H_4), 5.65 (t, $J = 7.55$ Hz, 1 H; C_7H_6), 5.67 (t, $J = 7.25$ Hz, 1 H; C_7H_6), 5.74 (t, $J = 7.25$ Hz, 2 H; C_7H_6), 5.85 (t, $J = 7.55$ Hz, 1 H; C_7H_6), 6.25 ppm (d, $J_{H,H} = 7.55$, $^4J_{H,H} =$ 17.65 Hz, 1 H; C_7H_6); $\{^1H\}^{11}B$ NMR (160.47 MHz, C_6D_6, 297 K): $\delta =$ 60.63, 66.95 ppm; $^{13}C\{^1H\}$ NMR (125.77 MHz, C_6D_6, 297 K): $\delta = 8.59$ (s, $J_{C,Pt} = 14.66$ Hz; $P(CH_2CH_3)_3$), 9.03 (s, $J_{C,Pt} = 16.49$ Hz; $P(CH_2CH_3)_3$), 20.01 (dd, $J_{C,P} = 18.32$, 5.50 Hz, $J_{C,Pt} = 20.63$ Hz; $P(CH_2CH_3)_3$), 21.12 (dd, $J_{C,P} = 17.41$, 5.50 Hz, $J_{C,Pt} = 21.01$ Hz; $P(CH_2CH_3)_3$), 41.35 (d, $J_{C,P} = 3.66$ Hz, $J_{C,Pt} = 32.99$ Hz; $N(CH_3)_2$), 43.17 (d, $J_{C,P} = 3.67$ Hz, $J_{C,Pt} = 32.99$ Hz; $N(CH_3)_2$), 48.72 (d, $J_{C,P} =$ 3.67, $J_{C,Pt} = 98.99$ Hz, $N(CH_3)_2$), 49.75 (d, $J_{C,P} = 3.67$, $J_{C,Pt} =$ 105.39 Hz; $N(CH_3)_2$), 76.99 (s, $J_{C,Pt} = 9.16$ Hz; C_5H_4), 78.15 (s, C_5H_4), 81.37 (d, $J_{C,P} = 2.75$, $J_{C,Pt} = 19.26$ Hz; C_5H_4), 85.43 (s, C_7H_6), 87.25 (s, C_7H_6), 87.43 (s, C_7H_6), 88.07 (s, $J_{C,Pt} = 32.09$ Hz, C_5H_4), 90.59 (s, C_7H_6), 91.18 (s, C_7H_6), 94.89 ppm (s, $J_{C,Pt} = 22.92$ Hz, C_7H_6); $^{31}P\{^1H\}$ NMR (202 MHz, C_6D_6, 297 K): $\delta = 10.69$ (s, $J_{P,Pt} = 1139.45$ Hz, $\Delta\nu_{1/2} =$ 70 Hz), 11.76 ppm (s, $J_{P,Pt} = 1186.22$ Hz, $\Delta\nu_{1/2} = 66$ Hz); elemental

[10] Two separated signals could only be detected at 161 MHz. At lower fields the compounds displayed one broad resonance in the ^{11}B NMR spectra (**3**: $\delta = 47.7$ ppm, **4**: $\delta = 62.5$ ppm).
[11] The crystal data for **3** and **4** were collected on a Bruker APEX diffractometer with a CCD area detector and graphite-monochromated $Mo_{K\alpha}$ radiation. The structure was solved by using direct methods, refined with the Shelx software package (G. Sheldrick, University of Göttingen, **1997**) and expanded by using Fourier techniques. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were assigned at idealized positions and were included in structure factor calculations. Crystal data for **3**: $C_{16}H_{22}B_2CrN_2$ $M_r = 315.98$, green rods, $0.25 \times 0.18 \times 0.12$ mm, orthorhombic, space group $P2(1)2(1)2(1)$, $a = 10.6876(7)$ Å, $b = 11.7017(7)$ Å, $c = 12.3316(8)$ Å, $V = 1542.23(17)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.361$ g cm^{-3}, $\mu = 0.734$ cm^{-2}, $F(000) = 664$, $T = 173(2)$ K, $R_1 = 0.0305$, $wR^2 = 0.0780$, 3559 independent reflections [$2\theta \leq 55.06°$] and 190 parameters. Crystal data for **4**: $C_{28}H_{52}B_2CrN_2P_2Pt$ $M_r = 747.37$, green plates, $0.31 \times 0.28 \times 0.17$ mm, monoclinic, space group $P2(1)/n$, $a = 8.5981(6)$ Å, $b = 17.6203(13)$ Å, $c = 21.1762(16)$ Å, $\beta = 91.3130(10)°$, $V = 3207.4(4)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.548$ g cm^{-3}, $\mu = 4.815$ cm^{-2}, $F(000) = 1504$, $T = 193(2)$ K, $R_1 = 0.0206$, $wR^2 = 0.0505$, 6339 independent reflections [$2\theta \leq 52.12°$] and 325 parameters. Details of the X-ray crystal structure determination can be found in the Supporting Information. CCDC-263858 (**3**) and CCDC-263859 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

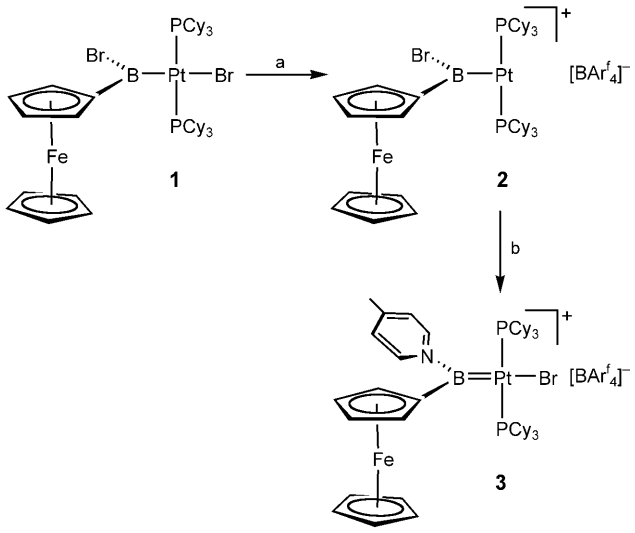
Boron Ligands

DOI: 10.1002/anie.200501588



A T-Shaped Platinum(II) Boryl Complex as the Precursor to a Platinum Compound with a Base-Stabilized Borylene Ligand**

Holger Braunschweig, Krzysztof Radacki, Daniela Rais, and David Scheschkewitz*

Transition-metal boryl complexes constitute an abundant and important class of boron-containing transition-metal compounds,[1] in view of their intermediacy in the catalyzed hydro-[2] and diboration[3] of unsaturated organic substrates, as well as the selective C–H bond activation of alkanes and arenes.[4] A number of synthetic routes have been applied to the generation of boryl complexes.[1] Among these, that involving B–X (X = Cl, Br) bond oxidative addition has seldom been employed, and examples of rhodium and iridium,[5] palladium,[6] and platinum[7] boryl complexes synthesized in this fashion have only relatively recently appeared in the literature.

