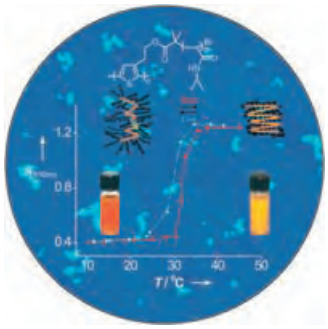
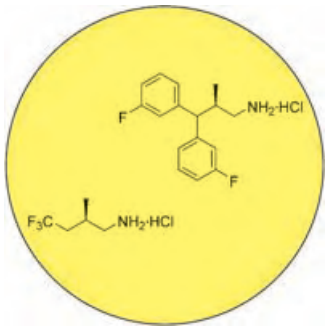
Cover Picture



Gopakumar Gopalakrishnan, Jean-Manuel Segura, Dimitrios Stamou, Cédric Gaillard, Marinela Gjoni, Ruud Hovius, Kurt J. Schenk, Pierre A. Stadelmann, and Horst Vogel*



Nanoscopic optical fibers of $CdCl_2 \cdot 4H_2O$ have been synthesized using multilamellar lipid membranes as templates. The cover picture shows a scanning electron micrograph of the nanowires in the background and, from left to right, the synthetic route and the optical waveguiding properties of the nanowires. The center of the nanowire is excited at 488 nm (green laser), and orange light is emitted from the other end. For more details, see the Communication by H. Vogel and co-workers on page 4957 ff.

Cucurbit[n]urils
The Review by L. Isaacs and co-workers on page 4844 ff. introduces the synthesis and properties of the macrocyclic family of cucurbit[*n*]urils. The benchmark for possible applications in molecular recognition is the host–guest chemistry of cyclodextrins.

Thermochromic Polymers
The exceedingly high water-solubility and unique thermochromic behavior of a molecular brush copolymer composed of a polythiophene main chain and polyacrylamide side chains is described in the Communication by R. L. McCarley et al. on page 4872 ff.

Asymmetric Hydrogenation
A ruthenium–phosphate complex catalyzes the asymmetric hydrogenation of allylphthalimides. X. Zhang and co-workers describe on page 4933 ff. the efficient synthesis of β-methylamines.

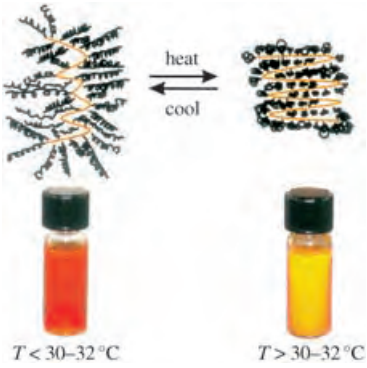
Reviews

Is there anything cucurbituril can't do? With the cucurbit[*n*]uril family (see space-filling models of some examples) growing to include homologues, derivatives, congeners, and analogues, the tentative answer looks to be "No". The aim of the Review is to convince the reader of this optimistic assessment.



Host–Guest Systems

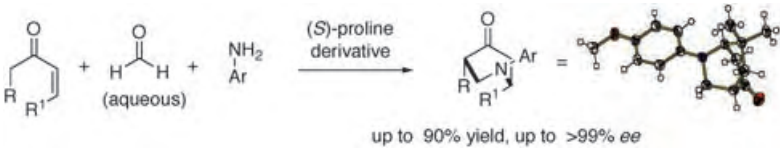
The Cucurbit[*n*]uril Family

Communications



A brush with success: Responsive brushes composed of poly(*N*-isopropylacrylamide) grafted onto a poly(thiophene) backbone display the highest water solubility ever reported for a neutral poly(thiophene) as well as temperature-dependent optical properties and water solubilities (see picture). The graft polymer exhibits shifts in the π–π* transition of the poly(thiophene) backbone near the collapse temperature of the poly(*N*-isopropylacrylamide) chains.

Thermochromic Polymers

Giving in to templation: Coordination of acid-functionalized $\{Ru(tpy)_2\}^{2+}$ units (tpy = 2,2′:6′,2″-terpyridine) to a tetracarboxylato rhodium dimer leads to multinuclear polypyridylruthenium(II) complexes (see crystal structure, orange: Ru, purple: Rh, blue: N, red: O). Efficient energy transfer from the Ru-based MLCT levels to the lower-lying level involving the Rh dimer takes place at room temperature.

Energy Transfer

M. W. Cooke, G. S. Hanan,* F. Loiseau, S. Campagna,* M. Watanabe, Y. Tanaka* ——— **4881 – 4884**

The Structural and Functional Roles of Rhodium(II)–Rhodium(II) Dimers in Multinuclear Ruthenium(II) Complexes

A question of orientation: The self-assembly of a dialkynylene-bridged zinc pyridylporphyrin dimer with rotational freedom preferentially leads to a cyclic tetramer consisting of the perpendicular conformer (⊥), rather than the more usual planar conformer (//, see picture). This preference most likely arises from an efficient cancellation of dipole moments in the self-assembled structure.

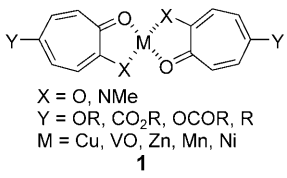
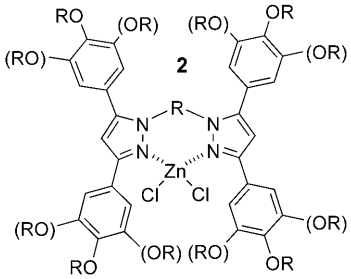
Metallomesogens**



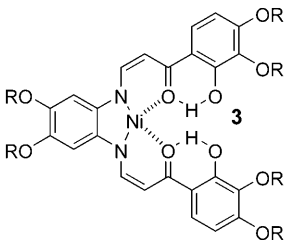
Stuart J. Rowan*

Over the past 25–30 years there has been significant growth in the area of metal-complex-containing liquid crystals (metallomesogens).[1] The incorporation of a metal ion into a mesogenic system offers the possibility of developing new materials with properties imparted by the metal component, such as magnetic, electrical, and optical properties. Furthermore, the wide range of coordination numbers and geometries that can be accessed through the metal component, along with the variety of known organic ligands offer a wealth of opportunities for the geometric design of new mesogenic materials. The design of liquid-crystalline materials which contain metal ions is not a facile process. Nonetheless, over the years a wide range of mesogenic systems that incorporate metal ions from all over the periodic table have been designed and developed. As a result, an assortment of liquid-crystalline phases (both thermotropic and lyotropic) can be accessed with metallomesogens.



The last day of May 2005 saw the opening of the 9th International Symposium on Metallomesogens in Lake Arrowhead, California. The meeting was chaired by Gerald Van Hecke of Harvey Mudd College in California. In addition to Van Hecke, the organizing committee included Robert Bachman (The University of the South), Lee Park (Williams College), Eric Scharrer (University of Puget Sound), and Jodi Wesemann. This group put together an outstanding international program that included not only researchers working in the field of metallomesogens but scientists interested in a range of related topics as well. These areas included organic liquid crystals, organic–inorganic soft materials, and ordered inorganic networks and materials. As such, the four-day conference allowed scientists from a range of different disciplines to share their own perspectives in the development of new ordered organic–inorganic hybrid materials.

One of the themes discussed was the development of new classes of metallomesogens that expand on the type of ligands and/or metal ion combinations which allow access to such materials. Akira Mori (Kyushu University) outlined the potential of troponoid cores as ligands in the formation of metallomesogens **1**, and Emma Cavero (University of Zaragoza) discussed the investigation of a series of metal-bound pyrazole-based ligands such as **2**. Jadwiga Szydlowska (Warsaw University) showed that the tetradentate enaminoketone-based ligand could be used to form a variety of metallomesomorphic materials **3** upon binding to Ni^{II} or Cu^{II} metal ions. The incorporation of more-complex metal structures into liquid-crystalline materials was a challenge taken up by Eric Scharrer (University of Puget Sound). He showed that through the careful design of alkyne-based ligands, dicobalt hexacarbonyl complexes, such as **4**, do exhibit enantiotropic liquid-crystalline behavior.



A number of research groups reported on the development of metallomesogens which contain lanthanide ions. The incorporation of such metal ions, which can exhibit interesting luminescent and/or paramagnetic properties, into liquid crystals opens the door to the development of new ordered materials with unique physical properties. For example, Koen Binnemans (Katholieke Universiteit Leuven) discussed the design, synthesis, and material properties of lanthanide ions bound to a series of imidazole[4,5-f]1,10-phenanthroline-based ligands such as **5**. These materials, in which the mesogenic 4-cyanobiphenyl unit is attached, not only exhibit a nematic phase but are also highly luminescent in the solid state as well as in a solution of a nematic liquid-crystal host. Claude Piguet (University of Geneva) discussed the effect lanthanide contraction has on the thermotropic liquid-crystalline behavior of a series of lanthanide metal ion complexes **6**, which consist of a rigid terdentate ligand based on the bis(1-ethylbenzimidazol-2-yl)pyridine moiety.[2] The larger lanthanide ions (Ce–Nd) allow the formation of 10-coordinate complexes that favor the formation of bimetallic rodlike nitrato-bridged dimers in the solid state; as a result, lamellar columnar phases are observed. However, upon heating, the formation of a cubic phase is observed in these systems,

which is assigned to the formation of monometallic complexes. Across the lanthanide series, structural changes occur as a result of the contraction in ionic radius; a 9-coordinate system is favored with a smaller radius (Sm–Ho), and as a result, the formation of monometallic complexes is favored. Consistent with the previous system, these monometallic complexes form a body-centered cubic phase. A further decrease in radius (Er–Lu) yields hemi-disklike monometallic complexes, which are compact enough to result in the formation of a hexagonal columnar phase.

Metal–metal interactions in the formation of controlled structures and the alteration of functional properties (e.g. luminescence) was described in a number of talks. Mohammad Omary (University of North Texas) discussed the effect that aurophilic bonding (Au–Au) has on the structure and luminescent behavior of a series of isonitrile gold complexes (RNCAuX).[3] He described how different aggregated structures—from extended linear structures of Au atoms to simple dimers—could be obtained by changing the alkyl and/or halide groups attached to the Au^{I} metal ion. In general, compounds which form infinite chains of associated Au atoms exhibit low-energy emissions in the yellow-orange-red region, whereas compounds that associate as Au dimers exhibit higher-energy emissions in the blue-green region. Alice Bruce (University of Maine) discussed how initial investigations of these isonitrile gold complexes, in a collaboration with Omary, suggested that microcrystalline samples of cyclohexylgold(I) chloride exhibit liquid-crystalline behavior. Robert Bachman (The University of the South) discussed mesogenic materials in which Pt–Pt interactions play an important role in the functional properties of these systems. In particular, he focused on how such systems could be used in a diverse range of applications including LEDs and chemosensors.

A number of researchers discussed lyotropic organic–inorganic hybrid systems, with particular attention placed on the use of an organic surfactant to template the inorganic component. Sung Yeun Choi (University of Toronto) discussed the use of an amphiphilic triblock copolymer to template the formation of regular mesoporous thin films of titania that exhibit pore sizes of around 7–8 nm with narrow polydispersities. The electrochromic performance of such templated mesoporous titania that had been modified with viologen was also discussed. These materials showed electronic conductivity similar to that of viologen nanocrystalline titania, but with enhanced color contrast; this is at least partially due to the presence of the ordered mesoporous architecture.[4] John Seddon (Imperial College) discussed collaborative work with Duncan Bruce (University of Exeter) on the use of cationic ruthenium-based surfactants to template the formation of mesoporous silicates. Seddon reported recent work on the phase behavior of these lyotropic templates. After calcination the resulting mesoporous silicates contain RuO_2 particles and exhibit efficient heterogeneous catalytic behavior as a result.[5]

A number of talks focused on the formation of ordered materials with processes that either differ from or expand upon the more traditional liquid-crystalline approach. Dan Talham (University of Florida) discussed the use of supramolecular assembly at the air–water interface to form extended two-dimensional inorganic networks. For this, a Langmuir monolayer of the amphiphilic pentacyanoferrate(III) was allowed to react with appropriate metal ions such as nickel(II), present in the aqueous subphase (Scheme 1).[6] The resulting film consisted of an iron–nickel face-centered two-dimensional square grid network bridged by cyanide moieties, and could be transferred to solid supports by using conventional Langmuir–Blodgett film techniques. This allowed the systematic formation of multilayers of these interesting materials, and studies on how the magnetic behavior of these materials changes from monolayer through bilayer to multilayer were discussed. The formation of metal-containing organogels was described by A. J. Zucherro (The University of the South/Georgia Institute of Technology). The gel formation in these systems occurs through in situ complexation of a metal ion to a lipid of low molecular mass and which contains a Lewis base moiety. James Martin (North Carolina State University) discussed the formation of intermediate-range order in amorphous molten metal halide sys-

tems. To obtain such pseudo-structured materials, an approach analogous to that used for the templating of zeolites was investigated.[7] Structural networks can be obtained in metal halide melts such as $ZnCl_2$ through the addition of equimolar amounts of CuCl and a templating cation (A^+, for example, alkylammonium salts) designed to match the size of an integral number of chloride ions. Such halozeotypes, $A_n[Cu_nZn_{m-n}Cl_{2m}]^{n-}$ show the formation of organized network structures in the melt that persist over nanometer-length scales. The formation of controlled structures in other metal halide melts based on $GaCl_3$ and $GeCl_4$ were also discussed.

As can be seen from above, one of the goals of the organizing committee was to significantly broaden the scope of the symposium beyond its traditional focus on the synthesis and phase properties of thermotropic metal-containing materials. It was hoped by opening the meeting to a more diverse range of researchers with interests in metallosurfactants, metal-containing gels, and ordered liquids, that new synergisms and new research directions would be identified. The closing session of the meeting was a panel discussion designed to reflect on the relationship of some of these nontraditional topics to the core focus of the community and to identify some of the potential new directions for research. Wolfgang Haase (Darmstadt University of Technology) discussed the "four pillars" of the field—synthesis, properties, models, and applications—and noted that the first of these pillars is the most developed, while the second is rapidly growing. Some areas that he felt warrant significant study are the magnetic, electric, conductometric, and light-scattering properties of metallomesogens. He also noted the need for more deliberate feedback from the last two pillars in guiding future synthetic efforts. He specifically suggested that researchers in the field avoid thinking solely about nematics and display applications, for which organic materials are so well-developed; devices that take advantage of the color of metallomesogens or changes in physical properties in response to light should be promising future directions. Haase further noted that metals with their various oxidation states and positive or negative charges can be important components of polymers, supramolecular compounds, coordination compounds, catalysts, photonic devices using luminescence, nanomaterials, colloidal systems, and biological systems. All of these types of materials should fit within the scope of future meetings by using the broader context of soft materials with mesogenic-like properties.

Actinide Materials Adopt Curvature: Nanotubules and Nanospheres

*Thomas E. Albrecht-Schmitt**

Keywords:
actinides · cluster compounds · nanostructures · polyoxometalates · uranium

The structural chemistry of the actinides has undergone what can be described as nothing less than a revolution over the past decade. Indeed, the number of structurally characterized inorganic U^{VI} compounds reported has increased from approximately 180 examples in 1996 to over 355 in 2005.[1,2] The recent excitement over this rapidly expanding group of compounds might even be comparable to that felt during Zachariasen's early years of elucidating the structures of transuranium compounds.[3] One of the primary driving forces behind this transformation is the remarkable structural versatility of the actinides. In oxidation states of +III or +IV, the actinides are typically found in eight- or nine-coordinate environments, which are similar to those observed with lanthanide ions. However, when the oxidation state is raised to +V or +VI, the approximately linear triatomic actinyl unit AnO_2^{n+} (An = U, Np, Pu, Am; $n = 1$ or 2) is observed. This cation is bound by additional ligands that lie perpendicular to the actinyl axis to create six-, seven-, and eight-coordinate tetragonal, pentagonal, and hexagonal bipyramids, respectively. If sterically demanding ligands are introduced, the coordination number can be reduced to as low as three ligands in the equatorial plane to yield trigonal-bipyramidal complexes as found for $[Na(thf)_2][UO_2\{N(SiMe_3)_2\}_3]$.[4]

There is a definite predisposition of An^V and An^{VI} compounds to adopt layered structures, as a direct consequence of the condensation of actinyl-containing polyhedra typically perpendicular to the terminal actinyl unit to form extended structures.[1,2] One of the trends in recent actinyl chemistry has been to move away from layered structures and instead prepare compounds with one-dimensional topologies such as in $A_2[(UO_2)_3(IO_3)_4O_2]$ (A = K, Rb, Tl)[5] and three-dimensional open-framework compounds such as $(C_6H_{14}N_2)_2[(UO_2)_6(H_2O)_2F_2(PO_4)_2(HPO_4)_4]\cdot 4H_2O$,[6] $K_2[(UO_2)_2(VO)_2(IO_6)_2O]\cdot H_2O$,[7] and $(C_6H_{16}N)_2[(UO_2)_6(MoO_4)_7(H_2O)_2(H_2O)_2]$.[8] Discrete cluster compounds have lagged behind their higher-dimensional counterparts, but rich examples of organometallic U^V clusters such as $[Cp^*_4(U_6O_{13})(bpy)_2]$ ($Cp^* = 1,2,4$-tris(*tert*-butyl)cyclopentadiene; bpy = 2,2′-bipyridine), which contain an isopolyoxometalate core, have been reported.[9]

The importance of nanoscale structural features in actinide chemistry has been known since it was first recognized that Pu^{IV} forms colloids that are important in its mobility in the environment.[10,11] Furthermore, pulsed laser ablation of hydrated plutonium oxalate has been shown to generate cluster ions that contain up to 18 Pu atoms.[12] What has been lacking from the literature regarding the actinides are examples of nanoscale features in well-defined compounds. This lacuna has now been partially filled with the recent discoveries of actinide-based nanotubules[13] and nanospheres.[14]

The finding by Krivovichev et al. that the organically templated uranyl selenate $(C_4H_{12}N)_{14}[(UO_2)_{10}(SeO_4)_{17}(H_2O)]$ contains $[(UO_2)_{10}(SeO_4)_{17}(H_2O)]^{14-}$ nanotubules is the first report of its kind in uranyl chemistry.[13] These nanotubules are constructed from $\{UO_7\}$ pentagonal bipyramids and $\{SeO_4\}$ tetrahedra and are shown in Figure 1. These tubules are somewhat elliptical and have outer dimensions of $2.5 \times 2.3\ nm^2$. They have a free crystallographic diameter of 12.6 Å, which is on the same scale as large-pore zeolites.[15] Note that tubular features have been observed in other uranyl phases such as in $K_2[(UO_2)_2(VO)_2(IO_6)_2O]\cdot H_2O$,[7] in which elliptical channels are formed from $\{UO_6\}$, $\{VO_6\}$, and $\{IO_6\}$ octahedra. However, in this latter structure the tubules are fused to form a three-dimensional structure. In $(C_4H_{12}N)_{14}[(UO_2)_{10}(SeO_4)_{17}(H_2O)]$, however, the tubules are isolated from one another. A further intriguing feature of this structure is found by displaying a nodal representation of the walls of the tubules. This graph provides a topology for the walls with a ratio of U/Se of 10:17, which is an entirely new pattern for inorganic compounds.

One of the key questions addressed by the authors is the mechanism by which these tubules form. It is proposed that the butylammonium templates form self-assembled cylindrical micelles in solution. The UO_2^{2+} cations and SeO_4^{2-} anions then assemble around these micelles to yield the final nanotubules. Some important questions remain unanswered regarding these uranyl nanotubules: First, will these compounds undergo ion-exchange reactions without collapsing? Do they display a selectivity for certain cations? Also, do these compounds have any other zeolitic

properties? Can they be used to perform new (catalytic) chemistry?

Independent of the report by Krivovichev et al. on uranium-based nanotubules is an extremely important communication on the synthesis and structures of actinyl peroxide nanospheres by Burns et al.[14] It was observed that when alkaline peroxide solutions of U^{VI} and Np^{V} were allowed to stand in air for 7–14 days, crystals of actinyl peroxides formed. Single-crystal X-ray diffraction analyses of these crystals demonstrated that they contain actinyl peroxide nanospheres designated as U-24, U-28, U-32, and Np-24 according to the number of actinyl (U or Np) polyhedra in the clusters: example formulae for these compounds are $\{Li_6(H_2O)_8(NpO_2)(H_2O)_4[(NpO_2)(O_2)(OH)]_{24}\}^{20-}$ (Np-24) and $\{K_{16}(H_2O)_2(UO_2)(O_2)_2(H_2O)_2[(UO_2)(O_2)_{1.5}]_{28}\}^{14-}$ (U-28). The charges were balanced by additional alkali-metal cations. Interestingly with regards to these syntheses, the conditions described are relevant to those found in some nuclear waste tanks where basic conditions are prevalent and peroxide is generated by α radiolysis of water. It has already been demonstrated that natural radioactivity from uranium-bearing ores or nuclear waste may generate enough peroxide for the mineral studtite,[16] $[(UO_2)O_2(H_2O)_4]$, to form.[17] While the one-dimensional chain structure of studtite is of interest,[18] the structures of the actinyl nanospheres are simply astounding, being both aesthetically pleasing and nothing less than seminal (Figure 2).

These actinyl peroxide clusters have approximate diameters of 16.4 to 18.6 Å. The nanospheres are constructed from the edge-sharing of hexagonal-bipyramidal $\{AnO_8\}$ units. For U-24, U-32, and Np-24, the fundamental building unit is an actinyl cation bound by two edge-on peroxide groups and two hydroxide ligands, and can be formulated as $[(AnO_2)(O_2)_2(OH)_2]$. For the U-28 cluster, the UO_8 unit is formed from three edge-on peroxide anions and a uranyl cation to yield $[(UO_2)(O_2)_3]$. These clusters are hollow and may host both alkali-metal cations and partially occupied $[(UO_2)(O_2)_2(H_2O)_2]$ units. These nanospheres apparently form because of the short edge lengths on the hexagonal-bipyramidal units which are invoked by the O–O bond in the peroxide anions. While the U centers in U-24, U-28, and U-32 can be expected to contain U^{VI}, the same is not true for Np-24, which is apparently a mixed-valent species that contains both Np^{V} and Np^{VI}. Burns et al. utilized the Np=O bond lengths in the neptunyl units to assign the oxidation states on the Np centers. However, there was ambiguity concerning the Np center that occupies the center of the cluster. Of greater importance is the black coloration of Np-24 which indicates that the charges are not localized in the cluster; such charge-delocalization could lead to both interesting magnetic properties and electrochemical behavior.

A large number of prospects remain to be explored for these actinyl nanospheres. Small-angle X-ray scattering experiments demonstrate that these clusters are also present in solution; however, do they actually form in nuclear waste and how can they be detected? Can their hollow nature be exploit-

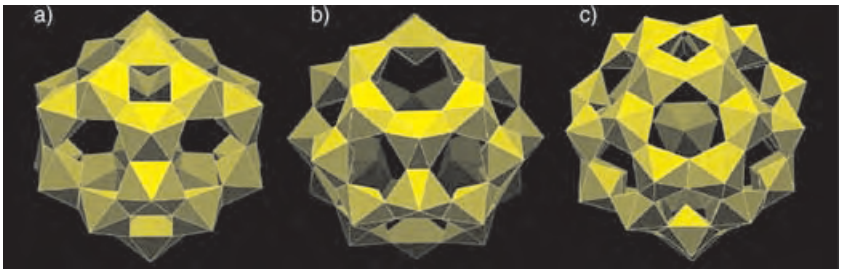

Figure 2. Polyhedral representations of actinyl peroxide nanospheres: a) U-24 and Np-24, b) U-28, and c) U-32. These nanospheres are constructed from UO_8 hexagonal bipyramids. For U-24, U-32, and Np-24, the fundamental building unit is an actinyl cation bound by two edge-on peroxide groups and two hydroxide ligands, and can be formulated as $[(AnO_2)(O_2)_2(OH)_2]$. For the U-28 cluster, the UO_8 unit is formed from three edge-on peroxide anions and a uranyl cation to yield $[(UO_2)(O_2)_3]$ units. Note the extremely short edges on these polyhedra invoked by the presence of O–O bonds.

ed for the transport and storage of other radionuclides, especially key fission products such as ^{90}Sr and ^{137}Cs? Do these compounds exhibit any of the important catalytic[19] and electrochemical[20] properties associated with polyoxometalates of Mo, W, and V? Answers to these questions will certainly underscore the importance of these actinyl nanospheres.

Aerogels from Semiconductor Nanomaterials

*Alexander Eychmüller**

Keywords:
aerogels · materials science · mesoporous materials · semiconductors · sol–gel process

In a recently published paper in Science[1] a remarkable wedding has been announced which unites two very active fields of current materials research: semiconductor nanocrystals and aerogels. The Wayne State University team of Mohanan, Arachchige, and Brock employs colloidally prepared II–VI (CdS, ZnS, CdSe) or IV–VI (PbS) semiconductor nanoparticles as building blocks for dry, mesoporous, high surface area, and light weight aerogels which form after solvent removal under supercritical conditions from the gelated material.

Semiconductor nanocrystals[2] have been the focus of research for about 20 years and have encountered interest over the years from such diverse disciplines as solid-state physics, inorganic chemistry, physical chemistry, colloid chemistry, materials science, and recently even biological sciences, medical sciences, and engineering. Narrow and intensive emission spectra, continuous absorption bands, high chemical and photobleaching stability, processability, and surface functionality are among the most attractive properties of these materials. The breath-taking development of "nanochemistry" is reflected in an immense number of publications on the synthesis of semiconductor nanoparticles. Nearly all II–VI semiconductors and many of the IV–VI compounds have been prepared in colloidal form, some of them in a variety of different approaches. A great number of these developments have been summarized in surveys, in special issues of journals, and in books.[3] The ability to achieve desired particle sizes over the largest possible range, narrow size distributions, good crystallinity, desired surface properties and—should the occasion arise—high luminescence quantum yields as well as adjustable electronic properties, are all considered to be characteristics of a "good preparation".

The properties of the semiconductor nanocrystals also known as quantum dots depend strongly on the type of nanocrystal, the size (quantum-confinement) and the capping agent, thus they can be tuned by a proper choice of the synthetic conditions. There is a wide range of very efficient light-emitting semiconductor nanocrystals which can be synthesized both in organic media or as aqueous solutions. Worthy of mention are CdS, CdSe, and ZnSe[4] (UV spectral region) CdSe, InP, CdTe[5] (visible light region), PbSe, HgTe, and InAs[6] (near-infrared and infrared region). Furthermore, phase transition pressures, melting points, optical and optoelectronic, catalytic, magnetic, and electrical properties of nanomaterials differ from those of the bulk as well as from those of the molecular species they consist of, a situation which is appealing both scientifically and for applications. Assemblies of nanoparticles have been formed by coupling the particles by linker molecules. The formation of bioconjugates has been performed by connecting the nanoparticles to biological material, for example, for the use as fluorescent labels. The build-up of complex nanoparticle superstructures has been demonstrated with a very elaborate concept using highly specific interactions between bound biological functional groups such as complementary DNA strands.[7]

The other field of research touched by the work of Brock et al. is that of aerogels[8] which was opened by Kistler as early as in 1931.[9] Even in his first Nature article on this class of materials he reported the successful preparation of aerogels from "*silica, nickel tartarate, stannic oxide, tungstic oxide, gelatine, agar, nitrocellulose, cellulose, and egg albumin*" and he saw "*no reason why this list may not be extended indefinitely*"! A small constraint to this optimistic statement was added by Kistler in a follow-up publication in 1932:[10] "*Rubber offered difficulties not yet surmounted, but the way has been indicated.*" In the early 1940s he completed a license agreement with industry for the production of silica aerogel and the commercialization of his ideas began. In the 1960s scientists started to consider them as a medium for storing liquid rocket fuel. Silica aerogels are nonflammable, nontoxic, lightweight, transparent, and thermally stable to about 650 °C. Organic aerogels have been made for their thermal capabilities and they are stiffer and stronger than silica aerogels. For aerogels containing a conducting skeletal material such as carbon, electronic conductivity is introduced into the material. Aerogels have continuous porosity, nanosized pores, and an extremely high surface area of up to 1000 m^2 per gram of material. Very recently, Leventis et al. reported[11] that the strength of silica aerogel monoliths has been improved by a factor of over 100 through cross-linking the nanoparticle building blocks of preformed silica hydrogels with a polymer (Figure 1). Additionally they showed that composite monoliths are much less hygroscopic than native

Figure 1. Strong silica aerogel resulting from cross-linking of the skeleton with a polymer.[11]

silica aerogels, and that they do not collapse when in contact with liquids.

Today, aerogels have broad applications in the commercial and military sectors, for example, as nanoporous thermal insulators, providing 3–10 times more thermal performance at a given thickness when compared to existing materials. Other reports stress the encapsulation capabilities of aerogels for bioactive molecules,[12] proteins, and even whole cells. Very promising is also the application of aerogels in the field of microphotonics.[13]

At this point it may have become more obvious why the paper from Brock and co-workers may be of such importance: by combining the properties of aerogels with those of semiconductor nanocrystals a new class of materials and new applications become accessible with possibly far reaching consequences. The monoliths prepared from CdS and ZnS have densities of between 0.07 and 0.35 $g\,cm^{-3}$ compared to the respective bulk values of 4.83 and 4.04 $g\,cm^{-3}$ and they contained mesopores of 2–50 nm in diameter. Most of the aerogels exhibit sharp absorption onsets at energies far above the respective bulk band gaps, thus, retaining their nanoparticle energetic features, namely the size quantization. This implies that the quantum dots remain electronically isolated which is attributed to the "fractal connectivity" of the network. This characteristic might be altered by post-preparative annealing of the structures which permits the absorption energy to be tuned to the red spectral region as the average crystallite size grows. The emission properties of the structures, however, are in need of considerable improvement: so far only weak and mainly trapped emission has been observed. In future efforts also pure band-to-band emission may be obtainable by using nanoparticles prepared by more elaborate synthetic routes such as, core–shell[14] or core–shell–shell[15] structures or nanocrystals with intrinsically stronger emission characteristics (Figure 2).[5d] Additionally, narrower distributions of nanocrystal sizes may be possible, which would lead to even sharper emission bands and consequently to purer colors.

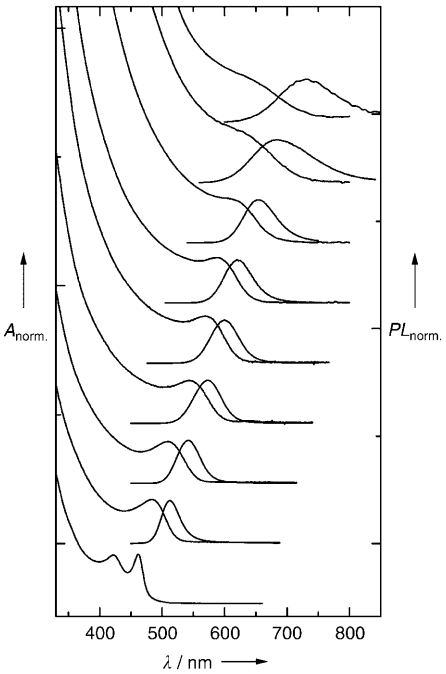

Figure 2. Absorption and emission spectra ($\lambda_{ex} = 400$ nm) of thiol-capped CdTe nanocrystals; *PL* = photoluminescence.[5d]

As optimistic as Kistler in his 1931 paper, Brock et al. state "*the generality of this method should lend itself to a number of new aerogel materials if the surface chemistry is appropriately tailored*". The latter can be agreed with completely and is largely based on the observations of Kotov, Peng, and others[16] that loss of particle-stabilizing molecules and/or photooxidation of surface ligands leads to aggregate formation in solution which is the basis of the production of robust gels.

Current efforts of the Wayne State team "*are devoted to preparing these materials in thin-film form and evaluating their potential for photovoltaic and sensing applications*". We are looking forward to many more papers on and possibly even applications of this door-opening synthetic route to materials combining two very topical areas of current materials research.

In 1981, the macrocyclic methylene-bridged glycoluril hexamer (CB[6]) was dubbed "cucurbituril" by Mock and co-workers because of its resemblance to the most prominent member of the cucurbitaceae *family of plants—the pumpkin. In the intervening years, the fundamental binding properties of CB[6]—high affinity, highly selective, and constrictive binding interactions—have been delineated by the pioneering work of the research groups of Mock, Kim, and Buschmann, and has led to their applications in wastewater remediation, as artificial enzymes, and as molecular switches. More recently, the cucurbit[n]uril family has grown to include homologues (CB[5]–CB[10]), derivatives, congeners, and analogues whose sizes span and exceed the range available with the α-, β-, and γ-cyclodextrins. Their shapes, solubility, and chemical functionality may now be tailored by synthetic chemistry to play a central role in molecular recognition, self-assembly, and nanotechnology. This Review focuses on the synthesis, recognition properties, and applications of these unique macrocycles.*

1. Introduction

In 1905—contemporaneous with the pioneering work of Schardinger on the cyclodextrins—Behrend et al. reported that the condensation of glycoluril (acetyleneurea) and formaldehyde in concentrated HCl yields an insoluble polymeric substance now known as Behrend's polymer.[1] Behrend et al. were able to obtain a crystalline substance in good yield (40–70%) by recrystallization of the product from concentrated H_2SO_4 and demonstrated its ability to form cocrystals (complexes) with a variety of substances including $KMnO_4$, $AgNO_3$, H_2PtCl_6, $NaAuCl_4$, congo red, and methylene blue. The constitution of this substance remained unclear until 1981 when Mock reinvestigated the report by Behrend et al., and disclosed the remarkable macrocyclic structure comprising six glycoluril units and twelve methylene bridges; they dubbed the compound cucurbituril in recognition of its resemblance to a pumpkin, the most prominent member of the *cucurbitaceae* family (Figure 1).[2] In this Review we refer to cucurbituril as cucurbit[6]uril and abbreviate this as CB[6] to distinguish it from cucurbit[*n*]uril (CB[*n*]) homologues containing a different number of glycoluril units.

In contrast to the host–guest chemistry of α-, β-, and γ-cyclodextrin which has developed steadily over the past century, the supramolecular chemistry of CB[6] only began to develop in the 1980s and 1990s as a result of the pioneering work of Mock,[3] Buschmann and co-workers,[4] and Kim and co-workers.[5,6] Interest in the CB[*n*] family has increased dramatically in the new millennium following the preparation of four new CB[*n*] homologues (CB[5], CB[7], CB[8], and CB[10]·CB[5]) by the research groups of Kim and Day.[7–9] CB[5]–CB[8] are now even available commercially. This increase in interest in the CB[*n*] family correlates with the great advances in many areas of fundamental and applied science—chemistry, biology, materials science, and nanotechnology—that rely on the ability to employ and control noncovalent interactions between molecules. Consequently, CB[6] and the CB[*n*] family have been the focus of numerous reviews[3,5,6,10–30] and patents.[30–48]

The pioneering work of Lehn, Cram, and Pedersen brought host–guest and supramolecular chemistry to the forefront of contemporary science.[49] The scientific insights gained from fundamental studies of noncovalent interactions have been of practical value in a wide range of applications including chromatographic stationary phases, sequestration of contaminants from solution, and the development of catalysts, chemical sensors, and new drugs. All of these applications require the availability of low-molecular-weight receptors,[50–52] natural or non-natural oligomers and polymers,[53,54] or solid-state materials[55–57] that interact with their analytes in high affinity, highly selective binding processes. In response, supramolecular chemists have designed, synthesized, and evaluated the recognition properties of a wide variety of non-

natural receptors—including cyclodextrins, calixarenes, cyclophanes, crown ethers, and many others—that display remarkable affinity and selectivity (Figure 2).[50–52] Amongst these non-natural receptors, α-, β-, and γ-cyclodextrin remain the

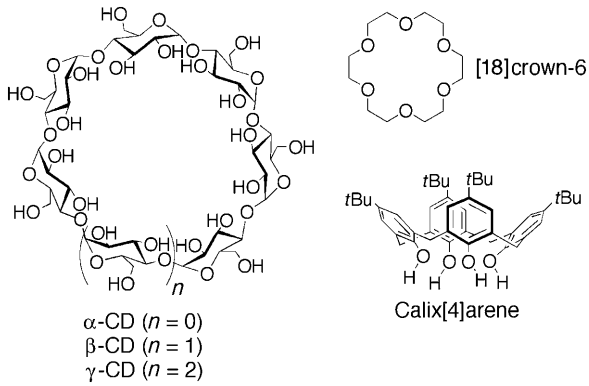

Figure 2. Structural formulas of α-, β-, and γ-cyclodextrin, [18]crown-6, and a calix[4]arene.

receptors of choice for industrial applications—despite a range of potential limitations which include low affinity, low selectivity, and challenges in their selective functionalization—because they are commercially available and inexpensive.

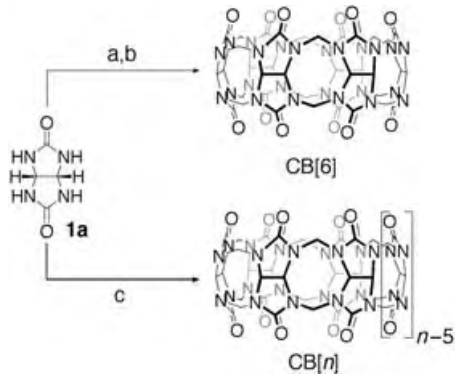
In this Review we trace the development of the supramolecular chemistry of CB[6] from its early days when it was plagued by issues—including poor solubility in aqueous and organic media, a lack of a homologous series of different sized hosts (for example, CB[*n*]), and an inability to access CB[*n*] derivatives and analogues by tailor-made synthetic procedures—to the present day when the CB[*n*] family is emerging as an outstanding platform for fundamental and applied molecular recognition and self-assembly studies. We, and others, believe that the CB[*n*] family is even poised to compete with the cyclodextrins as the platform of choice in industrial-scale applications. Today, the CB[*n*] family has overcome all of these early issues and currently possesses a confluence of properties that suggest their high potential in nanotechnology as components of molecular machines. These properties now include: 1) commercial availability in four different sizes, 2) binding interactions of high affinity, 3) high selectivity of binding, 4) synthetic control over size, shape, and functional-group placement, 5) high structural integrity, 6) solubility in both organic and aqueous solution, 7) association and dissociation with controlled kinetics, and 8) control of the molecular recognition processes by suitable electrochemical, photochemical, and chemical stimuli.

First, we begin with a discussion of the synthesis of CB[*n*] as well as their fundamental chemical and physical properties. Second, we present the recognition properties of the CB[*n*] family. In this section we emphasize the behavior of the most widely studied cucurbit[*n*]uril, CB[6], with an emphasis on those aspects of its recognition behavior—protonation, metal binding, selectivity based on size, shape, and charge, and the mechanism of binding—that are likely to apply universally to the CB[*n*] family. Third, we discuss the use of chemical, photochemical, and electrochemical stimuli to control recognition processes within CB[*n*]. Fourth, we discuss some applications of the CB[*n*] family in areas including catalysis,

Lyle Isaacs was born in New York City. After obtaining a BS from the University of Chicago (1991) he joined the group of Prof. François Diederich at the University of California, Los Angeles and then the ETH, Zürich. He was awarded the Silver Medallion of the ETH for his doctoral dissertation (1995). After a postdoctoral fellowship with Prof. George Whitesides at Harvard, he joined the faculty in the Department of Chemistry and Biochemistry at the University of Maryland, College Park in 1998 and was promoted to Associate Professor in 2004. His research interests focus on self-assembly, self-sorting, cucurbit[n]urils, and molecular clips.

Pritam Mukhopadhyay was born in Calcutta, India and obtained his BS and MS from the University of Calcutta and the University College of Science and Technology, respectively. He received his PhD from the Indian Institute of Technology, Kanpur in 2002 under the guidance of Professor Parimal K. Bharadwaj. He is currently a postdoctoral fellow with Professor Isaacs working on self-sorting systems involving cucurbit[n]urils.

Jason Lagona was born in Rochester, New York and earned his BS in Chemistry from the University of Maryland, College Park in 1999. He is currently pursuing his PhD with Professor Isaacs on the synthesis and applications of cucurbit[n]uril analogues.



Sriparna Chakrabarti was born in Calcutta, India and obtained her BS and MS from the University of Calcutta and the University College of Science and Technology, respectively. She received her PhD from the Indian Institute of Technology, Kanpur under the guidance of Professor Hiriyakkanavar Ila. She is currently a postdoctoral fellow with Professor Isaacs working on cucurbit[n]urils.

self-assembled monolayers, waste-stream remediation, DNA binding, gene transfection, and ion channels. Next, we discuss the use of the various CB[*n*] as components of molecular necklaces, rotaxanes and psuedorotaxanes, supramolecular amphiphiles, and self-sorting systems generated by self-assembly processes in solution and by crystal engineering in the solid state. Lastly, we discuss some mechanistic aspects of CB[*n*] synthesis based on our studies of the methylene-bridged glycoluril dimer as a model system and show how these insights lead to the synthesis of CB[*n*] derivatives, analogues, and congeners.

2. Synthesis of CB[n]

In the condensation of glycoluril (**1a**) and formaldehyde, neither Behrend et al. nor Mock detected any macrocyclic compounds (homologues) composed of a different number of glycoluril rings (for example, CB[5], CB[7], and CB[8]). It was not until nearly 20 years later when this reaction was conducted under milder, kinetically controlled conditions by the research groups of Kim and Day that CB[5]–CB[8] and CB[5]@CB[10] were detected and isolated (Scheme 1).[7–9,58]

Scheme 1. Synthesis of CB[6] from **1a** under forcing conditions and a mixture of CB[n] under milder conditions. a) CH_2O, HCl, heat; b) H_2SO_4; c) CH_2O, HCl, 100 °C, 18 h.

3. Fundamental Properties of CB[n]

3.1. Dimensions

CB[*n*] are cyclic methylene-bridged glycoluril oligomers whose shape resembles a pumpkin. Figure 3 shows the X-ray crystal structures for CB[5]–CB[8] and CB[5]@CB[10]. The cavity of CB[6] in the solid state contains three H-bonded H_2O molecules which can be released upon guest binding. The defining features of CB[5]–CB[10] are their two portals lined by ureido carbonyl groups that provide entry to their hydrophobic cavity.[59] Similar to the cyclodextrins, the various CB[*n*] have a common depth (9.1 Å), but their equatorial widths, annular widths *a*, and volumes vary systematically with ring size (Table 1). The portals guarding the entry to CB[*n*] are approximately 2 Å narrower than the cavity itself which results in constrictive binding that produces significant steric barriers to guest association and dissociation.[60] The cavity sizes available in the CB[*n*] family span and exceed those available with the cyclodextrins.

3.2. Solubility, Acidity, and Stability

One of the potential limitations of the CB[*n*] family is their relatively poor solubility in water: CB[6] and CB[8] are essentially insoluble, whereas CB[5] and CB[7] possess modest solubility in water (Table 1). The solubility of the CB[*n*] family is generally lower than the cyclodextrins. Like urea itself, however, the carbonyl groups lining the portals of CB[*n*] are weak bases: the pK_a value of the conjugate acid of CB[6] is 3.02. Although the pK_a values for CB[5], CB[7], and CB[8] have not been measured, they are likely to be similar to that of CB[6]. Accordingly, the solubility of CB[5]–CB[8] increase dramatically in concentrated aqueous acid (for example, 61 mM for CB[6] in HCO_2H/H_2O (1:1), about

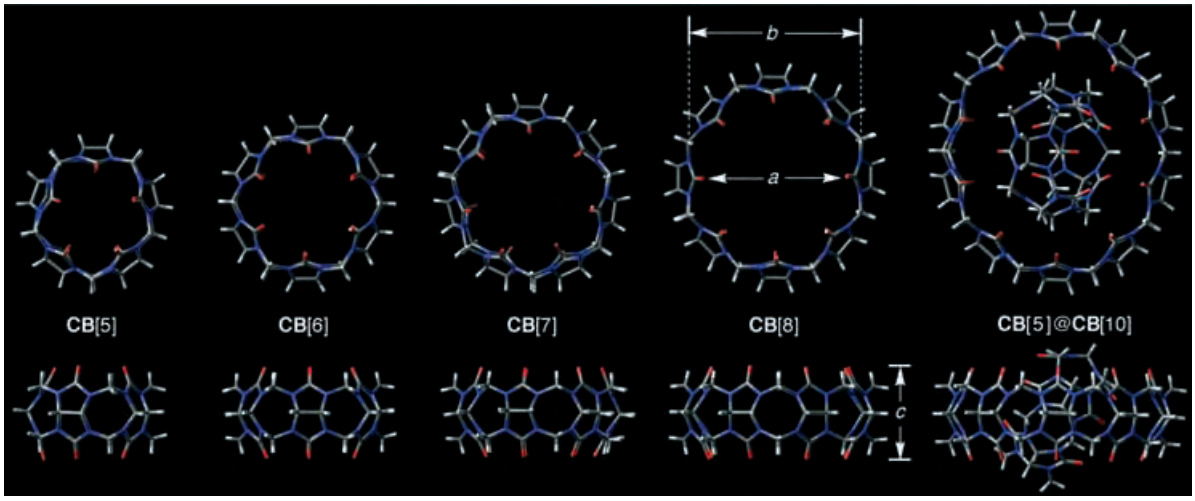

Figure 3. Top and side views of the X-ray crystal structures of CB[5],[7] CB[6],[2] CB[7],[7] CB[8],[7] and CB[5]@CB[10].[9] The various compounds are drawn to scale.

[a] The values quoted for a, b, and c for CB[*n*] take into account the van der Waals radii of the relevant atoms. [b] Determined from the X-ray structure of the CB[5]@CB[10] complex.[9]

60 mM for CB[5], about 700 mM for CB[7], and about 1.5 mM for CB[8] in 3 M HCl).[66–68] One of the outstanding features of CB[5]–CB[8] is their high thermal stability: thermal gravimetric analysis shows this to exceed 370 °C in all cases.

3.3. Electrostatic Potential

Electrostatic effects can play a crucial role in molecular recognition events in both aqueous and organic solution.[69] Figure 4 shows the electrostatic potentials of β-CD and CB[7]. Clearly, the electrostatic potential at the portals and within the cavity of CB[7] is significantly more negative than for β-CD. This difference in electrostatic potential has significant consequences for their recognition behavior: CB[*n*] exhibit a pronounced preference to interact with cationic guests whereas β-CD prefers to bind to neutral or anionic guests.

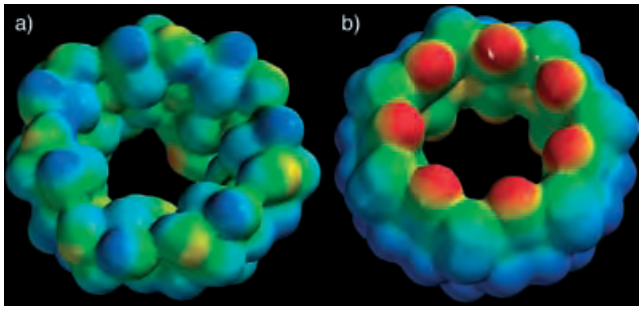

Figure 4. Electrostatic potential maps for a) β-CD and b) CB[7]. The red to blue color range spans −80 to 40 kcal mol^{-1}. Adapted from Kim and co-workers.[5]

4. Host–Guest Chemistry of CB[n]

The recognition properties of CB[6] are compared with those of α-CD and [18]crown-6 in this section. Many of the lessons learned from the chemistry of CB[6] can be generalized to the whole CB[*n*] family.

4.1 Comparison of the Thermodynamics of Complexation

Houk et al. recently reviewed the binding affinities for a wide variety of systems including synthetic host–guest, antibody–antigen, receptor–drug, and enzyme–substrate complexes.[70] The average binding affinity for 1257 α-, β-, and γ-CD complexes[71] ($K_a = 10^{2.5\pm1.1}$ M^{-1}) is an order of magnitude smaller and more narrowly distributed than the corresponding value for 973 synthetic host–guest pairs in water ($K_a = 10^{3.4\pm1.6}$ M^{-1}). A similar analysis using the 56 CB[6]·guest pairs reported by Mock and Shih[72] yields $K_a = 10^{3.8\pm1.5}$ M^{-1}. Table 2 compares the affinity of α-CD and CB[6] toward a series of alcohols, which are modest guests for both hosts. Despite its preference to interact with positively charged guests, CB[6] binds more tightly to the alcohols (except hexanol) than does α-CD although it does so in a nonselective manner. In general, CB[6] binds with higher affinity and higher selectivity toward its guest than do the cyclodextrins. A similar comparison between the affinity of CB[6] and [18]crown-6 toward several monovalent and divalent cations is given in Table 3. CB[6] shows higher affinity than [18]crown-6 toward all cations except Ba^{2+}, whose radius is a good match for the cavity of [18]crown-6. These examples are intended to illustrate that the binding ability of CB[6] generally equals or exceeds those of other well-known host molecules such as cyclodextrins and crown ethers.

Table 2: Calorimetrically determined log *K* values for the complexation of alcohols with CB[6] in HCO_2H/H_2O (1:1) at 25 °C and with α-CD in H_2O.[73,74]

4.2 Lessons Learned from CB[6]

Compared to CB[6], which recently celebrated its 100th birthday, the supramolecular chemistry of CB[5], CB[7], CB[8], and CB[10], which were isolated only 5 years ago, is relatively undeveloped. While these CB[*n*] homologues promise much new chemistry, many of the basic lessons learned from the studies of CB[6] can, we hypothesize, be transferred to CB[*n*]. This section presents those lessons from a largely mechanistic viewpoint: Scheme 2 depicts a comprehensive mechanism for the interaction of CB[6] with protons, metal ions, amines, and ammonium ions.

4.2.1. Protonation of CB[6] at the Carbonyl Groups Lining the Portals

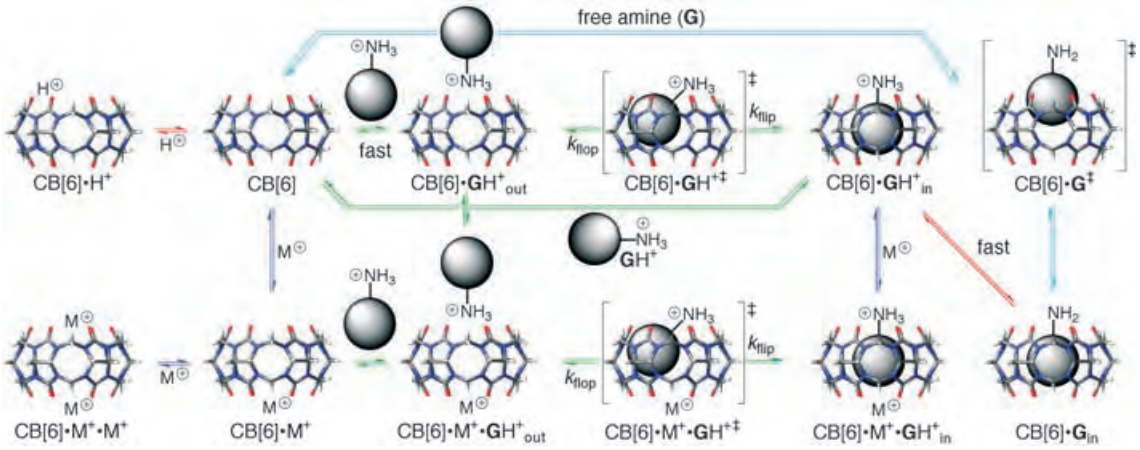
CB[6] is a weak base ($pK_a = 3.02$) that can be protonated in moderately acidic media. Accordingly, when binding studies are conducted with CB[6] in strongly acidic media (for example, HCO_2H/H_2O (1:1)) H^+ competes with guest binding (Scheme 2, red equilibria). Comparisons between binding constants measured in different media must, therefore, be treated with caution.

4.2.2. Binding of Metal Ions by CB[6]

Given that CB[6] binds H^+ at the ureido carbonyl groups of the portals, it is perhaps unsurprising that CB[6] also binds alkali-metal, alkaline-earth, transition-metal, and lanthanide cations in homogenous solution (Scheme 2, blue equilibria).[4,63,66,67,76–79] Table 3 shows the binding constants determined by Buschmann et al. for CB[6] with a variety of monovalent and divalent cations. The selectivity between the different cations is less than tenfold. The low selectivity observed and the lack of a simple trend in $\log K$ values is attributed to a mismatch between the ionic radii of the cations and the annular radius of the relatively rigid CB[6] ionophore (1.95 Å). The metal-binding equilibria (Scheme 2, blue equilibria) are in competition with protonation (red equilibrium); thus, as the acidity of the solution is increased the observed $\log K$ values for metal binding should decrease. Table 4 documents the decrease in the $\log K$ value of 2.4 units observed for CB[6]·Ba^{2+} upon changing the medium from water to water/HCO_2H (1:1).

Table 4: Calorimetrically determined log *K* values for the complexation of Ba^{2+} with CB[6] in HCO_2H/H_2O mixtures at 25 °C.[66,75]

HCO_2H/H_2O	50:50	40:60	30:70	25:75	0:100
log *K*	2.83	3.50	4.13	4.39	5.23



4.2.3. Preference of CB[6] for Positively Charged Organic Guests—Ion–Dipole Interactions

In their pioneering work, Mock and co-workers observed by a series of ^1H NMR competition experiments that alkylammonium ions bind tightly to CB[6] in HCO_2H/H_2O (1:1) and measured binding constants of 10^1–$10^7\ M^{-1}$. A selection of the results are given in Table 5.[2,72,80–82] Buschmann and coworkers have measured the corresponding thermodynamic parameters (ΔH and ΔS).[83] The experiments carried out by Mock and Shih were facilitated by two unusual characteristics

Table 5: Association constants measured for CB[6] with a variety of amines in H_2O/HCO_2H (1:1) at 40 °C.

of the host–guest complexes of CB[6]. First, the interior of CB[6] constitutes a ^{1}H NMR shielding region and upfield shifts of 1 ppm are common. The regions just outside the portals lined with carbonyl groups are weakly deshielding. Second, dynamic exchange processes between free and bound guest are often slow on the NMR time scale, thus allowing a direct observation of the free and bound guest simultaneously. To establish the importance of ion–dipole interactions relative to hydrogen bonds in the formation of CB[6] complexes (Figure 5), Mock and Shih considered the relative

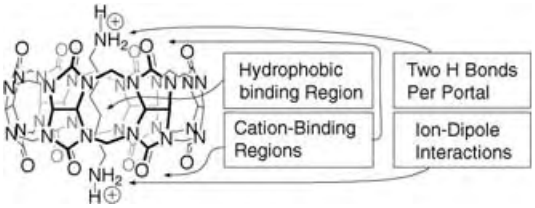

Figure 5. Representation of the different binding regions of CB[6] and the geometry of the complex between CB[6] and the hexanediammonium ion.

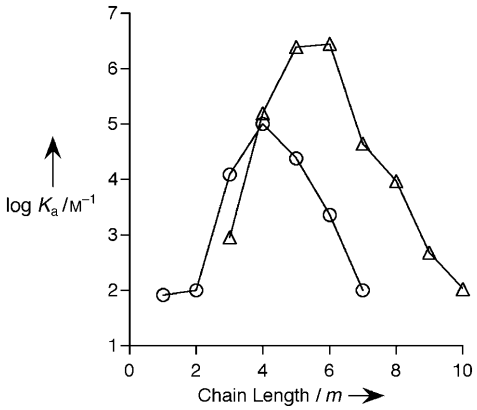
binding affinities of **2**–**4** (Table 4, entries 2–4). "Formal replacement of the terminal hydrogen of *n*-hexylamine with another amino group enhances binding 1200-fold. […] However, replacement of this hydrogen by a *hydroxyl* group contributes nothing to the stabilization of the complex. […] While the alcohol (and ammonium ions) may be hydrogen bonded in the complex, in the absence of CB[6] they would also be fully hydrogen bonded. […] The consequential feature of ammonium ions is that they are *charged*. […] Hence, it is our understanding that the high specificity for ammonium ions is largely an electrostatic *ion–dipole attraction*."[72] The preference of CB[6] for charged guests will transfer to the other members of the CB[*n*] family, but the relative importance of electrostatic interactions versus the hydrophobic effect may change as the cavity size increases. Blatov and coworkers recently developed a computational technique based on crystallographic data to identify suitable guests for each member of the CB[*n*] family.[84]

4.2.4. *Binding Selectivity of CB[6]*

The relative rigidity of CB[6] and the close juxtaposition of two binding regions that favor positively charged groups with one that favors hydrophobic residues imparts high selectivity to the binding of CB[6] (Figure 5). For example, Mock found that alkyl amines and alkane diamines exhibit length-dependent selectivity for CB[6]. Figure 6 shows a plot of the log K_a value versus chain length. CB[6] prefers butylamine relative to propylamine (8-fold) and pentylamine (4-fold) whereas pentanediamine and hexanediamine are preferentially bound relative to butanediamine (15-fold) and heptanediamine (64-fold). These high selectivities have been used to construct molecular switches (see Section 5.1). CB[6] is also size-selective: for example, it forms stable complexes with **6** and **7** whereas the three- and six-membered ring analogues **5** and **8** are rejected by CB[6] (Table 4, entries 5–8).



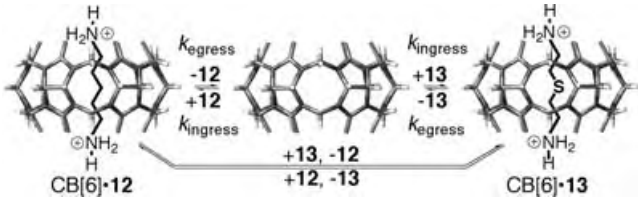


Figure 6. Relationship between the binding constant (log K_a) versus chain length m for $H(CH_2)_mNH_3^+$ (○) and $^+H_3N(CH_2)_mNH_3^+$ (△).

Similarly, CB[6] selects guests based on shape. For example, even though **7** and **9** have similar included volumes (86 versus 89 Å^3), the former binds 1000-fold more strongly (Table 4, entries 7 and 9).[60] Similarly, **9** is included within CB[6] whereas the *ortho* and *meta* isomers **10** and **11** are not bound (Table 4, entries 9–11). Lastly, CB[6] displays functional-group selectivity. For example, **12** binds 6-fold more tightly than **13**, which in turn binds 79-fold more tightly than **14** (Table 4, entries 12–14). Mock and Shih attribute this trend "to a solvation effect operating primarily on the uncomplexed guest; oxygen has greater intrinsic hydrophilicity than does sulfur, and a methylene group is more hydrophobic than is a thioether linkage."[72]

4.2.5. *Mechanistic Aspects of Association, Dissociation, and Exchange of Guests*

If CB[6] and other members of the CB[*n*] family are to become important components of molecular machines, it is critical that the factors controlling the kinetic and mechanistic aspects of their recognition behavior be thoroughly understood. In contrast to the behavior of most synthetic receptors in aqueous solution, CB[6] commonly displays slow kinetics of guest association, dissociation, and exchange on the NMR time scale. As discussed in Sections 4.2.1 and 4.2.2, CB[6] readily binds protons and metal ions at its portals that are lined with carbonyl groups. These equilibria compete with guest binding and lower the K_a value for guest binding accordingly (Scheme 2, red and blue equilibria).

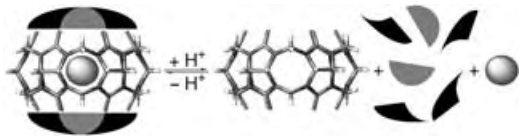
Mock and Shih initially investigated the kinetics of guest exchange[72,82] according to the two limiting mechanisms shown in Scheme 3: 1) an associative mechanism that resem-

Scheme 3. Associative and dissociative mechanisms for guest exchange.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

bles an S_N2 reaction, and 2) a dissociative S_N1-like mechanism. The kinetics of displacement, which can be followed by ^{1}H NMR spectroscopy, are first order in the CB[6]·**12** complex and independent of the concentration of the displacing guest which implies that the dissociative S_N1-like mechanism is followed. Values of k_{egress} range from $1.6\times10^{-5}\ s^{-1}$ (CB[6]·**7**) to $>10^2\ s^{-1}$ (CB[6]·**5**), which allowed the calculation of $k_{ingress}$ values of CB[6]·**7**: $5.5\ M^{-1}\ s^{-1}$; CB[6]·**5**: $>10^6\ M^{-1}\ s^{-1}$ based on a knowledge of the K_a value ($K_a = k_{ingress}/k_{egress}$). Interestingly, the rates of ingression *do not* correlate with values of K_a. Instead, the rates of ingression are influenced by the width of the guest (**7**: 5.7 Å) when that width exceeds the diameter of the portal of CB[6] lined with carbonyl groups (3.9 Å). Accordingly, significant deformation of the portals of CB[6] must occur in the transition state for ingression to allow access to its interior which raises its free energy and reduces the $k_{ingress}$ value. Although CB[6] is commonly regarded as being a rigid host, it is subject to deformation in the transition states during ingression and egression of the guests and even in the ground state of its complexes. For example, the X-ray crystal structure of CB[6]·4-Me$C_5H_4NH^+$ shows an ellipsoidal-shaped macrocycle that is elongated by 1.31 Å along the plane defined by the guest molecule.[86] Even larger deformations can be observed during molecular mechanics calculations of larger CB[*n*] complexes and even in the X-ray crystal structure of CB[5]@CB[10] which shows an ellipsoidal deformation of 2.1 Å.[9]

4.2.6. *Association and Dissociation Proceed via a Transiently Formed Exclusion Complex*



Mock and Shih recognized the possibility of two different modes of binding for an ammonium ion guest: the formation of an inclusion complex and an exclusion complex (for example, Scheme 2, CB[6]·**G**H^+_{in} and CB[6]·**G**H^+_{out}).[72] The equilibrium between those two isomeric complexes depends mainly on the size and shape of the attached alkyl groups. In a seminal study Knoche, Buschmann, and co-workers monitored the binding of **9**H^+ to CB[6] by UV/Vis measurements and found that the observed kinetic behavior could not be adequately explained by a simple equilibrium between CB[6], **9**H^+, and CB[6]·**9**H^+. Adequate modeling of the data requires the existence of two complexes: one in a fast pre-equilibrium with CB[6] and a second representing the spectroscopically observed inclusion complex CB[6]·**9**H^+_{in}.[4] Knoche, Buschmann, and co-workers proposed that the exclusion complex CB[6]·**9**H^+_{out} (shown in Scheme 2 as the general form CB[6]·**G**H^+_{out}) is the intermediate in fast pre-equilibrium. Nau and co-workers recently suggested that the transition state connecting the exclusion complex to the inclusion complex can be described by a flip-flop process (for example, Scheme 2, [CB[6]·**G**H^+]‡) in which the appended alkyl group pivots into the cavity without breaking its N-H···O hydrogen bonds.[60,85]

4.2.7. *pH-Dependency of the Transition States*

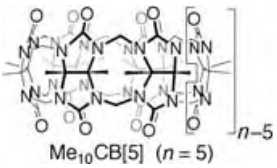
Although Mock and Shih showed early on that the rate of guest exchange does not respond to changes in pH in acidic solution (pH 1–4) they were unable to work at higher values of pH because of the limitations of the solvent mixture employed (HCO_2H/D_2O (1:1)). In important contributions, Nau and co-workers have studied the complexation of CB[6] with **8** as a function of pH (1–12), temperature (25–72 °C), cation identity, and cation concentration.[60,85] Most interestingly, the value of K_a is nearly constant in the region between the pK_a of CB[6] (3.02) and the pK_a of **8**H^+ (10.50); at lower and higher pH values, the value of K_a decreases as either H^+ competes with **8**H^+ for CB[6] (Scheme 2, red equilbria) or as the complex CB[6]·**8**H^+ is deprotonated to yield amine complex CB[6]·**8**. The rate constants for ingression and egression undergo dramatic increases near the pK_a of **8** and CB[6]·**8**H^+ (11.75), respectively. These dramatic changes can be explained by the involvement of the free amine **8** in the ingression and egression process (Scheme 2, **G**). Accordingly, Nau and co-workers included a new set of equilibria involving CB[6] and **8** into our general mechanistic understanding of CB[6] complexation (Scheme 2, light blue arrows). The free amine undergoes egression ($k_{egress}(\mathbf{8}) = 4.7\times10^{-6}\ s^{-1}$, $k_{egress}(\mathbf{8}H^+) = 1.45\times10^{-3}\ s^{-1}$) over 300-fold faster than its ammonium ion form. Similarly, the ingression rate constant ($k_{ingress}(\mathbf{8}) = 0.0145\ M^{-1}s^{-1}$, $k_{ingress}(\mathbf{8}H^+) = 8.0\times10^{-4}\ M^{-1}s^{-1}$) was 18-fold larger for the free amine. These results are extremely important for the development of molecular machines based on CB[*n*] since they indicate that not only can complexation be turned on and off by changes in pH, but also that the operational speed can be changed (up or down) by more than an order of magnitude.

4.2.8. *Studies on CB[6] in Saline Solution*

One of the major challenges that has faced the study of the CB[*n*] family is their poor solubility in aqueous and organic solution. For this reason, the majority of quantitative studies of binding with CB[6] have used HCO_2H/H_2O (1:1) as the solvent. It was known as early as 1992 that CB[6] binds to alkali and alkaline-earth cations in pure water and reaches a higher saturation concentration.[63] For example, the solubility of CB[6] increases dramatically in 0.2 M Na_2SO_4 (66 mM), LiCl (0.94 mM), KCl (37 mM), CsCl (59 mM), and $CaCl_2$ (70 mM). It was not until 1996, however, when Kim and co-workers reported that the solubilization of CB[6] in aqueous saline solution allows the study of guest binding in neutral water that the full importance of this discovery was realized.[87] The X-ray crystal structure of CB[6]·Na_4·$(H_2O)_{17}$·$(SO_4)_2$·THF revealed that the sodium ions act as lids that result in the encapsulation of THF (Scheme 4). Even more remarkably, the addition of CF_3CO_2H releases THF from this CB[6]·THF complex ($K_a = 510\ M^{-1}$) by competitive binding;[88] the process can be reversed by the addition of Na_2CO_3. In a related paper,

Scheme 4. Adding a lid to CB[6] and its removal. Sphere: THF, hemispheres: Na^+, wedges: H_2O.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



Kim and co-workers showed that the lids are not merely innocent by-standers, they actively participate in the binding of THF through formation of cesium–oxygen bonds.[89] Despite the reduced binding constants arising from competition with metal ions in solution, these pioneering studies showed that the supramolecular chemistry of CB[*n*] would not be limited to strongly acidic conditions. Currently, hydrochloride salts of suitable guests are often employed for the investigations since the resulting complexes are rendered water soluble in the absence of competing H^+ or M^+ ions.

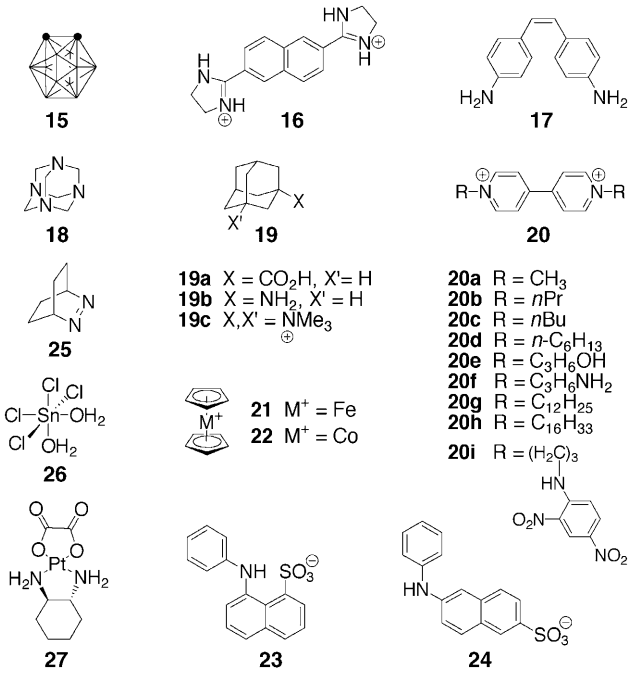
4.3. Host–Guest Properties of the Homologues

We have focused on selected examples to illustrate the general principles and applications of CB[*n*] chemistry. There are, of course, a wealth of elegant contributions from numerous research groups that we have not been able to cover. This section highlights those examples that are not presented elsewhere in this Review.

4.3.1. CB[5] and Me_{10}CB[5]

The supramolecular chemistry of CB[5] and Me_{10}CB[5][90] (see Section 8.4) is controlled by the narrow portals lined with carbonyl groups which provide entry to a cavity of low

Me_{10}CB[5] ($n = 5$)



volume. Consequently, much of the supramolecular chemistry of CB[5] has been limited to the binding of protons as well as metal and ammonium ions at their portals.[67,68,76,77,79,91] Bradshaw, Izatt, and co-workers studied the ability of Me_{10}CB[5] to bind monovalent and divalent cations in HCO_2H/H_2O (1:1) and found a remarkably high selectivity toward Pb^{2+} ions ($> 10^{5.5}$ relative to alkali cations).[79] Somewhat surprisingly, CB[5] itself does not display a similar selectivity for Pb^{2+} ions.[76] CB[5] and Me_{10}CB[5] form weak host–guest complexes with α-, β-, and γ-cyclodextrins ($K_a \approx 10$).[61] Recently, Tao and co-workers reported that hexamethylenetetramine is capable of forming a lid on CB[5].[92] The most remarkable property of CB[5] and Me_{10}CB[5] is their ability to bind gases[93] (for example, Kr, Xe, N_2, O_2, Ar, N_2O, NO, CO, CO_2, and CH_4) and small solvents (for example, CH_3OH and CH_3CN). Such complexes were observed by Dearden and co-workers[91,94,95] by mass spectrometric investigations, by Miyahara et al.[96] in aqueous solution and the solid state, and discussed by Day[34,41] and Miyahara[45] in the patent literature. Miyahara demonstrated the reversible sorption and desorption of gas by solid Me_{10}CB[5], with capacities up to 40 mL g^{-1} (N_2O). These results suggest that Me_{10}CB[5] and CB[5] may be of practical utility in reducing the level of NO_x gases from air.

4.3.2. CB[6]

The pioneering work of Buschmann et al. has established equilibrium constants and in many cases the enthalpic (ΔH) and entropic (ΔS) contributions to ΔG for the binding of CB[6] to ω-amino acids and ω-amino alcohols,[97] aliphatic alcohols, acids, and nitriles,[73] bipyridine derivatives,[98] aromatic compounds,[99,100] non-ionic surfactants and poly(ethylene glycols),[101] cyclodextrins,[61] diamides,[102] and α-amino acids and dipeptides.[103] Analogous to CB[6]·M^+ complexes, the values of K_a measured for the complexation of organic guests with CB[6] increase as the percentage of HCO_2H decreases as a result of reduced competitive protonation of CB[6].[104] Knoche and co-workers studied the complexation of azobenzenes with CB[6],[4,105] Bartik and co-workers the binding of neutral guests such as Xe, THF, and CF_3CO_2H in CB[6] by ^{129}Xe, ^{19}F, and ^{1}H NMR spectroscopy,[88,106] and Dearden and co-workers the formation and dissociation of CB[6] pseudorotaxanes and the corresponding exclusion complexes in the gas phase.[91] The research groups of Wagner and Buschmann have shown that CB[6] enhances the fluorescence of 1,6- and 2,8-anilinonaphthalene sulfonates in solution and the solid state,[107–109] while Wu and co-workers shown recently that CB[6] also binds diazonium compounds.[110]

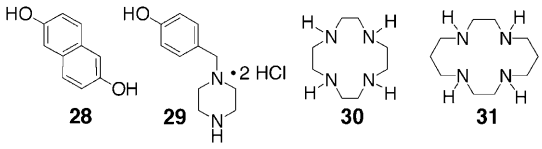
4.3.3. CB[7]

CB[7] is slightly more voluminous than β-CD (Table 1), and thus can bind a wider range of guests than CB[6] or CB[5]. CB[7] binds a variety of positively charged aromatic compounds including adamantanes and bicyclooctanes,[5,92,111,112] naphthalene,[7,113,114] stilbene,[115] viologen,[116–120] *o*-carborane,[121] ferrocene,[5,122] and cobaltocene[122] derivatives (**15**–**25**). CB[7] also binds the metal complexes

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

26[123] and **27**[5,41] as well as related compounds[124,125] which suggests the use of CB[7] to reduce toxicity in cancer treatment.

A number of elegant studies by Kaifer and co-workers have demonstrated that many of the unusual properties of CB[6] are retained by CB[7]. For example, Ong and Kaifer determined the values of K_a for CB[7]·**20a** in 0–0.2 M NaCl and 0–0.2 M $CaCl_2$ and demonstrated that Na^+ and Ca^{2+} ions compete with **20a** for binding to CB[7] which reduces the K_a value by a factor of 9–40.[119] In two elegant studies, the research group of Kaifer showed that the CB[7] bead can reside in different locations along guests containing multiple binding sites (for examplw, CB[7]·**20a**–CB[7]·**20g**).[120,126] CB[7] resides on the longer butyl and hexyl chains of **20c** and **20d** whereas it resides on the viologen nucleus of derivatives that contain shorter (**20a** and **20b**) or hydrophilic residues (**20e** and **20f**). These results imply that CB[7] retains the highly selective binding properties noted above for CB[6]. CB[7] forms a pseudorotaxane with **20i**. Nau and co-workers have used CB[7]·2,3-diazabicyclo[2.2.2]oct-2-ene to show that the polarizability of the CB[7] cavity is extremely low[127,128] and to distinguish between alternative mechanisms in fluorescence-quenching studies.[58,129] Wagner et al. have studied the enhancement in fluorescence observed upon binding of anilinonaphthalene sulfonates by CB[7].[113] CB[7] was recently reported to form a weak 1:2 exclusion complex with C_{60} by high-speed vibration milling,[130] and more recently CB[7] has been used as an additive to separate positional isomers by capillary electrophoresis.[131]



4.3.4. *CB[8]*

The cavity of CB[8] is similar in terms of volume to γ-CD, but is less conformationally flexible. CB[8] behaves like a larger version of CB[5]–CB[7] in many ways, but also exhibits more complex recognition behavior. Just like CB[5]–CB[7], CB[8] prefers to bind to positively charged guests by ion–dipole interactions.[7,132] CB[8] readily binds single guest molecules that partially (CB[8]·**20a**, $K_a = 1.1 \times 10^5\ M^{-1}$) or completely (CB[8]·**19b**) fill its cavity. In contrast to CB[5]–CB[7], the voluminous cavity of CB[8] is capable of simultaneously binding two aromatic rings (Figure 7), as shown by the ready formation of the termolecular complex CB[8]·**16**·**16**.[7,133] Even more strikingly, a mixture of CB[8] and CB[8]·$\mathbf{16}_2$ is formed when CB[8] and **16** are mixed in a 1:1 ratio. This result demonstrates there is cooperativity between the binding of the first and second aromatic rings. Kim and co-workers have also demonstrated the selective formation of a hetero-termolecular complex CB[8]·**20a**·**28** which results in

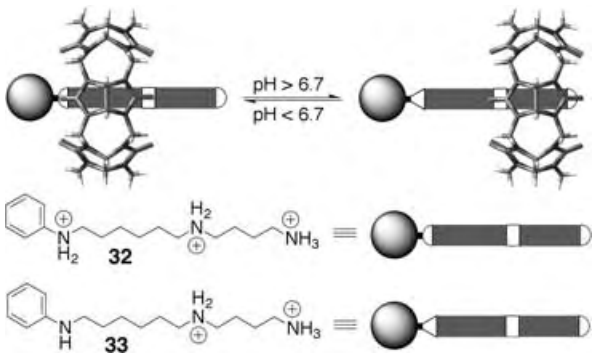
Figure 7. Schematic representations of the termolecular complexes CB[8]·**16**·**16** and CB[8]·**20a**·**28**.

enhanced charge-transfer interactions between **20a** and **28** in the complex.[134] This recognition motif has been used to

control intramolecular folding processes[135] and the formation of vesicles.[136] More recently, Tao and co-workers have shown that aromatic piperazine derivatives form a mixture of 1:1 and 1:2 complexes with CB[8] (for example, CB[8]·**29** and CB[8]·$\mathbf{29}_2$).[137] Similarly, Fedin and co-workers recently reported the crystal structure of the CB[8]·$PhPO(OH)_2$·$PhPO(OH)_2$ complex.[138] CB[8] is even capable of encapsulating cyclen (**30**) or cyclam (**31**). Even more remarkably, CB[8]·**30** and CB[8]·**31** can coordinate with Cu^{II} or Zn^{II} ions which results in macrocycle within macrocycle complexes that resemble the Russian Matrioshka dolls.[139]

4.3.5. *CB[10]*

Day et al. successfully isolated CB[10] as its CB[5]@CB[10] complex (Figure 3). The structure of this remarkable complex was established by X-ray crystallography to resemble a gyroscope.[9] Despite the fact that it was not possible to isolate free CB[10] by removal of CB[5], chemical exchange between free and bound CB[5] was demonstrated through the use of ^{13}C-labeled CB[5]. Such molecular gyroscopes and the related molecular ball bearing[121] CB[7]·**15** are potential components of future molecular machines.



5. Control over the Recognition Processes

The creation of molecular machines[140] by self-assembly processes is currently of great interest. One of the most fundamental molecular machines is a molecular switch that can toggle between two different states by appropriate environmental stimuli (chemical, electrochemical, or photochemical). The CB[*n*] family is ideally suited for such applications because of the high affinity and high selectivity of their binding processes.

5.1. Chemical Control—Molecular Switches

An early example of a molecular switch was published by Mock and Pierpont in 1990. In this study, CB[6] was induced to shuttle along a triamine string by changing the pH value (which resulted in changes in the protonation state of the aniline N atom; Scheme 5).[141] At pH values below the pK_a value of the anilinium group (6.73), the CB[6] bead resides in the hexanediammonium region with its higher binding constant (CB[6]·**32**, left); above the pK_a value, the bead moves to the still fully protonated butanediammonium region (CB[6]·**33**, right). Kim and co-workers have reported

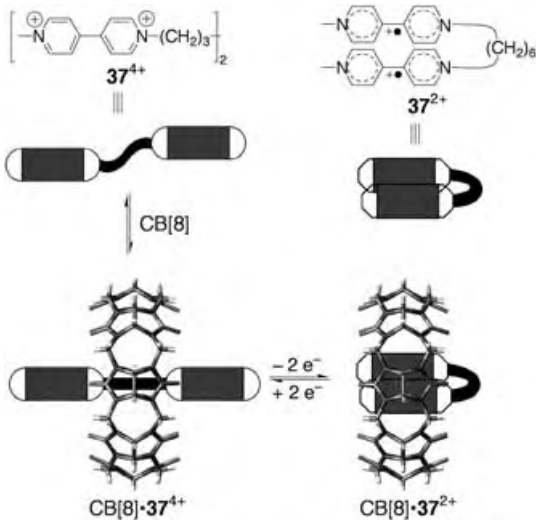
© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 5. CB[6]-based molecular switch.

molecular switches based on CB[6] rotaxanes with UV/Vis and fluorescence outputs[142] that can be actuated by changes in the pH value, but requires both the correct pH value and heat for the switch to be turned off,[143] and that a slow transformation occurs from the kinetic to the thermodynamically more-stable rotaxane.[144]

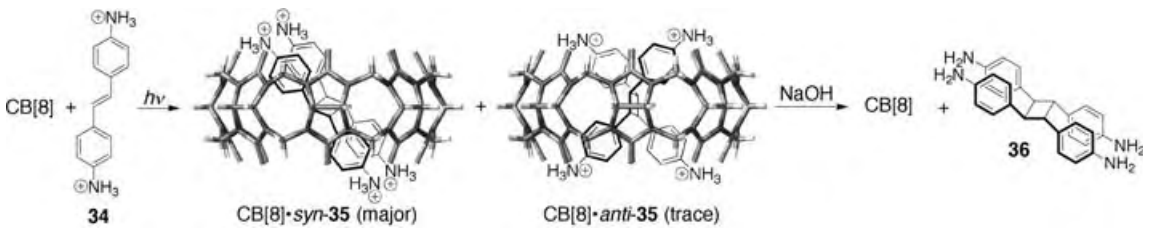
5.2. Photochemical Control

The ability of the two portals lined with carbonyl groups in the CB[*n*] family to orient two guests within their cavity (see Section 4.3.4) results in opportunities to accelerate and control chemical reactions. Kim and co-workers found that CB[8] binds two equivalents of (*E*)-**34** to form CB[8]·**34**·**34**.[145] Irradiation of this complex (300 nm, 30 min) results in the formation of CB[8]·*syn*-**35** and only a trace of CB[8]·*anti*-**35** (Scheme 6). Free **36** is released upon addition of base. The dimerization of (*E*)-**34** within γ-CD is slower (72 h) and less stereoselective (*syn*:*anti* = 80:20). CB[8] accelerates and controls the stereochemistry of the [2+2] photoreaction.



A solution of CB[7] and (*E*)-**34** forms the complex CB[7]·(*E*)-**34** which, upon irradiation (350 nm) converts nearly quantitatively into CB[7]·(*Z*)-**34**. Remarkably, CB[7]·(*Z*)-**34** is stable at room temperature for 30 days.[115] This result demonstrates that CB[7] is able to control the otherwise unfavorable equilibrium between CB[7]·(*E*)-**34** and CB[7]·(*Z*)-**34**.

5.3. Electrochemical Control



The CB[*n*] family displays a marked preference to interact with positively charged guest species. For example, the research groups of Kim[116] and Kaifer,[117] studied the interaction of CB[7] with $\mathbf{20a}^{2+}$ ($K_a = 2 \times 10^5\,\text{M}^{-1}$) and its reduced forms $\mathbf{20a}^{\bullet+}$ ($K_a = 8.5 \times 10^4\,\text{M}^{-1}$) and $\mathbf{20a}^{0}$ ($K_a = 2.5 \times 10^2\,\text{M}^{-1}$) by electrochemical measurements. Two unusual observations were made: 1) the presence of CB[7] prevents the dimerization of $\mathbf{20a}^{\bullet+}$ and 2) the reduction of $\mathbf{20a}^{\bullet+}$ occurs by a direct electron-transfer pathway. Related observations were made by Ong and Kaifer for the CB[7]·**21** and CB[7]·**22** complexes ($K \geq 10^6\,\text{M}^{-1}$).[122]

The cavity of CB[8] is large enough to accommodate two flat aromatic ring systems, provided they possess complementary electrostatic profiles (such as in the charge-transfer complex CB[8]·**20a**·**28**). Very interestingly, Kim and co-workers found that CB[8] binds a single molecule of $\mathbf{20a}^{2+}$ (CB[8]·$\mathbf{20a}^{2+}$, $K_a = 1.1 \times 10^5\,\text{M}^{-1}$); upon electrochemical reduction, however, the complex undergoes disproportionation to form a mixture of CB[8] and the termolecular complex CB[8]·$\mathbf{20a}^{\bullet+}$·$\mathbf{20a}^{\bullet+}$.[132a] The presence of CB[8] enhances the dimerization of $\mathbf{20a}^{\bullet+}$ by a factor of 10^5. Thus, electrochemistry allows quantitative control of the stoichiometry of the host–guest complex within CB[8]!

The dimerization of the tetrathiafulvalene radical cation is also promoted by CB[8].[146] Armed with this knowledge, Kim and co-workers prepared dimeric viologen $\mathbf{37}^{4+}$.[132b] This compound forms a stable 1:1 complex with CB[8] (CB[8]·$\mathbf{37}^{4+}$, $K_a = 2.3 \times 10^5\,\text{M}^{-1}$) where the CB[8] bead resides mainly on the hexamethylene spacer (Scheme 7). Electrochemical reduction (or light-induced chemical reduction with $[\text{Ru}^{\text{II}}(\text{bpy})_3]$) effects a folding process which results in the formation of molecular loop CB[8]·$\mathbf{37}^{2+}$ which displays dramatically reduced dimensions relative to CB[8]·$\mathbf{37}^{4+}$ (28 × 18 versus

Scheme 7. A [2]pseudorotaxane-based molecular machine.

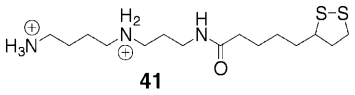
15 × 18 Å). The observed large changes in size and shape may be useful in the design of molecular actuators.[132c]

6. Applications of the CB[n] Family

The outstanding recognition properties of the CB[*n*] family have led to their use in numerous applications, some of which are highlighted in this section.

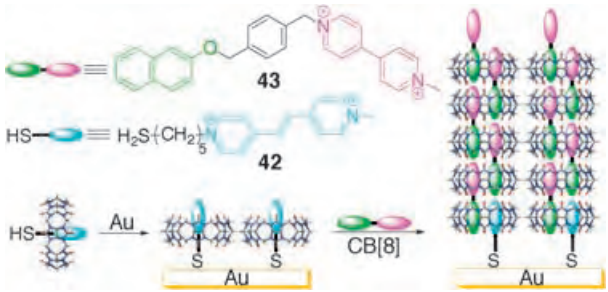
6.1. Catalysis

A long-standing challenge in supramolecular chemistry has been the design of catalysts. Mock et al. recognized that CB[6] was ideally suited for this purpose because of the presence of two portals lined with carbonyl groups that can potentially recognize two ammonium ions, thus forming a termolecular complex that orients and compresses those substrates for chemical reaction.[147,148] Mock et al. studied the dipolar cycloaddition between azide **38** and alkyne **39** catalyzed by CB[6] in an elegant example of click chemistry



Scheme 8. Catalysis of a [3+2] dipolar cycloaddition inside CB[6].

(Scheme 8).[149] They found that the CB[6]-catalyzed reaction of **38** and **39** is a rare example of what is known as the Pauling principle of catalysis, which states that "the complementarity between an enzyme and the *transition state* for its conducted reaction ought to be greater than that between enzyme and the reactants".[147] Remarkably, CB[6] accelerates this reaction by a factor of 5.5×10^4 compared to the bimolecular reaction and renders it highly regioselective. The reaction also displays several features that are commonly observed in enzymatic reactions, namely: 1) reaching a limit in the reaction rate at high concentrations of **38** and **39**, 2) product release from CB[6]·**40** is rate-limiting, 3) inhibition of the substrate through formation of nonproductive termolecular complex CB[6]·**38**·**38**, and 4) competitive inhibition by nonreactive substrate analogues. Steinke's research group has used the CB[6]-promoted dipolar cycloadditon of azides and terminal acetylenes for the preparation of catalytically self-threading rotaxanes,[150,151] [2]-, [3]-, and [4]-rotaxanes and pseudorotaxanes,[152] as well as oligotriazoles.[153]



6.2. Self-Assembled Monolayers (SAMs)

To realize the full potential of pseudorotaxanes as components of molecular machines it is necessary to develop methods for their immobilization on solid substrates. Kim and co-workers have reported the functionalization of a gold surface with the pseudorotaxane CB[6]·**41**.[154] Surface plas-

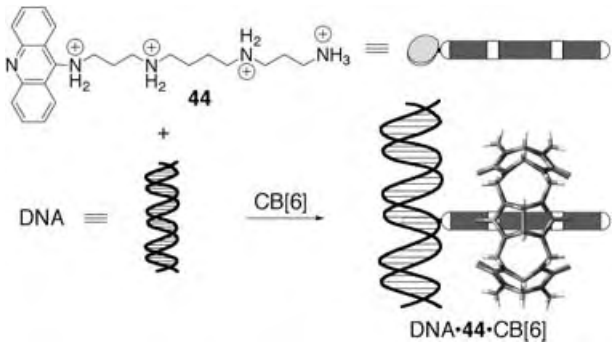
mon resonance (SPR) studies have shown that SAMs comprising CB[6]·**41** undergo reversible dethreading and rethreading of the CB[6] beads upon treatment with 0.1 M NaOH followed by CB[6]. Cyclic voltametry measurements indicate that the SAM formed by pseudorotaxane CB[6]·**41** constitutes an effective barrier to redox processes involving $[Fe(CN)_6]^{3-}$: a quasireversible redox wave is observed after dethreading. This reversible gating behavior may have application in the design of surface-bound molecular machines.

More recently, Kim and co-workers have reported a surface-initiated supramolecular polymer based on CB[8]-stabilized charge-transfer interactions (Scheme 9). An aque-

Scheme 9. Formation of pseudorotaxane CB[8]·**42** on a gold substrate and formation of a surface-bound supramolecular polymer based on CB[8]-stabilized charge-transfer interactions.

ous solution containing CB[8] and thiol **42** results in the formation of pseudorotaxane CB[8]·**42**; dipping a gold substrate into this solution results in the formation of a self-assembled monolayer. Supramolecular polymerization from the CB[8]·**42** SAM was initiated by immersing the substrate in a solution containing CB[8] and **43**. The course of the reversible supramolecular polymerization could be monitored by FT-IR, SPR, and AFM and controlled by changing the conditions (time and concentration). The polymer consists of four CB[8] beads per chain on average.[155]

6.3. Waste-Stream Remediation of the Textile Industry



The application of CB[6] toward the complexation of indicator dyes such as congo red and methylene blue was published by Behrend et al. in 1905. Since then, the research groups of Buschmann[30,31,104,156–171] and Karcher[172–176] have studied the ability of CB[6] to effectively remove heavy metals, chromates and dichromate, aromatic substances, acid dyes, direct dyes, and reactive dyes from textile waste streams, quantified the influence of key parameters such as pH, temperature, salts, and surfactants on the process, and studied methods for regeneration of the solid phase. Taketsuji and

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Tomioka found that Behrend's polymer was more efficient in these applications than CB[6].[35,177,178] Major issues that need to be resolved include loading levels, the covalent attachment of CB[6] to solid phases suitable for use in fixed-bed filters, and cost. The area has been reviewed previously.[14,19]

6.4. DNA Binding and Gene Transfection

Nakamura, Kim, and co-workers investigated a noncovalent approach to selectively deliver CB[6] to DNA.[179] The concept is illustrated in Scheme 10. Compound **44** contains

Scheme 10. Intercalation of acridine–spermine rotaxane CB[6]·**44** into DNA. The components are not drawn to scale.