We previously reported the synthesis of *trans*-$[(Cy_3P)_2Pt(Br)\{B(Fc)Br\}]$ (Fc = ferrocenyl, Cy = cyclohexyl) (**1**) by reaction of $[Pt(PCy_3)_2]$ with $FcBBr_2$.[7b] A remarkable structural feature of crystalline **1** is the rather long Pt–Br bond length (2.6183(8) Å), which provides an indication of the high *trans* influence of the B(Fc)Br group. Indeed, on account of its strong σ-donor character, the boryl ligand exerts a higher *trans*-labilizing influence[8] than that of other σ donors, such as hydrido[7a,9] and stannyl groups,[6a] or π acceptors, such as CO.[10] Herein, we demonstrate how strongly this property influences the reactivity of **1**. Thus, the reaction of **1** with $Na[BAr^f_4]$ (Ar^f = 3,5-$C_6H_3(CF_3)_2$) leads to the T-shaped, three-coordinate platinum complex *trans*-$[(Cy_3P)_2Pt\{B(Fc)Br\}][BAr^f_4]$ (**2**). Such a species constitutes the precursor to the cationic, base-stabilized borylene complex *trans*-$[(Cy_3P)_2Pt(Br)\{B(Fc)(NC_5H_4\text{-}4\text{-}Me)\}][BAr^f_4]$ (**3**), which is obtained upon addition of 4-methylpyridine, via an overall 1,2-bromide migration from the boron center to the platinum center.

Treatment of a solution of **1** in CD_2Cl_2 with $Na[BAr^f_4]$ led to an immediate color change from bright orange to cherry red, with concomitant precipitation of NaBr (Scheme 1, a).

Scheme 1. a) $Na[BAr^f_4]$ in CD_2Cl_2; b) 4-methylpyridine in CD_2Cl_2.

The $^{31}P\{^1H\}$ NMR spectrum of the reaction mixture conclusively revealed the quantitative formation of a new compound within a few minutes, with the presence of a single signal at δ = 41.7 ppm (^1J(P,Pt) = 2914 Hz), strongly downfield shifted with respect to that of **1** (δ = 21.5 ppm, ^1J(P,Pt) = 2892 Hz).

In the ^1H NMR spectrum, two broad signals for the protons of the $[BAr^f_4]^-$ ion appeared at δ = 7.74 and 7.58 ppm, alongside a new set of signals for the ferrocenylboryl ligand, namely two multiplets at δ = 4.71 ppm (2H) and δ = 4.52 ppm (2H), and a singlet at δ = 4.26 ppm (5H). Surprisingly, no resonance signal was observed in the $^{11}B\{^1H\}$ NMR spectrum, probably due to broadening of the signal as a consequence of unresolved coupling to the platinum and phosphorus nuclei.[11]

Orange bricklike crystals of **2** were obtained by layering a solution of the complex in CD_2Cl_2 with hexane and cooling the solution to −36 °C. The X-ray diffraction study performed

on a suitable single crystal confirmed that complex **2** was a three-coordinate platinum(II) boryl compound that displayed a distorted T-shaped geometry (P1-Pt1-P2 162.96(3)°; Figure 1).[12]

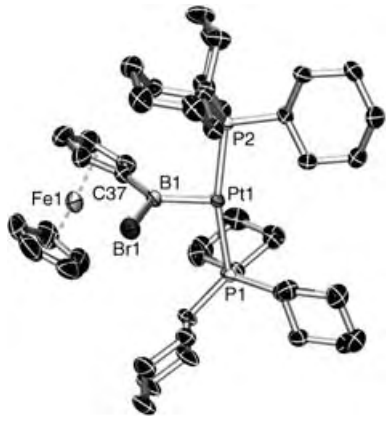

Figure 1. Molecular structure of **2**. Hydrogen atoms and the $[BAr^f_4]^-$ ion were omitted for clarity. Selected bond lengths [Å] and angle [°]: Pt1–B1 1.966(4), Pt1–P2 2.3071(8), Pt1–P1 2.3323(8), B1–Br1 1.955(4); P1-Pt1-P2 162.96(3).

Despite the absence of a ligand *trans* to the boryl group, the B1–Pt1 distance (1.966(4) Å) in **2** is, unexpectedly, only slightly shorter than that in crystalline **1** (1.9963(34) Å).[7b] This is presumably a consequence of the steric bulk of the tricyclohexylphosphane ligands, which prevents a closer approach of the boryl group to the metal center. The threefold coordination at the platinum center in the cationic portion of **2** is remarkable. It is well-established that the highly unsaturated, Lewis acidic nature of the metal center in 14-electron d^8ML_3 compounds greatly enhances the reactivity of these species, leading to interactions even with weak nucleophiles, such as solvent molecules, weakly coordinating anions,[13] or agostic C–H bonds.[14] In **2**, however, no such interaction is observed. Particularly noteworthy is the absence of any efficient agostic interaction between the metal center and the C–H bonds of the cyclohexyl groups. The shortest Pt···H–C distance is 2.542 Å (Pt···C–H 3.117 Å), which is considerably longer than corresponding distances in the complexes $[PtMe(P\textit{i}Pr_3)_2][1\text{-H-}\textit{closo}\text{-}CB_{11}Me_{11}]$ (Pt–H 2.24, Pt–C 2.859 Å)[14g] and $[Pt\{P(2,6\text{-}Me_2C_6H_3)Cy_2\}\{\kappa^2\text{-}P,C\text{-}P(2\text{-Me-6-}CH_2\text{-}C_6H_3)Cy_2\}][BAr^f_4]$ (Pt–C 2.432 Å)[14f] and in the range of those observed in truly three-coordinate *neutral* palladium complexes, in which the presence of agostic interactions was excluded.[15] Indeed, theoretical calculations on 14-electron d^8ML_3 boryl complexes of the type $[(R_3P)_2Rh(BX_2)]$ support the reluctance of such compounds to bind C–H bonds in the site opposite to the boryl group, owing to the extremely strong *trans* influence of the boryl ligand.[16] Thus, compound **2** represents a structurally characterized example of this class of complexes, and provides experimental confirmation of what was predicted from theoretical studies.

The absence of agostic interactions in **2** was supported by density functional calculations[17] and variable-temperature NMR studies. No appreciable change in the NMR spectra of **2** was observed upon cooling the sample to −60 °C. At lower temperatures, the signal in ^{1}H NMR spectrum at $\delta = 4.52$ ppm for two of the ferrocenyl protons broadened. At −90 °C, coalescence occurred, consistent with restricted rotation of the ferrocenyl group around the B–C(Fc) bond. Concomitant broadening of the initial singlet at $\delta = 41.7$ ppm was observed in the $^{31}P\{^1H\}$ NMR spectrum, and two separate broad signals at $\delta = 42.5$ and 38.3 ppm could be detected at −90 °C. However, none of these processes was accompanied by the appearance of a high-field resonance signal that could be assigned to an agostic hydrogen atom, suggesting the decreased fluxionality of the molecule at low temperatures as the likely origin of the spectral phenomena.

The bulky tricyclohexylphosphane ligands and the high *trans*-labilizing boryl ligand cooperate to inhibit coordination of more efficient nucleophiles, such as THF or CH_3CN, at the platinum center. Negligible decomposition of a solution of **2** in CD_2Cl_2 containing an excess (>10 equiv) of THF or CH_3CN was observed by NMR spectroscopy over the course of 24 h. Upon addition of the stronger Lewis base 4-methylpyridine, however, gradual darkening of the solution from cherry red to dark purple occurred within 2 h, and the predominant formation of a new species, **3**, which incorporated the added ligand was observed by NMR spectroscopy. Although binding of the pyridine unit to the platinum center might have been expected, on account of the electronic unsaturation at the metal center and its affinity for nitrogen donors,[13b–d] an X-ray diffraction study[12] performed on purple crystals of **3** revealed a different outcome of the reaction. As displayed in Figure 2, the constitution of complex **3** is that of a four-coordinate, cationic *trans*-bis(tricyclohexylphosphino)platinum complex, with the two remaining sites occupied by a bromide ligand and a 4-methylpyridine-stabilized ferrocenylborylene moiety. As such, **3** represents a unique example of a cationic[18] platinum(II) borylene complex and a rare instance of a base-stabilized borylene

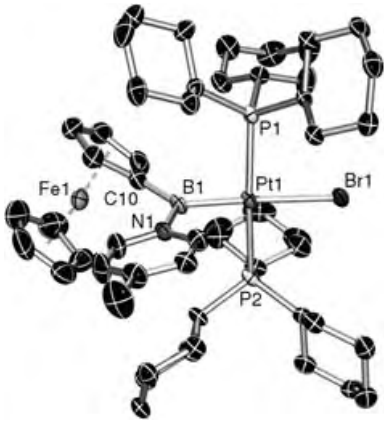

Figure 2. Molecular structure of **3**. The hydrogen atoms and the $[BAr^f_4]^-$ ion have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Pt1–B1 2.014(5), Pt1–P2 2.3452(11), Pt1–P1 2.3564(11), Pt1–Br1 2.6057(5), N1–B1 1.582(6); P2-Pt1-P1 171.83(4), C10-B1-N1 114.4(4), C10-B1-Pt1 131.0(3), N1-B1-Pt1 113.6(3).

compound.[10b,19] Previously, Roper et al. described formation of the only other reported organic base-stabilized borylene compounds, upon reaction of the osmium dichloroboryl precursor $[Os(BCl_2)Cl(CO)(PPh_3)_2]$ with 8-aminoquinoline[10b] or 2-aminopyridine.[19a] In analogy with the formation of the osmium system, it can be inferred that formation of **3** occurs by a Lewis base induced, formal 1,2-halide shift from boron to platinum, by which a strong B–N bond (B1–N1 1.582(6) Å) is formed within the borylene moiety and concomitantly the coordinative unsaturation at the metal center is relieved upon coordination of the bromide ligand. The latter appears to be an important factor. For example, intramolecular, particularly α-hydrogen, migrations within organometallic compounds are thought to be kinetically favorable, if through the shift a coordinatively unsaturated species can be converted into coordinatively more strongly saturated compound.[20] This principle, which plays a significant role in organometallic chemistry,[21] provided a viable route to silylene complexes of platinum.[22] The isolation of complex **3** and of the osmium compounds demonstrates that analogous 1,2-halide migrations might be similarly powerful synthetic tools in borylene chemistry.[23]

In contrast to the very short Fe–B distance (1.792(8) Å) in $[(\eta^5\text{-}C_5Me_5)(OC)_2Fe{=}BMes][BAr^f_4]$ (Mes = 2,4,6-$Me_3C_6H_2$),[18] the only other reported cationic terminal borylene complex, the Pt1–B1 distance (2.014(5) Å) in **3** is only slightly longer than that in the three-coordinate platinum precursor **2** (1.966(4) Å) and comparable to that in the four-coordinate boryl compound **1** (1.9963(34) Å).[7b] This is in line with the increased coordination number at the metal center and the enhanced steric congestion at the boron center.

Nonetheless, it must be stated that the comparable Pt–B bond lengths and angles at boron in the T-shaped complex **2** and the tetracoordinate complex **3** make the description of **2** as a boryl and of **3** as a borylene complex somewhat ambiguous. A similar ambiguity was pointed out by Roper et al. with regard to the "boryl" character of their base-stabilized borylene compounds of osmium,[10b,19a] and found to apply to base-stabilized silylene compounds, whose silylene character was judged to be limited.[24a,c] Hence, while the utilized description of complex **3** is based on the formalism that defines the B–R group a borylene, and hence a B(L)R group, where L is a Lewis base, a base-stabilized borylene ligand, this is only one of the possible descriptions. Elucidation of the bonding interactions that characterize complex **3** awaits theoretical calculations and reactivity studies, both of which are currently in progress.

The increased steric congestion at the boron center brought about by the coordination of pyridine is likely to be responsible for the nearly orthogonal disposition (78.42(13)°) of the plane of the borylene ligand with respect to the coordination plane of the platinum center. An analogous orientation of the boron-containing group was observed in the molecular structures of the boryl complexes **1** and **2**, as well as in those of square-planar platinum carbene[25] and silylene[24b] compounds, and attributed to steric interactions with the phosphane ligands. The Pt1–Br1 distance (2.6057(5) Å) in **3** is rather long and comparable to that in the neutral boryl complex **1** (2.6183(8) Å), in line with the high *trans* influence of the boron-containing ligand.

The spectroscopic data of complex **3** were in agreement with its solid-state structure. The $^{31}P\{^1H\}$ NMR spectrum exhibited a singlet at $\delta = 25.0$ ppm ($^1J(P,Pt) = 2554$ Hz), strongly high-field-shifted with respect to the corresponding signal of **2**. In the room-temperature ^1H NMR spectrum, broad signals were observed at $\delta = 7.90$ and 7.82 ppm for two of the 4-methylpyridine protons, as well as at $\delta = 4.54$ ppm for two of the ferrocenyl protons and for some of the cyclohexyl protons; this indicates slow hindered rotation of the methylpyridine ligands and of the ferrocenyl groups around the B–N and B–C bonds, respectively, with respect to the NMR time scale. At −20 °C, the four pyridine protons gave rise to two overlapping doublets at $\delta = 10.45$–10.42 ppm and two more doublets at $\delta = 7.92$ and 7.79 ppm ($^3J(H,H) = 6$ Hz). Only after the sample had been cooled to −60 °C were four separate signals for the four protons of the boron-bound cyclopentadienyl ring observed at $\delta = 4.92$, 4.88, 4.73, and 4.04 ppm. Finally, as for complex **2**, extreme broadening of the resonance in the $^{11}B\{^1H\}$ NMR spectrum of **3** prevented observation of a detectable signal.

In conclusion, we have described the synthesis of the T-shaped, three-coordinate boryl complex *trans*-$[(Cy_3P)_2Pt\{B(Fc)Br\}][BAr^f_4]$ (**2**) and its conversion into the cationic base-stabilized borylene complex *trans*-$[(Cy_3P)_2Pt(Br)\{B(Fc)(NC_5H_4\text{-}4\text{-}Me)\}][BAr^f_4]$ (**3**) by an overall 1,2-migration of bromide from the boron to the platinum center. Experiments aimed at verifying the generality of this approach to the synthesis of borylene complexes, as well as at exploiting the high *trans* influence of the boryl ligand to access highly unsaturated compounds are currently underway.

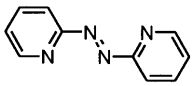
Mixed-Valent Complexes

DOI: 10.1002/anie.200501075

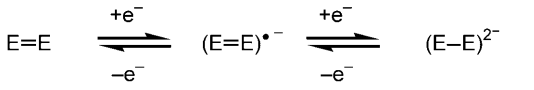


Theoretical and Experimental Evidence for a New Kind of Spin-Coupled Singlet Species: Isomeric Mixed-Valent Complexes Bridged by a Radical Anion Ligand**

Biprajit Sarkar, Srikanta Patra, Jan Fiedler, Raghavan B. Sunoj, Deepa Janardanan, Shaikh M. Mobin, Mark Niemeyer, Goutam Kumar Lahiri, and Wolfgang Kaim**

Singlet species composed from clearly identified odd-electron components have long been known in the form of antiferromagnetically spin–spin coupled transition-metal centers (M) of d^{2n+1} configuration bridged by ligands μ-L, giving rise to the phenomenon of "superexchange" in (M•)(μ-L)(M•) species.[1] More recently,[2] the reverse situation (L•)(M)(L•) with a bridging diamagnetic metal center was described and referred to in terms of "singlet diradical" species. Herein we present another alternative [Eq. (1)], involving the strong intramolecular interaction between a bridging anion radical ligand $L^{\bullet-}$ and two mixed-valent metal centers.

$$(M^{\cdot})(L^{\cdot-})(M) \leftrightarrow (M)(L^{\cdot-})(M^{\cdot}) \quad (1)$$