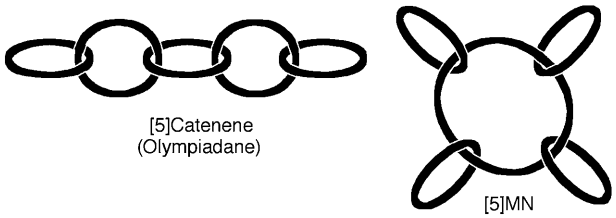
acridine and tetramine regions which function as DNA intercalator and CB[6] binding elements, respectively. Mixing DNA, CB[6], and **44** results in formation of a termolecular complex (DNA·**44**·CB[6]) as monitored by gel electrophoresis. The DNA·**44**·CB[6] complex partially protects supercoiled DNA against cleavage by the restriction enzyme *Ban*II. In a complementary study, Kim and co-workers demonstrated that G3, G4, and G5 poly(propyleneimine) dendrimers bearing diaminobutane moieties (PPI-DAB) for binding CB[6] functions as a gene-delivery carrier.[180] The PPI-DAB·CB[6] conjugates have low cytotoxicity and successfully transfect Vero 76 and 293 cells with efficiencies only tenfold lower than poly(ethyleneimine), which is one of the most potent gene-transfer carriers.

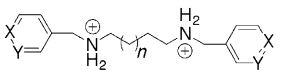
7. Self-Assembly Processes Using CB[n]

This section describes the use of CB[*n*] in multicomponent self-assembly processes in solution and the solid state. The formation of CB[*n*] complexes with high affinity for binding a guest as well as their well-defined geometrical features make them particularly well-suited for these studies.

7.1. Molecular Necklaces

Interlocked structures such as rotaxanes and catenanes are the subject of intense investigation in supramolecular chemistry because of their potential use as molecular machines in nanotechnological applications.[140] Kim and co-workers have demonstrated the utility of the CB[*n*] family as a molecular bead in the formation of molecular necklaces ([*n*]MN) which contain $n-1$ rings threaded onto a single ring.[181–184] The members of the [*n*]MN family are topological isomers of the linear oligocatenanes exemplified by olympiadane (Figure 8).[185]





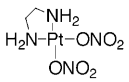


Figure 8. Oligocatenanes and molecular necklaces are topological isomers.

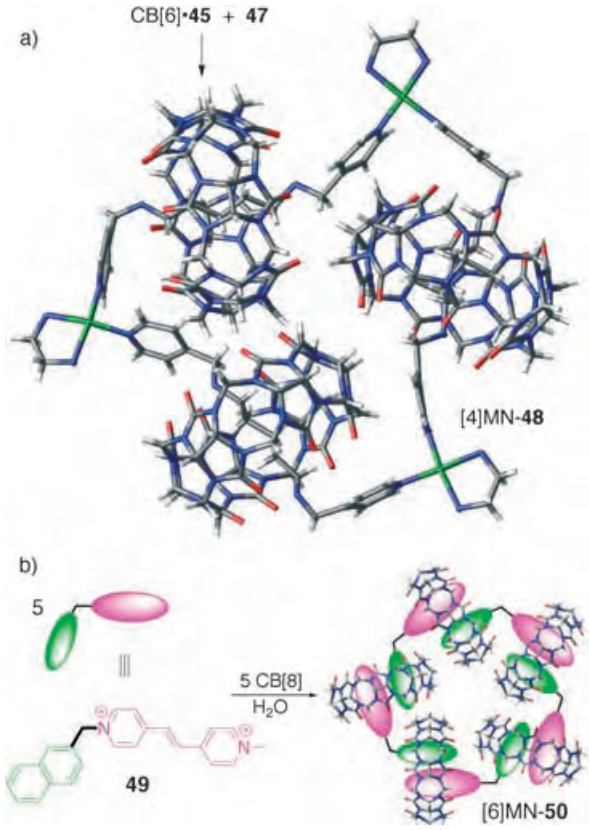
The interaction of **45** with CB[6] results in pseudorotaxane CB[6]·**45**. During this process the butanediammonium

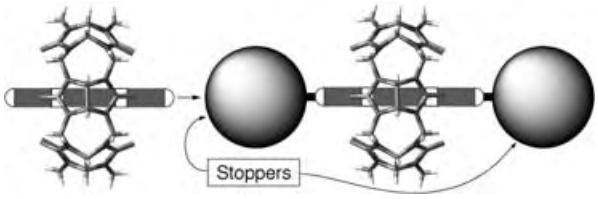
45 $n = 1$, X = N, Y = CH
46 $n = 2$, X = CH, Y = N



47

linker is rigidified in its all *trans* conformation, with the pyridyl groups displayed in roughly opposite directions. Heating CB[6]·**45** and **47** at reflux in water results in the formation of [4]MN-**48** through coordination of the pyridyl groups to the platinum centers (Scheme 11).[181] In a thorough study, the length of the alkanediammonium linker, the position of the pyridyl N atom (**45** versus **46**), and the temperature of the self-assembly process were found to control the equilibrium between [4]MN and [5]MN. Recently, Kim and co-workers demonstrated that their pseudorotaxane approach could be extended to different CB[*n*] and different noncovalent interactions. For example, **49** contains both electron-rich naphthalene rings and electron-poor dipyridylethylene units; these separate moieties are known to form a charge-transfer complex within CB[8]. To achieve formation of [6]MN, Kim and co-workers connected these two units by a methylene bridge whose angle of approximately 109° should favor the formation of a pentameric macrocycle. Indeed, the self-assembly process between CB[8] and **49** results in the formation of [6]MN-**50** as deduced by NMR spectroscopy, ESI mass spectrometry, and X-ray crystallographic analysis. Changing the length and angle of the linking groups should make it possible to synthesize molecular necklaces of different sizes, shapes, and number of CB[*n*] beads.

7.2. Pseudorotaxanes, Rotaxanes, and their Oligomeric Analogues



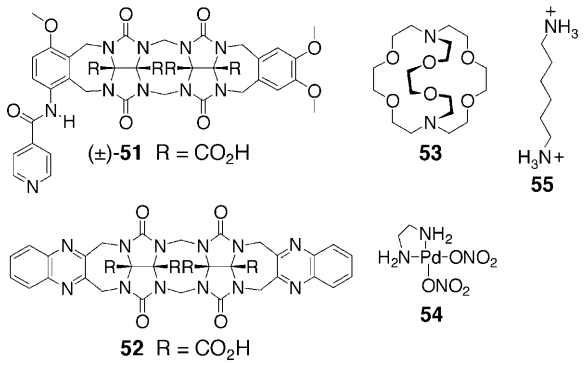
Rotaxanes—mechanically interlocked wheel and axle complexes—have assumed important roles in supramolecular

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 11. Formation of molecular necklaces using: a) CB[6] and b) CB[8] as beads.

chemistry and nanotechnology because of their ability to undergo controlled motions with respect to one another in response to environmental stimuli. Most commonly, rotaxanes are prepared from pseudorotaxanes—non-interlocked wheel and axle complexes—through the addition of bulky stoppers by reactions that result in the formation of covalent bonds (Scheme 12). The circular shape and outstanding

Scheme 12. The stoppering approach to rotaxane formation.



binding properties of CB[6] suggested its use as the wheel in rotaxane formation. Indeed, any CB[*n*] complex which extends past the rim of the cavity can be considered a pseudorotaxane starting material for reactions leading to the formation of rotaxane, polyrotaxane, and polypseudorotaxanes.[186] CB[6]-based rotaxanes have been prepared in solution by dipolar cycloadditions,[147,150–152,187] stoppering with dinitrophenyl groups,[188] amide-bond formation,[189–193] ionic interactions,[194] and coordination of alkylcobaloximes.[195,196] A variety of polymer backbones and side chains have been threaded with CB[6] beads including polyacrylamides and polystyrenes,[197] poly(hexamethyleneimine),[151,198] di- and polyviologen,[98,199] and poly(propyleneimine) dendrimers.[200] A rotaxane derived from Ph_2CB[6] (see Section 8.4) was stoppered with dinitrophenyl groups,[201] the CB[5]·spermine pseudorotaxane has been stoppered with benzoyl and furoyl groups,[202] and Newkome-type dendritic wedges containing viologen focal point functionality have been threaded with CB[7].[118]

7.3. Supramolecular Amphiphiles

Kim and co-workers reported the formation of a charge-transfer complex within CB[8] that triggered the assembly of vesicles.[136] Sonication of an equimolar mixture of CB[8], **28**, and **20g** or **20h** results in the formation of a turbid violet solution. Scanning electron microscopy (SEM), transmission electron microscopy (TEM), and dynamic light scattering measurements showed that the vesicles based on CB[8]·**20g**·**28** were nearly monodisperse with a diameter of 20 nm, whereas those based on CB[8]·**20h**·**28** had an average diameter of 870 nm. Remarkably, the vesicles are quite robust and retain their shape when allowed to dry on a substrate. Addition of cerium(IV) ammonium nitrate oxidizes **28** to the quinone which disrupts the charge-transfer complex and results in the collapse of the vesicles.

7.4. Self-Sorting Systems

Self-sorting—the ability to distinguish between identical and other molecules even within complex mixtures—is commonplace in natural and biological systems but is still rare in designed supramolecular systems.[203] The CB[*n*] family, with their high binding affinities, high selectivities, and reduced rates of chemical exchange are ideal components for self-sorting systems. Isaacs and co-workers demonstrated that a 12-component mixture comprising **51**$_2$·**54**$_2$, **52**$_2$, **53**·K^+, CB[6]·**55**, CB[8]·**20a**·**28**, and β-CD·**19a** undergoes a "social self-sorting" in aqueous solution.[111]

7.5. Crystal Engineering

The CB[*n*] family has been used extensively in crystal-engineering studies.

7.5.1. Polyrotaxanes

The use of CB[6] as a bead in the formation of polyrotaxanes in the solid state was the subject of an excellent review by Kim.[6] Kim's strategy uses the highly symmetrical CB[6] as a molecular bead to complex and conformationally order alkanediammonium ions containing pyridyl ligands at their termini. These pyridyl ligands subsequently coordinate to a variety of metal ions (for example, Cu^{II}, Co^{II}, Ni^{II}, Ag^{I}, and Cd^{II}). The X-ray structure of a polycatenated two-dimensional polyrotaxane net is illustrated in Figure 9.

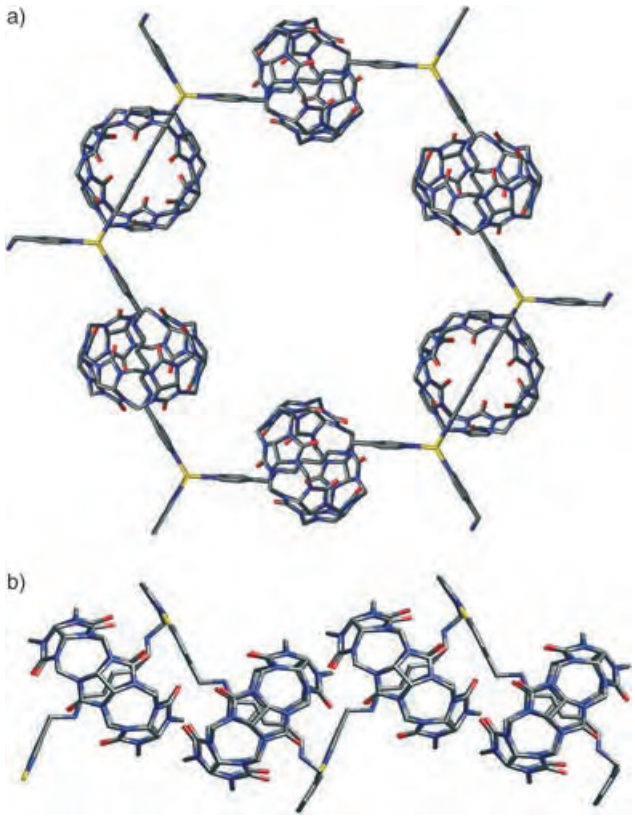

Figure 9. a) A portion of the polycatenated two-dimensional polyrotaxane network **56**, and b) the helical polyrotaxane **57** formed from CB[6], **46**, and $AgNO_3$. C: gray; N: blue; O: red; Ag: yellow.

Pseudorotaxane CB[6]·**45** is formed by threading CB[6] with **45**.[204] The CB[6] bead is held in position by ion–dipole interactions between the ammonium centers of the string (**45**) and the oxygen atoms of CB[6]. The addition of $AgNO_3$ results in a polyrotaxane (**56**) in which CB[6] is threaded on a 2D coordination polymer network (Figure 9a). The effects of structural variation of the components on the supramolecular structure are subtle: for example, the use of $Ag(O_3SC_6H_4CH_3)$ instead of $AgNO_3$ leads to the formation of a one-dimensional polyrotaxane coordination polymer whereas the use of **46** as the thread with $AgNO_3$ leads to helical polyrotaxane **57** (Figure 9b).[205] Other examples include zig-zag, square-wave, and linear one-dimensional polyrotaxanes, square-grid-shaped two-dimensional, and even three-dimensional polyrotaxane networks.[21,206–210]

7.5.2. CB[n] as a Ligand in Metal Complexes

The carbonyl groups lining the portals of CB[*n*] bind metal ions with high affinity and selectivity in solution and the solid state. Consequently, many X-ray crystal structures of CB[6] beads linked by various metal ions have been reported; we present three examples here that illustrate the approach. Fedin, Sykes, Clegg, and co-workers reported the crystal structure of an unusual trimetallic double cube cluster of $[Mo_6HgSe_8(H_2O)_{14}Cl_4]^{4+}$ which becomes sandwiched between adjacent CB[6] molecules and extends to form an infinite chain in the crystal (Figure 10a).[211,212] A triple-decker sandwich-type structure that forms upon crystallization of CB[6] and gadolinium bromide from water ($\{(CB[6])[Gd(H_2O)_4](CB[6])[Gd(H_2O)_4](CB[6])\}^{6+}$ Figure 10b) was reported by Fedin and co-workers.[213] An unusual aspect of this structure is that discrete structural units are formed containing only three CB[6] molecules connected by two Gd^{3+} ions and four hydrogen bonds. Such lanthanide-containing materials may be important in a variety of applications

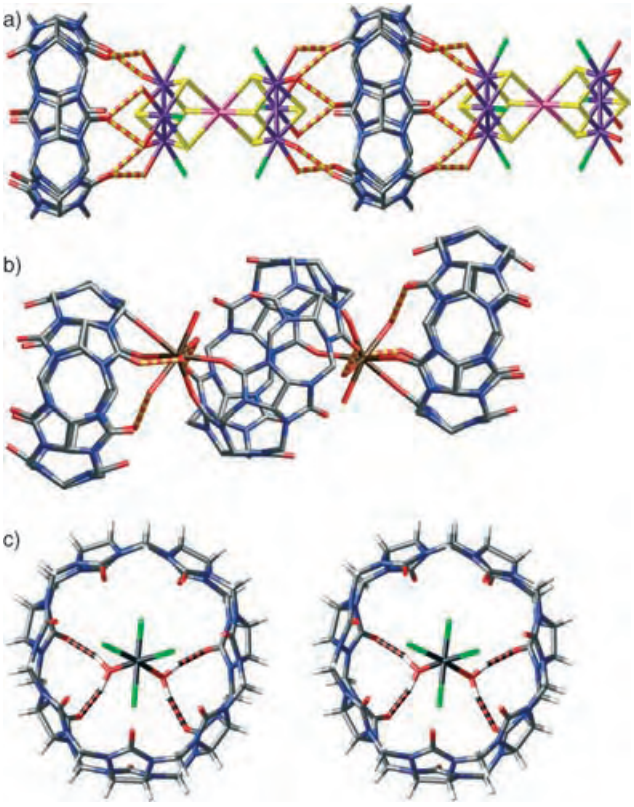

Figure 10. X-ray crystal structures of: a) $[Mo_6HgSe_8(H_2O)_{14}Cl_4]^{4+}$CB[6], b) $\{CB[6]\{Gd(H_2O)_4\}CB[6]\{Gd(H_2O)_4\}CB[6]\}^{6+}$, and c) a stereoview of *cis*-$[SnCl_4(OH_2)_2]$@CB[7]. including relaxation agents for magnetic resonance imaging, luminescent probes, and catalysts for the cleavage of DNA and RNA. The first endoannular metal halide complex of CB[7] was realized by Day and co-workers with the X-ray structure of *cis*-$[SnCl_4(OH_2)_2]$@CB[7] (**26**@CB[7], Figure 10c).[123] A CB[8] metal–aqua complex was recently realized by Fedin and co-workers with the structure of $Sr_2(H_2O)_{12}\cdot[Sr(H_2O)_3(NO_3)_2]_2CB[8]\cdot(NO_3)_4\cdot(H_2O)_8$ and a related complex.[214,215] Wu and co-workers recently reported a similar Cu(II) complex of CB[5].[216] Structures containing CB[6] complexed with a previously unknown tautomer of $HP(OH)_2$,[217] Rb^+,[218] Sm^{III},[219,220] Na^+,[87] Cs^+,[89] K^+,[221] Ca^{2+},[222,223] molybdenumselenide and tungstenselenide aqua complexes and related structures,[224–226] $[W_3S_4(H_2O)_9]^{4+}$ and related structures,[227–229] $[Nb_2(\mu\text{-}S_2)_2(H_2O)_8]^{4+}$,[230] $[ClPdMo_3Se_4(H_2O)_7Cl_2]^+$ and related structures,[231–233] $[W_3S_7Cl_6]_2$,[234] $[Mo_3S_4Ni(H_2O)_7Cl_3]^+$ and related structures,[235–237] *trans*-$[InCl_2(H_2O)_4]^+$ and *trans*-$[InCl_4(H_2O)_2]^-$,[238] $(H_7O_3)_4[FeCl_4]_2Cl_2(H_2O)_2$,[239] $(H_7O_3)_4[GaCl_4]_2Cl_2(H_2O)_2$,[240] $[(UO_2)_4O_2Cl_4(H_2O)_{11}]$,[241] $[Cl_3InW_3S_4(H_2O)_9]^{2+}$,[242] $[Cr(H_2O)_6(NO_3)_3(H_2O)_{13}]$,[243] and $[Zr_4(OH)_8(H_2O)_{16}]Cl_8\cdot(H_2O)_{16}$ are also known.[244]

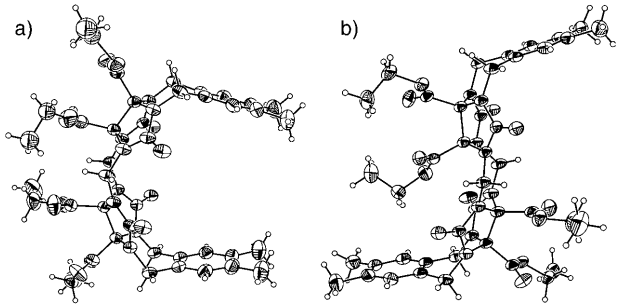
8. Derivatives, Analogues, and Congeners of the CB[n] Family

The preceding sections have demonstrated the great potential of the CB[*n*] family in molecular recognition, self-assembly, and nanotechnology. Potential limitations of the CB[*n*] family include their poor solubility in water, which necessitates the use of high salt concentrations (for example, 0.2 M NaCl), and their insolubility in polar or nonpolar organic solvents. A second potential limitation of CB[*n*] when we began our research in this area in 1998 was an inability to modify the internal or external molecular surfaces of the CB[*n*] molecule. It seemed likely that if the CB[*n*] family could be modified to improve their solubility in organic media, to alter the size and shape of the cavity, and to provide different functional groups that interact directly with guests then the range of potential applications of the CB[*n*] family would be dramatically expanded. The following sections describe the approaches that we,[245–249] and others,[8,90,201,250–254] have taken toward alleviating these potential limitations.

Over the years there have been numerous attempts to prepare CB[*n*] derivatives by the use of substituted glycoluril derivatives in CB[*n*]-forming reactions. Nolte and co-workers were the first to pursue this line of inquiry, which led to the development of molecular clips based on diphenylglycoluril (**1c**).[255] The first fully characterized CB[*n*] derivative was reported by Stoddart and co-workers in 1992 with the synthesis of Me_{10}CB[5] from dimethylglycoluril (**1b**) and formaldehyde under acidic conditions (Scheme 13).[90,256] These studies led to more questions than they answered. Why was the CB[*n*]-forming reaction of **1b** successful whereas the corresponding reaction with **1c** failed? What is the scope of glycoluril monomers that can be used in CB[*n*]-forming reactions? Why did the original cyclization of **1a** lead

Scheme 13. Synthesis of Me_{10}CB[5]. a) Conc. HCl, CH_2O, reflux, 16% yield.

to CB[6] exclusively, whereas **1b** led to a pentameric macrocyclic Me_{10}CB[5] exclusively? What factors are responsible for the remarkably high yield observed for CB[6] formation given that the formation of a pair of methylene bridges between two glycoluril rings can result in either C- or S-shaped diastereomers (for example, **58C** and **58S**, respectively, Figure 11)?



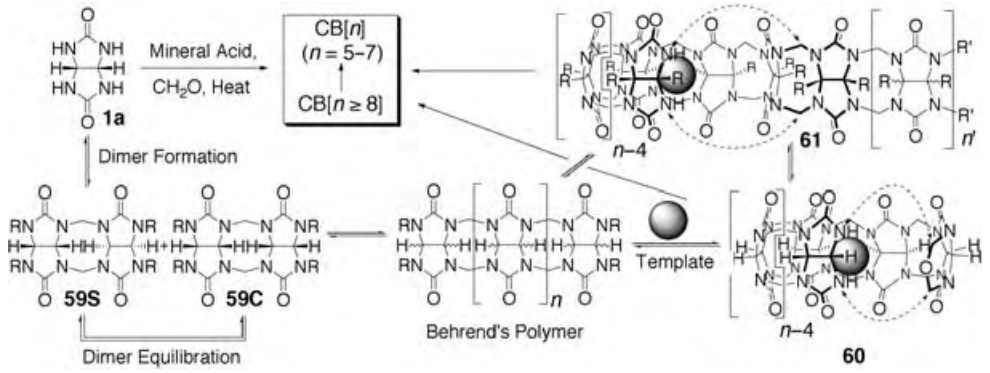


Figure 11. X-ray crystal structures of methylene-bridged glycoluril dimers: a) C-shaped **58C** and b) S-shaped **58S**.

8.1. Mechanistic Hypothesis for CB[n] Formation

Control over the tailor-made synthesis of CB[*n*] homologues, derivatives, and analogues was hampered by an inadequate understanding of the mechanism of CB[*n*] formation. A mechanistic framework advanced by Day et al.[8] and Isaacs and co-workers[247] is shown in Scheme 14. In brief, glycoluril (**1a**) undergoes condensation with H_2CO to yield a mixture of methylene-bridged glycoluril dimers **59C** and **59S** which can undergo further oligomerization to yield Behrend's polymer as a mixture of diastereomers. Further growth and isomerization of the S- to C-shaped structures in Behrend's polymer yields **60** and **61** under the potential control of suitable templating agents. Both **60** and **61** may undergo cyclization by end-to-end condensation (for example **60**→CB[*n*]) or by back-biting (for example, **61**→CB[*n*]) to enter the CB[*n*] manifold. Interconversions between the various CB[*n*] may then occur within the CB[*n*] manifold.

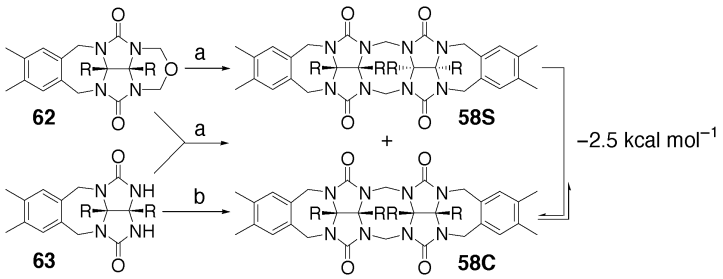
Scheme 14. Proposed mechanism for the formation of CB[*n*].

8.2. Effect of Acid, Salts, and Templates on the Product Distribution



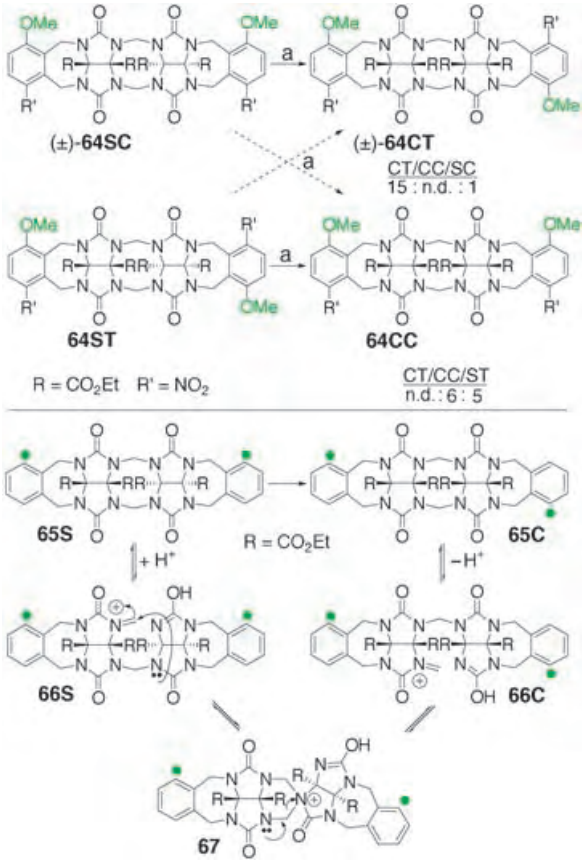
Day and co-workers performed a series of elegant experiments to determine the effect of acid type, acid and reactant concentration, salts, and templates on the distribution of CB[5]–CB[8] in the product mixture.[8,121,250] They surveyed a variety of acids for CB[*n*] formation (for example, HCl, H_2SO_4, HBF_4, CH_3SO_3H, PTSA, and trifluoroacetic acid (TFA)) and determined that a high concentration of strong acid, such as >5 M HCl, is necessary for conversion of oligomers **60** and **61** into CB[*n*]; weak acids such as TFA are insufficient. Decreasing the concentration of **1a** from 155 mg mL^{-1} to 0.125 mg mL^{-1} in concentrated HCl enhanced the combined yield of CB[5] and CB[6] from 67% to 100%, as would be predicted if the length of the oligomer **60** or **61** controls the size of the CB[*n*] formed. To address the fate of the formed CB[*n*] once it has entered the CB[*n*] manifold, Day and co-workers performed product resubmission experiments. CB[5], CB[6], and CB[7] are stable to the reaction conditions (conc. HCl, 100 °C, 24 h) whereas CB[8] contracted to give a mixture of CB[5]–CB[8] (4:13:38:45). These experiments suggest that the low abundance of the higher homologues ($n>8$) may be a consequence of their destruction under the reaction conditions. These experiments also suggest that fragmentation of the methylene-bridged glycoluril oligomers such as **61** to **60** are possible under aqueous acidic conditions.

Day et al. also found that salts such as LiCl, NaCl, KCl, RbCl, CsCl, and NH_4Cl have modest effects on the relative yields of CB[5]–CB[8].[250] For example, K^+ favors formation of CB[5] whereas Li^+ favors the formation of higher homologues; these salts are posited to exert their influence during the transformation of Behrend's polymer to **60** and **61**. Similarly, the addition of *o*-carborane as a potential template for the formation of CB[7] in CB[*n*]-forming reactions had a small but discernible effect on the CB[5]–CB[8] product distribution.[121] Theoretical studies suggest that H_3O^+ may act as a template during CB[*n*] synthesis.[257]

8.3. The Methylene-Bridged Glycoluril Dimer as a Model System

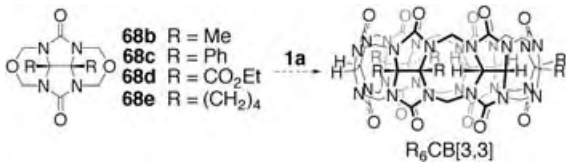
In contrast to the work of Day et al., which focused on the latter stages of the mechanism of CB[*n*] formation, we decided in 1998 to focus on the simplest building block of the CB[*n*] family, namely, the methylene-bridged glycoluril dimer substructure (**59C** and **59S**, Scheme 14). This section focuses on the insights that we gained from these model studies that led to the synthesis of CB[*n*] analogues.

We developed three related synthetic methods (two homodimerization and one heterodimerization) from **62** and **63** that provided efficient access to methylene-bridged glycoluril dimers, such as **58C** and **58S**, with *o*-xylylene "walls" and a variety of substituents (Scheme 15).[247,249] We found that substituted dimers bearing electron-withdrawing groups (for example, R = CO_2Et) form readily whereas those bearing groups such as R = Ph that stabilize adjacent positive charge form slowly and with significant formation of by-product. These experiments provide a rationale for the observed scope of CB[*n*]-forming reactions.[249] Since the equilibrium between **59S** and **59C** is of fundamental importance to CB[*n*] synthesis, we decided to investigate the equilibrium between the S-shaped and the C-shaped forms by following the separate isomerization of diasteromerically pure samples of **58S** and **58C** to yield equilibrium mixtures (**58C**:**58S** = 97:3, Scheme 15) of the two diastereomers.[247] The C-shaped form is about 2.5 kcal mol^{-1} more stable than



Scheme 15. Formation and isomerization of methylene-bridged glycoluril dimers. a) $ClCH_2CH_2Cl$, PTSA, reflux; b) $ClCH_2CH_2Cl$, CH_2O, PTSA, reflux. R = CO_2Et, PTSA = *para*-toluenesulfonic acid.

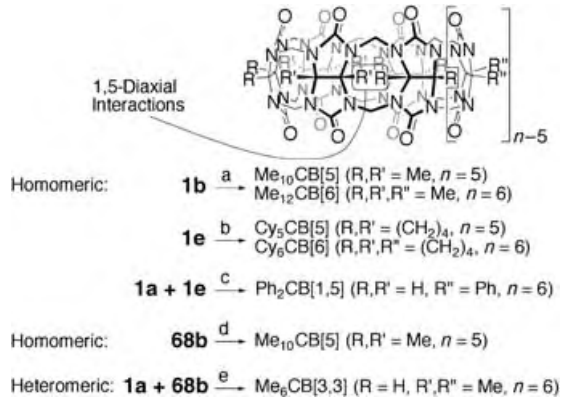
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



the S-shaped form, which provides a rationale for the high yields observed in the formation of the CB[*n*] family in which all the dimeric units adopt the C-shaped form.

During our studies of the model system with the methylene-bridged glycoluril dimer we also observed that the isomerization from the S-shaped to C-shaped dimer was highly diastereoselective. The isomerization of **64ST** (S-shaped, *trans*) and **64SC** (S-shaped, *cis*) under anhydrous acidic conditions ($ClCH_2CH_2Cl$, PTSA, reflux) gave **64CC** (C-shaped, *cis*) and **64CT** (C-shaped, *trans*), respectively (Scheme 16). In principle at least three different outcomes

Scheme 16. Isomerizations and a suggested mechanism.[258] a) PTSA, $ClCH_2CH_2Cl$, reflux. n.d. = not detected.

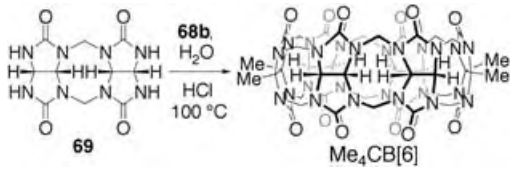


were conceivable: 1) scrambling, 2) retention, or 3) transposition of the relative position of the "methoxy labels" (green dots) as might occur during intermolecular (scrambling) or intramolecular (retention or trnscription) S- to C-shaped isomerization. Scheme 16 (bottom section) also shows our suggested mechanism for this *intramolecular* isomerization which proceeds by the intermediacy of a spirocyclic N-acylammonium intermediate (**67**). The implications of this result toward the synthesis of CB[*n*] derivatives and analogues are twofold: Under the anhydrous acidic conditions used, the methylene-bridged glycoluril dimer subunits do not undergo the fragmentation reactions observed during CB[*n*] synthesis (see Scheme 14, **61**→**60**). This result suggests that CB[8] and the higher homologues might display enhanced stability if synthesized under anhydrous acidic conditions. Since the methylene-bridged glycoluril dimer substructure does not become disconnected during isomerization, it should be possible to exploit the selective heterodimerization reactions between glycoluril NH compounds such as **1** and glycoluril cyclic ethers such as **68** to prepare CB[*n*] derivatives with control over their functionalization pattern and potentially their size. For example, we predicted that it might be possible to prepare CB[*n*] derivatives from two different glycoluril derivatives (for example, **1a** and **68**) and that those derivatives might alternate in the formed CB[*n*] derivative (for example, R_6CB[3,3]; Scheme 17).

Scheme 17. Proposed synthesis of CB[*n*] derivatives.

8.4. Preparation of CB[n] Derivatives

There are three potential pathways for the synthesis of CB[*n*] derivatives from glycolurils (**1**) and glycoluril cyclic ethers (**68**)—two homomeric cyclzations and one heteromeric cyclization. Examples of all three have now been demonstrated in the literature (Scheme 18). In 1992, Stoddart and

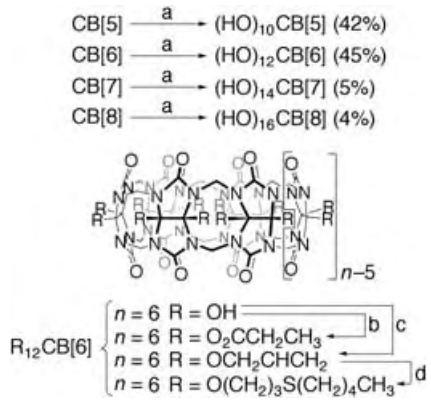


Scheme 18. Synthesis of CB[*n*] derivatives. a) CH_2O, HCl, heat; b) CH_2O, HCl, heat; then H_2SO_4, H_2O, heat; c) CH_2O, $(NH_4)_2SO_4$, H_2SO_4; then H_2O, 70–95 °C; d) HCl, H_2O, heat; e) HCl, LiCl, heat.

co-workers showed that the homomeric cyclization of **68b** yields the pentameric macrocycle Me_{10}CB[5] in low yield (Scheme 13).[90,256] Miyahara et al. reported an improved procedure to access Me_{10}CB[5] with a NH_4^+ lid (36%) and removal of the lid using Amberlite IRA410.[96] Keinan and co-workers recently reported a novel pentanediamine-derivatized polystyrene resin that allowed the isolation of Me_{12}CB[6].[259] Similarly, Kim and co-workers were able to isolate Cy_5CB[5] (16%) and Cy_6CB[6] (2%) by the cyclization of **1e**.[253] The distinguishing feature of Cy_5CB[5] and

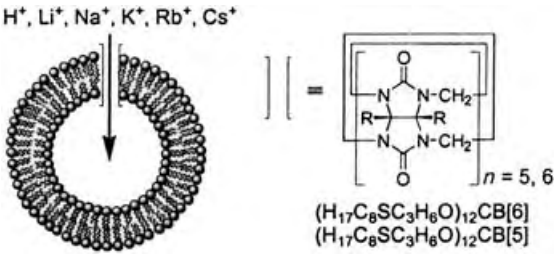
© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$Cy_6CB[6]$ is their enhanced solubility in water (200 mM) and organic solvents (up to 30 mM in MeOH, DMSO, DMF, and CH_3CN). This enhanced solubility of $Cy_5CB[5]$ and $Cy_6CB[6]$ allowed the preparation of ion-selective electrodes which displayed a high selectivity for Pb^{2+} ions and acetylcholine, respectively, relative to potentially interfering cations (K^+, NH_4^+, Na^+, Cu^{2+}, and choline). Nakamura and co-workers demonstrated that mixtures of **1a** and **1c** gave a CB[6] derivative containing a single diphenylglycoluril unit ($Ph_2CB[1,5]$) in a remarkable 30% yield. $Ph_2CB[1,5]$ even forms a rotaxane with a spermine axle.[201] Day et al. showed that **68b** is transformed into $Me_{10}CB[5]$ in high yield (85%).[8]



One potential drawback of the use of glycoluril derivatives in CB[*n*]-forming reactions is that derivatives of the smaller homologues CB[5] and CB[6] form preferentially. This result is attributed to 1,5-diaxial interactions between substituents on adjacent glycoluril rings that comprise the CH_2-bridged eight-membered rings; such interactions are postulated to increase as the size of the CB[*n*] increases.[33,34] To alleviate this problem, Day et al. studied CB[*n*]-forming reactions between substituted and unsubstituted glycoluril derivatives, with the reasoning that the presence of unsubstituted glycoluril would relieve the 1,5-diaxial interactions. The heteromeric cyclization reaction of **1a** and **68b** gave the D_{3h}-symmetrical $Me_6CB[3,3]$ in which substituted glycoluril units alternate with unsubstituted ones in 10% yield.[247,251] CB[5] and CB[7] derivatives were also present in the reaction mixture, but were not isolated in pure form. A related heteromeric cyclization reaction between **68b** and **69** delivers $Me_4CB[6]$ in 30% yield on multigram scale (Scheme 19).[260] Interestingly, the cavity of $Me_4CB[6]$ is ellipsoidal and binds 2,2′-bipyridine with its aromatic rings parallel to the long axis of the cavity.

Scheme 19. Synthesis of $Me_4CB[6]$.

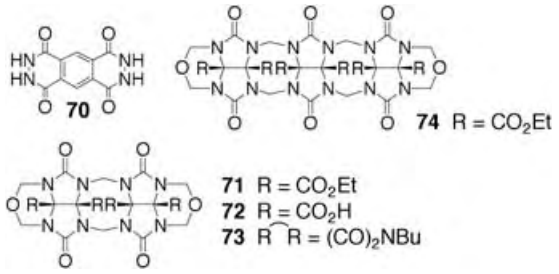


8.5. Direct Functionalization of CB[n]

Kim and co-workers recently made a major breakthrough in the synthesis of CB[*n*] derivatives by the direct functionalization of CB[5]–CB[8].[254] Scheme 20 shows the direct oxidation of CB[5]–CB[8] with $K_2S_2O_8$ in water to yield the perhydroxylated species $(HO)_{2n}CB[n]$. The reaction is efficient for CB[5] and CB[6] (yields of 42 and 45%, respectively); optimization of the reaction conditions is needed to improve the yields in the derivatization of CB[7] and CB[8] (ca. 5%). The cause of the low yields in these reactions is still unclear, but may be related to selective formation of CB[5] and CB[6] derivatives in the direct cyclization of glycoluril derivatives. $(HO)_{12}CB[6]$ has good solubility in DMSO and DMF which allows its subsequent derivatization. $(HO)_{2n}CB[6]$ can be acylated by treatment with propionic anhydride to yield $(CH_3CH_2CO_2)_{12}CB[6]$ and treated with allyl bromide to yield $(CH_2CHCH_2O)_{12}CB[6]$. The allylated compound $(CH_2CHCH_2O)_{12}CB[6]$ undergoes photochemical reaction with pentanethiol to afford $\{CH_3(CH_2)_4S(CH_2)_3O\}_{12}CB[6]$. These landmark reactions represent the first covalent derivatization reactions of CB[*n*] derivatives. $(CH_2CHCH_2O)_{12}CB[6]$ can even be covalently attached to slides derivatized with (3-sulfanylpropyl)triethoxysilane and can also be covalently attached to silica gel and used in chromatographic applications.[46,261]

Scheme 20. Direct functionalization of CB[*n*]. a) $K_2S_2O_8$, H_2O, 85 °C; b) Et_3N, $(CH_3CH_2CO)_2O$, DMSO; c) NaH, DMSO, allyl bromide; d) $CH_3(CH_2)_4SH$, *hν*.

Kim and co-workers have also demonstrated that these lipophilic CB[*n*] derivatives possess new properties. $\{CH_3(CH_2)_7S(CH_2)_3O\}_{12}CB[6]$ forms nanospheres with diameters of 50–150 nm when emulsified.[254] They also demonstrated recently that $\{CH_3(CH_2)_7S(CH_2)_3O\}_{12}CB[6]$ and $\{CH_3(CH_2)_7S(CH_2)_3O\}_{12}CB[5]$ become incorporated in large unilamellar vesicles and function as ion channels (Scheme 21).[262] The CB[6] derivative $(CH_3(CH_2)_7S(CH_2)_3O)_{12}CB[6]$ shows ion selectivity ($Li^+ > Cs^+ \approx Rb^+ > K^+ > Na^+$) which is opposite to the binding affinities of CB[6]. Remarkably, $\{CH_3(CH_2)_7S(CH_2)_3O\}_{12}CB[6]$ shows an ion flux of 5 pA (ca. 3×10^7 ions s^{-1}) which is comparable to that of gramicidin! In contrast, $\{CH_3(CH_2)_7S(CH_2)_3O\}_{10}CB[5]$ with its smaller portals (2.4 Å) only allows the smaller Li^+ and Na^+ ions to pass. Such lipophilic CB[*n*] derivatives show much promise for applications as sensors, in ion separations, and as components of molecular devices.



Scheme 21. Lipophilic CB[5] and CB[6] derivatives as ion channels.

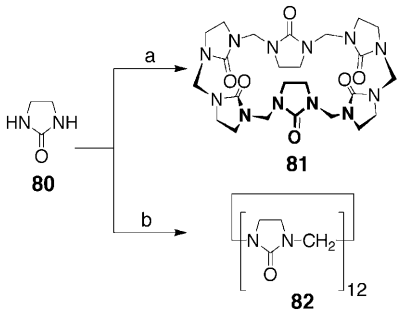
8.6. Preparation of Cucurbit[n]uril Analogues

We discovered that phthalhydrazides function as nucleophilic glycoluril surrogates in typical methylene-bridge-forming reactions. On the basis of the mechanistic reasoning described above, we hypothesized that combinations of bis(phthalhydrazide) **70** and glycoluril ether building blocks **68**, **71**–**74** would yield CB[*n*] analogues with predetermined size, shape, and functionalization patterns.[246,248,263]



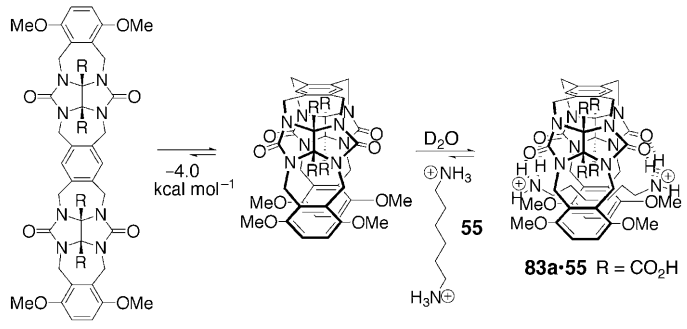
In accord with these expectations, cyclization reactions of **70** with **71**–**73** proceeded smoothly and delivered CB[6] analogues **75**–**77** in high yield (Scheme 22). Similarly, **70** reacts with **68d** to yield CB[5] analogue **78** in relatively low yield (6%). Remarkably, methylene-bridged glycoluril trimer **74** reacts with **70** to yield CB[7] analogue (±)-**79** incorporating a single bis(phthalhydrazide) unit rather than a CB[8] analogue with two such units. Several features of these cucurbit[*n*]uril analogues are noteworthy: 1) they contain electrochemically, UV/Vis, and fluorescently active "walls"; 2) their elongated shapes (**75**: 5.9 × 11.2 × 6.9 Å; **78**: 5.6 × 9.8 × 6.2 Å; (±)-**79**: 5.7 × 11.3 × 4.3 Å differ from those of the circular CB[*n*]; 3) the C_2-symmetric (±)-**79** is chiral and contains only a single bridging CH_2 group which points directly into the cavity; and 4) the analogues are soluble in both organic and aqueous media depending on the substituents. CB[6] analogue **77** retains the binding capacity of the parent macrocycles, as demonstrated by the complexation of the *p*-xylylenediammonium ion.[248]

Scheme 22. CB[*n*] analogues. a) $MeSO_3H$, 80°C.

8.7. Hemicucurbit[6]uril and Hemicucurbit[12]uril

Miyahara et al. recently further expanded the CB[*n*] family with the preparation of hemicucurbiturils by the acid-catalyzed condensation of ethyleneurea (**80**, Scheme 23).[264] Remarkably, hemicucurbit[6]uril (**81**) is

Scheme 23. Synthesis of **80** and **81**. a) CH_2O, 4 N HCl, RT; b) CH_2O, 1 N HCl, 55°C.



formed in 94% yield when the reaction is conducted at RT in 4 N HCl, whereas hemicucurbit[12]uril (**82**) is formed in 93% yield in 1 N HCl at 55°C. The X-ray crystal structure of **81** shows that it assumes the alternate conformation depicted in Scheme 23. Unlike CB[*n*], **81** does not bind metal cations, but does retain the ability to bind small organic molecules such as $HCONH_2$ and $HOCH_2CCH$. Interestingly, **82** gelates ethyleneglycol in the 0.5 to 5.0 wt% range. The detailed recognition properties and practical applications of **81** and **82** remain to be explored.

8.8. Preparation of Acyclic Cucurbit[n]uril Congeners

Issues associated with macrocyclization and stereochemistry (for example, S- versus C-shaped diastereomers) complicate the preparation of CB[*n*] derivatives and analogues that are poised to dramatically expand the scope of applications of the CB[*n*] family. Recently, we described an approach to acyclic CB[*n*] congeners (**83a**, Scheme 24) that circumvents these issues while maintaining the binding profile of CB[6] itself.[245,263b] Based on the precedent of Nolte,[265] we hypothesized that employing alternating glycoluril and aromatic rings would preorganize **83a** into the a,a,a,a conformation required

to act as an acyclic CB[*n*] congener. Indeed, **83a** displays several of the features characteristic of the CB[*n*] family, namely: 1) high affinity and selectivity for positively charged guests, 2) length-dependent affinity for alkanediammonium ions, 3) guest discrimination on the basis of size and shape, and 4) competitive binding with alkali metals present in solution. The use of longer aromatic spacers may result in CB[*n*] congeners whose recognition properties parallel those of the higher homologues.

9. Summary and Outlook

Cucurbit[6]uril is celebrating its 100th birthday this year! It was only in 1981 at age 76, that the structure of this unusual macrocycle was elucidated by Mock and co-workers. In their early pioneering work they demonstrated that CB[6] displays: 1) remarkably high affinity for alkanediammonium ions as a consequence of ion–dipole and hydrophobic interactions, 2) size, shape, and functional-group selectivity, 3) unusually slow kinetics of association and dissociation, and 4) behavior of an enzyme mimic. CB[6] was clearly a talented host, but a series of perceived problems limited the scope of applications to which it could be applied. Compared to α-, β-, and γ-cyclodextrin with their good solubility in aqueous solution, their commercial availability in a variety of sizes, their well-known chemical functionalization, and their affinity toward a wide variety of species, CB[6] was not in a position to challenge the cyclodextrins as the recognition platform of choice for studies of molecular recognition in aqueous solution.

In the intervening time, all of these perceived issues have been either partially or fully resolved, which has dramatically expanded the range of applications to which the CB[*n*] family can be applied. The solubility of CB[6] increases dramatically in the presence of salts which allows their recognition and self-assembly processes to be studied in neutral aqueous solution. It was not until the turn of the millennium, however, that the CB[*n*] family expanded dramatically with the preparation of CB[5], CB[7], CB[8], and CB[10]·CB[5] by the research groups of Kim and Day. The recognition properties of these new CB[*n*] homologues—which are now commercially available—parallel and exceed those of CB[6]. Recognition processes within CB[6], CB[7], and CB[8] are subject to efficient chemical, electrochemical, and photochemical control. These attributes along with the detailed knowledge of the mechanism of formation and dissociation of CB[6] complexes has led to the application of the CB[*n*] family in areas as diverse as gas purification, catalysis, molecular machines, waste-stream remediation, supramolecular polymers, self-assembling and self-sorting systems, crystal engineering, self-assembled monolayers, and even gene transfection.

The remaining issue—the tailor-made preparation of CB[*n*] derivatives, analogues, and congeners—has been tackled by several research groups including ours. Fully and partially substituted CB[5] and CB[6] derivatives can be prepared by the use of substituted glycoluril derivatives in CB[*n*]-forming reactions. More recently, the direct perhydroxylation of CB[5]–CB[8] was achieved by Kim and co-workers. We have prepared CB[*n*] analogues and congeners by mechanistically guided building-block approaches. These CB[*n*] derivatives possess enhanced solubility in aqueous and organic media and largely retain the binding profile of the parent CB[*n*]. CB[*n*] derivatives have already been used as molecular "molecular sieves", in the preparation of ion-selective electrodes, as amphiphiles for vesicle formation, for the functionalization of glass substrates, and as artificial ion channels.

Many of the major issues confronting CB[*n*] supramolecular chemistry—enhanced aqueous and organic solubility, the (commercial) availability of a range of different-sized CB[*n*] homologues, and the development of tailor-made synthetic procedures for the synthesis of CB[*n*] derivatives, analogues, and congeners—have now been partially or fully addressed. We, and others, believe that the CB[*n*] family is now in a position to challenge the cyclodextrins as the recognition platform of choice for studies of molecular recognition in water. The unusual recognition properties of the CB[*n*] family—strong binding, high selectivity, tunable kinetics of association and dissociation, and efficient methods for chemical, electrochemical, and photochemical control of binding—suggest that the CB[*n*] family will become important components in molecular machines and nanotechnology. The groundwork has been laid for a second century of CB[*n*] chemistry that promises advances even more dramatic than the first!

Addendum (6. July 2005)

Since submission of the final version of this review a number of papers,[266–299] reviews,[300–304] and patents[305–313] related to the CB[n] family have appeared in the literature.

We thank the talented and enthusiastic co-workers who have worked on the CB[n] project in our group: Dariusz Witt, Arindam Chakraborty, Anxin Wu, Avril Williams, Christopher Burnett, Daniel Coady, Katie Chiles, Marie Ofori, and Christian Ruspic. Our work in this area would not have been possible without the contributions of Dr. James C. Fettinger (X-ray analysis) and Dr. Yiu-Fai Lam (NMR spectroscopy) for which we are grateful. We thank the National Institutes of Health (GM61854) and the University of Maryland for financial support. L.I. is a Cottrell Scholar of Research Corporation.

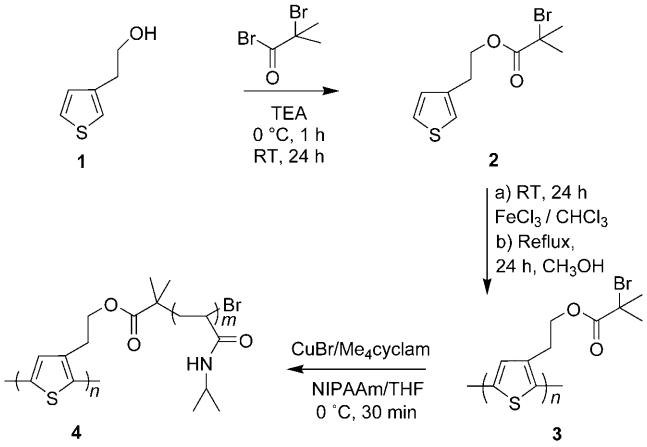
Highly Water-Soluble Thermally Responsive Poly(thiophene)-Based Brushes**



*Sreelatha S. Balamurugan, Grigor B. Bantchev, Yuming Yang, and Robin L. McCarley**

The need for highly water-soluble conducting polymers is great, particularly in applications that would benefit from environmentally friendly processing steps or those applications that center on use of conducting polymers in biological environments.[1] In addition, the chromic response of certain conducting polymers (due to changes in polymer conjugation length as a result of conformational changes of the polymer backbone)[2] should allow for development of sensing systems capable of detecting a multitude of analytes or stimuli, in a broad spectrum of environments, as long as conducting-polymer compatibility, solubility, and processability issues can be addressed. In particular, conducting polymers with a wide variety of solubilizing groups are needed, including those made soluble in aqueous media without the use of ionic solubilizing groups.

As the result of efforts to extend the unique optical and electrical properties of substituted poly(thiophene)s (PTs)[2–4] to aqueous media[5,6] and strategies for developing chromism-based PT materials that respond to biological analytes,[7–11] significant advances in the fabrication of water-soluble PTs have occurred. Water-soluble PTs possessing cationic side chains were recently used in the specific detection of DNA hybridization events,[10] nucleic acids,[12] and human thrombin.[11] Such aqueous-soluble PTs have been prepared by incorporating ionic groups into the side chains of the PT backbone[5,6,13–15] and by complexation of PT with cyclodextrins.[16] Recently, a low-molecular-weight oligo(thiophene) substituted with neutral oligo(ethylene oxide) groups at the 3-position ($M_n = 1400$) was shown to be water soluble to a level of approximately 1 g L^{-1}.[17,18]

Poly(*N*-isopropylacrylamide) (PNIPAAm) is an environmentally responsive polymer that has kindled interest in many researchers for a long time due to its unique lower critical solution temperature (LCST, 30–32 °C[19]) and its relative ease of synthesis. At its LCST, PNIPAAm undergoes a rapid and reversible conformational change from an extended hydrated coil to a collapsed hydrophobic globule that is insoluble in water;[19,20] the driving forces for this conformational change are associated with temperature-dependent hydrogen bonding and hydrophobic interactions. Substitution of responsive PNIPAAm units on PT at the 3-position should lead to a highly water-soluble conducting polymer possessing unique optical and electronic properties as the result of the extension and collapse of the PNIPAAm brushes toward the PT backbone; this system and its characteristics are the topic of the study reported here.

In general, the tethering of PNIPAAm brushes on PT (Scheme 1) involved functionalization of a thiophene monomer with an atom-transfer radical polymerization (ATRP) initiator to yield **2**, followed by its oxidative polymerization to afford a macro initiator **3**, and then growth of PNIPAAm chains from the PT macro initiator by ATRP.[21,22] Specifically, commercially available 2-(3-thienyl)ethanol (**1**) was esterified with 2-bromoisobutyryl bromide to yield 3-[1-ethyl-2-(2-bromoisobutyrate)]thiophene (**2**). Formation of **2** was confirmed by FTIR, GC-MS, and ^{1}H NMR analyses.[23] Compound **2** was polymerized by oxidative coupling[24] using $FeCl_3$ in chloroform to yield 2,5-poly(3-[1-ethyl-2-(2-bromoisobutyrate)]thiophene) **3** (83% yield). Because the initiator is anchored before polymerization, the presence of the grafting site at each repeat unit is ensured. The PT macroinitiator **3** is soluble in many organic solvents, such as tetrahydrofuran, dimethylformamide, chloroform, dichloromethane, and toluene, due to the presence of the bromoisobutyl initiator group at the 3-position. Formation of **3** was confirmed by ^{1}H NMR spectroscopy and gel permeation chromatography (GPC), the latter of which yielded $M_n = 1.09 \times 10^5$ and $M_w/M_n = 2.95$.[23] As expected owing to the $FeCl_3$-mediated polymerization, **3** was found to be regioirregular, as evident in its ^{1}H NMR spectrum; the protons on the 3-alkyl chain adjacent to the thiophene ring (65% head-to-tail coupling) give rise to a two-component signal at 3.24 ppm and 3.00 ppm.

PNIPAAm chains were grown from the PT macroinitiator **3** by the ATRP technique, using CuBr/1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane as the catalyst and THF as solvent (53% yield). This ATRP catalyst system has been used in the high-yield synthesis of PNIPAAm brushes having a polydispersity of ca. 1.4.[25–27] Formation of PNIPAAm grafts on the PT macroinitiator **3** to yield **4** was confirmed from ^{1}H NMR data, as indicated by the presence of a broad NH peak at $\delta = 6.59$ ppm and CH peak at $\delta = 3.98$ ppm, both associated with the PNIPAAm brushes.[23] Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry evaluation of PNIPAAm chains cleaved from **4** (ester hydrolysis)[28] led to the routine observation of mass spectra characteristic of polymer molecules possessing the NIPAAm repeat unit and molecular weights between 1000 and 5000 amu. The molar mass of **4** was found by GPC to be roughly 2×10^6. It is interesting to note that the graft polymer is soluble in a wide spectrum of organic solvents, such as THF, acetone, chloroform, dichloromethane, and methanol. Importantly, poly(thiophene-*g*-PNIPAAm) **4** is soluble in room-temperature water up to 11 g L^{-1}! To date, this is the highest reported water solubility for a PT possessing neutral substituents, and only the second such PT described in the literature.

The individual poly(thiophene-*g*-NIPAAm) molecules were readily observed by scanning force microscopy (SFM; Figure 1). Images such as that in Figure 1 were routinely

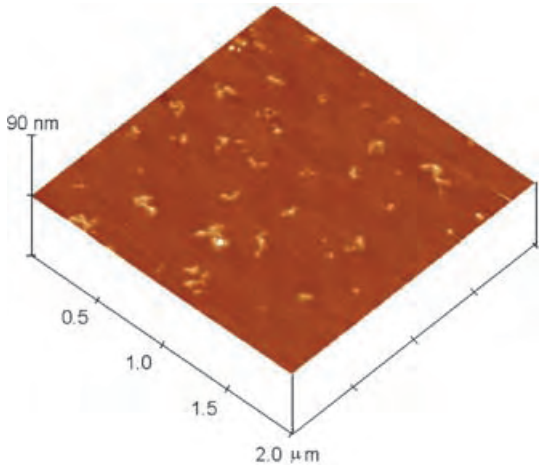

Figure 1. SFM image of poly(thiophene-*g*-NIPAAm) **4** on mica recorded in tapping mode.

obtained by imaging freshly cleaved mica that had a ≈ 1 mg L^{-1} solution of **4** (unfractionated) in acetone spin-coated on it. A broad distribution of random coiled structures for **4** on mica is noted in Figure 1, with lengths ranging from 30 to 260 nm and heights from 0.7 to 0.9 nm. This wide distribution in molecular size is in agreement with the GPC data for **4** and **3**, as well as that from MALDI-MS of the cleaved PNIPAAm.

The enthalpy of transition of the grafted polymer in water was monitored using differential scanning calorimetry (DSC) by repeatedly cycling the solution between 5 and 60 °C (four heating and three cooling cycles; Figure 2). Such temperature

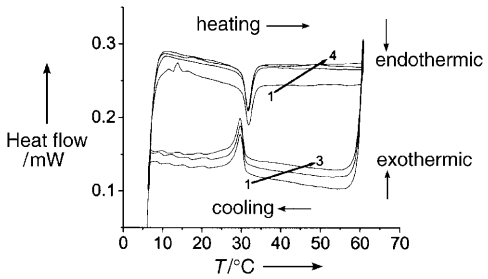

Figure 2. DSC data for 8.25 g L^{-1} poly(thiophene-*g*-NIPAAm) **4** in water; repeated cycles of heating (1–4) and cooling (1–3) between 5 and 60 °C.

excursions led to observation of an endothermic transition at 31.8 ± 0.2 °C and an associated exothermic peak at 29.6 ± 0.4 °C; these are assigned to the enthalpy change associated with the breaking/making of hydrogen bonds between PNIPAAm grafts and water.[20] These results are in agreement with previous studies of PNIPAAm and confirm that the stimuli-responsive conformational change of the poly(thiophene-*g*-NIPAAm) brushes is reversible and very sensitive to temperature variation.[19]

In Figure 3 are displayed the electronic absorption spectra of the PT macro initiator **3** and poly(thiophene-*g*-NIPAAm) **4**. In chloroform solution, **3** and **4** exhibit identical λ_{max} values (423 nm, 2.95 eV) for the absorption band associated with the $\pi \rightarrow \pi^*$ transition of the PT backbone. This indicates that PT

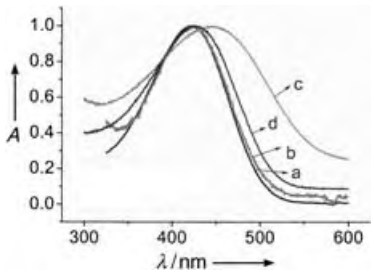

Figure 3. Electronic absorption spectra (normalized) of a) **3** and b) **4** in chloroform (0.01 g L^{-1}); films of c) **3** and d) **4** on quartz.

has a high degree of disorder in the main PT backbone. Thin films of **3** and **4** display bathochromic shifts of 21 nm and 8 nm, respectively, relative to their solution counterparts, indicating better structural ordering (increased conjugation length) of the PT backbone in the solid state.[28–30] The smaller increase in λ_{max} for the film of graft polymer **4** (8 nm) compared to that of the PT macroinitiator **3** (21 nm), versus the solution values, points to the fact that the PNIPAAm chains separate the PT backbones, preventing PT backbone–backbone interactions to some extent.[28] Aqueous solutions of the graft polymer **4** displayed a relatively low-energy λ_{max} at ca. 445 nm at room temperature (Figure 4) compared to that in chloroform solution ($\lambda_{max} = 423$ nm); this likely results from the nature of the solvent, for as the solvent quality decreases (becoming more polar), it is known for soluble PTs that the backbone units tend to adopt a more planar structure.[17]

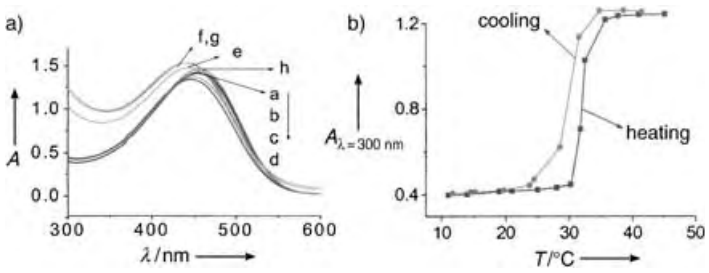

Figure 4. a) Electronic absorption spectra of 0.8 g L^{-1} poly(thiophene-*g*-NIPAAm) **4** in pure water at various temperatures: a) 11, b) 18, c) 28, d) 30, e) 32, f) 38, and g) 45 °C, all in the heating direction; h) at 11 °C after cooling from 45 to 11 °C. b) Absorbance intensity at 300 nm (heating and cooling).

Light-scattering studies of poly(thiophene-*g*-NIPAAm) **4** in water indicate that the polymer brush exhibits a change in molecular shape upon passing through the LCST of 32 °C.[23] Static light-scattering experiments of **4** in water demonstrate that at temperatures above the LCST, the scattering intensity is significantly greater than that below the LCST, and the radius of gyration of the poly(thiophene-*g*-NIPAAm) is approximately 50 % of that at temperatures below 32 °C ($\approx$70 nm vs. $\approx$150 nm). Confirming this decrease in molecular size on transition from below the LCST to above the LCST, analysis of low-angle (30°) dynamic light-scattering data leads to the observation of a roughly threefold increase in the apparent diffusion coefficient when the temperature is increased above the LCST (1.7×10^{-8} cm^2 s^{-1} vs. 5.2×10^{-8} cm^2 s^{-1}). Preliminary evaluation of the light-scattering data excludes the possibility for intermolecular aggregation of individual poly(thiophene-*g*-NIPAAm) molecules when the temperature is increased above the LCST and suggests that the shape of the molecules changes from a random coil to collapsed sphere when the LCST is traversed.[23] Finally, the light-scattering data points to a second, more subtle transition in the 25–28 °C temperature range that is associated with precollapse of the PNIPAAm chains; this is in agreement with theory and recent experimental work for surface-grafted PNIPAAm materials.[25,31] This precollapse is also noted in the electronic absorption spectra of **4** in water (see below). Extensive studies to more fully understand the temperature-induced changes in conformation of the poly(thiophene-*g*-NIPAAm) materials are planned.

In Figure 4a are displayed the electronic absorption spectra of poly(thiophene-*g*-NIPAAm) **4** in water as a function of temperature. As the temperature was increased from 11 °C to 30 °C, there was a small decrease in the intensity of the absorption band and a small blue-shift (456 to 446 nm). Above 30 °C, the solution became cloudy, and a significant increase in the absorption intensity, along with a 6-nm (from 446 to 440 nm) blue-shift of λ_{max} and a broadening of the absorption band, was noted. The temperature dependence of the absorption intensity at 300 nm for poly(thiophene-*g*-PNIPAAm) **4** in water upon heating and cooling is shown in Figure 4b; a very sharp change between 30 and 35 °C is evident. The data in Figure 4b demonstrate that this steep transition is reversible with some hysteresis, the latter which is most likely associated with PNIPAAm intrachain and interchain associations formed during collapse that require a significant amount of time to disentangle. Such hysteresis is observed in dilute solutions of PNIPAAm[32] and when the polymer is grafted on surfaces.[25] All of these observations reveal that the PT backbone responds to the temperature-induced conformational changes of the grafted PNIPAAm chains.

We propose that the temperature-dependent spectral shift and intensity change of the $\pi\rightarrow\pi^*$ transition of the poly(thiophene-*g*-NIPAAm) **4** in water are the result of changes in the effective conjugation length of the PT backbone caused by steric interactions between the collapsed PNIPAAm moieties and the PT backbone, as well as changes in the hydrophobicity of the environment near the PT main chain.[33] Furthermore, we conclude that the observed behavior is associated with the folding of a single chain (molecule) of poly(thiophene-*g*-NIPAAm). The spectroscopic changes are not due to the well-known thermochromic effect found in substituted regioregular and regioirregular PTs in solution[34] or in the solid state,[35–37] as the sensitivity of the changes in λ_{max} for the $\pi\rightarrow\pi^*$ transition for the poly(thiophene-*g*-NIPAAm) with temperature (21 °C increase yields a 16-nm blue-shift) is much higher than that previously reported for regioirregular poly(3-hexylthiophene) solutions in THF (100 °C increase yields a 20-nm blue-shift[34]). Instead, we propose that the collapse of the PNIPAAm chains toward the PT backbone causes an increase in the steric interactions between the PNIPAAm groups and the main PT chain, as well as an increase in the hydrophobicity of the PT backbone environment, the latter which would mimic an increase in the quality of the solvent. It is well known that upon its collapse above the LCST, PNIPAAm becomes quite hydrophobic due to expulsion of water from the polymer, loss of hydrogen bonding between amide groups, and substantially increased hydrophobic interactions between the isopropyl groups. The larger steric and environmental effects with increased solution temperature would result in a more twisted PT backbone (a lower conjugation length) for the poly(thiophene-*g*-NIPAAm) **4** in water. Also, the 10-nm blue-shift that occurs between 11 and 28 °C supports our conclusion and deserves further comment. It has been shown from theoretical[31,38] and experimental[25,39,40] points of view that tethered PNIPAAm brushes exhibit what is referred to as a continuous collapse before the precipitous collapse event at the LCST transition. That is to say, as the LCST is approached from lower temperatures, the solvent is expelled from the interfacial region from which the chains are grafted, and the interfacial PNIPAAm chains undergo precollapse. In our case, the interface is a poly(thiophene) backbone, and slow collapse toward it over the 11 °C to 28 °C range induces strain on the PT backbone and leads to an increase in the hydrophobicity of the interfacial region, both of which result in observation of the spectral changes. Finally, we found no effect of the concentration of the graft polymer (0.8–0.2 g L^{-1}) on the temperature-dependent spectral shift and intensity change for the $\pi\rightarrow\pi^*$ transition of the graft polymer in water, supporting a single-chain event for the temperature-dependent folding of poly(thiophene-*g*-NIPAAm) **4** in water.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

On the basis of the results obtained from light-scattering experiments, SFM, DSC, and electronic absorption spectroscopy, a proposal for the conformational transition of poly(thiophene-g-NIPAAm) **4** is schematically depicted in Figure 5. The highly water-soluble graft polymer possesses a

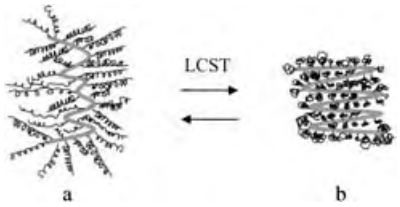

Figure 5. Conformational transition of poly(thiophene-*g*-NIPAAm) **4** at its LCST: a) extended random conformation of molecules that are soluble in water at $T < \text{LCST}$, and b) collapsed sphere conformation of molecules that are insoluble in water at $T > \text{LCST}$.

disordered backbone and adopts a roughly random-coiled structure at temperatures below the LCST. Once the solution temperature is above the LCST, **4** adopts a more globular structure, and the backbone is more ordered as a result of the combined steric interactions between the collapsed PNIPAAm and PT moieties and the hydrophobic environment afforded by the PNIPAAm.

In conclusion, the highly water-soluble, thermally responsive poly(thiophene-*g*-NIPAAm) was synthesized and characterized. The DSC, UV, and light-scattering measurements clearly show that between 28 and 35 °C in water this polymer undergoes a reversible phase transition from a coiled structure to a collapsed globule. By analyzing the optical properties of PT substituted with responsive PNIPAAm chains, we were able to gain insight into the mechanism for changes that happen to the PT backbone when transition of the PNIPAAm chains takes place. The unique optical and electronic properties that result from combining the PT with the water-soluble and temperature-responsive PNIPAAm side-chain groups promise important applications of this polymer brush system in responsive soft nanodevices, LEDs, bioelectronics, biosensors, actuators, fluorescent thermometers, and supramolecular materials. In particular, the use of regioregular PT materials will augment the capabilities of such applications.

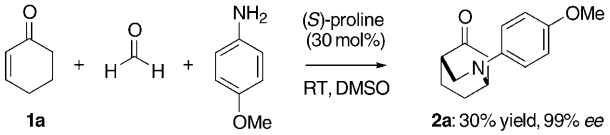
Asymmetric Catalysis

DOI: 10.1002/anie.200500811

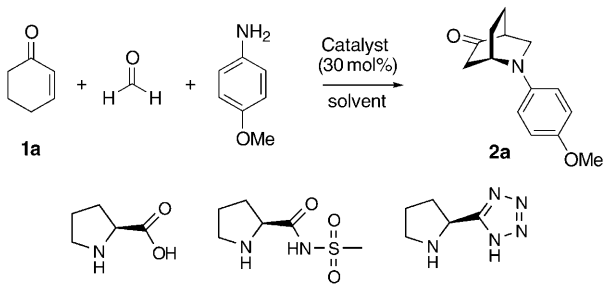
Direct Catalytic Enantioselective Aza-Diels–Alder Reactions**



*Henrik Sundén, Ismail Ibrahem, Lars Eriksson, and Armando Córdova**

The synthesis of optically active nitrogen-containing compounds is a very important task in chemistry as they are key building blocks for the construction of valuable compounds such as amino acids, aza sugars, and alkaloids. The aza-Diels–Alder reaction is one of the most powerful C–C bond-forming reactions for the preparation of nitrogen-containing compounds such as piperidines and quinolidine derivatives,[1,2] and thus chemists have developed several diastereoselective aza-Diels–Alder reactions.[3,4] Despite the potential advantages of utilizing asymmetric catalysis, there are only a few examples of catalytic asymmetric indirect aza-Diels–Alder reactions between preformed imines and dienes or enolethers. For example, the research groups of Kobayashi and Jørgensen have successfully used chiral Lewis acid complexes as catalysts for these transformations.[5–7] However, there is to our knowledge no report of a direct catalytic enantioselective aza-Diels–Alder reaction. Organocatalysis is a rapidly growing research field and has been applied successfully to several different enantioselective reactions.[8] In particular, amino acid derivatives have been utilized as catalysts for enantioselective cycloadditions such as the Diels–Alder reaction.[9–13] This research and our interest in applying amino acids as catalysts in asymmetric synthesis[14] led to us becoming interested in whether an amino acid derivative would be able to mediate the classical aza-Diels–Alder reaction through a catalytic enamine mechanism. Retrosynthetic analyses suggested that an imine generated in situ would be able to react with a catalytically generated chiral diene and form an aza-Diels–Alder product [Eq. (1)].[15] Thus, we embarked on the quest to develop a one-pot three-component asymmetric aza-Diels–Alder reaction. Herein, we report the first direct catalytic enantioselective aza-Diels–Alder reaction that yields the corresponding products with excellent stereoselectivity.

(1)



In an initial experiment, 2-cyclohexen-1-one (**1a**, 2 mmol), aqueous formaldehyde (1 mmol, 36 vol% aqueous solution), and *p*-anisidine (1.1 mmol) were mixed in the presence of a catalytic amount of (*S*)-proline (30 mol%). After vigorously stirring the mixture for 24 h, the reactions were quenched by extraction and the crude product purified by column chromatography on silica gel to furnish the desired aza-Diels–Alder product **2a** in 30% yield with excellent chemoselectivity and 99% *ee* [Eq. (2)]. Encouraged by this

(2)

experiment, we investigated different reaction conditions and the utilization of different proline derivatives as catalysts to increase the yield of the reaction (Table 1).

Table 1: Amine-catalyzed direct enantioselective aza-Diels–Alder reaction.[a]

Entry	Cat.	Solvent	*t* [h]	*T* [°C]	Yield [%][b]	*ee* [%][c]

We found that the organocatalytic aza-Diels–Alder reaction was most efficient in DMSO and that the yield of **2a** could be increased from 30 to 52% by performing the reaction at 50°C without affecting the stereoselectivity of the reaction.[16] Furthermore, in situ reduction of **2a** with excess $NaBH_4$ furnished the corresponding bicyclic alcohol product in 82% yield and 99% *ee*. We also investigated the novel direct enantioselective aza-Diels–Alder reaction with amine catalysts **4** and **5**.[17,18] Both catalysts **4** and **5** were able to catalyze the direct three-component reaction with excellent regio- and enantioselectivity to furnish the corresponding aza-Diels–Alder adduct **2a** in 31 and 61% yields and 94 and 99% *ee*, respectively. Hence, of all the amino acid derivatives tested proline (**3**) and tetrazole **5** were the most efficient catalysts for the aza-Diels–Alder reaction. The amino acid derivatives also catalyzed the reaction in *N*-methylpyrrolidine (NMP) and DMF with high enantioselectivity.

We next investigated the one-pot three-component aza-Diels–Alder reaction for a set of different cyclic α,β-unsaturated ketones (Table 2). We found that α,β-unsaturated cyclohexenones and heptenones were excellent substrates for the direct catalytic enantioselective aza-Diels–Alder reactions with amino acids as the catalysts, and the corresponding bicyclic amines **2a**–**2c** protected with *p*-methoxyphenyl (PMP) groups were isolated in high yield with high *ee* values (up to >99% *ee*). For example, azabicyclooctanone **2b** was isolated in 72% yield with >99% *ee*. Thus, protected azabicycles can be assembled asymmetrically in one chemical manipulation from simple inexpensive readily available starting materials. Proline was the most efficient organic catalyst when unsaturated ketone **1c** was utilized as the donor and furnished the corresponding bicycle **2c** in high yield with 98% *ee*. Furthermore, the amino acid catalyzed aza-Diels–Alder reactions were operationally simple and performed in wet solvents. The proline-catalyzed one-pot three-component reaction with 3-substituted cyclohexanone **1d** only furnished the α,β-unsaturated Mannich adduct **2d** in 40% yield and 94% *ee* and not the aza-Diels–Alder product. The reaction with 2-cyclopentenone (**1e**) only furnished trace amounts of the desired aza-Diels–Alder adduct **2e**. Proline-catalyzed reactions between *trans*-4-phenyl-3-buten-2-one, formaldehyde, and *p*-anisidine did not provide any product under our reaction conditions. The PMP group of the aza-Diels–Alder adduct **2b** was removed with cerium ammonium nitrate (CAN) followed by treatment with $(Boc)_2O$

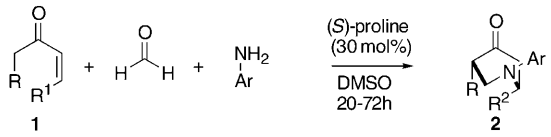

Table 2: Proline-catalyzed direct three-component enantioselective aza-Diels–Alder reaction.[a]

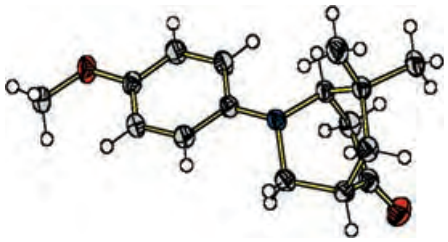
(Boc = *tert*-butoxycarbonyl) to furnish the desired Boc-protected azabicycle.

We next investigated the effect of the amine component on the reaction catalyzed by an amino acid (Table 3). The reaction advanced with excellent chemo-, regio-, and stereoselectivity to yield the corresponding bicycles **2b** and **2f–2i** with up to >99% *ee*. In particular, the hetero-Diels–Alder reactions with anilines having an electron-donating substituent at the *para* position furnished the corresponding aza-Diels–Alder products with excellent stereocontrol. The yields of the products derived from the aza-Diels–Alder reactions with *p*-chloro- and *p*-bromoanilines were moderate in comparison to the reactions with aniline and *p*-anisidine.

The stereochemical outcome of the reaction was determined by X-ray structure analysis of **2b** (Figure 1), which revealed that bicycle (1*R*,4*S*)-**2b** was assembled asymmetrically when amino acid derivatives **3**, **4**, and **5** were used as catalysts.

Scheme 1. The plausible reaction pathway and transition state.



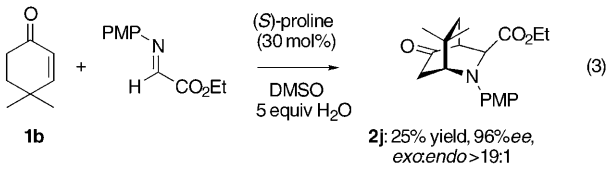


Figure 1. Structure of aza-Diels–Alder product **2b** (ORTEP picture).

On the basis of the absolute stereochemistry of the aza-Diels–Alder adducts and the isolation of Mannich adduct **2d**,[19] we propose the following reaction mechanism to account for the stereochemical outcome of the reaction (Scheme 1). The first step is that the proline-derived catalyst forms a chiral enamine with the α,β-unsaturated ketone **1**. Next, the in situ generated imine attacks the *si* face of the chiral diene via transition state **I**, and an activated iminium salt is formed. The secondary amine of the chiral iminium salt performs a subsequent selective 6-*endo-trig* cyclization to furnish the corresponding chiral azabicycle. Next, the amino acid derivative is released and the desired aza-Diels–Alder adduct **2** is obtained by hydrolysis and the catalytic cycle can be repeated. Thus, the reaction proceeds through a tandem one-pot three-component Mannich/Michael reaction pathway. The stepwise mechanism was further supported by the fact that in the aza-Diels–Alder reactions with *p*-chloroaniline and *p*-bromoaniline, minor amounts of the corresponding α,β-unsaturated Mannich bases were formed in addition to products **2h** and **2i**. This result is in accordance with the lower nucleophilicity of the secondary amine intermediate in the Michael step as compared to *p*-anisidine. Furthermore, the proline-catalyzed reaction with the substituted ketone **1d** failed to ring-close and provided the α,β-unsaturated Mannich base **2d** with excellent enantioselectivity.[16] Attempts to perform 6-*endo-trig* cyclizations of the unsaturated Mannich bases failed under our reaction conditions.

The proline derivatives also catalyzed the direct enantioselective aza-Diels–Alder reaction with preformed imines. For example, proline catalyzed the aza-Diels–Alder reaction between ketone **1b** and ethyl *N*-PMP-α-imino glyoxylate in wet DMSO, and the corresponding synthetically valuable bicyclic amino acid derivative **2j** was isolated exclusively as the *exo* adduct in moderate yield with 96% *ee* [Eq. (3)].

In summary, we have reported the first one-pot three-component direct catalytic enantioselective aza-Diels–Alder reaction. The reaction is catalyzed by proline and its derivatives with excellent chemo-, regio-, and stereoselectivity. For example, the amino acid catalyzed asymmetric aza-Diels–Alder reactions between aqueous formaldehyde, α,β-unsaturated cyclic ketones, and aromatic amines furnished the desired azabicyclic ketones with up to >99% *ee*. The reactions are operationally simple, performed in wet solvents, and environmentally friendly. Moreover, the reaction can be applied for the synthesis of protected azabicyclic amino acids with excellent *exo* and enantioselectivity. Further elaboration of this transformation and its synthetic application is ongoing.

Experimental Section

Typical experimental procedure (Table 2, entry 2): Ketone **1b** (2 mmol) was added to a vial containing aqueous formaldehyde (1 mmol, 36% aqueous solution), *p*-anisidine (1.1 mmol), and a catalytic amount of (*S*)-proline (30 mol%) in DMSO (4 mL). After vigorously stirring the mixture for 24 h at 50 °C, the reaction was quenched by purifying the reaction mixture by column chromatography on silica gel (EtOAc/pentane 1:5) to afford **2b** in 72% yield as a slightly yellow solid. The *ee* value of **2b** was >99% as determined by HPLC analysis on a chiral stationary phase. ^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 1.08$ (s, 3H), 1.10 (s, 3H), 1.77 (d, $J = 2.98$ Hz, 2H), 2.47 (dd, $J = 18.7$, 3.4 Hz 1H), 2.62 (m, 1H), 2.68 (dd, $J = 18.9$, 2.3 Hz 1H), 3.48, (d, $J = 2.5$ Hz, 2H), 3.75 (m, 1H), 3.76 (s, 3H), 6.61–6.63 (m, 2H), 6.84–6.86 ppm (m, 2H); ^{13}C NMR (100 MHz, $CDCl_3$): $\delta = 28.8$, 30.2, 36.1, 38.9, 41.3, 46.0, 47.9, 56.1, 58.5, 112.1, 115.54, 141.1, 151.4, 214.0 ppm; HPLC (Daicel Chiralpak AD, hexanes/*i*PrOH 99:1, flow rate 1.2 mL min^{-1}, $\lambda = 254$ nm): major isomer: $t_R = 24.94$ min; minor isomer: $t_R = 27.31$ min; $[\alpha]_D = -71.8$ ($c = 1.7$, $CHCl_3$); MALDI-TOF MS: 256.1689; $C_{16}H_{22}NO_2$ $[M+H]^+$: calcd 261.1683.

The Structural and Functional Roles of Rhodium(II)–Rhodium(II) Dimers in Multinuclear Ruthenium(II) Complexes**

*Michael W. Cooke, Garry S. Hanan,**
*Frédérique Loiseau, Sebastiano Campagna,**
*Masashi Watanabe, and Yasutaka Tanaka**

Polypyridylruthenium(II) complexes have received much attention as a result of their long-lived luminescent metal-to-ligand charge-transfer (MLCT) excited state, which is a useful property for intercomponent energy and electron-transfer processes in supramolecular systems.[1] In particular the characteristically rich electrochemistry of multinuclear Ru^{II}–polypyridyl assemblies make them excellent models for multicomponent systems capable of performing photo- and/or redox-active supramolecular functions, such as those occurring in light-harvesting antenna systems[2] and photo-activated molecular machines.[3]

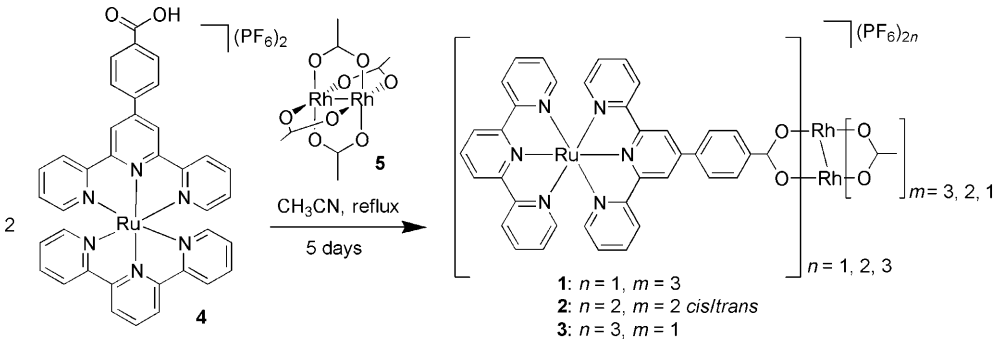
Among the Ru^{II} chromophores employed in photoactive devices, particularly attractive are those based upon 2,2′:6′2″-terpyridine (tpy), as the $\{Ru(tpy)_2\}^{2+}$ unit is achiral when substituted in the 4′-position,[4] and appropriate substitution can render the complex emissive from an otherwise quasi-non-emissive excited state.[5,6] However, synthesis and purification becomes increasingly tedious as a function of the nuclearity of the photoactive complexes, particularly when the formation of covalent bonds and protection/deprotection sequences are relied upon to create the linkages.[7] As earlier work had shown that molecular squares and polymers can be built up using metal tetracarboxylato dimers,[8,9] we decided that a more facile strategy toward multinuclear systems could rely upon the coordination chemistry of metal dimers. Their well-known paddlewheel-like motif offers a robust template from which to attach appropriately functionalized Ru^{II}–polypyridyl units by using ligand exchange reactions. We selected the Rh^{II} dimer to assemble these chromophores as it is typically air stable, diamagnetic, and inert to scrambling of the carboxylate groups.[10]

The Ru^{II} chromophores are based on the readily available $[Ru(tpy)\{4'\text{-}(4\text{-carboxyphenyl})tpy\}]^{2+}$ complex (**4**).[11] The methanol adduct of (tetra-μ-acetato)dirhodium(II,II) (**5**) can be substituted under relatively mild conditions to yield substitution products **1**–**3** in 63% yield in refluxing acetonitrile (Scheme 1).[12] The product distribution can be shifted to the higher substituted Ru complexes by increasing the ratio of **4** to **5**, the reaction time, and the temperature. However, no tetra-substituted ($n = 4$) product was detected in any of the cases. The structural formulas of the new multinuclear complexes are shown in Scheme 2.

The substitution products, including the *cis/trans* isomers of **2**, can be separated by column chromatography. Crystals suitable for X-ray diffraction of *trans*-**2** were grown by vapor diffusion of diisopropyl ether into a dilute solution of *trans*-**2** in acetonitrile containing $NaBF_4$ and NH_4BPh_4 (Figure 1).[13] The solid-state structure shows a familiar paddlewheel motif about the rhodium(II) dimer, with a tip-to-tip distance of 36 Å and a nearly eclipsed relative disposition of the ligands. The metal–metal bond length of 2.367(2) Å is typical of dirhodium carboxylates,[10] as are the Rh–O(acetate) and Rh–N(CH_3CN) bond lengths of 1.936(11) and 2.200(15) Å, respectively. However, the Rh–O(carboxylate-tpy) bond length in *trans*-**2** is markedly elongated at 2.052(7) Å and is, to our knowledge, the longest such bond known for dirhodium(II,II) carboxylates.

Complex **4** and the products **1**–**3** have been characterized by ^{1}H NMR spectroscopic analysis in CD_3CN. All of the complexes display a marked electronic effect on the phenyl protons that is dependent on the number of substituted ruthenium units. The identity of each complex is readily verified through integration of the methyl singlets corresponding to equatorially coordinated acetate groups, and this is also supported by electrospray mass spectrometry data.

Although the absorption spectra of multinuclear species **1**–**3** (Figure 2) are the sum of the spectra of the individual components, their luminescence properties are significantly different from those of model species **4** (Table 1). Indeed, the MLCT emission of **4** is totally quenched at room temperature in **1**–**3**, and greatly reduced, as evidenced by lifetime measurements, in a rigid matrix at 77 K (see Table 1 and inset of Figure 2).



Cyclic and differential pulse voltammetry studies showed that the new compounds all exhibit a single reversible

oxidation process in the potential window investigated (−1.70/+1.50 V versus the saturated calomel electrode (SCE)). The process is assigned to the oxidation of the Ru^{II} subunit(s) on the basis of the oxidation potential of **4** and of the constancy of the potential within the **1**–**3** series (Table 2). Oxidation of the Rh dimer apparently does not take place within the potential window, most likely because of the coordination of the positively charged Ru^{II} moieties. The new compounds all exhibit irreversible reduction processes, probably involving overlapping reduction of the Rh dimer and the Ru^{II} chromophores, namely the tpy ligands. The irreversibility of the reduction processes make their detailed discussion difficult.

The redox data indicate that reductive electron transfer cannot be considered as a viable route for quenching. In fact, oxidation of the Rh dimer unit in **1**–**3** does not occur until above +1.5 V, and since the first reduction of the Ru moieties is about −1.2 V in all the new species, reductive electron transfer would be endoergonic and not efficient. Similar arguments also apply to oxidative electron transfer. However, the lowest-lying excited state of Rh dimers similar to those used here as templating units has been reported to lie between 1.30 and 1.70 eV, as characterized by relatively long lifetimes in solution (up to 5 μs, depending on the solvent and substituents), although they were found to be nonluminescent.[14a] Despite the large uncertainty concerning the exact energy level of the Rh dimer subunits, there is a substantial driving force in **1**–**3** for energy transfer from the (potentially emitting) Ru-based MLCT states (whose energy is around 1.95 eV) to the excited state based on the Rh dimer. Even if it is assumed that the limiting value of the excited-state energy of the acceptor Rh dimers is 1.70 eV, a ΔG value of −0.25 eV is found (the excited-state energy of the donor Ru chromophores is approximately the same as the maximum value of the emission of **4** at 77 K), which is large enough to make the energy-transfer process efficient. As a consequence, we attribute the quenching of the Ru-based MLCT luminescence in **1**–**3** to energy transfer from the MLCT state(s) to the lowest-lying Rh dimer based level, which would play the role of the energy trap in the multinuclear systems. Therefore, **1**–**3** behave as efficient light-harvesting antennae, where the light energy collected by the Ru^{II}-appended chromophore(s) is conveyed to the Rh dimer subunit. Interestingly, the energy-transfer process appears to be partial at 77 K, thus indicating the presence of significant energy barriers and suggesting that the dominating energy-transfer mechanism of the fast room temperature process could be electron exchange. Ultrafast experiments are in progress to fully characterize the photophysical properties of the new species.