Evidence for the formulation in Equation (1) comes from structure determination in conjunction with density functional theory (DFT) calculations. Structural criteria have been increasingly used to establish the oxidation states of "non-innocent" ligands[3] and, by implication, of metal centers in the coordination compounds. Prominent examples include the bidentate 1,2-dioxolene chelate ligands $Q/Q^{\bullet-}/Q^{2-}$ for which structure–valency correlations were reported[4,5] and applied, and simple diatomic ligands such as the potentially metal–metal bridging redox system $O_2/O_2^{\bullet-}/O_2^{2-}$, a textbook case.[6] Related to the latter by the relation O ≙ NR are organic azo compounds $(NR)_2$ which in the *E* configuration can act as reducible bis-bidentate bridges if R is a coordinating group, such as 2-pyridyl to form 2,2′-azobispyridine (abpy).[7]

abpy

Abpy was first described by Lever and co-workers as a strongly π accepting but otherwise normal bridging ligand,[7b] a special feature of its complexes being the relatively short metal–metal distance of about 5 Å.[7a,c,e]

As with the O_2^{n-} system,[6] the addition of electrons to abpy causes a lengthening of the central N–N bond from double-bond values of about 1.25 Å via approximately 1.35 Å in the anion radicals[8] to approximately 1.42 Å for single bonds in the two-electron-reduced forms (Scheme 1).[9]

E=O:	1.21 Å	1.23–1.35 Å	1.40–1.50 Å
E=NR:	1.23–1.30 Å	ca. 1.35 Å	1.40–1.45 Å

Scheme 1. Bond lengths in E_2^{n-} systems.

Whereas coordination of π back-donating metal centers can result in a slight increase of the double-bond length relative to that in the free ligand,[7a] the lengthening caused by successive electron addition is so large and well documented through supporting spectroscopic data[8] that these criteria can be unequivocally applied to establish the bonding situation.

In the search for unusual mixed-valent configurations involving ruthenium and other platinum metals[10] we have now obtained the compound $[(\mu\text{-abpy})\{Ru(acac)_2\}_2]$ from abpy[7] and the neutral precursor $[Ru(acac)_2(CH_3CN)_2]$ ($acac^- = 2,4$-pentanedionate),[11] separated the *meso* and *rac* isomers[12] by chromatography, characterized them by ^1H NMR spectroscopy,[13] and identified them by crystal-structure analysis (Figure 1, Table 1).[14]

The molecules show the expected "S-frame" configurations[7a] with the bis-chelating abpy variably twisted; the C-N-N-C torsional angles are 26.1° in the *rac* form but only 15.5° and 0.0° for the two crystallographically independent molecules of the *meso* form. As expected,[7a] the bonds from the metal centers to the stronger π-accepting azo nitrogen atoms (ca. 1.965 Å) are shorter than those to the pyridine N centers (average 2.010 Å). Most remarkably, the central N–N bonds of the abpy ligand are considerably lengthened to 1.372(4) Å in the *rac* form and to 1.374(11) Å and 1.352(17) Å in the *meso* form whereas the adjacent C–N bonds are slightly shortened to about 1.395 Å. The average N–N distance of 1.366 Å lies in the same range as the 1.345(7) Å determined for a structurally and electronically well identified dicopper(I) complex containing the radical anion of the closely related 2,2′-bis(5-chloropyrimidine) (abcp) ligand.[8] A reduced N–N bond order of 1.5 would be compatible with the ease of twisting around the central CNNC backbone of abpy.

The abpy and related ligands are known to effect rather short metal–metal distances of about 5 Å.[7a,c] The unusually[7a,c] short metal–metal distances observed for *rac* (4.664 Å)

[a] Optimized parameters for singlet and triplet states obtained at the B3LYP/SDD/6-31G* level. [b] Bond lengths [Å] and angles [°]. [c] Two independent molecules in the unit cell of the crystallized *meso* isomer. [d] Torsional angle.

and *meso* forms (4.698 and 4.780 Å) are partly caused by the CNNC twisting. The structural data thus clearly indicate the presence of a one-electron reduced (i.e. radical anion) ligand bridge, leaving a $Ru^{II}Ru^{III}$ mixed-valent formulation for the metal centers. Since structural and spectroscopic results for this diamagnetic compound point to a symmetrical situation, this mixed valency would then have to be described as a Class III system (fully valence delocalized, that is, $Ru^{2.5}Ru^{2.5}$)[15] with strong antiferromagnetic coupling between metal- and ligand-based spins in accord with the observed diamagnetism. As noted previously,[7d] mixed-valent complexes with radical anion bridging ligands ($L^{\bullet-}$) can be invoked as metal-to-ligand charge transfer (MLCT) excited states of symmetrical dinuclear complexes [Eq. (2)].[16]

$$[M^n(\mu\text{-}L)M^n] \xrightarrow[MLCT]{h\nu} *[M^{n+1}(\mu\text{-}L^{\bullet-})M^n] \text{ or } *[M^{n+0.5}(\mu\text{-}L^{\bullet-})M^{n+0.5}] \qquad (2)$$

Reversible oxidation and reduction processes of both the *meso* and *rac* forms of $[(\mu\text{-abpy})\{Ru(acac)_2\}_2]$ occur at 0.05 (oxidation) and −1.03 V (reduction; versus saturated calomel electrode (SCE) in CH_3CN/0.1 M Bu_4NClO_4), yielding a very large comproportionation constant K_c of $10^{18.3}$. Reduction produces EPR signals at $g = 1.990$ that are indicative of a radical,[17a] and thus suggesting a $\{Ru^{II}(abpy^{\bullet-})Ru^{II}\}$ configuration. Oxidation produces EPR signals at $g = 2.25$, 2.14 and 1.98 (*rac* isomer) or $g = 2.35$, 2.15 and 1.81 (*meso* isomer) that are indicative of the presence of an Ru^{III} center,[17b] which would be compatible with a $\{Ru^{III}(abpy^{\bullet-})Ru^{III}\}$ or $\{Ru^{II}(abpy)Ru^{III}\}$ formulation. Absence of the near infrared band expected for a conventional mixed-valent compound[10,12,15] suggests the $\{Ru^{III}(abpy^{\bullet-})Ru^{III}\}$ alternative, implying metal-based electron transfer within the redox system $[(\mu\text{-abpy})\{Ru(acac)_2\}_2]^{+/0/-}$ as befits a mixed-valency situation for the neutral form $\{Ru^{2.5}(abpy^{\bullet-})Ru^{2.5}\}$.

The UV/Vis spectra of the neutral compounds are characterized by very intense bands ($\varepsilon = 29000\ M^{-1}\,cm^{-1}$) at 835 (*rac*) and 848 nm (*meso*) which are assigned to MLCT/MMCT (metal-to-ligand/metal-to-metal charge transfer) transitions between a metal-based occupied molecular orbital and a mixed abpy/metal LUMO.

DFT calculations at the B3LYP level were performed for both isomers.[18a] The calculated bond characteristics for the singlet ground states (Table 1) are in reasonable agreement with the experimental values, in addition, triplet states with longer N–N and shorter C–N distances (Table 1) were found comparatively close (*rac*: 840 cm^{-1}; *meso*: 1535 cm^{-1}) to the singlet ground states. The higher singlet–triplet gap for the *meso* isomer reflects the invariant coplanar CNNC backbone structure. Conversely, the energy difference between the singlet isomers is only 330 cm^{-1} whereas it increases to 1026 cm^{-1} between the triplet isomers, in both cases in favor of the *rac* form.

The wave functions were further analyzed using the natural bond orbital (NBO) method to probe the electron occupancies of the key orbitals as well as the extent of delocalization.[18f,g] The $\pi_{(N=N)}$ occupancies for both *rac* and *meso* isomers are about 1.87 e while $\pi^*_{(N=N)}$ was found to have a substantial population of 0.73 e. The corresponding values for the neutral ligand are 1.90 and 0.16 e, respectively. Although the change in occupancy is negligible for the π orbital on complex formation, it is significantly higher for the

π* molecular orbital, reflecting a substantial metal-to-ligand charge shift in the ground state. The donor–acceptor interaction energies obtained from the NBO analysis suggest that the cumulative effects of ligand-to-metal donation and π back-donation make the azo nitrogen atoms slightly better donors than pyridyl nitrogen atoms. This result is in agreement with the experimental differences in the Ru–N bond lengths. The high values for the metal-to-ligand donation together with the substantial population of $\pi^*_{(N=N)}$ clearly justify a description of the bridging ligand as a radical anion.

In summary, X-ray structure, spectroscopy, and DFT calculations have clearly established that the new stereoisomeric compounds *rac*- and *meso*-[(μ-abpy){Ru(acac)$_2$}$_2$] must be formulated as [Ru$^{2.5}$(abpy$^{\bullet-}$)Ru$^{2.5}$] complexes, thus constituting both a new kind of unconventional mixed-valent compound and a new class of singlet species composed from metal/ligand/metal intramolecular spin-spin coupling. The occurrence of radical anions as ligands,[19] either as small molecules such as $O_2^{\bullet-}$ [6] or $CO_2^{\bullet-}$ [20] or as larger entities,[2,4,5] has thus been extended to yield unprecedented electronic structures, using the rather simple inorganic complex fragment {Ru(acac)$_2$}. The additional feature of two separable stereoisomers will stimulate further investigations into configurational aspects of intramolecular interactions in these unconventional mixed-valent species.

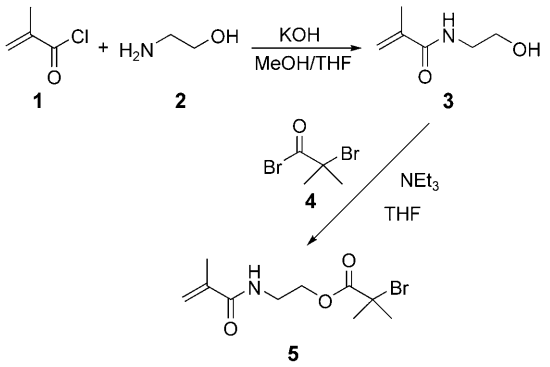
Unusual Solubility Properties of Polymethacrylamides as a Result of Supramolecular Interactions with Cyclodextrin

*Sarah Schmitz and Helmut Ritter**



Hydrophilic polymers with so-called LCST behavior are soluble within a certain temperature range but undergo phase separation or a change in volume above a critical temperature value, the lower critical solution temperature (LCST).[1] These phenomena can also be observed when other parameters are changed such as pH value,[2] electric field, and ionic strength.[3] For example, poly(*N*-isopropylacrylamide) shows a LCST at 34 °C in pure aqueous solution. This means that the polymer is soluble in water below 34 °C and precipitates simply when the solution is heated above that critical temperature.[4] The LCST value can be influenced, for example, by copolymerization of *N*-isopropylacrylamide or by chemical modification of the acrylamide polymer itself. The slightly cross-linked LCST polymers, so-called hydrogels, find potential application in the medical and biochemical fields, for controlled drug delivery[5] and as materials for bioreactors.[6] Although this LCST behavior of polymers cannot yet be explained, many studies have focused on this topic. One general explanation of the LCST effect is that strong hydrogen bonds exist between water molecules and the hydrophilic groups of the polymer at low temperature.[7] With increasing temperature, intramolecular interactions between hydrophobic chain components of the polymer increase. Reaching the LCST, polymer aggregation takes place, and the solubility in water decreases suddenly. We report here on a similar LCST-type solubility effect based on the reversible complexation of suitable polymers with β-cyclodextrin. Although the formation of complexes of hydrophobic polymers with cyclodextrins (CDs) has already been reported,[8] a characteristic LCST-type behavior has not yet been observed.

A functionalized polymer suitable for complexation with β-CD was prepared by the synthesis and radical polymerization of monomer **5** according to Scheme 1. Intermediate **3** was obtained from the reaction of **1** and **2** (Scheme 1).[9] The esterification of **3** with **4** led to formation of methacrylamide monomer **5**, which contains a bulky group suitable for complexation with CD and a bromine atom, which opens up the possibility of further modification by atom-transfer radical polymerization (ATRP).[10]

Scheme 1. Synthesis of monomer **5**.

The water-insoluble monomer **5** was treated with β-CD, and the resulting complex **5a** was soluble in water (Scheme 2). With a [CD]/[**5**] ratio of less than 1.5:1, it was

Scheme 2. Complex formation of monomer **5** with β-CD at room temperature in water.

possible to complex the monomer, but the polymer precipitated afterward polymerization. At larger [CD]/[**5**] ratios the polymer remained in the aqueous phase as a result of sufficient complexation.

The preferred stoichiometry of the monomer/β-CD complex can be evaluated by using Job's method[11,12] which was transferred to NMR spectroscopy by Blanda et al.[13] In this case monomer **5** represents the guest molecule, while β-CD corresponds to the host molecule. (For further information on the method see the Supporting Information.) A curve with a maximum around 0.4 was obtained (Figure 1a), which suggests that the stoichiometry of the **5**/β-CD complex is 1.5:1. That means that a temporary complexation of two monomer molecules by one β-CD ring takes place. The increase in the chemical shift of the NMR signal of the methyl protons with an increasing amount of β-CD is shown in Figure 1b. A 2D ROESY NMR spectrum indicates the interactions between the β-CD ring and the monomer **5** (Figure 2). The protons of the two methyl groups ($CBr(CH_3)_2$) at $\delta = 1.9$ ppm are directly correlated to the protons of β-CD at $\delta = 3.3$–3.9 ppm. We can assume that β-CD preferably includes the $CBr(CH_3)_2$ group of **5** (see the Supporting Information).

The free-radical polymerization of the complexed monomer **5a** was carried out in presence of a redox initiator at room temperature (Scheme 3). The average molar masses $\bar{M}$

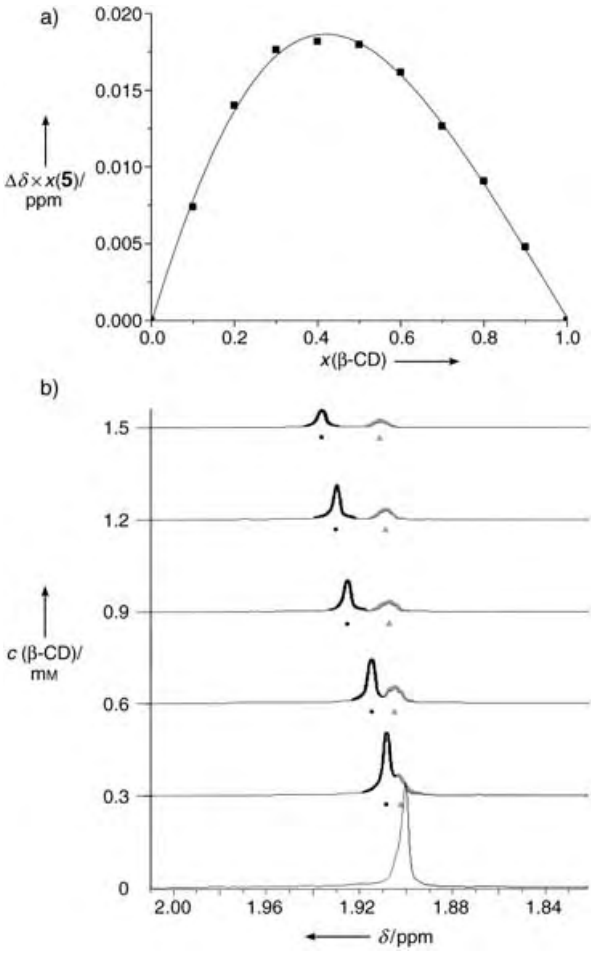

Figure 1. a) Job plot of monomer **5**: the chemical shift of the six protons of the methyl groups ($CBr(CH_3)_2$) was observed. b) Stacked plot of the NMR spectra. The chemical shift of the six protons [$CBr(CH_3)_2$ group (●)] and of the three protons [$C(CH_3)=CH_2$ group (▲)] of monomer **5** was observed with increasing amount of β-CD (500 MHz, D_2O).