In conclusion, we have developed a novel approach to build-up multinuclear polypyridylruthenium systems by relying upon coordination to a tetracarboxylato metal dimer. Multinuclear complexes are readily available by attaching mononuclear functional subunits (namely, Ru^{II} chromophores) to structural subunits (namely, metal dimers). This "chemistry-on-the-complex" approach simplifies the synthesis of multinuclear assemblies by allowing independent preparation of the different subunits.[8c,16] Intercomponent energy transfer between subunits is efficient, thus indicating that the metal dimers may play a functional role and not only act as a template. The rich chemistry of tetracarboxylato metal dimers and metal–polypyridine complexes with useful photophysical properties should provide ready access to diverse structures with different cores and/or peripheral chromophores and lead to a large library of novel and easily accessible multicomponent species with made-to-order properties. For example, replacement of the Ru chromophores employed here with Ru^{II}–polypyridine species having lower MLCT excited states would make the energy-transfer quenching inefficient and restore peripheral subunit luminescence, whereas the reaction of the partially "uncompleted" species bearing available coordinating units such as **1** and **2** with other metal chromophores (namely, Os^{II} species) should lead to more elaborated mixed-chromophore architectures.

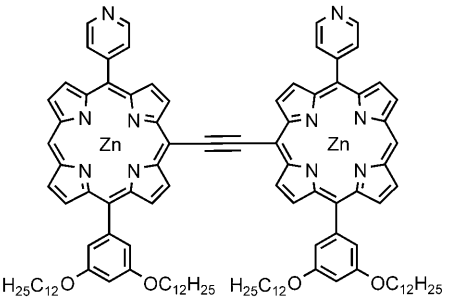
Planar or Perpendicular? Conformational Preferences of π-Conjugated Metalloporphyrin Dimers and Trimers in Supramolecular Tubular Arrays**

Akihiko Tsuda, Haifeng Hu, Ryo Tanaka, and Takuzo Aida**



Conformational aspects of π-conjugated molecules are important not only for the basic understanding of their electronic properties but also for their practical application in molecular electronics and photonics.[1–3] The absorption and fluorescence properties of porphyrin pigments are highly sensitive to their π-electronic structures and so π-conjugated multiporphyrin arrays have been studied extensively.[4–10] Another advantage of π-conjugated multiporphyrin arrays is the possibility of controlling their conformation through supramolecular chemistry.[11–13] Studies on the conformational aspects of monoalkynylene-bridged bisporphyrins have suggested that these compounds, despite their rotational freedom around the triple bond, prefer to adopt a planar conformation since planar conformers are enthalpically more favorable than perpendicular conformers as a consequence of the extension of the π conjugation.[8] We have reported that the zinc complex of a monoalkynylene-bridged bisporphyrin with *meso*-pyridyl functionalities **2(≡)$_1$** forms a box-shaped cyclic tetramer, in which the dyad incorporated into the supramolecular box exclusively adopts the planar conformation **2(≡)$_1$//** (Figure 1).[13] Although bisporphyrins with a dialkynylene bridge have a much higher rotational freedom than the monoalkynylene-bridged versions, theory still suggests an energetic bias toward the planar conformation.[9] Anderson and co-workers have succeeded in fixing a dialkynylene-bridged zinc porphyrin oligomer in the planar conformation during the bipyridine-mediated formation of a supramolecular ladder.[11] In the present study we investigated cyclotetramerization[13–17] of zinc complex **2(≡)$_2$**, a dialkynylene-bridged analogue of **2(≡)$_1$**.[18] As with **2(≡)$_1$**, cyclotetramerization of **2(≡)$_2$** can possibly form two isomeric supramolecular boxes **[2(≡)$_2$//]$_4$** and **[2(≡)$_2$⊥]$_4$**, where **[2(≡)$_2$//]$_4$** consists

2(≡)$_1$

2(≡)$_2$

ref-**2(≡)$_2$**

3(≡)$_2$

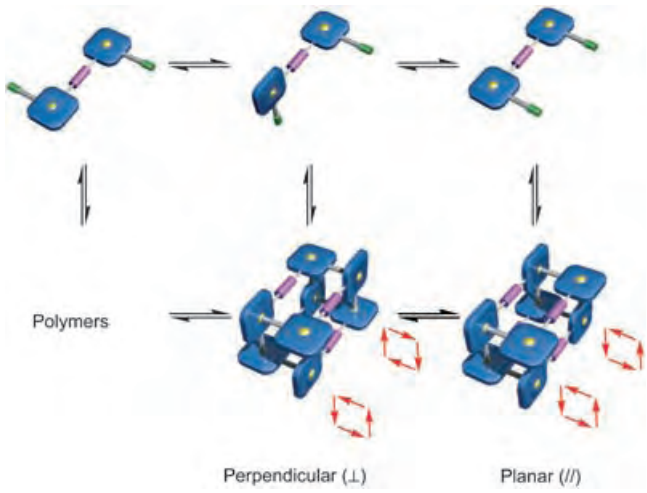

Figure 1. Schematic representation of the cyclotetramerization of alkynylene-bridged zinc pyridylporphyrin dimers. Pink cylinders represent either mono- or dialkynylene units. Red arrows indicate the direction of the Py→Zn coordination.

of the planar conformer of **2(≡)$_2$** (**2(≡)$_2$//**), while **[2(≡)$_2$⊥]$_4$** is composed of the perpendicular conformer (**2(≡)$_2$⊥**; Figure 1). To our surprise, detailed spectroscopic studies indicated that **2(≡)$_2$⊥** is favored over **2(≡)$_2$//** in the resulting supramolecular tubular array.

Compound **2(≡)$_2$** was prepared by treatment of the zinc complex of [5-(4-pyridyl)-10,20-bis(triisopropylsilylethynyl)-15-(3,5-didecyloxyphenyl)porphyrin (**1**) with 0.5 equivalents of tetrabutylammonium fluoride (TBAF), followed by Glaser–Hay coupling of the resulting mixture of derivatives in which the silyl group had been cleaved.[19] Demetalation under acidic conditions and subsequent preparative size-exclusion chromatography (SEC) allowed isolation of the free-base forms of **2(≡)$_2$** and **3(≡)$_2$** in 17 and 2% yields, respectively. Analytical SEC of zinc complex **2(≡)$_2$** with $CHCl_3$ as the eluent displayed a sharp elution peak with a shorter retention time (49.6 min) than that of a non-assembling reference compound without pyridyl groups (ref-**2(≡)$_2$**, 54.8 min).[19] Since the elution time of this chromatographic peak is shorter than that of the cyclic tetramer of the monoalkynylene-bridged analogue (**[2(≡)$_1$]$_4$**, 50.8 min) under identical SEC conditions, **2(≡)$_2$** most likely forms a cyclic oligomer with a larger hydrodynamic volume than **[2(≡)$_1$]$_4$** (Figure 1).[13]

^{1}H NMR spectroscopic analysis of **2(≡)$_2$** in $CDCl_3$ at 20°C provided two sets of characteristic signals corresponding to the porphyrin and pyridyl protons (Figure 2a). By analogy to the spectral patterns[19] of other box-shaped cyclic tetramers so far reported,[13,14] it is most likely that these two sets are both attributed to cyclotetrameric **[2(≡)$_2$]$_4$** (Figure 1). The most characteristic resonances are eight doublets a–d and e–h observed at $\delta = 2.4$–3.0 and 6.2–6.4 ppm, respectively. Addition of [D_5]pyridine (5%), a competitive ligand for the Zn-N coordination, to the system resulted in these characteristic signals disappearing completely, while new doublet signals appeared in the downfield region of $\delta = 8.05$ and 8.86 ppm. These new signals are

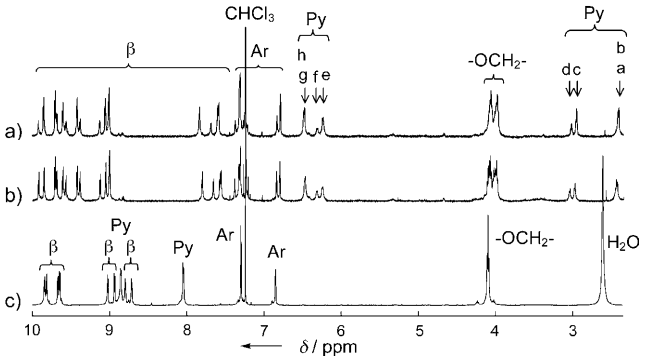

Figure 2. ^{1}H NMR spectra (500 MHz) of **2(≡)$_2$** at a) 20 °C, b) 50 °C in $CDCl_3$, and c) 20 °C in $CDCl_3$/[D_5]pyridine (0.95/0.05). β: β-Pyrrole, Ar: aryl, Py: pyridyl.

assigned to the *ortho* and *meta* protons of the pyridyl groups (Py), respectively, of non-associated **2(≡)$_2$** on the basis of the ^{1}H NMR spectral profile of the free-base form of **2(≡)$_2$** (δ = 8.10 and 9.01 ppm, respectively). Therefore, upfield-shifted signals a–d and e–h can be assigned to the Py groups of **2(≡)$_2$** coordinating to the metal centers. We have reported that the reference tetrameric complex **[2(≡)$_1$]$_4$**, which bears inner and outer Py protons as a result of its cyclic structure (Figure 1), shows a set of four upfield-shifted Py signals.[13] Together with the 2D {^{1}H-^{1}H} COSY spectrum of **2(≡)$_2$**,[19] the two sets of such unique multiple Py signals in Figure 2 can reasonably be assigned to cyclotetrameric **[2(≡)$_2$]$_4$**, provided that it is a mixture of two stereoisomers, namely, **[2(≡)$_2$⊥]$_4$** and **[2(≡)$_2$//]$_4$** which consist of the perpendicular and planar conformers of **2(≡)$_2$**, respectively (Figure 1). The ratio of the integrals of signals c and d, for example, indicates that the two stereoisomers exist in a ratio of 3:1 at 20 °C. We also found that the isomer ratio is temperature-dependent: raising the temperature from 20 to 50 °C results in the isomer ratio changing to 3:2 (Figure 2b).

Correlation of the ^{1}H NMR spectral profile of **2(≡)$_2$** with its absorption and emission spectral features allows the determination of which tetrameric stereoisomer is predominant in the self-assembly of **2(≡)$_2$** (Figure 3). A solution of **[2(≡)$_2$]$_4$** in $CHCl_3$ at 20 °C displayed Soret and Q-bands at 454 (A_I) and 657 nm (A_{III}), respectively. A pair of red-shifted minor bands were also observed at 490 (A_{II}) and 721 nm (A_{IV}). Photoexcitation of **[2(≡)$_2$]$_4$** at 450 nm (A_I) resulted in the appearance of a major fluorescence band at 663 nm (F_I), together with a minor emission at 735 nm (F_{II}; Figure 3b, black solid curve). However, photoexcitation at 500 nm (A_{II}) resulted in a notable enhancement of the minor emission F_{II} (Figure 3b, gray solid curve). A major band was observed at 454 nm (E_I) in the Soret-band region of the excitation spectrum monitored at 660 nm (F_I; Figure 3c, solid curve). Monitoring the fluorescence at 760 nm (F_{II}) provided an excitation spectrum with a split band at 464/494 nm (E_I/E_{II}) in the Soret-band region, along with two low-energy bands at 664 (E_{III}) and 720 nm (E_{IV}) in the Q-band region (Figure 3c, dashed curve). It is clear that the absorption profile of **[2(≡)$_2$]$_4$** (Figure 3a) can be represented by the summation of these two excitation spectra. Band-gap theory for π-conjugated molecules suggests that the higher-energy set of the Soret and Q-bands (A_I and A_{III}, respectively) most likely originates from **[2(≡)$_2$⊥]$_4$** containing the perpendicular conformer of **2(≡)$_2$**, while the lower-energy set (A_{II} and A_{IV}) can be assigned to the planar conformer of **2(≡)$_2$** in **[2(≡)$_2$//]$_4$**.[9] Non-associated **2(≡)$_2$**, generated upon addition of pyridine to **[2(≡)$_2$]$_4$**, showed a luminescence at 738 nm (Figure 3b, dashed curve) upon photoexcitation at 450 nm (A_I). Since alkynylene-bridged multiporphyrin arrays without any external conformational restriction have been reported to emit mainly from their planar conformers,[20] the fluorescence observed from **2(≡)$_2$** at 738 nm provides good experimental support for the assignment that the lower-energy F_{II} (735 nm) band in Figure 3b arises from **[2(≡)$_2$//]$_4$**. Heating the solution from 20 to 50 °C resulted in the latter set of signals arising from **[2(≡)$_2$//]$_4$** in the absorption spectrum intensifying at the expense of the former set assigned to **[2(≡)$_2$⊥]$_4$** (Figure 3a). The combination of this temperature dependency and the ^{1}H NMR spectral profile (see above) leads to the conclusion that **[2(≡)$_2$⊥]$_4$** is the major isomer, which exists in a ratio of 3:1 with the minor isomer **[2(≡)$_2$//]$_4$** at 20 °C and 3:2 at 50 °C. It should also be noted that the absorption and NMR spectral changes are both thermoreversible but extremely slow. As shown in Figure 4, the change in the absorption spectrum on

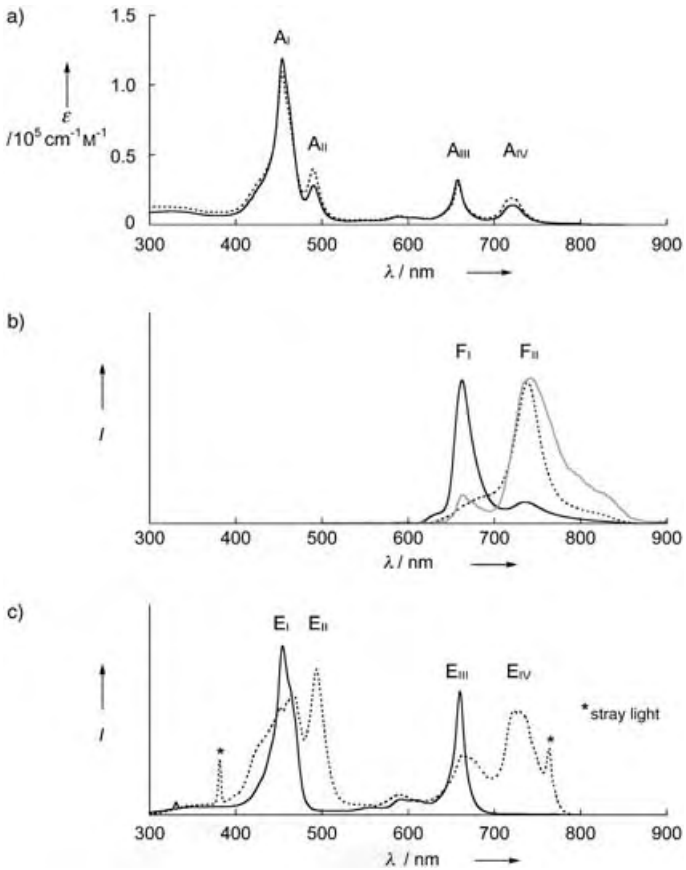

Figure 3. a) Absorption spectra of **2(≡)$_2$** at 20 °C (——) and 50 °C (----) in $CHCl_3$. b) Fluorescence spectra of **2(≡)$_2$** upon photoexcitation at 450 (——) and 500 nm (——) in $CHCl_3$, and 450 nm in $CHCl_3$/pyridine (9:1, ----) at 20 °C. c) Fluorescence excitation spectra of **2(≡)$_2$** monitored at 660 (——) and 760 nm (----) in $CHCl_3$ at 20 °C.

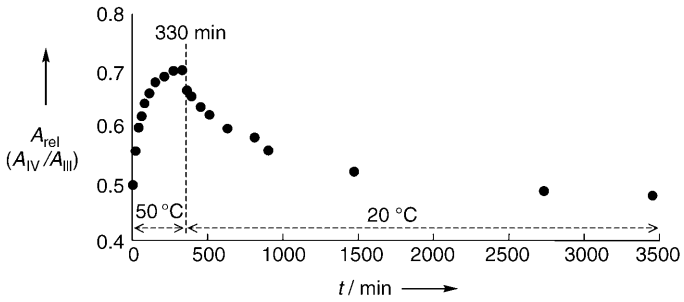

Figure 4. Changes in the relative absorbance (band A_{IV}/A_{III}) of **[2(≡)$_2$]$_4$** in $CHCl_3$ as a function of time upon heating from 20 to 50 °C and cooling from 50 to 20 °C.

heating from 20 to 50 °C subsided in 5 h. Subsequent cooling to 20 °C resulted in a complete recovery of the original spectrum in two days. Such a slow reorganization process indicates a very high thermodynamic stability of tetrameric **[2(≡)$_2$]$_4$**, most likely because of the presence of eight Zn–N coordination bonds.

As described earlier, it is considered that the perpendicular conformers of bis(porphyrins) with π-conjugated bridges are, in general, thermodynamically less stable than the planar conformers. However, the conformational preference toward **2(≡)$_2$**⊥ in the cyclotetramerization is opposite to this general consideration for monomeric **2(≡)$_2$**. We consider that this conformational preference may reflect the extent of the possible interaction of the dipole moments associated with the directions of the eight pyridyl groups in self-assembled **[2(≡)$_2$]$_4$**. Namely, cyclic tetramer **[2(≡)$_2$]$_4$** has two rotational arrays of pyridyl groups, whose directions are identical to one another in **[2(≡)$_2$//]$_4$** but opposite in **[2(≡)$_2$⊥]$_4$** (Figure 1). Since **[2(≡)$_2$⊥]$_4$** allows an efficient cancellation of the dipole moments of the pyridyl groups, **[2(≡)$_2$⊥]$_4$** is favored over **[2(≡)$_2$//]$_4$**.

With this assumption in mind, we investigated the self-assembling behavior of **3(≡)$_2$**, a trimeric version of **2(≡)$_2$**, which contains three dialkynylene-bridged zinc porphyrin units. Although the ^{1}H NMR spectral profile of **3(≡)$_2$** in $CDCl_3$ was less informative of its self-assembled structure, as a result of an enhanced complexity and considerable overlap of the signals, SEC of **3(≡)$_2$** with $CHCl_3$ as the eluent displayed a single, unimodal elution peak with a shorter retention time (47.6 min)[19] than **[2(≡)$_2$]$_4$** (49.6 min), thus suggesting that **3(≡)$_2$** also forms a cyclic oligomer (**[3(≡)$_2$]$_n$**), most likely a discrete cyclic tetramer ($n = 4$) analogous to **[2(≡)$_2$]$_4$**. The electronic absorption spectrum of **[3(≡)$_2$]$_n$** in $CHCl_3$ at 20 °C was very similar to that of **[2(≡)$_2$]$_4$** (Figure 5a). However, photoexcitation of **[3(≡)$_2$]$_n$** at its major absorption band (460 nm; A_I) resulted in a slightly different emission profile from that of **[2(≡)$_2$]$_4$** (Figure 5b, black solid curve). The fluorescence spectrum obtained consists of two distinct bands at 676 (F_I) and 746 nm (F_{II}), which are nearly identical in wavelength to those of **[2(≡)$_2$]$_4$** (Figure 3b). In addition to these major bands, a shoulder (F_{III}) appeared around 790 nm. However, the F_{II} and F_{III} bands were intensified relative to that of F_I when **[3(≡)$_2$]$_n$** was excited at a lower-energy minor absorption band (510 nm,

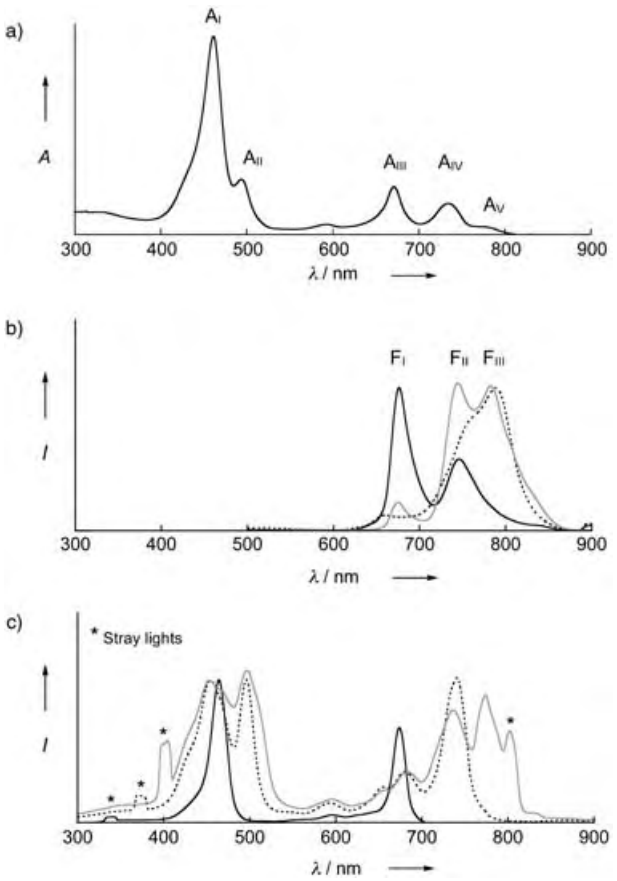

Figure 5. a) Absorption spectrum of **3(≡)$_2$** in $CHCl_3$ at 20 °C. b) Fluorescence spectra of **3(≡)$_2$** upon photoexcitation at 460 (——) and 510 nm (——) in $CHCl_3$, and 460 nm in $CHCl_3$/pyridine (9:1, -----) at 20 °C. c) Fluorescence excitation spectra of **3(≡)$_2$** monitored at 675 (——), 744 (-----), and 800 nm (——) in $CHCl_3$ at 20 °C.

A_{II}; Figure 5b, gray solid curve). From the HOMO–LUMO gap theory of π-conjugated molecules, along with the spectral analogy to **[2(≡)$_2$]$_4$**, the highest-energy F_I and lowest-energy F_{III} bands are assigned to isomers formed exclusively from the perpendicular and planar conformers **[3(≡)$_2$⊥]$_n$** and **[3(≡)$_2$//]$_n$**, respectively, while the middle band (F_{II}) is attributable to **[3(≡)$_2$⊥//]$_n$** consisting of both the planar and perpendicular conformers (Figure 6). Photoexcitation at 460 nm resulted in the non-associated **3(≡)$_2$**, formed by the addition of pyridine to **[3(≡)$_2$]$_n$**, displaying a luminescence centered at 789 nm (Figure 5b, dashed curve), which is close

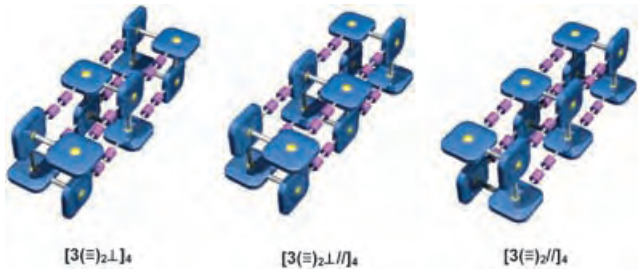

Figure 6. Schematic structures of three conformational isomers in the cyclotetramerization of **3(≡)$_2$**.

to the F_{III} band assigned to $[3(\equiv)_2//]_n$ composed exclusively of the planar conformer of $3(\equiv)_2$. Examination of the excitation spectra of $[3(\equiv)_2]_n$ monitored at 675 (F_I), 744 (F_{II}), and 800 nm (F_{III}; Figure 5c) showed that the Q-bands observed at 671 (A_{III}), 735 (A_{IV}), and 780 nm (A_V) in the absorption spectrum (Figure 5a) originated mainly from $[3(\equiv)_2\perp]_n$, $[3(\equiv)_2\perp//]_n$, and $[3(\equiv)_2//]_n$, respectively. Provided that the molar absorption coefficients of the Q-bands of these three isomers are identical to one another, the relative intensity of A_{III}, A_{IV}, and A_V in Figure 5a may indicate that isomer $[3(\equiv)_2//]_n$ appears to be the least abundant among the three possible isomers. It should be noted that the dipole moments are cancelled to only a small extent in $[3(\equiv)_2\perp]_n$. Thus, similar to the case of $[2(\equiv)_2]_4$, a conformer that allows an efficient cancellation of the dipole moments in its supramolecular tubular array is preferred even if its enthalpic gain at the monomer level, associated with the π-electronic conjugation, is smaller than that of its counterpart. The trend observed for $[2(\equiv)_2]_4$ and $[3(\equiv)_2//]_n$ is in sharp contrast with that of $[2(\equiv)_1]_4$, which has only a single triple bond between the zinc porphyrin units, where the π-electronic conjugation at the monomer level is a dominant factor for determining the conformational aspect of $2(\equiv)_1$.[13]

In conclusion, we have reported the first supramolecular approach to the preferential fixation of the perpendicular conformers of dialkynylene-bridged zinc porphyrin dimer $2(\equiv)_2$ and trimer $3(\equiv)_2$ by coordinative cyclooligomerization. The contrasting conformational preferences of $2(\equiv)_2$ and $3(\equiv)_2$ with $2(\equiv)_1$[13] in cyclooligomerization are clearly the result of the lower enthalpic gains of the former two complexes upon planarization compared to the latter. Since cyclic tetramer $[2(\equiv)_2\perp]_4$ is chiral, and therefore has a variety of potential applications, structural optimization of $2(\equiv)_2$ to realize the perfect conformational selectivity toward $[2(\equiv)_2\perp]_4$ is one of the interesting subjects worthy of further investigations.

lines **4**[1,2a,b] and the aza bisoxazolines **5**,[3] the backbone of which contains a planar, negatively charged π system. In

addition, neutral variants **2**[1] and **3**,[3] which contain a planar bridging N atom or a neutral dialkylated methylene bridge **6**, have been developed. The ligand charge, the geometry of the bridging atom, and the electronic properties of the coordinating N atoms all influence the reactivity and enantioselectivity of a metal catalyst.[1,3] Among the various semicorrin analogues reported to date, the bisoxazolines (box) **6** stand out as particularly versatile ligands that have been successfully applied in a wide range of metal-catalyzed reactions.[2] As a further variation of this structural motif, we report herein a class of readily available, anionic bisoxazoline ligands (borabox) **7** that contain a tetrasubstitued B atom that bridges the two oxazoline rings. In contrast to the known anionic ligands **1**, **4**, and **5**, the negative charge in the borabox structure is located in the backbone and the geometry of the bridging atom is tetrahedral as in the neutral box ligand **6**. Anionic ligands of this type that can form neutral zwitterionic complexes with metal cations have recently received increased attention, and a number of N, P, and S ligands which contain tetraorganoborate or indenyl anions as structural elements have been reported.[4–6]

The borabox ligand structure can be readily assembled by reaction of a metalated oxazoline with a dialkyl or diaryl haloborane (Scheme 1). This strategy, which differs from known synthetic approaches to bisoxazolines, is attractive because simple and readily accessible oxazolines **8** can be used as precursors. Lithiation of **8** following the procedure of Meyers and Novachek[7] and subsequent treatment with 0.5 equivalents of haloborane at low temperature led to the lithium salts of bora bisoxazolines **7a–f**. These compounds were isolated in analytically pure form as highly hygroscopic white powders in moderate to good yields, depending on the nature of the substituents at the B atom. The lithium salts could be converted into the protonated ligands **9a–f** by chromatographic workup on silica gel using hexanes/ethyl acetate/triethylamine as the eluent. Regeneration of the lithium salts of **7a–f** was readily accomplished by treatment of

compounds **9a–f** with one molar equivalent of *n*-butyllithium in diethyl ether at room temperature.

A wide variety of sterically and electronically different ligands can be prepared by structural variation of the haloborane and the oxazoline **8**. The borabox ligands readily form stable complexes with transition-metal ions, such as Cu^{II}, Zn^{II}, Pd^{II}, Rh^{I}, and Ir^{I} ions, starting from the lithium salts [Li(**7**)] or the protonated precursors **9** in the presence of a base such as K_2CO_3. Figure 1 shows the crystal structure of the homoleptic Cu^{II} complex of **7a** alongside a Cu^{II} complex derived from the analogous diphenylmethyl-bridged box derivative **6a**.[8,9]

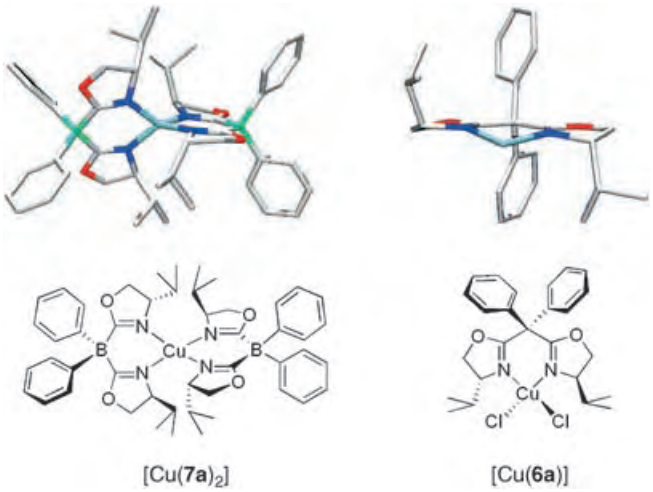

Figure 1. Crystal structures of complexes [Cu(**7a**)$_2$] and [$CuCl_2$(**6a**)]. Hydrogen and chlorine atoms have been omitted for clarity.

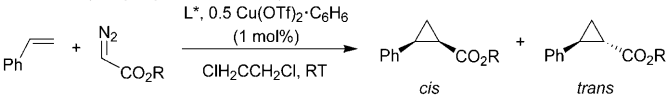

In contrast to the slightly distorted boatlike conformation of **6a**, the borabox ligand **7a** adopts an almost flat conformation. The average bond lengths between the bridging atom and the oxazoline rings, as well as the bite angle, are

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

larger in complex [Cu(**7a**)$_2$] than in complex [$CuCl_2$(**6a**)] (B–C_{oxa} = 1.61 Å versus C–C_{oxa} = 1.50 Å (oxa = oxazoline), and N-Cu-N = 94.5° versus N-Cu-N = 89.9°). As a consequence, the substituents at the stereogenic centers in [Cu(**7a**)$_2$] are farther away from the metal ion than in [$CuCl_2$(**6a**)].

As a first test of the borabox ligands, we carried out a comparative study of the cyclopropanation of styrene with Cu^I catalysts prepared in situ from CuOTf (Tf = trifluoromethanesulfonyl), lithium salts of **7a–f**, and analogous box ligands **6a–b**, and **6d** (Table 1).[1,10] In this reaction, which

often serves as a benchmark for new ligands, the borabox complexes showed similar reactivities to the corresponding box complexes.[11] As observed for the box ligands, bulkier *tert*-butyl substituents at the stereogenic centers of the borabox ligands induced higher *ee* values than isopropyl groups. However, this effect was less pronounced than in the box series. In the reaction with ethyl diazoacetate, the borabox catalysts gave only moderate enantioselectivities. On the other hand, with *tert*-butyl diazoacetate and 2,6-di-*tert*-butyl-4-methylphenyl (BHT) diazoacetate, the performance of the borabox ligands was much better, with ligand **7f** rivaling the most efficient box derivative **6d**. Consistent with previous studies, the more bulky esters gave much higher ratios of *trans*/*cis* isomers. The best result, 98% *ee* and almost perfect diastereoselectivity, was obtained in the reaction of the BHT ester with borabox derivative **7f** (entry 17).

The borabox catalyst [Cu(**7f**)] also performed well with other alkenes (Table 2). Overall, the enantioselectivities were

similar to those obtained with box derivative **6d**, but in several cases the *trans* selectivitiy of the borabox catalyst was higher (compare entries 1, 5, and 9 with 2, 6, and 10, respectively).

To explore further the potential of the borabox ligands, we studied the Cu-catalyzed enantioselective monobenzoylation of *meso* 1,2-diols, a reaction recently reported by Matsumura et al. (Table 3).[12]

The monobenzoylated products were obtained in good yields (62–83%) under the optimized conditions. The borabox derivative **9h** proved to be the most effective ligand for all three substrates with *ee* values of 76, 90, and 94% being obtained. The corresponding benzyl-substituted bisoxazoline

6c and the diphenyl analogue **6e**, which in the study of Matsumura et al.[12a] had given the best results, induced distinctly lower enantioselectivities.

In summary, we have developed a new class of anionic, boron-bridged analogues of the box ligands. These ligands are of interest because they are anionic with the negative charge located in the backbone, but otherwise closely resemble the netural box ligands **6**. The results obtained in the asymmetric cyclopropanation and, especially, in the desymmetrization of *meso* diols point to a considerable potential for borabox ligands in asymmetric catalysis.

A Calix[5]arene-Based Heterotetratopic Host for Molecular Recognition of Long-Chain, Ion-Paired α,ω-Alkanediyldiammonium Salts**

Domenico Garozzo, Giuseppe Gattuso, Anna Notti, Andrea Pappalardo, Sebastiano Pappalardo, Melchiorre F. Parisi,* Marta Perez, and Ilenia Pisagatti*

Ion-pair recognition, that is, the simultaneous complexation of cation and anion guest species by neutral hosts, is an emerging field of topical interest in supramolecular chemistry with great potential for biological, analytical, and environmental applications.[1] It is well known that the ion-binding process with neutral receptors is adversely affected by the ion-pairing of guest salts,[2] so that it is common practice to make use of salts with weakly coordinating counterions,[3] which result in enhanced host-guest associations. On the other hand, the ion-pairing interference can be circumvented either by using an appropriate combination of anion and cation receptors (binary host strategy)[4] or by designing specific heteroditopic receptors that take advantage of favorably positioned binding sites as well as induce positive cooperative and allosteric effects.[5] So far a plethora of heteroditopic receptors have been developed for inorganic ion pairs,[6] but much less has been reported for organic salts.[5c,7]

The molecular recognition of α,ω-alkanediyldiammonium salts has been actively investigated with different classes of artificial homo(poly)topic receptors. Among these, cylindrical macrotricyclic hosts,[8] cucurbiturils,[9] crown ether[10] and glycoluril derivatives,[11] bimetallic porphyrin dimers,[12] as well as *p-tert*-butylcalix[5]arenes[13] have been employed. However, none of the receptors used so far has been equipped with complementary counterion-binding sites.

Following our specific interest in the development of neutral multisite receptors for biogenic (poly)ammonium salts,[14] we report herein the synthesis and unique molecular recognition abilities of the first heterotetratopic receptor, **1**, which consists of two convergent, conformationally fixed, cone calix[5]arene units (cation-binding sites) that are covalently linked at their upper rims by means of a 1,4-bis(ureido)phenylene spacer (anion-binding sites). Host **1** readily forms overall charge-neutral, unimolecular capsules (ligand-separated ion-pair complexes) of nanoscale dimensions by tight encapsulation[15] of linear α,ω-alkanediyldiammonium ions, which range from 1,12-dodecane- to 1,16-hexadecanediammonium, inside the inner space defined by the two converging calix[5]arene cavities by simultaneously binding each of the two counteranions to the peripheral ureido functions through hydrogen bonds.

The target biscalixarene **1** was synthesized in six steps from the known 31-benzyloxy-*p-tert*-butylcalix[5]arene (**2**)[16] according to the sequence illustrated in Scheme 1. The exhaustive *O*-alkylation of **2** with 4-methylpent-1-yl tosylate and K_2CO_3 in CH_3CN at reflux produced pentaether **3** in 77% yield which, upon Pd/C-catalyzed hydrogenolysis in EtOAc, gave monohydroxy intermediate **4** in 93% yield. The

Scheme 1. Synthesis of **1**: a) $TsO(CH_2)_3CH(CH_3)_2$, K_2CO_3, CH_3CN, reflux, 12 h, 77%; b) H_2, Pd/C, EtOAc, room temperature, 4 h, 93%; c) 68% HNO_3/AcOH, CH_2Cl_2, 0°C, 25 min, 77%; d) $TsO(CH_2)_3CH(CH_3)_2$, NaH, THF, reflux, 48 h, 70%; e) $SnCl_2 \cdot 2H_2O$, EtOAc/EtOH, reflux, 24 h, 68%; f) 1,4-C_6H_4-$(NCO)_2$, $CHCl_3$, room temperature, 6 h, 66%. Ts = *p*-toluenesulfonyl; Bn = benzyl.

InterScience © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

subsequent selective *ipso*-nitration of **4** with 68% HNO_3 and acetic acid in CH_2Cl_2 afforded 5-nitro derivative **5** in 77% yield. Further *O*-alkylation of the residual hydroxy group with 4-methylpent-1-yl tosylate and NaH in dry THF furnished the 5-nitro pentaether **6** in 70% yield which was converted into 5-amino-calixarene **7** in 68% yield by reduction with $SnCl_2{\cdot}2H_2O$ in EtOH/EtOAc at reflux. Final coupling of two molecules of **7** with 1,4-phenylene diisocyanate in dry $CHCl_3$ led to biscalix[5]arene **1** in 66% yield.

The binding affinity of receptor **1** for linear, long-chain α,ω-alkanediyldiammonium ($\mathbf{C_8}$–$\mathbf{C_{16}}$) dichloride salts, as well as the host-guest architectures they form, were investigated by a combination of ^{1}H NMR spectroscopy and electrospray mass spectrometry (ESI-MS). The former method takes advantage of the large upfield shifts experienced by the methylene resonances of the guest upon encapsulation of the dication[4a,14] and the downfield shifts of the NH resonances of the host (in nonprotic media) which signal the simultaneous binding of the counteranions. ESI-MS exploits the remarkable tendency of the π-basic calix[5]arene cavity to include alkylammonium guests, thus providing ion labels for the detection of encapsulated complexes in the gas phase.[13,17,18]

H_3N^+—$(CH_2)_n$—$^+NH_3$

$\mathbf{C_8}$: n = 8
$\mathbf{C_{10}}$: n = 10
$\mathbf{C_{12}}$: n = 12
$\mathbf{C_{14}}$: n = 14
$\mathbf{C_{16}}$: n = 16

The affinity of **1** for α,ω-alkanediyldiammonium dichloride salts was initially investigated by ^{1}H NMR titration experiments in $(CDCl_2)_2/CD_3OD$ (2:1 *V*/*V*). Addition of the guest salt (up to 4 equivalents) to a solution of **1** (1.0×10^{-3} M) caused the formation of very strong inclusion complexes, whose host–guest stoichiometries (1:1 and/or 2:1) and geometries depend on the length of the diammonium ion and the [host]/[guest] ratio (see Figure 1). The ^{1}H NMR spectra of the inclusion complexes of calix[5]arenes with alkylammonium guest ions normally show distinct signals for the free and complexed host and guest species in slow exchange on the ^{1}H NMR timescale.[13,14,18] Here, signals corresponding to the free host and guests could barely be seen in the spectra of equimolar host–guest mixtures of **1** with the longer alkyldiammonium ($\mathbf{C_{12}}$–$\mathbf{C_{16}}$) dichloride salts, which suggests very high association constants ($K_a > 10^6\,M^{-1}$) for the formation of the capsular (C-shaped) 1:1 host–guest complexes with C_s symmetry. Similar results were observed using other solvent systems (including neat $(CDCl_2)_2$, $CDCl_3$, and CD_2Cl_2, or mixtures thereof with up to 50% content of CD_3OD), or on changing—in the case of $\mathbf{C_{12}}$—the nature of the counteranion (diacetate, dibromide, and dipicrate salts). Notably, the spectra did not change upon further addition of salt or on tenfold dilution of the solution.

In contrast, titration experiments of **1** with the shorter alkyldiammonium ($\mathbf{C_8}$ and $\mathbf{C_{10}}$) dichloride guest salts gave rise to changes in the ^{1}H NMR spectra that are consistent with the initial formation of the S-shaped (for $\mathbf{C_8}$) or C-shaped (for $\mathbf{C_{10}}$) 1:1 host–guest complexes for equimolar host–guest solutions and which eventually evolved toward the formation of the S-shaped 1:2 host–guest complexes (C_{2h} symmetry) after further addition of salt (Figure 1). This is clearly shown by the evolution of the ^{1}H NMR spectra in the titration experiment of **1** with $\mathbf{C_{10}}{\cdot}2\,Cl^-$ (Figure 2). Addition of one

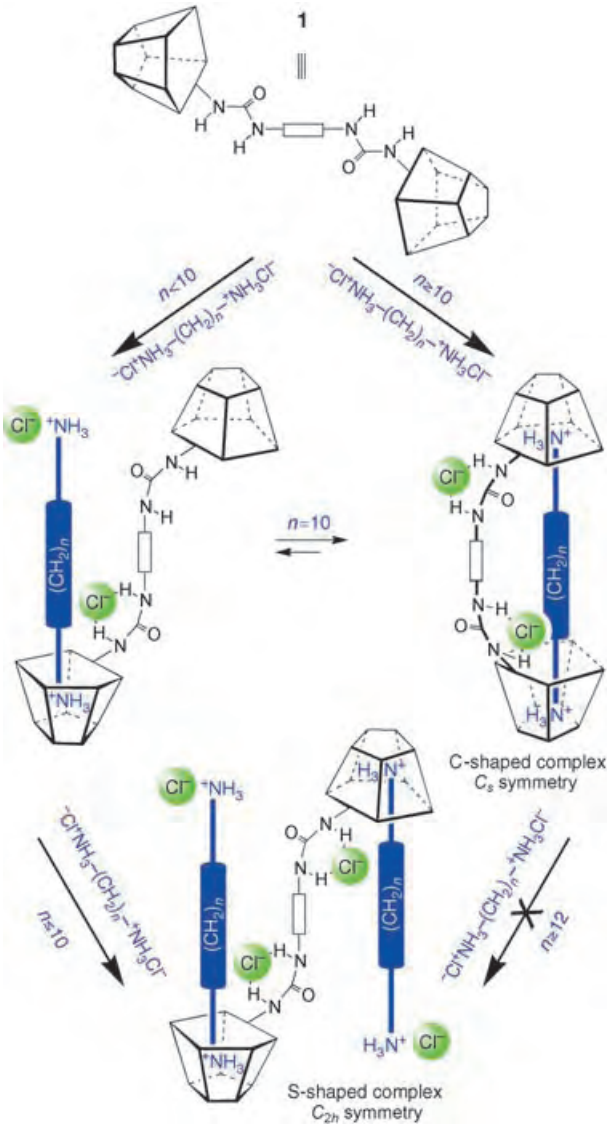

Figure 1. Schematic representation of the influence of the spanning of the guest α,ω-alkanediyldiammonium ions on the complexation pathways leading to C-shaped and/or S-shaped inclusion complexes with host **1**.

equivalent of salt caused the almost exclusive formation of the C-shaped 1:1 complex, as revealed by the presence of a set of five upfield methylene resonances for the included dication (Figure 2b).[19] Upon further addition of salt, a second more-spread set of signals for the included guest became evident in the highfield region of the spectra ($\delta = -1.9$ to 0.7 ppm) as a result of the incipient formation of the S-shaped 1:2 host–guest complex (Figure 2c and d). This conclusion is validated by the triplet detected at $\delta = 2.55$ ppm which is assigned to the α′-CH_2 protons of the guest and is judged of diagnostic value for the S-shaped complexes.[18] The latter architecture was the only host–guest species present in solution when a total of four equivalents of $\mathbf{C_{10}}{\cdot}2\,Cl^-$ had been added to **1** (Figure 2e).

The use of nonprotic solvents revealed the beneficial effect of the ureido functions of **1** which facilitate the loosening of the ion-paired salt and the association of the

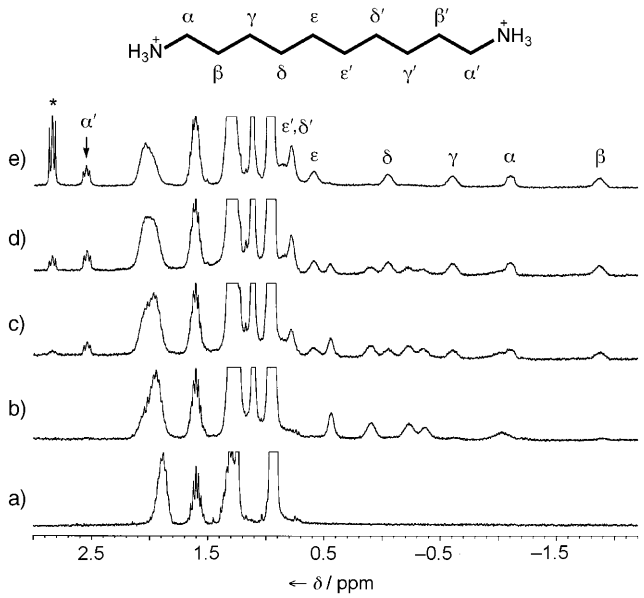

Figure 2. Highfield regions of the ^{1}H NMR spectra (300 MHz; 22 ± 1 °C; 2:1 $(CDCl_2)_2/CD_3OD$) recorded during the titration experiment of **1** (1.0×10^{-3} M) with $\mathbf{C_{10}}\cdot2Cl^-$: a) **1**; b) $\mathbf{1}/\mathbf{C_{10}}\cdot2Cl^-$ (1:1); c) $\mathbf{1}/\mathbf{C_{10}}\cdot2Cl^-$ (1:1.5); d) $\mathbf{1}/\mathbf{C_{10}}\cdot2Cl^-$ (1:2); e) $\mathbf{1}/\mathbf{C_{10}}\cdot2Cl^-$ (1:4). The triplet labeled with an asterisk refers to the α- and α′-CH_2 of uncomplexed $\mathbf{C_{10}}\cdot2Cl^-$, which is present in excess.

anion by formation of six-membered chelate rings with halide or picrate anions and eight-membered chelate rings with carboxylate anions.[20]

The shifts of the N-H resonances of **1** upon ligand-separated ion-pair complexation of the various $\mathbf{C_{12}}$ salts in $(CDCl_2)_2$ provide a qualitative picture of the strength of the anion-binding site (Table 1). Entries 3–6 suggest an anti-Hofmeister[21] trend in the complexation of the counteranion by heterotetratopic **1**, with the largest $\Delta\delta$ values being observed for the more densely charged Cl^- and $CH_3CO_2^-$ anions (in $(CDCl_2)_2$: $CH_3CO_2^- \approx Cl^- > Br^- > Pic^-$). A comparison between entries 2 and 4 shows also that the encapsulation of the dication enhances the acidity of the urea NH groups through an electron-withdrawing effect to result in a better uptake of chloride anions (positive allosteric effect).[5]

Table 1: Variation of the chemical shift of urea NH resonances of **1** (300 MHz, 1.0×10^{-3} M in $(CDCl_2)_2$) after the addition of one equivalent of guest salt.

Entry	Guest	δ [ppm]		Δδ [ppm]	
		NH_a[a]	NH_b[a]	NH_a[a]	NH_b[a]
1	none	6.44	5.88

3	$\mathbf{C_{12}}\cdot2CH_3CO_2^-$	8.91	8.60	2.47	2.72
4	$\mathbf{C_{12}}\cdot2Cl^-$	8.81	8.51	2.37	2.63
5	$\mathbf{C_{12}}\cdot2Br^-$	8.28	8.08	1.84	2.20
6	$\mathbf{C_{12}}\cdot2Pic^-$	7.40[c]		1.24	

[a] NH_a and NH_b refer to the two groups close to the calixarene unit and the 1,4-phenylene moiety, respectively. [b] Fast complexation equilibrium on the NMR timescale; data refer to the addition of two equivalents of salt. [c] Broad signal, partly buried under the aromatic protons of the calixarene units. Pic = picrate.

The slow exchange in the capsular complexes of **1** with diammonium salts allowed TROESY (transverse rotating-frame Overhauser effect spectroscopy) NMR spectroscopy to be carried out at room temperature, and the spectra obtained were fully consistent with the expected structure and symmetry of the complexes. Most importantly, the TROESY spectra (Figure 3b) showed clear intermolecular NOE cross

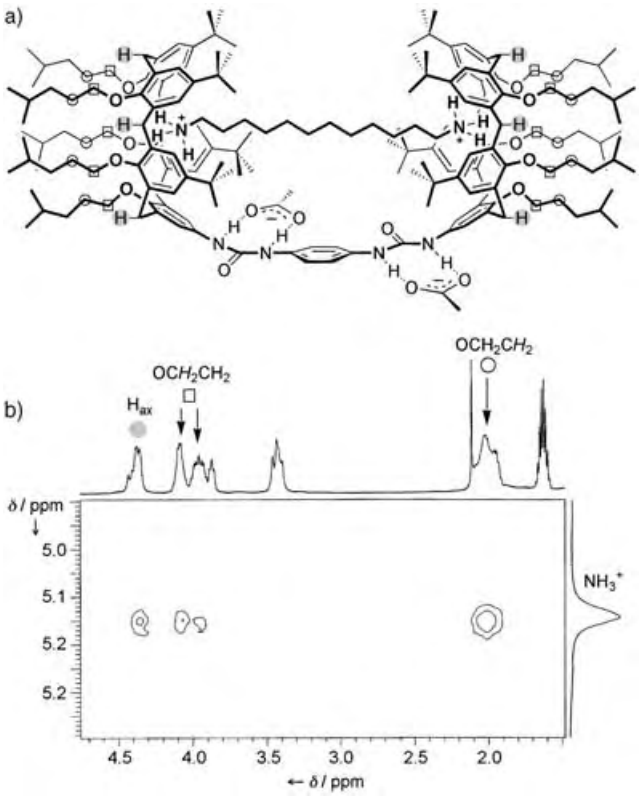

Figure 3. a) Structure of the C-shaped capsular $\mathbf{1}\cdot\mathbf{C_{12}}\cdot2CH_3CO_2^-$ complex with labeling of the relevant hydrogen atoms showing NOE interactions between the host and guest. b) Selected region of the TROESY NMR spectrum (500 MHz) of $\mathbf{1}\cdot\mathbf{C_{12}}\cdot2\ CH_3CO_2^-$ (5.0×10^{-3} M in $(CDCl_2)_2$). ax = axial.

peaks between the host and the guest. In particular, the NH_3^+ protons of the salt showed NOE peaks to the axial bridging methylene protons as well as to α- and β-oxymethylene protons of the lower rim substituents of the calix[5]arene moieties (Figure 3a), which provides evidence that the ammonium end group is held in position by hydrogen-bonding interactions with the ethereal oxygens. Moreover, the encapsulated ε-methylene protons of the $\mathbf{C_{12}}$ guest and the aromatic protons of the host gave rise to a cross peak.

The formation of capsular complexes between **1** and long-chain α,ω-alkanediyldiammmonium dichloride salts is further corroborated by the positive ESI mass spectra of equimolar host–guest mixtures which show prominent doubly-charged ions that correspond to $[\mathbf{1}\cdot\mathbf{C}_n]^{2+}$ (base peak) and low-intensity ion peaks for $[\mathbf{1}\cdot\mathbf{C}_n\mathrm{Cl}]^+$.[22]

The binding selectivity of **1** for the guest salts studied here was eventually determined by decreasing in highly coordinating solvents the cooperativity factors that arise from the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

anion-binding sites. Addition of dimethyl sulfoxide (DMSO) to a solution of **1** in chloroform led to a strong solvation of the hydrogen-bond donor sites of the ureido functions.[23,24] This solvation caused a weakening of the binding ability of **1** toward ion-paired salts[25] and allowed the determination of the association constants by ^{1}H NMR spectroscopy. Table 2 shows that among the substrates investigated the longer $\mathbf{C_{12}}$ and $\mathbf{C_{16}}$ guest salts are more tightly bound than $\mathbf{C_8}$ and $\mathbf{C_{10}}$ by **1** as the result of capsular complexation.

Table 2: Association constants (K_a) of α,ω-alkanediyldiammonium dichloride salts with receptor **1** in $CDCl_3$/[D_6]DMSO (3:2).[a]

$H_3N^+(CH_2)_n{}^+NH_3\cdot 2Cl^-$	K_a [M^{-1}]
$n=8$	212[b]
$n=10$	163[b]
$n=12$	2.4×10^3
$n=14$	–[c]
$n=16$	2.6×10^3

[a] Determined by ^{1}H NMR spectroscopy at 22 ± 1 °C using equimolar (1×10^{-3} M) host–guest mixtures. Values are derived from the average of at least three independent measurements (standard error ≤ 15%). [b] K_a values refer to the S-shaped 1:1 complex. [c] Measurements of K_a were precluded by the limited solubility of the salt.

The binding selectivity order of **1** toward $\mathbf{C_{12}}$, $\mathbf{C_{14}}$, and $\mathbf{C_{16}}$ as chloride salts was estimated from the ESI-MS distribution percentages[26] of the relevant capsular complexes ($[\mathbf{1}\cdot\mathbf{C}_n]^{2+}$ ions). A competitive complexation experiment of **1** with a mixture of the three salts ($\mathbf{1}/\mathbf{C_{12}}\cdot 2Cl^-/\mathbf{C_{14}}\cdot 2Cl^-/\mathbf{C_{16}}\cdot 2Cl^- = 1:1:1:1$; $c=1.0\times10^{-4}$ M in $CHCl_3/CH_3OH$ (1:1)) gave the order $\mathbf{C_{14}} > \mathbf{C_{16}} > \mathbf{C_{12}}$ (60.5, 24.6, and 14.9%, respectively).[27,28]

In conclusion, we have synthesized a novel heterotetratopic receptor, **1**, that efficiently and selectively forms ligand-separated ion-pair complexes with long-chain α,ω-alkanediyldiammonium dichloride salts by combining the cooperative action of two converging calix[5]arene cavities in the encapsulation of the dication with the ability of the two ureido functions to bind the relevant counteranions. Future work will be directed toward the design of new heteropolytopic systems with specific recognition patterns.

Ultramacrocyclization through Reversible Catenation**

*Akiko Hori, Tomohisa Sawada, Ken-ichi Yamashita, and Makoto Fujita**

Dedicated to Professor Iwao Ojima on the occasion of his 60th birthday

Whereas the cyclization of small (five- or six-membered) rings is a facile and high-yielding process in synthetic chemistry, that of larger rings becomes increasingly difficult with increasing number of ring members (n).[1–3] Macrocyclization with $n \approx 10$–30 is a difficult task, but is often achieved under high-dilution conditions. However, ultramacrocyclization[4] with $n > 100$ has scarcely been described because the entropy cost is too high in bringing the ends of a long acyclic compound together for cyclization to proceed (Figure 1 a). However, if the reaction sites are sufficiently large, the probability of the association of the both ends prior to cyclization should significantly increase and ultramacrocyclization should proceed efficiently. Such an idea prompted us to examine the reversible catenation[5,6] of coordination rings for ultramacrocyclization (Figure 1 b). Palladium(II)-clipped macrocycle **1** has a nanometer-sized framework and easily transforms into its catenated dimer in polar media through π–π aromatic interactions between the two rings.[7] In expectation of ultramacrocyclization through catenation, we designed the long acyclic compound **2**, which comprises Pd^{II}-clipped macrocyclic units at both ends. Accordingly, we found that compound **2** selectively catenates into ultramacrocyclic dimer **3**, which contains over 200 non-hydrogen atoms in its backbone.

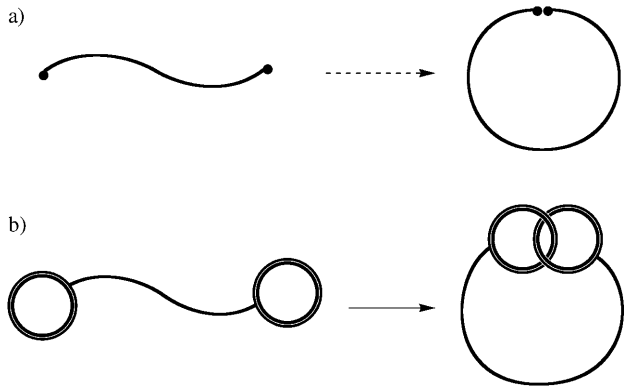

Figure 1. Cartoon representation for macrocyclization through a) the formation of a chemical bond and b) reversible catenation.

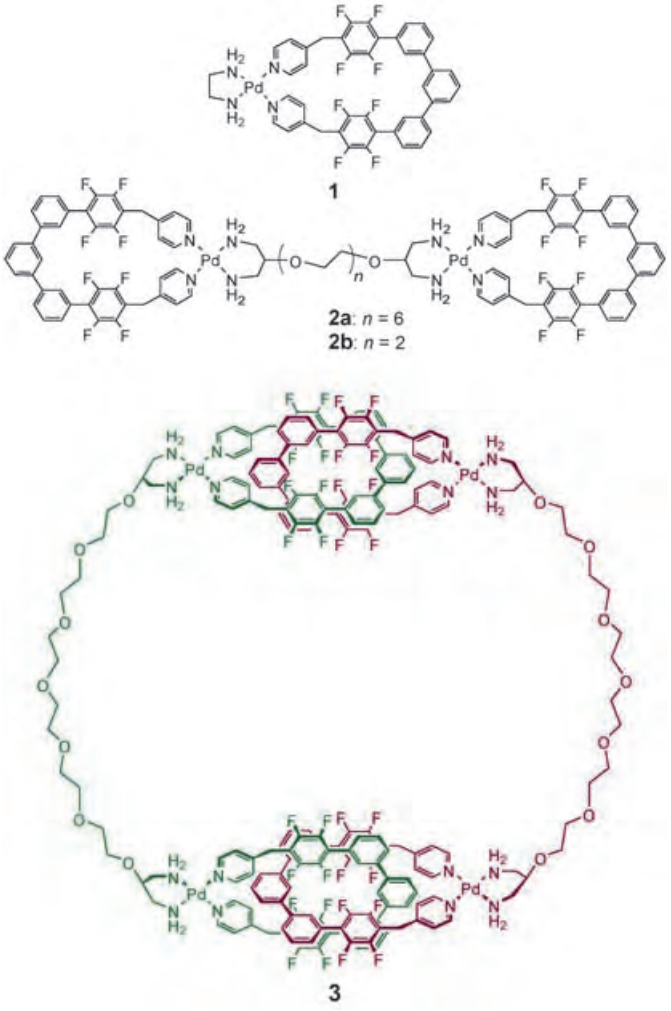

Double-loop compound **2a** was obtained by treating ligand **4** with bimetallic linker **5**[8] in dimethyl sulfoxide (DMSO; Scheme 1). Typically, ligand **4** (7.1 mg, 10 μmol) was treated with **5** (4.6 mg, 5.0 μmol) in DMSO (0.50 mL) for a few minutes at ambient temperature. The formation of **2a** as a single product was confirmed by ^{1}H NMR spectroscopy (Figure 2 a) and cold-spray ionization mass spectrometry (CSI-MS[9]).[10] Subsequently, we examined the catenation of **2a** at both loops by adding water to the solution in DMSO.[7] As revealed by ^{1}H NMR spectroscopy (Figure 2 b–g), peaks for the protons of the monomer **2a** decreased with increasing water content. Instead, significantly highfield-shifted aromatic protons appeared around $\delta = 8.20$–6.75 ppm, characteristic of the catenation of the Pd^{II}-clipped rings. CSI-MS clearly indicated that the newly formed product was cyclic dimer **3**, which contains two catenated frameworks. The spectrum from a solution in *N*,*N*-dimethylformamide (DMF) and H_2O (1:2) showed a series of peaks for $[\mathbf{3}-(NO_3)_n+(dmf)_m]^{n+}$: for example, $m/z = 669.7$ corresponds to $[\mathbf{3}-(NO_3)_7+(dmf)_7]^{7+}$;

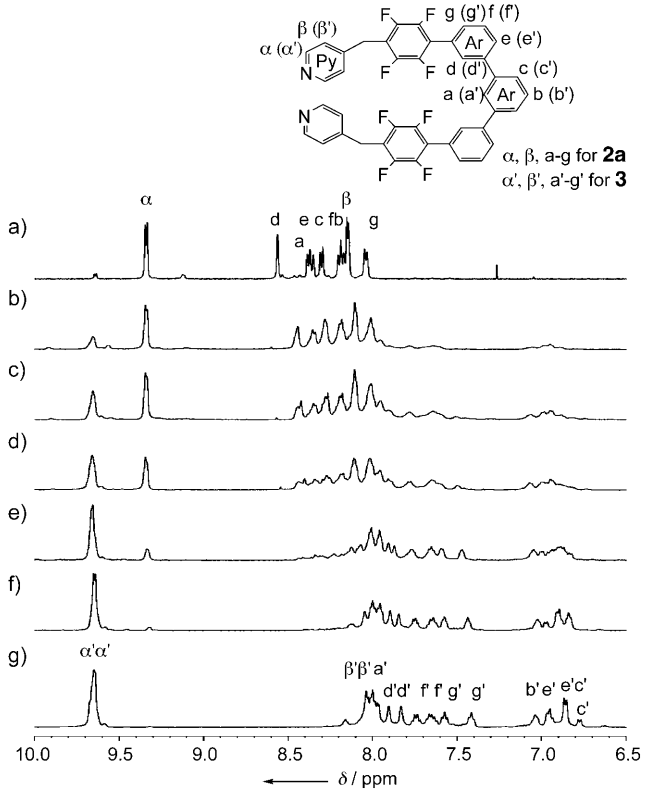

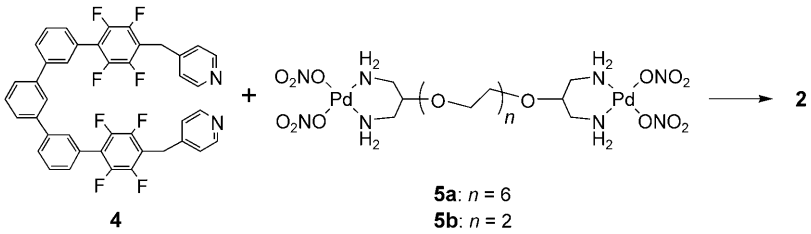

Figure 2. Observation by ^{1}H NMR spectroscopy (aromatic region, 500 MHz, 25 °C) of the ultramacrocyclization of monomer **2a** (5 mM) to dimer **3**. Spectra were obtained by treating the solution of **2a** in DMSO with water at room temperature. Solvent systems: a) [D$_6$]DMSO only, b) [D$_6$]DMSO/D$_2$O (3.5:1), c) [D$_6$]DMSO/D$_2$O (3:1), d) [D$_6$]DMSO/D$_2$O (2.5:1), e) [D$_6$]DMSO/D$_2$O (2:1), f) [D$_6$]DMSO/D$_2$O (1.5:1), and g) [D$_6$]DMSO/D$_2$O (1:1).

Scheme 1. Synthesis of double-loop compounds **2**.

$m/z = 767.5$ corresponds to $[\mathbf{3}-(NO_3)_6+(dmf)_5]^{6+}$; and $m/z = 874.7$ corresponds to $[\mathbf{3}-(NO_3)_5+dmf]^{5+}$ (Figure 3). Whereas the Pd^{II}-clipped ring is achiral, its catenated form is chiral. Therefore, equivalent proton pairs in each Pd^{II}-clipped ring become diastereotopic after catenation and are independently observed (see pairs for $H_{\alpha'}$, $H_{\beta'}$, and $H_{a'}$–$H_{g'}$ in Figure 2g).[11] Probably, **3** is a mixture of two diastereomers because of the chirality of the two catenated moieties, but the diastereomers are not clearly distinguishable.

The solution of catenated species in a mixture of [D$_6$]DMSO/D$_2$O (1:1) was subjected to a DOSY (diffusion-ordered NMR spectroscopy) study[12–14] to confirm the purity of the component (Figure 4). The spectrum clearly showed the appearance of all the signals at the same diffusion coefficient ($\log D = -10.35$) which indicates the selective formation of a single product.[15] It is remarkable that despite the flexible structure of the linker, no other products were formed. Presumably, a cyclic monomer derived from the intramolecular catenation of **2a** is less stable because of the unfavorable orientation of the two Pd^{II}-clip-

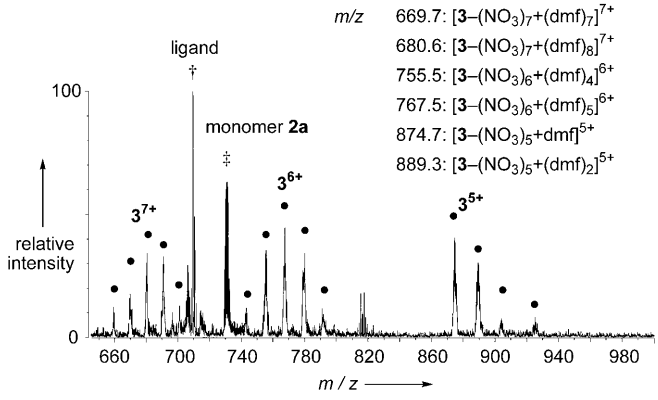

Figure 3. CSI mass spectrum of **3** as a solution in DMF/H$_2$O (1:2).

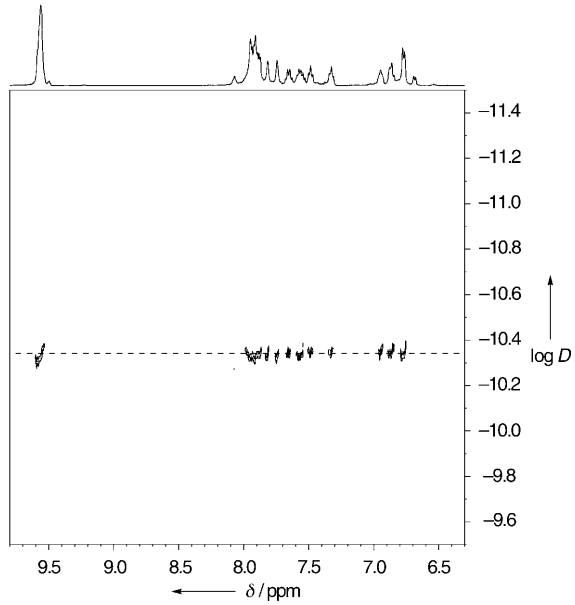

Figure 4. DOSY spectrum of **3** showing the formation of a single product. The spectrum was obtained after treatment of **4** (5 mM) with **5** (5 mM) for 5 minutes at room temperature in [D_6]DMSO/D_2O (1:1).

ped rings, whereas a cyclic trimer or higher oligomers are disfavored because of the higher entropy cost.

CPK modeling showed that an expanded conformation of **3** has an external diameter of approximately 4 nm (Figure 5). The backbone of **3** comprises 238 non-hydrogen atoms ($C_{204}N_{16}O_{14}Pd_4$), and it is one of the largest macrocyclic compounds to be synthesized in reasonable yields and characterized well.

Ultramacrocyclization through double catenation also proceeded smoothly when the length of the oligo(ethylene oxide) chain was limited.[8] The double catenation of **2b** ($n = 2$), which was also quantitatively prepared from **5b** in a polar solvent (Scheme 1), was examined. Upon addition of water, **2b** was efficiently transformed into an ultramacrocyclic dimer as indicated by ^{1}H NMR spectroscopy and CSI-MS studies.[16] Although conformational strain was anticipated to some extent, no other oligomers were detected. From a modeling study, the dimension of the dimer in its extended conformation is estimated to be 3.0 nm.

In the construction of nanoscopic assemblies from extraordinarily large components, close proximity of the reaction centers between the components is entropically unfavorable. As we have demonstrated here, the Pd^{II}-linked coordination ring can be regarded as a nanoscale reaction center. We suggest that the use of such large reaction centers may overcome the entropic disadvantage in nanoscopic molecular manufacturing. Accordingly, we expect that large nanoscopic objects, such as protein molecules or metal nanoparticles, can be easily linked together and aligned through reversible catenation.

Reverse Spin Transition Triggered by a Structural Phase Transition**

Shinya Hayami, Yuji Shigeyoshi, Motoko Akita, Katsuya Inoue, Kenichi Kato, Keiichi Osaka, Masaki Takata, Ryo Kawajiri, Tadaoki Mitani, and Yonezo Maeda*

Designing molecules that could be used for information processing and information storage is one of the main challenges in molecular materials science. Molecules that are suitable for such applications must be bistable: a characteristic that allows the presence of two different stable electronic states over a certain range of external perturbation. Typical examples of molecular species that exhibit such bistability are the spin-crossover (SCO) compounds. Since the discovery of the first SCO compound,[1] a variety of d^n ($n = 4$–7) transition metal compounds exhibiting bistability between the high-spin (HS) and low-spin (LS) states have been reported.[2–4] Spin transition can be induced by variation of temperature, pressure, or illumination.[2–9] In general, temperature-dependent SCO behavior involves reversible spin transition from LS to HS upon heating and from HS to LS upon cooling.

Although the SCO transition is due to the electronic structure of the single molecule and can be observed even in

solutions or polymer matrices,[10,11] interaction between SCO molecules can dramatically influence the transition. Gradual or abrupt spin transitions may be observed in the solid state, depending on cooperativity.[12–14] The understanding of cooperative behavior in SCO transition can be a key to designing materials that are useful for information technology. In contrast, flexibility in the synthesis of molecular assemblies based on molecular units is also very important for synergy among the various interesting and novel physical properties of advanced materials.[15,16] The flexibility of ligands is one factor that can both directly and indirectly influence the cooperative interaction. The direct influence arises from the structural changes of the ligands, and the indirect influence comes from their random packing structure.

The SCO cobalt(II) compounds exhibit a 1/2↔3/2 spin change. The cobalt(II) compounds $[Co(terpy)_2]X_2 \cdot n\,H_2O$ (terpy = 2,2′:6′,2″-terpyridine; X = halide, pseudohalide, NO_3^-, ClO_4^-; $n = 0$–5) exhibit incomplete and gradual SCO behavior.[17,18] Not only liquid-crystal properties, but also unique physical properties can be expected for compounds with long alkyl chains because of the thermal motion of the alkyl chains. On the basis of these observations, we prepared cobalt(II) compounds with long alkyl chains and succeeded in observing "reverse spin transition" by using a major structural phase transition for the first time. Notably, reverse spin transition is unexpected because the driving force of the SCO phenomenon is entropy change, which is temperature-dependent.

The focus of the work reported herein was the cobalt(II) compound $[Co(C_{16}\text{-terpy})_2](BF_4)_2$ (**1**, in which C_{16}-terpy = 4′-hexadecyloxy-2,2′:6′,2″-terpyridine) having terpy ligands with long alkyl chains. Unsolvated **1** was obtained as a brown–orange powder by treating a solution of $Co^{II}(BF_4)_2$ in methanol with 2 equiv C_{16}-terpy. Single crystals of **1**·MeOH suitable for X-ray diffraction (XRD) studies were isolated by slow recrystallization from MeOH. The compound crystallizes in triclinic space group $P\bar{1}$. The cobalt(II) ion of **1**·MeOH is octahedrally coordinated by six nitrogen atoms of two C_{16}-terpy ligands (Figure 1). The bond lengths are intermediate between those of typical LS and HS cobalt(II) compounds.[19] The Co–N distances of the central pyridine ring of the terpyridine ligand (1.99 Å) are shorter than those of the peripheral pyridine rings (2.13 Å), and this induces a pronounced distortion of the CoN_6 octahedron. The three pyridine rings of the C_{16}-terpy ligand are coplanar, and the two tridentate C_{16}-terpy ligands are nearly perpendicular to one another. The long alkoxy chains $C_{16}H_{33}O$ form rodlike structures that protrude from the 4′-positions of the terpyridine moieties. The chain from O1 extends straight in zig-zag form, whereas the other is bent at C48–C49 and then extends straight in a zig-zag fashion. The thermal motions of the end carbon atoms C60, C61, and C62 of the long chain connected to O2 are larger than those of C29, C30, and C31 in the O1 chain. The two BF_4^- counteranions and one MeOH molecule are located in the intermolecular space, and there are short contacts between $[Co(C_{16}\text{-terpy})_2]^{2+}$ cations, BF_4^- anions, and MeOH molecules. The $[Co(C_{16}\text{-terpy})_2]^{2+}$ cations form short contacts (3.49 Å) between nearest-neighbor peripheral pyridine rings in the *ab* plane, and thus a 2D sheet is formed by π–π interactions. Furthermore, a fastener effect is present between the chains which face each other in the complexes. The very tight molecular packing of the compound suggests the presence of strong intermolecular interactions in the molecular assembly.

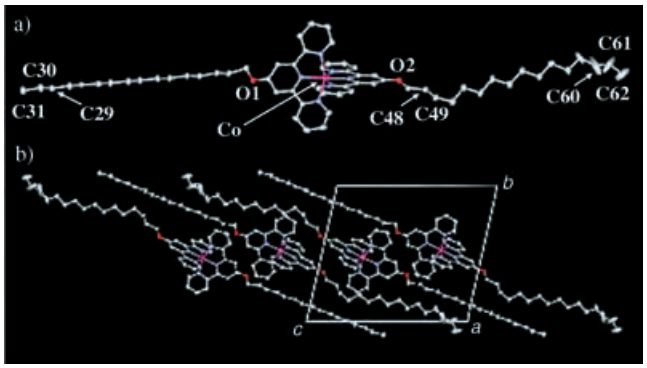

Figure 1. a) ORTEP plot of **1**·MeOH showing 50% probability displacement ellipsoids. b) Projection of the crystal structure of **1**·MeOH on the *bc* plane; BF_4^- ions, MeOH molecules, and H atoms are omitted for clarity.

The crystal structure of unsolvated **1** could not be determined, because the removal of MeOH induced cracks in the crystal that made single-crystal XRD studies impossible. However, powder XRD data suggested that the structure of unsolvated **1** is similar to that of **1**·MeOH (Supporting Information).

The temperature dependence of the molar magnetic susceptibility of unsolvated **1** is shown in Figure 2a. Solvated **1**·MeOH exhibited gradual SCO behavior in the temperature range of 5–360 K. The $\chi_m T$ value of **1**·MeOH gradually increases from 0.54 to 1.83 $cm^3 K mol^{-1}$ at 360 K, and then decreases to 1.58 $cm^3 K mol^{-1}$ at 400 K from the removal of MeOH. Unsolvated **1** was obtained by annealing **1**·MeOH at 400 K. The $\chi_m T$ value of **1** gradually decreases from 1.58 $cm^3 K mol^{-1}$ at 400 K to 0.41 $cm^3 K mol^{-1}$ at 226 K, and the gradual decrease in the $\chi_m T$ value shows normal thermal SCO behavior. Upon further cooling, the $\chi_m T$ value increases abruptly at around $T_{1/2}\downarrow = 217$ K to 2.01 $cm^3 K mol^{-1}$ at 206 K. The magnetic behavior shows that compound **1** exhibits reverse spin transition from the LS to the HS state upon cooling. Upon heating, $\chi_m T$ undulates between 1.70 and 2.15 $cm^3 K mol^{-1}$ in the temperature range of 5–251 K. Undulating magnetic behavior is also unusual and difficult to understand. It may be caused by structural changes. Powder XRD measurements showed that the structure at 50 K is different from that at 130 K ($2\theta = 8.8$, 11.9, 13.2, and 14.8°; Figure 3a). With further heating, the $\chi_m T$ value abruptly drops at around $T_{1/2}\uparrow = 260$ K with transition from the HS to the LS state. Then the $\chi_m T$ value gradually increases in the temperature range of 267–400 K. The wide thermal hysteresis loop ($\Delta T = 43$ K) remained unchanged in successive thermal cycles, and this confirms that compound **1** exhibits reverse spin transition. This is important because an abrupt transition

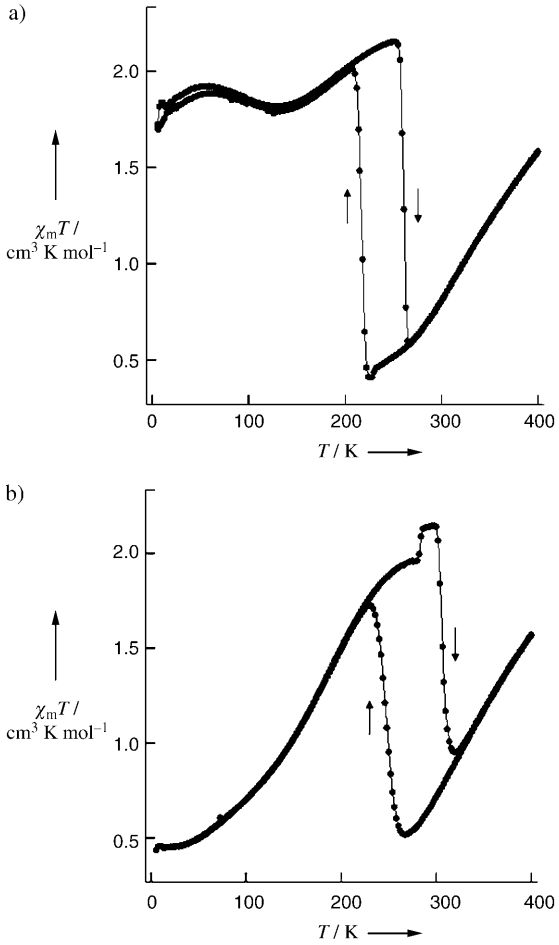

Figure 2. $\chi_m T$ versus T plots for a) **1** and b) **2**.

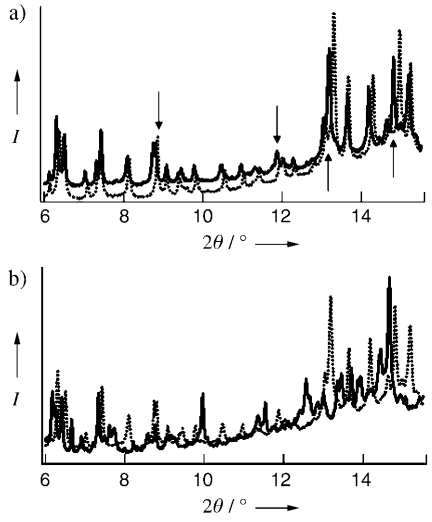

Figure 3. Temperature dependence of powder XRD patterns for **1** upon heating: a) (•••••): 50 K, (——): 130 K; b) (•••••): 130 K, (——): 270 K.

with a hysteresis loop appears only if the cooperative effect is strong enough. To confirm reverse spin transition, the variable-temperature ESR spectrum of **1** was measured. The spectrum shows a signal for the HS form at 3 K, and a signal for the LS form at 270 K. Powder XRD measurements show that the HS structure at 130 K differs greatly from the LS structure at 270 K, and a major structural phase transition is thought to occur in this temperature range (Figure 3b).

Upon warming, the reverse spin transition from the HS to the LS state ($T_{1/2}\uparrow = 260$ K) was found to be an endothermic phase transition ($\Delta H = 14.3$ kJ mol^{-1}, $\Delta S = 54.6$ J K^{-1} mol^{-1} at 262 K) by differential scanning calorimetry (DSC, Figure 4a).

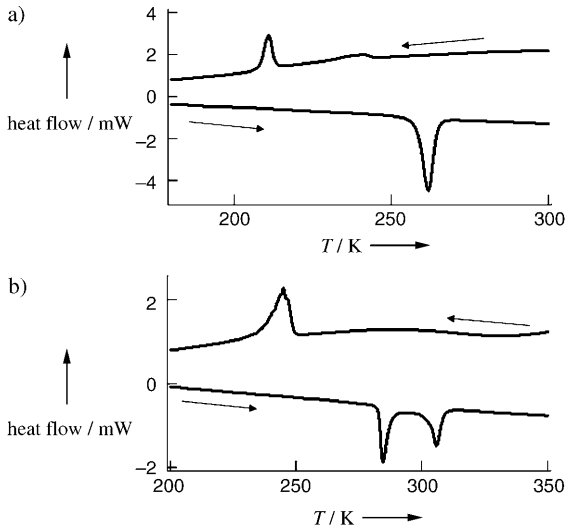

Figure 4. a) DSC curves of **1**. b) DSC of **2**.

Upon cooling, two peaks were observed, one at 211 K ($\Delta H = -6.1$ kJ mol^{-1}, $\Delta S = -28.6$ J K^{-1} mol^{-1}) and a broad peak at higher temperature. The exothermic peak at 211 K corresponds to the reverse spin transition temperature ($T_{1/2}\downarrow = 217$ K), and the broad peak can be assigned to another structural change. The sum of the two heat capacities upon cooling is equal to that of the peak at 262 K on heating. It has been reported that the change in entropy is 16–35 J mol^{-1} K^{-1} in SCO cobalt(II) compounds, and 40–65 J mol^{-1} K^{-1} in SCO iron(II) compounds.[7,18–21] The ΔS value for reverse spin transition ($\Delta S = 54.6$ J K^{-1} mol^{-1}) is larger than those previously reported for SCO cobalt(II) compounds, and is in the range of those observed in SCO iron(II) compounds ($\Delta S = 40$–65 J K^{-1} mol^{-1}). The ΔS value of **1** is much larger than the change in electronic spin expected for a cobalt(II) ion ($\Delta S_{spin} = R[\ln(2S+1)_{HS} - \ln(2S+1)_{LS}] = 5.8$ J K^{-1} mol^{-1}). The remaining entropy difference of 48.8 J K^{-1} mol^{-1} is mainly due to intramolecular vibrational changes. Furthermore, the iron(II) SCO compound $[Fe(ptz)_6](BF_4)_2$ (ptz = 1-propyltetrazole) undergoes spin transition with a structural phase transition from $R\bar{3}$ in the HS state to $P\bar{1}$ in the LS state, as deduced from powder diffraction experiments.[22] In such cases, the observed hysteresis is only the result of cooperative effects, as it is well-known that a first-order phase transition is generally accompanied by a hysteresis loop. We suggest that the major structural change in **1** is the origin of the reverse spin transition.

A similar compound, $[Co(C_{14}\text{-terpy})_2](BF_4)_2$ (**2**), which was synthesized by an analogous method, also exhibited reverse spin transition (Figure 2b). The $\chi_m T$ value of **2**

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

gradually decreases from 1.57 $cm^3 K mol^{-1}$ at 400 K to 0.52 $cm^3 K mol^{-1}$ at 268 K, and then abruptly increases around $T_{1/2}\downarrow = 250$ K to 1.73 $cm^3 K mol^{-1}$ at 230 K. The magnetic behavior also shows that compound **2** exhibits reverse spin transition from the LS to the HS state upon cooling. With further cooling, the $\chi_m T$ value gradually decreases to 0.44 $cm^3 K mol^{-1}$ at 5 K which is normal SCO behavior. On heating, $\chi_m T$ value gradually increases to 1.96 $cm^3 K mol^{-1}$ at 280 K, and a jump in $\chi_m T$ from 1.96 $cm^3 K mol^{-1}$ to 2.15 $cm^3 K mol^{-1}$ was observed at 298 K. Upon further heating, $\chi_m T$ abruptly decreases, and shows the features of reverse spin transition from the HS to the LS state at $T_{1/2}\uparrow = 307$ K to 0.95 $cm^3 K mol^{-1}$ at 320 K. Then $\chi_m T$ gradually increases up to 400 K. The thermal hysteresis loop ($\Delta T = 57$ K) remained unchanged in successive thermal cycles, and thus confirmed that **2** exhibits reverse spin transition. An important characteristic of the present phenomenon is the wide hysteresis loop of 57 K. Furthermore, we emphasize that room temperature lies within the hysteresis loop.

Upon cooling, one peak was observed at 245 K ($\Delta H = -9.9$ kJ mol^{-1}, $\Delta S = -30.3$ J $K^{-1} mol^{-1}$), corresponding to a reverse spin transition from the LS to the HS state at $T_{1/2}\downarrow =$ 250 K. Upon warming, two peaks were observed for **2** up to 400 K, at 284 K ($\Delta H_1 = 3.3$ kJ mol^{-1}, $\Delta S_1 = 11.5$ J $K^{-1} mol^{-1}$), and 306 K ($\Delta H_2 = 3.3$ kJ mol^{-1}, $\Delta S_2 = 10.8$ J $K^{-1} mol^{-1}$) by DSC (Figure 4b). The peak at 284 K corresponds to the jump in $\chi_m T$ in the magnetic data. Powder XRD measurements showed that the pattern at 280 K differs greatly from that at 300 K, and it is thought that a major structural phase transition occurs in this temperature range (Figure 5a). The second peak at 306 K corresponds to reverse spin transition from the HS to the LS state at $T_{1/2}\uparrow = 306$ K. The ΔS value for reverse spin transition ($\Delta S = 30.3$ J $K^{-1} mol^{-1}$) is in the range of those observed in other SCO Co^{II} compounds.[18–21] The powder XRD pattern at 300 K differs greatly from that at 350 K (Figure 5b). The jump in $\chi_m T$ and the reverse spin transition are thought to be accompanied by a major structural change.

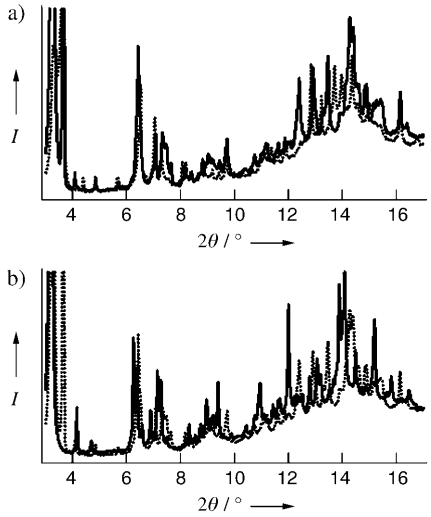

Figure 5. Temperature dependence of powder XRD patterns for **2** upon heating: a) (••••): 280 K, (——): 300 K; b) (••••):300 K, (——): 350 K.

Upon further heating, additional phase transitions due to the long alkyl chains were observed for **1** and **2** above 400 K by DSC (Supporting Information). Two peaks were observed for **1** at 437 and 512 K upon heating. The DSC peak at 437 K ($\Delta S = 33.9$ J $K^{-1} mol^{-1}$) can be assigned to a crystal–mesophase or crystal–crystal transition, and the peak at 512 K ($\Delta S = 17.7$ J $K^{-1} mol^{-1}$) can be assigned to the melting point. It is difficult to determine whether **1** exhibits mesophase transition. Two peaks were also observed for **2** at 443 K and 520 K upon heating. The DSC peak at 443 K ($\Delta S = 18.8$ J $K^{-1} mol^{-1}$) can be assigned to a crystal–crystal transition, and the peak at 520 K is assigned to the melting point.

Finally, we comment on the reverse spin transition observed in unsolvated compounds **1** and **2**. The molecular arrangement shows short contacts between $[Co(C_{16}\text{-terpy})_2]^{2+}$ cations, BF_4^- anions, and MeOH molecules, as well as between the long alkyl chains. The short contact distances are shorter than the sum of the van der Waals radius. Therefore, intermolecular interactions are strong and SCO behavior becomes cooperative. In such a case, the spin transitions between the HS and LS states are not only very abrupt, but also occur with hysteresis. The structural phase transitions that occur for **1** and **2** are likewise the result of strong intermolecular interactions. When one phase at low temperature prefers the HS state and another at high temperature prefers the LS state, reverse spin transition may be triggered by structural phase transitions.

In summary, we have synthesized $[Co(C_n\text{-terpy})_2](BF_4)_2$ ($n = 0$–22) with novel organic ligands based on a terpyridine frame. Compounds **1** and **2** with long alkyl chains exhibit reverse spin transition, which has been observed for compounds in which $n = 12$–16 so far. The reverse spin transitions have wide thermal hysteresis, which is important in switchable molecules. Thus, novel physical properties that could be important to the field of materials science may be discovered in compounds with long alkyl chains.

Experimental Section

1·MeOH: C_{16}-terpy (170 mg, 0.36 mmol) was dissolved in $CHCl_3$/MeOH (1:1, 20 mL) and added to a solution of $Co(BF_4)_2 \cdot 6H_2O$ (60 mg, 0.18 mmol) in MeOH (10 mL). The brown–orange solution was concentrated to ≈10 mL, and the resulting microcrystals were collected by filtration and recrystallized slowly from MeOH. Yield: 94 mg (43%); brown-orange crystals. Elemental analysis (%) calcd for $C_{63}H_{90}O_3N_6B_2F_8Co$: C 62.43, H 7.48, N 6.93, Co 4.86; found: C 62.48, H 7.53, N 6.98, Co 4.93. Elemental analysis (%) for **1** after removal of MeOH calcd for $C_{62}H_{86}O_2N_6B_2F_8Co$: C 63.11, H 7.35, N 7.12, Co 4.99; found: C 63.21, H 7.42, N 7.20, Co 4.83.

Crystallographic data for **1**·MeOH at 130 K ($C_{63}H_{90}O_3N_6B_2F_8Co_1$): $M_r = 1211.98$, brown–orange platelet ($0.35 \times 0.35 \times 0.15$ mm^3), triclinic, space group $P\bar{1}$, $a = 9.0412(6)$, $b = 17.598(1)$, $c = 20.684(2)$ Å, $\alpha = 102.545(3)$, $\beta = 101.622(3)$, $\gamma = 90.470(3)°$, $V = 3141.9(4)$ $Å^3$, $Z = 2$, $\rho_{calcd} = 1.281$ g cm^{-3}. Refinement by full-matrix least-squares methods gave an R factor of 0.08 from 9255 reflections with intensity $I > 3\sigma(I)$ for 748 variables; linear absorption coefficient $\mu(Mo_{K\alpha}) = 3.46$ cm^{-1}. Non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included but not refined.

The magnetic susceptibilities $\chi(T)$ were measured between 5 and 300 K with a superconducting quantum interference device (SQUID) magnetometer (Quantum Design MPMS-5S) in an external field of 0.5 T. EPR spectra were recorded on a Bruker ESP 300 X-band (9.4 GHz) spectrometer equipped with a Hewlett-Packard 5350B

microwave-frequency counter. Thermogravimetric data for **1** and **2** were collected on a Perkin-Elmer DSC-6 instrument over the temperature range of 290–450 K under an N_2 atmosphere.

To obtain X-ray powder diffraction data with good statistics and high angular resolution, XRD measurements were carried out at SPring-8, BL02B2 beam line (temperature dependence and illumination effect). The as-grown sample powders were sufficiently fine and gave a homogeneous intensity distribution in the Debye–Scherrer powder ring. At the BL02B2 beam line, the sample powders were sealed in glass capillaries in which the temperature was controlled in the range of 20–300 K. Reflections were collected on an imaging plate installed on a large Debye–Scherrer camera ($r = 286.5$ nm). The wavelength of the incident X-rays was ≈ 1.0 Å (slightly below the K edge of Rb), and typical exposure time was 15 min. The true wavelength was calibrated by using a standard CeO_2 powder obtained from NIST.

Structurally Simple Farnesyltransferase Inhibitors Arrest the Growth of Malaria Parasites**

*Matthew P. Glenn, Sung-Youn Chang, Oliver Hucke, Christophe L. M. J. Verlinde, Kasey Rivas, Carrie Hornéy, Kohei Yokoyama, Frederick S. Buckner, Prakash R. Pendyala, Debopam Chakrabarti, Michael Gelb, Wesley C. Van Voorhis, Saïd M. Sebti, and Andrew D. Hamilton**

The development of antimalarial agents is not only constricted by the parameters common to the development of all new drugs (efficacy, toxicity, pharmacology), but importantly, must also recognize the economic reality of the countries most affected. It is estimated that there are 300–500 million acute cases of malaria each year, resulting in 1–3 million deaths, with 90% of the mortality occurring in Africa.[1] The severe poverty in the regions most affected by malaria and the staggering number of people infected necessitate very inexpensive treatment. In an effort to decrease the cost of developing new antimalarial drugs, recent attention has been

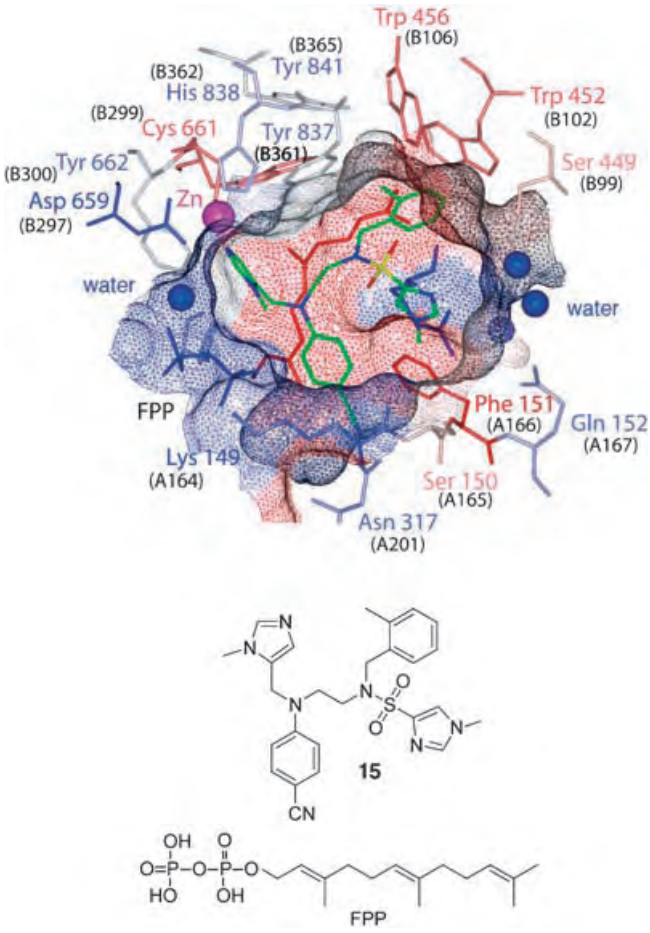
directed at investigating parasitic proteins that are validated therapeutic targets in other diseases, thereby accelerating access to new classes of inhibitors.[2,3]

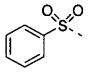
Recently, prenylated proteins and associated prenyltransferases have been identified in the malarial protozoa *Plasmodium falciparum*.[2] Prenylation is a required modification for the function of a variety of cellular proteins, including small G proteins,[4] heterotrimeric G-protein γ subunits,[5] protein kinases,[6] and nuclear lamins.[7] Studies of the role of prenylation in modulating the function of the GTP-binding proteins Ras and Rho, which have oncogenic forms common to many human cancers (≈30%), have identified the ubiquitous eukaryotic enzyme protein farnesyltransferase (PFTase) as a key target for the interception of aberrant Ras activity.[8] Subsequent efforts to identify small-molecule inhibitors of PFTase have led to several potential anticancer agents currently in clinical trials.[9,10] The application of related PFTase inhibitors to cells infected with *P. falciparum* led to a decrease in farnesylated proteins and to the associated lysis of the parasites.[11] Importantly, the PFTase inhibitors studied were found to be significantly more toxic against the parasite than to mammalian cells. In this study, we developed a new series of PFTase inhibitors as novel antimalarial agents, emphasizing simple molecular architecture and straightforward chemical synthesis as a prerequisite for access to low-cost treatment.

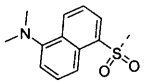
PFTase is one of three closely related heterodimeric zinc metalloenzymes (protein farnesyltransferase and geranylgeranyltransferases I and II) that catalyze the transfer of prenyl groups from farnesyl or geranylgeranyl pyrophosphate to the free thiol group of a cysteine residue within the tetrapeptide recognition sequence CaaX (a = aliphatic amino acid, X is often M, S, A, or Q for PFTase) located at the carboxyl terminus of the substrate protein.[12] A homology model of malarial PFTase (*Pf*PFT) was generated with MODELLER,[13] by using the crystal structure of rat PFT complexed with the nonsubstrate tetrapeptide inhibitor CVFM, and farnesyl diphosphate (FPP) as the template structure (PDB entry 1JCR). The sequences of the two subunits (α and β) of *Pf*PFT were obtained from the PlasmoDB database (gene loci: PFL2050w, α and chr11.glm_528, β)[14,15] and aligned with the template with the program T-COFFEE.[16] Only regions with reasonable reliability in the alignment were included. The model of *Pf*PFT comprises the following sequence segments (the residue numbers of the corresponding segments of the rat PFT subunits are given in parentheses): α: 72–164 (87–179), 300–411 (184–283); β: 421–677 (71–315), 806–896 (330–417). *Pf*PFT and rat PFT share 23% identity and 53% similarity for the α subunit; the respective values for the β subunit are 37 and 56%. The catalytic zinc ion, six structurally conserved water molecules, and FPP were included in the model. The conformation of FPP was considered flexible during the model calculations. For this purpose, the force-field parameters for FPP were added to the MODELLER force field on the basis of the lipid parameters of the charmm27 force field.[17] The model with the lowest value of the objective function of MODELLER from twenty different calculations was used for docking studies.

The homology model indicates a large, open, and predominately hydrophobic cavity for the active site (≈20 × 20×20 Å^3), with the phospholipid binding partner (FPP) extending across the cavity base. The Zn ion coordinates to three residues (Cys661, Asp659, and His838) with a water molecule hydrogen bonded between the terminal phosphate of FPP and Asp659, defining the limit of the Zn binding domain (Figure 1). The remainder of the active-site cavity includes two well-defined hydrophobic pockets (Lys149, Asn317 Ser150, Phe150 and Trp456, Trp452, Tyr837), a larger hydrophilic domain formed by Arg564, and three water molecules participating in a hydrogen-bonded network between Ser449 and Gln152.

Flexible ligand-docking studies (GOLD)[18] indicate that the four pockets of the homology model active site can be efficiently accessed from a simple aliphatic tether, affording PFTase inhibitors with an acyclic scaffold that can be conveniently prepared through a short series of straightforward chemical transformations (Figure 1). One of the simplest scaffolds conceivable, ethylenediamine, provides an inexpensive and fourfold substitutable tether of appropriate size to project four different groups into the active site







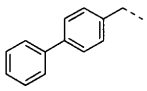


Figure 1. Active-site conformation of **15** (colored by atom type), as determined by flexible ligand docking[18] in the homology model of the active site of *Pf*PFT (red = hydrophobic, blue = hydrophilic residues). Values in parentheses refer to the corresponding positions in rat PFT (PDB entry 1JCR).

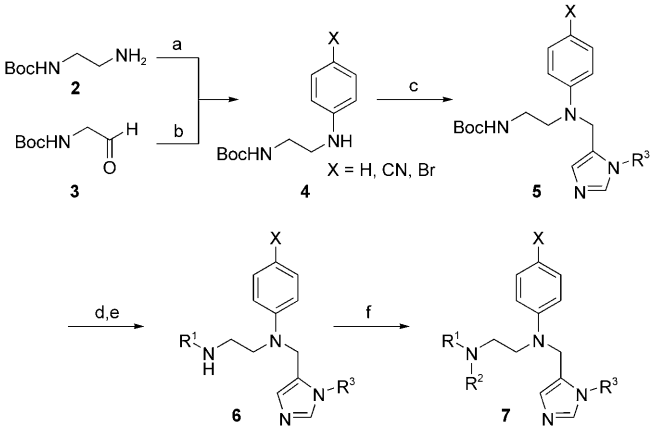
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



pockets. The incorporation of imidazole provides a zinc binding group that has been consistently demonstrated to confer activity in other series of inhibitors, whereas small hydrophobic (phenyl, benzyl) and simple sulfonamides (*N*-methylimidazole, phenyl) are predicted as suitable substitutions to access the remaining hydrophilic and hydrophobic pockets.

An initial series of PFTase inhibitors was prepared as outlined in Scheme 1. Substituted anilines **4** were formed either by the reductive amination of aniline (4-H, 4-Br), or by nucleophilic substitution of *para*-fluorobenzonitrile with monoprotected ethylenediamine. Chemoselective alkylation of aniline **4** through double deprotonation with LDA and subsequent alkylation at the anilide anion proceeds smoothly in THF with no evidence of alkylation of the carbamate. Some cyclic urea is observed, presumably generated through the elimination of *tert*-butoxide from the carbamate to provide the corresponding isocyanate and subsequent intramolecular cyclization to the anilide. Alkylation of carbamate **5**, deprotection, and coupling to sulfonyl chlorides furnishes the desired series of inhibitors (**1**, **8**–**15**, Table 1).

[a] Inhibitor concentration required to decrease *Pf*PFT activity twofold. [b] Inhibitor concentration required to decrease hypoxanthine incorporation into parasites twofold. [c] Not determined.

Scheme 1. Conditions: a) 4-fluorobenzonitrile, TEA, DMSO, 120 °C; b) 4-bromoaniline, $NaCNBH_3$, acetic acid, molecular sieves (3 Å), MeOH; c) LDA, NaH, 5-chloromethyl-1-methyl-1*H*-imidazole·HCl (R^3), THF, −78 °C→RT; d) NaH, alkyl bromide (R^1), DMF, 0 °C; e) TFA; f) arylsulfonyl chloride (R^2), TEA, DMF. Boc = *tert*-butoxycarbonyl, DMF = *N*,*N*-dimethylformamide, LDA = lithium diisopropylamide, TEA = triethylamine, TFA = trifluoroacetic acid.

A focused set of diversity elements, predicted by docking studies (GOLD)[18] to efficiently occupy the four binding domains of the active site, were applied in the preparation of nine compounds, and their inhibition of *Pf*PFT was determined by using a scintillation proximity assay with partially purified *Pf*PFT (Table 1).[19] Eight of the nine compounds inhibit *Pf*PFT at concentrations of 50 nM or lower, with four compounds having IC_{50} values below 5 nM (**1**, **9**, **12**, and **15**). The growth of parasites in whole cells (3D7, K1) treated with inhibitors was monitored through the incorporation of tritium-labeled hypoxanthine. Six compounds displayed ED_{50} values below 1 μM, with compound **15** showing significant whole-cell activity (ED_{50}: 3D7, 93 nM; K1, 150 nM). The significantly improved activity of compounds **1** and **9**, relative to that of **8**, reflects docking solutions that suggest the *para* substituent of aniline (X) contacts a hydrophilic domain formed by Ser150, Asn317, and Lys149, whereas methylation of the zinc binding group complements a small adjacent hydrophobic pocket. Of the four substitutions investigated for the R^1 hydrophobic pocket, benzyl and cyclohexylmethyl groups afforded best activity, whereas *tert*-butylcarbamate and 4-phenylbenzyl groups are significantly less active. Three substitutions were assessed for the hydrophilic cavity formed predominately by Arg564. The small basic 1-methyl-1*H*-imidazole-4-sulfonamide conferred the best potency against both the enzyme and in whole-cell assays, whereas dansyl sulfonamide afforded significantly lower enzyme inhibition, but retained good potency (ED_{50} 300 nM) against whole cells.

Importantly, these early examples of a new series of simple acyclic *Pf*PFT inhibitors demonstrate their reasonable metabolic stability, and oral bioavailability. Treatment of **15** with rat liver microsomes resulted in a steady transformation of the inhibitor over one hour ($t_{1/2} = 20$ min), with principal metabolites observed by MS corresponding to oxidation of the inhibitor (+O), and loss of the aniline imidazole (R^3, data not shown). The promising metabolic stability of this series of inhibitors is further reflected by the reasonable plasma

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

concentration of inhibitor observed after oral dosing. Oral gavage of rats with **15** induced peak plasma concentrations of inhibitor 10-fold above the ED_{50} value within 30–40 min. A plasma concentration at least fivefold above ED_{50} was maintained for approximately two hours, with inhibitor clearing observed ($t_{1/2} \approx 33$ min, Figure 2).

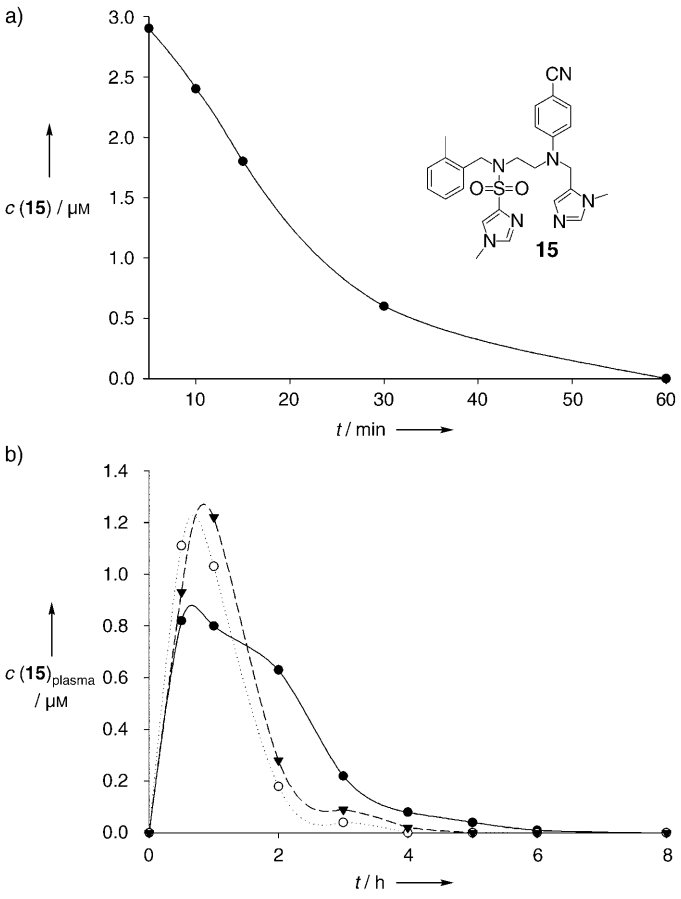

Figure 2. a) Metabolism of **15** by rat liver microsomes ($t_{1/2} = 20$ min); b) inhibitor concentration in plasma of **15** in three rats after oral garage (○ = rat 1, ▼ = rat 2, ● = rat 3; dose: 12.5 mg kg^{-1}, $t_{1/2} \approx 33$ min, $c_{max} = 1.05 \pm 0.21$ μM, $t_{max} = 40 \pm 17$ min).

In summary, a new series of simple acyclic *Pf*PFT inhibitors was developed, and their potency evaluated in enzyme and whole-cell assays. Compounds based on this readily accessible scaffold are highly active inhibitors of *Pf*PFT, with promising oral bioavailability. Expansion of this inhibitor series is expected to provide potent, orally available compounds as promising new low-cost drugs for the treatment of malaria.

Monomeric Thallium(I) Complexes of Fluorinated Triazapentadienyl Ligands**

H. V. Rasika Dias, Shreeyukta Singh, and Thomas R. Cundari*

Thallium(I) derivatives of monoanionic, nitrogen-based ligands show interesting structures and properties.[1–3] For example, $[\{Tl[(Me_3Si)_2N]\}_2]$ has a dimeric structure with a four-membered $\{[TlN]_2\}$ motif,[4] and these dimer units further aggregate to form Tl···Tl-linked extended chains. The related Tl^I amido derivative $[\{Tl[(dipp)(Me_3Si)N]\}_4]$ (dipp = 2,6-$iPr_2C_6H_3$) is also known,[5] but it is a tetramer in the solid state with weak Tl···arene interactions (mean Tl···Ct distance 3.11 Å; Ct = arene ring centroid) and long Tl···Tl contacts (average 4.06 Å). The pentaazapentadienylthallium(I) complex $[\{Tl\{[N(tol)N]_2\}\}_2]$ (tol = tolyl) has intermolecular Tl···Tl, Tl···N, and Tl···arene interactions,[6] and the tris(pyrazolyl)-borate complex $[\{Tl\{HB[3\text{-}(cyclopropyl)Pz]_3\}\}_4]$ (Pz = pyrazole) is a tetramer with a perfect tetrahedral Tl_4 core.[7] A rare, monomeric Tl^I species $[Tl\{HC[(Ph)C(Me_3Si)N]_2\}]$ involving a diazapentadienyl ligand was also reported recently.[8] In general, neutral thallium(I) compounds tend to aggregate into interesting structures with intermolecular Tl···Tl and/or Tl···donor-atom interactions.[1–3] Mononuclear complexes of Tl^I are relatively uncommon in the solid state, with most known examples, such as $[Tl\{MeB[3\text{-}(tBu)Pz]_3\}]$, being confined to sterically demanding poly(pyrazolyl)borate ligands.[1,3] It is also noteworthy that, in contrast to poly(pyrazolyl)borate complexes of Tl^I, thallium adducts of other monoanionic, nitrogen-based ligands are relatively less explored.[1–3]

We have recently investigated the chemistry of triazapentadienyl ligands[9,10] as these ligands show an interesting ability to vary their mode of coordination to fit the needs of the metal fragment.[9–12] Thallium(I) derivatives of triazapentadienyl ligands are of particular interest because they could serve as good ligand-transfer agents (like the commonly used thallium adducts of poly(pyrazolyl)borates and diazapentadienyl systems).[1,3,13–16] We discovered that it is possible to isolate mononuclear thallium(I) complexes containing fluorinated triazapentadienyl ligands. Specifically, $[Tl\{N[C(C_3F_7)N(Mes)]_2\}]$ (**1a**) and $[Tl\{N[C(C_3F_7)N(dipp)]_2\}]$ (**1b**; Mes = 2,4,6-$Me_3C_6H_2$) could be obtained in high yield by treating the parent ligands $HN[C(C_3F_7)N(Mes)]_2$ and $HN[C(C_3F_7)N(dipp)]_2$ with one equivalent of TlOEt in hexane (Scheme 1).[17] These thallium(I) complexes are colorless, crystalline solids that decompose slowly if exposed to air and light for prolonged periods. The ^1H and ^{19}F NMR spectra of **1a** and **1b** in $CDCl_3$ at room temperature are much simpler than the corresponding spectra of the related free ligands. For example, the ^1H NMR resonances of the *i*Pr protons of **1b** appear as four doublets (two of which are overlapping) and two septets, whereas in $HN[C(C_3F_7)N(dipp)]_2$ [10] these protons give rise to nine separate doublets and four separate septets. This is similar to changes observed during the formation of the silver adducts $[AgL\{N[C(C_3F_7)N(dipp)]_2\}]$ (L = MeCN, *t*BuNC) from the free ligand.[10,17]

Scheme 1. Synthesis of triazapentadienylthallium(I) complexes **1a** and **1b**.

The X-ray structures of **1a** and **1b** (Figure 1) reveal that the thallium ion coordinates to the triazapentadienyl ligand at the central nitrogen atom in both these systems.[18] The ligand backbones adopt a W-shaped configuration (an all-*trans* or zigzag arrangement of the N_3C_2 core) with the two aryl (Mes or dipp groups) moieties flanking the thallium atom. They show a short-long-long-short C–N bond distance pattern consistent with the resonance form illustrated in Scheme 1. The mesityl compound **1a** crystallizes in the *P*2/*n* space group with two molecular halves in the asymmetric unit, and is located on a crystallographic twofold rotation axis containing the Tl–N bond. It is monomeric, and has no close Tl···Tl contacts. The dipp analog **1b** crystallizes in the $P2_12_12_1$ space group with three molecules in the asymmetric unit. These molecules also do not show intermolecular Tl···Tl contacts: the closest contact involving the Tl^I ion and a neighboring molecule is of the Tl···F–CF type (3.21 Å), which is at the long end of weak thallium–fluorine interactions[19] and is probably a result of crystal packing. Furthermore, this interaction does not affect the C–F bond distance.

The Tl–N bond distances of **1a** are 2.608(3) and 2.675(4) Å. In **1b**, two molecules have similar Tl–N distances

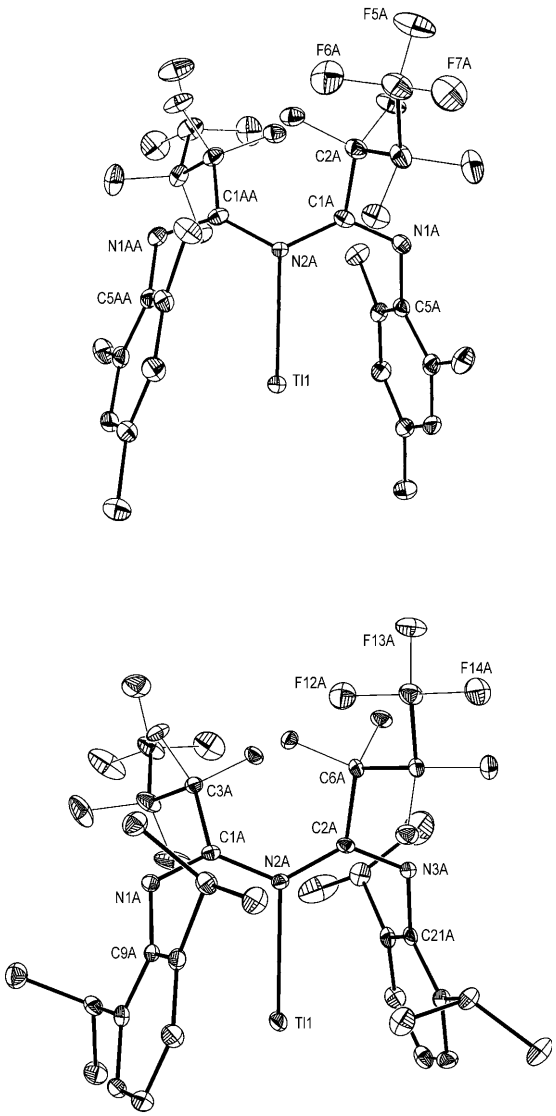

Figure 1. Molecular structures of $[Tl\{N[C(C_3F_7)N(Mes)]_2\}]$ (**1a**, above) and $[Tl\{N[C(C_3F_7)N(dipp)]_2\}]$ (**1b**, below). Only one molecule in the asymmetric unit is shown; hydrogen atoms have been omitted for clarity.

(2.672(2) and 2.666(2) Å) while the third molecule has a slightly longer Tl–N (2.732(2) Å) bond. These distances exceed the sum (2.30 Å) of the covalent radii of Tl (1.55 Å)[20] and N (0.75 Å). The Tl–N bonds in these adducts could therefore be considered as somewhat ionic. For comparison, the Tl–N bond distance in $[\{Tl[(dipp)(Me_3Si)N]\}_4]$ is 2.307(6) Å.[5] Further analysis of Tl–N distances for neutral complexes in the Cambridge Structural Database (CSD; the N center is restricted to three-coordination) yields a mean distance of 2.42 ± 0.20 Å (345 complexes),[21] thus the observed Tl–N distances in **1a** and **1b** are toward the long end of the range of reported Tl–N bonds, and most similar to Tl–N distances seen in tris(pyrazolyl)borate complexes of Tl^I. Indeed, restricting the search to bis- and tris(pyrazolyl)borate complexes yields a mean Tl–N distance of 2.63 ± 0.20 Å ($n = 107$).

The thallium(I) adducts **1a** and **1b** feature an intriguing structure. In addition to the Tl–N bond, as illustrated in Figure 1, each thallium center is flanked by two aryl moieties. Although the Tl–C distances are significantly longer than the typical Tl–C single bonds (e.g., 2.34(1) Å found in [(2,6-trip$_2$C$_6$H$_3$)Tl]; trip = 2,4,6-*i*Pr$_3$C$_6$H$_2$),[22] some separations are within the sum of the van der Waals radii of Tl and C (3.66 Å).[23] For example, the Tl–Ct distances (Ct = arene ring centroid) in the two molecules of **1a** and the three molecules of **1b** are 3.00, 3.00; 3.10, 3.10 (with shortest Tl–C separations of 3.02, 3.02; 3.04, 3.04) Å and 2.85, 3.44; 2.85, 3.56; 2.95, 3.08 (with closest Tl–C separations of 3.09, 2.94; 3.10, 2.92; 3.09, 3.08) Å, respectively. Furthermore, the Tl–carbon distances of structurally characterized Tl–arene π complexes are 3.29 ± 0.08 Å (72 complexes),[21] which corresponds to a mean Tl–Ct distance of around 3.00 Å, which is close to the shorter of the Tl–Ct values in the present crystal structures. On the other hand, the Tl···arene contacts in the complexes reported here do not seem to substantially modify the ligand parameters. For example, the C–N distance and C–N–C and N–C–N angles of the W-shaped ligand backbone are very similar in **1a** and **1b**, in the related anion $[N\{C(C_3F_7)NPh\}_2]^-$,[24] and in the κ^1N(central)-bonded metal adducts $[LM\{N[C(C_3F_7)N(dipp)]_2\}]$ (LM = MeCNAg, *t*BuNCAg, MeHg).[10,12,17]

To clarify whether Tl···arene contacts are "enforced" by the W-shape ligand conformation that places the aryl groups in a quasi-perpendicular arrangement (see Figure 1) or energetically driven, we undertook a computational study. A density functional (B3LYP/CEP-31G(d)) geometry optimization of D_6 $[Tl(\eta^6\text{-benzene})_2]^+$ yields a Tl–Ct distance of 2.92 Å,[15] in good agreement with the average values obtained from the CSD and the shorter distances measured here for **1a** and **1b**, thus indicating the potential for stabilization of the Tl by π-arene interactions. B3LYP/CEP-31G(d) calculation of the gas-phase dissociation energy of D_6 $[Tl(\eta^6\text{-benzene})_2]^+$ to Tl^+ and two benzene molecules shows the reaction to be exothermic by 42 kcal mol^{-1}, thus indicating an average Tl–π-arene interaction energy of 21 kcal mol^{-1}. Not surprisingly, neutral models such as $[Tl\{N[C(R')NR]_2\}]$ yield weaker, Tl–π-arene interaction energies of 11 (R′ = H, R = Ph) and 12 kcal mol^{-1} (R′ = F, R = Ph). These energies were estimated by taking the difference in the homolytic Tl–ligand bond energies for $[Tl\{N[C(R')NPh]_2\}]$ and $[Tl\{N[C(R')NH]_2\}]$, in which R′ = H or F.

Hybrid quantum/molecular mechanical calculations (see Figure 2 and the Supporting Information) on a full experimental model (geometries optimized starting from the three different molecules in the asymmetric unit of **1b**) yield commensurate Tl–π-arene interaction energies of 13 kcal mol^{-1}. The [Tl(2,6-trip$_2$C$_6$H$_3$)] complex reported by Niemeyer and Power, which to the best of our knowledge represents the most bona fide example of Tl^I monocoordination,[22] has arene interaction energies of around 3 kcal mol^{-1} between Tl and each aryl substituent. The Tl···arene interaction energies in the triazapentadienyl complexes can be compared to the Tl–N bond energies calculated from triazapentadienyl models without arene substituents—63 (R′ = R = H) and 64 kcal mol^{-1} (R′ = H, R = F)—at the same B3LYP/CEP-31G(d) level of theory. Therefore, computational estimates

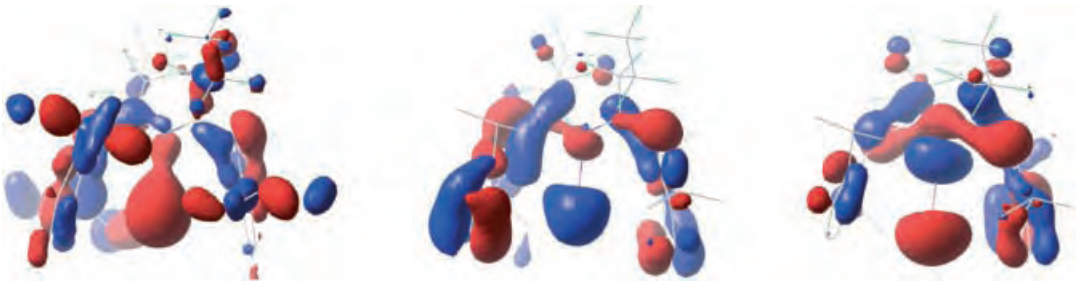

Figure 2. Orbitals derived from QM/MM (UFF force field for C_3F_7 and *i*Pr substituents; B3LYP/CEP-31G(d) for remainder of complex **1b**) geometry optimization that displays delocalization between the arene π-ring and the Tl 6s orbital.

imply an essentially monocoordinate Tl^I center in **1a** and **1b** whose stability is supplemented by Tl···arene interactions. A plot of the Kohn–Sham orbitals of **1b** shows three orbitals that display significant interactions; these correspond to the in-phase and out-of-phase combinations of the lowest energy arene π orbital and the Tl 6s orbital (Figure 2). Furthermore, the analogous orbitals (see the Supporting Information) for $[Tl(\eta^6\text{-benzene})_2]^+$ show greater Tl–π-arene delocalization for this cationic system, thus supporting the contention of weaker, albeit significant, Tl–π-arene interactions for the present neutral triazapentadienyl complexes.

The coordination properties of $[N\{C(C_3F_7)NR\}_2]^-$ also merit some comment as it binds to metal ions in several different fashions (e.g., κ^1N(central), κ^1N(terminal), or κ^2N-(terminal) with W- or U-shaped ligand conformers).[9–12] The two lowest energy conformations found for the full ligand models at the PM3 level of theory are U-shaped and W-shaped,[17] with the U-shaped conformer being only 0.1 kcal mol^{-1} lower in energy than the W-shaped conformer. Hence, these conformations are essentially degenerate. One may infer that the backbone conformation adopted upon ligation by a metal fragment will be primarily determined by the steric and electronic characteristics of the metal. The electronic properties for the two lowest energy conformations of $[N\{C(C_3F_7)NR\}_2]^-$ were thus calculated. A plot of the highest-unoccupied molecular orbital (HOMO) for $[N\{C(C_3F_7)NR\}_2]^-$ shows it to be the expected nonbonding π orbital of a conjugated five-atom entity. The HOMO for the W conformer is shown in Figure 3 (the HOMO of the U conformer is the same). Evidently, the HOMO is more or less evenly distributed among the three N atoms of the anionic ligand, which implies that in an orbitally controlled or covalent regime there will be little bias for ligation of the metal at either the terminal or central nitrogen atoms. Thus, it is plausible to infer that discrimination among different coordination modes will be made on the basis of charge considerations, the chelate effect, and/or steric effects. To probe the first of these inferences, the Mulliken charges of the U and W conformations were calculated. They are interesting in that they point to the central nitrogen atom of the N_3C_2 core being more nucleophilic/basic than the terminal nitrogen atoms. The calculated Mulliken charges are −0.2 for the terminal nitrogens and −0.4 for the central nitrogen. Hence, electrophiles/acids are expected to coordinate to the central nitrogen, as seen in the thallium(I) adducts described herein.

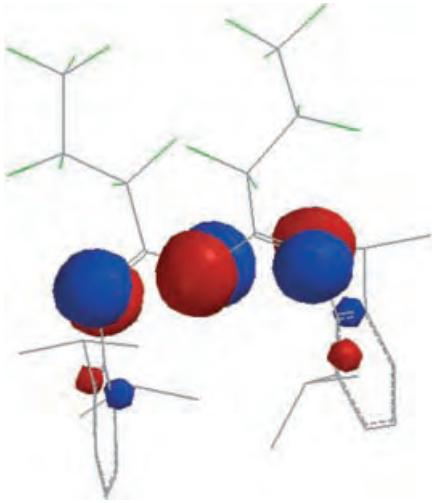

Figure 3. Highest energy molecular orbital (PM3 calculation) of $[N\{C(C_3F_7)N(dipp)\}_2]^-$.

Overall, we report here the isolation of the first monomeric, Tl–N-bonded complexes of triazapentadienyl ligands. Compounds **1a** and **1b** also feature weak Tl···arene contacts. The computational investigation has revealed that these interactions are energetically important, although secondary to Tl–N bond interactions. The thallium(I) ion coordinates to the more nucleophilic nitrogen site of the ligand anion. The triazapentadienyl ligands used in this study may be compared to the diazapentadienyl and pentaazapentadienyl systems. Few thallium(I) adducts of the latter two ligand types are known,[1] and only $[Tl\{PhC[C(H)N(dipp)]_2\}]$,[8] $[Tl\{HC[C(Ph)N(Me_3Si)]_2\}]$,[8] and $[\{Tl\{N[N(tol)N]_2\}\}_2]$[6] have been structurally characterized. Thus, the title compounds represent a rare addition to thallium derivatives of the azapentadienyl ligand family.[25]

The Thermal Unfolding of Native Cytochrome *c* in the Transition from Solution to Gas Phase Probed by Native Electron Capture Dissociation**

Kathrin Breuker and Fred W. McLafferty*

The effect of hydration on protein structure, dynamics, folding, and stability has been studied for decades and still is a topic of active research.[1–4] Removal of solvent results in the formation of stable gas-phase protein conformations that can be dramatically different from the original native state,[5–9] but so far nothing is known about the sequence of structural changes of a native protein that is suddenly exposed to vacuum. We address here the effect of hydration on structure and stability, and report for the first time site-specific data on the thermal unfolding of a native protein structure in the transition from solution to gas phase. Our data support a sequential unfolding mechanism dominated by the loss of hydrophobic bonding.

We have shown recently that electrospray ionization (ESI)[10] of aqueous solutions of ferric Cytochrome *c*, (Fe^{III})-Cyt *c*, in concentrations favorable for the formation of noncovalently bound homodimers (≈ 75 μM) produces unexpected backbone-cleavage products, a phenomenon we termed "native electron capture dissociation" (NECD).[11] Briefly, as an electrosprayed dimer ion is introduced into the Fourier transform mass spectrometer (FTMS) and passes the heated capillary for desolvation, one of its monomers partially unfolds. This causes proton transfer from the compact monomer **II** to the partially unfolded monomer **I**, and induces a substantial charge asymmetry.[12] In turn, this prompts intermolecular transfer of two electrons to the heme of monomer **I**, one reducing the heme iron and the other causing protein backbone cleavage (NECD) next to residues in contact with the heme.[11,13] Finally, the two cleavage products and monomer **II** separate and are detected in the trapped-ion cell of the FTMS.

Figure 1 shows the yield[14] of fragment ions from NECD of two aqueous solutions of horse heart (Fe^{III})Cyt *c* (75 μM, pH 5) versus backbone cleavage site; the capillary temperature was ≈ 31 °C.[15] Solutions A (for the experiment in Figure 1a) and B (for the experiment in Figure 1b) were prepared in the same way, except that A was stored overnight and B was stored for three months. In agreement with the proposed NECD mechanism,[11] protein backbone cleavage occurs next to residues with noncovalent bonding to the heme in the native structure. The NECD fragments from solution A result from cleavage next to K13, Y48/T49, L68, K79/M80, F82, and I85, while solution B gives additional products from cleavage next to L35, T40, F46, N52, and W59.

Thus the dimers in solutions A and B appear to represent different structures; that of solution B stabilizes more protein–heme bonds in monomer **I** so that they are still intact when NECD occurs.[16] The cleavage products from solution A are consistent with monomer **II** binding near K79/M80 of monomer **I**, and stabilization of its protein–heme interactions through the hydrogen-bond network that involves residues 49, 67, and 78–82 (Figure 2). The products from solution B indicate binding near Y48/T49 of monomer **I**, which in addition stabilizes its heme contacts of the residues associated with the extensive hydrogen-bond network of 37, 38, 40, 49, 50, 52–55, 57, and 59. This binding close to Y48/T49 actually corresponds to that found in the asymmetric dimer unit in crystals of (Fe^{III})Cyt *c* (horse heart) at low ionic strength in which T47 and D50 of monomer **I** bind to V11, Q12, and Q16 of monomer **II**.[17] Interestingly, the structure of the crystal monomer corresponding to our partially unfolded monomer **I** is somewhat more disordered than its counterpart.

Neither of the NECD spectra shows fragments from cleavage in the terminal regions, that is, next to F10, L94, and L98, or in the 18–34 segment. This suggests that the initial unfolding causing charge asymmetry in either dimer structure involves separation of the terminal helices, rupture of the H18–Fe coordinative bond,[18] and unfolding of the associated Ω-loop. Proton transfer to the newly exposed residues causes charge asymmetry, the extent of which can be calculated from the sum of the average charge values for the quasi-complementary fragment ions $\boldsymbol{c}_{48}$ and $\boldsymbol{y}_{56}$, +8.5 (Figure 3a), and the average monomer ion charge of +7.2 at 50% yield (representing all monomer **II**, as all monomer **I** ions are fragmented). Taking into account the two electrons for heme iron reduction and backbone cleavage, these +8.5 and +7.2 values correspond to +10.5 and +5.2 charges, respectively, prior to electron transfer. Thus a 2.0:1 charge asymmetry drives NECD for both of these solutions at pH 5, independent of temperature (Figure 3a), whereas the total NECD yield goes up from 4% at 28.5 °C to 23% at 42 °C and then down to 15% at 45.5 °C for solution A, and from 21% at 29 °C to 54% at 40 °C to 30% at 48 °C for solution B (Figure 3b).

A 75 μM solution at pH 4 gave cleavage products from the same sites as in Figure 1a, except none next to K13. The sums of the fragment-ion charges were $\approx +12.5$ at 27.5 and 29.5 °C, indicating the presence of more highly charged dimeric NECD precursors at pH 4. Although heating lowered the

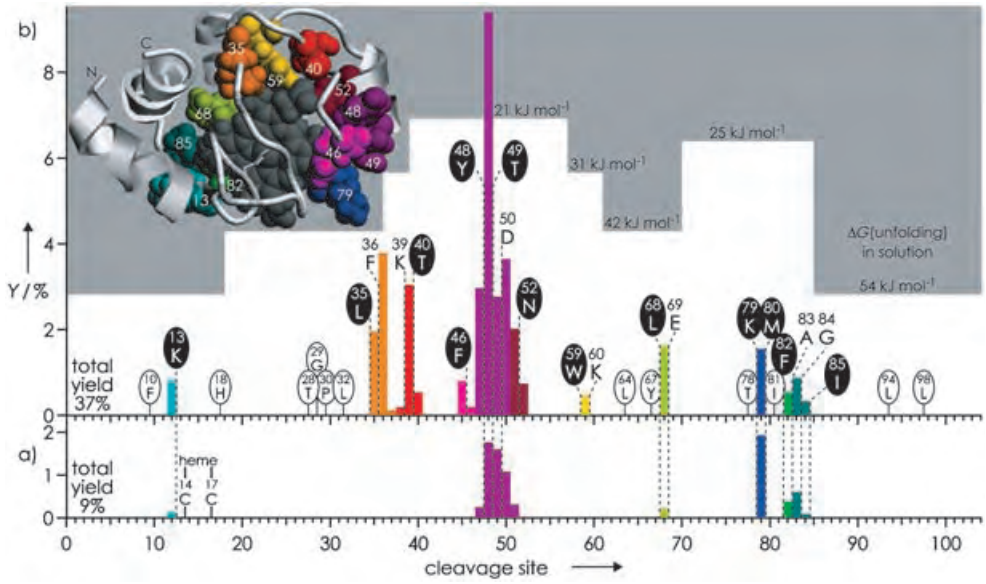

Figure 1. NECD fragment-ion yields (*Y*) versus backbone cleavage site from ESI of aqueous solutions of horse heart (Fe^{III})Cyt*c* (75 μM, pH 5). The samples were prepared by dissolving the lyophilized protein in pure water and storing a) overnight at 4 °C, b) at 4 °C for three months; capillary temperature ≈31 °C. Ellipses: residues with native heme contacts (filled black where NECD was observed). Upper left: Structure of native (Fe^{III})-Cyt*c* in solution;[23] heme: dark gray; contacting residues giving rise to NECD: same colors as in (a) and (b). Gray areas: unfolding free energies of (Fe^{III}) Cyt*c* in solution relative to the native state.[21,22]

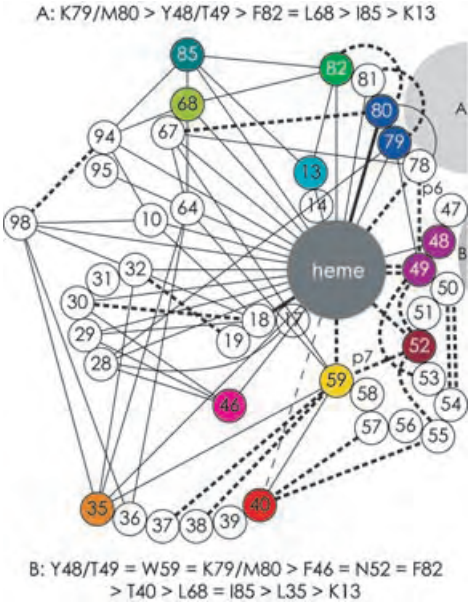

Figure 2. Schematic representation of hydrophobic (thin solid lines), hydrogen (thick dashed lines), and coordinative (thick solid lines) bonds (<3.5 Å) of heme-contacting residues in native horse heart (Fe^{III})Cyt*c*.[23] The T40–heme interaction (thin dashed line) is unspecific but within 2.9 Å. N52 and W59 are connected by hydrogen bonds to the same heme propionate 7 (p7) oxygen atom, and T49 and T78 are connected by hydrogen bonds to the same heme propionate 6 (p6) oxygen atom.

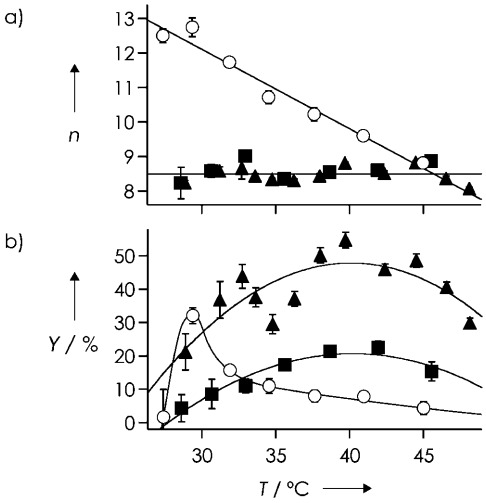

Figure 3. NECD of (Fe^{III})Cyt*c* solutions versus capillary temperature: a) summed average charge states (*n*) of c_{48} and y_{56}, b) total yields (*Y*). Solution A, pH 4 (○), pH 5 (■); solution B, pH 5 (▲).

fragment-ion charge of ≈+12.5 to the +8.5 value of the solutions at pH 5 (Figure 3a), the charge asymmetry before electron transfer changed little with temperature; the average value of +8.9 for monomers at 29.5 °C indicates a charge asymmetry of ≈14.5:6.9 (2.1:1) before electron transfer. Increasing temperature effects a dramatic yield increase from 2% at 27.5 °C to 32% at 29.5 °C, falling to 4% at 45 °C (Figure 3b).

This strong positive and negative effect of heating on NECD yields for both dimer solutions, one at both pH 4 and 5, without a change in the required charge asymmetry, indicates several competitive dissociations of the solution dimer structure. The lowest energy pathway must be the direct dissociation of the intermonomer bond, as no dimer ions were detected in the NECD spectra measured under any conditions. The increasing yield of NECD cleavage products

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

with heating is then consistent with an increasingly competitive unfolding of monomer **I** and more dimer ions reaching the critical charge asymmetry for NECD before the intermonomer bond dissociates; NECD of solution B reaches a 50% fragment-ion yield at 40°C, corresponding to complete dissociation of all monomers **I**. Higher temperatures open up yet another pathway, the competitive unfolding of monomer **II**, which increases the proportion of dimer ions whose charge asymmetry stays below the critical level. Note that the less favored unfolding of monomer **II** is consistent with the asymmetric dimer structure of (Fe^{III})Cyt *c* crystals,[17] in which unfolding of the terminal helices of monomer **II** would be restricted by the V11, Q12, and Q16 binding in the dimer interface (Figure 1). However, an asymmetric dimer structure is not necessarily a requirement for asymmetric unfolding; many gas-phase dimer ions exhibit this phenomenon, although none as yet has shown NECD.[12,19,20]

The branching ratio of products from different cleavage sites can also be strongly affected by temperature, as illustrated for solution A in Figure 4. For example, the yield

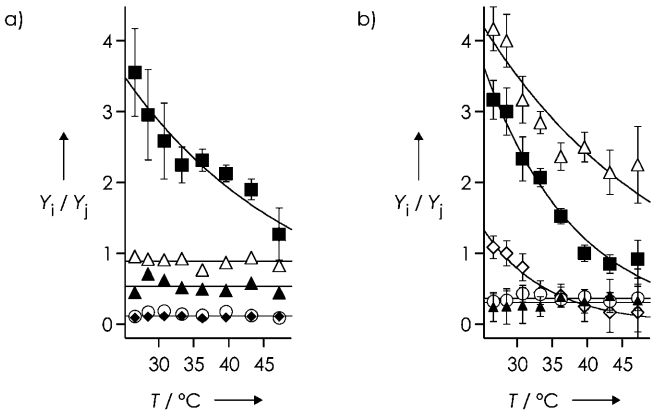

Figure 4. Branching ratio of NECD fragments from cleavage at sites i versus j, (Y_i/Y_j), for solution A, pH 5: a) Y_{47}/Y_{48} (◆), Y_{49}/Y_{48} (△), Y_{50}/Y_{48} (▲), Y_{51}/Y_{48} (○), $(Y_{47} + Y_{48} + Y_{49} + Y_{50} + Y_{51})/Y_{79}$ (■); b) Y_{82}/Y_{47} (■), Y_{83}/Y_{68} (△), Y_{84}/Y_{83} (▲), Y_{12}/Y_{84} (◇), Y_{68}/Y_{82} (○).

of fragments from cleavage at site 12, Y_{12}, versus that from cleavage at site 84, Y_{84}, decreases with increasing temperature, revealing that fewer dimers had retained the K13–heme interaction than the I85–heme interaction at higher temperatures. Y_{68}/Y_{82} does not change with temperature, suggesting a similar stability for the L68–heme and F82–heme interactions. The entire data set gives the order of stability, and the reverse order of unfolding: K79/M80 > Y48/T49 > F82 = L68 > I85 > K13; that for solution B is Y48/T49 = W59 = K79/M80 > F46 = N52 = F82 > T40 > L68 = I85 > L35 > K13 (see the Supporting Information).

From this order of unfolding, the most stable heme binding sites of monomer **I** for both the solution A and B dimers are those postulated to be close to the dimer binding interface (Figure 2). However, both dimers have initially unfolded in the same manner as indicated by the lack of fragments in the terminal and the 18–34 regions, and by the same charge asymmetry for both dimers. As shown in Figure 2 (solid lines), these initially unfolded regions are generally stabilized by hydrophobic bonding, in sharp contrast to the hydrogen-bond stabilization (dashed lines, Figure 2) of the least unfolded protein–heme bonding of monomer **I**. As previously postulated,[5–9] removal of water should weaken hydrophobic bonding (no solvent to avoid) but should also strengthen hydrogen bonding (no solvent to compete with).

Of further interest, this solution-to-gas phase stability order is essentially the reverse of the unfolding in solution. Englander and co-workers recently characterized five cooperative folding–unfolding units ("foldons") in native Cyt *c*, whose free energies of unfolding are shown in Figure 1 (K13 > L68 = L35 > W59 > K79/M80 = F82 = I85 > T40 = F46 = Y48/T49 = N52).[21,22] The most stable foldon in solution comprises the terminal helices that are held together by hydrophobic bonding; NECD found no bonding to the heme at F10, L94, and L98; bonding at K13 was found to be the next least stable. In solution, extensive hydrophobic bonding from the terminal helices (V20 with F10, Y97, L98, A101; L32 with L98) also stabilizes the 18–34 Ω-loop, as part of the second most stable foldon. In this region NECD finds L35 and L68 as the next weakest heme binding partners, with six other cleavage products missing. On the other hand, among the most stable interactions in the gas phase is the Y48/T49–heme contact, which is part of the least stable solution foldon. Dehydration of the native protein structure, plus the stabilization by monomer **II**, almost inverts the stabilities of the individual interactions in solution.

In conclusion, site ordering for the unfolding of a native protein in the transition from solution to gas phase greatly favors hydrophobic bonds, even those that are the last to unfold in solution. Surrounding such a bond by vacuum instead of water of course weakens it; intermediate effects of this type have been observed with protein conformations in nonpolar solutions.[24] The main requirement for NECD of the Cyt *c* dimers appears to be fast initial unfolding of a peripheral region, so that monomeric native proteins with peripheral hydrophobic bonding in extended structures should also be investigated for NECD. Although here NECD yields could be seriously reduced by heme absence or competitive unfolding of another part of the protein, competitive dissociation of intermolecular noncovalent bonds (e.g. dimer interface) would be no problem. The occurrence of NECD should also be sought in the dissociations of gaseous ion dimer structures that exhibit asymmetric charge partitioning.[12,19,20]

Experimental Section

This study utilized a 6-Tesla FTMS described previously.[25] Ions formed by ESI entered the instrument through a heated capillary where NECD occurs;[11] the products were transferred into the ion cell ($< 10^{-9}$ Torr) through quadrupole ion guides. ESI utilized homemade emitters with a tip inner diameter of ≈ 5 μm, flow rate of 200–500 nL min^{-1}, and spray potential of 1 kV. Horse heart Cyt *c* (Sigma, USA) was dissolved in pure water, with pH adjustment by addition of acetic acid.

[13] NECD of (Fe^{II})Cyt*c* yields the same products but involves transfer of only a single electron.
[14] The yield was calculated as [fragments]/([fragments] + [molecular ions]); dimer ions were not detected in the mass spectra.
[15] Measured at the capillary orifice, the temperature inside is estimated to be two times this value.
[16] Many of the cleavage sites found for solution B are far apart on the monomer structure of Figure 1, so that it is only possible for a fraction of these sites to participate in the intermolecular bonding of a single dimer structure. Thus it is implausible that a direct electron transfer from monomer **II** to the cleavage site causes NECD. Multiple dimer structures are also less likely for solution B than for solution A, as the B dimers should have far more time to isomerize to a minimum-energy structure.

Stable Reagents for the Generation of N-Centered Radicals: Hydroamination of Norbornene**

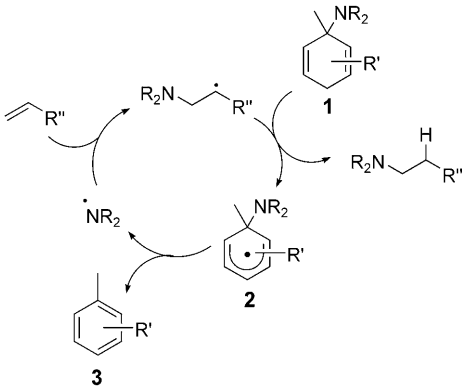
*Jens Kemper and Armido Studer**

The transition-metal-mediated hydroamination of olefins has been investigated intensively during the last few years. Despite these efforts the methods developed so far are still limited to activated systems.[1] Radical chemistry may be an alternative. However, radical additions of amines or amine derivatives to olefins by H-transfer processes are not known to date. Whereas the addition of N radicals to alkenes is well established,[2,3] the H transfer from N to C radicals is not an efficient process [Eq. (1)]. In fact, the reverse reaction, H

(1)

transfer from C to N, has been successfully used. The well-known Hofmann–Löffler–Freytag reaction is an example.[4]

N radicals are generally generated via N–halogen, N-PTOC (PTOC = *N*-hydroxypyridine-2(1*H*)thione) and N-phenylthio derivatives either photochemically or by using an added reducing reagent.[2] However, most of these precursors are unstable and must be prepared in situ. Herein we present new stable N-radical precursors. Moreover, we show that these reagents can be applied for the intermolecular hydroamination of norbornene derivatives and electron-rich olefins.



Walton et al. nicely demonstrated that substituted 1,4-cyclohexadienes can be used as precursors for C radicals.[5] We have further extended this concept to the generation of Si radicals.[6] Based on these results we assumed that 3-N-substituted 1,4-cyclohexadienes can be used as new stable N-radical precursors for the transition-metal-free transfer hydroamination of alkenes (Scheme 1). Addition of an N radical to an alkene will afford the corresponding C radical,

type rearrangement followed by alcoholysis of the intermediate isocyanate provided dienes **5** and **6**. Cyclohexadienes **8**–**10** were prepared by a Diels–Alder reaction using dienes **5** and **6**. The syntheses of cyclohexadienes **11** and **12** are described in the Supporting Information.

We first tested the stability of the reagents. To this end, dienes **7**–**12** were heated in C_6D_6 in sealed tubes at 140 °C (oil bath temperature) for 18 h. No decomposition was observed for compounds **8**–**10** as judged by ^{1}H NMR spectroscopy. For **11**, however, toluene (around 16 % yield) was identified as a product of aromatization. Compounds **7** and **12** turned out to be highly unstable: they underwent complete aromatization yielding methyl 2,4-dimethylbenzoate and toluene, respectively, in the stability test experiments. Hence, substituent at the 1-position of the cyclohexadiene that would destabilize a positive charge is important to suppress ionic decomposition.

The radical amination of norbornene using reagent **9** (→**13**) was studied next. Optimizations were conducted in benzene in sealed tubes at 140 °C using di-*tert*-butylperoxide (DTBP) as an initiator (Table 1). We were very pleased to

[a] Determined by GC analysis with methyl benzoate as an internal standard.

observe that metal-free transfer hydroamination occurred. Variation of the initiator concentration revealed that the best results (36 % yield) for the reaction with 1 equiv of **9** and 1.1 equiv of norbornene at a concentration of 0.25 M were obtained with 0.4 equiv of peroxide (runs 1–5). Higher yields were obtained with 2 or 3 equivs of olefin (44 and 45 %, runs 6,7). However, a further increase of the norbornene concentration did not lead to better results (runs 8–10). The highest yield was obtained when **9** was used in a large excess: with a 5.7-fold excess a 57 % yield was obtained (run 13). Running the aminations at higher concentrations provided lower yields (runs 15,16). We found that the amination can be performed under solvent-free conditions (run 17). As a result of the optimization studies all subsequent experiments were performed with a threefold excess of olefin at a concentration of 0.25 M with 0.4 equiv of initiator.

The yield was improved further upon switching from the Moc derivative **9** to the Boc-protected reagent **8** (→**14**, 56 %). As expected from the stability tests, cyclohexadiene **7** is not an efficient hydroamination reagent (→**14**, 18 %). We also believe that the aromatization step delivering the carbamoyl radical is very slow for the cyclohexadienyl radical arising from **7**. Indeed, the methyl fragmentation product methyl 2-*tert*-butoxycarbonylaminyl-4-methyl benzoate was isolated as

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

the major product in 44% yield. The position of the electron-withdrawing group is obviously important. However, the methoxycarbonyl substituent can be replaced by a cyano group without affecting the yield greatly. Thus, the reaction with **10** afforded **14** in 45% yield. Substituents at the vinylic positions of our reagents are not mandatory. Amination using the unsubstituted diene **11** provided **14** in 47% yield. As expected, hydroamination of norbornene with phthaloyl-protected cyclohexadiene **12** did not work. The stability of **12** is a problem, as shown by the tests discussed above. Moreover, the addition of the sterically hindered *N*-phthaloyl radical is probably slow. Phthalimide was isolated in 61% yield. Our method delivers the amination products as Boc- or Moc-protected derivatives. This is highly desirable since most of the chemical manipulations on amine-functionalized molecules require N protection.

Finally, the most efficient reagents identified (**8**, **9**) were used to study other hydroaminations (Scheme 3). Products **15**–**19** were obtained in moderate-to-good yields as 1:1 mixtures of regioisomers. Hydroamination of benzannulated norbornene with **8** provided **20** in 40% yield. Hydroamination of vinyl pivalate under standard conditions afforded **21** along with telomers comprising two, three, and four monomer units, as identified by ESI-MS. Obviously, reduction of the α-oxy radical generated after N-radical addition onto vinyl pivalate cannot efficiently compete with telomerization. However, we found that this problem can be circumvented upon using polarity reversal catalysis.[7] Thus, hydroamination in the presence of methyl thioglycolate (10%) delivered the desired hydroamination product **21** in 48% yield.[8,9] Carbamoyl radical addition onto vinyl pivalate delivers a nucleophilic α-oxy radical, and a polar effect should favor H abstraction from the electronegative thiol. The electrophilic thiyl radical generated in this way will, in turn, abstract an H atom more readily from the cyclohexadienyl site of **8**, thus regenerating the thiol catalyst and continuing the chain (polymerization is suppressed).[8] Vinyl phthalimide was also successfully hydroaminated in the presence of 10% thiol catalyst (→**22**, 43%). The highest yield was obtained for the hydroamidation of dihydropyran (→**23**, 60%).[10]

As expected, addition of the electrophilic carbamoyl radicals derived from **8** or **9** onto electron-deficient olefins such as acrylonitrile and butyl acrylate did not occur. Pleasingly, we found that the highly challenging hydroamination of 1-octene could be accomplished (→**24**). Although the yield is currently not satisfactory (17%), manipulation of the electronic nature of the N-centered radical (varying the N-protecting group) should allow increasing the efficiency of the process. Work along this line is currently under way.

In conclusion we have presented a new method for the generation of N radicals under neutral conditions. In contrast to well-established procedures using N–halogen derivatives as N-radical precursors,[2] an additional stoichiometric reducing reagent such as the toxic tributyltin hydride is not necessary for N-radical generation. Moreover, the radical precursors are readily prepared and are stable compounds. To the best of our knowledge, this is the first report on a radical hydroamination reagent. Moreover, transition-metal-free transfer hydroaminations are unknown.[11]

Size-Dependent Optical Properties of MgO Nanocubes**

Slavica Stankic, Markus Müller, Oliver Diwald, Martin Sterrer, Erich Knözinger, and Johannes Bernardi*

Understanding the nature and chemical activity of well-defined surface structures on polycrystalline oxide systems requires atomic-scale characterization.[1,2] However, the properties of surface ions on polycrystals usually vary over a wide range, because different crystallographic faces are disposed to form edges, steps, and point defects. This situation leads to a substantial energetic heterogeneity in the surface properties. Consequently, it is one of the major challenges in current catalysis research to single out ions and point defects associated with specific surface structures and to characterize their role in the complex surface chemistry.[1–4] Magnesium oxide (MgO) is a particularly well-suited model system for such studies because of its straight-forward rock-salt crystal structure, the large abundance of thermodynamically stable (100) faces, and the purely ionic, nonconducting nature of the compound. Low-coordinate surface anions, which are considered to be chemically reactive sites, give rise to specific optical transitions in the UV light range, which can be assigned to the formation of surface excitons.[2,5] Their investigation provides an opportunity to establish a correlation between topological surface features such as corners, steps, and edges and the corresponding chemical and spectroscopic properties.[5–8] For the efficient investigation of surface sites, nanocrystalline model systems (where the number of surface ions is of the same order of magnitude as the number of bulk ions) are required.[9–11]

Herein we report the production of nanometer-sized MgO nanoparticles by chemical vapor deposition (CVD). They attain an almost perfect cubic shape after thermal activation at 1170 K under high-vacuum conditions ($p < 5 \times 10^{-6}$ mbar).[12] Depending on the CVD parameters they can adopt different average sizes between 3 nm and 10 nm. Preferential adjustment of the cube size is important since it sets the relative concentrations of corner and edge anions and thus determines the optical and chemical properties. Size-dependent trends in the relative intensities of absorption bands and photoluminescence emission bands were observed in the UV light range. A novel photoluminescence emission band was observed for nanocubes with edge lengths smaller than 9 nm and is attributed to the radiative deactivation of surface excitons at corner anions of the MgO nanocube.

The MgO nanoparticles are prepared by CVD in a flow-reactor system by the reaction of metal vapor with different gaseous oxidizing agents. At pressures under 20 mbar, metal atoms are evaporated from metal grains and transported by argon at a fixed flow rate to the downstream end of a quartz glass tube where the oxidant is introduced. There the metal vapor is combusted either with dry air (sample A), O_2 (sample B), or N_2O (sample C). The resulting metal oxide nanocrystals are then deposited downstream in a stainless steel net at room temperature.[13] Afterwards, the material is subjected to thermal activation at 1170 K. Figure 1 shows typical TEM images of MgO nanocube samples A, B, and C after such treatment. The nature and concentration of the oxidizing agent has a major influence on the nucleation process and consequently affects the average size of the particles after thermal activation. This feature is shown by the size distribution plots in Figure 2.[14] The particles of sample A are slightly less regular cubes and have an average edge length of 10 nm, whereas samples B and C consist of 5 and 3 nm sized nanocubes, respectively.

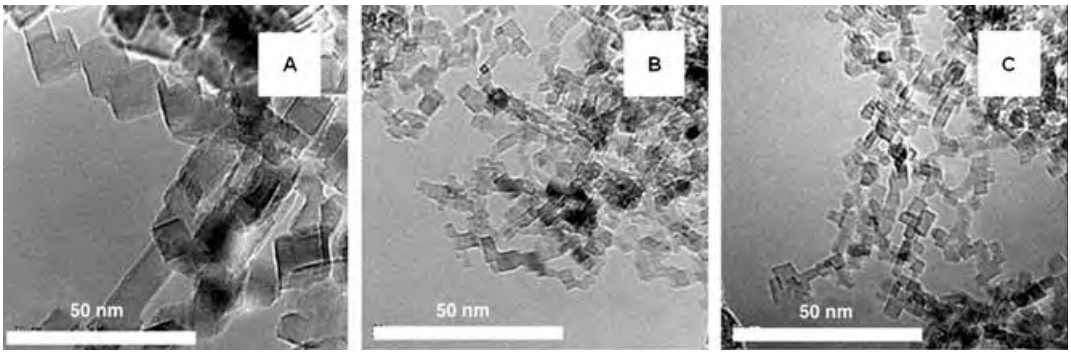

Figure 1. Typical TEM images of MgO nanocubes that result from CVD in conjunction with subsequent thermal activation at 1170 K and $p < 5\times10^{-6}$ mbar. For samples A, B, and C different oxidants were used at the same flow rates for the CVD process, as outlined in the text.

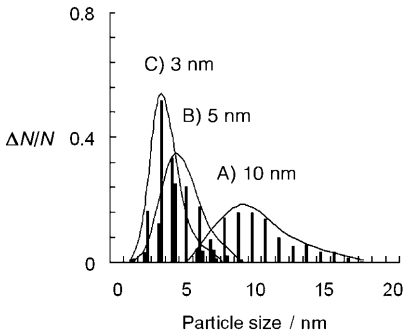

Figure 2. Size distribution plots of CVD MgO nanocubes. About 200 particles were observed to plot each distribution.

The optical properties of the nanocubes were measured by UV diffuse reflectance spectroscopy. The spectra, recorded in the presence of 10 mbar of O_2 to avoid photoluminescence (Figure 3),[15] reveal two clear trends with decreasing average cube size from sample A (10 nm) to sample C (3 nm):

1) The maximum of the high-energy absorption shifts from 220 nm (5.6 eV) to 230 nm (5.4 eV).
2) The absorption at 270 nm (4.6 eV), which is essentially absent on sample A (10 nm), gains relative intensity.

The second observation is perfectly in line with previous assignments of these optical features: with an energy of 5.4 eV ($\lambda = 230$ nm) four-coordinate anions in cube edges are excited whereas the 4.6 eV ($\lambda = 270$ nm) absorption band is attributed to the excitation of three-coordinate anions in corner positions.[2,5,8] Larger cube sizes imply lower relative concentrations of corner anions with respect to edge anions. This feature is exemplified in Table 1, where the calculated numbers of surface O^{2-} ions for the three particle sizes are listed. For the calculation we used an Mg^{2+}–O^{2-} distance of 2.1 Å and assumed a perfect cubic shape, where the particle is terminated by (100) planes, cube edges, and cube corners. For a constant quantity of 100 mg, the total number of corner anions ranges from 4×10^{16} for 10 nm cubes to 144×10^{16} ions for 3 nm cubes and the ratio of corner anions to edge anions increases from 0.01 to 0.04. This enhancement in the relative concentration of corner anions is qualitatively reflected in the relative growth of the 270 nm band (absorption on corners) compared to the one at 240 nm (absorption on edges) shown in Figure 3.

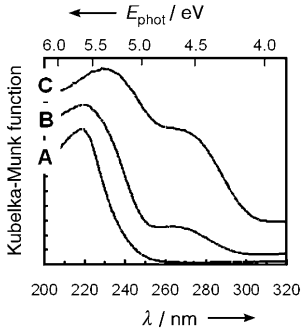

Figure 3. UV diffuse reflectance spectra of samples A, B, and C. For the sake of clarity, the curves were shifted on the ordinate scale.

Table 1: Calculated numbers of three- and four-coordinate surface anions located in ideal MgO nanocube edges and corners as a function of particle size.

Average edge length [nm]	Number of particles[a]	Number of corner O^{2-} ions[a]	Number of edge O^{2-} ions[a]	Ratio of corner to edge O^{2-} ions[a]
3	3.6×10^{17}	1.4×10^{18}	3.5×10^{19}	0.04
5	8.4×10^{16}	3.4×10^{17}	1.5×10^{19}	0.02
10	1.0×10^{16}	4×10^{16}	3.7×10^{18}	0.01

[a] In 100 mg of MgO powder.

Luminescence spectra of the three types of nanocube samples were recorded at 300 K and $p < 10^{-6}$ mbar (Figure 4). Depending on the excitation wavelength $\lambda = 240$ nm (5.2 eV) or $\lambda = 270$ nm (4.6 eV) the spectra are characterized by broad emission bands with maxima at $\lambda = 370$ nm (3.4 eV) and $\lambda = 380$ nm (3.3 eV), respectively. The full width at half maximum (FWHM) for both bands is 0.8 eV. The photoluminescence signal at 370 nm (excitation at 240 nm) is in general agreement with results from previous studies.[16–20] However, to our knowledge, the feature which is centered at slightly higher wavelength $\lambda = 380$ nm (excitation at $\lambda = 270$ nm) has not been reported as a distinct band to date.[21] The intensity of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

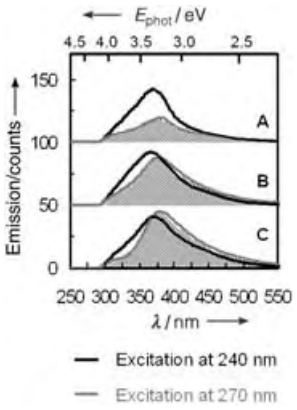

Figure 4. Photoluminescence emission spectra of samples A (10 nm), B (5 nm), and C (3 nm). For comparison, the emission signals excited at 240 nm (black curves) are set to the same nominal intensity as for the bands following excitation at 270 nm (gray curves).

this band is significantly higher for samples B and C with short cube edges than for sample A.[22] Excitation of corner anions produces surface excitons at these sites which then deactivate radiatively at 3.3 eV ($\lambda = 380$ nm). This photoluminescence effect is thus preferentially observed on small MgO cubes (samples B and C; Figure 4) and can only be understood in terms of the enhanced surface concentration of corner anions (Table 1). The higher Stokes shift of the emission band at 370 nm (5.4 to 3.4 eV compared to 4.6 to 3.3 eV) is explained by an energy transfer from the four-coordinate edge anion, where excitation initially occurs, to a three-coordinate corner anion acting as the emission site[6,8,16] On the basis of the demonstrated size-dependence, we attribute the novel band at 380 nm to a new electronic transition on MgO surfaces. This interpretation is in line with a recent electron paramagnetic resonance (EPR) study where the formation of two types of trapped hole centers, that is, O^- radicals on the MgO surface was reported.[23] The fact that the local crystal-field splittings of these two types of radicals are similar, connects well to the two emission bands of similar energy observed in this study. The linking of optical properties and the generation of surface radicals suggests that on MgO nanostructures the selective physical and chemical activation of well-defined surface structures is feasible. Further work is needed to understand the nature and mobility of surface excitons on MgO nanostructures and to investigate how changes in the concentration ratio of corner to edge ions affect surface reactivity.

In conclusion, size control over MgO nanocubes has been achieved through the CVD technique in conjunction with subsequent thermal activation steps at $p < 5 \times 10^{-6}$ mbar. The resulting adjustment of the ratio between corner and edge ions is clearly reflected in the optical properties of the MgO nanocubes as measured by UV diffuse reflectance and photoluminescence spectroscopy. Adjustment of the average particle size makes MgO nanocubes a powerful model system for surface-science studies on dispersed materials. In addition, it represents a promising building block element for the construction of functional nano- and mesostructures.

Experimental Section

The three types of MgO nanocube samples A, B, and C were obtained by using dry air ($N_2/O_2 = 4{:}1$ (A), O_2 (B), and N_2O (C) as the oxidizing agent in the CVD process.[13] Flow rates for Argon and the oxidizing agent were 1220 and 82 $s\,cm^3\,min^{-1}$, respectively. For UV Diffuse reflectance and photoluminescence measurements the sample material was transferred into a high-vacuum tight quartz cell providing pressures better than $p < 10^{-6}$ mbar. For each type of measurement, thermal treatment was carried out to remove hydroxy and carbonate groups from the surface (confirmed by IR spectroscopy). During this treatment the annealing rate was 5 $K\,min^{-1}$ and the pressure above the sample was $< 10^{-5}$ mbar. The sample was first heated to 873 K and treated with oxygen to remove organic contaminants. The final annealing temperature of 1173 K was kept for 3–10 h at pressures $< 5 \times 10^{-6}$ mbar. Photoluminescence measurements were carried out with a Perkin Elmer LS 50 B system equipped with a pulsed Xe discharge lamp as the excitation light source. The excitation light beam was passed through a UG 5 filter (Schott) in conjunction with a 295 nm long pass filter. UV diffuse reflectance measurements were performed on a Perkin Elmer Lambda 15 spectrometer with an integrating sphere. For TEM investigations a holey carbon grid was immersed into the metal oxide powder samples which had been previously investigated by spectroscopy. The TEM measurements were carried out with a TECNAI F20 analytical transmission electron microscope equipped with a field-emission electron source and a S-Twin objective lens. Images were recorded with a Gatan 794 MultiScan camera. No nitrogen impurities were detected on all samples as measured with electron energy loss spectrometry (EELS) using a Gatan Image Filter GIF 2001.

[21] Emission were also observed at higher wavelengths $\lambda > 450$ nm in the course of these studies on samples which had not been entirely dehydroxylated.
[22] Intensity trends of the absorptions bands at 240 nm and 270 nm in Figure 3 do not directly scale with those of the associated emission bands in Figure 4. This fact is attributed to one or the combination of the following reasons: a) the cross sections for absorption (measured in the presence of O_2) and emission (measured at $p < 10^{-6}$ mbar) are unknown and may be subject to particle size, b) Rayleigh scattering into the interior of the sample cell causes the loss of detectable light and has a distinct dependence on particle size ($\sim d^3$) and frequency ($\sim \nu^4$). The relative extent of scattering loss is expected to be different for both measurements owing to inherent differences in the optical set up. c) Photoluminescence spectroscopy is by far the more sensitive technique.

Antimony–Tungsten Triple Bond: A Stable Complex with a Terminal Antimony Ligand**

*Gábor Balázs, Marek Sierka, and Manfred Scheer**

Dedicated to Professor Wolf-Walther du Mont on the occasion of his 60th birthday

Complexes with transition-metal–element triple bonds of the heavier main-group elements constitute an exciting area in chemistry, since the investigation of the bonding situation as well as the reactivity potential open up a significant area of research. However, stability and reactivity are often opposing tendencies; thus existing complexes are often kinetically stabilized by bulky substituents to encumber the reactive triple bond. Exciting examples for this particular development in the chemistry of Group 14 elements are the recently synthesized complexes with a metal–lead triple bond.[1] Now, this series in Group 14 chemistry is almost complete.[2] For Group 15 elements however,[3] there still remains the challenge to synthesize stable complexes with terminal stibido as well as bismutido ligands. Indications of existing complexes with a terminal stibido ligand as intermediates were first reported by Rheingold et al. They were able to generate briefly existing complexes of the formulae $[(OC)_4MSb]^-$ (M = Cr, Mo, W) and $[(OC)_3FeSb]^-$ in the gas phase under the conditions of a Fourier transform cyclotron resonance spectrometer (FT-ICR).[4] The breakthrough for the synthesis of stable triply bonded terminal ligands of heavier[5] Group 15 elements occurred almost 10 years ago in 1995 when we were able to characterize spectroscopically the stable phosphido complex $[(t\mathrm{BuO})_3W{\equiv}P{\rightarrow}W(CO)_5]$ (**1**) [6] which was structurally characterized in 1999.[7] The difficulties in isolation arise from the high reactivity potential of this complex, since the

*t*BuO groups only protect the triple bond in the solid state, whereas in solution the bond is still accessible.

Independently Cummins[8] and Schrock and co-workers[9] chose the steric protection of the M≡P triple bond by bulky substituents at the amido ligands, when they reported in 1995 the synthesis and the first structural characterization of terminal phosphido complexes $[(Ph''RN)_3Mo{\equiv}P]$ (**2**; Ph″ = 3,5-$Me_2C_6H_3$; R = $C(CD_3)_2CH_3$) and $[(N_3N)W{\equiv}P]$ (**3**; N_3N = tren = $N(CH_2CH_2NSiMe_3)_3$). Compound **3** was synthesized by treating $[(N_3N)WCl]$ (**5**)[10] with two equivalents of LiP(H)Ph. The use of $Li[E(SiMe_3)_2]$ (E = P, As) in reaction with **5** enabled us, in addition to an alternative route to **3**, the synthesis of $[(N_3N)W{\equiv}As]$ (**4**), the first terminal arsenido complex,[11] which was independently obtained by Schrock et al.[12] Our efforts to obtain the stibido complex $[(N_3N)W{\equiv}Sb]$ (**6**) in the same manner as the arsido and phosphido complexes **4** and **3** failed, probably because of the bulkiness of the $[(Me_3Si)_2Sb]^-$ fragment which did not fit into the cone formed by the three $SiMe_3$ groups of the tren ligand. Sterically less-demanding alkyl groups on the tris(amido)amine ligand such as isopropyl or neopentyl permitted the reaction of $[(Me_3Si)_2E]^-$ (E = Sb, Bi) with **5** but did not prevent further dimerization to form the heterocumulene complexes $[\{N(CH_2CH_2NR)_3W\}_2(\mu\text{-Sb})]$ (R = *i*Pr, Np).[13,14] Now we have finally succeeded in the synthesis and spectroscopic and structural characterization of the first isolable stibido complex $[(N_3N)W{\equiv}Sb]$ (**6**) which contains an antimony–tungsten triple bond.

For the synthesis of **6**, $(Me_3Si)_2CHSbH_2$ was lithiated at −60 °C with *n*BuLi in THF to generate $Li[(Me_3Si)_2CHSb(H)]$ as a reactive intermediate. The reaction of this solution with **5** leads to the formation of the stibido complex **6** [Eq. (1)].

5 **6** (1)

Owing to the instability of the lithiated stibane, it was necessary to use an excess of $RSbH_2$ and *n*BuLi to achieve total consumption of **5**. Thus, as side products the ethylidyne complex $[(N_3N)W{\equiv}CCH_3]$ and Sb_7^{3-} were formed as a result of the degradation of the tris(amido)amine ligand and the stibane, respectively. Furthermore, depending on the solvents used and the lithium base other side products could be identified.[15]

Decrease of the steric bulkiness of the antimony reactant was expected to increase the yield of **6**. Therefore we treated the comparatively slender $[Me_3SiCH_2(H)Sb]^-$ moiety with **5** under the conditions described above. Against our expectations the alkylidyne complex $[(N_3N)W{\equiv}CSiMe_3]$ (**7**) was obtained in about 50% yield. The low thermal stability of $Li[Me_3SiCH_2(H)Sb]$ gives rise to transmetalation reactions with the formation of $Li[Me_3SiCH_2]$, which reacts with **5** to give **7**. The characterization of **7** was achieved spectroscopically and by single-crystal X-ray diffraction (see Supporting Information).[16] The synthesis and spectroscopic data of **7** have been reported previously, as it is obtained in the reaction of **5** with $Li[CH_2SiMe_3]$.[17]

Complex **6** is a diamagnetic, air-sensitive, brown crystalline compound, which is readily soluble in hydrocarbons. In the mass spectra the molecular ion peak was observed. The relatively weak emission band at 240 cm^{-1} in the Raman spectra of **6** is in agreement with a tungsten–antimony triple bond. In comparison the stretching frequencies for the lighter W≡E homologues were found at 343 cm^{-1} (E = As) and 516 cm^{-1} (E = P).[18] The solution ^{1}H- and ^{13}C NMR spectra of **6** show the presence of a C_3 symmetric ligand system. The C_3 symmetry is also preserved in the solid state. Complex **6** crystallizes as brown cubes in the cubic space group $Pa\bar{3}$.[16]

The main feature of the structure of **6** (Figure 1) is a terminally coordinated antimony ligand. The observed W–Sb distance in **6** of 2.5255(17) Å is the shortest reported to date,

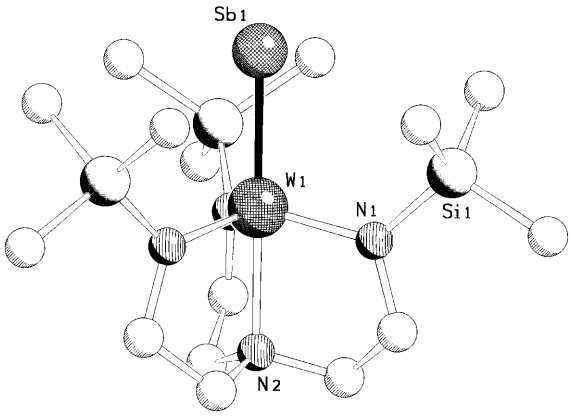

Figure 1. Crystal structure **6**. Hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: W1-Sb1 2.5255(17), W1-N1 1.994(8), W1-N2 2.330(12), Si1-N1 1.759(8); N1-W1-N1′ 115.93(15), N1-W1-N2 78.2(2), N1-W1-Sb1 101.8(2), N2-W1-Sb1 180.0(4), Si1-N1-W1 125.8(4), C1-N1-W1 118.1(6), C1-N1-Si1 115.8(6).

consistent with the representation as a triple bond, and is comparable only with the W–Sb distances in the heterocumulene complexes $[\{N(CH_2CH_2NR)_3W\}_2Sb]$ (2.5275(5) Å R = *i*Pr;[13] 2.574(1) Å R = $CH_2C(CH_3)_3$[14]). Longer W–Sb bonds were observed in the stibinidene complexes $[\{(OC)_5W\}_2SbCl(thf)]$ (2.662(1) and 2.670(2) Å)[19] and $[\{(OC)_5W\}_2SbCH(SiMe_3)_2]$ (2.687(1) Å).[20] The tungsten atom has a distorted trigonal bipyramidal coordination geometry with three N atoms in equatorial and one N and a Sb atom in axial positions. The N_{eq}–W distance of 1.994(8) Å is comparable with the corresponding distances in $[(N_3N)WCl]$ (**5**) (1.985(11) Å),[10] $[(N_3N)W{\equiv}P]$ (**3**) (1.975(6) Å)[9] and $[(N_3N)W{\equiv}As]$ (**4**) (1.989(4) Å).[11] The N_{ax}–W distance (2.330(12) Å) is longer than in **5** (2.182(6) Å) but similar to those in **3** (2.343(4) Å) and **4** (2.336(6) Å). The N_{eq}-W-N_{eq} (115.9(2)°) and N_{eq}-W-N_{ax} (78.2(2)°) angles compare well with the equivalent angles in **5** and **3** (115.8(11), 78.1(2)°, and 115.69(8), 77.9(1)°, respectively). Along the series **3**, **4**, and **6** a very slight shortening of the N_{ax}–W distance is observed, reflecting the increase of the electropositive

character of the terminal Group 15 ligand. None other structural parameters of the tren ligands is significantly influenced by the nature of the terminal ligand. As the size of the ligand E increases going from As to Sb, the cone formed from the three $SiMe_3$ groups is widened. This effect can be observed in the W-N_{eq}-Si angles (125.0(2) for **4** and 125.8(4)° for **6**). The wider angle for **3** (125.5(4)°) in comparison to **4** can be explained by the shorter W–P bond.

Density functional theory (DFT) calculations of complexes **3**, **4**, **6**, and a hypothetical complex [(N_3N)W≡Bi] (**8**) were performed to compare the [(N_3N)W≡E] (E = P, As, Sb, Bi) triple bonds of the Group 15 elements (Table 1 and Table 2). The calculated structural parameters of **3**, **4**, and **6** (Table 1) are similar to other reported values[11,21] and in a reasonable agreement with experimental data, except for the W–N2 distance. The experimental values are 0.16–0.19 Å shorter which may be due to solid-state effects.[21] As expected, the calculated W≡E bond lengths increase from E = P to E = Bi. This trend has also been found in similar metal–pnicogen complexes with alkoxy ligands.[22] The calculated W≡E harmonic stretching frequencies of 515 cm^{-1} (E = P) and 342 cm^{-1} (E = As) are in excellent agreement with observed data.[18] For E = Sb the calculated value of 264 cm^{-1} is slightly overestimated with respect to the experiment, probably due to the neglect of anharmonicity and approximate treatment of relativistic effects. Additionally, the W≡Sb stretching mode shows a strong coupling to other framework modes.

Analysis of the bonding situation using the natural bond orbital (NBO)[23] scheme and Wiberg bond indices (WBI)[24] strongly support the presence of W≡E triple bond in all calculated complexes (Table 2). Similar to other terminal pnicogen ligands in alkoxy substituted tungsten–pnicogen complexes[22] the σ and π components of the triple bonds obtained by the NBO analysis show only weak polarization. The W atom in the W–E σ bond is approximately sd hybridized, with a slight increase of s character for heavier pnicogen atoms. This situation is in disagreement with earlier published results using the PESHO method,[11] which indicate a largely d character of the tungsten contribution. The hybridization of the pnicogen atom in W≡E σ bond has a significant p character which increases from P to Bi and the two π components are composed mainly of d and p orbitals of the tungsten and pnicogen atoms, respectively.

Further support for the W≡E triple-bond character arise form the inspection of calculated molecular orbitals. The orbital picture of the W≡E is very similar for all investigated Group 15 elements and shows one σ and two degenerate π components. Figure 2 shows an example of the W≡Sb bond orbitals of **6**. The calculated NBO partial charges indicate that the tungsten atom carries significant positive charge while the pnicogen atoms are almost neutral or slightly positive charged (Sb, Bi). This result supports a strong covalent character of the tungsten–pnicogen triple bond. The calculated bond-dissociation energies decrease monotonically from P to Bi confirming that the heavier pnicogen atoms have significantly weaker W≡E bonds. Finally, the calculated [(N_3N)W≡E] complexes

show orbital and partial-charge patterns similar to those calculated for $[(MeO)_3W{\equiv}E]$ by Pandey and Frenking,[22] except for less positively charged tungsten atoms.

The results have shown the tris(amido)amine ligand complex of tungsten to be an excellent system for stabilization of terminal pnicogenido ligand complexes containing a W≡E triple bond. Now that the synthesis of the first stable terminal stibido ligand complex has been realized the path has been cleared for reactivity studies and the synthesis of the unknown bismutido complex.

Experimental Section

All manipulations were performed under an atmosphere of dry nitrogen using a glovebox and Schlenk techniques. Solvents were purified and degassed by standard procedures.

6: *n*BuLi in hexane (1.59 mL, 2.55 mmol, 1.6 M) was added to a stirred solution of $(Me_3Si)_2CHSbH_2$ (720 mg 2.55 mmol) in THF (5 mL), at −60 °C. The solution became dark red and gas evolution was observed. The reaction mixture was allowed to warm slowly to room temperature and a solution of $[N(CH_2CH_2NSiMe_3)_3WCl]$ (369 mg, 0.64 mmol) in toluene (12 mL) was added. The mixture was stirred for 20 h at 80 °C. All volatiles were removed in vacuum and the remaining black product was extracted with pentane (70 mL). Compound **6** was isolated from the orange-brown solution as brown cubes by fractionated crystallization at 5 °C. Yield: 37 mg (9 %). ^{1}H NMR (250 MHz, C_6D_6, 25 °C, TMS): $\delta = 0.847$ (s, ^2J(Si,H) = 5.85 Hz, 27 H; CH_3), 1.40 (t, ^3J (H,H) = 5.6 Hz, 6 H; CH_2), 3.58 ppm (t, ^3J(H,H) = 5.6 Hz, 6 H; CH_2); ^{13}C NMR (62.89 MHz, C_6D_6, 25 °C, TMS): $\delta = 7.70$ (s, CH_3), 51.66 (s, CH_2), 54.36 ppm (s, CH_2); EI-MS (70 eV): *m*/*z* (%): 666 (40) [M^+], 651 (100) [$M-CH_3$]$^+$, 636 (2) [$M-2CH_3$]$^+$, 621 (4) [$M-3CH_3$]$^+$, 593 (5) [$M-(CH_3)_3Si$]$^+$, 73 (95) [$(CH_3)_3Si$]$^+$. Raman (solid): $\tilde{\nu} = 240$ cm^{-1} (W≡Sb). Elemental analysis (%)calcd for $C_{15}H_{39}N_4Sb_1Si_3W_1$ (665.35): C 27.08, H 5.91, N 8.42; found: C 27.39, H 6.19, N 8.37.

The synthesis and X-ray structure of **7** is given in the Supporting Information

Structure optimizations and vibrational analyses at the DFT level were performed using the TURBOMOLE program package.[25] The BP86[26] exchange-correlation functional was used along with the triple zeta plus polarization (TZVP) basis set on all atoms.[27] To speed up calculations the Coulomb part was evaluated using the MARI-J method.[28] Quasi-relativistic pseudopotentials were used for the elements W, Sb, and Bi.[29] The NBO analysis was performed using the Gaussian03 program.[30] Calculations for **3**, **4**, **6**, and **8** were performed assuming C_3 symmetry and the nature of the stationary points was confirmed by vibrational analysis (no imaginary frequencies).

[15] A large number of reactions according to Eq. (1) were carried out to clarify the formation of the additional side-products (besides $[(N_3N)W{\equiv}CCH_3]$ and Sb_7^{3-}): for example, the reaction in toluene with *n*BuLi as metalation reagent leads to $[N_3NW{\equiv}CC_3H_7]$ as a result of the reaction of **5** with *n*BuLi, whereas with *t*BuLi in toluene, $[N_3NW{\equiv}CC_6H_5]$ was observed, formed as a result of the metalation of toluene and subsequent reaction with **5**. In contrast the use of THF or toluene as solvent with KH as metalation reagent as well as the reaction in benzene at 5 °C with *n*BuLi leads only to the "usual" side-products $[(N_3N)W{\equiv}CCH_3]$ and Sb_7^{3-}.