Scheme 3. Free-radical polymerization of the monomer/β-CD complex **5a** to give the complexed water-soluble polymer **6a**.

of the obtained polymers, as determined by MALDI-TOF measurements, are in the range between 4300 (**7**) and 5400 g mol^{-1} (**6**) depending on the amount of initiator (Table 1). In the mass spectrum (Figure 3) the differences between the signals of the main series correspond to the molar mass of the monomer unit, 278 g mol^{-1}, as expected.

Table 1: Pseudo-LCST behavior of the polymers.

Polymer	Initiator [mol %]	$\bar{M}$ [g mol^{-1}][a]	Clouding point [°C][b]	Clearing point [°C][c]
6	2.5	5400	54	50
7	5	4300	68	61

[a] Determined by MALDI-TOF mass spectrometry. [b] Determined by turbidity measurement during heating. [c] Determined by turbidity measurement during cooling.

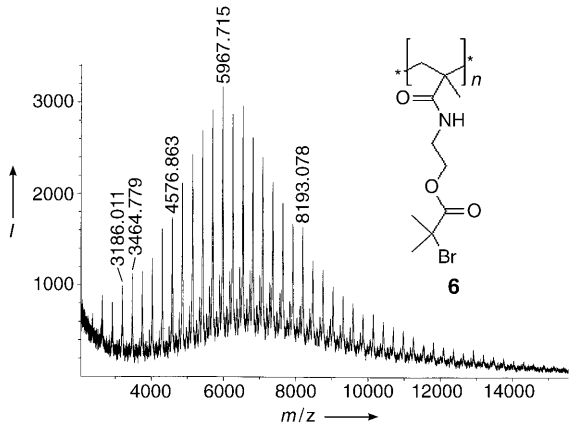

Figure 3. MALDI-TOF mass spectrum of polymer **6**.

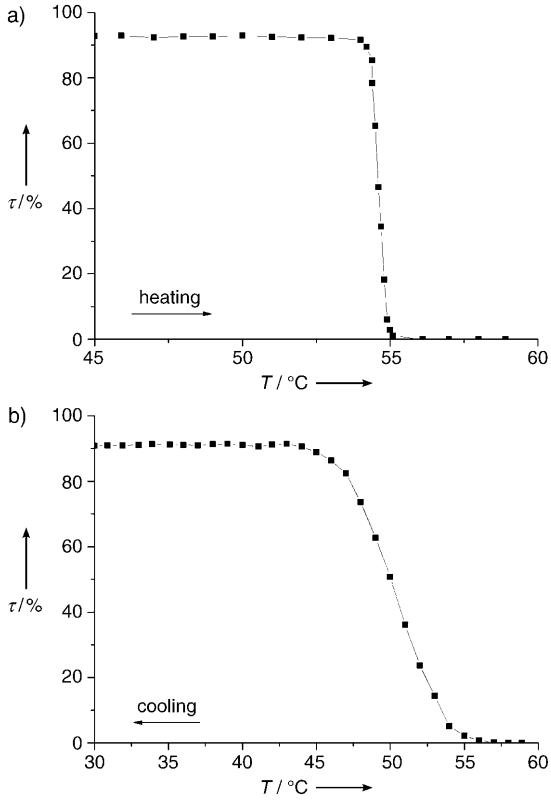
When the optically clear aqueous solutions of the complexed polymers **6a** (see the Experimental Section for the synthesis of polymer **6**) were heated above 70 °C, a sudden turbidity was observed. Surprisingly, when the solution was cooled, transparency was completely restored. Exact turbidity measurements were performed to evaluate the solubility as a function of the temperature. We found that the complexed monomer **5a** is completely soluble in the temperature range from 10 up to 85 °C. This means that the monomer complex is stable enough to keep the monomer in solution independent of temperature. In contrast, the polymer complex **6a** showed a definite clouding point at a temperature of 54 °C for the heating run (Figure 4a) and a clearing point of about 50 °C for



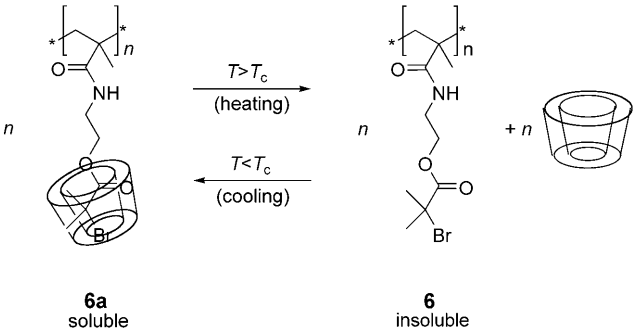


Figure 4. Transmittance of a solution of complexed polymer **6a** versus temperature during a) heating and b) cooling.

the cooling run (Figure 4b). These temperatures were found to be a function of the molecular mass $\bar{M}$ of the β-CD-free polymers. The corresponding values are listed in Table 1. Scheme 4 shows the reversible decomplexation–complexation process of polymer **6** in water.

The transmittance change of a solution of **6a** is plotted as a function of temperature in Figure 4. The decrease in the transmittance of the complexed polymer to 0 % occurs within a temperature interval of roughly 5 °C. In the subsequent

Scheme 4. Temperature-dependent reversible unthreading of CD from the bulky side group of **6a** during the heating procedure.

cooling step the polymer returns to solution by new formation of polymer/β-CD complex. In contrast, the β-CD-free polymer is not soluble in water at any temperature in this range. The interesting polymer-solubility behavior led us to compare this phenomenon with classical LCST effects. In our case, because of the reversible complex formation between the polymer **6** and cyclodextrin, the optical effect is based on supramolecular interactions. This means that the discovered pseudo-LCST behavior is a result of noncovalent interactions between the CD host and polymer guest. Furthermore, in this system competitive inhibition or control of the LCST is possible by addition of other suitable guest molecules of low molecular weight, for example, potassium 1-adamantylcarboxylate. CD complexes these molecules preferably, and the polymer precipitates. This special effect cannot be observed in "normal" LCST systems.

To prove the postulated dissociation of the polymer/CD complex at temperatures higher than the clouding point, the total amount of β-CD in solution was determined by ^{1}H NMR measurements before polymerization and after filtration of the precipitated polymer. DMSO was added to the monomer/β-CD solution as an internal standard. After polymerization, the solution was heated and the precipitated polymer was filtered off. Integration of the NMR signals showed the same amount of β-CD relative to DMSO at each time. The filtered polymer was nearly free of CD. This is in accordance with the "pseudo-LCST" effect described above which is caused by reversible complex formation.