[16] Crystal-structure analyses of **6** and **7** were performed on a STOE IPDS diffractometer with $Ag_{K\alpha}$ radiation ($\lambda = 0.56087$ Å). The structures were solved by direct methods with the program SHELXS-97,[31a] and full-matrix least-squares refinement on F^2 in SHELXL-97[31b] was performed with anisotropic displacements for non-Hydrogen atoms. Hydrogen atoms were located in idealized positions and refined isotropically according to the riding model **6**: $C_{15}H_{39}N_4SbSi_3W$, $M_r = 665.37$, Crystal size $0.20 \times 0.15 \times 0.04$ mm^3, cubic space group $Pa\bar{3}$ (no. 205); $a = 17.297(2)$ Å, $T = 203(2)$ K, $Z = 8$, $V = 5174.8(10)$ Å^3, $\rho_{calcd} = 1.708$ Mg m^{-3}, $\mu(Ag_{K\alpha}) = 3.022$ mm^{-1}, 1640 unique reflections ($2\theta_{max} = 40°$), 79 parameters, $R_1 = 0.0527$, $wR_2 = 0.1565$. **7**: $C_{19}H_{48}N_4SbSi_4W$, $M_r = 628.82$, crystal size $0.50 \times 0.40 \times 0.20$ mm^3, monoclinic space group $P2_1$ (no. 4); $a = 10.266(2)$, $b = 11.711(2)$, $c = 12.290(3)$ Å, $\beta = 91.62°$, $T = 203(2)$ K, $Z = 2$, $V = 1477.0(5)$ Å^3, $\rho_{calcd} = 1.414$ Mg m^{-3}, $\mu(Ag_{K\alpha}) = 2.199$ mm^{-1}, 6620 unique reflections ($2\theta_{max} = 45°$), 267 parameters, $R_1 = 0.0217$, $wR_2 = 0.0554$, flack parameter −0.019(9). Total Synthesis of Halipeptins A and D and Analogues**

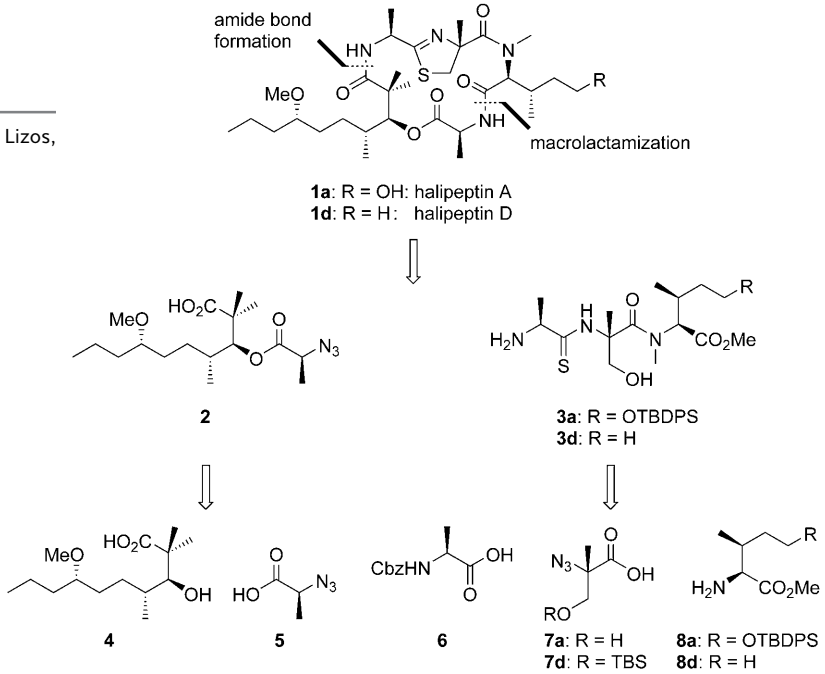
K. C. Nicolaou, David W. Kim, Daniel Schlawe, Dimitrios E. Lizos, Rita G. de Noronha, and Deborah A. Longbottom*

The halipeptins are a group of natural products whose structural identity and biological properties are still shrouded in mystery. In 2001 Gomez-Paloma et al. reported the isolation of halipeptins A and B from the marine sponge *Haliclona* sp. and showed that halipeptin A exhibits impressive antiinflammatory properties that exceed those of well-established drugs.[1] Their later isolation of halipeptin C prompted them to revise their structural assignment to that of thiazoline containing macrocycles as shown for halipeptins A–C (**1a–c**) in Scheme 1 leaving open the absolute configuration at the marked positions.[2] The isolation of a fourth member of this family of marine natural products, halipeptin D (**1d**, Scheme 1), by the group of Faulkner soon after,[3] did not reveal further stereochemical details but raised our interest in this class of natural products once halipeptin D (**1d**) was reported to exhibit strong inhibitory activity in vitro against different human cancer-cell lines.[4]



1a: R^1 = Me, R^2 = CH_2OH: halipeptin A
1b: R^1 = H, R^2 = CH_2OH: halipeptin B
1c: R^1 = H, R^2 = H : halipeptin C
1d: R^1 = Me, R^2 = Me : halipeptin D

Scheme 1. Structures of halipeptins A–D (**1a–d**). Positions of uncertain stereochemical assignment are marked *.

Determining their structural identity beyond any doubt[5] and rendering them available for further biological investigations were two reasons we undertook their total synthesis. There was a third motivation: their intriguing molecular architectures and the (subtle) challenge they posed for chemical synthesis. Indeed, these depsipeptides include in their molecular frameworks a novel, highly substituted peptide backbone connected to a hydroxylated carbon chain wrapped into a 16-membered macrolide ring. The entire C_{31} structure contains eight stereocenters (three of which are, in principle, epimerizable) and 11 methyl groups. The highly congested and conformationally rigid macrocyclic ring contains within its thread a Me-substituted thiazoline ring adjacent to an *N*-methyl-substituted amide, an arrangement that forces this linkage into a cisoid geometry, unlike the other two amide bonds that reside in their usual transoid forms. This highly substituted cisoid bond, postulated to persist even in open chain intermediates, is rare and was expected to present an unprecedented and adventurous challenge in the total synthesis of these molecules.

Our retrosynthetic analysis of halipeptins A (**1a**) and D (**1d**) (Scheme 2) relied on a retrolactamization to open the macrocycle and a subsequent retro amide-bond formation to dissect the generated chain into two key fragments, thioamides **3a** and **3d** as direct precursors for thiazoline formation, and alanine ester **2** within which are embedded both a 3-hydroxydecanoic acid domain and a masked L-alanine residue. This approach allows a late-stage construction of the thiazoline moiety, thus avoiding likely epimerization at its α position.[6] Further disconnection of these frag-

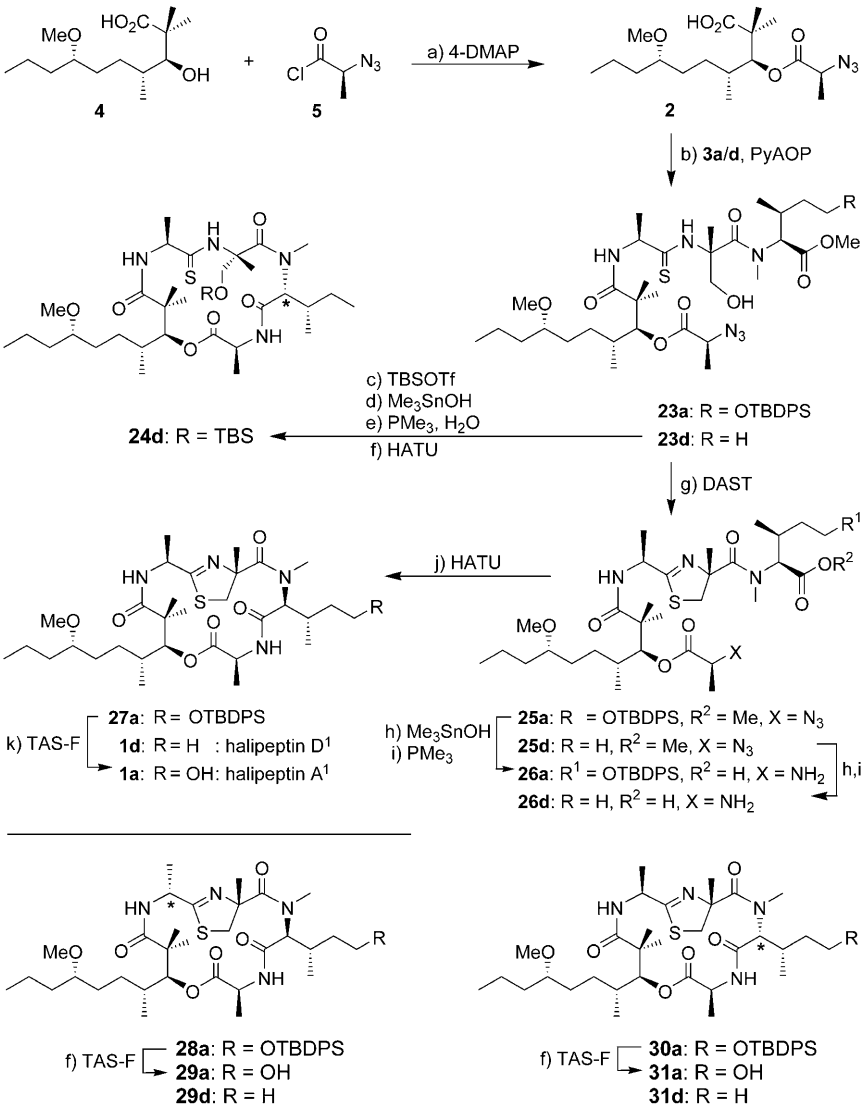
DET = diethyl tartrate; DMF = *N*,*N*-dimethylformamide; M.S. = molecular sieves; TBDPS = *tert*-butyldiphenylsilyl; Tf = trifluoromethanesulfonyl.

ments led to the identification of building blocks **4**–**7** and **8a** for halipeptin A (**1a**), and **4**–**7** and **8d** for halipeptin D (**1d**), as shown in Scheme 2.

After having established[3] a stereochemically flexible route to hydroxydecanoic acid **4**,[5,7] our first objective towards the synthesis of halipeptin A (**1a**) was the construction of suitably protected δ-hydroxyisoleucine derivative[8] **8a** (Scheme 3). Silylation of homopropargylic alcohol **9** and trapping of the corresponding acetylide with formaldehyde gave propargylic alcohol **10** in 71% overall yield. Partial hydrogenation[9] of **10** with Lindlar catalyst gave the corresponding *Z* allylic alcohol (98% yield), which was subjected to Sharpless asymmetric epoxidation conditions to yield epoxy alcohol **11** in almost quantitative yield (99%). Compound **11** was then oxidized to the corresponding epoxy acid (80% yield), which was subsequently treated with $AlMe_3$[9] at ambient temperature to afford, upon methylation with MeI, hydroxyester **12** as a single isomer in 72% overall yield for the two steps. Treatment of **12** with triflic anhydride, followed by exposure of the resulting triflate to sodium azide furnished, with inversion of configuration, the orthogonally protected isoleucine derivative **13** in 75% overall yield. δ-Hydroxyisoleucine methyl ester **8a** was then obtained from **13** in quantitative yield by reduction of the azide group.

Initial attempts to obtain alanine–α-methylserine–*N*-methylisoleucine tripeptides as **3** (Scheme 2) by sequential peptide coupling failed as a result of cyclization of the dipeptide precursors upon activation (e.g. diketopiperazine formation upon reduction of azide **17d**). Instead, we devised a strategy to attach the N-terminal alanine unit that did not involve a free amino group as shown in Scheme 4. The *O*-silylated dipeptides **16a** and **16d** were obtained from α-methyl serine derivative **14**,[10] after suitable protection/deprotection steps and coupling to isoleucines **8a** and **8d**,



Scheme 4. Synthesis of thioamides **3a** and **3d**. a) TBSOTf (2.0 equiv), 2,6-lutidine (4.0 equiv), CH_2Cl_2, 0 °C, 1.5 h, 98%; b) LiOH·H_2O (3.0 equiv), MeOH/H_2O (4:1), 0→25 °C, 2 h, 100%; c) **8a** (1.0 equiv), EDC (1.2 equiv), HOAt (1.2 equiv), *i*Pr_2NEt (3.0 equiv), CH_2Cl_2, 25 °C, 17 h, 55% (**15a**); **8d** (2.0 equiv), EDC (2.0 equiv), HOAt (2.0 equiv), *i*Pr_2NEt (3.0 equiv), CH_2Cl_2, 25 °C, 17 h, 91% (**16d**); d) TESOTf (1.3 equiv), 2,6-lutidine (2.0 equiv), CH_2Cl_2, 0 °C, 20 min, 85%; e) NaH (4.0 equiv), MeOTf (2.5 equiv), THF, 0 °C, 1 h, 83% (**17a**); NaH (3.0 equiv), MeI (4.0 equiv), DMF, 0 °C, 1 h, 96% (**17d**); f) aqueous HCl (1 N; 20 equiv), THF, 25 °C, 1 h, 100%; g) TBAF (3.0 equiv), THF, 25 °C, 2 h, 98%; h) CDI (4.0 equiv), Cbz-Ala-OH (4.0 equiv), CH_2Cl_2, 25 °C, 0.5 h; then **18a** or **18d**, 18 h, **19a**: 88%, **19d**: 96%; i) PMe_3 (1.0 M in THF; 1.8 equiv), toluene, 25 °C, 2 h, **20a**: 79%, **20d**: 83%; j) H_2 (1 atm), 20% Pd(OH)$_2$/C (30% by weight), EtOH, 25 °C, 1 h, 100%; k) H_2S (excess), MeOH/Et_3N (2:1), 25 °C, 48–72 h, complete conversion, product not isolated. Cbz = benzyloxycarbonyl; CDI = carbonyldiimidazole; EDC = 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride; HOAt = 1-hydroxy-7-azabenzotriazole; TBAF = tetra-*n*-butylammonium fluoride; TBS = *tert*-butyldimethylsilyl; TES = triethylsilyl.

respectively. Deprotonation of the amide with NaH allowed selective methylation with MeOTf (→**17a**) or MeI (→**17d**), and selective desilylation with HCl or TBAF furnished the desired azide fragment **18a** (HCl) or **18d** (TBAF), respectively, which were converted into their alanine ester counterparts, **19a** (88% yield) and **19d** (96% yield), by CDI-mediated couplings with Cbz-Ala-OH in preparation for the impending tripeptide construction. It was postulated[11] that reaction of the azide group of **19a** and **19d** with a suitable phosphine reagent would generate the corresponding azaylide (**22a** and **22d**, respectively) which, upon intramolecular collapse onto the closest ester grouping, could furnish the desired oxazolines **20a** and **20d**, respectively. Indeed, this much-anticipated cascade proceeded smoothly upon exposure of **19a** and **19d** to PMe_3 in benzene or toluene at ambient temperature to furnish oxazolines **20a** (79% yield) and **20d** (83% yield) accompanied by only small amounts of the undesired six-membered rings (that is, dihydropyrazinones **21a** (17%) and **21d** (16%)). The chromatographically purified **20a** and **20d** were then converted into thioamides **3a** and **3d**, respectively, by hydrogenolytic cleavage of their Cbz group (100% yield) followed by thiolysis of the oxazoline rings with H_2S–Et_3N.[12] After evaporation of the solvents, the products **3a** and **3d** were used directly in the next step without further purification.

In our first attempt to synthesize halipeptin D (**1d**) from thioamide **5d** we improvised for a last-stage construction of the thiazoline moiety due to fears of epimerization[6] of the adjacent stereocenter (Scheme 5). The sterically congested ester **2** was prepared in 94% yield from hydroxydecanoic acid **4** and excess acid chloride **5** (10 equiv, prepared in situ from the corresponding carboxylic acid[13] and oxalyl choride in DMF) in the presence of Et_3N and 4-DMAP at 50°C. It is noteworthy that no epimerization at the azide-bearing center was observed in this step despite the basic conditions employed, as confirmed by the synthesis and characterization of the alanine epimer of **2** from **4** and *ent*-**5**. Coupling of carboxylic acid **2** with amino fragments **3a** and **3d** was best achieved by PyAOP activation in the presence of iPr$_2$NEt (92% yield). Protection of **23d** as a TBS ether (99%), selective hydrolysis of the methyl ester with Me_3SnOH[14] (52%), followed by Staudinger reduction of the azide group within the resulting carboxylic acid, and direct macrolactamization (HATU, HOAt, iPr$_2$NEt) yielded macrocycle **24d** as the only product (38%) with complete epimerization of the C-terminal isoleucine unit.

Scheme 5. Completion of the total synthesis of halipeptins A (**1a**) and D (**1d**) and their epimers **29a**, **29d**, **31a**, and **31d**. a) **5** (10.0 equiv), 4-DMAP (0.5 equiv), Et_3N (12 equiv), DMF, 50°C, 2 h, 94%; b) **3a** (1.0 equiv), PyAOP (1.5 equiv), iPr$_2$NEt (2.0 equiv), DMF, 25°C, 17 h, 71% (**23a**); **3d** (2.0 equiv), PyAOP (2.5 equiv), iPr$_2$NEt (2.5 equiv), DMF, 25°C, 17 h, 92% (**23d**); c) TBSOTf (1.2 equiv), 2,6-lutidine (1.5 equiv), CH_2Cl_2, 0°C, 0.5 h, 99%; d) Me_3SnOH (20 equiv), CH_2ClCH_2Cl, 80°C, 48 h, 52% at 79% conversion; e) PMe_3 (3.0 equiv), THF/H_2O (9:1), 25°C, 48 h; f) HATU (2.0 equiv), HOAt (2.0 equiv), iPr$_2$NEt (2.0 equiv), CH_2Cl_2 (0.5 mM), 25°C, 18 h, 38% (two steps); g) DAST (1.5 equiv), CH_2Cl_2, −78→−20°C, 1 h, **25a**: 85%; **25d**: 84%; h) Me_3SnOH (20 equiv), CH_2ClCH_2Cl, 90°C, 48–72 h, 82% from **25a**; 85% from **25d**; i) PMe_3 (2.5 equiv), THF/H_2O (9:1), 25°C, 2 h; j) HATU (2.0 equiv), HOAt (2.0 equiv), K_2CO_3 (10.0 equiv), CH_2Cl_2 (0.5 mM), 25°C, 24 h, **27a**: 31%, **28a**: 10%, **30a**: 14%; **1d**: 25%, **29d**: 5%, **31d**: 18%; k) TAS-F (5.0 equiv), DMF, 25°C, 24 h, **1a**: 85%; **29a**: 81%; **31a**: 85%. DAST = (diethylamino)sulfur trifluoride; 4-DMAP = 4-(dimethylamino)pyridine; HATU = *O*-(7-azabenzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate; PyAOP = (7-azabenzotriazol-1-yloxy)tripyrrolidinophosphonium hexafluorophosphate; TAS-F = tris(dimethylamino)-sulfur (trimethylsilyl)difluoride.

This problem was overcome by a detour, which adopted thiazoline formation prior to macrocyclization as shown in Scheme 5. Thus, exposure of thioamide intermediates **23a** and **23d** to DAST[15] in CH_2Cl_2 at −78°C led to thiazolines **25a** (85% yield) and **25d** (84% yield). Selective hydrolysis of the methyl esters of **25a** (82% yield) and **25d** (85% yield) was achieved by the mild action of Me_3SnOH,[14] delivering, upon Staudinger reduction with PMe_3/H_2O, amino acids **26a** and

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

26d, respectively. The latter were utilized without isolation in the macrocyclization experiments.

Initial attempts to cyclize **26d** to halipeptin D (**1d**) under the influence of HATU in the presence of HOAt and *i*Pr_2NEt resulted in the predominant formation of, again, the isoleucine epimer **31d** (epimeric at the indicated (*) site, 17% yield from the corresponding azido carboxylic acid) which, however, this time was accompanied by the natural product, halipeptin D (**1d**, 13% from the corresponding azido carboxylic acid) and traces of **29d**, epimeric at the indicated (*) site adjacent to the thiazoline moiety. Changing the base to K_2CO_3 in the macrolactamization step increased both the yield and selectivity for the natural product (**1d**: 25% yield; **29d**: 5% yield; **31d**: 18% yield; Table 1). Owing to the profound differences in their R_f values, all isomers could be separated easily by preparative TLC (silica gel) by using hexane/EtOAc or CH_2Cl_2/acetone mixtures.

Under the HATU/HOAt/K_2CO_3 conditions for the macrolactamization step, amino acid **26a** was converted into halipeptin A TBDPS derivatives **27a** (31%; yield) and its epimers **28a** (10% yield) and **30a** (14% yield; Scheme 5). Exposure of these compounds to TAS-F liberated halipeptin A (**1a**, 86% yield) and its epimers **29a** (81% yield; Table 1) and **31a** (85% yield). Synthetic halipeptins A (**1a**) and D (**1d**) exhibited identical physical properties to those reported (**1a**,[1] **1d**[3]) for the natural products. Intriguingly, however, and despite previous reports regarding naturally derived halipeptin D,[4] synthetic halipeptin D (**1d**) and its synthesized epimers exhibited only weak toxicity against tumor cells (HCT-116 human colon carcinoma, IC_{50} values, **1d**: 32.5 μM; **29d**: 105.4 μM; **31d**: 111.4 μM).[16] Since natural halipeptin D (**1d**) was isolated from a marine species that contained several potent cytotoxic agents,[3] we attribute this discrepancy to contamination of the naturally derived material by one or more such contaminants.

The chemistry described herein confirmed the structures of halipeptins A (**1a**) and D (**1d**), highlighted their interesting chemical properties, and rendered them and their analogues readily available for further biological investigations.

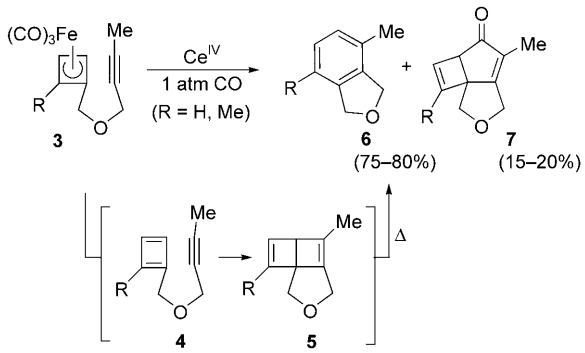
Intramolecular [2+2+1] Cycloadditions with (Cyclobutadiene)tricarbonyliron**

*Benjamin A. Seigal, Mi Hyun An, and Marc L. Snapper**

Oxidative decomplexation of (cyclobutadiene)tricarbonyliron (**1**) is a convenient method for the generation of free cyclobutadiene (**2**).[1] Once released from the metal, this reactive, antiaromatic species can undergo rapid dimerization [Eq. (1)]. When cyclobutadiene is generated in the presence of olefins or dienes, intermolecular cycloadditions can occur which lead to various cyclobutene-containing adducts [Eqs. (2) and (3)].



(1)

(2)

(3)

In 1974, Grubbs et al. studied intramolecular cycloadditions between cyclobutadiene and tethered alkynes [e.g., Eq. (4)].[2] The major product isolated from this reaction was compound **6**, which presumably was generated through rearrangement of the Dewar benzene cycloadduct **5**. In

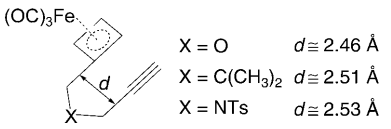
addition, a minor amount of ketone **7** was also obtained.[3] Elegant studies with chiral, nonracemic iron complexes (such as **3**, R = Me) suggested that **5** was formed through a [4+2] cycloaddition of a metal-free intermediate **4**, whereas the generation of cycloadduct **7** appeared to involve a more participative role for the ironcarbonyl component.

Given the synthetic utility of intramolecular cycloadditions of cyclobutadiene,[4] coupled with the established usefulness of the fused-ring system found in **7**,[5] we sought to develop this intramolecular cyclobutadiene [2+2+1] cycloaddition (the Pauson–Khand reaction) into an effective methodology.[6] Specifically, our goals were to improve the efficiency of the [2+2+1] cycloaddition and expand the substrate scope of the reaction.[7] Our preliminary steps towards these objectives are reported herein.

Our first aim was to improve the yield of the carbonylative cycloaddition process. We reasoned that a slower rate of oxidation of the iron complex in the presence of carbon monoxide would favor the iron-mediated Pauson–Khand reaction over the oxidative release of free cyclobutadiene required in the Diels–Alder reaction. Our initial efforts focused on the cycloaddition of alkyne **8** [Eq. (5)]. After

8 **9** **10** (5)



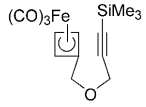
optimization of the reaction conditions (solvent, oxidant, reaction temperature, rate of addition of oxidant, CO pressure, and additives), we were able to improve the yield of adduct **10** obtained from the Pauson–Khand reaction from 15 to 60%, while minimizing the formation of the Diels–Alder product **9**. Further optimization of the workup, combined with the use of purified ammonium cerium(IV) nitrate (CAN),[8] increased the efficiency of the [2+2+1] cycloaddition to provide ketone **10** in 77% yield.[9]

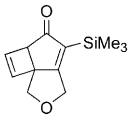
The investigation of additional substrates is summarized in Table 1. Under the optimized Pauson–Khand conditions, the original Grubbs alkyne **11** afforded the [2+2+1] cycloadduct **12** in 91% yield (entry 2). Likewise, the sterically hindered *t*Bu alkyne **13** underwent [2+2+1] cyclization to provide **14** in 78% yield (entry 3). On the other hand, the cycloaddition of electron-deficient alkynes, such as **15**, did not undergo the desired [2+2+1] cycloaddition, but instead only generated the [4+2] cycloadduct **16** (entry 4).

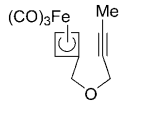
On the basis of the emerging trend of electron-rich alkynes performing efficiently in this cycloaddition, we expected aryl alkynes to act similarly. In this regard, the oxidation of a *p*-methoxyphenyl alkyne **17** generated the desired [2+2+1] cycloadduct **18** in 71% yield as well as the [4+2] cycloadduct **19** in 20% yield (entry 5). Similar results were seen with a phenyl alkyne substrate **20**, which provided the [2+2+1] cycloadduct **21** in 69% yield, along with **22** in 24% yield (entry 6). Furthermore, it was demonstrated that terminal alkynes, such as **23**, will also take part in the Pauson–Khand reaction, as cycloadduct **24** was obtained in 60% yield (entry 7).

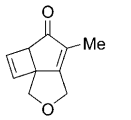
We next examined the influence of the tether functionality on the course of the cycloaddition. We replaced the oxygen atom in the tether with a *gem*-dimethyl group, thereby taking advantage of the reactive rotamer effect in the cycloaddition.[10] Oxidative carbonylation of the propargyl methyl ether **25** led to the desired [2+2+1] cycloadduct in 55% yield as a mixture of hydroxy diastereomers ($\beta/\alpha = 1.8{:}1$), with only a trace amount of the [4+2] cycloadduct (entry 8). In contrast, a phenyl alkyne **27** delivered a Pauson–Khand product **28** that favored the opposite diastereoselectivity ($\beta/\alpha = 1{:}3$) in 57% yield of combined product, as well as the Diels–Alder product **29** in 30% yield (entry 9). When the hydroxy group of **25** was protected as a MOM ether to generate **30**, oxidation resulted in the formation of the [2+2+1] cycloadduct **31** as a single diastereomer in 62% yield (entry 10). The sensitive role of the tether functionality in these cycloadditions was further demonstrated in entry 11 (compare with entries 6 and 9): oxidation of the *p*-toluenesulfonate-protected amine **33** favored the formation of the [4+2] cycloadduct **35** over the [2+2+1] cycloadduct **34**.

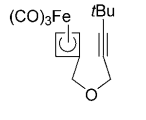
Previous studies have indicated that the intramolecular [4+2] cycloaddition of cyclobutadiene is sensitive to distortions imparted by the tether functionality on the transition-state geometries.[4c,d] The Pauson–Khand cycloadditions presented above also appear to be influenced by the geometry of the tether group. Although the transition state in the iron-mediated Pauson–Khand reaction is unclear at this time the span, or "bite size", of the tether group does correlate with the ratio of [2+2+1]/[4+2] cycloadducts obtained. The identity of the atoms used to connect the cyclobutadiene and the alkyne units can provide different idealized ground-state geometries (Scheme 1). Thus, the energetic cost of the distortion in each of these systems in their respective cycloaddition transition states may be different.

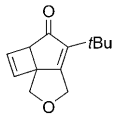


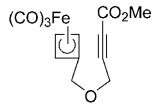


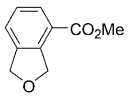


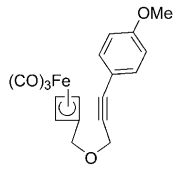


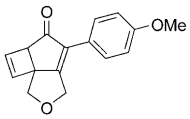


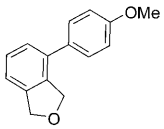


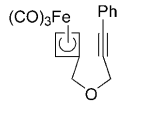


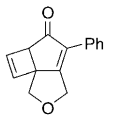


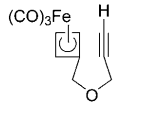


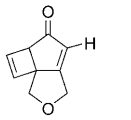


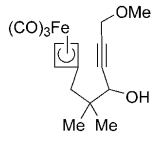


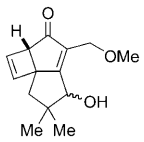


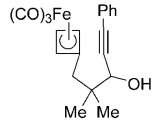


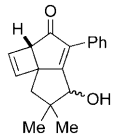


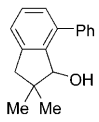


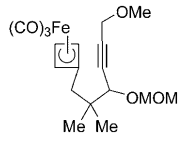


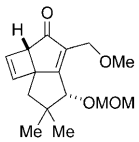


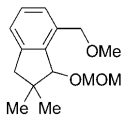


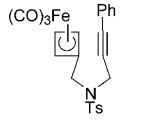


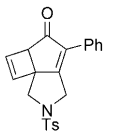


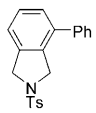












Scheme 1. Composition and geometry of the tether.

The results of the cyclization reactions for phenyl alkynes **20**, **27**, and **33** showed that an increase in the distance between the alkyne and the cyclobutadiene units disfavors the Pauson–Khand process relative to the Diels–Alder reaction. The cycloaddition of **20** (X = O), in which the ether tether allows a closer relationship between the reactive functionalities, provided the highest ratio of [2+2+1]/[4+2] cycloadducts (**21**/**22** = 2.9:1, entry 6). On the other hand, the *p*-toluenesulfonate amide linker in **33** (X = NTs) increases the distance between the alkyne and cycloabutadiene units, thus leading to an unfavorable ratio of [2+2+1]/[4+2] cycloadducts (**34**/**35** = 0.5:1, entry 11). Substrate **27**, with a *gem*-dimethyl linker (X = $C(CH_3)_2$), has a bite size between that of **20** and **33** and,

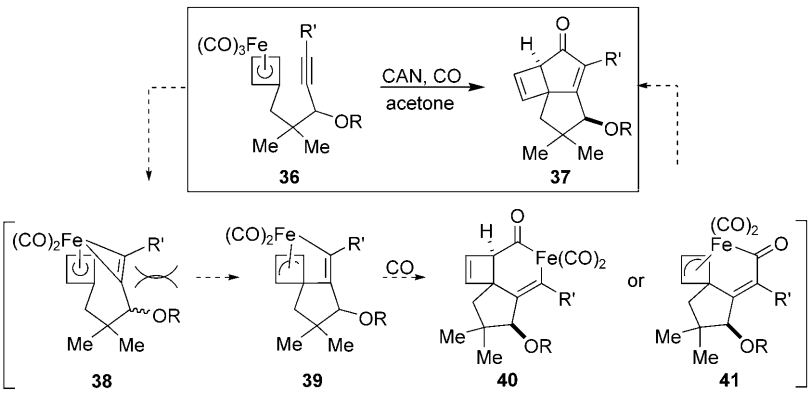
Table 1: Intramolecular [2+2+1] cycloadditions.[a]

Entry	Alkyne	[2+2+1] Cycloadduct	Yield [%][a]	[4+2] Cycloadduct	Yield [%][a]
1			77	–	–
2			91	–	–
3			78	–	–
4		–	–		67
5			71		20
6			69		24
7			60	–	–
8			55[b]	–	–
9			57[c]		30
10			62		21
11			29		63

[a] An average of the two highest yields of isolated product. [b] $\beta/\alpha = 1.8{:}1$. [c] $\beta/\alpha = 1{:}3$. MOM = methoxymethyl. Ts = *p*-toluenesulfonate.

accordingly, provided an intermediate ratio of products (**28**/**29** = 1.9:1, entry 9).



In addition to the influence of the tether geometry, there are also diastereoselectivity questions regarding the cycloaddition reactions of the hydroxy-substituted *gem*-dimethyl substrates **25**, **27**, and **30**. The mechanism of the [2+2+1] cycloaddition needs to be considered to gain insight into these trends (Scheme 2).[3] Conversion of alkyne **36** into the Pauson–Khand product **37** is likely to involve several steps. Depending on the reversibility of the steps, the diastereomeric control observed could result from favorable hydrogen-bonding interactions (entry 8) or unfavorable allylic strain (entries 9 and 10) in intermediates such as **38**. The importance of this latter interaction was particularly evident in the cyclization of the MOM-protected substrate **30**, where only diastereomer **31** was observed (entry 10).

In summary, we have developed a cyclobutadiene [2+2+1] cycloaddition that allows the efficient preparation of highly functionalized cyclobutene-containing systems in synthetically useful yields. In this process, the tricarbonyliron functionality, which usually serves to protect the cyclobutadiene against unwanted side reactions, also mediates a [2+2+1] cycloaddition with various alkynyl side chains. Both electronic and steric factors were found to influence the course of the reaction. Further studies will focus on expanding the scope of the cyclobutadiene [2+2+1] cycloaddition, as well as evaluating the transformation in the syntheses of targets of interest.

[9] Representative cycloaddition procedure: Carbon monoxide was bubbled through a solution of (cyclobutadiene)tricarbonyliron in acetone for 20 min, and then the solution was stirred in an atmosphere of carbon monoxide at room temperature for the remainder of the reaction. A solution of CAN (5 equiv) in acetone was added over 3.0 h by syringe pump to the reaction mixture. At the conclusion of the slow addition, the reaction mixture was quenched with saturated aqueous $NaHCO_3$ and then concentrated under vacuum (to remove the acetone). The aqueous solution was extracted with CH_2Cl_2, the combined organic layers were washed with brine, dried over $MgSO_4$, and the organic solvent was removed under vacuum. The cycloaddition product was then purified by chromatography on silica gel.

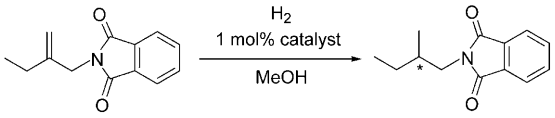
Enantioselective Hydrogenation of Allylphthalimides: An Efficient Method for the Synthesis of β-Methyl Chiral Amines**

*Chun-Jiang Wang, Xianfeng Sun, and Xumu Zhang**



Chiral amines bearing a β-methyl group on the chiral center, and their derivatives, are key structural elements in natural products and pharmaceuticals.[1–3] For example, compound **A** is a key intermediate in the synthesis of the leukotrienes (LTs) receptor antagonist (Zeneca ZD 3532, a phase II drug candidate; Scheme 1). This compound is particularly useful for the treatment of asthma.[2] Compound **B** (NPS 1392) is a potent stereoselective antagonist of the NMDA receptor, which can be used for the control of ischemic strokes.[3] To our knowledge, there has been no successful catalytic method to make such important functional groups. Although some stoichiometric asymmetric synthesis or resolution routes have been reported for constructing this class of chiral amines,[2–4] the development of efficient and catalytic synthetic methods remains a significant challenge. Herein we report the first highly enantioselective catalytic asymmetric hydrogenation of disubstituted allylphthalimides[5] to form chiral phthalimides, which act as precursors to the β-methyl chiral amines [Eq. (1)].

(1)

We initiated our studies on the asymmetric hydrogenation of an *N*-2-ethylallylphthalimide (**6a**) by screening several known catalysts. Since the asymmetric hydrogenation of functionalized olefins using chiral phosphine/Rh complexes is well known,[6] a diverse array of bisphosphine/Rh complexes could be applied as catalyst precursors in this hydrogenation reaction. Some representative results are shown in Table 1.

Table 1: Asymmetric hydrogenation of **6a**.

Scheme 1. Examples of β-methyl chiral amine hydrochlorides and Zeneca ZD 3525.

Although the complexes [Rh(cod){(1*S*,1*S*′,2*R*,2*R*′)-tangphos}]BF_4 (**1**)[7] (cod = cycloocta-1,5-diene, tangphos = 1,1′-di-*tert*-butyl-[2,2′]-diphosphanyl) and [Rh(cod){(*R*,*R*)-Et-duphos}]BF_4 (**2**)[8] (duphos = 1,2-bis(phospholanyl)benzene) were successful for the highly enantioselective hydrogenation of various substituted olefins, only low enantioselectivities were obtained at room temperature under low hydrogen pressure (Table 1, entries 1 and 2). However, Ru–diphosphine complexes have also been applied to asymmetric hydrogenation reactions. Catalyst **3c**[9] exhibited no reactivity under similar conditions (Table 1, entry 3). However, up to 96% *ee* and 100% conversion was observed when high hydrogen pressure (100 atm) and high temperature (80°C) were employed (Table 1, entry 4)

Encouraged by the results described above, we investigated the effects of solvents and catalyst precursors to enable the reaction conditions to be optimized (Table 2). A dramatic solvent effect was observed. Complex **3c** performs well in a number of alcohols to give **7a** with moderate to high enantioselectivities (Table 2, entries 1–4); an excellent level of enantioselectivity was observed when the reaction was carried out in methanol. Reaction in other solvents such as

CH_2Cl_2, EtOAc, or THF led to lower enantioselectivities and reactivities (Table 2, entries 5–7). To test the effect of the dihedral angle of the chiral biaryl ligands on the enantioselectivity of the reaction, a set of tunephos[9] ligands with different dihedral angles were employed (Table 2, entries 1 and 8–12). The best result was observed when (*S*)-C_3-tunephos was used as the ligand (Table 1, entry 1).

The asymmetric hydrogenation reaction was carried out on a variety of substrates under the optimal reaction conditions (Table 3). Substrates with a primary *n*-alkyl substituent such as ethyl, *n*-butyl, or benzyl group at the 2-position of the allylphthalimides afforded products with high *ee* values (Table 3, entries 1–3). Several substrates with bulky substituents were also employed to probe the steric effects of the substituent on this hydrogenation system. The enantioselectivities decreased gradually along with increased steric hindrance of the substituents in the substrates (Table 3, entries 2 and 4–6). However, hydrogenation of cyclohexyl- and cyclopentyl-substituted substrates (**6g** and **6h**) still afforded products in 98 and 96% *ee*, respectively (Table 3, entries 7 and 8). The hydrogenation of the aromatic substrate **6i** proceeded smoothly with moderate enantioselectivity (Table 3, entry 9). To our surprise, 2-chloroallylphthalimide (**6j**) can also be hydrogenated and **7j** was obtained with up to 93% *ee* (Table 3, entry 10).

Table 3: Asymmetric hydrogenantion of *N*-2-substituted allylphthalimides.

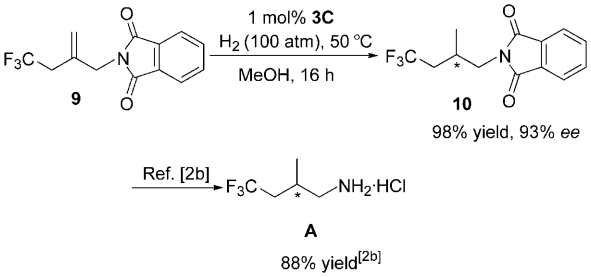
[a] Yield of isolated product. [b] The reaction was performed at 50 °C in 16 h. [c] Determined by chiral-phase GC. [d] Determined by chiral-phase HPLC.



To determine the configuration of the hydrogenation product **7a** obtained with (*S*)-C_3-tunephos as a chiral ligand, phthalimide **7a** was hydrolyzed in refluxing ethanol in the presence of $NH_2NH_2{\cdot}H_2O$ followed by treatment with concentrated HCl according to a literature procedure to form the known compound **8** in 65% yield [Eq. (2)].[2b,10] The absolute

7a **8** 65% yield (2)

stereochemistry of **7a** was assigned as *S* by comparing the sign of the optical rotation of the obtained compound **8** with the reported data[4] (see the Supporting Information).

This asymmetric hydrogenation method can be applied to the preparation of the key intermediate **A** for the synthesis of the LTs receptor antagonist (Zeneca ZD3532;[2] Scheme 1). To the best of our knowledge, asymmetric hydrogenation provides the simplest method for the synthesis of this compound [Eq. (3)].

9 **10** **A** 88% yield[2b] (3)

In conclusion, we have developed the first highly enantioselective method for the synthesis of chiral phthalimides with a β-methyl group on the chiral center based on asymmetric hydrogenation, and up to 98% *ee* has been achieved with a Ru–C_3-tunephos catalyst. The synthetic utility has been demonstrated through the synthesis of the key intermediate **A** of the LTs receptor antagonist (Zeneca ZD3532). Since these hydrogenation substrates are easily obtainable, this methodology is potentially practical for the synthesis of such chiral amines, which are important pharmaceutical intermediates.

Experimental Section

General hydrogenation procedure: $[RuCl_2(cymene)]_2$ (6.2 mg, 0.01 mmol) and (*S*)-C_3-tunephos (12.5 mg, 0.021 mmol) were dissolved in degassed DMF (3 mL) in a Schlenk tube under N_2. The solution was heated at 100 °C for 3.5 h. After the mixture had cooled to 50 °C, the solvent was removed under vacuum to give the catalyst as an orange-red solid. The catalyst was dissolved in degassed methanol (16 mL) in a glovebox and divided equally between eight vials. Substrate (0.25 mmol) was then added to the catalyst solution and the resulting mixture transferred to an autoclave and charged with H_2 (100 atm). The autoclave was stirred at 50 or 80 °C for 16–48 h, before cooling it to room temperature and carefully releasing the H_2. The solvent was then evaporated and the residue was purified by column chromatography to give the corresponding hydrogenation product, which was then analyzed directly by chiral-phase GC (gamma dex 225) or HPLC (Chiralpak AD) to determine the enantiomeric excess.

Asymmetric Catalysis

DOI: 10.1002/anie.200501318

Construction of Pseudo-Heterochiral and Homochiral Di-μ-oxotitanium(Schiff base) Dimers and Enantioselective Epoxidation Using Aqueous Hydrogen Peroxide

*Kazuhiro Matsumoto, Yuji Sawada, Bunnai Saito, Ken Sakai, and Tsutomu Katsuki**

Remarkable advances in asymmetric synthesis using optically active metal complexes as catalysts have been achieved in the last half century.[1] Monometallic complexes are used as the catalysts in most of the asymmetric reactions developed so far. Particularly in the last two decades, it has been revealed that chiral metallosalen complexes result in diverse and excellent asymmetric catalysis.[2] Chiral salen ligands can be synthesized in a single step from chiral diamine and chiral and/or appropriately substituted salicylaldehydes and form complexes with a variety of metal ions. Moreover, metallosalen complexes are conformationally flexible as a result of the presence of two methylene carbon atoms and they can adopt three different configurations (*trans*, *cis*-α, and *cis*-β). Metallosalen complexes usually adopt *trans* configurations, but they can be readily transformed in the presence of a bidentate ligand into the corresponding *cis*-β complexes.[2,3] Thus, various chiral metallosalen complexes have been synthesized and used as catalysts for a wide range of asymmetric reactions. Most of the metallosalen complexes used are monomeric, but for some reactions, depending on their mechanisms, dimeric or oligomeric metallosalen complexes have proven to be superior catalysts to the corresponding monomeric ones.[4] Nevertheless, the use of such dimeric or oligomeric metallosalen complexes as catalysts has been limited mainly because their synthesis involves laborious routes, except for metallosalen complexes prepared by self-assembly. Thus, di-μ-oxotitanium(salen) complexes that can be prepared spontaneously by treatment of monomeric [Ti(salen)] complexes with water,[5] attracted our attention.[6] Furthermore, in contrast to the usual monomeric [Ti(salen)] complexes that adopt *trans* configurations, each {Ti(salen)} unit of the di-μ-oxo complexes take a *cis*-β configuration. In contrast to the *trans* isomer, the *cis*-β isomer is chiral and exists in enantiomeric forms (Δ or Λ; Figure 1). Thus, there are six possible isomers for the di-μ-oxotitanium(salen) dimer

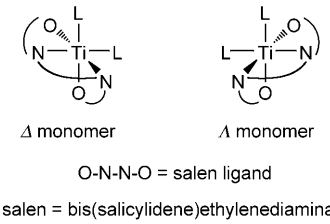

Figure 1. Enantiomeric isomers for the monomeric *cis*-β-titanium-(salen) complex.

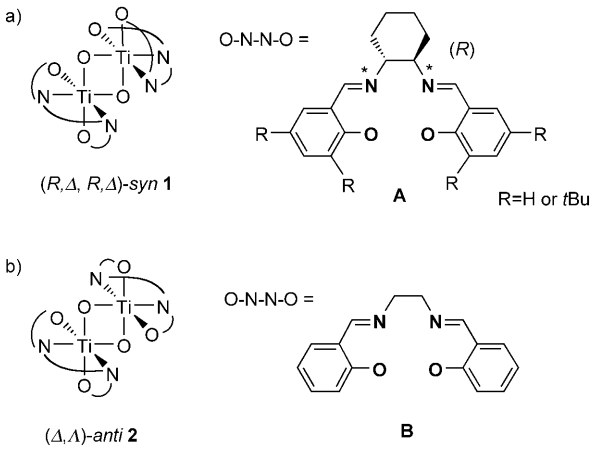
(two enantiomeric pairs and two *meso* isomers).[5b] However, Belokon', North, et al. have reported that treatment of a *trans*-[$TiCl_2$(salen)] ([$TiCl_2$**A**]) complex with water in the presence of amine spontaneously gives homochiral dimer **1** as the sole product [(*RΔ*,*RΔ*)-*syn*-**1**] (Figure 2a).[5] This result indicated that the salen ligand **A** which included an (*R*,*R*)-cyclohexanediamine moiety as a constituent part forced the {Ti(salen)} unit to adopt the *Δ* configuration.



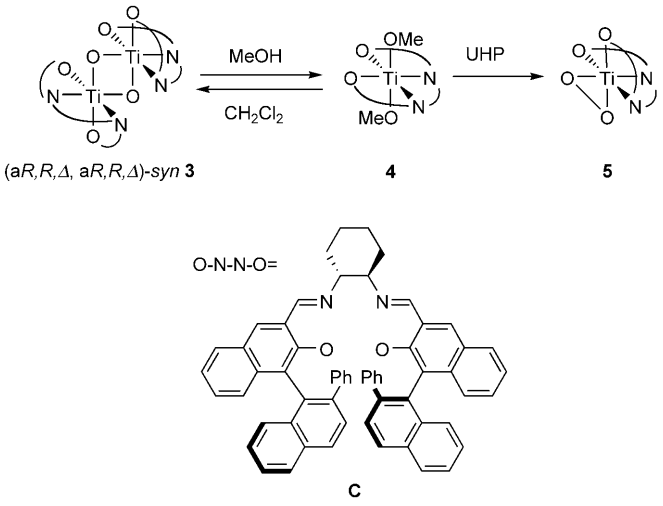


Figure 2. a) Structure of **1**. b) Structure of **2**.

In contrast to the report by Belokon', North, et al., Tsuchimoto has recently reported that di-μ-oxo dimer **2** bearing achiral ligand **B** is heterochiral: each {Ti(salen)} unit has opposite chirality (Figure 2b) and X-ray diffraction analysis has shown **2** to have a (*Δ*,*Λ*)-*anti* configuration.[7] This structure indicates that the interaction between the *Δ* and the *Λ* ligands is more favorable than the interaction between two *Δ* (or two *Λ*) ligands. This situation is reminiscent of asymmetric amplification (positive nonlinear effect) observed in asymmetric addition of diethylzinc to aldehydes using a chiral amino alcohol as the chiral auxiliary: the enantiomeric excess of the chiral auxiliary correlates nonlinearly with the enantioselectivity of the reaction, that is, carrying out the reaction even with a chiral auxiliary of low enantiomeric excess results in enantioselectivity similar to that obtained with the enantiopure auxiliary.[8] This unusual phenomenon has been rationally explained by self-recognition of the chirality of the complex upon its dimerization: the equilibrium between enantiomeric monomers, as well as homochiral and heterochiral dimers is weighted heavily towards the heterochiral dimer as a consequence of a favorable interaction between the enantiomeric monomers.

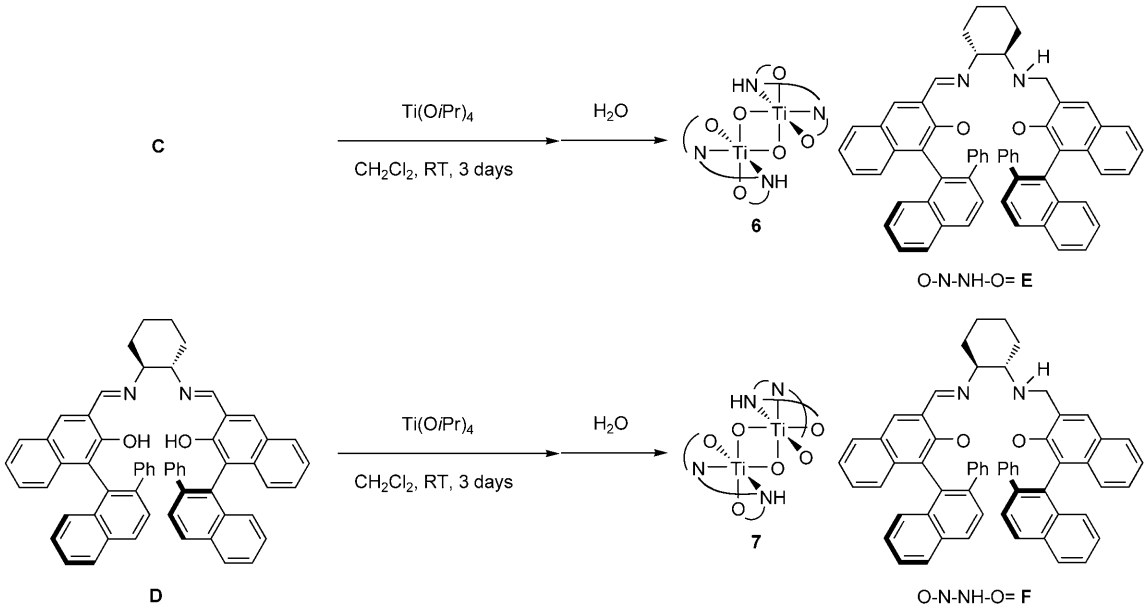
We also found that, in analogy with di-μ-oxo dimer **1**, complex **3** that was prepared from [$TiCl_2$**C**] also adopted a homochiral *aR*,*R*,*Δ*,a*R*,*R*,*Δ* configuration (Scheme 1) and it

Scheme 1. Structural change of di-μ-oxotitanium(salen) complex **3** bearing chiral salen ligand **C** as a result of the solvent or reagent.

served as an excellent catalyst for asymmetric sulfoxidation in the presence of urea·hydrogen peroxide (UHP).[9] However, complex **3** did not catalyze epoxidation. On the other hand, it was found that the asymmetric sulfoxidation with **3** showed a strong positive nonlinear effect and that di-μ-oxo-**3** and monomeric *trans*-**4** were readily interconverted by changing the solvent. This result indicated that the mixing of a*R*,*R*,*Δ* and the a*S*,*S*,*Λ* isomers made a heterochiral (a*R*,*R*,*Δ*,a*S*,*S*,*Λ*) dimer preferentially.[10] Taking into account Tuchimoto's and our own results, we expected that the pseudo-heterochiral (*aR*,*R*,*Δ*,a*R*,*R*,*Λ*)-**6**, in which each titanium ion carries the same but conformationally enantiomeric ligand, would be formed if the salen ligand became more flexible and if the a*R*,*R*,*Λ* configuration that is otherwise unstable is sufficiently stabilized by the interaction with the a*R*,*R*,*Δ* ligand. Furthermore, the unprecedented pseudo-heterochiral dimer might show unique asymmetric catalysis. Herein, we describe the construction of stable dimeric titanium/tetradentate Schiff base complexes that provide unique reaction sites as shown by in situ intramolecular Meerwein–Ponndorf–Verley (MPV) reduction in combination with self-assembly of the resulting titanium/tetradentate Schiff base complexes. We also describe their use as catalysts in the presence of hydrogen peroxide for asymmetric epoxidation.

We tried reducing one of the two imine bonds of a salen ligand to make it more flexible without losing its high asymmetry-inducing ability. Since titanium isopropoxide is known to undergo MPV reduction, we expected that the [Ti(salen)(O*i*Pr)$_2$] complex might undergo intramolecular MPV reduction of one or two of the imine bonds. Unfortunately, no reaction was observed for [Ti**A**(O*i*Pr)$_2$] (R = *t*Bu) that was prepared in situ and then left to stand. However, the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

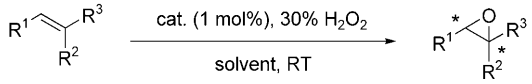


corresponding [Ti**C**(O*i*Pr)$_2$] complex prepared in situ from ligand **C** and Ti(O*i*Pr)$_4$ in dichloromethane was found to undergo the desired MPV reduction at room temperature, and the subsequent water treatment gave a new di-μ-oxo complex **6** that could be crystallized from heptane and dichloromethane (Scheme 2). X-ray diffraction analysis unambiguously demonstrated that the configuration of **6** was pseudo-heterochiral [(a*R*,*R*,*Δ*,a*R*,*R*,*Λ*)-*anti*].[11] Furthermore, the C–N bond lengths indicated that one of the two imine bonds of each salen ligand **C** was reduced to a single bond and the phenolic oxygen atom *ortho* to the reduced imine group occupied the apical position.[12] Encouraged by this result, we also synthesized the (a*RS*,a*RS*)-di-μ-oxotitanium complex **7**, bearing the corresponding half-reduced salen ligand **F**, according to the method described for the preparation of **6**. It is, however, noteworthy that complex **7** was found to adopt a homochiral configuration (a*R*,*S*,-*Δ*,a*R*,*S*,*Δ*) by X-ray diffraction analysis (Scheme 2).[11] These results suggested that the configuration of a di-μ-oxotitanium complex bearing a half-reduced salen ligand is determined by equilibrium involving ligand chirality, its structural flexibility, and weak intra- and interligand interactions such as CH–π interactions. To our delight, complexes **6** and **7** were much more stable than complex **3**: although complex **3** immediately dissociated into the corresponding monomeric {Ti(salen)} species **4** in methanol at room temperature (Scheme 1), complex **6** was stable in [D$_4$]MeOH for at least 5 h and complex **7** was stable even under aqueous epoxidation conditions for at least 24 h. On the basis of these findings, we examined epoxidation using hydrogen peroxide in the presence of complex **6** or **7**.[13]

The catalytic activities of **6** and **7** for epoxidation were examined with 1,2-dihydronaphthalene (**8**) as the test material (Table 1, entries 1–8). Epoxidation using **6** as the catalyst in the presence of the urea·hydrogen peroxide adduct proceeded with good enantioselectivity, but was slow and the turnover number (TON) of **6** was modest (TON = 14) (entry 1).[14] Epoxidation using **7** was performed in the presence of 1.01 equivalents of aqueous (30%) hydrogen peroxide at room temperature[15,16] and it was found that the epoxidation proceeded with excellent enantioselectivity as well as high yield (entry 2). The turnover number of **7** was 4600 when hydrogen peroxide was added slowly over a period of 8 h (entry 4).

Epoxidation of other conjugated olefins also proceeded smoothly with high enantioselectivity (entries 9–13). It is noteworthy that epoxidation of (*Z*)-5-phenylpent-2-en-3-yne (**11**) was stereospecific and gave the corresponding *cis*-epoxide as a single product, albeit with a slightly inferior enantioselectivity of 88% *ee* (entry 11). This result suggested that oxygen transfer proceeds in a concerted rather than a stepwise manner. This proposal was also supported by the fact that epoxidation of styrene (**12**) was highly enantioselective (entry 12). Moreover, the epoxidation of the nonconjugated olefin 1-octene (**14**) proceeded with slightly reduced but good enantioselectivity, albeit somewhat slowly (entry 14).

Although the reaction mechanism of the present epoxidation is unclear, a peroxotitanium species **15** or **16** is considered to act as the active species because the epoxidation is stereospecific (Figure 3).[17] Furthermore, we speculate that the peroxotitanium species may be activated by an intramolecular hydrogen bond with the amine proton. This speculation might explain why complex **3** that does not possess such an NH group cannot catalyze the epoxidation.



The oxidation of methyl phenyl sulfide was also examined in dichloromethane with **6** as the catalyst in the presence of UHP. The reaction smoothly proceeded but the enantioselectivity was moderate (67% *ee*), although the oxidation with **3** under the same conditions showed a high enantioselectivity of 95% *ee*. It is, however, noteworthy that the sense of asymmetric induction by **6** was opposite to that by **3**, thus suggesting that the structure of the active species derived from **6** was different from **5**.

Figure 3. Possible peroxo intermediates for the epoxidation.

In conclusion, we were able to synthesize stable di-μ-oxo dimers—not only a homochiral **7** but also an unprecedented pseudo-heterochiral di-μ-oxo dimer **6**—by using an in situ intramolecular Meerwein–Ponndorf–Verley reduction in combination with self-assembly of the resulting titanium/tetradentate Schiff base complexes. Furthermore, we were able to show that these stable di-μ-oxo dimers (**6** and **7**) catalyzed epoxidation with hydrogen peroxide; in particular, complex **7** efficiently catalyzed a highly enantioselective epoxidation using aqueous (30%) hydrogen peroxide as the oxidant. Other applications of the current oxidation are under investigation.

Experimental Section

7: Ti(O*i*Pr)$_4$ (2 equiv) was added to a solution of salen ligand **D** (1 equiv) in dry dichloromethane in a nitrogen atmosphere and the resultant solution was stirred at room temperature. After 3 days, water (4 equiv) was added and the reaction mixture was stirred for 2 h. The resulting yellow precipitate was collected by filtration and recrystallized from diethyl ether and dichloromethane to give crystalline complex **7** in 60% yield.

General procedure for epoxidation: Titanium complex **7** (1.8 mg, 1 μmol) and olefin (0.1 mmol) were dissolved in an appropriate solvent (1.0 mL) in a nitrogen atmosphere. After addition of 30% aqueous hydrogen peroxide (0.101 mmol), the resultant mixture was stirred at room temperature for the time indicated in Table 1. The solvent was removed in vacuo and the residue was purified by chromatography on silica gel (pentane/Et_2O 40:1) to give the corresponding epoxide. The *ee* values were determined by HPLC on a chiral stationary phase or by ^{1}H NMR analysis using [Eu(hfc)$_3$] (hfc = 3-(heptafluoropropylhydroxymethylene)-D-camphorate) under the conditions described in the footnotes to Table 1.

Engineering Enhanced Protein Stability through β-Turn Optimization: Insights for the Design of Stable Peptide β-Hairpin Systems**

*Emma R. Simpson, Jill K. Meldrum, Roger Bofill, Maria D. Crespo, Elizabeth Holmes, and Mark S. Searle**

β-Hairpins are a common component of protein structure and represent the smallest increments of protein β-sheets that are accessible through peptide model systems for studying sequence-dependent folding and stability.[1] A number of model hairpin systems are proving useful vehicles for quantitative studies of noncovalent interactions and for the analysis of the cooperative assembly of multistranded sheets. The choice of β-turn plays a key role in dictating β-strand alignment and stability, and these models have evolved around a few key turn sequences that are found to be statistically abundant in protein β-hairpins.[1] In more general terms, not only have β-turns and β-hairpins been implicated in nucleating protein folding and accelerating folding kinetics[2] but they also constitute binding epitopes in protein–protein and protein–nucleic acid recognition.[3,4] They have been used in the design of small peptide-based protease inhibitors, as recognition motifs in HIV therapeutics, as structured peptides that trigger a specific immune response as the basis for the design of vaccines,[5] and as novel minimalist peptide–DNA recognition scaffolds.[6] Protein engineering studies have shown that the rational redesign of, for example, protein secondary structure and surface charge distribution can lead to enhanced protein stability,[7] which may be a desirable feature for proteins of potential use in a range of biotechnological applications or in the large-scale use of enzymes in

synthesis. Proteins have been shown to be tolerant to large sequence variability in turn regions, with stabilities modulated according to loop size and geometry.[8] Similarly, the population of folded β-hairpin peptides has been shown to be particularly sensitive to small changes in sequence, although quantitative analysis has proved more problematic.[1] With a view to improving the rational design of model peptide systems, we have determined the contribution to β-hairpin stability of the commonly occurring type I′ turn by using native ubiquitin as a "host" system. Herein, we present some energetic guidelines for the optimization of β-turn stability in peptide-based model systems.

High-resolution structures have shown that two-residue type I′ β-turns are particularly abundant in protein β-hairpins.[9] The turn geometry strongly complements the right-handed twist of the antiparallel β-sheet. Following the nomenclature of Sibanda and Thornton,[9] the turn is described by the sequence (−B1)-(L1)-(L2)-(+B1), where −B1 and +B1 are the β-strand residues preceding and following the turn, and L1 and L2 are the turn residues. The backbone ϕ and ψ angles of L1 and L2 both lie in the left-handed α-helical (L-α) region of the Ramachandran plot. In an analysis of 512 high-resolution structures we identified 408 two-residue type I′ turn sequences and were able to demonstrate clear residue preferences at the various sites,[10] in agreement with earlier studies that used a smaller database.[11] The data showed that Gly is by far the most abundant residue at position L2 (308 out of 408 cases) as the required backbone angles ($\phi \approx 90°$ and $\psi \approx 0°$) are disallowed for all residues other than Gly.[11] At position L1, the dihedral angles are accessible to other non-β-branched residues, with Asn, Asp, and Gly appearing in around 60% of cases, with Asn preferred. In contrast, Val, Ile, and Thr are rarely found in this position. On this basis the Asn-Gly type I′ turn has been widely used in model hairpin peptide systems for stability and folding studies and has proved highly effective at inducing folded structures.[1] In other cases, the use of D-Pro at position L1 to induce the correct L-α backbone geometry has also proved highly successful.[1]

To examine the influence of β-turn sequences on hairpin stability, we used the N-terminal 17-residue β-hairpin of native ubiquitin as a "host" for mutational studies (Figure 1a).[12–14] By using a fluorescent ubiquitin construct with a background F45W mutation (which we subsequently term wild-type ubiquitin, **WT***),[15–17] we engineered a series of turn mutations into the ubiquitin hairpin to examine quantitatively the effects on protein stability (Figure 1b). In the X-ray crystal structure of native ubiquitin,[12] the first and last of the five residues of the TLTGK loop close the native 3:5 type I G-bulged turn through cross-strand hydrogen bonding. We initially mutated the native turn sequence to the more flexible TGGGK loop (**G3** mutant) without affecting these closing residues. Protein stability was determined through fluorescence-detected chemical denaturation methods using guanidinium chloride (GdmCl). Sigmoidal unfolding curves were fitted to a two-state model from which transition midpoints (c_m), denaturant m values, and free energies of folding were determined (see Table 1).[18] Using this approach, **WT*** was observed to unfold with a transition midpoint (c_m) of 2.68 M GdmCl at pH 5.0 in acetate buffer (25 mM) at 298 K (Figure 2) from which we estimate a free energy of folding of $-27.3(\pm 0.6)$ kJ mol^{-1} (see Table 1). Strikingly, the **G3** mutant appears to be marginally more stable ($\Delta\Delta G \approx -1.6$ kJ mol^{-1}) despite the enhanced flexibility of the Gly-rich turn sequence and loss of side-chain interactions across the loop sequence.

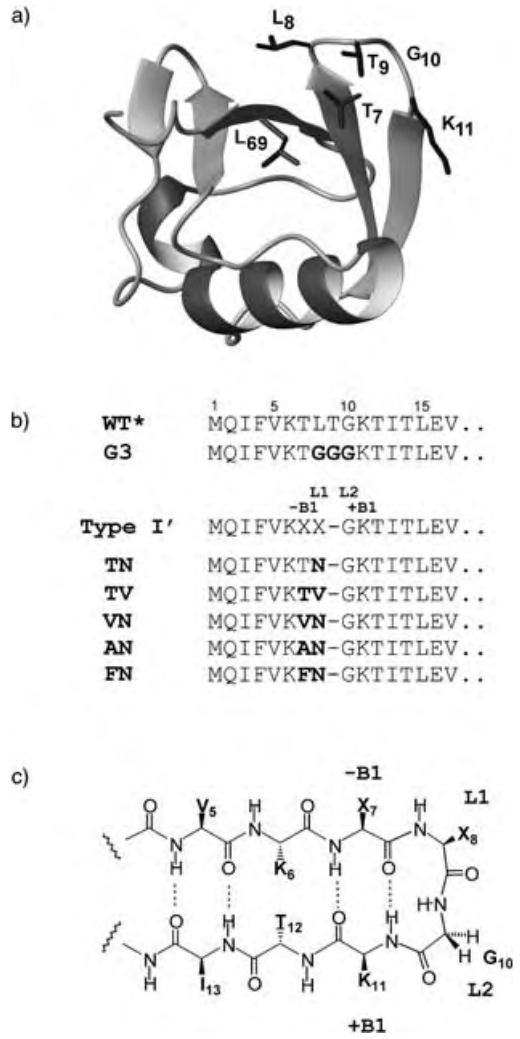

Figure 1. a) X-ray crystal structure of ubiquitin (1UBQ[12]) showing the solvent-exposed TLTGK type I G-bulged turn at the end of the N-terminal β-hairpin sequence. The position and orientation of the side chains of the β-turn residues T_7, L_8, T_9, and K_{11}, and also the L_{69} side chain on the C-terminal β-strand are also illustrated. b) Sequences of ubiquitin mutants containing type I′ β-turn substitutions. Only the N-terminal 17 residues that encompass the β-hairpin are illustrated. c) Two-residue type I′ β-turn conformation showing the mutated residues X_7 and X_8 and cross-strand hydrogen-bonding interactions. The residue numbering in (b) follows that in the **WT*** sequence (residue 9 has been deleted in the mutants). Residues X_7, X_8, G_{10}, and K_{11} represent turn residues −B1, L1, L2, and +B1, respectively, according to the nomenclature of Sibanda and Thornton (ref. [9]).

Subsequently, we replaced the native loop sequence (TLTGK) with the type I′ turn sequence (TXGK) by substituting LT with residue X at position L1 (Figure 1c).[9] We considered residues at position X which occur with either high frequency (X = Asn) or low frequency (X = Val) in protein β-

[a] Transition midpoints (c_m, 50% unfolded protein relative to [GdmCl]) were determined by fluorescence measurements at 298 K on 1.0 μM solutions of protein in acetate buffer (25 mM) at pH 5.0; fitting errors are typically less than 0.02 M. [b] Equilibrium stabilities calculated using $m = 10.18$ kJ mol^{-1} M^{-1} (with a standard error of ± 0.23 kJ mol^{-1} M^{-1}).

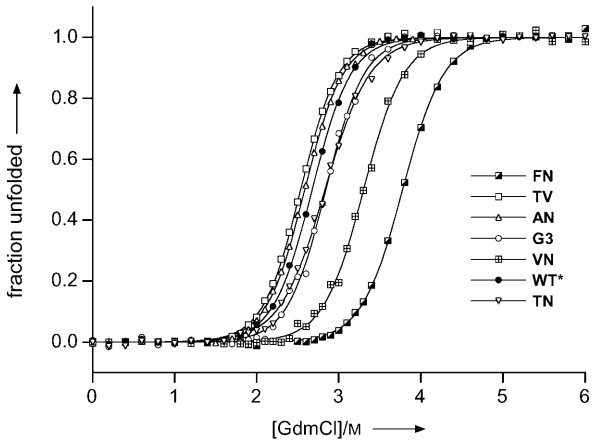

Figure 2. a) Guanidinium chloride (GdmCl) denaturation curves for the family of β-turn mutants measured at 298 K and pH 5.0 in acetate buffer (25 mM). Unfolding transitions were measured by fluorescence changes at $\lambda = 358$ nm, and the data were converted into the fraction unfolded versus the concentration of GdmCl. Stabilities were determined using the linear extrapolation method by fitting the curves to a two-state unfolding model to determine the midpoint denaturant concentration (c_m) and the slope (m value). Stability data are shown in Table 1.

hairpins (**TN** and **TV** mutants, respectively) while retaining the same β-strand residues present in the **WT*** sequence at positions −B1 and +B1.[10] The requirement for ϕ and ψ angles at position L1 which lie in the left-handed α-helical region highly disfavors Val at this position.[11] Despite the high abundance of type I′ turns in protein hairpins, the insertion of the Asn-Gly sequence produces only a small incremental increase in stability of −1.5 kJ mol^{-1} relative to that of the native G-bulged turn, suggesting that these are equally good turn sequences in this context. Substitution with the least favored L1 residue (TVGK) resulted in a modest reduction in stability of 2.9 kJ mol^{-1} relative to that of the most favored (TNGK) type I′ turn sequence. Although this is a relatively small overall effect on the stability of native ubiquitin, in the context of small hairpin peptides of only marginal stability ($\Delta G_{fold} \approx 0$), this equates to a significant change in the folded population (threefold change in equilibrium constant).[1]

To confirm that both the TNGK and TVGK turns are accommodated with the same turn conformation, rather than the stability difference reflecting grossly different backbone geometries, we examined in detail the **TN** and **TV** ubiquitin mutants by NMR spectroscopy. A complete assignment of the backbone NH and Hα protons enabled us to identify cross-strand NOEs and Hα chemical shift perturbations. By comparison with **WT***, Hα chemical shift perturbations from random coil values (ΔδHα [ppm]) for **TN** are shown in Figure 3a and demonstrate that the structural changes arising from the substitution of the turn sequence are largely confined to the region immediately adjacent to the mutated residues. Residues within the N and C termini of the β-strands (1–5 and 12–17) are perturbed by $\Delta\delta H\alpha < 0.1$ ppm. Intense cross-strand Hα–Hα NOEs, particularly between K_6 Hα and T_{12} Hα, confirm the nativelike strand alignment close to the type I′ turn. The ratio of NOE intensities at the T_7-N_8 step ($H\alpha_i$-NH_{i+1}/$H\alpha_i$-$NH_i \approx 1$) together with a small $^3J_{NH\text{-}H\alpha} < 5$ Hz for N_8 and a strong sequential NH_i-NH_{i+1} NOE between G_{10} and K_{11} identifies an abrupt change in direction of the peptide

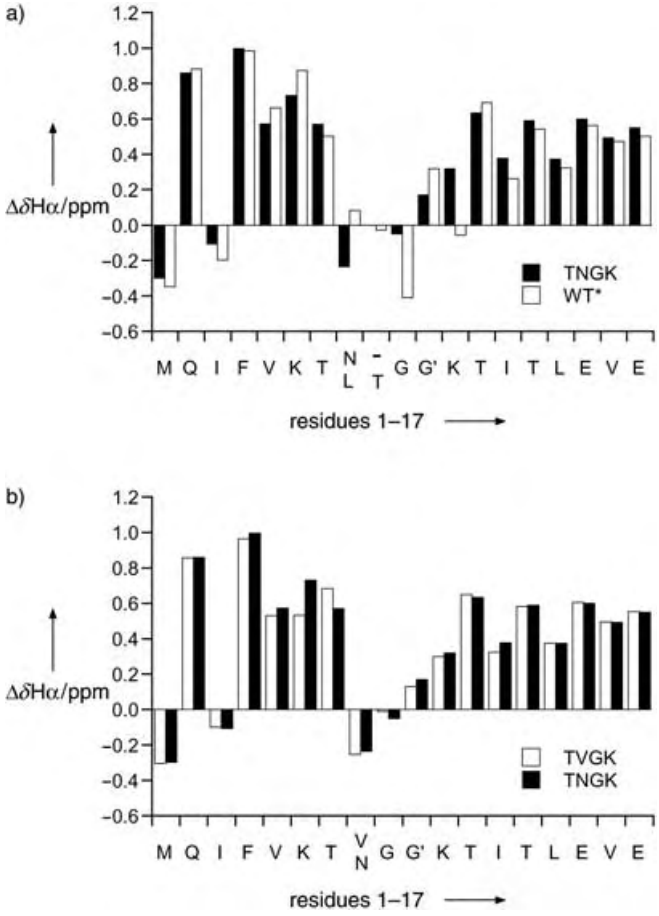

Figure 3. Perturbations to chemical shifts of Hα (measured values versus random coil values, ΔδHα [ppm]) of residues 1–17 in the N-terminal β-hairpin. NMR data were collected at 600 MHz at 298 K and pH 5.0. a) NMR data for **WT*** are compared to the **TN** mutant (TNGK turn sequence) and show that perturbations are largely confined to residues immediately adjacent to the mutated turn residues. b) Comparison of ΔδHα values for the **TN** and **TV** mutants, representing the most favored (Asn-Gly) and the least favored (Val-Gly) substitutions at position L1 in type I′ turns.

chain at the T_7-N_8 and G_{10}-K_{11} steps which is consistent with N_8 and G_{10} occupying the L-α region of ϕ,ψ space. In Figure 3b, the Hα chemical shift data for mutants **TN** and **TV** show similar perturbations that are consistent with the two turns adopting the same conformation. Analogous patterns of NOEs and $^3J_{NH\text{-}H\alpha}$ values (not shown) confirm these conclusions. Thus, the two turns appear to be readily accommodated in the desired geometry with only modest local disruption to secondary structure, despite the differences in steric demand and frequency of occurrence of Val and Asn at the L1 position.

The earlier statistical analysis of type I′ turns also showed some preference for residues at the −B1 and +B1 positions flanking the turn sequence.[10] For example, Lys occurs with high frequency at position +B1 and, consequently, this residue has been retained in all constructs as well as being present in the native sequence. At position −B1 there is a clear preference for the β-branched residue Val,[10] however, there was little apparent discrimination between remaining side chains on the basis of size or hydrophobicity. Introduction of Val at this position (**VN** mutant) resulted in a noticeable increase in stability, with a shift in the denaturant-induced transition midpoint from 2.83 M GdmCl observed for **TN** to 3.33 M for **VN** ($\Delta\Delta G = -5.1$ kJ mol^{-1}). NMR data for the **TN** and **VN** mutants show that the isosteric Thr and Val residues at the −B1 position are accommodated with the same side-chain rotamer conformation. The substitution of the β-OH group of T_7 with the V_7 methyl affects the contacts largely within the β-turn, as evident from cross-strand NOEs from the V_7 CH_3 to protons of the aliphatic side-chain of K_{11} (β-CH_2/γ-CH_2). On the basis of intrinsic β-sheet-forming propensities, Thr and Val were anticipated to promote hairpin folding, whereas Ala has a high helical propensity and was expected to be destabilizing in the context of the β-hairpin. Accordingly, the ANGK turn (**AN** mutant) resulted in a loss of stability of +2.5 kJ mol^{-1} compared to TNGK (see Table 1). Overall, the relative turn stabilities appear to reflect the intrinsic β-sheet-forming propensity of the residue at the −B1 position at the end of the β-strand. We conclude that optimization of residues at positions −B1 and L1 in the context of the type I′ turn can lead to substantial net changes in protein stability in a manner that appears to correlate well with backbone ϕ,ψ structural propensities.[10]

We also modeled a number of other nonpolar residues at the −B1 position to investigate the possibility of engineering new stabilizing tertiary interactions at this site. The models suggested that the introduction of bulky aromatics such as Phe at the −B1 position should lead to very favorable context-dependent hydrophobic contacts with L_{69} and L_{71} on the adjacent C-terminal β-strand, even though Phe does not have a particularly high frequency of occurrence at position −B1 in type I′ turns.[10] As predicted from the model, the FNGK turn (**FN** mutant) showed a substantial further increase in stability over TNGK of −9.7 kJ mol^{-1}. As confirmation of the engineered F_7–L_{69}/L_{71} interactions, we observed significant upfield ring-current effects of between 0.6–0.9 ppm on the H_β, H_γ, and $C_\delta H_3$ resonances of L_{69}, placing the latter in a well-resolved region of the spectrum at $\delta = 0.03$ ppm. Upfield shifts (≈ 0.4 ppm) are observed for both $C_\delta H_3$ resonances of L_{71} (Figure 4a). We were readily able to identify NOEs from the side chain of F_7 to L_{69} and L_{71} which confirm the hydrophobic contacts. Local refinement of our structural model using the NOE data and restrained molecular dynamics enabled these local interactions to be visualized (Figure 4b). Thus, the high apparent β-sheet propensity of Phe at position −B1 appears to be rationalized largely on the basis of engineered tertiary interactions rather than intrinsic secondary structure propensity.

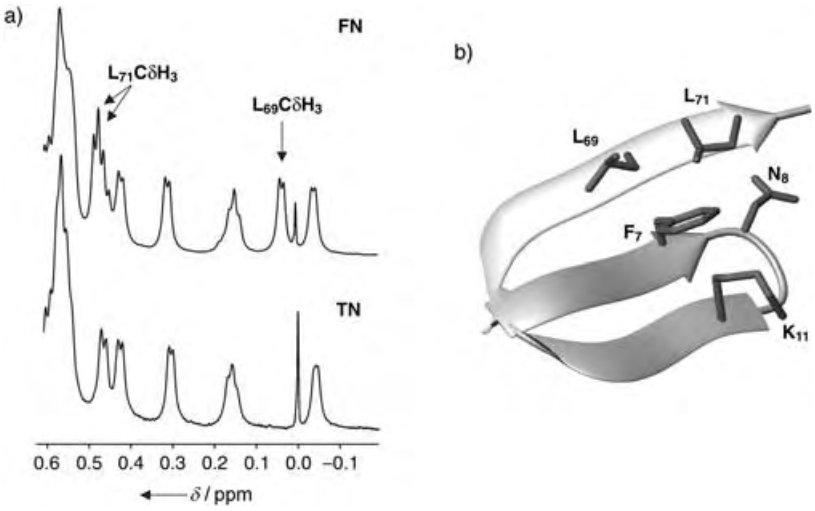

Figure 4. a) 1D ^{1}H NMR spectra of the **TN** and **FN** mutants showing the highfield-shifted methyl region ($\delta = -0.1$ to 0.6 ppm) at 298 K (pH 5.0). The spectra are similar except for the appearance of the two ring-current-shifted $C_\delta H_3$ resonances of L_{71} at $\delta = \approx 0.47$ ppm and that of L_{69} at $\delta = 0.03$ ppm owing to hydrophobic contacts with F_7 at position −B1 in the turn. b) Model of the **FN** mutant showing hydrophobic contacts between F_7 and L_{69}/L_{71} which account for the stability enhancement of the **FN** mutant and observed ring-current shifts to L_{69} and L_{71}. Other side chains of the turn residues N_8 and K_{11} are also shown.

In conclusion, we set out to examine quantitatively the effects of β-turn mutations on protein stability using the N-terminal hairpin sequence of ubiquitin as a "host" system. As demonstrated from a statistical analysis of β-hairpins in high-resolution protein structures and from work on model hairpin peptide systems, type I′ turns are effective promoters of hairpin folding, although the energetic contributions have not been systematically studied.[1,9–11,19] We have shown that optimization of residues at positions −B1 and L1 lead to substantial increases in stability that correlate well with backbone ϕ,ψ structural propensities. In the context of a weakly folded peptide model system of only marginal stability ($\Delta G \approx 0$), it is clear that the choice of type I′ turn sequence can be a critical factor in determining whether a significant population of the folded conformer can be detected.[1,11] The

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

work of Gellman has shown that D-Pro at position L1 is also highly effective in nucleating hairpin folding in model peptide hairpin systems because the preferred ϕ,ψ backbone angles, together with the entropic constraints imposed by the backbone-to-side-chain cyclization, match the right-handed twist of the β-sheet.[1a–c] Substituting with the mirror image L-Pro switches the turn geometry from right-handed (type I′ or II′) to left-handed (type I or II) and makes the latter incompatible with the twisted alignment of the two β-strands which leads to a completely unfolded state.[20] However, to our knowledge a quantitative estimate of the difference in stability between the pair of diastereomeric hairpin peptides has not been reported.

We have presented some energetic guidelines for the stability contributions of type I′ turns to hairpin stability. These estimates probably represent an upper limit for model peptide systems because we have measured the incremental free energy contribution of the various turn sequences in the context of the cooperative folding transition of native ubiquitin. These limiting values may not be fully realized in the context of a more dynamic folded peptide system, although enthalpy/entropy compensations may play some part in achieving these stability differences.[21] Such compensatory effects may also be evident in the case of the TGGGK turn sequence for which intrinsic flexibility potentially compensates for any reduction in enthalpic benefits from poorer side-chain interactions or locally weaker hydrogen bonds. With regard to the design of model peptide systems that contain β-hairpin motifs, we have presented a quantitative analysis of the energetic contribution of the type I′ β-turn to β-hairpin stability in ubiquitin. The N-terminal β-hairpin sequence has previously been studied in isolation as a possible protein folding nucleation site and has been used as the basis of a number of other model systems for folding studies.[1a,14,22] However, the results presented here should be of more general use in peptide and protein design and in understanding aspects of the energetics of molecular recognition and self-assembly.

Experimental Section

A pKK223–3 plasmid construct containing the yeast ubiquitin gene was used to express the wildtype protein in *Escherichia coli* strain BL21(DE3) under the control of the IPTG-inducible *tac* promoter. The F45W mutant gene was cloned by overlap PCR methodology using the wild-type yeast ubiquitin gene in pKK223-3 (Pharmacia Biotech) as a template. Competent *Escherichia coli* cells were transformed with this construct. Expression and purification of **WT*** yielded typically 10–15 mg L^{-1} of ubiquitin. All other mutations using the **WT*** background were introduced using the QuikChange site-directed mutagenesis protocol (Stratagene, La Jolla, CA) and confirmed by DNA sequence analysis (School of Biomedical Sciences, Nottingham) and by NMR studies.

Protein stabilities were determined using methods previously described in references [15] and [17a] and by using established protocols.[18a,b] Protein stability was determined by fluorescence measurements on 1.0-μM solutions of protein in acetate buffer (25 mM) at pH 5.0 and 298 K. The change in fluorescence at $\lambda =$ 358 nm was monitored as a function of the concentration of guanidinium chloride (GdmCl). The linear extrapolation method was employed assuming that the stability varies with the concentration of denaturant, [D], according to the expression $\Delta G^{D} = \Delta G_{eq} + m[D]$, where ΔG^{D} is the stability at a given [D], m is the constant of proportionality, and ΔG_{eq} is the stability in water alone. The data were plotted as the fraction of unfolded protein versus [D]. The midpoint of the unfolding transition c_m for each mutant was determined by nonlinear least-squares fitting (see references [16] and [18a]). The equilibrium stability ΔG_{eq} was determined from the expression $\Delta G_{eq} = -m\,c_m$. For the mutants described we observed only a small variation in m values, 10.18 ± 0.23 kJ mol^{-1} M^{-1} (± standard error), and the expression $\Delta\Delta G_{eq} = -m(c_m^{mut} - c_m^{WT})$ was used to calculated changes in stability. This approach is justified by NMR spectroscopic analysis of all mutants which shows that they all fold to a nativelike structure with only minor localized chemical shift perturbations and changes in the hydrophobic surface area buried.[18c,d]

All NMR spectroscopy experiments were performed on a Bruker Avance600 spectrometer. Total correlation spectroscopy (TOCSY) and nuclear Overhauser effect spectroscopy (NOESY) experiments were used as previously described on 1-mM protein samples at pH 5.0.[15] Spectra were referenced internally to trimethylsilylpropionate (TSP), and random coil peptide shifts were used as reported.[23] Data were processed and assigned using Bruker XWINNMR and ANSIG software,[24] and structural models were visualized using MOLMOL.[25] The structure of the **FN** mutant was modeled from random unfolded starting structures using 345 NOE-derived distance restraints and 63 torsion angle restraints. 100 structures were refined using a combination of distance geometry and simulated annealing using the XPLOR-NIH program.[26] Acceptance criteria of no NOE violations greater than 0.5 Å and no angle restraint violations of greater than 5° were applied. Root-mean-square deviations for bonds and angles from ideality were less than 0.01 Å and 2°, respectively, for all structures. From this, 72 structures were accepted, the lowest energy of which is shown in Figure 4.

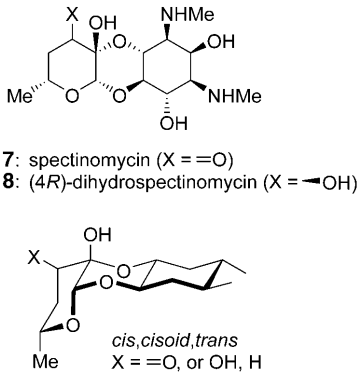
invariably contain a single sugar—the rare 4,6-dideoxy-D-hexos-2,3-diulose or its epimeric C-3 reduction products—in a unique "dioxanoid" attachment. The common β-glycosidic bond to the steroidal 3-OH is complemented by a hemiacetal linkage between the 2-carbonyl group of the sugar and the 2-OH group of the aglycone to result in a *cis,cisoid,trans*-fusion of pyran, dioxane, and cyclohexane rings. The antibiotic spectinomycin (**7**) and its dihydro derivative **8**, elaborated by *Streptomyces spectabilis*, contain the same 2-ketosugars in an analogous double attachment to actinamine, an *N*-methylated diaminoinositol (Figure 1).[5]



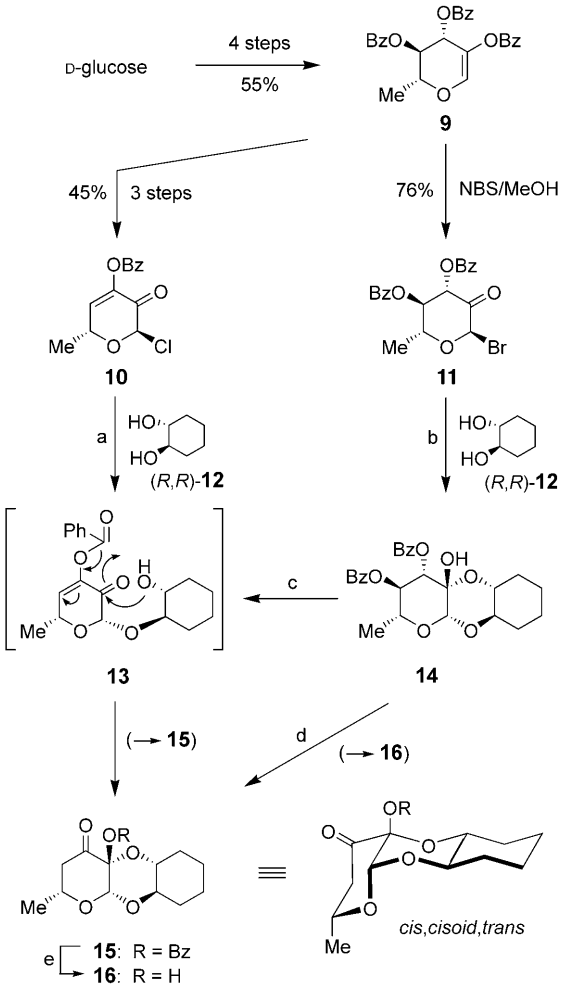


Figure 1. Two antibiotics (**7**, **8**) produced by *Streptomyces spectabilis*, each comprising a 4,6-dideoxy-2-ketohexose moiety doubly attached to a cyclohexanoid aglycone-diol in *cis,cisoid,trans* fusion.

Synthetically, the double attachment of a 2-ketosugar to a natural aglyconediol has only been addressed in the case of spectinomycin (**7**), for which two total syntheses (one in 9 steps from L-glucose,[6a] and the other in 23 steps from D-glucose[6b]) have been reported that comprise monoglycosylation of a readily accessible *N*-protected actinamine and subsequent gradual elaboration of the 2-carbonyl group of the sugar. In the case of cardenolide glycosides of type **1**–**6**, however, the aglycons are only laboriously available. Thus for annulation of their sugar portion, alternatives that are capable of reaching this objective more directly became imperative. On the basis of our previous studies on the extension of the "ulosyl donor approach"[7] to glycol and (*R*,*R*)-1,2-cyclohexanediol, which smoothly led to *cis*-fused pyranodioxanes[8] and to pyran-dioxane-cyclohexane tricycles[9] in *cis,cisoid,trans* fusion, we inferred that the D-glucose-derived 2-ketohexosyl donors **10** and **11** would be particularly well-adjusted for targeting natural products with annulated sugar components. The donors not only contain the 2-carbonyl function, which is essential for generation of the cyclohemiacetal linkage, but in the case of **10**, an enol-ester-protected carbonyl at C-3 is also present thereby closely matching the tricarbonyl sugar units in **3**, **6**, and **7**. Furthermore, these donors are fairly well accessible from D-glucose through the 6-deoxy-2-hydroxyglucal ester **9**:[10] ulosyl bromide **11** can be obtained in five, large-scale adaptable steps from D-glucose[11,12] versus seven steps for its unsaturated chloro analogue **10**,[12] with overall yields of 42 and 25%, respectively (Scheme 1).

The feasibility of advancing from donors **10** and **11** to cardenolides of type **1**–**6** was first probed with (*R*,*R*)-1,2-cyclohexanediol (**12**) as a model aglycon. On exposure of **12** to equimolar amounts of Ag_2CO_3 and donor **10**, a single product was obtained (TLC) and isolated in high yield (81%) which on the basis of cogent NMR evidence proved to be *cis,cisoid,trans*-fused pyran-dioxane-cyclohexane tricycle **15**. Thus, an essentially β-specific mono-*O*-glycosylation of diol **12** to glycosidulose **13** is spontaneously followed by a cascade reaction in which the second OH group engages in hemiacetal formation and the 3-*O*→2-*O*-benzoyl group (arrows in **13**) subsequently shifts, with seemingly exclusive preference for OH→C=O attack occurring from the lower (axial) face of the pyran ring.[13] Here, electronic interactions are minimized by *trans*-diaxial disposition of the oxygen of the pyran ring and the benzoyloxy acetal group—a consequence of the anomeric effect—and steric interactions are at a minimum due to chair conformations of the three rings.

Scheme 1. Synthesis of linear fused pyran-dioxane-cyclohexane tricycles that correspond to dioxanoid cardenolide glycosides in structure and linkage geometry. Reagents and conditions: a) **12** (1.0 equiv), Ag_2CO_3 (1.0 equiv), molecular sieves, CH_2Cl_2, 40°C, 8 h, 81%; b) **12** (1.0 equiv), Ag_2CO_3 (1.0 equiv), CH_2Cl_2, 25°C, 20 h, 87%; c) nBu_4NOAc, CH_2Cl_2, 25°C, 20 h, 85% (**15**); d) nBu_4NOAc, moist MeCN, 25°C, 6 h, 81% (**16**); e) K_2CO_3, MeOH, 25°C, 10 min, 87%. Bz = benzoyl; NBS = *N*-bromosuccinimide.

In the case of the ulosyl bromide **11**, the Ag_2CO_3-mediated glycosylation of one OH group of diol **12** expectedly[7,12] proceeded in β-specific fashion and was similarly followed by sterically uniform hemiketalization with the other OH group to provide the *cis,cisoid,trans*-interconnected tricycle **14**, with the high yield (87%) emphasizing the extent of stereocontrol in the two reactions involved. Owing to its free ketalic OH group, **14** is prone to react in the ring-opened glycosidulose form, particularly under basic conditions. Thus, on stirring **14** with tetra-*n*-butylammonium acetate in CH_2Cl_2, 3,4-elimination of benzoic acid to the enolone ester **13** was induced; however, the ester was not isolable under these conditions, as hemiketalization and migration of the *O*-benzoyl group readily took place (arrows in **13**; see Scheme 1), thereby elaborating the tricyclic ketone **15** (85%). When β elimination of **14**→**13** was attempted with nBu$_4$NOAc in aqueous acetonitrile, the benzoyl migration step was intercepted by hydrolysis to afford instead the free hemiketal **16** in crystalline form[14] and 81% yield. Expectedly, **16** was also obtained on de-*O*-benzoylation of **15** (87%).

Thus, having established the utility of donors **10** and **11** for the dioxanoid annulation of 4,6-dideoxy-2-ketosugar units—the *cis,cisoid,trans*-fused **15** has all the structural and stereochemical essentials of the natural products—the methodology developed for (*R*,*R*)-1,2-cyclohexanediol was then applied to gomphogenin (**17**),[15] the steroid aglycone of gomphosides **1**–**3**. As **17** is an unsymmetric diol, it was expected to give two products as Ag_2CO_3-mediated *O*-glycosylation with donors **10** or **11** followed by folding of the hemiketal can occur on either of the OH groups. Fortunately, it appeared that the 3-OH group of gomphogenine is the more reactive of the two OH groups from the fact that the major components of the 3:1 mixtures obtained in each case proved to be the naturally fused products **18** (from ulosyl bromide **11**) and **20** (from donor **10**). These products were purified by preparative HPLC to afford **18** and **20** in yields of 61 and 54%, respectively (Scheme 2). De-*O*-benzoylation of **20** was readily effected by exposure to mild base to provide crystalline cardenolide **3** in excellent yield (95%). In analogy to the model conversion **14**→**16**, **3** could also be obtained from **18** by stirring with nBu$_4$NOAc in hydrous acetonitrile (81% yield). Compound **3** as synthesized here was identical in all respects with the 3′-dehydrogomphoside derived from *Asclepias fruticosa*[3] with respect to the melting point (300–301 °C; lit.: 302–304 °C[3]) and ^{1}H and ^{13}C NMR spectroscopic characteristics.

The integrity of synthetic **3** could further be verified through conversion into the epimeric 3′-hydroxy analogues. Hydrogenation over 5% Rh/C[16] led to a mixture of gomphoside (**1**) and its 3′-epimer **2**, from which **1** was secured in 80% yield and proved to be identical to the natural product[2b,17] with respect to melting point and spectral data. Reduction of **3** with $NaBH_4$ proceeded stereospecifically to afford 3′-*epi*-gomphoside (**2**) as a crystalline solid,[18] whose structure was analyzed by X-ray diffraction and clearly exposes the *cis,cisoid,trans* interconnection of the pyran, dioxane, and ring A cyclohexane rings (Figure 2).

The methodology developed so far for the dioxanoid annulation of sugars to cyclic 1,2-diols was also probed with *N*,*N*-bis(benzyloxycarbonyl)actinamine (**21**), the aglycon of spectinomycin in an accessible and suitably *N*,*N*-protected form.[19] As the bulky *N*-protecting groups impede glycosylation at the vicinal hydroxy groups through steric shielding,[6] a highly regioselective attack of donors **10** or **11** at 3-OH was anticipated. However, the acceptor reactivity of this 3-hydroxy group proved to be considerably lower than that in

Scheme 2. Reagents and conditions: a) **11** (2 equiv), Ag_2CO_3 (1 equiv), molecular sieves, CH_2Cl_2, 25 °C, 16 h, 61% (**18**), 14% (**19**); b) **10** (1.0 equiv), Ag_2CO_3 (1.0 equiv), molecular sieves, CH_2Cl_2, 40 °C, 2 h, 54% (**20**); c) nBu$_4$NOAc, MeCN/water 50:1, 25 °C, 15 h, 89% (**3**); d) 5% Rh/C, MeOH/water 9:1, 25 °C, 24 h, 80%; e) $NaBH_4$ (1.0 equiv), dry MeOH, 0 °C, 10 min, 81%; f) K_2CO_3, MeOH, 25 °C, 10 min, 95%.

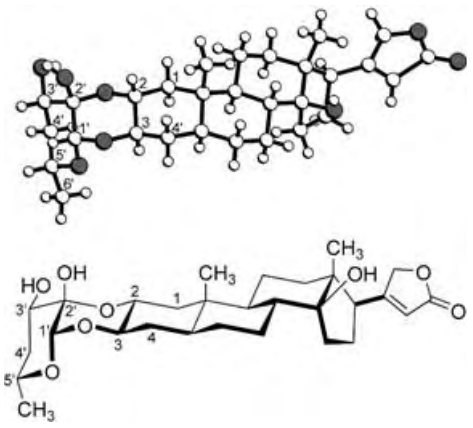

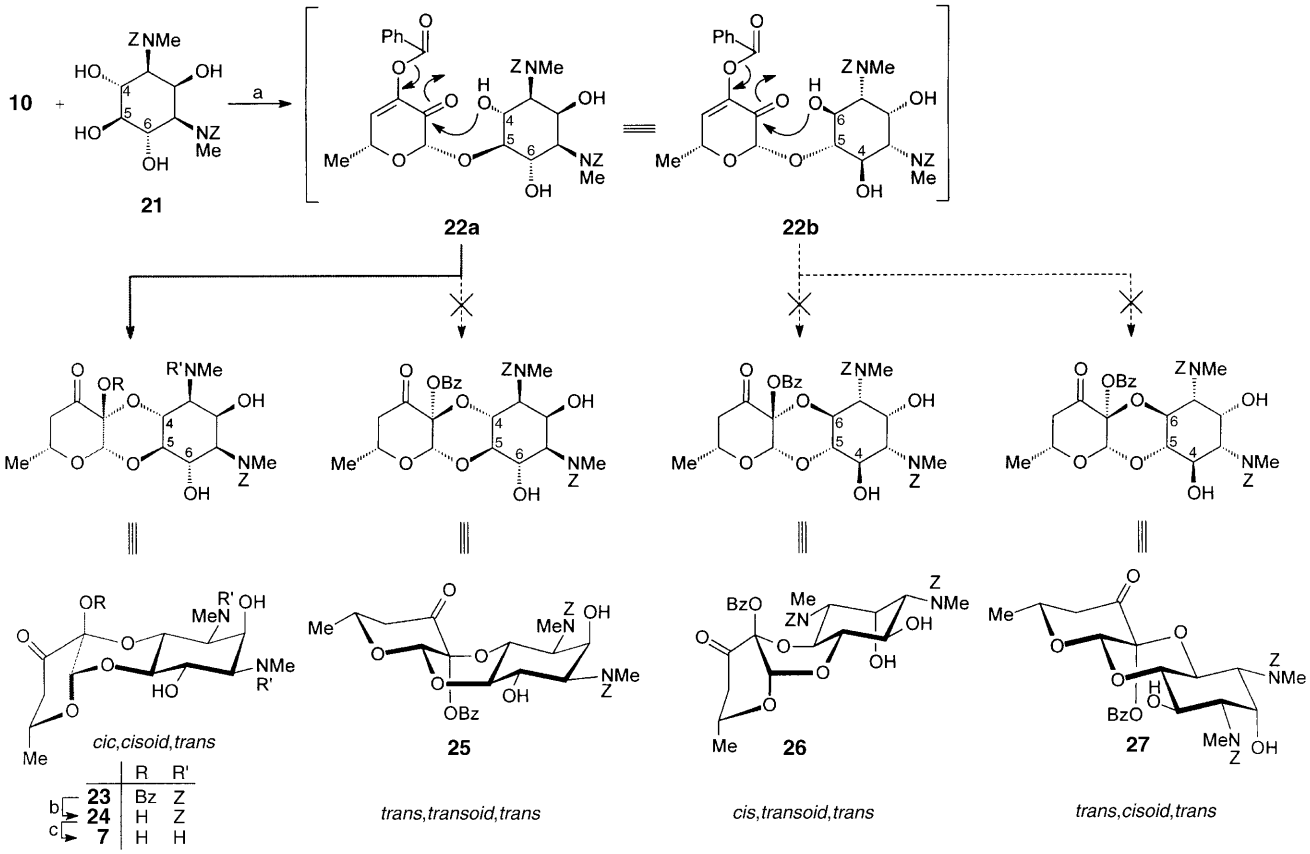

Figure 2. X-ray crystal structure of 3′-*epi*-gomphoside (**2**). The lactone ring is twofold disordered, as is the solvent molecule CH_2Cl_2 (omitted for clarity). The pyran, dioxane, and cyclohexane rings are all in near-perfect chair conformations. Dihedral angles [°] relevant to the dioxanoid attachment: C2-O2-C2′-C3′ −173.0, C3-O3-C1′-O5′ 64.7, O3-C1′-C2′-C3′ 172.7, O2′-C2′-C1′-O5′ 172.3.

diol **12** or in gomphogenine, seemingly due to the high oxygen substitution in its cyclohexane ring, and entailed sluggish glycosylations when promoted with Ag_2CO_3. After substantial experimentation with various insoluble silver catalysts—the more-reactive soluble promoters such as silver triflate were excluded as they entail α selectivity—silver aluminosilicate[20] in THF/CH_2Cl_2 or in toluene was found to effect β-selective *O*-glycosylation of **21** with donor **10**[21] to give **23** as the major product in 51 % isolated yield after removal of 4-*O*- and 6-*O*-glycosylated analogues (ca. 5 % each) by preparative HPLC (Scheme 3). The integrity of **23**, the 2′-*O*-benzoyl derivative of *N*,*N*-bis-(benzyloxycarbonyl)spectinomycin in its *cis,cisoid,trans*-fused tricyclic framework, was confirmed from its spectral data, its ready de-*O*-benzoylation to the known Boc-protected **24**,[6b,22] as well as from its hydrogenolysis to spectinomycin (**7**), which was found to be identical to the natural product in all respects.

The regioselectivity and β selectivity of the glycosylation reaction are remarkable, whereas the stereocontrol exercised in the hemiketal folding of the glycosidulose intermediate is even more so as it leads from a compound that contains two stereogenic centers to a product that contains nine! As a result of the thermodynamics derived from two anomeric effects and the propensity to form the sterically most favorable linear-fused tricycle, the glycosidulose C=O group in **22** is attacked with high and exclusive preference by the 4*R*-OH group from the axial (lower) face of the pyran ring to elaborate **23**, with the oxygen of the pyranoid ring and the ketalic OBz group positioned in the favorable *trans*-diaxial conformation, as well as chair conformations of the three rings. In contrast, the alternate possibilities—attack of 4*R*-OH from the β (equatorial) face (**22a**→**25**) or of 6*S*-OH in the two conceivable steric modes (**22b**→**26** or **27**)—invariably leads

Scheme 3. Unique stereocontrol in the intramolecular hemiketal folding of glycosidulose intermediate **22** towards the *cis*,*cisoid*,*trans*-fused framework of spectinomycin. Reagents and conditions: a) Ag aluminosilicate (1.2 equiv), toluene, 80 °C, 3 h, 51 %; b) K_2CO_3, MeOH, 25 °C, 10 min, 89 %; c) H_2, 5 % Pd/C, *i*PrOH, 25 °C, 12 h, 90 %. Z = benzyloxycarbonyl.

to thermodynamically less stable products either because the central dioxane ring is forced into a boat conformation (**25** and **26**) or as unfavorable dipolar interactions are operative (**25**, **27**). The ease with which the glycosidulose intermediate spontaneously "folds" into the natural *cis,cisoid,trans* geometry may even be taken as evidence for such a process to be operative in non-enzyme-mediated fashion in the biosynthesis of spectinomycin from D-glucose,[23] with an unprotected form of glycosidulose **22** conceivably being the decisive intermediate.

In summary, the chemistry detailed herein defines a concise and general method for the construction of natural products with a *cis,cisoid,trans*-interconnected pyran-dioxane-cyclohexane framework and has enabled the first syntheses of cardiac glycosides with ring A annulated sugars and an alternate synthesis of the antibiotic spectinomycin. A key feature of the methodology is the monoglycosylation of the respective aglycon diols with 4,6-dideoxy-2-ketohexosyl donors, promoted by an insoluble silver salt, which thereby substantially extends the utility of the "ulosyl donor approach".[7]

Catalytic Tandem Reactions

DOI: 10.1002/anie.200501150

An Ir^I-Catalyzed *exo*-Selective Tandem Cycloisomerization/Hydroalkoxylation of Bis-Homopropargylic Alcohols at Room Temperature**

Emilie Genin, Sylvain Antoniotti, Véronique Michelet, and Jean-Pierre Genêt**

Over the past few years, significant research has been directed toward the development of new methodologies that provide synthetic efficiency and atom economy.[1] Among them, tandem reactions, which allow the formation of several new bonds in a single step from readily available materials, are of particular interest.[2] Moreover, the potential of transition-metal-catalyzed heterocyclization reactions of unsaturated substrates has been regularly demonstrated, as they give a direct method for the synthesis of highly valuable nitrogen- and oxygen-containing heterocycles.[3] Palladium catalysis, in particular, has been the driving force behind many advances in the synthesis of heterocyclic derivatives.[4] However, cyclizations mainly occur at high temperature or in the presence of a base, copper co-catalysts, or other oxidants, and this has stimulated the search for alternative transition-metal catalysts.[3,4] In the course of our ongoing program concerning catalytic tandem reactions with functionalized enynes,[5] we became interested in the cyclization of bis-homopropargylic alcohols, which have shown challenging behaviors either in their *endo*- or *exo*-selective cyclizations in the presence of palladium, molybdenum, tungsten, ruthenium, and rhodium catalysts (Scheme 1).[1,3,4,6] We therefore turned our attention to iridium complexes, which have recently been reported to exhibit promising catalytic properties,[7,8] and we wish to report herein the first Ir^I-catalyzed *exo*-selective tandem cycloisomerization/hydroalkoxylation that proceeds exclusively and efficiently at room temperature and that involves inter- and intramolecular C–O bond formation.

Scheme 1. Metal-catalyzed cyclization of bis-homopropargylic alcohols. M′ = Pd; M″ = Mo, W, Ru, Rh, Pd.

Our initial experiments were performed with bis-homopropargylic alcohol **1a** as a model substrate, which is easily prepared by malonic addition to the corresponding halide and reduction of the resultant diester. Even though Ir^I catalysts have recently been shown to promote 1,6-enyne carbon–carbon cycloisomerization,[7j] the $[\{Ir(cod)Cl\}_2]$ dimer catalyst led to a completely different reaction in methanol at room temperature. The cyclization occurred very smoothly in the presence of 2.5 mol% of $[\{Ir(cod)Cl\}_2]$ at room temperature in a very short time with the concomitant addition of methanol to give the functionalized furanyl ketal **2a** in 99% yield (Table 1, entry 1). The use of an Ir^I catalyst is crucial as no reaction occurred either without catalyst or with $IrCl_3$. Interestingly, whereas the reaction of such bis-homopropargylic substrates catalyzed by transition metals such as Rh, Ru, W, and Mo usually leads to 6-*endo* cyclization products,[6] the cyclization was found to be 5-*exo*-selective, as no six-membered cyclic derivative was detected. The tandem addition of methanol was particularly intriguing as it has only rarely been reported in the literature: scarce examples are limited to the use of Pd catalysts and need a co-catalyst or other additive to be effective.[4e,9] We therefore embarked on a general study of this reaction in the presence of an Ir^I catalyst (Table 1). With the aim of examining the influence of the side chain R^1, we prepared several bis-homopropargylic alcohols by malonic addition of the corresponding alkyl bromide, reduction of the resultant diester functions, and, for some substrates, monoprotection of the diols.[10] The reactions were conducted in MeOH at room temperature in the presence of 1–2.5 mol% of $[\{Ir(cod)Cl\}_2]$.

The butyl-substituted alkyne **1b** was transformed into the ketal **2b** in a high 99% yield (Table 1, entry 2). Surprisingly, the addition of the remaining alcohol was not observed in these cases, presumably because MeOH, which is a potential ligand for the Ir complex, is present in excess close to the substrate.[11] The reaction conditions are compatible with other substitution patterns on alcohols **1**, such as a propargyl group (entry 3). Alcohols **1d–f** underwent smooth and rapid cyclization and functionalization (entries 4–6) to give the corresponding acetals **2d–f** in excellent yields (90–99%). Lowering the catalyst loading was possible (entry 6) with a slight enhancement of the reaction time. These derivatives constitute important building blocks for an easy access to natural product[12] and can be easily transformed into C1-substituted furans by treatment with functionalized silanes in the presence of a Lewis acid.[13]

To illustrate the synthetic utility of this tandem reaction, we envisaged the use of other alcohols for the intermolecular addition step. Other nucleophiles such as ethanol and allylic alcohol could be successfully used under the same reaction conditions at room temperature in the presence of 1–2.5 mol% of the $[\{Ir(cod)Cl\}_2]$ catalyst (Table 2).

Such a process offers a control of the R^1 and R^3 groups in the final furanyl product simply by varying the halide used in the preliminary malonate alkylation and the nature of the alcohol used as the solvent. This mode of functionalization also allows the introduction of structural diversity that cannot

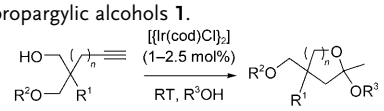
6[c]	**1f**	(*E*)-cinnamyl	Ac		**2f**	4	99

[a] Yield of isolated product; 1/1 mixture of diastereomers. [b] 2.5 mol% of catalyst. [c] 1 mol% of catalyst. [d] Bn = benzyl.

be achieved selectively by the functionalization of simple furanyl rings. Alcohols bearing either an unsaturated (entries 1, 2, and 4) or an alkyl (entry 3) side chain were cleanly, and in a very short time, cyclized with concomitant addition of EtOH to the ethoxy-substituted derivatives **3a**, **3c**, **3e**, and **3g** in good to excellent yields (78–99%). The cycloisomerization/hydroethoxylation was also effective with phenyl- (entry 5) and benzyl-substituted (entry 6) alcohols, as the substituted furans **3h**,**i** were obtained in 71% and 99% yields.

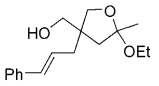
The addition of allyl alcohol was also very interesting as it could give an entry to further functionalization and other transition-metal-catalyzed reactions. Various substrates were efficiently converted into the corresponding allyloxy-substituted furans (entries 7–11). The reaction of diols **1a** and **1c**, which bear an (*E*)-cinnamyl and propargyl side chain, respectively, afforded the ketals **4a** and **4c** in high yields (entries 7 and 8). Benzyl-protected alcohols and allyl derivative **1g** (entries 9–11) could also be cyclized and functionalized to give furans **4e**, **4g**, and **4i** in 86–99% yield. These promising results prompted us to test the efficiency of our system for the formation of six-membered functionalized rings that are found as subunits of a number of cytotoxic natural products.[9d,12] Dimethyl 3-butynylmalonate[14] was alkylated in the presence of cinnamyl bromide to give the diester, which was subsequently reduced and monobenzylated to give the alcohol **1j**. Indeed, this cycloisomerization/hydroalkoxylation process is not limited to the synthesis of functionalized furans, as alcohol **1j** undergoes an equally facile and efficient Ir^I-catalyzed *exo*-selective tandem reaction to give, in 24 h, the functionalized pyrans **2j** and **3j** in high (99%) yield (Table 2, entries 12 and 13).

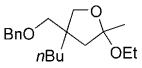
Next, we focused on the mechanism of the reaction. Two competitive mechanisms for this transformation may be envisioned, one based on a metal–vinylidene intermediate[6,8] and the other based on electrophilic alkyne activation.[3] Despite the fact that iridium catalysts can promote the formation of vinylidene intermediates from alkynes,[8] this mechanism was excluded owing to the *exo*-selective nature of the cyclization instead of the expected 6-*endo*-cyclization. A second mechanism based on the Lewis acidic character of the metal is much more probable (Scheme 2). The reaction may

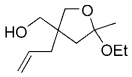


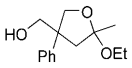
Scheme 2. Postulated mechanism for the formation of cyclic ketals from bis-homopropargylic alcohols.

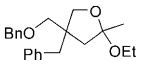
be initiated by the formation of the π-alkynyl complex **A** by the complexation of the unsaturated triple bond to the Ir^I catalyst. Subsequent addition of the alcohol, which was supposed to occur *anti* to the π-complex **A**,[3a] would lead to a σ-complex **B**, which is favored in polar protic solvents such as MeOH, via a transient zwitterionic intermediate.[15] Proton transfer may then be followed by the intermolecular addition of MeOH to give the cyclic ketal **2a**.[16,17] An alternate pathway involving an Ir^{III} hydride species, and therefore a reductive elimination, cannot be ruled out.

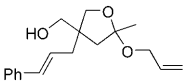


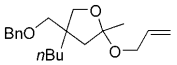


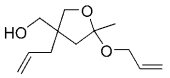


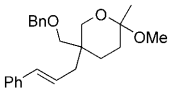


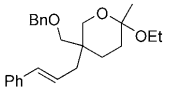












Labeling studies performed in the presence of 2.5 mol% of $[\{Ir(cod)Cl\}_2]$ either in CD_3OD for the cyclization of **1a** or in MeOH for the reaction of the deuterated alkyne $[D_1]$-**1a**

were in good agreement with the proposed mechanism, as the cycloisomerization/hydroalkoxylation reactions afforded the unique formation of the corresponding deuterated derivatives [D_6]-**2a** or [D_1]-**2a**, respectively (Scheme 3). No deuterium scrambling, which would result from insertion of iridium into a C–H(D) bond, was observed.

In summary, we have developed a general, efficient, and atom-economic method for the synthesis of cyclic ketals starting from easily accessible bis-homopropargylic alcohols. The [{Ir(cod)Cl}$_2$] dimer is used for the first time to promote a tandem cyclization/hydroalkoxylation reaction at room temperature in a very short time to give functionalized derivatives. The reaction conditions are compatible with various functional groups. Considering the ease of preparation of these substrates, this method provides a new route for constructing functionalized furanyl and pyranyl building blocks and is therefore a valuable tool for the synthesis of natural or biologically active products. The proposed reaction mechanism presumably involves a Lewis acid type activation, followed by an intramolecular cyclization, a protonolysis step, and the intermolecular addition of an alcohol molecule. The

high catalytic activity of [{Ir(cod)Cl}$_2$], along with the very mild reaction conditions, would probably allow the use of weaker nucleophiles, both as inter- and intramolecular partners.

Experimental Section

Representative standard procedure: A mixture of bis-homopropargylic alcohol **1a** (70 mg, 0.3 mmol) and [{Ir(cod)Cl}$_2$] (5.1 mg, 2.5 mol%) in degassed methanol (0.6 mL) was stirred under argon at room temperature for 30 min. After completion of the reaction, the mixture was filtered through a short pad of celite (eluent: EtOAc) and the solvents were evaporated under reduced pressure to give 79 mg of ketal **2a**. ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 1.43$ (s, 3H), 1.44 (s, 3H), 1.72 (d, $J = 13.3$ Hz, 1H), 1.84 (d, $J = 13.3$ Hz, 1H), 1.98 (d, $J = 13.3$ Hz, 1H), 2.00 (d, $J = 13.3$ Hz, 1H), 2.36–2.50 (m, 4H), 3.21 (s, 3H), 3.22 (s, 3H), 3.51–3.85 (m, 8H), 6.18 (dt, $J = 15.7$, 7.3 Hz, 2H), 6.47 (d, $J = 15.7$ Hz, 2H), 7.21–7.37 ppm (m, 10H). ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 21.0$, 21.8, 38.8, 41.8, 47.0, 47.7, 48.3, 48.6, 48.5, 48.7, 67.9, 68.0, 73.7, 73.9, 108.3, 108.5, 126.0, 126.4, 126.9, 127.5, 127.6, 128.8, 132.9, 133.7, 137.6 ppm. CI MS (NH_3): *m*/*z*: 248 $[M-MeOH+NH_4]^+$, 231 $[M-MeOH+H]^+$. HRMS calculated for $C_{15}H_{19}O_2$ $[M-MeOH+H]^+$: 231.1385; found 231.1389.

An Unusual Ditelluride: Synthesis and Molecular and Electronic Structures of the Dimer of the Tellurium-Centered Radical [TeP*i*Pr$_2$N*i*Pr$_2$PTe]$^{\bullet}$**

Tristram Chivers, Dana J. Eisler, Jamie S. Ritch, and Heikki M. Tuononen*

The coordination chemistry of diselenoimidodiphosphinate ligands [SePR$_2$NR$_2$PSe]$^-$ (**1a** and **1b**)[1] has been extensively investigated.[2] In a series of recent articles, O'Brien and co-workers demonstrated that metal complexes of the isopropyl derivative **1b** are suitable single-source precursors for the generation of thin semiconducting films such as MSe (M = Zn, Cd),[3] HgSe,[4] M$_2$Se$_3$ (M = Ga, In),[5] PbSe,[6] Bi$_2$Se$_3$,[7] and CuInSe$_2$,[8] as well as CdSe quantum dots.[9] The analogous tellurium-containing ligands were not available until recently when we described a new synthetic methodology that facilitated the generation of the phenyl derivative **1c.**[10] Since a reasonably high volatility is needed for metal complexes in CVD applications, we turned our attention to the synthesis of the isopropyl analogue **1d**, and its protonated precursor, **2**. We report herein that the attempted synthesis of **2** unexpectedly produced the dimer **3**, which can be viewed to result from the association of two tellurium-centered radicals [TeP*i*Pr$_2$N*i*Pr$_2$PTe]$^{\bullet}$. The monotelluride **4** is obtained as the P–H tautomer HP*i*Pr$_2$N*i*Pr$_2$PTe (**4a**) rather than the N–H tautomer **4b**.

The reaction of P*i*Pr$_2$NH*i*Pr$_2$P with one equivalent of tellurium in *n*-hexane at 23 °C produced **4** in 81 % yield. Complex **4** was characterized in solution by NMR spectroscopy and in the solid state by IR spectroscopy and an X-ray structural determination.[11] The NMR spectra indicated the preferential formation of the P–H tautomer **4a**; there was no indication of the presence of the N–H tautomer **4b**. The resonance for the P–H proton in the ^{1}H NMR spectrum appears as a doublet of doublets of multiplets located at δ = 6.34 ppm, with a $^1J_{P,H}$ coupling of 443 Hz, which is consistent with values reported for related systems.[13–16] In the ^{31}P{^{1}H} NMR spectrum, two mutually coupled signals for phosphorus are observed, one of which exhibits ^{125}Te satellites ($^1J_{Te,P}$ = 1654 Hz). In the proton-coupled ^{31}P NMR spectrum the other signal appears as a doublet ($^1J_{P,H} \approx$ 445 Hz) of multiplets. The solid-state IR spectrum of **4a** exhibits a sharp band at 2329 cm^{-1}, which is in the middle of the range of values (2200–2460 cm^{-1}) reported for analogous compounds with a P^V–H functionality.[13–16]

The X-ray crystal structure (Figure 1) confirms the assignment of **4a** as the P–H tautomer. The P–H proton was located in the electron difference map and refined. The two P–N bond lengths are significantly different (P1–N1 1.622(2) versus P2–N1 1.589(2) Å). The phosphorus–tellurium bond length of 2.3798(8) Å is similar to that observed in related compounds that contain a terminal P=Te bond.[17] The preferential formation of the P–H tautomer, **4a**, may be contrasted with the series of monochalcogenides

Selected bond lengths [Å] and angles [°] [calculated values are given in brackets]: Te1–Te1A 2.946(1) [2.954], P1-Te1 2.489(2) [2.475], P2-Te2 2.394(2) [2.388], P1-N1 1.571(5) [1.610], P2-N1, 1.623(5) [1.642], P1-N1-P2 135.2(3) [124.5], τ P1-Te1-Te1A-P2 180.0 [180.0], τ Te1A-Te1-P1-N1 147.7 [135.1], τ Te1-P1-N1-P2 30.1 [37.7], τ P1-N1-P2-Te2 2.4 [10.0].

$PPh_2NHPh_2P(E)$ (E = O, S, Se), which all exist exclusively as the N–H tautomer, both in solution and in the solid state.[18,19] Consequently, we prepared the monoselenide by stoichiometric oxidation of $PiPr_2NHiPr_2P$ with selenium in *n*-hexane at 23 °C. This product also exhibits the characteristic spectroscopic signatures of a P^V–H functionality, namely, a signal centered at $\delta = 6.49$ ppm with $^1J_{PH} = 441$ Hz in the ^{1}H NMR spectrum and a strong band at 2342 cm^{-1} in the IR spectrum. Substituents that increase the basicity of the lone pair on the phosphorus atom are known to favor the formation of the P–H tautomer in related systems, for example, $HP(NMe_2)_2NPPh_2S$.[16] The present results show that a change in the substituent on the phosphorus atom from phenyl to isopropyl is sufficient to tip the balance in favor of the P–H tautomer.

Attempts to oxidize both phosphorus(III) centers in $PiPr_2NHiPr_2P$ by the direct reaction with tellurium to give **2** were unsuccessful under a variety of reaction conditions. During the course of these investigations, it was observed that direct exposure of pale-yellow solutions of **4a** to air resulted in the rapid formation of deep red solutions from which dark red, X-ray quality crystals of **3** could be grown. An X-ray crystal-structure determination revealed that **3** is the centrosymmetric dimer $[(TeP iPr_2NP iPr_2Te\text{-})_2]$ (Figure 2).[20]

The Te–Te interatomic distance of 2.946(1) Å in **3** indicates a significantly weaker bond than those in organic ditellurides (2.72–2.76 Å)[21] or that in the dianion $[Te–Te]^{2-}$ (2.79 Å).[22] The two P–Te bonds in **3** differ in length by about 0.1 Å, with the shorter separation indistinguishable from that observed for the terminal P=Te bond in **4a**. The metrical parameters of the P-N-P backbone in **3** and **4a** are also similar. In light of the structural determination, an alternative high-yield (87 %) synthesis of **3** was devised that involved the stoichiometric oxidation of the sodium salt of **1d** with iodine.

Complex **3** can be viewed as involving the association of two $[TeP iPr_2NHiPr_2PTe]^{\bullet}$ radicals through a Te···Te contact. To gain some insight into the nature of the bonding in **3**, we have carried out density functional theory (DFT) calculations for the model system $[(TePMe_2NPMe_2Te\text{-})_2]$ and the corresponding radical $[TePMe_2NPMe_2Te]^{\bullet}$.[23] The structure optimized with the PBE0/TZVP functions for the C_i symmetric dimer is in reasonable agreement with the X-ray crystal structure of **3** (Figure 2). Of particular note, the calculated Te–Te bond length is 2.954 Å, compared with 2.946(1) Å in **3**. The structure of $[TePMe_2NPMe_2Te]^{\bullet}$ is C_2 symmetric and the radical has a ^{2}B doublet ground state. The calculated Te–P and P–N bond lengths are 2.431 Å and 1.626 Å, respectively. The P-N-P and Te-P-N bond angles are 123.2° and 115.7°, respectively, and the dihedral angle τ Te-P-N-P is 23.8°. A comparison with the metrical parameters of the ditelluride shows the bond angles to be virtually identical and the bond lengths and the dihedral angle to be exactly averages of the bond parameters found for the monomeric unit in the dimer.

The bonding interaction between the singly occupied molecular orbitals (SOMOs) of two radicals is depicted in Figure 3. The SOMO is an almost pure linear combination of

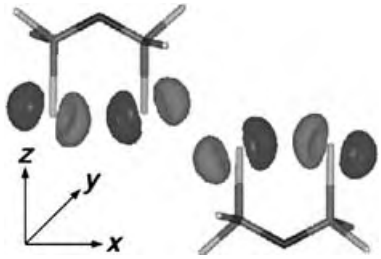

Figure 3. The bonding interaction between two $[TePMe_2NPMe_2Te]^{\bullet}$ SOMOs (±0.065 isosurface level). Hydrogen atoms are omitted for clarity.

tellurium p_x and p_y orbitals. Mulliken population analysis shows that the spin-density distribution mirrors the composition of the SOMO and is equally distributed among both tellurium centers. The spin densities on both nitrogen and phosphorus atoms are very small, 0.004 and 0.009, respectively. Consequently, the EPR spectrum of $[TePR_2NPR_2Te]^{\bullet}$ is expected to show large hyperfine couplings to two tellurium atoms and only very small couplings to nitrogen and two phosphorus centers. The calculated hyperfine coupling con-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

stants validate this hypothesis; hyperfine couplings of −68.1, 4.8, and −0.8 G were obtained for ^{125}Te, ^{31}P, and ^{14}N, respectively. Dissociation of the dimer, **3**, into the corresponding radical was not detectable by EPR spectroscopy in hexane, toluene, or THF solutions within the temperature range 20–90 °C.

In view of the modest steric protection around the radical centers in $[TePMe_2NPMe_2Te]^{\bullet}$ and the composition of the spin density in the SOMO, both the ease and the direction of the dimerization are apparent (see Figure 3). However, the spatial orientation of monomers in the dimer and the multicentered nature of the radical SOMO effectively weakens the Te–Te bonding interaction in $[(TePR_2NR_2Te\text{-})_2]$ compared with that in organic ditellurides, RTe–TeR. The calculated dimerization energy for the reaction $2\,[TePMe_2NPMe_2Te]^{\bullet} \rightarrow [(TePMe_2NMe_2Te\text{-})_2]$ is −80 kJ mol^{-1}, (Te–Te, D = 138 kJ mol^{-1}).[27] An electron localization function (ELF)-based[28] bonding analysis is in agreement with this result as it revealed that no pure disynaptic, bonding, valence basin can be found between Te1 and Te1A. This finding indicates a Te–Te covalent bond order of less than one for $[(TePMe_2NMe_2Te\text{-})_2]$. Calculations done for the R = H derivative $[(TePH_2NH_2Te\text{-})_2]$ show that the absence of organic R groups allows the dimeric structure to deform, and a twisted C_1 symmetric structure with a Te–Te bond length of 2.802 Å now becomes the global minima. However, the predicted Te–Te bond length for the *tert*-butyl derivative $[(TeP\textit{t}Bu_2N\textit{t}Bu_2Te\text{-})_2]$ is 3.010 Å, which implies that the use of very bulky substituents on the phosphorus atom may foster dissociation into the radical monomer $[TePR_2NPR_2Te]^{\bullet}$.

The NMR spectra of **3** exhibit broad signals at room temperature. The broad signal observed in the $^{31}P\{^1H\}$ NMR spectrum at 23 °C $[D_8]$THF resolves into two signals at 0 °C, which sharpen into mutually coupled doublets (δ = 45.8 and 42.2 ppm) at −60 °C. Each signal exhibits ^{125}Te satellites. The magnitude of the $^1J_{Te,P}$ coupling constants differs substantially (1500 versus 1026 Hz), which reflects the difference in the P–Te bond lengths. At +80 °C in $[D_8]$toluene, a relatively narrow signal at δ = 43 ppm ($\Delta\omega_{1/2} \approx 80$ Hz) with ^{125}Te tellurium satellites is observed. The value of the $^1J_{Te,P}$ (1290 Hz) is approximately the average of the two distinct coupling constants observed at −60 °C. Thus, the ^{31}P NMR spectroscopic data indicate that a rapid exchange process that leads to equivalent phosphorus environments on the NMR time scale occurs above 0 °C. Attempts to distinguish between an intermolecular and an intramolecular exchange process by variable-concentration ^{31}P NMR spectroscopy experiments were inconclusive as a result of the very low solubility of **3**.

In summary, the characterization of the novel ditelluride **3** represents a new aspect of the well-studied chemistry of dichalgenoimidodiphosphinate ligands. The facile formation of **3** suggests that the synthesis of potential single-source precursors of binary metal tellurides from reactions of the anionic ligand **1d** with metal halides may be accompanied by a redox transformation for certain p- or d-block metals. Compound **3** also exemplifies a new type of reagent for the direct synthesis of ditelluroimidodiphosphinate complexes by oxidative addition to electropositive metal centers, for example, upon photochemical activation.

Experimental Section

All reactions and the manipulations of products were performed under an argon atmosphere by using standard Schlenk techniques or an inert atmosphere glove box. Solvents were freshly distilled, dried, and degassed prior to use. NMR spectra were obtained by using a Bruker AMX 300 spectrometer. ^{125}Te NMR spectra were referenced to the external standard Te_2Ph_2. The reagent $[(tmeda)NaN(P\textit{i}Pr_2Te)_2]$ (tmeda = *N*,*N*,*N*′,*N*′-tetramethyl-1,2-ethanediamine)was prepared by modification of the procedure reported for the corresponding phenyl derivative.[10]

3: A solution of $[(tmeda)NaN(P\textit{i}Pr_2Te)_2]$ (0.204 g, 0.32 mmol) in THF (25 mL) was cooled to −78 °C and a cold (−78 °C) solution of I_2 (0.040 g, 0.16 mmol) in THF (25 mL) was added dropwise by cannula over 15 min. The resulting cherry red solution was stirred at −78 °C for 30 min and then warmed slowly to 23 °C to give a deep red solution, which was stirred for an additional 30 min. The solvent was removed in vacuo and the residue was dissolved in toluene then filtered to remove NaI. Toluene was then removed in vacuo to afford **3** as a dark red powder (0.138 mg, 87 %). Elemental analysis calcd (%) for $C_{24}H_{56}N_2P_4Te_4$: C 28.62, H 5.61, N 2.78; found: C 29.07, H 5.66, N 2.64; ^{1}H NMR ($[D_8]$THF, 23 °C): δ = 2.23 (br, 4H; C*H*-$(CH_3)_2$), 1.31 (d, ^3J(H,H) = 6 Hz, 6H; CH(C*H*$_3$)$_2$), 1.25 (d, ^3J(H,H) = 6 Hz, 12H; CH(C*H*$_3$)$_2$), 1.19 ppm (d, ^3J(H,H) = 6 Hz, 6H; CH-(C*H*$_3$)$_2$); $^{31}P\{^1H\}$ NMR: δ = 42.4 ppm (br); ^{1}H NMR (−60 °C): δ = 2.36 (m, 2H; C*H*$(CH_3)_2$), 1.95 (m, 2H; C*H*$(CH_3)_2$), 1.44, 1.39, 1.30, 1.24, 1.17, 1.15, 1.11, 1.08 ppm (eight doublets, ^3J(H,H) = 6 Hz, 3H each; CH(C*H*$_3$)$_2$); $^{31}P\{^1H\}$ NMR: δ = 45.8 (d, ^2J(P,P) = 26 Hz, ^1J-(^{125}Te,P) = 1026 Hz), 42.2 ppm (d, ^2J(P,P) = 26 Hz, ^1J(^{125}Te,P) = 1500 Hz). X-ray quality crystals of **3** were grown from a THF/*n*-hexane solution.

4: *n*-Hexane (120 mL) was added to a mixture of elemental tellurium (1.20 g, 9.40 mmol) and $P\textit{i}Pr_2NH\textit{i}Pr_2P$ (2.00 g, 8.02 mmol) and the mixture was stirred at 23 °C for 16 h. The resulting pale yellow solution was filtered and concentrated to about 10 mL, which caused **4** to precipitate as a pale yellow crystalline solid (2.45 g, 81 %). Elemental analysis calcd (%) for $C_{12}H_{29}NP_2Te$: C 38.24, H 7.76, N 3.72; found: C 38.59, H 7.73, N 3.76; ^{1}H NMR ($[D_8]$toluene, 23 °C): δ = 6.34 (ddm, ^1J(P,H) = 443 Hz, ^3J(P,H) = 10 Hz, 1H; PH), 1.86 (m, 4H; C*H*$(CH_3)_2$), 1.14, 1.10, 1.08, 1.04, 0.93, 0.90, 0.87, 0.84 ppm (eight doublets, ^3J(H,H) = 6 Hz, 3H each; CH(C*H*$_3$)$_2$); $^{31}P\{^1H\}$ NMR: δ = 48.2 (d, ^2J(P,P) = 18 Hz, ^1J(^{125}Te,P) = 1654 Hz; P(Te)), 44.0 ppm (d, ^2J(P,P) = 18 Hz; PH); $^{125}Te\{^1H\}$ NMR: δ = −846 ppm (dd, ^1J-(^{125}Te,P) = 1642 Hz, ^3J(^{125}Te,P) = 13 Hz).

Synthesis of Nanoscopic Optical Fibers Using Lipid Membranes as Templates**

*Gopakumar Gopalakrishnan, Jean-Manuel Segura, Dimitrios Stamou, Cédric Gaillard, Marinela Gjoni, Ruud Hovius, Kurt J. Schenk, Pierre A. Stadelmann, and Horst Vogel**

Nanostructures of various materials with different sizes and shapes have been synthesized and studied in the past few years as a result of their high impact in optoelectronic applications. In particular, one-dimensional (1D) nanostructures (nanowires, nanorods, nanotubes, etc.) show optical and electronic properties[1] that are of importance to downsize optoelectronic components to the nanometer scale.[2] The development and integration of such 1D nanostructures relies on suitable synthetic procedures. Several methods have been designed such as template-directed synthesis,[3–6] solvothermal synthesis,[7] microfabrication,[8] metal-nanocluster-catalyzed growth,[1a] and surfactant-mediated self-assembly.[9] In particular, template-directed synthesis offers significant advantages: ease of performance, the possibility to work under mild reaction conditions, and above all the control over unique, well-defined morphologies of the resulting nanostructures. Various kinds of templates, such as porous alumina,[3] molecular sieves,[4] proteins,[5a] DNA,[5b] viruses,[5c] and self-assembled monolayers,[6] have been reported to guide the synthesis of 1D nanostructures. The critical issues in many template-directed syntheses are to obtain high yields and to achieve monocrystallinity.

Until now, lipid bilayers have not been used as templates for asymmetric synthesis although they are well-known self-organized nanostructures. The closed compartments of single phospholipid vesicles have already been used as nanoreactors to perform simple chemical reactions.[10,11] Upon drying from aqueous dispersions, many phospholipids spontaneously form well-organized periodic multilayers of lipid membranes separated by distinct nanometer-thick water films.[12] The rich variability of the lipid hydrocarbon chains and lipid polar head groups results in numerous lyotropic and thermotropic phases.[12] Of particular interest in the present context are lipid polar head groups that bind certain cations selectively and reversibly. This opens the possibility to modulate the concentration of precursor ions, for example, when a second reactant is added, and thus control the synthesis of nanomaterials in the confined, nanometer-sized water films of multilamellar lipid phases. Here, we have applied this strategy to synthesize high-aspect-ratio (≈ 1000) cadmium chloride nanowires, which exhibit interesting optical properties when doped in situ with fluorescent CdS quantum dots.

The nanowires were synthesized in hydrated, multilamellar stacks of lipid bilayers comprising lipid-bound Cd^{2+} ions. A proper design of the lipid template was crucial for the formation of nanowires. The lipid bilayers comprised 70 mol% of 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine (DMPC), which acts as a stable matrix, and 30 mol% of a thiolipid, 1,2-dilauroyl-*sn*-glycero-3-phosphothioethanol (DLPSH), which was added for its strong ability to bind Cd^{2+} ions through the -SH groups (see Supporting Information). With a molar ratio of lipid/Cd^{2+} of about 2, large quantities of Cd^{2+} ions were complexed by the lipid head groups. Upon exposure to HCl vapor, Cd^{2+} ions were released as a result of competitive binding of protons to the polar lipid head groups,[13] leading to supersaturation of Cd^{2+} ions in the nanometer-sized water film and finally to the initiation of growth of nanowires. When either the concentration of Cd^{2+} was reduced by a factor of two or DLPSH was omitted, no nanowires were formed which shows that a critical concentration of Cd^{2+} is necessary (see Supporting Information).

The nanowires show high aspect ratios with a narrow distribution of diameters ranging from 80 to 200 nm and lengths extending up to 170 μm (Figure 1a). The lengths of the nanowires could be tuned by varying the duration of exposure to HCl while the diameters showed little variation. Transmission electron microscopy showed that the nanowires are monocrystalline along their entire lengths (Figure 1b). Selected-area electron diffraction patterns revealed that the nanowires are composed of orthorhombic $CdCl_2 \cdot 4H_2O$ crystals grown along the [100] direction (Figure 1c).

The synthesis of anisotropic structures requires that the template, here the lipid lamellar phase, restricts or promotes the growth in specific directions. Orthorhombic $CdCl_2 \cdot 4H_2O$ consists of [001] molecular chains formed by edge-sharing $[CdCl_4(H_2O)_2]^{2-}$ octahedrons (Figure 2a) that define a preferential growth direction along the octahedral chain axis to result in slightly elongated crystals of $CdCl_2 \cdot 4H_2O$ when

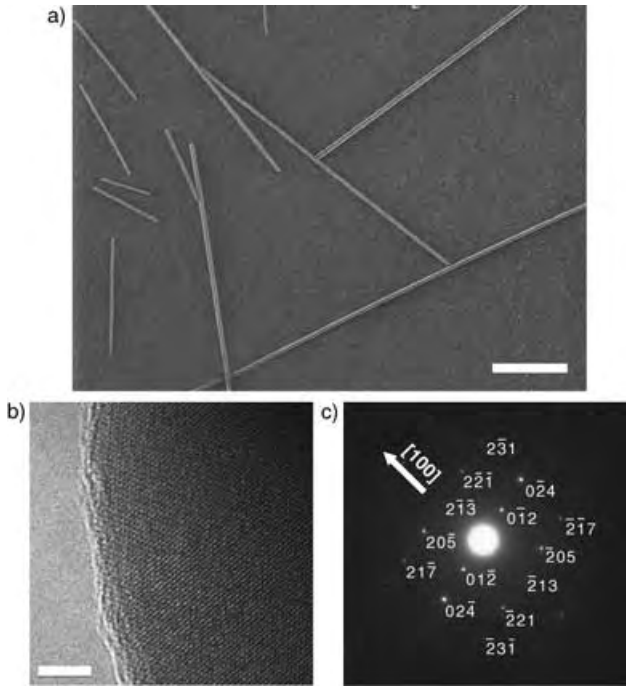

Figure 1. a) Scanning electron micrograph of typical $CdCl_2{\cdot}4\,H_2O$ nanowires illustrating the high aspect ratios. In this particular image, diameters of the nanowires are around 100 nm and lengths range from 1.5 μm up to more than 20 μm (scale bar = 2 μm). b) High-resolution transmission electron micrograph of the edge of a nanowire showing the regular atomic arrangement in the crystal lattice (scale bar = 5 nm). c) Selected-area electron diffraction pattern on a nanowire, with indexation corresponding to orthorhombic $CdCl_2{\cdot}4\,H_2O$. The arrow indicates the [100] direction, which is the long axis as well as the growth direction of the nanowires.

grown in aqueous solution.[14] It is remarkable that the growth direction of our nanowires is perpendicular to the preferential growth direction of bulk $CdCl_2$ crystals. Online monitoring of the synthesis of nanowires indicates that the initiation of growth critically depends on a rate-limiting step. Two sequential phases were observed with the rapid appearance of small nucleation points followed, after a certain delay, by the sudden and continuous, nonsynchronous 1D growth of the crystals (see Figure 2b and Supporting Information). By using fluorescent lipids, a close colocalization of lipids and nanowires was observed which demonstrates that the lipid membranes are intimately involved in the growth of the nanowires (Figure 2c). Taking these observations together, we propose a mechanistic model for the unusual, asymmetric growth of the nanowires. $CdCl_2{\cdot}4\,H_2O$ crystal nuclei grow unperturbed up to a critical size, at which point a collective binding of numerous protonated, positively charged head groups of the planar lipid membranes to the crystal planes that are rich in Cl^- (i.e. high negative-charge density) becomes favorable. This occurs for all crystal planes except the (100) plane, in which Cl^- ions are shielded by a layer of coordinated water molecules, thus inhibiting growth in these directions.

While $CdCl_2{\cdot}4\,H_2O$ crystals are nonfluorescent, CdS compounds and particularly their nanocrystals, show size-dependent fluorescence. To provide the nanowires with fluorescence properties, HCl vapor was supplemented with H_2S during the growth process. As a result, the nanowires became intensely fluorescent with high photostability as shown in the confocal image of Figure 3a, while a weak diffuse background fluorescence was observed within the lipid bilayer stacks. The diffuse fluorescence in the lipid stacks featured a broad emission band upon excitation at 458 nm, with a maximum at 522 nm typical for CdS nanoparticles (see Figure 3b and Supporting Information). TEM images revealed a heterogeneous mixture of crystallites of CdS nanoparticles (Figure 3c). Single nanoparticles were also detected by optical microscopy at high excitation intensities as diffraction-limited spots[15] in the middle of a fluorescent background (see Figure 3d and Supporting Information). The nanowires exhibited spectra that are identical to that of the diffuse background in the lipid stacks which shows that their fluorescence results from associated CdS nanoparticles. No nanoparticles could be observed by TEM on the surface of the nanowires which suggests that they intercalate in the $CdCl_2{\cdot}4\,H_2O$ lattice during crystal growth (see Supporting Information).

The extended length of the nanowires as well as their diameter, which is on the order of 100 nm, make them

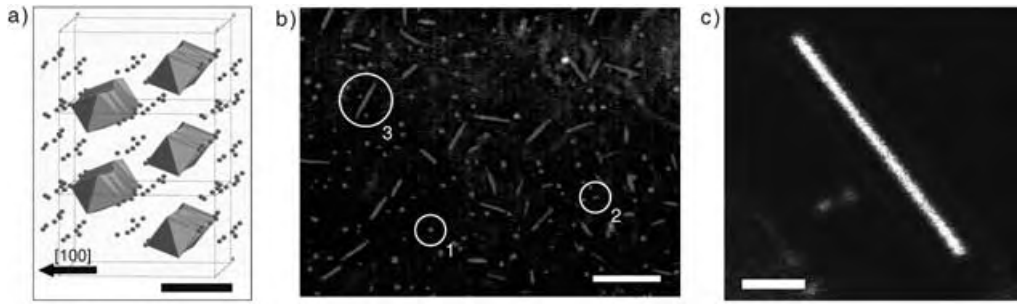

Figure 2. a) Crystal structure of orthorhombic $CdCl_2{\cdot}4\,H_2O$ showing the 1D molecular chains formed by edge-sharing $[CdCl_4(H_2O)_2]^{2-}$ octahedrons. The arrow indicates the [100] growth direction (scale bar = 6 Å; see Supporting Information for a more-detailed crystal structure). b) White-light transmission image of growing nanowires. As the initiation of growth is asynchronous, the various phases of the growth of the nanowires are present in a single image. Growth of nanowires occurs in two distinct steps: first, numerous nucleation points appear (1); after a while, some nucleation points grow into small nanowires (2); these latter continuously elongate upon addition of HCl vapor (3) without noticeable change in the diameter (scale bar = 60 μm). c) Fluorescence confocal image showing colocalization of a nanowire and rhodamine-labeled lipids (scale bar = 2 μm, λ_{ex} = 543 nm, λ_{em} = 560–610 nm).

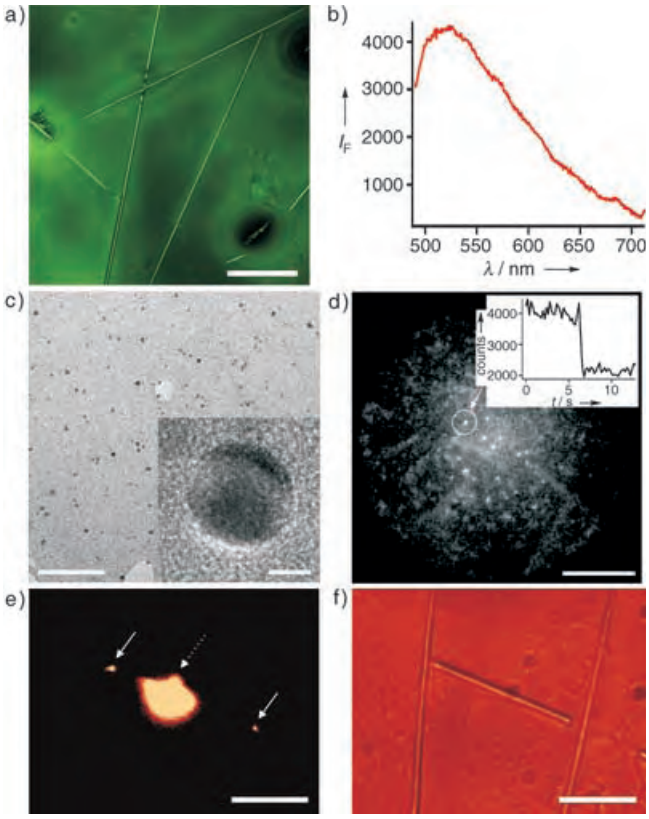

Figure 3. a) Fluorescence confocal image of nanowires (false color) grown in presence of H_2S showing that the as-prepared 100 μm-long nanowires are intensely fluorescent (scale bar = 20 μm, λ_{ex} = 488 nm, λ_{em} = 505–550 nm). b) Fluorescence emission spectrum of a single washed nanowire upon excitation at 457.9 nm. The emission maximum is at 522 nm with a full width at half-maximum larger than 100 nm. The spectrum of the fluorescent background is identical. c) Transmission electron micrograph of the background lipid multilayers showing the presence of a heterogeneous mixture of nanometer-sized CdS crystallites (scale bar = 200 nm). The inset shows the high-resolution transmission electron micrograph of a CdS nanoparticle (scale bar = 5 nm). d) Wide-field image showing single quantum dots, recognized as diffraction-limited spots, which appear in a structureless fluorescent background. Only a small fraction of the quantum dots is observed at the single-quantum-dot level owing to the stringent requirements for such observations, while the major fraction contributes to the structureless fluorescent background. The inset shows a time trace of the emission from the encircled quantum dot which features the characteristic single-step photobleaching (scale bar = 10 μm, λ_{ex} = 457.9 nm, integration time = 100 μs, measurement frequency = 5 Hz). e) False-color photoluminescence image of a nanowire upon local excitation at the middle (dotted arrow) with excitation at 488 nm. Luminescence is observed at the excitation location (dotted arrow) and from both ends (solid arrows) as result of optical waveguiding along the nanowire (scale bar = 10 μm). f) The corresponding false-color white-light transmission image of the nanowire (scale bar = 10 μm).

attractive candidates for optical waveguiding.[1a,16] When fluorescent nanowires were locally excited, fluorescence emission was detected not only at the excitation spot but also from the ends of the nanowires (Figure 3e and f). Nanowires waveguide light over tens of micrometers, thus acting as effective nanoscopic optical fibers. The ability to waveguide light is associated with the high refractive index of the nanowires, n_{nw}, which is expected to lie between the refractive indices of pure $CdCl_2 \cdot 2.5\,H_2O$ ($n = 1.65$) and CdS ($n = 2.5$). The corresponding minimal diameters, D, needed for the nanowire to act as a single-mode optical waveguide at the emission maximum at $\lambda = 520$ nm are thus between 80 and 190 nm by using the relationship, $D = (\lambda/\pi)(n_{nw}^2 - n_{medium}^2)$, where n_{medium}, the refractive index of the medium, is 1.4. The range of diameters found for the nanowires fall well within the theoretical sizes of the optical waveguides.

In conclusion, a novel synthetic route for state-of-the-art nanowires has been presented based on lipid membranes as an anisotropic template. This allows a straightforward, high-yield production of high-aspect-ratio monocrystalline nanowires under mild reaction conditions. The synthesized $CdCl_2 \cdot 4\,H_2O$ nanowires can be furthermore endowed with fluorescent properties by addition of H_2S. The appearance of highly fluorescent CdS quantum dots demonstrates that such nanoparticles can be synthesized in the confined interlamellar water film which might open novel synthetic routes for quantum dots. Our fluorescent nanowires could find a broad range of applications in optoelectronics, for instance in the development of nanolasers, as a complement to CdS nanowires.[1a] We furthermore speculate that this novel procedure using lipid membranes as templates may be extended to the synthesis of other materials by exchanging the thiolipid with other lipids that have suitable head groups which reversibly bind various ions. The possibility to manipulate the nanowires laterally, for instance by using laser tweezers (see Supporting Information) encourages the use of these nanowires for the nanofabrication of devices. In this respect, particularly attractive are the recent developments to form networks of lipid vesicles and lipid nanotubes,[11] which may be used as a template to build an array of connecting nanowires, opening a way to preassemble nanocomponents for future optoelectronics.

Experimental Section

Synthesis of nanowires: Solutions of DMPC (4 mM (Fluka); 100 μL) and DLPSH (16 mM (Avanti Polar Lipids); 10 μL) in chloroform were mixed and dried in vacuum, and the resulting lipid film was hydrated in deionized water (110 μL) at room temperature for 10 min. An aqueous solution of $CdCl_2$ (10 mM (Fluka); 30 μL) was added, then the mixture was dispersed for 5 min in a bath sonicator. A 15-μL aliquot of the obtained clear solution of vesicles was transferred onto a microscope glass coverslip and dried in vacuum. The resulting transparent lipid film was rehydrated in a 100 % humid atmosphere in a closed desiccator at 60 °C for 3 h. Then, a recipient containing 32 % hydrochloric acid (Merck) was inserted in the desiccator, and the lipid film was incubated for another 2 h with maintained humidity while the temperature was slowly decreased from 60 °C to room temperature. To produce fluorescent nanowires, the procedure was identical except that HCl was mixed with a small flake of FeS (Fluka, Germany) to produce H_2S while the dessicator was evacuated (400 mbar) to enhance the production of H_2S. A typical synthesis yielded around 1×10^6 nanowires of which 10–20 % showed lengths that exceeded 20 μm (see Supporting Information). Changing the ratio of DLPSH to DMPC reduced the yield and afforded shorter nanowires. Lipids could be removed from the produced nanowires by washing with toluene (Fluka). To observe colocalization of lipids and

A Stable Structurally Characterized Phosphorus-Bound Isocyanide and Its Thermal and Catalyzed Isomerization to the Corresponding Cyanide**

*Jesudoss V. Kingston, Arkady Ellern, and John G. Verkade**

Although the chemistry and structural characteristics of carbon-bound isocyanides and cyanides have been well documented,[1] the relatively few examples of isocyanides that possess CN–heteroatom bonds are largely restricted to sulfur, nitrogen, oxygen, and phosphorus heteroatoms.[2–6] Isocyanides that are bound to heteroatoms are chemically reactive, thermally unstable, and, thus, are readily isomerizable to the corresponding cyanides, which are more stable. Indeed, these properties were reported for the first and only time 30 years ago by Stec et al. for a phosphorus-bound isocyanide.[7] The cationic halogen-bearing azaphosphatranes **1a** and **1b** are robust species stabilized by relatively short

$N_{ax}\rightarrow P$ transannular bonds (ax = axial).[8] It occurred to us that the pseudo-halogen character of the CN group might allow the formation of similarly stabilized isocyano analogues, which might isomerize to the cyano-bound species sufficiently slowly to be monitored by spectroscopic means. Herein, we report the facile synthesis of such analogues that were sufficiently stable to permit the structural parameters of a phosphorus-bound isocyano group and its cyano isomer to be determined for the first time and the thermal and Lewis acid catalyzed transformations of the P–NC species into the

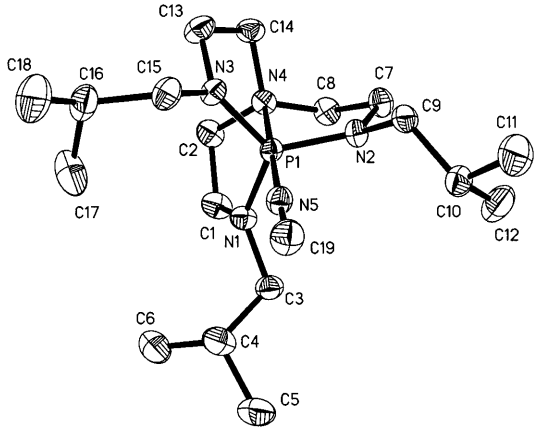
isomeric P–CN species to be followed by ^{31}P NMR spectroscopic analysis.

The reaction of proazaphosphatranes **2a** and **2b** with bromine at room temperature resulted in the formation of **1c** and **1d**, respectively, in near quantitative yield (Scheme 1) as

Scheme 1. Synthesis of isocyano azaphosphatranes **1e** and **1f**.

pale yellow solids that are soluble in polar solvents. Trimethylsilyl cyanide reacted quickly with **1c** and **1d** at room temperature in dry acetonitrile (Scheme 1), and immediate removal of all volatiles at room temperature resulted in the formation of off-white solids. Characterization of the product from **2b** revealed the first example of a stable species **1f** that possesses a P–NC linkage, and the product from **2a** was found to be a mixture of **1e** and **1g**. The ^{31}P NMR spectrum of **1f** in solution showed a signal at $\delta = -40.3$ ppm (−40.8 ppm, solid-state ^{31}P MAS NMR spectroscopy). A strong isocyanide stretching vibration at 2088 cm^{-1} that is comparable with the N–C stretching frequencies reported for other known examples of heteroatom-bound isocyanides[6] was observed in the IR spectrum. The ^{13}C NMR spectrum of **1f** showed a doublet at $\delta = 173$ ppm with ^{2}J(P-C) = 26.4 Hz that is assignable to the isocyanide carbon atom. Compound **1f** is stable in the solid state and can be stored in an inert atmosphere at room temperature without observable decomposition or isomerization for at least one month. A single crystal of **1f**[9] suitable for X-ray crystallographic study was obtained by recrystallization from a cooled solution of acetonitrile/diethyl ether. Its molecular structure revealed a trigonal-bipyramidal geometry about the phosphorus center with a P–N_{ax} bond length of 1.9178(13) Å and an apical isocyano group with P–N and N–C bond lengths of 1.7814(14) and 1.154(2) Å, respectively (Figure 1; see also the Supporting Information). The stability of **1f** may, at least in part, be attributed to a linear delocalized



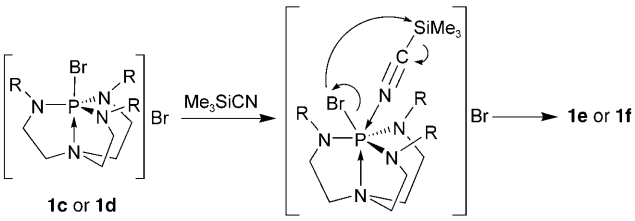


Figure 1. Molecular structure of isocyano azaphosphatrane **1f**.[9]

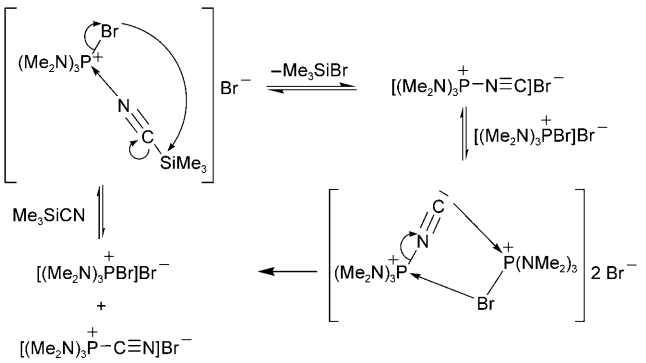
four-center six-electron σ-bonding framework along the pseudo-threefold axis of the cation. Interestingly, when the reaction of trimethylsilyl cyanide was attempted with the acyclic trisaminophosphine analogue (namely, $[(Me_2N)_3PBr]Br$),[10] no product formation was observed at room temperature over 16 h. At 80 °C, however, the cyanophosphonium salt $[(Me_2N)_3PCN]Br$ formed quantitatively in 48 h.

The initial formation of isocyanides **1e** and **1f** in the reaction of trimethylsilyl cyanide with **1c** and **1d**, respectively, is intriguing. Useful speculation on a reasonable pathway from **1c** and **1d** to **1e** and **1f**, respectively, is somewhat complicated by the assertion that Me_3SiCN exists in equilibrium with its more reactive isocyanide isomer.[11] However, the formation of Me_3SiNC is rather slow in solution (albeit in 1-chloronaphthalene rather than MeCN), thus taking approximately 10 minutes at 225 °C to reach an approximate concentration of 0.15 % relative to that of the cyano isomer.[12] It is therefore reasonable to conclude that this equilibrium would be reached even more slowly at room temperature, thus suggesting that the provenance of the isocyano isomers **1e** and **1f** and, through their isomerization, the cyano isomers **1g** and **1h**, respectively, is Me_3SiCN and not Me_3SiNC because of the almost instantaneous formation of **1e** and **1f** at room temperature.



It has also been reported that the ability of Me_3SiCN to act as a source of either cyanide or isocyanide in reactions with ketones and epoxides is greatly affected by the presence of hard or soft Lewis acids that favor the formation of C–CN and C–NC linkages, respectively.[13] Compounds **1c** and **1d** could possess soft Lewis acid character, thus leading to the creation of the corresponding isocyanide isomers as the kinetically favored stable species **1e** and **1f** (Scheme 2). It is

Scheme 2. Possible mechanism for the formation of isocyanides **1e** and **1f**.

interesting in this regard that acyclic $[(Me_2N)_3PBr]Br$ does not form detectable amounts of $[(Me_2N)_3PNC]Br$ with Me_3SiCN but rather gives $[(Me_2N)_3PCN]Br$ (albeit only on heating). The preferential formation of the cyano isomer in the latter reaction may be associated with the harder Lewis acidity of the phosphorus center in the cation of $[(Me_2N)_3PBr]Br$ as a result of the greater concentration of positive charge at the phosphorus center than in **1d**, which delocalizes this charge more extensively over the nitrogen atoms. Therefore, it is possible that $[(Me_2N)_3PNC]Br$ is formed kinetically followed by rapid isomerization (Scheme 3). As the reaction proceeds, the Lewis acid catalyst, the $[(Me_2N)_3PBr]^+$ ion, in Scheme 3 would be replaced by Me_3SiBr (see later) or by the $[(Me_2N)_3PCN]^+$ ion as a Lewis

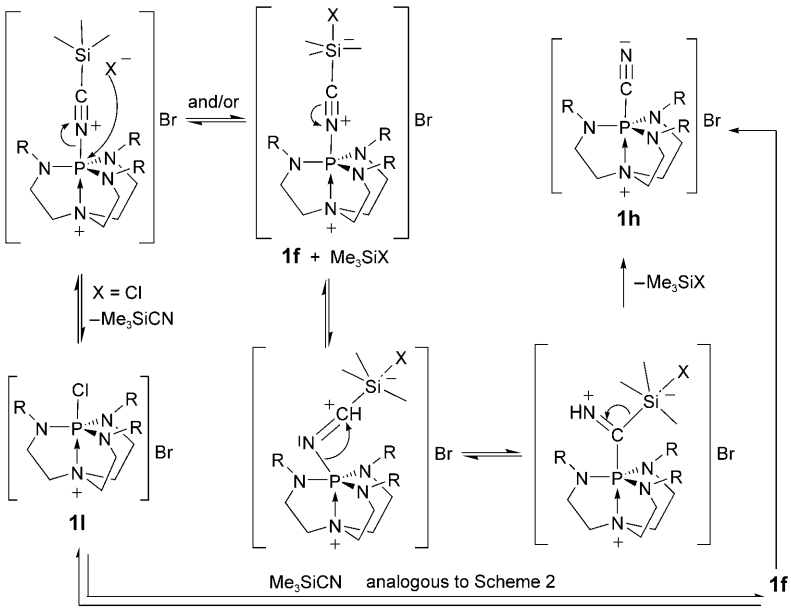
acid isomerization catalyst (Scheme 4). However, the $[(Me_2N)_3PCN]^+$ ion in this role would form an unlikely dicationic intermediate. Such a mechanism might be contemplated, however, for the thermal isomerization of **1e** and **1f**



Scheme 4. Possible mechanism for the self-catalyzed isomerization of $[(Me_2N)_3PNC]Br$ to $[(Me_2N)_3PCN]Br$.

because the analogous intermediate $^+\overline{P(RNCH_2CH_2)_3N}^+$ is isoelectronic with boratrane ($\overline{B(OCH_2CH_2)_3N}$) (**4**), the structure of which has been determined by X-ray crystallographic studies.[14] Dipositive heterocyclic cations with charges on adjacent atoms are known, as in the cases of $^+\overline{S[(CH_2)_x]_2S}^+$ in which $x = 2$ or 3[15ab] and $^+\overline{P[(CH_2)_x]_3P}^+$ in which $x = 3$ or 4.[15c]

Heating a solution of **1f** in acetonitrile at 80 °C resulted in quantitative isomerization to **1h** in 120 h, as shown by ^{31}P NMR spectroscopic analysis. The rate of isomerization of **1f** was found to be dramatically influenced by the solvent polarity (Table 1, entries 1 and 2) and the presence of one equivalent of a Lewis acid (see Schemes 3–5 and the Supporting Information). Almost instantaneous isomerization occurred with the addition of one equivalent of $AlCl_3$ or Me_3SiOTf at room temperature. The trend $Me_3SiOTf > Me_3SiBr > Me_3SiCl$ in Table 1 parallels their decreasing Lewis acidity.[11] Interestingly, when the isomerization of **1f** promoted by Me_3SiCl was followed by ^{31}P NMR spectroscopic analysis, a transient signal at $\delta = -1.7$ ppm corresponding to **1l**, perhaps from an intermediate in a competing pathway, was observed (Scheme 5). It was expected that the addition of one equivalent of a Lewis acid (e.g., $AlCl_3$ or Me_3SiX) to the isomerization reaction of **1f** to **1h** would establish an equilibrium that involves the formation of the $[AlCl_3Br]^-$ ion or the pentavalent silicate $[Me_3Si(X)Br]^-$ ion (formed from $AlCl_3$ and Me_3SiX as the Lewis acids, respectively), which are both complex anions that would result from the addition of the bromide anion in **1f**. The presence of these anions containing coordinatively saturated central atoms was found to suppress the concentration of $[Me_3SiX]/[AlCl_3]$; consequently, the Lewis acid catalyzed izomerization of P–NC linkages to P–CN in **1f** was inhibited. It was interesting in this regard to observe that the conversion of **1i** into **1j** followed by the addition of a catalytic amount of $AlCl_3$ (10 mol %) resulted in the complete isomerization of **1j** to **1k** in CH_3CN in five minutes at room temperature.

Evidence to support an equilibrium process for the Lewis acid catalyzed isomerization of the phosphorus-bound isocyanides **1e** or **1f** was obtained as follows: Treatment of **1c** with one equivalent of Me_3SiCN at room temperature led to a

Scheme 5. Lewis acid promoted isomerization of isocyanide **1f** to cyanide **1h** by Me_3SiX.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

mixture of **1e** and **1g** in a ratio of 10:90 being obtained within five minutes. This ratio became 50:50 on addition of two equivalents of Me_3SiCN and 90:10 on addition of five equivalents of Me_3SiCN within the same time period. This observation suggests that a silicon-based Lewis acid catalyst does interact with the isocyano compound **1e** (or **1f**), perhaps as shown in Scheme 5, because in the presence of five equivalents of Me_3SiCN, which is a very weak Lewis acid relative to Me_3SiBr, it is more probable that Me_3SiCN will interact with **1e**, thus inhibiting the isomerization process.

Although an isomerization of tertiary alkyl isocyanides catalyzed by $BF_3{\cdot}Et_2O$ has been described,[16] neither $AlCl_3$ nor silicon-based Lewis acids have been reported to isomerize isocyanides of any type. Moreover, it is interesting that $AlCl_3$ and Me_3SiX (X = Cl, Br, OTf) are capable of converting **1f** into **1h**, even though **1f** bears a positive charge and might be expected to behave poorly as a Lewis base.

Although uni- and bimolecular mechanisms for the isomerization of carbon-bound isocyanide have been proposed, the available experimental and theoretical results suggest a unimolecular pathway that involves a three-membered-ring transition state.[17] Initial kinetic studies of the isomerization of **1f** to **1h** suggest that the mechanism for the uncatalyzed thermal isomerization involves a pathway more complicated than the uni- or bimolecular mechanisms.

A white solid was isolated after complete isomerization of **1f** in acetonitrile. The ^{31}P NMR spectrum of this compound showed a single resonance at $\delta = -35.3$ ppm with $^1J(P\text{-}C) = 122.4$ Hz consistent with **1h**, and the ^{13}C NMR spectrum revealed a doublet for the carbon atom of the cyano group at $\delta = 123$ ppm with $^1J(P\text{-}C) = 122.3$ Hz. IR spectroscopic analysis revealed a rather weak C–N stretching vibration at 2197 cm^{-1}, which is comparable with frequencies of other known examples of phosphorus-bound cyanides.[18] A single-crystal X-ray structural analysis of **1h**[9] supports its formation from the isomerization of **1f** (P–C: 1.854(2) Å; C–N: 1.148(3) Å) because the P–C bond is longer than the P–N bond in **1f**, which is as expected (see Figure 2 and the Supporting Information).

A detailed kinetic analysis of the isomerization of **1f** to **1h**, for example, and theoretical calculations aimed at a deeper understanding of the bonding and the isomerization pathways of these systems will be reported in due course.

Latent, Thermally Activated Organic Catalysts for the On-Demand Living Polymerization of Lactide**

Olivier Coulembier, Andrew P. Dove, Russell C. Pratt, Alan C. Sentman, Darcy A. Culkin, Laetitia Mespouille, Philippe Dubois, Robert M. Waymouth,* and James L. Hedrick**

The last decade has seen significant advances in carbene chemistry, including the isolation of the first heteroatom-subsituted singlet carbene and persistent triplet diarylcarbenes.[1,2] These advances have stimulated renewed interest and expanded the scope of possibilities engendered by these reactive species. Following the pioneering work by Wanzlick et al.,[3] the research groups of Bertrand[4] and Arduengo[5] isolated and characterized stable N-heterocyclic carbenes, and over the last decade the steric and electronic requirements for stable imidazolin-2-ylidene and imidazol-2-ylidene carbenes have been described.[6] Consequently, investigation into the properties and uses of N-heterocyclic carbenes (NHCs) has become a major area of research.[2,7] For example, the use of NHCs in place of phosphine ligands produces transition-metal complexes that exhibit enhanced catalytic performance and stability.[8] N-Heterocyclic carbenes have also proven to be effective organic catalysts for benzoin condensations, Stetter reactions, acylation/transesterification reactions, and the polymerization of cyclic esters.[9]

Despite advances in structural modifications to enhance the stability of N-heterocyclic carbenes[10] and the development of in situ methods for their generation,[11,12] the use of NHCs is complicated by their extreme air and moisture sensitivity, which necessitates the use of glove-box techniques. Our attention has been drawn towards the preparation and application of protected NHCs, particularly those that could be activated thermally. Many research groups realized in early studies that strongly nucleophilic carbenes underwent C–H insertion reactions with compounds containing acidic C–H bonds to form adducts in high yields.[13] Chloroform and pentafluorobenzene adducts of saturated carbenes[12] are useful precursors to transition-metal–carbene complexes; they also catalyze the ring-opening polymerization (ROP) of lactide (Scheme 1) at elevated temperatures.[12h] Grubbs

Scheme 1. Polymerization of lactide with adducts of saturated N-heterocyclic carbenes.

and co-workers showed that imidazolium tetrafluoroborate salts could be treated with potassium *tert*-butoxide to reversibly generate 2-alkoxy-4,5-dihydroimidazoles.[14] Enders et al.[15] prepared alcohol adducts of the triazolylidene carbene; thermolysis of these adducts (80 °C) generated free carbene and alcohol. Our attention was drawn to alkoxytriazolines as possible unimolecular catalyst/initiator systems. Moreover, we anticipated that the hydroxy-terminated polymer and free carbene present in solution during the polymerization could react reversibly with each other to form an adduct after each propagation step,[14b] hence minimizing the concentration of the active species and possible adverse transesterification side reactions, which is a problem typical of other controlled/living polymerization procedures above 85 % conversion.[16] Herein, we describe the use of the commercially available 1,3,4-triphenyl-4,5-dihydro-1*H*-1,2-triazol-5-ylidene carbene (**1**) for the living ROP of lactide to generate functional, block, and dendritic star copolymers.

Polymerization of L-lactide (LA: 1–2 M solution in THF or toluene) by imidazolylidene carbenes in the presence of an initiator such as methanol (one equivalent of initiator to catalyst) is generally accomplished within a few minutes at 25 °C, depending on the targeted molecular weight.[14b] Only 16 % conversion was observed at 25 °C after 100 h for the polymerization of LA (1 M in toluene) with the triazolylidene carbene under similar conditions, whereas 40 % conversion was observed at 50 °C. Polymerization of LA at 90 °C proceeded with near quantitative monomer conversion in 50 h to give polylactide with a degree of polymerization (DP)

of 70 ($M_n = 10000$) and a polydispersity (M_w/M_n) of 1.09. The diminished reactivity of the triazole carbenes for lactide polymerization compared to that observed with saturated imidazolin-2-ylidene or unsaturated imidazol-2-ylidene carbenes[9o,14b] suggested that some process was attenuating the reactivity of these carbenes towards polymerization. On the basis of the pioneering work by Enders et al. on the reactivity of triazolylidenes, we suspected that the reversible formation of alcohol adducts might be responsible for this behavior (Scheme 2).[15]

Scheme 2. Polymerization of lactide with triazole carbenes.

As reported by Enders et al.,[15] treatment of the triazolylidene with a slight excess of MeOH at room temperature readily generates the methoxytriazoline, as evidenced by resonances at $\delta = 46.8$, 101.0, and 142.9 ppm in the ^{13}C NMR (C_6D_6) spectrum. This alcohol adduct is stable at 50 °C, but dissociates at 90 °C into a mixture of the methoxytriazoline, free triazolylidene **1**, and free methanol, as evidenced by ^1H and ^{13}C NMR spectroscopic analysis. Spectroscopic analysis shows that cooling this mixture to room temperature regenerates the methoxytriazoline, thus revealing a temperature-dependent equilibrium between the triazolylidene carbene and methanol adduct: only the alcohol adduct is observed at room temperature in the presence of alcohols, and elevated temperatures are required to generate the free carbene and the alcohol.

The reversible formation of alcohol adducts provides an explanation for the low reactivity of the triazole carbenes in the polymerization of LA at room temperature. Therefore, the polymerization of LA with a variety of initiating alcohols was carried out at 90 °C (1 M in toluene). The molecular weights obtained under these conditions correlated with those predicted with monomer to initiator ratios ranging from 25:1 to 350:1 and yielded polymers with narrow dispersities (Table 1). A plot of the molecular weight and polydispersity versus conversion for the ROP catalyzed by **1** was linear (Figure 1) and the gel permeation chromatography (GPC) traces of polylactide generated with a 4-pyrene-1-butanol initiator and using both refractive index and UV detectors (410 and 350 nm, respectively) clearly show pyrene is distributed throughout the sample (Figure 1). This was corroborated by ^1H NMR analysis of the polymer end-groups which indicated the presence of one initiator per polymer chain, thus confirming the end-group fidelity.

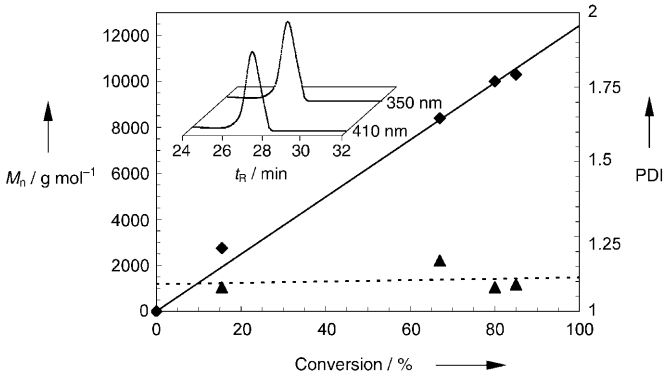

Figure 1. Evolution of molecular weight (◆), as determined by GPC, and PDI (▲) versus conversion for the polymerization of LA (Table 1, entry 4) together with GPC scans using both RI (410 nm) and UV (350 nm) detectors.

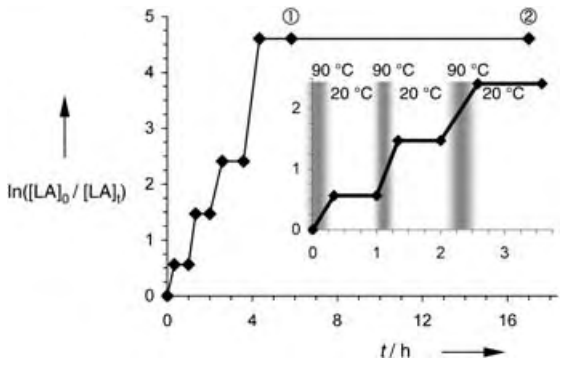
A chain-extension experiment with an initial polymerization ($[LA]_0 = 1$ M; $[\text{pyrenebutanol}]_0 = 0.04$ M; $[\text{catalyst}]_0 = 0.02$ M) was performed at 90 °C for 19 h to give polylactide of $M_n = 2500\ g\,mol^{-1}$, as determined by ^1H NMR spectroscopic analysis. L-lactide (3.47×10^{-4} mol) and **1** (2.36×10^{-5} mol) were added to this solution and the solution heated to 90 °C for an additional 7 h. The molecular weight of the sample increased to $9000\ g\,mol^{-1}$ as deduced by ^1H NMR spectroscopic analysis. GPC analysis of the sample revealed an absolute molecular weight of $7300\ g\,mol^{-1}$ and a PDI of 1.36. This solution was charged again with 3.47×10^{-4} mol of L-lactide without any further catalyst and heated to 90 °C for 7 h. The final molecular weight increased to $14000\ g\,mol^{-1}$, as determined by ^1H NMR spectroscopic analysis ($M_n(GPC) = 12000\ g\,mol^{-1}$), with no change in the polydispersity (1.34). Thus, this system exhibits the characteristics of a living polymerization.[16a]

A unique feature of this particular system is that polymerization can be reversibly terminated simply by modulating the temperature. Heating a 1 M solution of LA

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

to 90 °C in the presence of **1** and 4-pyrene-1-butanol results in the conversion of LA, which stops upon rapid cooling of the solution to 20 °C (Figure 2; 4-pyrene-1-butanol/catalyst = 3:1, L-lactide/4-pyrene-1-butanol = 50:1). Re-initiation of the polymerization occurs upon re-heating at 90 °C, with deactivation occurring upon cooling again to 20 °C. This process was repeated four times. Figure 2 demonstrates clearly that the polymerization can be activated/deactivated with temperature on demand. Significantly, analysis of the polymer after four successive heating and cooling cycles revealed quantitative conversion of the monomer to give polylactide with M_n = 5900 (DP = 41) and M_w/M_n = 1.13:1. Further heating of this sample at 90 °C for 720 minutes revealed little discernable change in the molecular weight or polydispersity (M_n(GPC) = 5400; PDI = 1.29), thus suggesting that the polylactides prepared under these conditions are resistant to further transesterification reactions.



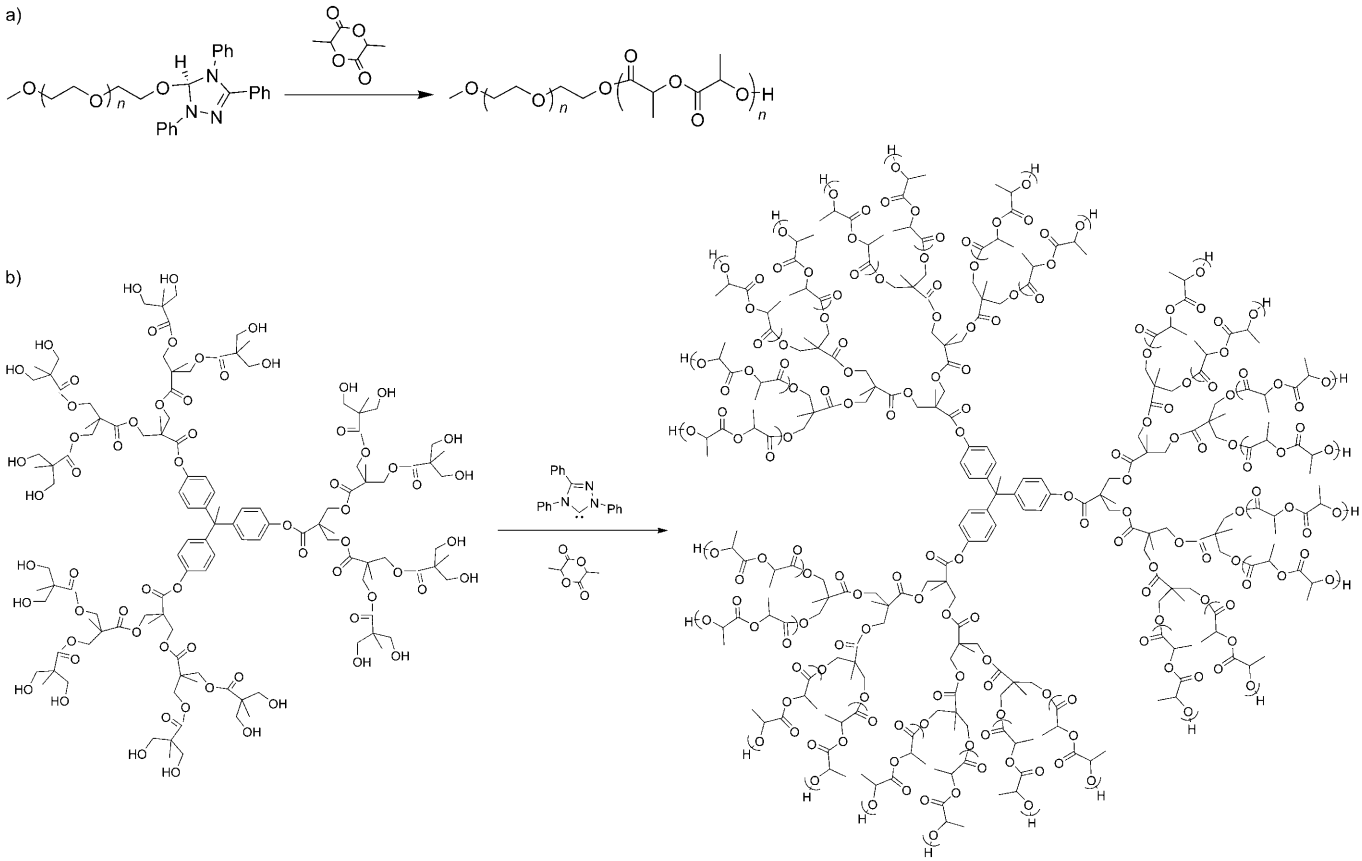


Figure 2. Time dependence of ln([LA]$_0$/[LA]) as a function of time ([LA]$_0$ = 1 M; [alcohol]$_0$ = 0.02 M; [alcohol]$_0$/[catalyst]$_0$ = 1:3) with alternation of high (90 °C) and low (20 °C) temperature. The molecular weights and polydispersity index for ① and ② are 5900 (1.13) and 5400 (1.29), respectively, as determined by GPC. Inset: the first 4 h of the reaction.

A kinetic study of the polymerization of L-lactide (LA) initiated by 4-pyrene-1-butanol (ROH) and catalyzed by **1** was performed at 90 °C using an initial monomer concentration [LA]$_0$ of 1 M. The dependence of ln([LA]$_0$/[LA]) on time at constant triazole concentration ([triaz]$_0$ = 0.02 M) was linear with an intercept at zero, which indicates that the polymerization is first order in monomer and that the number of growing species does not change during the polymerization. Plots of k_{obs} versus [triaz] or [ROH] reveal that the rate is first order both in triazole and alcohol for [triaz]/[ROH] = 1:1. These results demonstrate that the polymerization is first order with respect to catalyst, alcohol, and monomer, according to the rate law given in Equation (1), where [ROH] = [ROH]$_0$, [triaz] = [triaz]$_0$, and k_p = 530 $L^2 mol^{-2} s^{-1}$.

$$-\frac{d[LA]}{dt} = k_p[LA][ROH][triaz] \quad (1)$$

Scheme 3. Generation of block and star copolymers from triazolium alcohol adducts.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

The well-defined polymerization behavior of the alkoxytriazoline catalyst systems is ideally suited for the preparation of block copolymers and complex macromolecular architectures. Several adducts of hydroxy-functionalized oligomers and multifunctional alcohols were synthesized either in situ, or isolated and used as thermally stable macroinitiators for the ring-opening polymerization of lactide at 90 °C. A monohydroxypoly(ethylene oxide) oligomer (PEO-OH) ($M_W = 2000\ g\,mol^{-1}$, PDI = 1.05) was treated with **1** in toluene at RT for 12 h to give quantitative conversion of the corresponding alkoxytriazoline. The oligo-alkoxytriazoline is stable at room temperature, but readily polymerizes LA at 90 °C to yield a narrowly dispersed diblock copolymer in near quantitative yields (ca. 90 %; Table 1, entry 7; Scheme 3 a). Dendritic star-shaped polymers were prepared from a hydroxy-functionalized third generation dendrimer derived from 2,2′-(bishydroxymethyl)propionic acid (bis-MPA).[17,18] The dendrimer, 24 equivalents of **1**, and lactide were suspended in toluene and after approximately two hours at room temperature, the solution became homogeneous. The temperature was then increased to 90 °C to yield a narrowly dispersed, 24-arm star polymer (Table 1, entry 8; Scheme 3 b, 40 h, ca. 96 % conversion). The functional groups of the bis-MPA repeating units provide sensitive markers for the spectroscopic analysis of the polymers, since the quartenary carbon atom and the protons on the methylene group are very sensitive to the substitution of the neighboring hydroxy groups.[19] ^1H and ^{13}C NMR spectroscopic analyses showed that the efficiency of the initiation was quantitative and afforded a well-defined 24-arm star polymer (Table 1, entry 8; Scheme 3 b). Significantly, the ester functionality of the dendritic core was retained, thus indicating that the catalyst polymerizes lactide without degrading the polyester-derived dendritic core under these conditions.