These experiments and results clearly show that the investigated system of β-CD and polymethacrylamide (**5**) reveals new opportunities in the field of thermosensitive systems based on noncovalent interactions between host and guest compounds. The noncovalently attached β-CD ring keeps the insoluble polymer in aqueous solution at lower temperature. At higher temperatures the CD ring slips off and the polymer precipitates; this process is reversible. Currently detailed studies about the temperature-dependent formation of aggregates and changes in viscosity are underway for a better understanding of the observed phenomenon and to investigate the suitability of polymer/β-CD solutions as novel thermosensitive gels.

Experimental Section

For materials and methods, see the Supporting Information. Monomer **3** was synthesized according to the work of Bertozzi and coworkers.[9]

Monomer **5**: 2-Bromoisobutyryl bromide (**4**; 10.12 mL, 81.9 mmol) was added dropwise to a cold mixture of **3** (8.8 g, 68.2 mmol) and triethylamine (14.1 mL, 100.8 mmol) in 180 mL of THF over 20 min. The mixture was stirred for 4 h at 0 °C and 42 h at room temperature. The precipitated salt was removed by filtration. The solvent was removed under vacuum, and the resulting yellow oil was then purified by column chromatography (silica gel, ethyl acetate/petroleum ether 1:1) ($R_f = 0.4$). Yield: 85 %. For elemental analysis and NMR and IR data, see the Supporting Information.

Complex **5a**: Monomer **5** (1 g, 3.6 mmol) was added to a stirred aqueous solution of β-CD (40 wt %; 7.2 g of β-CD in 10.8 mL of doubly distilled water). The molar ratio of monomer **5** to β-CD was 1:1.5.

Polymer **6**: Monomer **5** (1 g, 3.6 mmol) was added to a stirred aqueous solution of β-CD (40 wt %). After the solution had been flushed with argon for 20 min, a mixture of potassium peroxodisulfate (24.3 mg) and sodium disulfite (17.1 mg, 2.5 mol %) was added. The polymerization was carried out at room temperature for 12 h. The synthesized polymer was purified by several precipitation cycles in a low concentrated sodium chloride solution first from the crude solution and then from methanol. NMR and IR data are given in the Supporting Information.

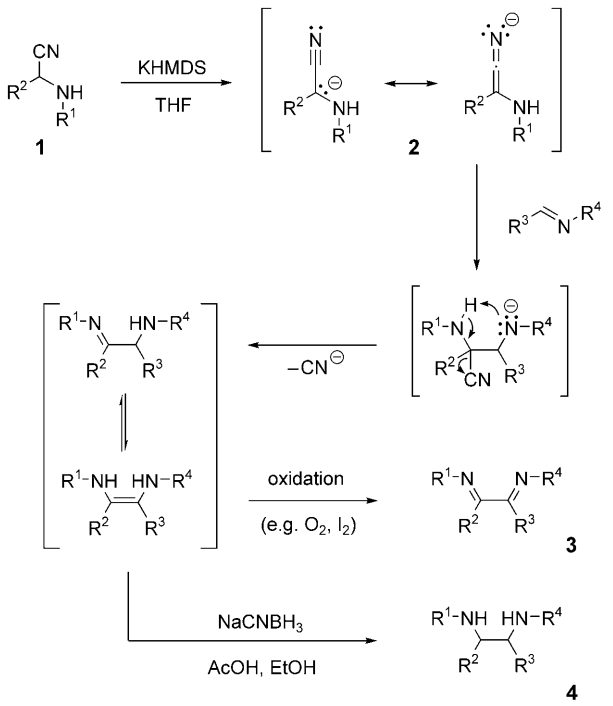
Cross-Couplings



DOI: 10.1002/anie.200501705

An Aldimine Cross-Coupling for the Diastereoselective Synthesis of Unsymmetrical 1,2-Diamines**

*Coralie Kison, Nino Meyer, and Till Opatz**

Procedures for the reversible umpolung of the natural reactivity of functional groups are valuable additions to organic chemists' repertoire of methods.[1–3] One of the most prominent examples of such a reversal of polarity is the benzoin condensation, in which an electrophilic aromatic aldehyde is converted into a CH-acidic cyanohydrin, and hence a pronucleophile, by addition of cyanide. Because of the fast reversibility of cyanohydrin formation under the basic reaction conditions, the addition of the α-deprotonated cyanohydrin to an aldehyde cannot be used for the selective preparation of unsymmetrical benzoins. To assign unambiguous roles to the reactants during the course of the reaction, the temporary introduction of a hydroxy protecting group is necessary.[4] While the OH acidity of cyanohydrins is higher or at least equal to their CH acidity, the CH acidity of α-aminonitriles should surpass their NH acidity. This holds true in particular for Strecker products derived from aromatic aldehydes. Therefore, it should be possible to convert *N*-mono- and *N*-unsubstituted α-aminonitriles into their conjugate anions avoiding the base-induced elimination of HCN (retro-Strecker reaction).

Indeed, α-aryl-substituted aminonitriles yield the ketene iminates **2** upon deprotonation with potassium hexamethyldisilazide (KHMDS; Scheme 1), while lithium bases such as LDA lead to deprotonation at nitrogen and thus to the irreversible retro-Strecker reaction. Only *N*,*N*-disubstituted α-aminonitriles can be converted into stable lithium salts, which may be used as acylanion equivalents.[5–8] In contrast to these and other α-amino-substituted carbanion equivalents,[9] the ketene iminates **2** have the advantage that after their addition to an electrophile, no additional deprotection steps are necessary to liberate the amino function. The cyano group can be removed from the addition products under mild conditions,[10] thus rendering these ketene iminates easily accessible α-amino carbanion equivalents bearing a variable N substituent.[11] Upon addition of the carbanions **2** to imines, amide ions are formed which undergo an intramolecular

Scheme 1. Mechanism of the diamine synthesis.

elimination of cyanide, finally yielding α-aminoimines or the tautomeric enediamines (Scheme 1).

The course of the reaction is similar to that of the aldimine coupling, the aza analogue of the benzoin condensation, which requires only catalytic amounts of cyanide but does not allow the selective cross-coupling of two different imines.[12–16] Oxidative workup of the reaction mixture by addition of iodine or oxygen yields diimines **3**, which can serve as starting materials for the preparation of highly substituted imidazolium salts or nucleophilic carbenes.[17,18] On the other hand, the one-pot reduction of the addition products with sodium cyanoborohydride in the presence of acetic acid leads to the formation of the diamines **4** (Table 1). In accordance with a chelated transition state, the *anti*-configurated products are predominantly formed, albeit with low diastereoselectivity: At best, an *anti*/*syn* ratio of 4.3:1 was observed. The relative configuration of the main products could be determined based on the reported characteristic ^{1}H and ^{13}C chemical shifts of vicinal diamines as well as the NOE data of the diastereomeric formaldehyde aminals of the diamines **4a** and **4m**.[19–22]

In attempts to improve the diastereoselectivity of the reduction, we found that the reaction of the pure diimines **3** with BH_3·THF containing $NaBH_4$ furnishes preferentially the *syn*-configurated diamines **4** in quantitative yield (Table 2, Method A). Compounds of this type may be applied as combinatorially diverse pseudo-C_2-symmetric N,N ligands for asymmetric aldol reactions,[23] dihydroxylations,[24] and reductions.[25] If, on the other hand, phthalic acid is added to the reaction mixture instead of $NaBH_4$ (Table 2, Method B),[26] the reduction of the diimines yields the *anti*-configurated products.[27]

[a] Method A: BH_3·THF, $NaBH_4$; Method B: BH_3·THF, phthalic acid. [b] Overall yield after chromatographic purification of the diimine. The reduction is quantitative.