In summary, alkoxytriazolines were shown to reversibly dissociate at 90 °C to generate an initiating/propagating alcohol and triazolium carbene for the on-demand living polymerization of lactide. The kinetic results demonstrate that the polymerization is first order with respect to catalyst, alcohol, and monomer, thus suggesting that all the components have an equal role in the propagation step of the mechanism. We have also demonstrated that **1** reversibly forms alcohol adducts that result in an active and dormant form of the catalyst. We postulate that dissociation of the carbene and alcohol from the adduct results in activation of the monomer by the nucleophilic carbene, with propagation occurring through a step involving the activated monomer–carbene adduct and the alcohol. The recombination of the carbene with the new alcohol species results in the formation of the dormant carbene–alcohol adduct. This reversible dissociation is believed to be responsible for the exquisite control of molecular weight, narrow polydispersities, and end-group fidelity, analogous to modern controlled radical procedures.[20]

Observation of Weak C–H···O Hydrogen Bonding to Unactivated Alkanes**

*Xue-Bin Wang, Hin-Koon Woo, Boggavarapu Kiran, and Lai-Sheng Wang**

The hydrogen bond plays an essential role in chemistry and biochemistry.[1] It generally has the form X–H···Y, where X and Y are highly electronegative atoms such as O or N. The fact that a relatively less electronegative carbon can also behave as a proton donor to form C–H···O-type hydrogen bonds has been the subject of controversy for many years.[2–4] However, it is now well accepted and has been identified in many biological systems[5–13] and crystal engineering.[14–18] Most C–H···O hydrogen bonds have been observed for the so-called activated C, where the hydrogen-donor C atom is attached to electronegative groups such as halogen atoms or NH groups in the protein backbone. In biological systems or molecular crystals, C–H···O hydrogen bonds are usually accompanied by other stronger molecular interactions that make it difficult to evaluate their relative contributions. Despite the importance of the C–H···O hydrogen bond and extensive theoretical studies,[19–25] its nature is still being debated,[26–29] and there have been no experimental characterizations of its strength to date. We report here the first direct experimental observation of conformation changes induced solely by C–H···O hydrogen bonding in a series of unactivated aliphatic carboxylate molecules, $CH_3(CH_2)_nCO_2^-$, in the gas phase, where the C–H···O hydrogen bonding is the only molecular interaction driving the conformational changes.

Photoelectron spectra of $CH_3(CH_2)_nCO_2^-$ ($n = 0$–8) were measured at both room and low temperatures, as shown in Figure 1. We observed very similar spectra at room temperature for all the species, which all have adiabatic detachment energies (ADEs) of around 3.4 eV because the aliphatic chain

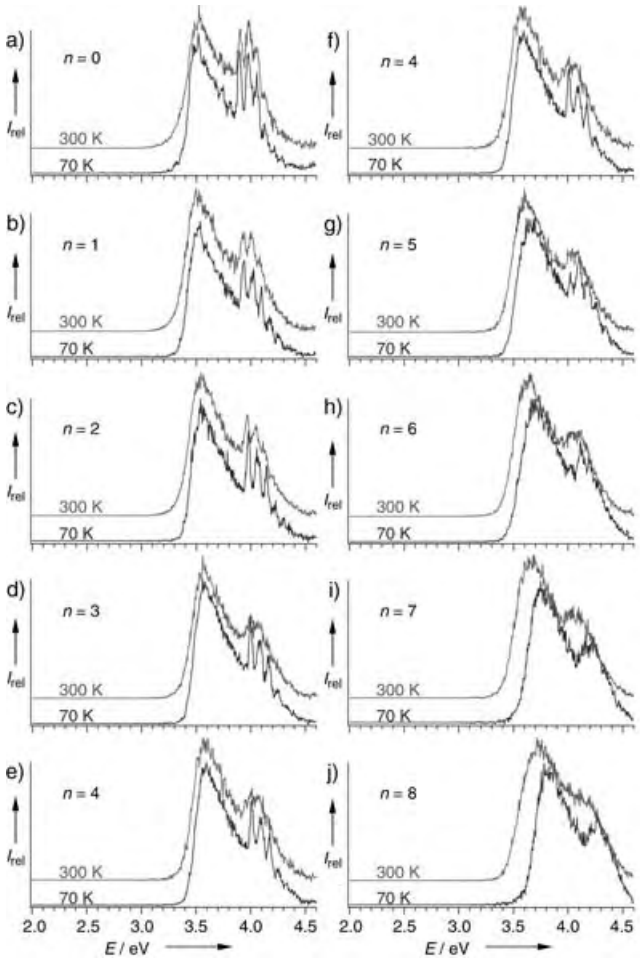

Figure 1. Photoelectron spectra of $CH_3(CH_2)_nCO_2^-$ ($n = 0$–8) measured at 266 nm (4.661 eV) and at two different ion-trap temperatures. Note the blue shift of the 70 K spectra starting from $n = 5$.

has very little effect on the electron binding energies of the carboxylate group. The two observed bands in all the spectra are due to detachment from three oxygen lone-pair orbitals on the carboxylate, and the first broad band actually contains two detachment channels.[30,31] The second spectral band was vibrationally resolved for $n = 0$–2, with a vibrational frequency of about 640 cm^{-1} that is characteristic of the CO_2 bending motion.[32] The vibrational structure is smeared out in the larger systems in the room temperature spectra. Significant changes were observed in the PES spectra at a trapping temperature of 70 K. For $n = 0$–4 (Figure 1, left column), the low-temperature spectra are much sharper and the CO_2 bending vibrational progression in the second band is much better resolved in all the spectra. The reduction of the vibrational hot band can clearly be observed by comparing the threshold regions of the spectra taken at 70 and at 300 K. For $n = 5$–8, in addition to the spectral sharpening, the 70 K spectra surprisingly exhibit a systematic blue shift, which ranges from 50 meV for $n = 5$ to 150 meV for $n = 8$. Vibrational structures in the second band were also resolved for these larger species, more clearly for $n = 5$ and 6, but the Franck–Condon envelope is quite different in the larger systems than in the smaller species.

The blue shift observed for $n = 5$–8 in the low-temperature spectra suggests a conformational change in which the negative charge on the carboxylate is stabilized, most likely resulting from the formation of C–H···O hydrogen bonds between the terminal CH_3 group and the -CO_2^- group to form a folded structure.[32,33] Because of the anticipated weakness of this C–H···O hydrogen bonding, the folded conformation can only be observed at lower temperatures owing to the large entropy contributions at higher temperatures for the linear structure. To obtain further insight into the folding transition, we performed temperature-dependent studies for $n = 6$ and 8 at trapping temperatures from 300 to 18 K (Figure 2). For

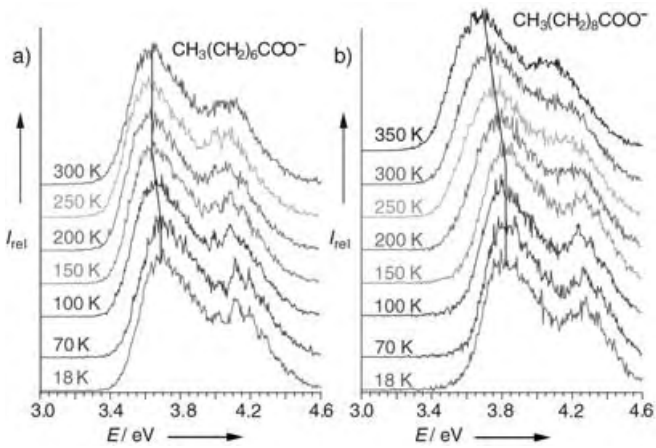

Figure 2. Temperature-dependent photoelectron spectra of $CH_3(CH_2)_6CO_2^-$ and $CH_3(CH_2)_8CO_2^-$. The lines drawn are intended to guide the eyes and have no other significance.

$CH_3(CH_2)_6CO_2^-$ there was no observable blue shift from 300 K to 200 K, but at 150, 100, and 70 K the PES spectra exhibit successive blue shifts of about 10, 10, and 40 meV, respectively. The spectrum shows no blue shift upon further cooling the trap to 18 K. These observations suggest that the folding transition starts at around 150 K for $CH_3(CH_2)_6CO_2^-$, and at around 70 K all the anions are already in the folded conformation due to the C–H···O hydrogen bonding. For $CH_3(CH_2)_8CO_2^-$, a blue shift of about 30 meV was already observed upon cooling the trap from 300 K to 250 K. Further blue shifts of about 45 and 65 meV were observed at 200 and 150 K, respectively. No measurable shift was observed upon further cooling, which suggests that at 150 K all the $CH_3(CH_2)_8CO_2^-$ anions are already in the folded conformation. The blue shift observed immediately upon cooling from 300 K indicates that there might already be folded conformations present at room temperature for $CH_3(CH_2)_8CO_2^-$. We therefore made one more measurement by heating the ion trap to 350 K, and indeed observed a red shift relative to the 300 K spectrum by about 50 meV. The 300 K spectrum seems to be slightly broader than the 350 K spectrum, which is consistent with the fact that both linear and folded conformations coexist at room temperature. The ADE of $CH_3(CH_2)_8CO_2^-$ at 350 K is now about 3.47 eV, similar to those of the smaller species, thus indicating that the linear structure dominates for $CH_3(CH_2)_8CO_2^-$ only at 350 K.

Our temperature-dependent PES data yielded the following blue shifts between the folded and linear structures: 50, 60, 130, and 190 meV for $n = 5$–8, respectively. These shifts reflect the stabilization of the negative charge on the -CO_2^- group by the C–H···O hydrogen bonding, as illustrated in Figure 3. As the strength of the C–H···O hydrogen bonding in the neutral $CH_3(CH_2)_nCO_2^{\bullet}$ radical is expected to be small (0.5 kcal mol^{-1} or less),[20] the observed blue shifts provide lower limits for the C–H···O hydrogen bonding strength in the $CH_3(CH_2)_nCO_2^-$ anions (1.2, 1.4, 3.0, and 4.4 kcal mol^{-1} for $n = 5$–8, respectively).

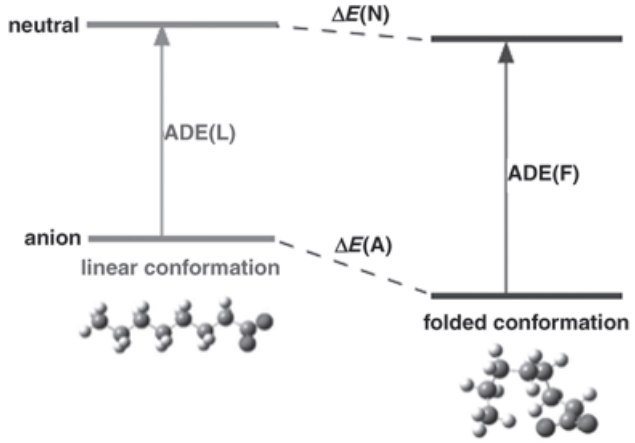

Figure 3. The energetic relationships between the anions and the neutral species and between the linear and folded configurations. ADE(L) and ADE(F) are the adiabatic detachment energies of the linear and folded conformations, respectively. ΔE(A) and ΔE(N) are the stabilization energies of the folded relative to the linear conformations for the anions and neutrals, respectively. The stabilization energies have two components, the C–H···O hydrogen-bonding energies in the folded conformations (E_H(A) and E_H(N) for the anions and neutrals, respectively) and the strain energies in the folded backbones (E_s(A) and E_s(N) for the anions and neutrals, respectively). The strain energies in the anions and neutrals are expected to be similar for a given chain length. Thus, the measured spectral shift (ΔADE) between the folded and linear conformations is equivalent to the difference of the C–H···O hydrogen-bond strength in the anions and neutrals: ΔADE = -ADE(F) − ADE(L) = ΔE(A) − ΔE(N) = E_H(A) − E_H(N).

To obtain further insight into the nature of the C–H···O hydrogen bonding in the $CH_3(CH_2)_nCO_2^-$ anions, we performed theoretical calculations on the linear and folded conformations for $n = 3$–8 (Figure 4). We found that the folded conformations are more stable than the linear structures in all cases. However, we also observed that there is no C–H···O hydrogen-bonding interaction in the cases of $n = 3$ and 4 because either the CH···O distances or the ∢C-H-O angles are outside the normal ranges expected for such interactions. One C–H···O hydrogen bond was observed for $n = 5$ and 6, whereas for $n = 7$ and 8 two C–H···O hydrogen bonds are formed, consistent with the large ADE shifts observed for these two species in the PES spectra at low temperature. The calculations also revealed that the two C–O bond lengths become different upon hydrogen-bond formation as a result of the charge localization onto the hydrogen-bonded O atom. The abrupt change in the CO_2 bending vibrational progression in the second PES band for $n = 5$–8 is consistent with the subtle geometric changes as a result of the C–H···O hydrogen-bond formation. The C–H···O hydrogen-bond strengths are different in each system owing to the different steric effects that lead to different C–H···O hydrogen-bonding geometries. The strengths of the two C–H···O hydrogen bonds in the $n = 7$ and 8 species are also not equivalent. However, an average bond strength for each C–H···O hydrogen bond in $n = 7$ and 8 can be obtained from the PES spectral shifts. Thus, we obtained the following lower limits of the bond strength for a single C–H···O hydrogen bond in $CH_3(CH_2)_nCO_2^-$: 1.2, 1.4, 1.5, and 2.2 kcal mol^{-1} for $n = 5$–8, respectively.

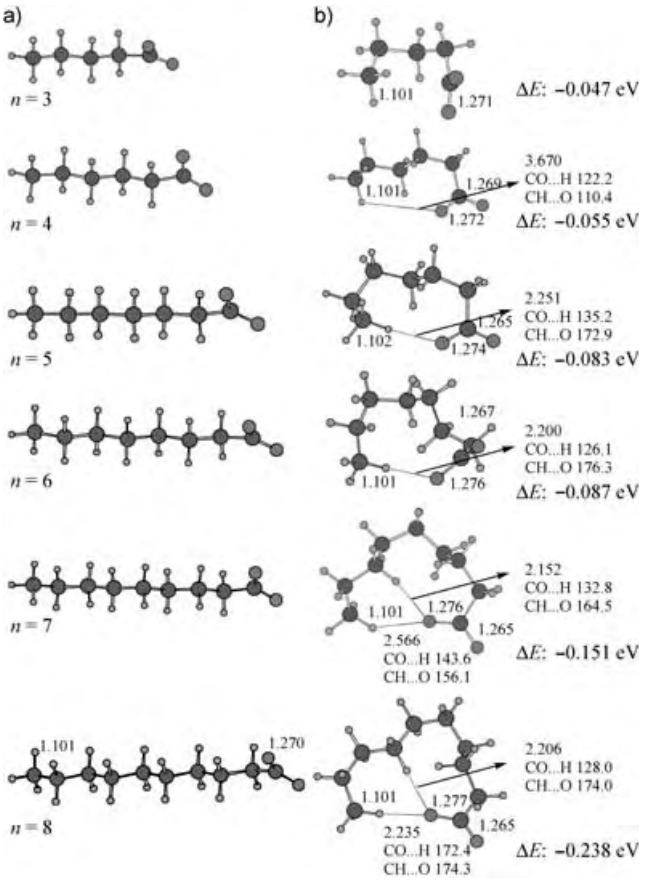

Figure 4. Optimized structures for the a) linear and b) folded conformations of $CH_3(CH_2)_nCO_2^-$ ($n = 3$–8) at the MP2/aug-cc-pVDZ level of theory. Selected C–H, C–O, and H···O bond distances are indicated in Å. The CO···H and CH···O bond angles are given in degrees. ΔE: the stabilization energies of the folded relative to the linear conformation.

Unactivated alkanes form the weakest C–H···O hydrogen bonds.[20] For example, the calculated C–H···O hydrogen-bond strength in the $H_2C{=}O/CH_4$ complex is only 0.46 kcal mol^{-1} which increases to 1.2 kcal mol^{-1} in $H_2C{=}O/CH_3F$.[20] The relatively large C–H···O hydrogen-bond strength in $CH_3(CH_2)_nCO_2^-$ is due to the negative charge on the carboxylate group, which usually forms a strong ionic hydrogen bond.[34] Thus, even unactivated alkanes can form relatively strong C–H···O hydrogen bonds to strong acceptors. The current work provides the first examples that pure C–

H···O hydrogen bonding can play a significant structural role in determining molecular conformations. These results should have major implications to assess the role of C–H···O hydrogen bonding in biological structures and reactivities. The quantitative experimental data can also be used to verify theoretical calculations and help evaluate the dependence of the C–H···O hydrogen-bond strength on its geometry. We have also demonstrated that the low-temperature capability is not only valuable to remove vibrational hot bands and enhance photoelectron spectral resolution, but also opens up new research opportunities and allows weak molecular interactions to be isolated and investigated.

Experimental Section

Low-temperature photoelectron spectroscopy with electrospray: The experiments were carried out with a brand new home-built instrument that couples electrospray ionization with a magnetic-bottle time-of-flight photoelectron spectrometer, with a new capability of being able to control the ion temperatures. The electrospray source and the magnetic-bottle photoelectron spectrometer are similar to those described previously.[35] Briefly, the anions of interest, $CH_3(CH_2)_nCO_2^-$ ($n = 0$–8), were produced from solutions of the corresponding acids under slightly basic conditions in a mixed methanol/water solvent (3/1 volume ratio). Anions from the source were guided by a RF-only octopole device into a quadrupole mass filter, which was operated in the RF-only mode in the current experiment. Following the mass filter, the ion beam was guided by a 90 degree ion bender into a 3D Paul trap, which was attached to the cold head of a closed-cycle helium refrigerator. The temperature of the cold head can be controlled between 10–350 K. A portion of the incoming ions was trapped and collisionally cooled with a background gas (≈ 1 mTorr N_2 in most cases for temperatures between 350–70 K, or 5% H_2 in helium for lower-temperature operations). The ions were trapped for a period of 20–100 ms and cooled by translational and rovibrational energy transfers to the background gas (the number of collisions was estimated to be about 2000–10000). The trap was operated at low q values (< 0.3) to avoid RF heating.[36,37] The trapped ions were pulsed out into the extraction zone of a time-of-flight mass spectrometer at a 10 Hz repetition rate.

The ions of interest were mass-selected and decelerated before being intercepted with a 266-nm laser beam in the interaction zone of the magnetic-bottle photoelectron analyzer. The laser was operated at a 20 Hz repetition rate with the ion beam off at alternate shots for background subtraction. The photodetached electrons were collected with nearly 100% efficiency by the magnetic-bottle and analyzed in a 5-meter-long electron flight tube. The electron energy resolution was $\Delta E/E \approx 2\%$, i.e., 20 meV for 1 eV electrons. Photoelectron time-of-flight spectra were collected and then converted into kinetic energy spectra, calibrated by the known spectra of ClO_2^- [33] and I^-. The electron binding energy spectra presented were obtained by subtracting the kinetic energy spectra from the detachment photon energies.

Two known anions,[38,39] ClO_2^- and C_{60}^-, were used to test the effectiveness of the ion cooling. At a trap temperature of 70 K, vibrational hot bands in the photoelectron spectrum of ClO_2^- were completely removed. At the same trap temperature, vibrational hot bands were still detectable in the photoelectron spectrum of the relatively large C_{60}^- anion, whose vibrational temperature was estimated to be about 100 K, which yields a difference of around 30 K between the trapping temperature and the C_{60}^- vibrational temperature. We expected that this difference would be smaller for the $CH_3(CH_2)_nCO_2^-$ anions because of their relatively smaller size.

Theoretical methods: All calculations were performed with the programs Gaussian 03[40] and NWChem.[41] An initial search of the stable conformers was done with local density functional theory (LSDA) with an augmented correlation consistent polarized valence double-ζ basis set (aug-cc-pVDZ). The lowest energy geometries were used for geometry optimization at the second-order Moller–Plesset Perturbation Theory (MP2) level with the same basis set. Frequencies and other thermodynamic values were calculated at the LSDA level. All DFT calculations were performed with Gaussian 03 and MP2 optimizations with NWChem.

C_9 Helices and Ribbons in γ-Peptides: Crystal Structures of Gabapentin Oligomers**

Prema G. Vasudev, Narayanaswamy Shamala, Kuppanna Ananda, and Padmanabhan Balaram**

The insertion of additional atoms into α-polypeptide backbones by the introduction of β-, γ-, and higher ω-amino acid residues expands the range of polypeptide secondary structures.[1] Two new helices, the 2.5_{12} ((*P*)-2.5_1) helix and the 3_{14} ((*M*)-3_1) helix, were first identified in studies of oligopeptides containing β-amino residues.[2] Several recent studies have focused on the conformations of peptides containing β- and γ-amino acids.[3] The symmetrically β,β-disubstituted γ-amino acid gabapentin (Gpn, Figure 1a) is a readily available

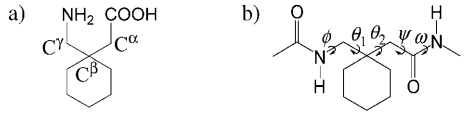

Figure 1. a) The amino acid gabapentin (Gpn); b) parameters used to define the backbone dihedral angles of the Gpn residue.

stereochemically constrained γ-amino acid residue.[4] Four degrees of torsional freedom, ϕ, θ_1, θ_2, and ψ (Figure 1b), are available for the Gpn residue. The presence of geminal substituents at the central C^β atom limits the range of conformations about the C^γ–C^β (θ_1) and C^β–C^α (θ_2) bonds to the two possible *gauche* conformations ($\theta_1 \approx \theta_2 \approx \pm 60°$).[4a,5] Herein, we describe the crystal structures of the peptides Boc-Gpn-Gpn-NHMe and Boc-Gpn-Gpn-Gpn-Gpn-NHMe (Boc = *tert*-butoxycarbonyl), which provide examples of C_9-hydrogen-bond-stabilized, folded conformations (in which the hydrogen bonds enclose a ring of nine assorted atoms). Repetition of this hydrogen-bonded motif reveals new families of C_9 ribbons and C_9 helices.

Figure 2 shows the molecular conformations determined in crystals by X-ray diffraction for Boc-Gpn-Gpn-NHMe and

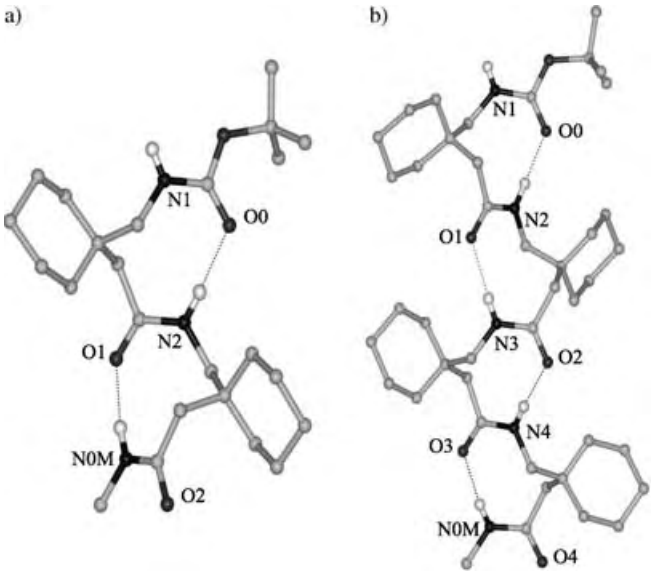

Figure 2. Molecular conformation of a) Boc-Gpn-Gpn-NHMe and b) Boc-Gpn-Gpn-Gpn-Gpn-NHMe in crystals; the intramolecular hydrogen bonds are represented as dotted lines.

Boc-Gpn-Gpn-Gpn-Gpn-NHMe. The observed backbone torsion angles and hydrogen-bond parameters are summarized in Table 1 and Table 2. In all six independent Gpn residues in these two structures, a C_9 hydrogen bond between the C=O moiety of the preceding residue (i–1) and the N–H group of the succeeding residue (i+1) is observed. The

Table 1: Backbone torsion angles [°] for Boc-Gpn-Gpn-NHMe and Boc-Gpn-Gpn-Gpn-Gpn-NHMe.[a]

	ϕ	θ_1	θ_2	ψ	ω	Orientation of aminomethyl group
Boc-Gpn-Gpn-NHMe						
Gpn (1)	108.9	−63.2	−76.6	87.2	−174.9	axial
Gpn (2)	108.2	−61.9	−78.2	88.0	−178.1	equatorial
Boc-Gpn-Gpn-Gpn-Gpn-NHMe						
Gpn (1)	100.5	−69.6	−72.8	84.5	−171.6	equatorial
Gpn (2)	−103.8	69.9	73.4	−90.5	−174.5	axial
Gpn (3)	−112.2	66.8	72.6	−88.4	174.8	axial
Gpn (4)	104.6	−70.7	−71.5	97.2	179.0	equatorial

[a] Estimated standard deviation for the dihedral angles is approximately 0.4°.

Table 2: Intramolecular hydrogen bonds in Boc-Gpn-Gpn-NHMe and Boc-Gpn-Gpn-Gpn-Gpn-NHMe.[a]

Donor	Acceptor	N···O [Å]	H···O [Å]	∢ N–H···O [°]
Boc-Gpn-Gpn-NHMe				
N2	O0	2.90	2.00	172.5
N0M	O1	2.86	2.00	170.8
Boc-Gpn-Gpn-Gpn-Gpn-NHMe				
N2	O0	2.82	1.90	176.3
N3	O1	2.89	2.05	173.6
N4	O2	2.87	2.03	169.9
N0M	O3	2.90	2.05	168.4

[a] Estimated standard deviations in the hydrogen-bond lengths N···O and H···O and angles are approximately 0.01 Å, 0.02 Å, and 2.5°, respectively.

backbone torsion angles for all six residues reveal that they adopt very similar *gauche*,*gauche* conformations. Interestingly, three of the observed cyclohexane rings have the amino methyl group in an axial orientation, whereas in the other three this group adopts an equatorial orientation. A comparison of the di- and tetrapeptide structures, however, reveals an important difference. In the protected dipeptide the two Gpn residues adopt the same combination of signs for the four backbone torsion angles. In sharp contrast, in the protected tetrapeptide the combination of signs for the torsion angles for residues 1 and 4 is opposite to that of residues 2 and 3. Notably, as both structures are of achiral peptides crystallizing in centrosymmetric space groups, the choice of sign reported in Table 1 is arbitrary. However, differences in the handedness of conformations between residues in the same structure can be observed.

The repetitive C_9-hydrogen-bonded structures determined in the two peptides can be viewed as analogues of the corresponding C_7-hydrogen-bonded structures described for polypeptides composed of α-amino acids. The isolated γ turn stabilized by a 3→1 hydrogen bond between C=O ($i-1$) and N–H ($i+1$) has been observed in the structure of proteins and peptides.[6] The repetitive C_7 structure, the 2.2_7 helix, was first proposed for α polypeptides by Donohue.[7] Subsequently, two structures were theoretically considered, the 2_7 ribbon ($\phi = -70°$, $\psi = 70°$) and the 2.2_7 helix ($\phi = -78.1°$, $\psi = 59.2°$).[8] However, these structures have not been experimentally observed in the crystal structures of polypeptides and proteins. A recent report describes two consecutive γ-turn conformations in a synthetic dipeptide.[9] Ab initio molecular orbital calculations have been used to examine all possible periodic structures of γ-peptides. These studies suggest that helical structures with hydrogen bonds enclosing 14- and 9-membered rings are most stable.[10] An isolated C_9 hydrogen bond has been described in the crystal structure of a γ-dipeptide.[11] A C_9-ribbon structure has also been postulated on the basis of NMR spectroscopy data for γ-peptide oligomers of *cis*-γ-amino-L-proline.[12] The C_9 structures described above constitute an expansion of the C_7 structures by the insertion of two additional backbone atoms.

Figure 3 shows views of three possible repetitive polypeptide structures generated by using the C_9-repeat motif. Figure 3b shows the C_9 helix generated by repeating the structure determined for the dipeptide Boc-Gpn-Gpn-NHMe. In this case, the monomeric unit is a single Gpn residue and the combination of signs for the torsion angles is the same for all residues in the helical structure. The number of residues/turn (n) value in this C_9 helix is 2.67 and the height/residue (h) value is 3.40 Å. The view down the axis of this 2.7_9 helix is shown in Figure 3c. A projection of the analogous C_7-helical structure of α polypeptides (2.2_7 helix) is also shown for comparison (Figure 3a).

Inspection of the torsion angles in Table 1 for the tetrapeptide Boc-Gpn-Gpn-Gpn-Gpn-NHMe reveals that the signs of the four torsion angles between adjacent Gpn residues can also be inverted. It is thus possible to consider a range of repetitive C_9 structures employing different handedness at adjacent residues. The helical structure pictured in Figure 3b may be represented by the notation ++++, which indicates that the handedness of all residues along the polymeric chain is identical. Two alternative structures, +−+− and ++−−++−−, are illustrated in Figure 3d–g. The regular alternation of sign in the +−+− structure leads to a C_9 ribbon with a significant degree of curvature, which can result in cyclization after 79 residues (Figure 4). Figure 3f and g illustrates two views of the ++−−++−− structure, where the repeating unit consists of four Gpn residues. This structure can be obtained by repeating the backbone torsion angles determined in the structure of Boc-Gpn-Gpn-Gpn-Gpn-NHMe. Once again, the structure can be viewed as a ribbon but one with a much smaller degree of curvature than the C_9 ribbon obtained from the regular +−+− combination (Figure 3d).

The structures described herein for Gpn oligomers reveal a new family of polypeptide structures which are C_9 ribbons and helices. The C_9-hydrogen-bond structure is determined by a specific combination of the four degrees of torsional freedom at the Gpn residue and is independent of the flanking residues. In Gpn homooligomers, C_9 helices and ribbons will undoubtedly be the energetically favored structures. In mixed sequences, where Gpn is inserted into polypeptides containing α- and β-amino acids, alternative hydrogen-bonding patterns may be anticipated.[1b]

Experimental Section

Peptides Boc-Gpn-Gpn-NHMe (peptide 1) and Boc-Gpn-Gpn-Gpn-Gpn-NHMe (peptide 2) were synthesized by conventional solution-phase procedures. Coupling was mediated by *N*,*N*′-dicyclohexylcarbodiimide (DCC) and *N*-hydroxysuccinimide (HOSu) in tetrahydrofuran (THF). Boc-Gpn-NHMe was synthesized from Boc-Gpn-OH by using a mixed anhydride strategy and employing methylamine as the amino compound. Subsequent elongation of the chain was carried out by formic acid mediated deprotection of the Boc group, followed by coupling to Boc-Gpn-OH. Stepwise elongation was used up to the tetrapeptide structure. The peptides, which were obtained as crystalline solids, were further purified by medium-pressure liquid chromatography over a reversed-phase C_{18} column (40–60 μm) and characterized by 500 MHz ^{1}H NMR spectroscopy; m.p.: 96–97 °C for peptide 1; 162–163 °C for peptide 2.

Single crystals suitable for X-ray diffraction were grown by slow evaporation from mixtures of ethyl acetate/petroleum ether (peptide 1) and methanol/chloroform (peptide 2). X-ray intensity data were collected at room temperature on a Bruker AXS SMART APEX CCD diffractometer, by using $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å). The ω scan type was used. In total, 37219 reflections were measured (5232 independent reflections) with $2\theta_{max} = 53.6°$ and $R_{int} = 0.06$ for peptide 1 ($C_{24}H_{43}N_3O_4$, $M_w = 437.6$). The data were collected from a crystal of dimensions $0.14 \times 0.10 \times 0.03$ mm. The space group is *Pbca* with unit cell dimensions and parameters of $a = 11.771(6)$, $b = 20.724(11)$, and $c = 22.206(12)$ Å, $V = 5233(5)$ Å^3, $Z = 8$, $\rho_{calcd} = 1.11$ g cm^{-3}, $\mu = 0.07$ mm^{-1}, and $F(000) = 1920$. For peptide 2 ($C_{42}H_{73}N_5O_6$, $M_w = 744.0$) 31521 reflections were measured (8500 independent reflections) with $2\theta_{max} = 53.4°$ and $R_{int} = 0.03$. The crystal dimensions are $0.22 \times 0.14 \times 0.10$ mm. The space group is $P2_1/c$ with unit cell dimensions and parameters of $a = 10.004(7)$, $b = 12.648(8)$, and $c = 35.240(2)$ Å, $\beta = 92.632°$ (12), $V = 4454.0(5)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.11$ g cm^{-3}, $\mu = 0.07$ mm^{-1}, and $F(000) = 1632$. Both the structures were solved by direct methods by using SHELXS-97[13a] and refined against F^2, with full-matrix least squares methods, by using SHELXL-97.[13b] All the hydrogen atoms were located from the difference Fourier map. The final R value for peptide 1 was $R_1 = 0.0616$ ($wR_2 = 0.1461$) for 3134 observed reflections with $F_o \geq 4\sigma|F_o|$ and for 452 parameters. The data to parameter ratio is 6.9:1.0 and the goodness of fit $S = 0.99$. The largest difference peak was 0.18 e Å^{-3} and the largest difference hole was −0.15 e Å^{-3}. The final R value for peptide 2 was $R_1 = 0.0655$ ($wR_2 = 0.1782$) for 5474 observed reflections with $F_o \geq 4\sigma|F_o|$ and for 758 parameters. The data to parameter ratio is 7.2:1.0 and the goodness of fit $S = 1.16$. The largest difference peak was 0.27 e Å^{-3} and the largest difference hole was −0.16 e Å^{-3}. CCDC 266651 (Boc-Gpn-Gpn-NHMe) and CCDC 266652 (Boc-Gpn-Gpn-Gpn-Gpn-NHMe) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Development and Biological Evaluation of Acyl Protein Thioesterase 1 (APT1) Inhibitors**

Patrick Deck, Dirk Pendzialek, Markus Biel, Melanie Wagner, Boriana Popkirova, Björn Ludolph, Goran Kragol, Jürgen Kuhlmann, Athanassios Giannis,* and Herbert Waldmann**

Lipidation of proteins is often an unalterable prerequisite for correct biological function. Prime examples are the N and H isoforms of the signal transducing Ras protein, which in the normal and oncogenic state are anchored to the plasma membrane by means of *S*-farnesylation and *S*-palmitoylation at their C terminus and which have to be palmitoylated to exert their full biological activity.[1,2] Inhibition of the enzyme protein farnesyltransferase has opened up an unprecedented opportunity for the treatment of tumors carrying a mutation in the Ras oncogene.[3] However, the enzyme responsible for palmitoylation of H- and N-Ras and other proteins crucial to biological signaling, like heterotrimeric G proteins, G-protein-coupled receptors, and nonreceptor tyrosine kinases, has not been identified so far. Clearly the development of potent inhibitors for this biocatalyst might open up new opportuni-

ties for the treatment of cancers with a mutation in the H- and N-Ras oncogenes.

In yeast, the Erf2 and Erf4 proteins were found to palmitoylate the yeast Ras oncogene homologues.[4,5] While orthologues of the Erf2 gene can be found in the genomes of various eukaryotes including *Homo sapiens*, proteins with the corresponding *S*-palmitoylating activity have not been identified to date.[6] Erf4 homologues have only been identified in closely related yeasts. Instead, acyl protein thioesterase 1 (APT1) was described as "the first bona fide player" in the regulated thioacylation of intracellular proteins.[7] APT1 was found to depalmitoylate the H-Ras protein and the α subunits of heterotrimeric G proteins. Herein we report a chemical biology approach aimed at determination of the involvement of APT1 in H-Ras palmitoylation in vitro and possibly in vivo.

For a reverse chemical genetics approach,[8] inhibitors to antagonize the biological function of the enzyme were designed based on the structure of the H-Ras C terminus **1** (Scheme 1). To this end, a peptide-imitating benzodia-

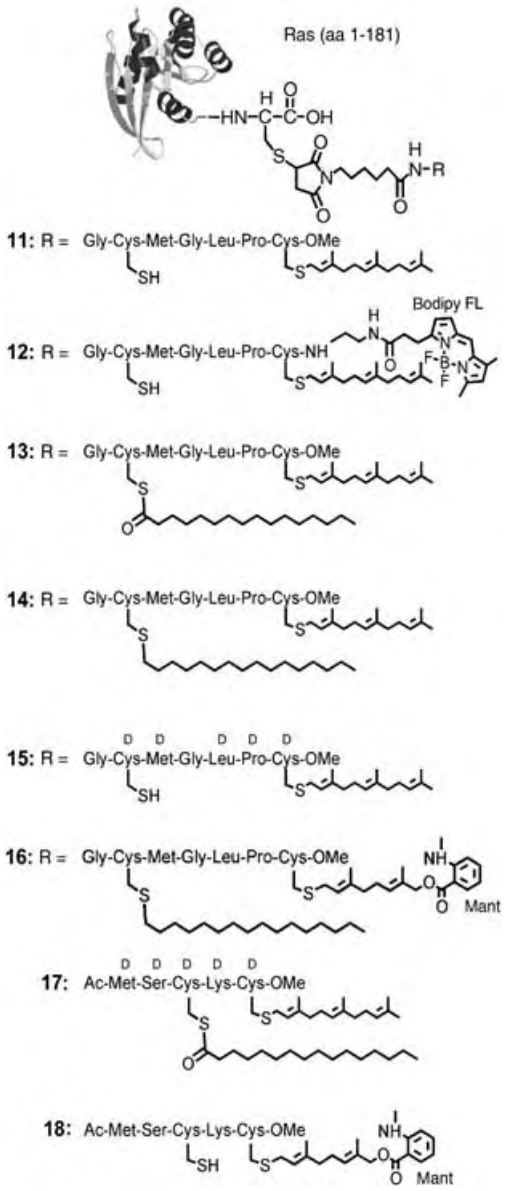
zepinedione core[9] was chosen as the underlying scaffold and equipped with a hydrolysis-stable sulfonamide to mimic the tetrahedral intermediate passed in the hydrolysis of the thioester (see **10**, Scheme 1).

For the synthesis of the desired compounds, 4-(*R*)-hydroxyproline and 5-bromoisatoic acid anhydride were condensed to give the benzodiazepinedione framework **2**, which was subjected to a ten-step synthesis sequence yielding central intermediates **5** and **6**. Methanesulfonamide **5** was converted into *N*-acylated and *S*-farnesylated cysteine methyl ester **7**. The *tert*-butyl ester was cleaved from hexadecylsulfonamide **6**, thereby giving rise to acid **8**. Alternatively, the amino group was masked and *S*-farnesylated cysteine methyl ester was attached to the C terminus to yield **9**, which was selectively *N*-deprotected to give benzodiazepinedione **10**, a mimic of the C terminus of fully processed H-Ras.

For determining the APT1-inhibiting potency of the synthetic benzodiazepinediones, a fluorescence-based biochemical assay was developed by employing the acrylodated intestinal fatty acid binding protein (ADIFAB) as the detecting system.[10]



The results of the biochemical assay are shown in Table 1 (for additional data, see the Supporting Information). Compound **10** proved to be the most potent APT1 inhibitor with

Table 1: Inhibition of APT1 by benzodiazepinediones **5**–**10**.

Compound	IC_{50} [nM]
10	27 ± 5
9	149 ± 30
6	148 ± 6
8	97 ± 8
7	27 000 ± 17 000
5	250 000 ± 160 000

an IC_{50} value of 27 nM. The data indicate that a hexadecylsulfonamide moiety mimicking the palmitic acid thioester is required for high inhibitory activity (compare **7** and **10** or **5** and **6**). The primary amine moiety representing the ε-amino group of the lysine residue found at the C terminus of H-Ras should be liberated to obtain full inhibitory activity (compare **9** and **10**). An *S*-farnesylated cysteine methyl ester at the C terminus is beneficial for activity but not as essential as the palmitic acid mimic (compare **7**, **8**, and **10**). If both lipid residues are lacking, inhibitory activity is lost, that is, the benzodiazepinedione core is not sufficient for activity. The investigated compounds were not inhibitors of the enzyme protein farnesyltransferase (data not shown).

The biological activity of the APT1 inhibitors was investigated by employing the rat pheochromocytoma cell line PC-12. Under normal growth conditions, this cell line has a chromaffin-cell-like morphology. Upon microinjection of full-length recombinant oncogenic RasG12V proteins, these cells differentiate into nonreplicating sympathetic neuron-like cells.[11] The same morphological change is observed upon microinjection of semisynthetic oncogenic Ras protein **11** (Scheme 2), which carries an *S*-farnesylated cysteine methyl ester and a second unmasked, and therefore palmitoylatable,

Scheme 2. Structures of the semisynthetic Ras proteins **11**–**16** and the synthetic lipopeptides **17** and **18**; bodipy FL = 4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*s*-indacene-3-propionyl, mant = *N*-methylanthranilate.

cysteine residue at the C terminus.[12–14] In both cases lipidation of Ras is completed by *S*-palmitoylation in the cell, that is, protein **11** is converted into protein **13**, thereby resulting in plasma-membrane localization of and active signaling by the Ras proteins,[14] which is quantifiable by determining the frequency of neurite outgrowth in PC-12 cells. Microinjection of farnesylated but not *S*-palmitoylatable synthetic Ras (because of omission of a second cysteine in the synthesis) does not lead to neurite outgrowth. Consequently, a change in neurite outgrowth correlates directly with the degree of Ras palmitoylation.

Microinjection of synthetic, palmitoylatable N-Ras protein **11** was adjusted to give a neurite outgrowth rate of approximately 50% (see Figure 1). Depalmitoylation of Ras

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

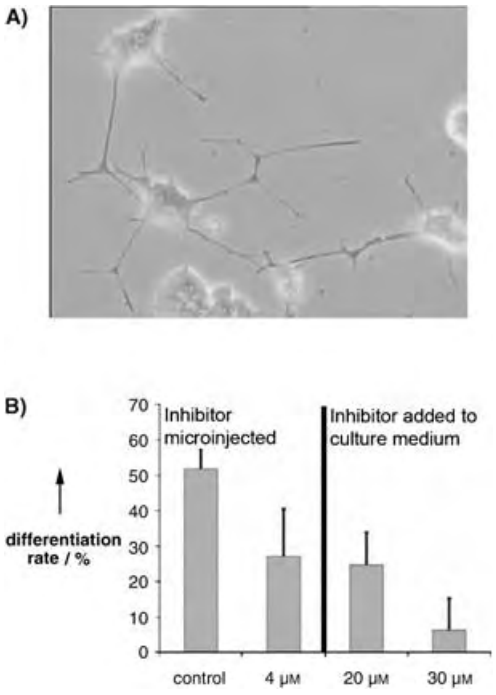


Figure 1. Reduction of PC-12 cell differentiation rate by APT1 inhibitor **6**. PC-12 differentiation assays were performed according to the procedure of Bader et al.[12] A 50 μM solution of the palmitoylatable lipopeptide coupling product of N-RasG12V(1–181) and **11** was microinjected into cells, thereby inducing a neurite outgrowth in approximately 50% of the injected cells (A). If APT1 inhibitor **6** was either coinjected (4 μM stock solution) with the Ras lipoprotein or added to the medium 1 h before microinjection (20 and 30 μM), the differentiation rate decreased significantly (B). For each experiment, an average of 100 cells were treated.

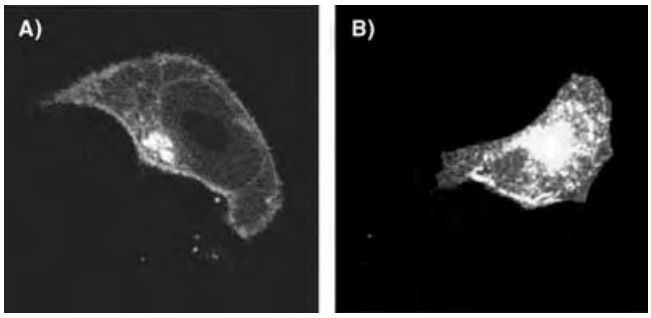

Figure 2. Inhibition of plasma-membrane localization of fluorescently labeled Ras protein **12** by APT1 inhibitor **6**. A 40 μM solution of the coupling product of N-RasG12V(1–181) and lipopeptide **12** was microinjected into MDCK cells. Localization of the fluorescent lipoprotein was monitored 7 h after microinjection by confocal microscopy. Although Ras protein alone shows a distinct staining of the plasma membrane (A), coinjection of 2 μM inhibitor **6** results in an accumulation of the lipoprotein in cytoplasmic structures, which is typical for nonpalmitoylatable Ras constructs (B).

by APT1 should result in reduced membrane binding of the oncogenic proteins[12,14] and in a reduction of neurite outgrowth. Therefore, upon inhibition of this process, an increased differentiation rate was to be expected.

Surprisingly, however, coinjection of a 4 μM solution or addition of APT1 inhibitor **6** to the culture medium (final concentration 20 μM) 1 h before microinjection of the Ras protein resulted in a *decrease* in the neurite outgrowth rate from above 50 to below 30%. An increase in the inhibitor concentration in the medium to 30 μM reduced the neurite outgrowth rate to a value below 10% (Figure 1).

To ascertain that the reduction in proliferation rate correlates with a lack of localization of Ras at the plasma membrane and consequently with inhibition of *S*-palmitoylation, synthetic fluorescent *S*-farnesylated and *S*-palmitoylatable N-Ras protein **12** was coinjected with compound **6** into MDCK cells. Confocal fluorescence microscopy revealed that the fluorescent protein had accumulated in cytoplasmic structures and the Golgi (Figure 2). In the absence of inhibitor, localization of the protein to the plasma membrane was clearly observed. When the corresponding fluorescent Ras protein in which the palmitoylatable cysteine residue was replaced by a nonpalmitoylatable serine residue was microinjected into Madin–Darby Canine Kidney (MDCK) cells, the protein was also localized in the cytoplasm and the Golgi (not shown).

When Ras protein **14**, which incorporates a hydrolysis-resistant hexadecyl thioether, was coinjected with inhibitor **6** at the same concentration as the palmitoylatable Ras protein had been, no reduction in neurite outgrowth was observed, as compared to the results after microinjection of lipidated protein **14** alone (not shown).

Microinjection of protein **15**, which carries only D-amino acids at the C terminus, into PC-12 cells surprisingly induced a differentiation rate that was comparable to the rate induced by the protein containing the natural L-amino acids.[14] This result indicates that the enzyme catalyzing the *S*-palmitoylation reaction must be fairly stereotolerant. To determine whether APT1 fulfills this criterion, the H-Ras-derived D-peptide **17** and the corresponding L-peptide were synthesized and subjected to depalmitoylation by APT1. The enzyme depalmitoylates both compounds with nearly identical rates (for the corresponding data, see the Supporting Information).

These results indicate that benzodiazepinedione **6** specifically inhibits Ras localization to the plasma membrane in the cells and, consequently, inhibits Ras palmitoylation rather than depalmitoylation. The fact that compound **6** displays an IC_{50} value for APT1 in the nanomolar range and that in the cells that were used for the microinjection experiments only *S*-palmitoylation remained to complete all the steps of posttranslational Ras modification required for plasma-membrane localization and induction of neurite outgrowth suggested that the observed effect might be linked to the inhibition of processes mediated by APT1. This includes the possibility that APT1 might be involved directly in Ras palmitoylation and in further downstream events that lead to Ras acylation by a different mechanism. We also cannot exclude the possibility that the effects described above are due to inhibition of other enzymes by benzodiazepinedione **6**.

To investigate whether APT1, in principle, can function as an *S*-palmitoylating enzyme in vitro, fluorescent palmitoylable peptide **18**, which represents the characteristic C termi-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

nus of the H-Ras protein and incorporates a geranyl-*N*-mant function as a fluorescent substitute for the farnesyl group,[13] was treated with APT1 in the presence of palmitic acid. The palmitoylation reaction was monitored spectroscopically since conversion of the substrate **18** into the palmitic acid thioester results in a diagnostic shift of the fluorescence emission maximum from 440 to 410 nm, as determined by employing synthesized reference compounds (Figure 3).

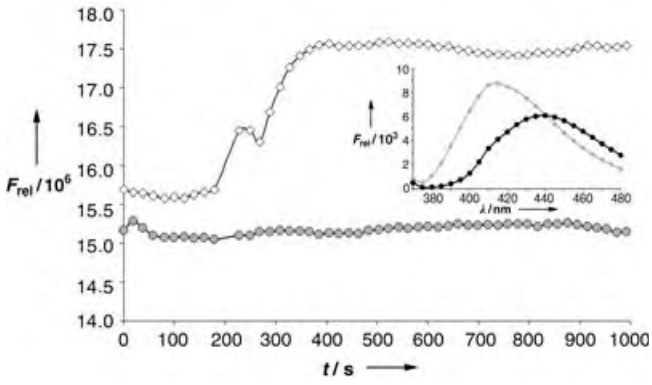

Figure 3. Palmitoylating activity of APT1 indicated by the change in relative fluorescence units (F_{rel}; measured at 410 nm) over time. Gray circles: control, that is, H-Ras peptide **18** and palmitic acid without APT1; white diamonds: H-Ras peptide **18**, palmitic acid, and added APT1. Conditions were as described in the Supporting Information). For better solubility of the palmitic acid, 10% dimethylsulfoxide (DMSO) was added to the reaction mixture. The concentrations for substrate **18**, APT1, and palmitic acid were 1, 1, and 100 μM, respectively. After the reaction mixture was incubated for 13 min, the reaction was started by addition of APT1. The result of a representative experiment is shown. Each data point represents the average of two independent measurements. The experiment was repeated six times with similar results (not shown). Small inset: emission spectra (370–480 nm) of palmitoylated (gray diamonds) and depalmitoylated (black circles) substrate peptide upon excitation at 360 nm.

Addition of APT1 to the reaction mixture led to a significant increase in fluorescence at 410 nm, thereby indicating *S*-palmitoylation of the substrate. The formation of the *S*-palmitoylated peptide was additionally confirmed by HPLC analysis of the reaction mixture and MALDI mass spectrometry (data not shown).[15]

A similar shift in fluorescence emission maximum was also observed when APT1 and palmitoyl coenzyme A were incubated with the synthetic, palmitoylatable N-Ras lipoprotein **16**, which again incorporates a fluorescent geranyl-mant instead of the farnesyl group.[13] Ras lipoprotein and palmitoyl donor or enzyme alone did not result in a shift of the emission maximum (see the Supporting Information). We utilized the hypsochromic effect to test whether inhibitors of APT1 were capable of preventing the enzyme-catalyzed palmitoylation of the Ras lipoprotein. Indeed, addition of compound **8** resulted in a clear blocking of the APT1-mediated shift in the fluorescence emission of the N-Ras construct (Figure 4).

To further determine whether APT1 does palmitoylate N-Ras in vitro, the protein was incubated with APT1 and [9, 10-^{3}H]-palmitic acid and the incorporation of radioactivity was

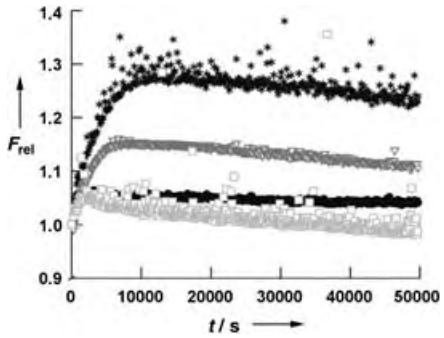

Figure 4. The APT1-mediated *S*-palmitoylation of N-Ras lipoprotein **16** employing palmitoyl coenzyme A (CoA) is inhibited by compound **8.** The change in relative fluorescence emission at 400 nm (F_{rel}) was measured under continuous stirring as a function of time. The concentrations of substrate **16**, APT1, and palmitoyl CoA were 500 nM, 50 nM, and 50 μM, respectively. After the reaction mixture was incubated for 15 min in the presence of different inhibitor concentrations, the reaction was started by addition of the enzyme. The result of one representative set of experiments (out of three) is shown. The palmitoylating reaction was studied in the absence of inhibitor (stars) or upon addition of compound **8** to the reaction mixture (triangles: 20 μM; circles: 40 μM; squares: 60 μM). The excitation wavelength was 360 nm. Measurements were performed at 20°C in 20 mM Hepes buffer (pH 7.4), 150 mM NaCl, 5 mM KCl, and 1 mM Na_2HPO_4. Palmitoyl CoA was stored at −20°C in aqueous solution containing 5 mM Na_2HPO_4. In each reaction mixture, the content of DMSO used as a solvent for compound **8** was adjusted to 0.3%.

determined by scintillation counting. In three separate experiments, the activity determined for the bands corresponding to the Ras protein in sodium dodecylsulfate PAGE was approximately 100% above the background value, thereby proving that N-Ras was palmitoylated (see the Supporting Information).

These results demonstrate that APT1 cannot only mediate Ras depalmitoylation but also Ras palmitoylation in vitro. Since the compounds shown in Table 1 may therefore be regarded as Ras-palmitoylation inhibitors we would like to refer to them as Raspalins 1–6 (according to the entries in the table, that is, compound **6** is termed Raspalin 3).

Enzymatic acylation by hydrolase-catalyzed reversal of the hydrolysis reaction, including that for plasma-membrane constituents,[16] is well-known[17] and incorporation of [^{3}H]-palmitic acid into N-Ras-derived farnesylated peptides in CV-1 cells has been noticed before.[18] In particular, Schuchman, Sandhoff, and co-workers convincingly demonstrated that acid ceramidase can catalyze ceramide synthesis in vitro and in vivo from free fatty acids and sphingosine by reverse hydrolysis, thereby providing a "salvage" pathway for ceramide biosynthesis.[16]

In addition, very recently Rando and co-workers reported that the enzyme lecithin retinal acyl transferase (LRAT) catalyzes the reversible interconversion of all-*trans*-retinal, *trans*-retinyl palmitate, and the triply *S*-palmitoylated membrane-associated protein mRPE65.[19]

The notion that APT1 may not only function as a thioesterase but also as an acyltransferase is furthermore supported by the fact that the nucleophilic serine residue 114

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

that forms part of the catalytic Ser-His-Asp triad of the protein is located within a Gly-Xaa-Ser-Xaa-Gly motif (Gly112-Phe113-Ser114-Glu115-Gly116). This motif has previously been identified as typical for enzymes with acyltransferase and thioesterase activity[20] and proven to be of diagnostic and predictive value.[21] Finally, we note that the broad substrate tolerance displayed by APT1 would also explain the finding that a consensus palmitoylation peptide sequence motif does not seem to exist.[4]

Our results demonstrate that the thioesterase APT1 can depalmitoylate and palmitoylate the Ras protein in vitro. From these observations a direct involvement of APT1 in Ras palmitoylation in vivo cannot be conclusively delineated. However, this possibility exists. Future in-depth evaluation of the biological role of APT1 by biology and chemical biology techniques is required to prove such a hypothesis.

[15] The enzymatic synthesis of a thioester from a carboxylic acid and a thiol a priori is an energetically uphill process; in this respect, it is comparable to the enzymatic synthesis of a peptide from the thermodynamically more favorable amine. The principle by which a thioesterase can catalyze the formation of a thioester from a thiol and an acid can therefore be regarded as analogous to peptide synthesis by proteases if both enzyme types employ the same mechanism. APT1 is a cysteine hydrolase displaying the same catalytically active triad as cysteine and serine proteases; the enzymes chymotrypsin (serine protease) and papain (cysteine protease) can serve as analogous cases. For these enzymes, it has been demonstrated that catalysis of the synthesis reaction is achieved by lowering the transition state of the transformation through entropic and enthalpic contributions. Thus, the enzymes concentrate and correctly orientate the substrate and restrict the mobility of the groups concerned with the transition state, thereby causing changes in activation entropy. In addition, charge distinction in the active site and the geometry of substrate binding are changed, which affects the activation enthalpy. Furthermore, in the presence of solvents other than water and in the presence of a second phase, criteria that both are fulfilled in a membraneous environment, the hydration of ionic groups, most notably carboxy functions, is diminished, thereby making them more prone to nucleophilic attack. Also, the formed product, which is more hydrophilic than the starting materials, is sequestered away under these conditions, particularly in a two-phase system, for example, at a water/membrane interface. The free-energy change of this transfer also provides a driving force for synthesis. In addition, the decision between deacylation of an intermediary acyl–enzyme complex by water (that is, hydrolysis) and acyl transfer to a different nucleophile like an amine or a thiol (that is, synthesis) is strongly influenced by the nucleophilic strength of the competitors. In this respect, amines and, even more so, thiols have an unequivocal advantage over water. For instance, leucine amide (0.25 M) deacylates an acyl–chymotrypsin complex 20 times faster than water (55 M); see: K. Morihara, T. Oka, *Biochem. J.* **1977**, *163*, 531.

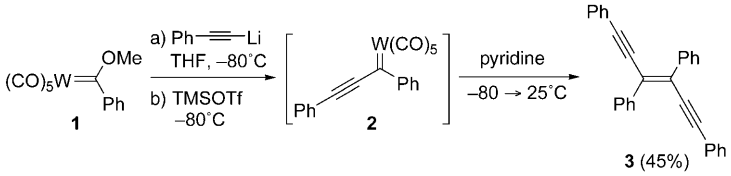
Formal Alkyne Insertion into Alkoxycarbene Complexes: Simple Access to Enantiopure Group 6 Alkynyl(alkoxy)carbene Complexes**

José Barluenga, Ramón Bernardo de la Rúa, Diana de Sáa, Alfredo Ballesteros, and Miguel Tomás*

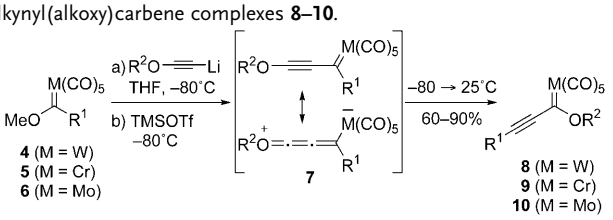


Dedicated to Professor Heinz Hoberg on the occasion of his 80th birthday

Since their discovery in 1964, Fischer carbene complexes have been developed into efficient carbene-transfer agents.[1] The successful implementation of enantioselective processes through chiral nonracemic carbene complexes of chromium and tungsten has greatly increased their potential in selective synthesis.[2] In particular, chiral alkoxy carbenes **A** and **B**

derived from enantiopure alcohols (X* = OR) are efficient systems in a wide array of reactions,[3] while the less reactive chiral amino carbene complexes **A** and **B** (X* = NR_2) have proved to be useful when the metal carbene function is not involved, for example, in aldol, Michael, and Diels–Alder reactions.[4] It is remarkable that there was previously no methodology to access chiral alkynyl(alkoxy)carbenes of type **C** (X* = OR).[5]

We report herein that group 6 enantiopure alkynylcarbene complexes derived from chiral alcohols, as well as related polyalkynyl(alkoxy)carbenes, can be readily prepared from ordinary alkoxy carbenes via non-heteroatom-stabilized carbene complexes. First, the tungsten phenyl(methoxy)carbene complex **1** was treated in THF at −80 °C with lithium phenylacetylide (Scheme 1). Once the addition was completed the color of the solution changed from orange to yellow. Trimethylsilyl triflate (TMSOTf) was added, and the mixture was stirred for a few minutes until the solution



Scheme 1. Generation and dimerization of non-heteroatom-stabilized alkynyl carbene complex **2**.

became deep blue. The nonstabilized carbene complex **2**, which is presumed to be formed by elimination of methyl trimethylsilyl ether from the tetrahedral addition species,[6] were not isolated, but allowed to dimerize in the presence of pyridine (5 equiv) to (*E*)-1,3,4,6-tetraphenyl-3-hexen-1,5-diyne (**3**; 45 % yield).[7]

Unlike some previous reports regarding alkynylcarbene complexes of rhodium,[8] rhenium,[9] and manganese,[10] neither 1,3-migration of the metal center nor products derived thereof were observed in the case of intermediates of type **2**. Focused on this point, we checked whether the rearrangement is an electronically controlled process by using appropriate lithium reagents such as alkoxyacetylides. Gratifyingly, phenylethynyl(ethoxy)carbene complex **8a** was obtained in 90 % yield from carbene complex **4a** and ethoxyethynyl lithium (Table 1, entry 1). We observed that the initially formed nonstabilized carbene **7** undergoes rapid rearrangement, even at low temperatures (below −50 °C), to the more stable alkoxy carbene **8a**. Since alkynyl carbenes were also found to react readily, the reaction was extended to the preparation of elusive Fischer carbene complexes such as

diynyl(alkoxy)carbenes.[11] This is exemplified for 4-phenyl-1,3-butadiynyl carbenes of tungsten **8b** (81%) and chromium **9b** (89%) (Table 1, entry 2). Moreover, (6-phenyl-1,3,5-hexatriynyl)carbene complex **8c** (Table 1, entry 3) was synthesized in 60% yield from the tungsten diynylcarbene complex **8b** as starting material.

This finding prompted us to investigate whether it was feasible to access group 6 alkynylcarbenes with a chiral alkoxy group, as the preparation of such compounds had hitherto been unsuccessful. Importantly, a number of alkynyl carbenes derived from chiral alcohols were readily synthesized in high yields by following the routine protocol (Table 1, entries 4–8). The process seems to be of wide scope on the basis of the following observations: 1) common chiral bulky alkoxy groups are efficiently assembled into the carbene structure (menthyloxy, 8-phenylmenthyloxy, *trans*-2-phenylcyclohexyloxy); 2) the process is applicable not only to tungsten and chromium metals (compounds **8** and **9**), but also to the much more elusive molybdenum metal (compounds **10**);[12] 3) besides aryl-substituted complexes, enolizable carbenes ($R^1 = i$Pr; Table 1, entry 8) can also be employed successfully.

As enantioselective cycloaddtition reactions with chiral alkynes are very rare,[13–15] the chiral induction by the alkoxy group was then examined in the [4+2]-cycloaddition with 1-azadienes (Scheme 2).[16] Thus, the reaction of 1-azadiene **11**

Scheme 2. Diastereoselective [4+2] cycloaddition of 1-azadiene **11** and carbene **8e**. Synthesis of enantiopure 1,4-dihydropyridine **14**.

with phenylethynyl(8-phenylmenthyloxy)carbene complex **8e** in THF at room temperature furnished, after chromatographic purification, the dihydropyridine complex **12** in 70% yield as a sole regio- and diastereoisomer (by NMR spectroscopic analyis). The structure of the cycloadduct was determined by a X-ray crystallographic analysis.[16] According to our previous reports[17,18] we propose a working model that involves, 1) diastereoselective conjugate addition of the nitrogen atom of **11** to the more accessible face of alkyne (probably due to a π-stacking effect as shown) to form the intermediate **13** with central and axial chirality; and 2) cyclization of **13** through the *Re* face of the C=C bond to afford the observed cycloadduct **12**.[19] The latter was demetalated, and the chiral auxiliary removed by treatment with $[Cu(MeCN)_4]BF_4$ in wet CH_2Cl_2 to provide the aldehyde **14** (65%, >99.5% *ee*).[20]

In conclusion, new aspects that enhance the synthetic utility of Fischer carbene complexes are featured in this report: 1) 1,3-alkynyl carbene ligand rearrangement is a very easy process for non-heteroatom-stabilized alkynyl carbenes and seems to be thermodynamically controlled; 2) based on this finding a facile and general access to novel chiral alkynyl(alkoxy)carbene complexes was undertaken; 3) their efficient chiral induction was proved and allowed the first enantioselective synthesis of 1,4-dihydropyridines through [4+2]-cycloaddition;[21] 4) this procedure should find application in the extensive chemistry already reported for achiral alkynyl(alkoxy)carbene complexes of various transition metals;[1c] 5) this methodology might provide access to different achiral and chiral heteroatom-susbstituted carbene complexes of metals and heteroatom substituents other than Group 6 and alkoxy or amino groups.

Experimental Section

General procedure (**8**, **9**, **10**): The appropriate Fischer carbene complex **4**–**6** (1 mmol) was added to a solution of lithium alkoxyacetylide (1.5 mmol) in THF (10 mL) at −80 °C. After stirring for 15 minutes at this temperature, the mixture was transferred with a cannula into a solution of trimethylsilyl triflate (1.6 mmol, 290 μL) in THF (5 mL) at −80 °C. The deep coloured solution was allowed to reach room temperature. Removal of the solvents and chromatographic purification of the residue on silica gel (hexanes) gave the corresponding Fischer carbene complexes **8**–**10**.

12 and **14**: 1-Azadiene **11** (0.122 g, 1.1 mmol) was added to a solution of the complex **8e** (0.484 g, 1 mmol) in THF (20 mL), and the mixture was stirred at room temperature for 16 h. Removal of solvents followed by chromatographic purification on silica gel (10% ethyl acetate in hexanes, $R_f = 0.55$) yielded pure dihydropyridine complex **12** as a sole regio- and diastereoisomer (0.55 g, 70%). Further crystallization from pentane gave crystals suitable for X-ray crystallographic analysis. A solution of cycloadduct **12** (0.4 g, 0.5 mmol) in CH_2Cl_2/H_2O (49:1 v/v; 50 mL) was stirred at room temperature with $[Cu(CH_3CN)_4]BF_4$ (0.15 g,0,5 mmol) for 48 h. The mixture was quenched with water (10 mL) and extracted with dichloromethane (3 × 20 mL). The organic layer was washed with water (2 × 20 mL) and dried over Na_2SO_4. The solvents were removed, and the residue purified by chromatography on silica gel (hexanes/EtOAc/Et_3N 5:1:1; $R_f = 0.45$) to afford the metal-free cycloadduct **14** (79 mg, 65%).

Favorable binding of gold nanoparticles to single-stranded DNA decreases the likelihood of mispair formation during annealing and clearly increases the specificity and yield of PCR, one of the most important standard methods of molecular biology. In their Communication on pp. 5100 ff., Z. Zhang, C. Fan, J. Hu, and co-workers report on this promising field of biotechnology. (Xiaobin Wang assisted in the production of this image.)

Cationic Boron Compounds
The possible synthetic uses of boronium, borenium, and borinium ions are increasing rapidly. W. E. Piers et al. explore the chemistry of these reactive electrophiles in their Review on page 5016 ff.

Drug-Delivery Systems
In their Communication on pp. 5038 ff., V. S.-Y. Lin et al. introduce a model system for the site-specific delivery of drugs. For this purpose, mesoporous MCM-41-type silica nanorods (MSNs) covered with superparamagnetic iron oxide nanoparticles were used.

Self-Assembly
Helical bis(merocyanin)dye nanorods organize themselves through an inversion of the exciton chirality as well as through structural changes that occur in the transition from kinetic to thermodynamic self-assembly. For more information, see the Communication by F. Würthner et al. on pp. 5071 ff.

Reviews

Any old ion? The title boron cations (see scheme) are elusive and have largely been regarded as chemical curiosities. However, as potent electrophiles the enormous potential of these species is beginning to be recognized. Advances in mass spectrometry have made a systematic investigation of the gas-phase chemistry of these ions possible and have facilitated predictions of practical relevance to their reactivity in the condensed phase.

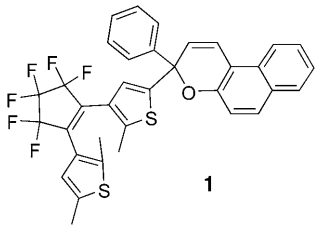
Stimuli-Responsive Controlled-Release Delivery System Based on Mesoporous Silica Nanorods Capped with Magnetic Nanoparticles

In a spin: The mixed-valent $\{Mn^{III}_{20-x}Mn^{II}_{x}\}$ cage complexes ($x = 2$–6) have structures corresponding to a fragment of a cubic close-packed lattice (see picture, Mn large sphere, O small sphere). Magnetic studies show for the cage with $x = 2$ that the ground state has a spin (S) of 19 ± 1 in low field, which increases to about $S = 30$ at higher fields. The cage is a "single molecule magnet" with a high energy barrier (43 K) to reorientation of the magnetization.



Molecular Magnets

A wide variety of well-defined multivalent peptides and proteins can be made by conjugating synthetic peptides and recombinantly expressed proteins to cysteine-functionalized dendrimers using native chemical ligation (see picture). This modular approach provides access to dendrimers that are attractive both for understanding fundamental issues of multivalency in biological interactions as well as for biomedical applications.

Awarded...

F. D. Toste Receives Pfizer Award

F. Dean Toste (University of California, Berkeley) is the recipient of the 2005 Pfizer Award for Creativity in Organic Chemistry. Toste was awarded for his contributions to the development of catalysts and catalytic methods for organic synthesis, particularly gold(I)-catalyzed propargyl Claisen rearrangements, Conia-ene reactions, 1,5-enyne isomerizations and 5-*endo-dig* cyclizations of acetylenic β-keto esters.[1] The goal of his work is to facilitate the synthesis of complex molecules with interesting structural, biological, and physical properties. Toste's research group is also involved in the development of new methods for the addition of water and alcohols to enones, providing an alternative access to aldol adducts.

F. D. Toste

Toste studied at the University of Toronto and received his PhD for work with B. M. Trost at Stanford University in 2000. He carried out his postdoctoral research in the group of R. H. Grubbs at the California Institute of Technology (Pasadena) between 2001 and 2002. Since that time, he has been an assistant professor at the University of California in Berkeley.

A. Zumbusch Receives Sommerfeld Prize and Goes to London

Andreas Zumbusch (University College London) received the Arnhold Sommerfeld Prize of the Bavarian Academy of Sciences for his contributions to biophysical chemistry. He was awarded for the development of coherent anti-Stokes Raman scattering (CARS) microscopy, which permits the examination of living cells in high three-dimensional resolution without the need for staining. Moreover, he was honored for his contributions to single-molecule spectroscopy, for example, in the use of green fluorescent protein as a biological probe. His research group recently reported in *ChemPhysChem* on the vibronic excitation of single molecules as a new technique for the study of low-temperature dynamics.[2]

Zumbusch studied Chemistry in Munich and Bordeaux. He received his PhD in 1996 under the direction of H. Schnöckel at the University of Karlsruhe (Germany). From 1997 to 1998 he worked as a postdoc in the research group of X. S. Xie at the Pacific Northwest National Laboratory in Richland, Washington. Starting in 1999, he led a research group in the chemistry department at the University of Munich (C. Bräuchle), where he was promoted to professor for his work in high-sensitivity optical microscopy and its application in biophysics. Since February of 2005 he has been working as a Reader at University College London.

A. Zumbusch

Several Awards for A. Müller

Achim Müller (University of Bielefeld, Germany), whose large metal clusters continue to gather attention, received three additional distinctions. The Université Pierre et Marie Curie (Paris) awarded him an honorary doctorate. The title was conferred during a colloquium about the frontiers of inorganic chemistry, at which Müller discussed perspectives in nanotechnology, including porous capsules, artificial cells, sphere surfaces, and "super-supramolecular" chemistry. Furthermore, he was accorded with the Premio Elhuyar Goldschmidt of the Real Sociedad Española de Química (RSEQ, Spanish Chemical Society), and he also delivered this year's annual Lewis Lecture at the University of Cambridge. He recently reported on uniquely linked triangular motifs and their magnetic properties at the surfaces of spherical capsules composed of molybdenum and vanadium or iron in *Angewandte Chemie*.[3]

A. Müller

Müller received his PhD in 1965 from the University of Göttingen (Germany) under the direction of O. Glemser in work on thermochemistry and completed a habilitation there in the field of vibrational spectroscopy. In 1971, he accepted a professorship at the University of Dortmund (Germany), and has been working at the University of Bielefeld since 1977. His research involves the chemistry of transition metals, particularly inorganic supramolecular chemistry and bioinorganic chemistry in synthesis, spectroscopy, and theory. "The Chemistry of Nanomaterials", edited by A. Müller, C. N. R. Rao, and A. K. Cheetham, and published by Wiley-VCH appeared at the beginning of 2004.

Cellular Profiling of Small-Molecule Bioactivities: an Alternative Tool for Chemical Biology**

*Thorsten Berg**

Keywords:
fluorescent probes · inhibitors · phenotypic screening · proteins · signal transduction

One of the main goals of chemical biology is to identify cell-permeable organic molecules that interfere with protein function to provide the scientific community with novel research tools for the investigation of biological questions.[1] There are currently two major approaches for the primary screening of chemical libraries to identify such bioactive organic molecules. In the first approach, inhibitors or activators of purified proteins or reconstituted, narrowly defined signaling pathways are sought in vitro. In the second approach, cells or organisms are treated with small molecules; those compounds which cause a desired phenotype are selected. The success of research projects that begin with such a phenotypic screen is dependent on the subsequent identification of the molecular target(s) of the identified compounds that elicit the phenotype, as a meaningful analysis of the biological profiles of the hit compound can only be performed when the cellular target is known. Most of the current methods used to pinpoint the molecular target(s) of compounds identified in phenotypic screens can be classified into two subgroups: 1) affinity-based biochemical methods based on small-molecule binding to target proteins and the subsequent identification of the protein bound and 2) genetic approaches that monitor cellular changes in response to treatment with the compound. As discussed at the end of this Highlight, neither approach is generally applicable; alternative approaches aimed at the identification of molecular targets of bioactive compounds from phenotypic screens would therefore be highly welcome.

The research groups of Altschuler, Wu, and Mitchison recently reported a method which can be used to profile the effects of interfering agents on cells by the analysis of multiple parameters related to the expression, post-translational modification, and localization of preselected proteins.[2] This approach registers the biological effects of a compound with an unknown mode of action on a defined set of biological markers and then compares them with the effects observed with a set of reference compounds with known activities.[3] If the biological effects of a compound with unknown target(s) resemble one of more of the biological profiles of the reference compounds, a potential mechanism of action for the new inhibitor can be proposed. This could provide valuable information for decreasing the number of potential targets for subsequent investigation.

To demonstrate the principle of this method, cells grown in microtiter plates were treated with 100 different chemical substances at a range of concentrations. 90 of the 100 compounds had a known mechanism of action, and thereby served as references for the classification of the remaining 10 test compounds. Six of these 10 were simply blinded references, three had an unknown biological mechanism, and one compound was known to have multiple effects. Treated cells were then stained with fluorescently labeled antibodies raised against a small number of proteins involved in a range of cell signaling pathways. In this way, a very broad overview of the effects of compounds on the cells was obtained. The wells were photographed with an automated microscope, and special software was employed to convert the large amount of data obtained into interpretable information. Changes in various parameters related to the fluorescence of the antibodies in response to various compound concentrations were analyzed; these changes were subsequently expressed as color codes, as shown in the example case of the topoisomerase inhibitor camptothecin (Figure 1a).

For a meaningful comparison of the biological effects of two compounds, it is necessary to depict the compound profiles in a manner that is independent of the absolute concentration at which an effect is initially observed. Otherwise, two compounds with identical biological mechanisms yet different potencies would be erroneously regarded as having different biological effects, as the observation of any effect would occur at different concentration thresholds. Therefore, the authors devised a method to analyze the similarity of the compound effects in a concentration-independent manner and used this information for the unsupervised clustering of the compounds depicted in Figure 1b. The names of the compounds and their mode of action as described in the

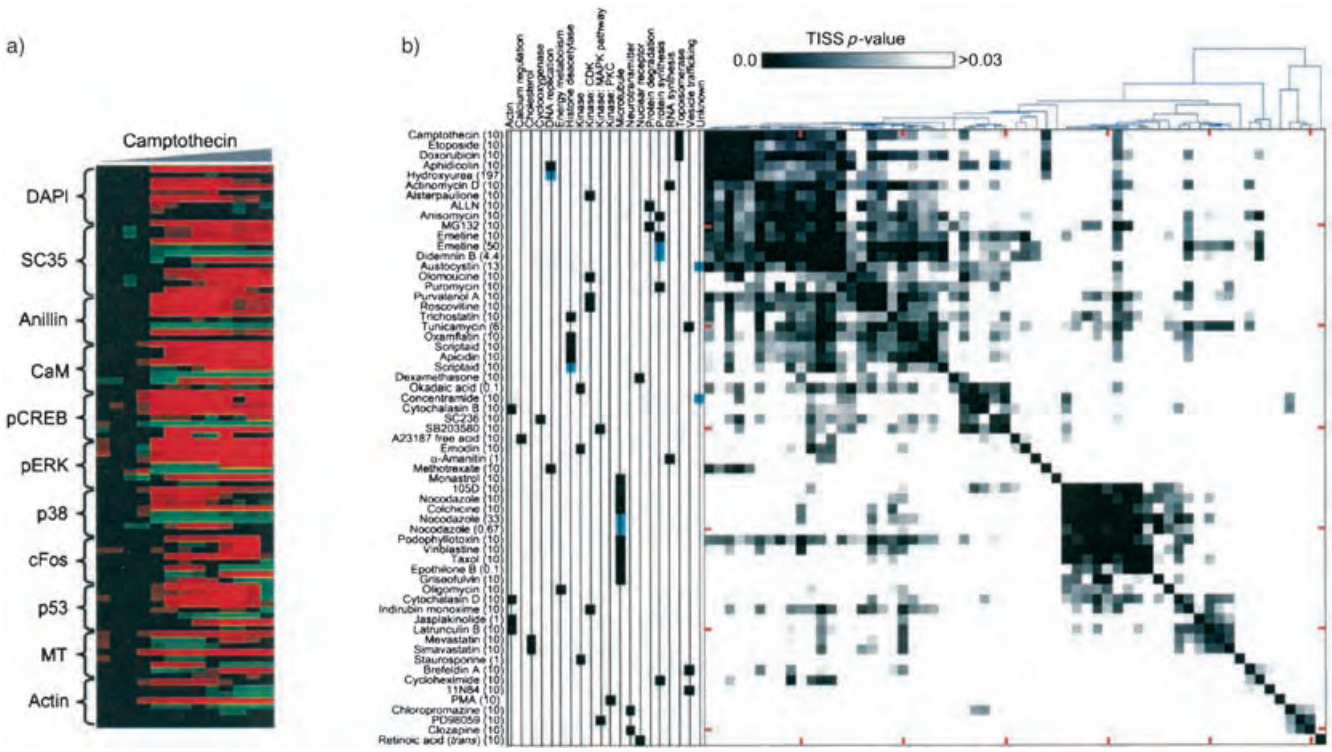

Figure 1. a) Cellular responses to different concentrations of the topoisomerase inhibitor camptothecin. The response of each parameter to a given concentration of the drug is expressed as a colored rectangle. The vertical axis depicts 93 biological parameters. b) Clustering analysis of drug effects; excerpted from Ref. [2] (Copyright 2004, AAAS).

literature are given in the left, and on the right, the similarities between compound pairs are given: high similarities are indicated by dark squares; lower degrees of similarity are represented with lighter squares. (The list of compounds as given on the left side of Figure 1b is omitted from top of the right part of the figure.) Naturally, the biological profiles of each compound match perfectly in self-comparison, which explains the diagonal line of black squares.

Successful clustering analysis lists compounds with similar modes of action adjacent to each other, as observed by adjacent black squares in the left part of Figure 1b, and leads to an accumulation of dark squares around the diagonal line in the right portion. Good clustering is indeed observed for histone deacetylase inhibitors, topoisomerase inhibitors, and microtubule poisons. However, for other compound classes such as protein synthesis inhibitors, clustering was not ideal.

Another criterion for success was to determine if the 10 test compounds mentioned above could be properly classified. Five of the six blinded alternate titrations of known drugs showed usable activity profiles and clustered well with their unmasked counterparts, or at least with drugs of similar mechanism, as indicated by the blue squares in the left part of Figure 1b. The single compound with many cellular functions clustered correctly with others known to have one of its functions.[4] Of the three remaining compounds with uncharacterized mechanisms, only one could be grouped with a certain inhibitor class (it would have been helpful to see the independent experimental data supporting the correct classification of the compound).

Whereas the success rate of the current study is not optimal, it is the principle of the approach which deserves credit. About 60 of the 100 compounds showed a meaningful response in the experiment, and it is possible that the other 40 compounds either acted on proteins or pathways not represented by the relatively small set of antibodies used in this study, or that their biological targets were not expressed in the chosen cell line. A larger set of reference compounds would also improve the chances of pinpointing the biological functions of novel compounds identified in phenotypic screens. Therefore, the power of this method is likely to be improved with the use of larger sets of antibodies and reference compounds, and by extending the experiments to additional cell lines. The antibodies and reference compounds could be adapted to the specific needs of the researcher. A distinctly positive aspect of the method is that it permits the analysis of compound concentrations at which various cellular parameters change. Such information could be useful for the identification of an optimal dose below the threshold of undesirable (toxic) effects. One severe limitation of the approach, however, is that the hardware and software necessary for these experiments are not currently in place at most academic settings; acquisition of these resources may require an industrial-level budget. The expansion of the set of reference compounds, anti-

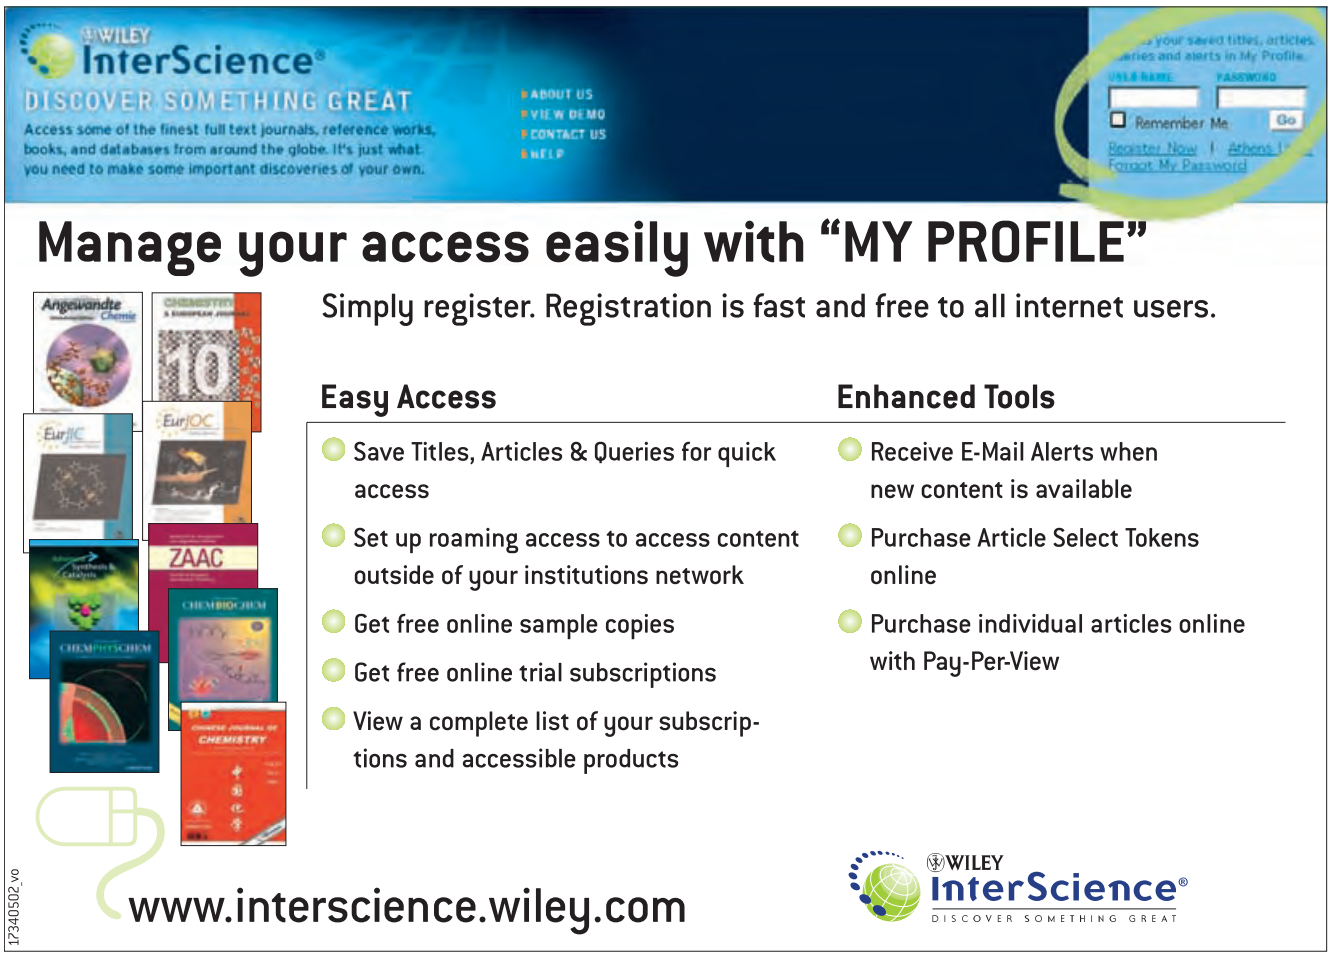
© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

body probes, and cell lines might require even more investment in screening infrastructure and computing power.

The cellular targets of most chemical genetic screens have been identified through biochemical affinity-based techniques.[5–8] Such approaches require the attachment of a tag that facilitates immobilization of the bioactive molecule. The resulting hybrid molecule is then attached to a solid support by the tag and then incubated with cell lysates. Proteins successfully immobilized through specific interactions with the compound are subsequently analyzed by protein microsequencing, MS-based methods, or immunoblotting. Examples of successful applications of this approach include the discovery of the molecular targets of the natural product FK506[9] and of several kinase inhibitors.[10–13] One general concern is that compound-binding proteins identified by this method may not be the physiologically relevant binding partners in vivo. In this respect, irreversible inhibitors with reactive functional groups are advantageous, in that intact cells, instead of cell lysates, can be treated with the tagged inhibitor. Therefore, it can be assumed that only the physiologically relevant proteins will bind to the inhibitor. Examples of the successful discovery of cellular targets of irreversible inhibitors include the natural products fumagillin,[14] parthenolide,[15] epoxomicin,[16] and lactacystin.[17]

In a variation of the approach referred to as "photoaffinity labeling", a reversible inhibitor is tagged with a photolabile group, which inserts itself into chemical bonds in close proximity upon irradiation, thereby forming covalent bonds with its protein-binding partners.[18,19] Despite the success of affinity-based purification approaches, they suffer from the following limitations: 1) the approach requires a tight interaction between the small molecule and its protein target, 2) the protein target must be abundant in the cell, and 3) the addition of a tag without significant loss of biological activity requires precise knowledge of structure–activity relationships, and there is no guarantee that a tagged inhibitor with sufficient biological potency can be identified and synthesized. Several modified approaches have been suggested to overcome these hurdles, for example: 1) the alignment of proteins on solid supports (protein arrays)[20] or their display on the surface of phages[21] to artificially increase the local concentration of potential target proteins, 2) the yeast three-hybrid system,[22] and 3) the screening of small-molecule libraries pre-equipped with a linker that allows rapid immobilization without the need for structural modification of the inhibitor.[23] Future research will assess the power of these modified approaches.

Most genetic approaches for target identification have been developed in yeast, and make use of the availability of complete sets of viable homozygous and heterozygous gene-deletion mutants. The most obvious approach is to compare the effect of an interfering agent on the gene expression profile of a wild-type yeast strain with that of yeast strains in which single genes have been deleted.[24–27] Another experimental approach exploits the phenomenon that heterozygous deletion mutants (yeast strains in which only one of the two alleles of the respective gene is deleted) are more susceptible to inhibition by compounds which act on the gene product encoded by the remaining undeleted gene.[28–30] Genetic approaches with yeast as a model system may be an interesting alternative for cases in which the affinity purification approach cannot be applied; perhaps the main drawback is that a homologue of the gene product targeted in human cells (30000–40000 genes) may not be present in yeast ($\approx$6000 genes).



The cellular profiling of small-molecule bioactivities highlighted herein represents a significant advantage over most methods in current use, as it does not require a tag and is not restricted to yeast. However, it appears unlikely that this method will permit the definition of the target of an interfering agent down to a single protein, as the information provided is of a more general nature. Therefore, this novel method may represent a useful supplement to the toolbox of chemical geneticists in cases in which 1) the affinity purification approach fails, 2) the aim is to decrease the mode of action of a compound to a pathway or a group of proteins, or 3) cellular systems other than yeast are necessary. It will be interesting to witness the results obtained with this method in its future applications.