Compared to other methods[28] that employ the attachment of amino groups to preexisting carbon frameworks such as alkenes,[29,30] aziridines,[31] epoxides,[32] and diols,[33] the selective aldimine cross-coupling has the advantage that a single regioisomer is formed independent of the substitution pattern of the reactants. The reaction sequence does not require protecting-group operations and can be performed in one pot. In addition, either the *syn*- or *anti*-configurated vicinal diamine can be obtained, depending on the choice of the workup and reduction conditions. Therefore, the aldimine cross-coupling represents a simple and flexible method for the synthesis of a class of highly substituted unsymmetrical 1,2-diamines, of which only a few members are known.

Experimental Section

Diamines **4** (general procedure): To a stirred solution of the aminonitrile **1** (1.7 mmol) in anhydrous THF (1.5 mL) was added a solution of KHMDS (373 mg, 1.87 mmol) in anhydrous THF (2 mL) at −50 °C under an argon atmosphere. After 3 min, a solution of the imine (1.7 mmol) in anhydrous THF (1 mL) was added, and the reaction mixture was allowed to warm up to −20 °C within 100 min. Solid $NaCNBH_3$ (427 mg, 6.8 mmol) was added to the solution followed by a mixture of acetic acid (0.6 mL, 10.5 mmol) and ethanol (6.4 mL, 109 mmol). The reaction mixture was stirred overnight at room temperature. After addition of ethyl acetate (40 mL) and phase separation, the organic layer was washed several times with 1N NaOH and finally with brine and dried over Na_2SO_4, and the solvent was removed in vacuo. The product was purified by preparative thin-layer chromatography.

For the preparation of the diimines **3**, the argon atmosphere was replaced by air when the reaction mixture reached −20 °C. The solution was allowed to warm up to room temperature, and after extraction with ethyl acetate and washing with brine, the product was isolated in analogy to the procedure described for the diamines **4**.

Analytical data of **4b** (mixture of diastereomers, *anti*/*syn* 1.3:1): weakly reddish solid, R_f (silica gel 60; cyclohexane/EtOAc 10:1 + 1% $EtNMe_2$): 0.70. ^{1}H NMR (300 MHz, $CDCl_3$), COSY, HMQC, HMBC: $\delta = 7.34$–6.56 (m, 44H, *anti* + *syn*), 6.40 (pseudo-d, 2H, aniline-2,6-H *syn*, $J_{app} = 8.5$ Hz), 6.31 (pseudo-d, 2H, aniline-2,6-H *anti*, $J_{app} = 8.5$ Hz), 4.58 (s, 1H, Ph_2CH *anti*), 4.56 (s, 1H, Ph_2CH *syn*), 4.45 (d, 1H, 1-H *anti*, $J = 5.3$ Hz), 4.30 (d, 1H, 1-H *syn*, $J = 7.5$ Hz), 3.88 (d, 1H, 2-H *anti*, $J = 5.3$ Hz), 3.63 (d, 1H, 2-H *syn*, $J = 7.5$ Hz), 2.17 (s, 3H, Ph-CH_3 *syn*), 2.15 ppm (s, 3H, Ph-CH_3 *anti*). ^{13}C NMR, DEPT (75.5 MHz, $CDCl_3$), HMQC, HMBC: $\delta = 145.2$ (aniline-C1 *syn*), 144.5 (aniline-C1 *anti*), 144.1 (2C), 142.9, 142.4, 140.0, 139.9, 139.2, 138.6, 132.8, 132.6, 129.5–126.6 (partly overlapping signals), 114.0 (2C, aniline-C2,6 *syn*), 113.6 (2C, aniline-C2,6 *anti*), 65.6 (C2 *syn*), 64.4 (C2 *anti*), 63.9 (C1 *syn*), 63.5 (Ph_2CH *anti*), 63.4 (Ph_2CH *syn*), 62.5 (C1 *anti*), 20.3 ppm (2C, Ph-CH_3). IR (NaCl, film): $\tilde{\nu} = 3405$ (m, NH), 3347 (m, NH), 3060 (m), 3026 (m), 2917 (m), 2863 (m), 1616 (m), 1519 (s), 1490 (s), 1453 (m), 1090 (m), 700 (s) cm^{-1}. FD-MS: *m*/*z* (%) = 230.4 (16) [Cl-PhCH=NHPh-CH_3]$^+$, 231.4 (2), 232.4 (7), 272.5 (42) [Ph_2CH-NH=CHPh]$^+$, 273.5 (9), 503.0 (100) [*M*+H]$^+$, 504.0 (44), 505.0 (37), 506.0 (10). ESI-HRMS: calcd for [$C_{34}H_{31}ClN_2$+H]$^+$: 503.2254, found: 503.2246.

Reduction of the diimines **3** (Method A): To a stirred solution of the diimine **3** (0.5 mmol) in anhydrous THF (4 mL) was added solid $NaBH_4$ (9.5 mg, 0.25 mmol) under argon atmosphere, and the mixture was cooled to 0 °C. A fresh solution of BH_3·THF (0.75 mL, 1M in THF) was added, and stirring was continued for 30 min at 0 °C and for a further 15 h at room temperature. After addition of ethanolamine (0.5 mL), the mixture was stirred for 3–18 h and partitioned between ethyl acetate and water. The organic layer was washed with water and dried over Na_2SO_4, and the solvent was removed in vacuo.

Reduction of the diimines **3** (Method B): A stirred solution of the diimine **3** (0.5 mmol) and phthalic acid (166 mg, 1 mmol) in anhydrous THF (4 mL) was cooled to −20 °C under argon atmosphere.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

After addition of a BH_3·THF solution (1 mL, 1M in THF), the mixture was gradually warmed to room temperature, and stirring was maintained for a further 15 h. The workup procedure and the isolation of the product were performed as described for Method A.

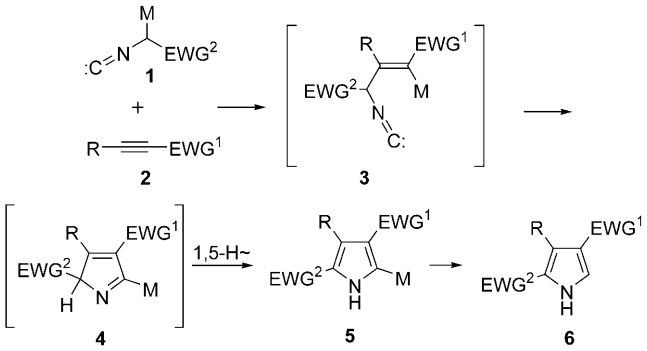
Versatile Direct Synthesis of Oligosubstituted Pyrroles by Cycloaddition of α-Metalated Isocyanides to Acetylenes**

*Oleg V. Larionov and Armin de Meijere**

Dedicated to Professor Rolf Huisgen on the occasion of his 85th birthday



Oligofunctional pyrroles play a pivotal role among five-membered heterocycles, being basic constituents of numerous natural products,[1] potent pharmaceuticals,[2] molecular sensors, and devices.[3] We envisaged that formal cycloaddition of an α-metalated isocyanide **1** across a C–C triple bond in an electron-acceptor-substituted acetylene **2** (Scheme 1) might furnish a transient 2*H*-pyrrole **4**, which would undergo a 1,5-hydrogen shift and protonation to give a 2,3,4-trisubstituted pyrrole **6**. Although a number of pyrrole syntheses[4] from alkenes and isocyanides via pyrrolines, which contain a leaving group appropriate for elimination, have been described,[5] a direct access to pyrroles from acetylenes has been elusive so far.[6]

Methyl isocyanoacetate (**7a**) and methyl cyclopropylpropiolate (**8**-Me) were chosen for a test reaction, because the expected cyclopropyl-substituted pyrroles would supplement other cyclopropyl-substituted heterocycles, which are relevant for the pharmaceutical industry[7] (Scheme 2). Screening of various reaction conditions (Table 1) showed that most of