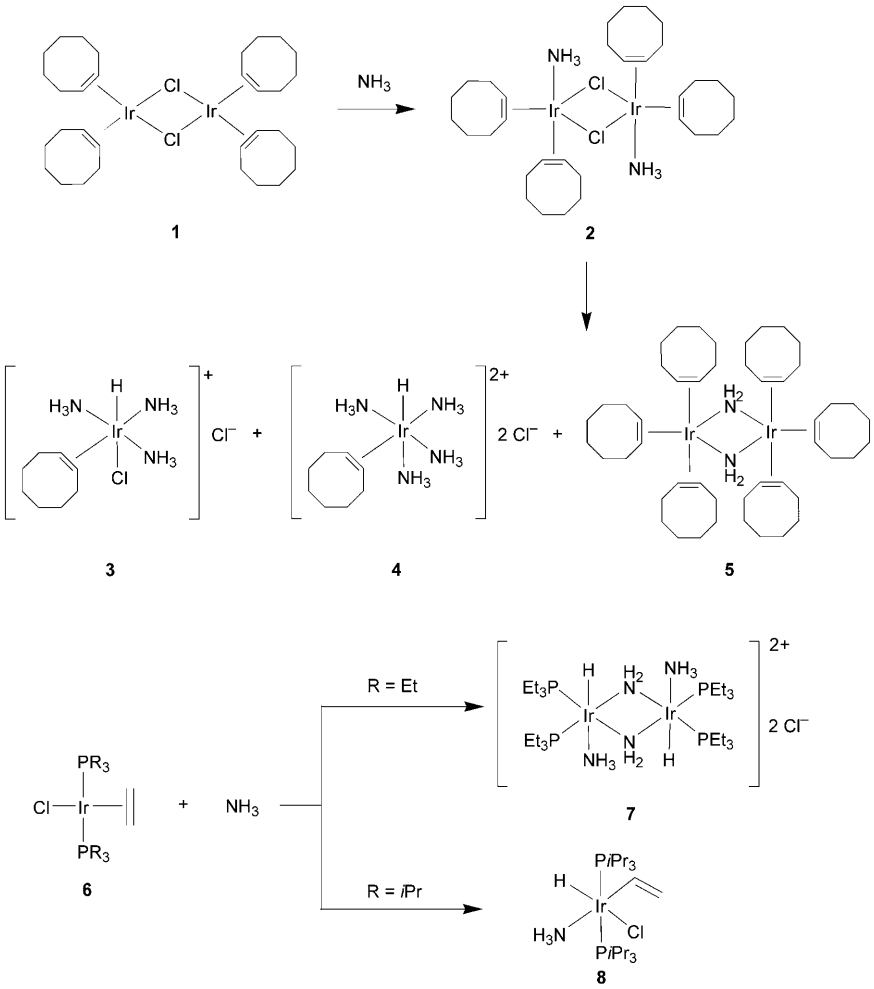
Oxidative Addition of NH_3 to a Transition-Metal Complex: A Key Step for the Metal-Mediated Derivatization of Ammonia?

*Thomas Braun**

Keywords:
N–H activation · amido complexes · hydroamination · iridium · oxidative addition

The oxidative addition of element–hydrogen bonds, which have been considered to be "unreactive" at transition-metal centers, has been a long-standing challenge.[1] One major focus of the investigations has been the C–H activation of alkanes by insertion of a transition-metal center into the carbon–hydrogen bond.[2] Matrix isolation techniques, laser flash photolysis, isotope labeling techniques, and NMR spectroscopic studies provide considerable evidence that an alkane σ complex is formed prior to the oxidative addition of the C–H bond.[2–4] In principle, several coordination modes for an alkane are conceivable, but an η^2-C,H interaction is thought to precede the oxidative addition step (Scheme 1).[1–3] Low-temperature IR spectroscopy in liquid xenon or krypton provides evidence for complexes with an alkane coordinated to a $\{(\eta^5\text{-}C_5Me_5)Rh(CO)\}$ moiety, which subsequently undergoes C–H bond cleavage.[5] The coordination of methane—as the simplest alkane—*and* its C–H activation reaction have not been observed to date, although the oxidative addition of methane is well known.[1–4] For SiH_4 a tautomeric equilibrium between an η^2-Si,H silane species and the oxidative addition product has been detected in solution by NMR spectroscopy (Scheme 1).[6]

Scheme 1. Coordination and activation of CH_4, SiH_4, and NH_3; an equilibrium has been observed for SiH_4 only.[6]



In contrast, reactions of ammonia with transition-metal complexes usually generate simple Lewis acid–base adducts, although there is some precedent for the activation of ammonia by transition-metal complexes.[7] It is known that aromatic amines are reactive towards N–H bond cleavage by oxidative addition,[8] but very little has been reported on the oxidative addition reaction of an N–H bond in ammonia itself (Scheme 1).[9,10] Early work reveals that such a reaction is feasible at cluster compounds.[9] Binuclear oxidative additions to give μ-amido complexes have also been demonstrated.[10] Milstein and Koelliker described the stepwise coordination and activation of ammonia at the iridium complex **1**.[10c] The ammonia complex **2** was obtained as the initial product, which then reacts further at room temperature to give **3**, **4**, and the amido compound **5** (Scheme 2). In another example ammonia was activated by binuclear oxidative addition at the ethylene iridium complex **6** to give the hydrido compound **7**, which also exhibits bridging amido ligands (Scheme 2).[10a,b] Interestingly, if $PiPr_3$ is used instead of PEt_3, C–H activation of the olefin yields complex **8**.

Another significant development in this field was made recently by Zhao, Goldman, and Hartwig, who reported on the insertion of an iridium center in one of the N–H bonds of NH_3 to give the mononuclear iridium hydrido amido complex **10**.[11] The iridium complex **9a** bearing a tridentate pincer ligand reacts at room temperature with NH_3 to generate the oxidative addition product **10** (Scheme 3). Complex **10** can also be prepared independently by an alternative route on treatment of the chloro complex **11** with NH_3 followed by deprotonation with $K[N(SiMe_3)_2]$ (Scheme 3). The oxidative addition of 3,5-dimethylaniline to **9a** or **9b** to yield the amido compound **12** is thermodynamically less favored than the reaction with ammonia. This has been shown by the determination of equilibrium constants for **9b**⇄**10** and **9b**⇄**12** (Scheme 3). The iridium complex **13** bearing an aromatic pincer ligand shows a different reactivity: the oxidative addition of aniline to **13** gives **14**, whereas in the reaction of **13** with ammonia no insertion into the N–H bond occurs;[8d] instead, the ammonia complex **15** is formed.

Mechanistic investigations on the formation of **10** from **9b** have been performed.[11] Isotope labeling studies using $[D_3]$ammonia showed no incorporation of deuterium into the pincer ligand. This suggests that no C–H acti-

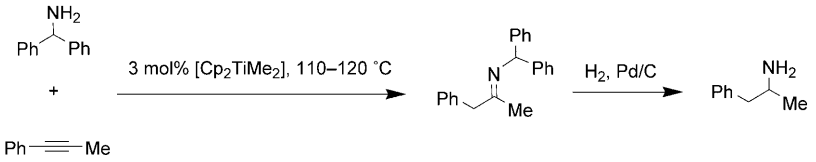

Scheme 2. Oxidative addition of ammonia at transition-metal complexes.

vation of the pincer ligand occurs prior to the oxidative addition of ammonia.[11] In addition, kinetic studies reveal that the activation proceeds by a dissociative reaction pathway, in which ammonia reacts with a 14-electron complex generated after dissociation of the olefin in **9b**.

Considering the importance of oxidative addition reactions of H–H, Si–H, C–H, or B–H bonds in various catalytic processes,[1,3,12] comparable N–H bond cleavage reactions of amines or ammonia at transition-metal centers can be regarded as model reactions for the development of new catalytic reaction cycles. To date, only a few catalytic conversions are known that proceed by the insertion of a late transition metal into an N–H bond, such as some homogeneously catalyzed hydroaminations.[12a,13–15] In an early report Milstein et al. described the iridium-catalyzed hydroamination of norbornene with aniline;[8a] model reactions provide strong evidence for an oxidative N–H addition pathway. Togni and co-workers investigated the same reaction with various iridium complexes bearing chiral diphosphane ligands as catalysts and a source for "naked fluoride" as cocatalyst.[14] Other recently developed transformations include the rhodium-catalyzed oxidative amination of vinylarenes

Scheme 4. Dimethyltitanocene-catalyzed hydroamination of alkynes using aminodiphenylmethane as ammonia equivalent.

and their hydroamination with unusual anti-Markovnikow selectivity as well as the palladium-catalyzed oxidative amination of alkenes.[15] The activation of amines by oxidative N–H addition followed by the insertion of an olefin into the metal–nitrogen bond are considered to be key steps in these conversions.

It has been shown that aminodiphenylmethane can serve as an ammonia equivalent in the dimethyltitanocene-catalyzed intermolecular hydroamination of alkynes to give primary amines after hydrogenation of an intermediate imine (Scheme 4).[16] The homogeneously catalyzed hydroamination of olefins with ammonia has so far remained elusive.[7g,12a,13a] The studies by Zhao, Goldman, and Hartwig on the insertion of a transition-metal center into an N–H bond of NH_3 to give a mononuclear amido hydrido complex might provide a new pathway to use ammonia itself as a feedstock in catalytic reactions. This discovery is therefore an important step forward for the development of new N–C coupling reactions based on the oxidative addition of an N–H bond in ammonia.

Boron cations are elusive and highly electrophilic species that play a key role in the chemistry of boron. Despite early interest in the chemistry of boron cations, until recently they have largely remained chemical curiosities. However, hints at harnessing their potential as potent electrophiles have begun to appear and developments in weakly coordinating anion technology suggest that this is an area of research that is ripe for exploration. It has been nearly 20 years since the last major review on boron cations; herein we summarize the progress in the area since that time.

3. Reactivity of Borocations 5029
4. Summary and Outlook 5034

1. Introduction

The chemistry of the boron-group elements is defined by their exceptional Lewis acidity, which is induced by their intrinsic electron deficiency. The observed bonding motifs of these elements, as well as their propensity to undergo reactions that serve to saturate their coordination sphere and/or fill their valence shell, are largely dictated by this deficiency. For example, neutral three-coordinate boron-group species, which can readily abstract hydride, halide, alkyl, and aryl functional groups to give anionic four-coordinate products, have been exploited in the field of olefin polymerization as Lewis acid co-catalysts.[1] Inasmuch as neutral boron-group compounds exhibit significant electrophilic character, the corresponding cationic species have been found to be even more reactive owing to their even greater electronic deficiency and their (sometimes) coordinative unsaturation. The chemistry of the heavier boron-group-element cations (Al, Ga, In, and Tl) has been recently reviewed.[2] However, low-coordinate cationic boron compounds have not been thoroughly examined since 1985,[3] and their four-coordinate analogues since 1975[4,5] despite the attention being paid to main-group Lewis acid catalysts and an ever-increasing search for the limit at which Lewis acidity is maximized without there being a decrease in synthetic utility.[6]

Boron cations can be classified into three distinct structural classes based on the coordination number at boron. Borinium cations (**I**) are two-coordinate and typically bound by two substituents that can relieve the electron

borinium (I) borenium (II) boronium (III)

deficiency at boron through π donation of lone pairs. Borinium compounds are notoriously reactive, and condensed-phase analysis is often hampered by significant interactions with solvent and/or counterions. Conversely, gas-phase studies of these species have proven to be powerful in the elucidation of their intrinsic reactivity. Borenium cations (**II**) are three-coordinate species that comprise two σ-bound substituents (R) and one dative interaction with a ligand (L) that serves to occupy a third coordination site as well as to reduce some of the electron deficiency at boron. Although the valence shell of boron in such species is not full, the added stability imparted by the donor ligand (L) renders borenium cations notably more amenable to solution studies than their two-coordinate counterparts. The third, and most common, class of boron cations is that of the tetrahedral, four-coordinate boronium cations (**III**), with two coordination sites occupied by σ-bound substituents and the other two populated by neutral donor ligands. The stability gained by the filled coordination sphere and the electron density provided by the donor ligands is reflected in the prevalence of reports that describe the generation of these species or invoke them as intermediates in various chemical transformations.

The donor ligands in **II** and **III** serve to partially quench the positive charge at boron and, indeed, are often depicted with the charge formally localized on the ligand L (or on the donating atom of L e.g. N or O). Given that 1) B is more electropositive than most of the donor elements in L, 2) computations indicate significant positive charge on boron, and 3) these compounds generally react as though they were boron cations, we prefer to represent these compounds with the positive charge on boron and the bonds between L and B as being dative in nature and do so throughout this review. While some contribution from a resonance structure in which charge resides on L and the bond is more covalent in nature must be present, the "cationic boron" view of these compounds emphasizes their potential reactivity as boron Lewis acids.

The innate reactivity of borocations,[+] particularly in the condensed phase, has made their characterization rather difficult. The majority have been characterized by NMR and IR spectroscopy, some by mass spectrometry, and a few examples by X-ray diffraction. The chemical shifts observed for these cations in ^{11}B NMR spectra are diagnostic and are typically found significantly downfield of neutral tricoordinate borane precursors or analogues. The $\delta = 30$–38 ppm range is typical for resonance signals from ion-separated bis(dialkylamido)borinium cations, while slightly lower

values ($\delta = 25$–30 ppm) are observed for the analogous amine-ligated borenium salts. A much larger range is observed for boronium species, although signals between 0 and 15 ppm are typical. In general, more cationic charge density on the boron center and a lower degree of electronic stabilization results in a more downfield-shifted resonance signal; for example, the presence of alkyl substituents in **I** can yield ^{11}B shifts of close to $\delta = 60$ ppm,[7] whereas the corresponding signals for alkoxy derivatives of **I** have been measured at $\delta \approx 23$ ppm.[8] Isolated cases that involve a boron atom coordinated in an η^5 fashion by a cyclopentadienyl ring display anomalously upfield-shifted resonances in the ^{11}B NMR spectrum (at ca. $\delta = -40$ ppm) which is a result of the unique electronic properties of such ligands (see Section 2.2.4). An increased line width associated with an increase in field gradient and resultant rapid relaxation, is also typical in the ^{11}B NMR spectrum of borinium ions.[3]

As nitrogen-based substituents are prevalent for boron complexes, the B–N stretching modes, in the infrared spectrum, are often cited. However, they are not always apparent and may be absent as a result of molecular symmetry. Perhaps more diagnostic is a hypsochromic trend, in the UV/Vis spectrum, upon going from a parent borane to the corresponding borocation.

Although powerful, mass spectrometry is not a routinely employed form of characterization, except in the case of gas-phase studies, where it dominates. And, while crystal structures are extremely informative with regards to condensed-phase conformations, their availability is largely dependant on the crystalline integrity and condensed-phase stability of the species in question. Indeed, only five examples of crystallographically characterized borinium and borenium ions were reported prior to Nöth's review of the field in 1985.[3,7,9,10]

Previous reviews on the topic of boron cations[3–5,11] have focused largely on their synthesis and characterization. However, although there have been synthetic advances over the past 20 years, often involving unique routes to highly stabilized species, much of the interim work in the area has focused on the gas-phase reactivity of borinium ions. The development of condensed-phase applications has, however, been initiated with promising results. Thus, advances in the syntheses of novel condensed-phase borocations as well as reactivity studies, both in the gas and condensed phases, will be detailed herein, thus emphasizing activity over the last two decades. The emergence of new applications for borocations is growing and the area is poised for rapid development.

2. Syntheses and Structures of Borocations

In all three classes of boron cations, the unfilled p orbitals of the boron atom in the parent borinium cation can become partially occupied as a result of either π donation from covalently bound substituents (e.g. **I**) or the donation of singlet lone pairs from donor ligands (e.g. **II** and **III**). The progression from **I**–**III** is characterized by a steady increase in the p character in the hybridized σ-bonding orbitals at boron, this increase is directly induced by the incoming ligands. Calculations[7,12] as well as the few structurally characterized examples of borinium cations **I**[7,9,13] give an R-B-R angle at boron that is nearly linear and indicative of sp hybridization, while bond angles for **III** that approach 109.5° (tetrahedral, sp^3 hybridized) are expected and observed (see Section 2.2.3).

The linearity observed for structures in class **I** is representative of an energetic minimum that allows for optimal orbital overlap between the empty p orbitals on boron and lone-pair-containing orbitals of π-donor substituents. Thus, these species adopt structures analogous to that observed for allene (Figure 1 a), with the substituents oriented 90° out of phase to one another to facilitate stabilization by means of π backbonding and reduce the interligand steric repulsions. This situation is particularly true for condensed-phase examples of **I**, for which dual-purpose ligands that include both a sterically bulky periphery and a functional group capable of π bonding to boron, are usually required. The steric bulk is

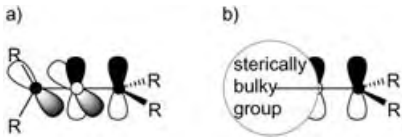

Figure 1. Schematic representations of the geometries required for stabilization of coordinatively unsaturated borinium cations (**I**) by a) two π-donating/sterically bulky substituents and b) one π-donating/sterically bulky substituent and one highly sterically demanding substituent (○ boron atom, ● π-donor atom (e.g. nitrogen), R = large alkyl or aryl groups).

Warren Piers obtained his B.Sc. (1984) and Ph.D. (1988) from the University of British Columbia. He then went to the California Institute of Technology as an NSERC and Killam Postdoctoral Fellow with Prof. John Bercaw. From 1990–1995, he was an Assistant Professor at the University of Guelph before moving to the Chemistry Department at the University of Calgary as an Associate Professor. In July 2000, he was appointed to the S. Robert Blair Chair in Polymerization Catalysis and Polymer Synthesis, a research chair sponsored by Nova Chemicals. His research interests include the chemistry of perfluoroaryl diboranes, catalysis, and the development of boron-based organometallic materials.

Korey Conroy was born in New Brunswick, Canada in 1980 and received his B.Sc. in 2002 from Dalhousie University under the supervision of Prof. Neil Burford. Since September 2002 he has been pursuing his Ph.D. as an NSERC and AIF scholar under the supervision of Prof. Warren Piers at the University of Calgary. His current research is focused on catalysis and the organometallic chemistry of neutral and cationic scandium-group compounds.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

generally achieved by the inclusion of large alkyl and aryl groups, while the π-donation character is usually provided by a nitrogen or oxygen atom that can offer electron density from nonbonding lone pairs into the vacant p orbitals on boron. Alternatively, condensed-phase examples of **I** in which only one substituent is capable of π backdonation generally require an extremely bulky group to afford added protection of the electron-deficient boron center (Figure 1b).

Although these specific ligand properties enable the isolation and characterization of condensed-phase borinium ions, the steric restriction and lessened effective nuclear charge at boron hamper nucleophilic attack and dampen reactivity. Thus, gas-phase experiments that allow the study of reactive borinium ions (**I**) in the absence of the influences of solvation and ion pairing have been developed (see Section 3.1).

The stabilization provided by π-backdonating substituents is less critical for the higher coordinate borocations (**II** and **III**) in condensed phases, primarily because of the additional σ-electron density offered to the electrophilic boron center by the donor lone pairs of the ligand(s). Three-coordinate borenium ions ($R_2B{\leftarrow}L^+$, **II**) can be considered as neutrally ligated analogues of anionically ligated boranes (R_2BR'). As such, they are sp^2-hybridized and trigonal planar in geometry. Because of the reduced electronic demand of the boron center, the need for strong σ- and π-donor substituents R is lessened.[12] The electrostatic and steric properties of the neutral donor ligands L determine the strength of their interactions with the borinium fragment $\{R_2B\}^+$, with nitrogen- and oxygen-based σ-donors, particularly aromatic amines, being most effective.[12] Three-coordinate borenium ions **II** can be formed when sufficient steric stabilization is achieved.

In the case of boronium ions **III**, stabilization of the four-coordinate cations becomes increasingly dominated by steric factors because of the small size of boron.[4] With two neutral σ-donor species (e.g. amines) that can satisfy boron's demands for electronic stabilization, steric congestion around the boron atom can readily reach a critical limit. Small donors are more readily accommodated and larger donors are more prone to displacement from the coordination sphere, often by the anion. Thus, the size of the covalently bound substituents and the size and nucleophilicity of the anion play a significant role. The majority of isolable boronium salts are air and water stable, which makes them much more stable than their low-coordinate counterparts. Thus, in terms of applications, access to borenium ions (**II**) and to a lesser extent borinium ions (**I**) is desirable. This access is potentially provided by boronium ions (**III**) through dissociation equilibria.

Sara Bourke was born in Ottawa, Canada. She obtained her B.Sc. at Queen's University in 1997 after completing her honours project with Prof. Michael C. Baird in the area of the metal-derivatizion of C_{60}. She subsequently completed her M.Sc. (2000) and Ph.D. (2004) degrees under the supervision of Prof. Ian Manners at the University of Toronto where her studies focused on the fundamental reactivity of strained inorganic silicon-containing rings. She is currently pursuing interests in science writing and post-secondary education at the University of Calgary.

2.1 Synthesis of Gas-Phase Borinium Ions

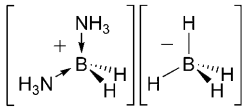
Early mass spectrometric studies made it clear that electron ionization (EI) of a wide variety of boranes (BR_3) can yield the corresponding disubstituted borinium cations (BR_2^+; e.g. R = H, Me, Et, F, Cl, OR′, SMe),[14,15] often among the most abundant cationic products. As early as 1948, Dibeler and Mohler described the generation of BH_2^+ ions by means of EI of diborane (B_2H_6).[14] Many of these studies focused on identifying and/or determining relative abundances and appearance potentials for the ionic products. More recently, studies have moved on to explore, in conjunction with computational investigations, the nature of these ions as well as their gas-phase reactivities (see Section 3.1).

To facilitate reactivity studies, some research into alternative strategies for the generation of borinium ions (**I**) have been investigated. Murphy and Beauchamp determined that, in addition to generation by EI, BMe_2^+ ions could be generated through gas-phase reactions of BMe_3 with self-protonating gases G (G = CH_4, H_2S, and CH_2O), with the concomitant release of methane [Eq. (1)].[16] The generation

$$GH^+ + BMe_3 \rightarrow BMe_2^+ + CH_4 + G \qquad (1)$$

of the BMe_2^+ ion was indicative of the ease of heterolytic cleavage of one B–Me bond in BMe_3, as well as stability of this cationic fragment in the gas-phase under low-pressure conditions. Staley and co-workers took advantage of this inherent stability to minimize the generation of ions other than BMe_2^+ under EI conditions; by lowering the ionization voltage (from the typical values of 50–70 eV to 15 eV) they were able to generate ionization products that consisted of only BMe_3^+ and BMe_2^+.[17]

The use of alternative precursors has improved the accessibility of particular species. For example, methyl boronic acid ($MeB(OH)_2$) has been shown to be an effective precursor for the generation of $B(OH)_2^+$ ions under fairly standard EI conditions (70 eV), whereas the previously employed precursor, orthoboric acid, is problematic owing to a tendency to decompose in the ion source.[18,19] Calculations at the G2 level of theory have revealed an almost linear O-B-O geometry (172°) for this ion, consistent with the expected π-type interactions for this borinium ion.[18]

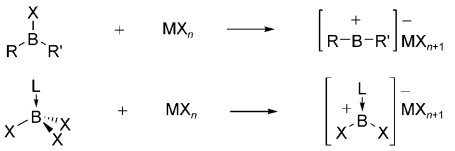


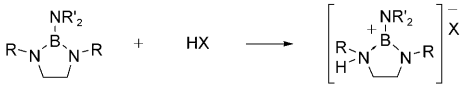
Advances in mass spectrometric methods have also allowed for the generation of previously inaccessible borinium ions. Despite the simplicity of the system, the gas phase ion chemistry of the BH_2^+ ion was not looked at in detail until 1998. The use of a flowing afterglow-selected ion flow tube (FA-SIFT) instrument for ionization of diborane (low flow), allowed a collisionally cooling flow of helium to minimize the

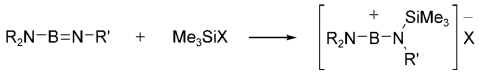
© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

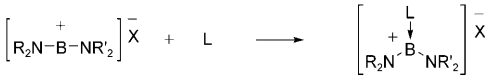
production of higher cluster ions that result from the reaction of the parent BH_2^+ ion with excess diborane;[20] normally EI spectra are typically dominated by the B_2H^{5+} ion.[21]

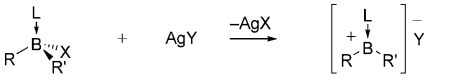
2.2 Synthesis in the Condensed-Phase and Structural Characterization



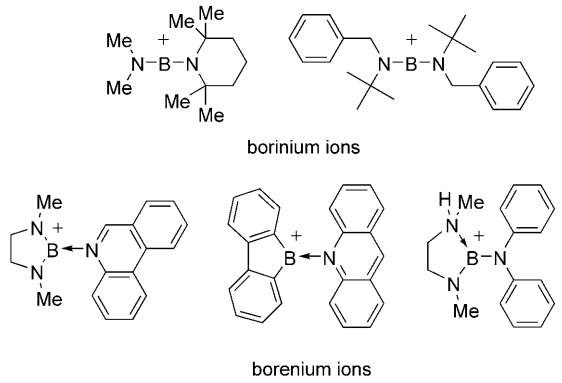








The first condensed-phase borocation, discovered in 1955, was originally misconstrued as a "diammoniate of diborane" and later found to be a boronium salt **1** that consists of two



1

tetracoordinate boron centers.[22,23] Since then various synthetic routes to borocations have been described,[3] the most common of which is boron–halogen (B–X) bond heterolysis. Heterolysis can be employed to generate borinium ions (Table 1, entry 1) and, in the presence of auxiliary donors, borenium ions (Table 1, entry 1). Other methods, summarized in Table 1, include protic attack of the boron–nitrogen bond (Table 1, entry 2), electrophilic attack at boron–nitrogen bonds (entry 3), nucleophilic substitution (entry 4), base addition to borinium ions (entry 5), and metathesis (entry 6). As a generalization, boronium ions can be generated by any of these methods in the presence of another equivalent of an appropriate donor molecule.

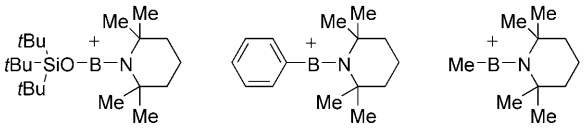
Table 1: Common routes to condensed-phase low-coordinate borocations.

Entry	Preparation Method	Equation
1	B–X bond heterolysis	
2	Protic attack of B–N bond	
3	Electrophilic attack at B–N bond	
4	Nucleophilic displacement	
5	Base addition to borinium ions	
6	Metathesis	

Although these diverse preparative techniques summarized in Table 1 allow for facile generation of borocations in situ, isolation of crystals suitable for X-ray analysis has been considerably more challenging, particularly for the low-coordinate borinium and borenium cations, for which only five structures were reported prior to 1985 (Scheme 1).[3,7,9,10]

Scheme 1. Borinium and borenium ions that had been characterized by X-ray crystallography by 1985.

Furthermore, since then, there has been only one additional crystal structure of a borinium cation reported (see Section 2.2.1),[13] a handful of structures of borenium cations (Section 2.2.2), and fewer than ten structures of boronium cations (Section 2.2.3) have been published. It is also noteworthy that the discovery of novel borocations has often been serendipitous, rather than by rational design.

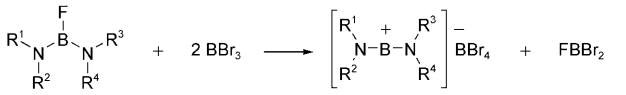


2.2.1 Borinium Cations

It was not until 1982 that the first report of a stable condensed-phase borinium cation, bis(diisopropylamido)borinium, appeared.[24] The first crystallographically characterized species, an $[AlBr_4]^-$ salt in which the electrophilic boron center is stabilized by the tetramethylpiperidino ligand, was reported later that year (Scheme 1).[7] These results prompted the generation and characterization of a number of bis(amido)borinium ions with varied amido substituents and/or counterions,[7,9,25,26] although only one other compound, with very bulky benzyl-*tert*-butylamido substituents,[9] has been successfully characterized by X-ray crystallography.

The prevalence of reports of such species is consistent with quantum mechanical calculations (MP2 and CCSD(T) levels of theory) which indicate the effective stabilization of Group 4 cations (C and Si) by amido substituents.[27] These studies showed that the stabilization energies of carbenium and silylium ions decreased with the increasing electronegativity of the π-donor substituents in the order: pnictogens >

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

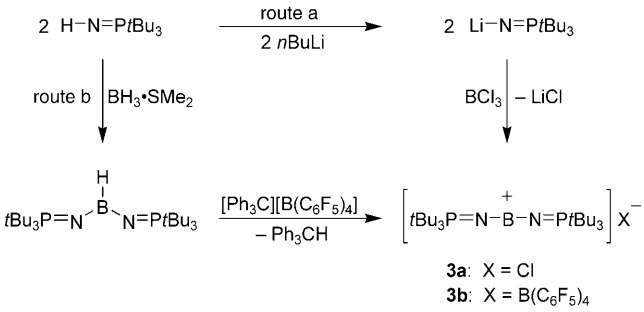


chalcogens > halogens. A similar ligand–cation interaction is likely for borinium ions. This assumption is supported by the paucity of reports of stable oxy-substituted borinium ions, although the larger relative steric shielding capacity of amido ligands also plays a role. Reports of condensed-phase alkyl- and aryl-substituted borinium cations are equally scarce, as accessible stabilization mechanisms (e.g. hyperconjugation) are not as effective. Indeed, none of the three reported species (Scheme 2) are stable at room temperature, and all have required the extremely bulky tetramethylpiperidino group as the second substituent.[7,8]

Scheme 2. Known borinium cations (that are unstable at room temperature) with aryl or alkyl substituents

Among the strategies employed to generate solution-stable species is the placement of sterically cumbersome trimethylsilyl (TMS) groups on the nitrogen atom of the donor ligand.[26] A series of reactions between an assortment of fluoro(trimethylsilyl)aminoboranes and excess boron tribromide resulted in preparation of a new family of borinium cations (**2**) that are stabilized by very bulky amino groups (Table 2). In the absence of X-ray data, extensive spectroscopic studies were performed to confirm the identity of the salts (see Table 2 for ^{11}B NMR spectroscopy data). Each salt **2** consisted of both a borinium cation and a borate anion; these resonate in distinctly different regions of the ^{11}B NMR spectrum. In all cases the borinium resonance lies in the expected range $\delta = 32$–36 ppm, while the borate signal appears significantly upfield ($\delta = -24.5$ ppm). The IR spectra of these compounds provide diagnostic bands near 1800 cm^{-1} for the B–N stretch and the N-B-N bend.

Table 2: Synthesis of trimethylsilyl-substituted bis(amido)borinium ions **2** by means of halide abstraction.



2

Product	R^1	R^2	R^3	R^4	$\delta(^{11}B)$ [ppm][a]
2a	*t*Bu	Bz[b]	*t*Bu	$SiMe_3$	35.8
2b	*t*Bu	$SiMe_3$	*t*Bu	$SiMe_3$	35.2
2c	*t*Bu	*t*Bu	$SiMe_3$	$SiMe_3$	32.8
2d	*t*Bu	$SiMe_3$	$SiMe_3$	$SiMe_3$	33.3
2e	$SiMe_3$	$SiMe_3$	$SiMe_3$	$SiMe_3$	32.8

[a] The chemical shift of the signal of the BBr_4^- ion is $\delta = -24.5$ ppm. [b] Bz = Benzoyl.

Despite a multitude of reports of borinium ions in the mid-1980s, research in the area of condensed-phase borinium ions had been somewhat neglected until a recent report by Stephan and co-workers that described an "extended borinium cation" **3**.[13] This bis(tri-*tert*-butylphosphinimide)borinium cation was prepared by two routes a) by the reaction of two equivalents of the lithium salt of the phosphinimide ligand with boron trichloride to yield the chloride salt **3a**-Cl (Scheme 3 route a), and b) by the reaction of two equivalents of phosphinimide ligand with $BH_3{\cdot}SMe_2$ to generate the disubstituted borane and subsequent trityl salt-induced hydride abstraction to yield the analogous borate salt **3b**-$B(C_6F_5)_4$ (Scheme 3, route b). This B–H heterolysis is analogous to the previous examples of BX heterolysis (Table 1, entry 1).

Scheme 3. Synthetic routes (a and b) to the bis(tri-*tert*-butylphosphinimide)boronium cation **3**.

These borinium salts contain two very sterically demanding tri-*tert*-butylphosphinimide ligands that serve to dictate both the geometry and electronic properties of the borinium center. The phosphinimide ligands sterically protect the highly Lewis acidic boron atom and allow for delocalization of the positive charge onto the four adjacent pnictogen centers. The generation of **3a** in the absence of a halide-abstraction agent suggests that, upon addition of two phosphinimide ligands, the boron center becomes so sterically congested that it can no longer accommodate the chloride ion in a covalent bond. This sterically induced halide dissociation marked a new synthetic approach to borocations.

The ^{11}B NMR spectrum of the parent borane shows a single broad resonance at $\delta = 24.6$ ppm, which is considerably downfield shifted from those seen for **3a** and **3b** ($\delta = -6.1$ and 11.1 ppm, respectively). The chemical shifts of the boron resonances demonstrate the π-donation ability of the phosphinimide ligands and their ability to relieve electron deficiency at the boron center. However, the chemical shift differences observed for **3a** and **3b** (despite their similar solid-state conformations) demonstrate that tight ion pairing between the Cl^- ion and **3a** is likely in nonpolar (C_6D_6) solutions, a proposal that is supported calculations. In **3a**-Cl the boron–anion separation is 7.30 and **3b**-$B(C_6F_5)_4$) it is 10.43 Å. The crystal structures of **3a** and **3b** (Figure 2), both reveal a linear geometry at boron (**3a**: N-B-N 180.0(4)°; **3b**: N-B-N 180.0(3)°). Although the linearity is imposed by the cell symmetry, the B–N bonds (1.258(5) and 1.236(3) Å, respectively) are considerably shorter than those of B-$(NPPh_3)_3$[28] or for the bis(dialkylamido)boron cations,[7] and thus indicate strong donation from the phosphinimide ligand.

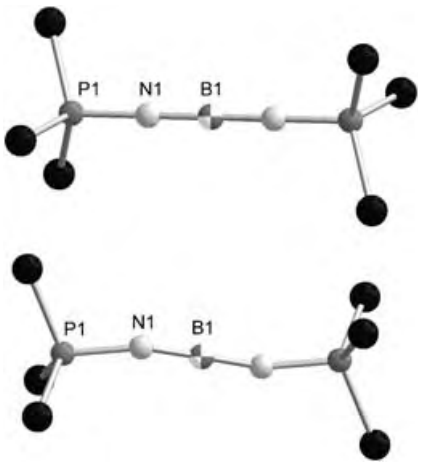

Figure 2. Molecular structures of the cations **3a** (top) and **3b** (bottom), the *tert*-butyl methyl groups and counterions are omitted for clarity.

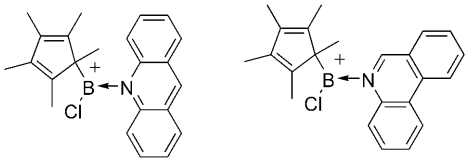
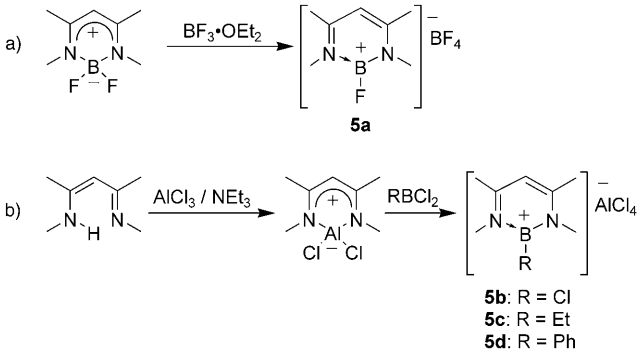


The N–P bond lengths are within the range of typical phosphinimide derivatives.

A final family of two-coordinate boron compounds worthy of mention are the cationic terminal borylenes $[Cp^*Fe(CO)_2{=}BAr]^+[BAr^F_4]^-$ ($Ar = 2,4,6\text{-}Me_3C_6H_2$; $Ar^F = 3,5\text{-}(CF_3)_2C_6H_3$) studied in detail by Aldridge et al.[29] In these compounds, density functional theory (DFT) calculations and metrical parameters point to a bonding description which involves an Fe–B double bond and charge localization on the electropositive iron center. Strictly speaking, then, these interesting compounds may not qualify as borinium ions, although reactions with small, hard nucleophiles (e.g. halide ions) result in addition to the boron center. Reactions with softer nucleophiles (e.g. olefins, CO), however, results in borylene ligand displacement.

2.2.2 *Borenium Cations*



Reports for well defined three-coordinate borenium cations have been almost as elusive as for their borinium counterparts. Only three structural reports were made prior to 1985 (Scheme 1),[10] and in each case a bulky auxiliary base capable of electronic stabilization was required and a five-membered borocyle was formed that is incapable of achieving the linear geometry necessary for electronic stabilization of a borinium cation. Since then, there have been only a handful of reports on tricoordinate borenium cations.

Jutzi and co-workers reported synthesis and characterization of two novel borenium cations, **4a** and **4b**, from reactions of dichloro(η^1-pentamethylcyclopentadienyl)borane with the bulky nitrogen-based donors acridine and phenanthridine, respectively.[30] These salts were characterized by ^{11}B NMR spectroscopy, they gave broad downfield resonances for the boronium center of **4a** at $\delta = 32.8$ ppm (full width at half height (FWHH) 158 Hz) and that of **4b** at $\delta =$ 30.9 ppm (FWHH 155 Hz). Crystallographic characterizations were impeded by the solvolysis of these species in polar aprotic solvents.

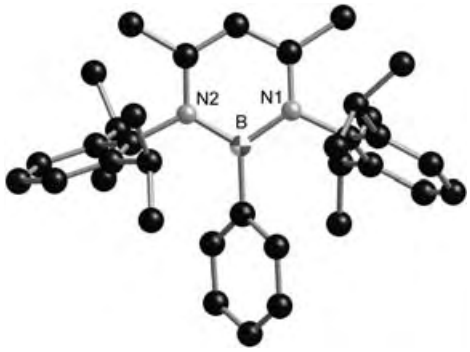
4a **4b**

A series of 1,3,2-diazaborenium cations, which are isoelectronic with benzene, have been reported by Kuhn and coworkers.[31] Fluoride abstraction from a zwitterionic six-membered β-diketiminato ("nacnac") boron chelate by the strong Lewis acid $BF_3{\cdot}OEt_2$ resulted in the generation of a 1,3,2-diazaborenium heterocycle **5a**-BF_4 that has a formal positive charge (Scheme 4a). The ^{11}B NMR spectrum

Scheme 4. Syntheses of 1,3,2-diazaborenium cations **5** by means of a) fluoride abstraction and b) an aluminocycle intermediate.

revealed a doublet ($^1J_{F\text{-}B} = 12.3$ Hz) at $\delta = 23.05$ ppm and AM1 calculations predicted a planar geometry for the six-membered ring with B–N bond lengths of 1.468 Å, a N-B-N angle of 118.6°, and π interactions of boron with both of the nitrogen atoms. Other cations of this type were prepared by initial deprotonation of the "nacnac" ligand, subsequent aluminum insertion, and treatment with $RBCl_2$ (R = Cl, Et, Ph) to afford the 1,3,2-diazaborenium cations **5b–d**-$AlCl_4$ (Scheme 4b).

By replacing the methyl substituents on nitrogen with bulky aryl groups, Cowley and co-workers were able to synthesize an analogue that was suitable for X-ray characterization (Figure 3).[32] A metathesis reaction of the potassium



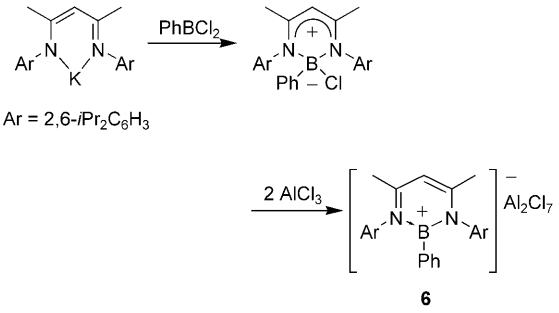


Figure 3. Molecular Structure of **6**, hydrogen atoms are omitted for clarity.

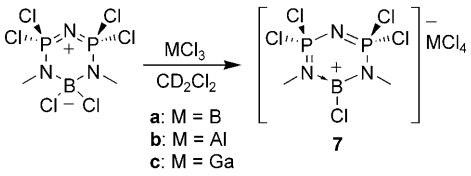
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



salt of the β-diketiminate ligand $K[HC(CMe)_2(NAr)_2]$ (Ar = 2,6-*i*$Pr_2C_6H_3$) with $PhBCl_2$, and subsequent treatment with $AlCl_3$ yielded the salt **6**-Al_2Cl_7 [Eq. (2)] which was characterized by a chemical shift in the ^{11}B NMR spectrum of $\delta =$ 72 ppm. Structural characterization showed the BN_2C_3 ring to

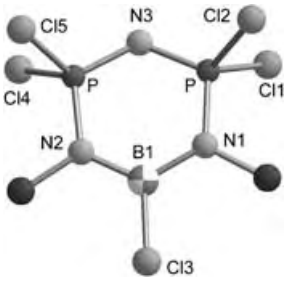
(2)

be planar and DFT calculations at the B3LYP level produced data for HOMO-6 and HOMO-7 that demonstrated BN_2C_3 π-bonding character.

Manners and co-workers showed that halide could be abstracted from a boratophosphazene to yield the borazine–phosphazine hybrid cation **7**, which has a PNP fragment in place of the ring carbons of **5b** [Eq. (3)].[33] The borenium

(3)

cations of **7**-MCl_4 (M = B, Al, Ga; e.g. Figure 4) show only slight deviations from planarity as well as shortened B–N bonds (1.43–1.45 Å) that are indicative of increased π character relative to the boratophosphazene. In the ^{11}B NMR



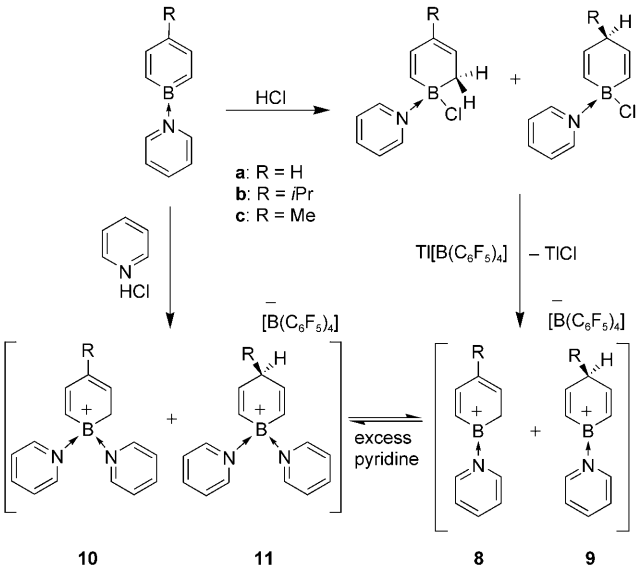


Figure 4. Molecular structure of the borazine–phosphazene hybrid cation **7a**, hydrogen atoms and counterion are omitted for clarity.

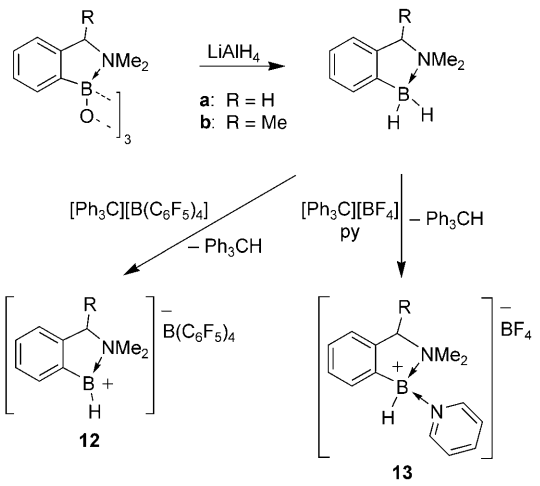
spectrum, the signals for **7b** (M = Al) and **7c** (M = Ga), at $\delta =$ 29.6 ppm and 30.2 ppm, respectively, are consistent with the tricoordinate planar environment around boron and are downfield shifted from that of the boratophosphazene precursor ($\delta = 5.4$ ppm), however, the solution spectrum of **7a**-BCl_4 showed evidence for an exchange process between free **7a** and a chloride-bridged species.

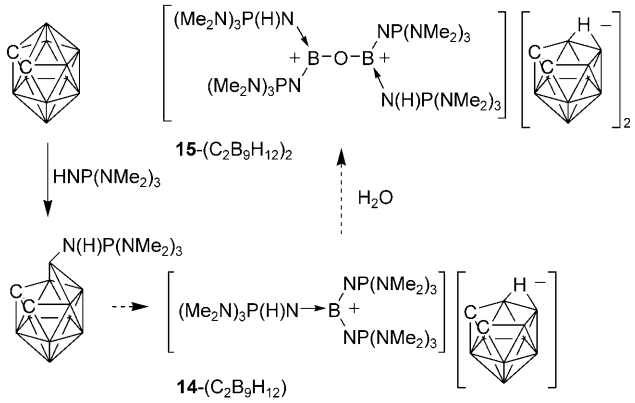
We have recently shown that the presence of nitrogen atoms in the boracyclic unit of such species are not necessary for the generation of borocations. Thus, the pyridine-stabilized borenium ions **8** (R = H, *i*Pr, or Me) and **9** (R = H) have been generated by chloride abstraction from the corresponding pyridine–borane adducts (Scheme 5).[34] ^{11}B NMR spectroscopic characterization of these species revealed signals at $\delta \approx 56$ (**8**) and 46 ppm (**9**). Interestingly, in the presence of



Scheme 5. Synthetic routes to the isomeric borenium ions **8** and **9** and their boronium analogues **10** and **11**.

excess pyridine, the chloroborane precursor adducts appear to be in equilibrium with the boronium chloride species **10** and **11**, which have also proven accessible by electrophilic attack of pyridinium chloride on the neutral borabenzene–pyridine adducts (see Section 2.2.3).

Vedejs and co-workers generated two borenium ions **12a** and **12b** by reduction of arylboronic anhydrides with lithium aluminum hydride (Scheme 6).[35] Initially the corresponding 2,3-benzazaborolidines are formed which then undergo hydride abstraction with trityl tetrakis(pentafluorophenyl)-borate (trityl = triphenylmethyl). The low-temperature ^{11}B NMR spectrum of **12a** revealed a singlet at $\delta -17.2$ ppm for the borate counterion and a broad resonance at $\delta \approx 38$ ppm (FWHH 460 Hz). However, this species is transient and the signal disappears as the solution is warmed to room temperature. Compounds **12** are interesting since the majority of borenium cations reported have strong π-donating ligands that provide crucial stabilization to the electropositive boron center. In species **12**, however, the boron center is bound by a phenyl substituent of almost negligible π-donating ability as well as an electronically benign hydride ligand. These results show that boron cations without π stabilizing ligands are viable intermediates. Interestingly, hydride abstraction from the 2,3-benzazaborolidine (R = Me) with trityl tetrafluoroborate in pyridine did not yield the anticipated borenium species



© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 6. 2,3-benzazaborolidines as precursors to the corresponding borenium (**12**) and boronium (**13**) ions.

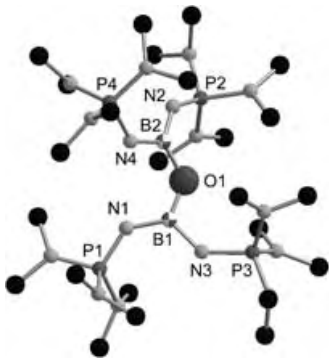
but, rather, the corresponding pyridine-coordinated boronium cation **13b** which was crystallographically characterized (see Section 2.2.3).

With the deboronation of *ortho*-carborane by iminotris (dimethylamino)phosphorane, Fox and co-workers discovered a novel route to borenium ions (Scheme 7).[36] The

Scheme 7. Generation of the protonated tris(imino)borane cation **14** and its conversion into the diborenium dication **15** by adventitious water.

phosphorane effectively converts *closo*-$C_2B_{10}H_{12}$ into *nido*-$C_2B_9H_{12}^-$ through formal loss of a B^{3+} unit. Among the counterions detected in solution was the protonated tris(imino)borane cation **14**, with a ^{11}B NMR resonance at $\delta =$ 22.3 ppm. Attempts to isolate crystals of **14**-$C_2B_9H_{12}$ led to X-ray crystallographic characterization of the first reported diborenium dication **15** (Figure 5), which is presumably the product of reaction of **14** with adventitious water.

There are distinct differences in the B–O bond lengths (B1–O 1.373(5) vs. B2–O 1.416(5) Å), which may indicate a greater π donation to one boron atom (B1) to form a pseudo B=O structure in the solid state. Bond order calculations carried out on the structure indicate strong B–N π bonding to the imino residue (NR) of each BN_2 unit and enough



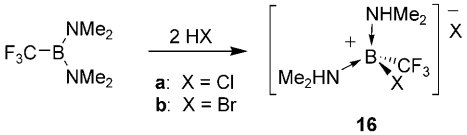


Figure 5. Molecular structure of dication **15**, hydrogen atoms are omitted for clarity.

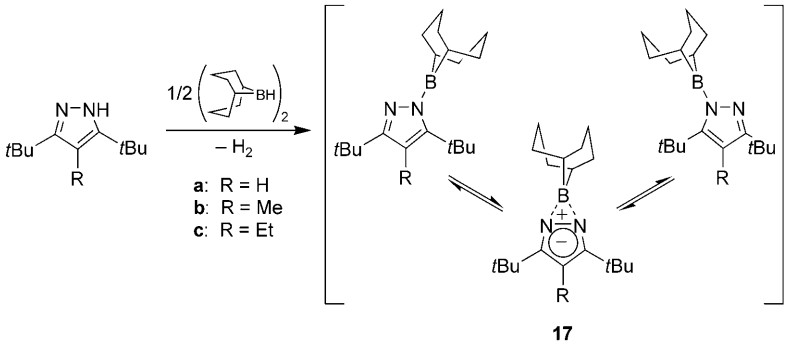
π bonding to the amino residue (RNH) to maintain the planarity of each $(PN)_2BO$ unit. Unfortunately, no ^{11}B NMR data was reported for **15**.

2.2.3 *Boronium Cations*

Tetracoordinate borocations have received the most attention, undoubtedly because of their relative stability, which arises from a filled octet and a complete coordination sphere. In almost all cases, boronium cations consist of two covalently bound ligands and two σ-donating ligands that serve to partially occupy the unfilled orbitals on boron and thus facilitate a depression of the ground-state energy of these species. This area has been thoroughly reviewed[4,5] and, owing to the volume of reports of these species and their more common nature, only a selection of recent synthetic results are highlighted herein.

The reaction of trifluoromethylbis(dimethylamido)borane with excess HCl and HBr, to yield, in situ, the trifluoromethylhalide boronium salts **16a** (X = Cl) and **16b** (X = Br), respectively [Eq. (4)], was reported in 1987.[37] These salts are



(4)

colorless, nonvolatile solids and are insoluble in nonpolar solvents. The ^{11}B NMR spectrum in acetonitrile of the more soluble **16a** provided a single signal at $\delta = 1.5$ ppm. This reaction represents protic attack on each of the B–N bonds in the precursor, in a manner similar to that described for the generation of borenium ions (Table 1, entry 2)

Although aminoboranes are susceptible to self-association (e.g. dimerization), the equilibria can be pushed towards the monomer through the incorporation of very bulky substituents. For example, the reaction between sterically restricted trisubstituted pyrazoles with 9-BBN (BBN = borabicyclononane), a bulky and rigid borane[38] led to the facile generation of a series of diorgano(pyrazolyl)boranes (R = H,

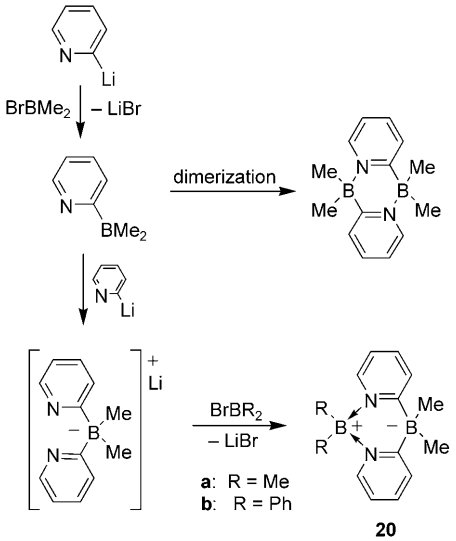
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Me, Et; Scheme 8). X-ray analysis and low-temperature studies of one of these species (R = Et) reveal a very constrained geometry with the boron bound to only one of the two nitrogen centers. However, room-temperature analysis indicates a rapid exchange of the borane moiety between the two nitrogen centers, a process that may be facilitated by a symmetrical zwitterionic boronium intermediate **17**. Evidence for this structure has been abstracted from UV/Vis spectroscopic data, which reveals a hypsochromic shift indicative of an increased dipole character. In addition, MNDO (modulated neglect of diatomic overlap approximation) calculations performed on the three boranes indicate a progressive decrease in the enthalpy of formation of **17** as the pyrazole becomes more sterically crowded, to the extent that for R = Et, formation of the cyclic boronium is only endothermic by 14.4 kJ mol^{-1}.

Scheme 8. Equilibrium generation of the zwitterionic boronium intermediate **17** from organopyrazolylboranes.

Pyrazoles have also been involved in the production of boronium-salt intermediates in the synthesis of polypyrazolylborate ligands. A series of boronium cations **18a–d** has been prepared from the reaction of the 3,5-dimethylpyrazole·iodoborane with one equivalent of another functionalized pyrazole [Eq. (5)].[39] Unfortunately, characterization of the proposed cations was limited to IR and ^{1}H NMR spectroscopy and elemental analysis.

(5)



The isosteric relationship between boronium ions and secondary ammonium ions prompted Davis and Madura to prepare a boronium analogue of the conjugate acid of the biologically active bicyclic tropane ring 8-azabicyclo[3.2.1]octane (a structural element of several neuroactive compounds; for example, atropine).[40] The boronium cation **19** was prepared in a one-step, one-pot synthesis from equimolar quantities of homopiperazine and bromoborane·dimethylsulfoxide. The white solid was characterized by multinuclear NMR spectroscopy and the ^{11}B NMR spectrum revealed an overlapping doublet of doublets with chemical shift of $\delta = -3.87$ ppm (D_2O).

8-azabicyclo[3.2.1]octane **19**

While not tested for biological activity, computational studies at the DFT/6-31G* level illustrated a remarkable structural similarity between the two bicyclic species, with the major discrepancy originating in the longer bridgehead bonds in **19** (B–N 1.624 Å vs. N–C 1.556 Å) which fall in the range between dative and non-π-bonding covalent B–N bond lengths. While the positive charge in 8-azabicyclo[3.2.1]octane is associated with the apical nitrogen atom the charge in **19** is distributed along the sides of the molecule (N→B) and not completely at the apical boronium site, although the hydrogen atoms on boron do remain slightly hydridic (charge −0.05).

In a previous report by Hodgkins and co-workers[41] it was noted that slow addition of bromodimethylborane and 2-lithiopyridine, to form novel pyrazabole ligands, did not exclusively produce the anticipated dimeric dimethyl(2-pyridyl)borate; the dimethylboronium dimethylbis(2-pyridyl) borate zwitterion **20a** was also formed, with the two products observed in a 15:85 ratio (Scheme 9). Initial reaction between the lithiated pyridine and bromodimethylborane is believed to form the monomeric borane which can either dimerize in a head-to-tail fashion or react with unconsumed 2-lithiopyridine to form a dimethyl borate intermediate which can

Scheme 9. Generation of the zwitterionic diboracycle **20**.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

further react with borane to generate the boronium–borate complex **20**.

In addition to boronium **20a**, the diphenyl analogue (**20b**) was prepared through addition of bromodiphenylborane to the isolated borate precursor. Zwitterion **20b** was isolated as a crystalline solid and its ^{11}B NMR spectrum showed a resonance at $\delta = 4.0$ ppm for the boronium center and at $\delta = -17.6$ ppm for the borate moiety. Crystallographic data were collected for both **20a** and **20b**, however only **20b** presented a $C_2B_2N_2$ ring that was not disordered (Figure 6). The equivalent B–N bond lengths of 1.59 Å are indicative of the σ-donating nature of these stabilizing interactions.

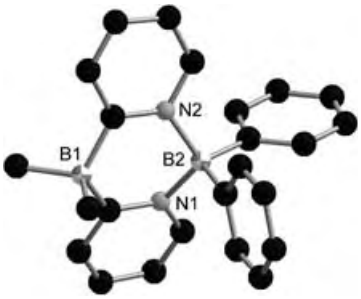


Figure 6. Molecular structure of zwitterion **20b**, hydrogen atoms are omitted for clarity.

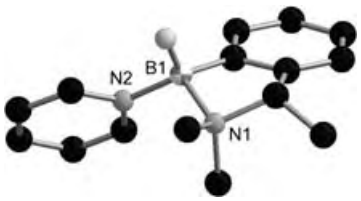
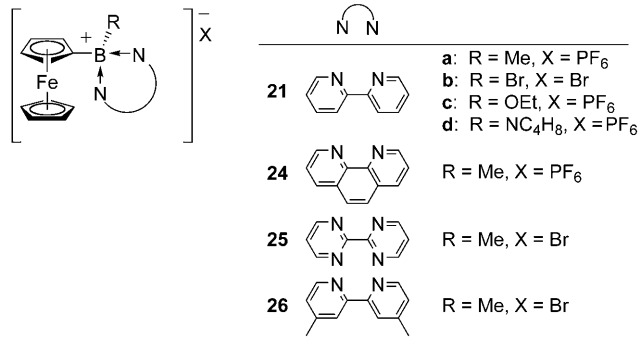
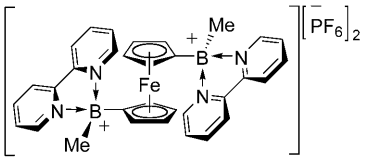
As already mentioned, during the preparation of various borenium compounds, Vedejs and co-workers were able to isolate and structurally characterize a boronium cation (**13b**) of the 2,3-benzazaborolidine series (Section 2.2.2, Scheme 6).[35] The boronium cation was characterized by multinuclear NMR spectroscopy, however, no ^{11}B chemical shift was reported and the B–H coupling in the ^{1}H NMR spectrum is not observed owing to quadrupolar line broadening. The crystal structure of **13b** revealed a distorted tetrahedral geometry around boron with the most constrained angle (C-B1-N1 99.5°) resulting from the location of the boron atom within a 5-membered ring (Figure 7). A related boronium ion partnered by a dinuclear manganese counterion was reported by Braunschweig and Ganter.[42]







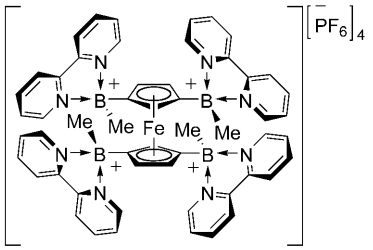


Figure 7. Molecular structure of **13b**, the BF_4^- counterion and protons are omitted for clarity.

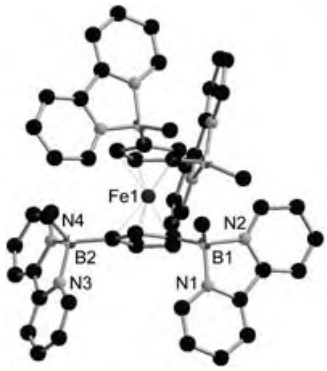
Wagner and co-workers have prepared series of ferrocene-based 2,2′-bipyridylboronium salts to investigate their utility as novel electron acceptors in charge-transfer complexes. The first family prepared consisted of ferrocene cores functionalized by one (**21a–d**), two (**22**), and four (**23**) boron substituents and were synthesized from their correspondingly

22

23

substituted ferrocenylborane precursors.[43] Boronium salts analogous to **21**, with differing N-donor ligands, were also prepared (**24**–**26**). All of the compounds were characterized by multinuclear NMR spectroscopy studies as well as elemental analysis. Broad singlets were observed in the ^{11}B NMR spectrum for each salt and ranged from $\delta = 6$–11 ppm (FWHH 140–500 Hz).

In all cases, the boronium cations were isolated from the reaction mixtures as solid precipitates and crystal structures of the 2,2′-dipyridyl salts were obtained (e.g. Figure 8). Crystals of **21a** and **22** were deep purple in color while **23** was isolated as a black solid. The electrochemistry of these



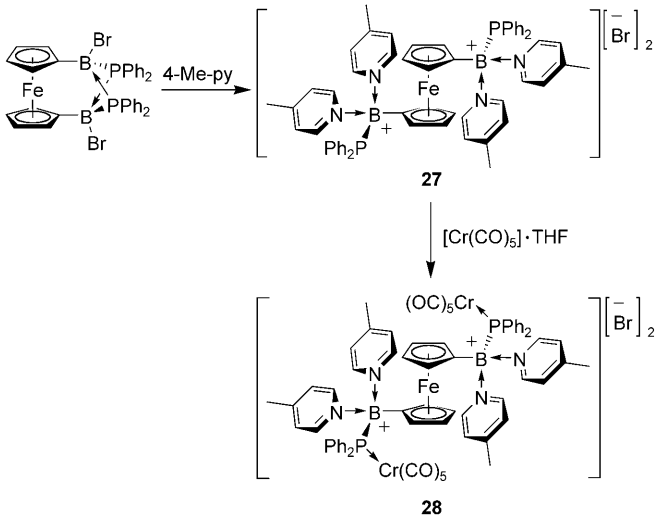


Figure 8. Molecular structure of **23**, the hydrogen atoms and Br^- counterions are omitted for clarity. The PF_6^- salt can be obtained by precipitation of the Br^- salt from aqueous solution by using NH_4PF_6.

boronium salts was evaluated and they were found to display one chemically reversible oxidation and two consecutive chemically reversible reductions in DMF. This data suggest the possibility to develop these species and their derivatives as redox catalysts, nonlinear optical materials, or as components of electronic devices (e.g. amperometric biosensors and modified electrodes).

Wagner and co-workers have also reported the preparation of a tetrapyridyl diboronium dication **27** analogous to **22** from an interesting *ansa*-bridged ferrocene as well as the preparation of an analogous trinuclear complex (**28**) linked through the two phosphido moieties (Scheme 10).[44] Complex

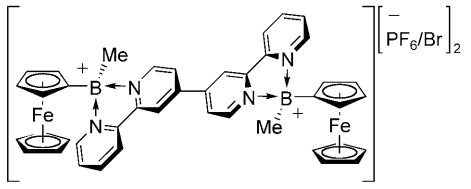
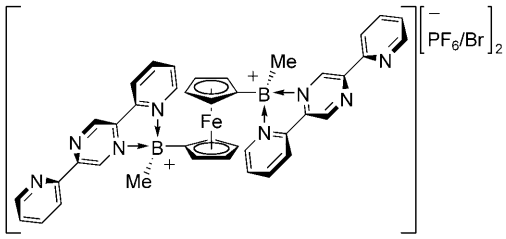
28

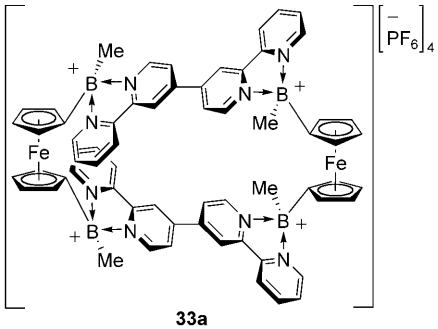


Scheme 10. Generation of the cation **27** and its reaction with $[Cr(CO)_5]$·THF to produce the trinuclear metal complex **28**.

28 was prepared in an effort to confirm the presence of three-coordinate phosphorus centers in the noncomplexed boronium salt **27**. The ^{11}B NMR spectra of both **27** and **28** show resonances at $\delta = 7.3$ ppm (FWHH 500 Hz) and 8.4 ppm (FWHH 500 Hz), respectively, which are downfield relative to that of the precursor ferrocenophane. A similar downfield shift in the ^{31}P NMR spectrum is noted between the precursor ferrocenophane and the boronium complex **27** ($\Delta\delta_P = 9$ ppm).



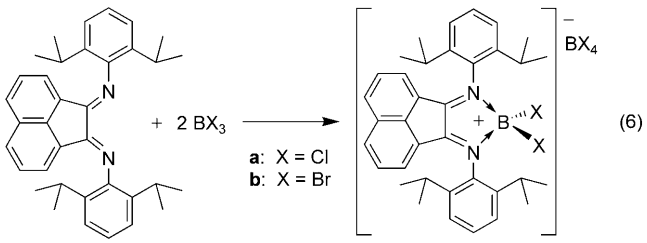
Further exploration of dichelating nitrogen-based ligands has demonstrated the potential for forming oligomeric and macrocyclic ferrocene-based boronium cation complexes.[45] The bases 2,5-bis(pyridyl)pyrazine (bppz) and 2,2′:4′,4″:2″,2‴-quaterpyridine (qpy) were used to generate linear chains and macrocycles, respectively. After reactions of the ligands in appropriate stoichiometries with ferrocenyl-based boron precursors, ^{11}B and ^{1}H NMR spectroscopy and, importantly, FAB-MS spectrometry, provided evidence of formation of novel mono- (**29**) and dicationic (**30**–**32**) boronium compounds. Furthermore, reactions of equimolar amounts of qpy with a disubstituted ferrocene precursor yielded a mixture of macrocyclic stereoisomers, **33a** and **33b**. Although, X-ray quality crystals were elusive, analyses of related structures present suitable evidence to suggest that isomer **33a** is the more favorable.[46] The ^{11}B NMR spectrum of **33** exhibited a



29 30

31

32



33a

broad signal at $\delta = 12.4$ ppm characteristic of tetracoordinate boronium center while ESI-MS of **33** yielded two prominent peaks at m/z 691 and 412 corresponding to $[\mathbf{33}\text{-}(PF_6)_2]^{2+}$ and $[\mathbf{33}\text{-}PF_6]^{3+}$, respectively.

Recent reports of chloroboration reactions analogous to hydroborations prompted Clyburne and co-workers to prepare a series of cationic complexes capable of undergoing facile addition across a C=O or C=N bond, for example.[47] The very bulky bis(2,6-diisopropylphenylimino)acenapthene ligand was used which was expected to provide π stabilization as well as steric bulk. Reactions with two equivalents of BCl_3 or BBr_3 yielded red crystals of the boronium ions **34a** and **34b**, respectively [Eq. (6)]. NMR spectroscopic studies were hampered by the insolubility of these species as well as their propensity to decompose in CD_2Cl_2. X-ray quality crystals of **34a** (albeit with an *R* factor of only 12%) showed the two dative B–N bonds (1.57(2) and 1.54(2) Å) to be in the range typical for nitrogen-based ligands bound to tetracoordinate borocations.

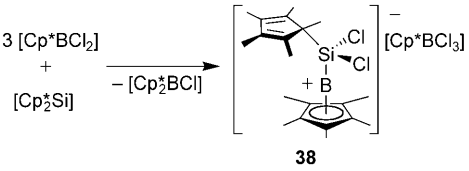
(6)

As mentioned in section 2.2.2 our group has synthesized the boronium ions **10** (R = H, *i*Pr) and **11** (R = H) in which the cationic boron center is part of a BC_5 ring and stabilized by two equivalents of pyridine (Scheme 5).[34] Crystallographic characterization of **11a** showed a roughly tetrahedral coordination environment around the boron atom with similar B–C bonds (1.582 and 1.588 Å) and more disparate B–N bond lengths (1.622 and 1.608 Å).

Jutzi and co-workers have demonstrated that the η^1-Cp* (Cp* = pentamethylcyclopentadienyl) coordinated boronium cations **35** and **36** could be prepared by reaction of equimolar



quantities of η^1-Cp*BCl_2 and a bidentate nitrogen donor (bipyridine or phenanthrene) or reaction of [Cp*BI][BI_4] with excess pyridine (compare with **4**, Section 2.2.2).[30] While ^{11}B and ^{1}H NMR spectroscopic analyses of these salts confirmed their identity in solution (^{11}B NMR spectrum $\delta = 7.0$ (**35a**), 6.5 (**35b**), and −19.1 ppm (**36**)) none of the compounds were sufficiently crystalline to allow for X-ray structural analysis.

2.2.4 Borocations with Nonclassical Coordination Environments

Jutzi[30,48,49] and Cowley[50] have developed a number of η^5-Cp*-substituted borocations that can be viewed as dicoordinate borinium ions; alternatively, as the boron atom is closely associated with six other atoms it could be viewed as being hypercoordinate. However, the η^5-coordinated ligands formally act as six-electron donors. Therefore, although these compounds display some of the structural and reactivity features of borinium ions, they can also be viewed electronically as boronium ions and should thus be considered independently as hybrids of these two types of boracations.

As early as 1979 Jutzi demonstrated that the η^5-coordinated borocations [Cp*BX]$^+$ (X = Cl, Br, I) (**37**) could be formed by reaction of η^1-coordinated Cp*BX_2 (generated in situ for X = I) with an appropriate trihaloborane (or $AlCl_3$) in a classical halide elimination reaction.[48] In their ^{11}B NMR spectra these species have highly upfield-shifted resonances ($\delta = -39$ to -51 ppm) relative to the precursor dihalides ($\Delta\delta = 100$–110 ppm) and most other borocations. This is similar to the situation observed in hypercoordinate *nido*-boranes[48b] and is indicative of the change in coordination of the Cp* ring relative to the boron atom and the efficient transfer of charge to the cationic boron center of the product. Notably, interaction between the Cp* methyl groups and the boron center was demonstrated by coupling observed by multinuclear NMR spectroscopy.

A recent report by Jutzi and co-workers demonstrated that the reaction of three equivalents of Cp*BCl_2 with Cp^*_2Si can yield the novel η^5-Cp* boronium cation **38** as a borate salt [Eq. (7)].[49]

(7)

The salt of **38** with a $[Cp^*BCl_3]^-$ ion is rather insoluble in common hydrocarbon solvents and thus the analogous tetrachloroborate salt was generated and subsequently characterized by multinuclear NMR spectroscopy. The ^{11}B NMR spectrum of **38**-BCl_4 has signals at $\delta = 6.1$ and -54.6 ppm that corresponded to the borate and boronium centers, respectively. The upfield boronium resonance agrees with the range characteristic for the previously discussed [Cp*BX]$^+$ ions **37**.[51]

In the crystal structure of **38**, boron is bound to a Cp* ring in a η^5 fashion with an average B–C bond length of 1.75 Å (Figure 9). The slight deviation from linearity for the Si-B-$Cp^*_{cent.}$ angle (170.8°) was attributed to crystal packing forces.

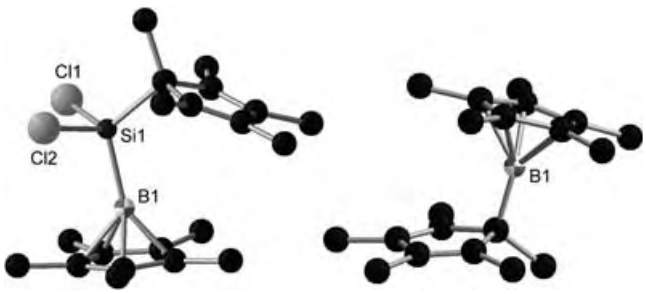


Figure 9. Molecular structures of **38** (left) and one of the two independent cations of **39** (right), the hydrogen atoms are omitted for clarity.

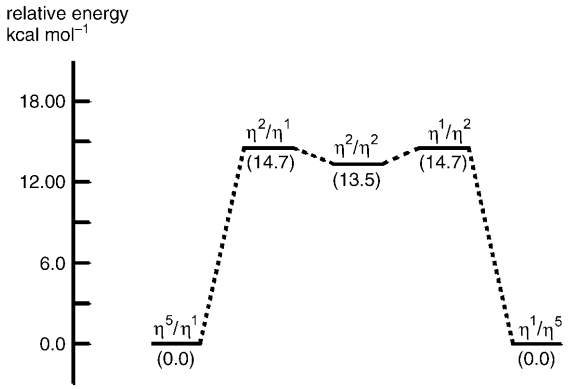
The electrophilic nature of the boronium center is exemplified by the bending of the Cp* methyl groups out of the plane of the ligand (angle of 4.2°) towards the Lewis acidic center.

Further studies involving Cp*-ligated boranes have resulted in the formation of the decamethylborocenium cation (**39**), which is described by Cowley and co-workers as "the most tightly-squeezed metallocene", because of its short intramolecular contacts.[50] X-ray quality crystals of **39** were isolated upon reaction of a chloride-abstraction reagent ($AlCl_3$ was most effective) with Cp^*_2BCl (Figure 9). A

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

single resonance at $\delta = -41.5$ ppm was found in the solution ^{11}B NMR spectrum, however, in the solid state the cation was found to have both η^1- and η^5-bound Cp* rings, with the η^1-bound Cp* B–C bond considerably longer than that to the centroid of the η^5-bound Cp* ring ($\Delta_{B-C} = 0.313$ Å). The structure has a near linear arrangement (avg. of 177.6°) along the C-B-centroid axis. Calculations on this structure, as well as the hypothetical nonmethylated analogue $[Cp_2B]^+$ ($Cp = C_5H_5$) at the BP86/A level were carried out to determine the reason for the highly constrained geometry. Geometry optimization studies, in agreement with the experimental results, showed that the η^1–η^5 geometry lies in a global minimum, with a predicted ring tip of 123°, similar to the experimentally observed 113.4° (avg.). The η^5–η^5 configuration resides almost 50 kcal mol^{-1} higher in energy than the observed geometry. It is believed that the small size and the increased effective nuclear charge of the boronium center is responsible for the tightly bound Cp* rings.

Further theoretical studies concerning the ring exchange of the borocenium cation were performed by Kwon and McKee and supported the findings of Cowley et al.[52] The small size of the degenerate p_x and p_y orbitals at boron prohibit effective π-type interactions with the appropriate orbitals on the Cp rings and make the η^5–η^5-Cp structure unfavorable relative to the η^1–η^5 structure. This situation is in contrast with metallocene complexes of heavier elements which have sufficiently diffuse orbitals to undergo π bonding. In addition, a series of relative energies was computed at the B3LYP/6-311 + G(2d,p) level for the exchange of the two Cp rings in $[Cp_2B]^+$ (Figure 10). The data depicts a significant barrier to exchange (approximately 15 kcal mol^{-1}). Similar results were found for $[Cp^*_2B]^+$.



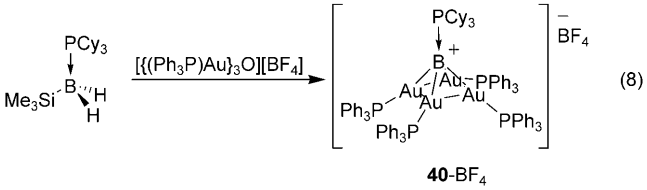


Figure 10. Relative energies for the exchange of η^1- and η^5-bound rings of $[Cp_2B]^+$.

A second type of "hypercoordinate" borocation has been prepared by Schmidbaur and co-workers, in this case the borocation is part of a gold cluster.[53] Reaction of tricyclohexylphosphine(trimethylsilyl)borane with tris[(triphenylphosphine)gold(I)] oxonium tetrafluoroborate provided the formally pentacoordinate boronium cation **40** [Eq. (8)]. The yellow crystalline material is air stable and, upon recrystallization from CH_2Cl_2, yielded crystals suitable for X-ray analysis. The FAB-MS and exhibits a molecular cation signal

40-BF_4

at m/z 2127.5 as well as diagnostic lower m/z signals. The ^{11}B NMR spectrum reveals a broad resonance at $\delta = 12.2$ ppm for the cluster-centered borocation and a sharp resonance at $\delta = -4$ ppm for the borate counterion. The crystal structure reveals an asymmetric square-based-pyramid core with the apical boron atom bridging the four gold atoms. The B-Au-P angles are near to linear and the B–Au bonds are relatively short compared with those of other boron-centered bimetallic clusters.[54]

While significant steps forward have been made in terms of the determination of the types of substitution and conditions necessary for the production of relatively stable borocations, much less has been elucidated with regards to the reactivity of the less-stable congeners and the potential applications of their enhanced reactivity. This situation is due in part to the difficulty involved in the design of experiments that can probe this behavior in a discernable manner (e.g. in the gas phase) and in part to the required development of metastable species that incorporate fewer stabilizing features (especially in the condensed phase). However, progress is being made in these areas and the results show promise for the development of both fundamental structure–reactivity relationships and catalytic applications for borocations.

3. Reactivity of Borocations

3.1 Gas-Phase Reactivity

As the gas phase eliminates the perturbing influences of solvation and ion pairing it can facilitate the study of chemical and physical properties of highly reactive ions and molecules. Thus, mass spectrometric studies of highly electron-deficient borocations, particularly borinium cations, have been used extensively to probe their stabilities and reactivities. Avenues of interest currently include the determination of fundamental physical constants, such as binding affinities, and the potential use of borinium ions as chemical ionization agents. Adducts with organic molecules tend to display highly diagnostic fragmentation patterns which may be useful for structure determination when used in conjunction with a knowledge of reactivity patterns and spectral libraries.[55]

Although electron ionization (EI) mass spectrometry has been used since the middle of the 20th century to detect borinium ions in the gas phase (Section 2.1) more sophisticated experimental techniques needed to be developed to effectively study the gas-phase chemistry of these highly electrophilic species. Specifically, isolation strategies and the ability to study the interactions of specific ions with various substrates were necessary.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Kenttämaa and co-workers performed pioneering work in the field of gas-phase borinium ion (BR_2^+) chemistry in the 1990s with a dual cell Fourier-transform ion cyclotron mass spectrometer,[56,57] an effective instrument for the isolation and examination of ions of specific m/z ratios in an environment devoid of solvent molecules. Ionic fragments other than those of the desired borinium ions that are present following ionization of neutral borane precursors can be expelled from the cell by precise voltage sweeps and quenching pulses.[57] Upon isolation of the desired borinium cation, introduction of neutral substrates can yield explicit data regarding the reactivity of these ions in the vapor phase. Cooks and co-workers have developed the use of quadrupole ion trap tandem mass spectrometry[59] and pentaquadrupole mass spectrometry[60] to investigate reactions of organic substrates with borinium cations.[61–63] These MS^2 and MS^3 experiments also allow for isolation of the borinium cation and subsequent reactions with neutral substrates. The use of a flowing afterglow-selected ion flow tube (FA-SIFT), as already mentioned (Section 2.1), has allowed for the moderate-pressure generation of BH_2^+ ions. The additional capability of this instrument to select for a single m/z ratio has facilitated the study of the reactivity of these ions.[20]

Chemical ionization mass spectrometry (CI-MS) has also been employed by both Yaozu[64] and Brodbelt.[55] However, this technique differs principally from the previous two in that the borinium cation is often not isolated prior to reactions with neutral reagents. This approach makes the assignment of the fragment ions more arduous and isotopic-labeling studies are often essential to verify the molecular formula of the fragment ions.

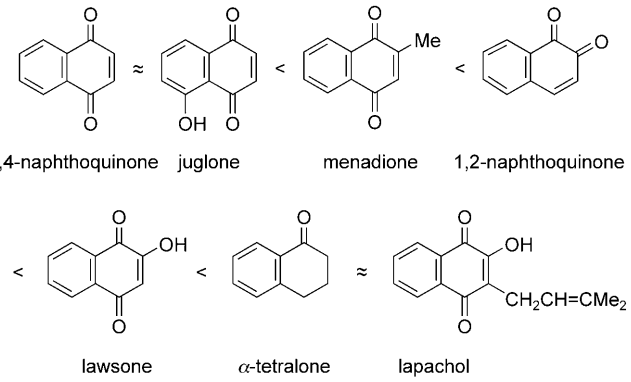
Both ^{10}B and ^{2}D (deuterium) labeling of reactants have proven useful in the confirmation of product-ion identities. Reactions performed with ^{10}B-doped borinium ions provide diagnostic signals for the boron-containing product ions one m/z value lower than the analogous nonlabeled ions; the reaction of ions with deuterated substrates gives the expected perturbations to the m/z ratios.

3.1.1 Gas-Phase Affinities for Donor Molecules

Thermochemical information can play an important role in the development of ion-molecule chemistry, the elucidation of product-ion structures, and the prediction of mechanisms.[65] Thus, in addition to serving as potent electrophiles for various organic conversions (Section 3.1.2), borinium cations have also been utilized as reagents for the determination of relative gas-phase binding affinities. Many such studies have used the readily generated $B(OMe)_2^+$ and BMe_2^+ ions.

Prior to the development of more advanced MS technology Staley and co-workers looked at the reactivity of the BMe_2^+ ion by ICR-MS and determined binding affinities for several species, both anionic and neutral. By studying the transfer of anionic groups to and/or from the BMe_2^+ ion in exchange reactions with species of known affinities for these groups they were able to determine the chloride (192.5 ± 3 kcal mol^{-1}), fluoride (238.5 ± 3 kcal mol^{-1}), and methide (250 ± 15 kcal mol^{-1}) anion affinities for the BMe_2^+ ion. Relative affinities for a variety of neutral donors L that form monoadducts $[BMe_2(L)]^+$ with BMe_2^+ were determined, by the preferred direction of displacement reactions, to be: $Me_2S < MeCN < C_6H_5OMe < Me_2O < C_6H_5CN <$ pyridine, in keeping with previously described preferences for stabilization by nitrogen-based donors, particularly aromatic amines.[17]

Brodbelt and co-workers have used an equilibrium method, which looks at the position of equilibrium or the rate of cation transfer between two bases, to determine gas-phase affinities of several substituted pyridines for B(OMe) BMe_2^+.[66] Results showed a general correlation with gas-phase basicities, with the differences in binding affinities for dimethyl- and methyl-substituted pyridines consistent with the differences in the analogous gas-phase basicities upon comparison of species with either no *ortho*-substitution (e.g. 3,5-dimethylpyridine vs. 3-methylpyridine) or a consistent degree of *ortho*-substitution (e.g. 2,4-dimethylpyridine vs. 2-methylpyridine). However, comparison of an *ortho*-substituted pyridine such as 2,3-dimethylpyridine with *meta*-methylated 3-methylpyridine showed deviation from this trend and indicated that different steric effects near the site of cation attachment can have a significant effect on binding affinities for the anisotropic borinium ions, when compared with the small spherically symmetric proton.

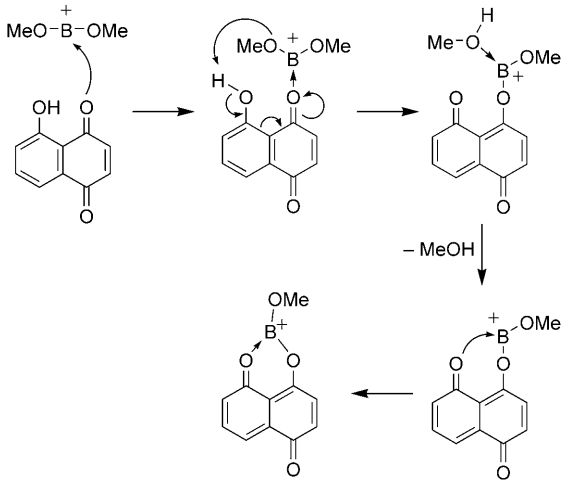


In an effort to obtain more systematic and reliable thermochemical data on borinium ions Cooks and co-workers carried out similar studies on the gas-phase affinities of the borinium ions B(OMe) BMe_2^+ and $HBOMe^+$ for a large set of pyridines. The investigation was by means of kinetic methods that involve the competitive dissociation of mass-selected cluster ions under collision-induced dissociation (CID) or metastable ion conditions.[65] In such studies, the ratio of rates of competitive dissociations of cation-bound diadducts (A-M^+-B) can be used to estimate the difference in affinity ($\Delta M^+_{affinity}$) of the cation for two substrates (A and B), based upon the relative abundances of the monoadduct products ($[AM^+]/[BM^+]$) of dissociation [Eq. (9)]. This method is sensitive to small thermochemical differences and has been widely used to measure proton affinities of various compounds. In addition, the method has been extended towards the measurements of electron and small-ion affinities (e.g. NH_4^+, NO_2^+, $OCNCO^+$, $SiCl^+$, $SiCl_3^+$, SF_3^+).[65,67] The relative affinities of $B(OMe)_2^+$ or $HBOMe^+$ for a variety of pyridines were also determined via on-molecule reactions using similar methods.[65]

$$\ln \frac{[AM^+]}{[BM^+]} = \frac{\Delta M^+_{affinity}}{R T_{eff}} \quad (9)$$

Brodbelt and co-workers have also used the $B(OMe)_2^+$ ion to assess the relative basicities and binding affinities of a number of classes of bioactive molecules.[55,68,69] Ion trap mass spectrometry,[59] was used to monitor the reactions of isolated $B(OMe)_2^+$ ions with various quinones (Q).[69] The initial product in most cases was the quinone–borinium adduct $(Q1)\cdot B(OMe)_2^+$ which could be isolated. Addition of a second quinone (Q2) and analysis of the relative intensities of the $(Q1)\cdot B(OMe)_2^+$ and $(Q2)\cdot B(OMe)_2^+$ signals yielded the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



relative binding affinities of the two substrates. The relative scale of binding affinities shown in Scheme 11 closely parallels the gas-phase basicities, the exception being the inversion of the relative affinities for 1,2-naphthoquinone and lawsone which is due an interaction between a secondary hydroxy group proton and the borinium methoxide.

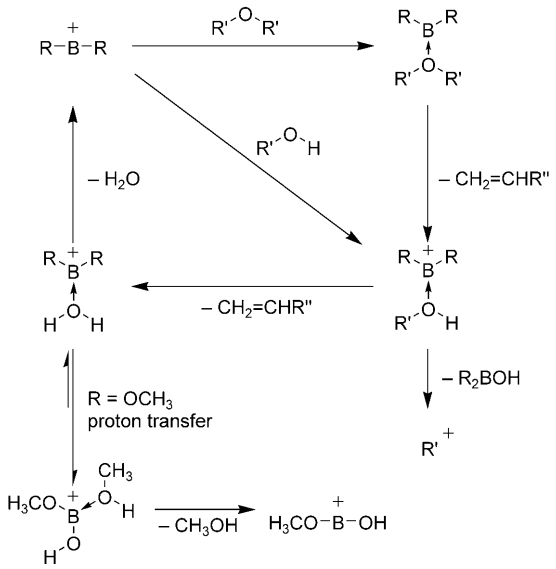
Scheme 11. Relative $B(OMe)_2^+$-ion affinity for a series of quinones (Q).

Although many of these adducts are relatively stable, upon collisional activation the presence of a proximal hydroxy substituent can lead to further reactions. It has been proposed that this reaction occurs first by internal proton transfer of the acidic hydroxy proton to one of the Q·$B(OMe)_2^+$ methoxy oxygen atoms and subsequent collapse of the complex with the concomitant loss of methanol. In the case of juglone this reaction leads to the generation of a tricyclic borenium ion (Scheme 12, which poses a potentially interesting synthetic target for the solution chemist.

Complex organic substrates that have multiple functional groups have also been adopted for the evaluation of the reactivity of gas-phase borinium cations. Barbiturates are a common family of pharmaceutical reagents based primarily on derivatized (e.g. with carbonyl and amine substituents)

Scheme 12. Proposed mechanism for the cyclization of juglone in the presence of $B(OMe)_2^+$.

pyrimidine rings. Studies of reactions between barbiturates and the $B(OMe)_2^+$ ion have provided valuable information about the binding affinities of these highly Lewis acidic reagents for various functional groups.[68] A test reaction performed with barbital revealed a signal in the CI-MS that corresponds to the borinium–barbital adduct less methanol. This result offered little evidence for the site of nucleophilic attack as possible mechanisms can implicate either oxygen or nitrogen binding. Other competition studies between piperidine, cyclohexanone, and glutarimide indicated that, although carbonyl groups are characteristically stronger Lewis bases than amidic nitrogen atoms, nitrogen in the barbital ring is the thermodynamically favored binding site for such rings. This observation is consistent with the vast number of stable condensed-phase borocations bearing nitrogen-containing ligands and the dearth of analogous alkoxy-based cations.[3] The observed affinities also imply that adjacent carbonyl groups can reduce the binding affinity of the amidic site.



3.1.2 ***Gas-Phase Reactions***

In many cases borinium ions generated upon electron ionization of borane or borate precursors have been found to react strongly and relatively selectively with organic substrates. These reactions give only a few ionic products that yield valuable structural information about the substrates (e.g. with quinines, Section 3.1.1). Thus, borinium ions can act as efficient chemical ionization reagents for the mass spectrometric analysis of a variety of organic molecules. It must be noted that the reactivity seen in the gas phase is under highly idealized nonsolvated conditions and is probably not directly transferable to condensed phases. Therefore, although these studies are collectively fairly comprehensive and offer insights into the kinds of rearrangements triggered by borinium ions, they will not be treated in detail herein.

However, to exemplify the character of these reactions, we will discuss some of the first investigations to evaluate the reactivity of borinium cations with neutral organic molecules, namely the reactivity of BMe_2^+ and $B(OMe)_2^+$ towards a series of ethers (R′OR′)[56] and alcohols (R′OH).[70] Generation, collisional cooling, and isolation of the borinium ion BR_2^+ (R = Me or OMe), introduction of a R′OR′ or R′OH, and subsequent monitoring of the ionic reaction products by mass spectrometry led to a proposal for the mechanism of the observed dehydration of the ROH and ROR substrates (Scheme 13).

The first step of the proposed mechanism necessarily involves nucleophilic attack at the borinium center, by oxygen, to form a borenium ion (R_2B-OR'_2^+ or R_2B-$O(H)R'^+$). This type of interaction is supported by analogous results obtained for ethers in the presence of other electrophilic species; ethers in acidic media become protonated to form the analogous oxonium ion before proceeding to form an alcohol through counterion-induced loss of an alkyl or aryl function.[71] Under gas-phase conditions interaction of the borenium ion with a counterion is unlikely and the ionic products support the proposed C–O cleavage and loss of a neutral alkene, by way of a proton-bound adduct. While

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 13. Proposed mechanism for the gas-phase dehydration of alcohols and ethers by borinium ions R_2B^+ (R = Me or OMe).[56,70]

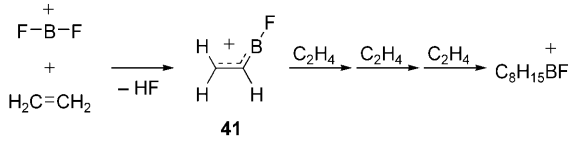
ethers must undergo two stepwise alkene eliminations, alcohols need only undergo one to give the ionic dehydration product $R_2B\text{-}OH_2^+$, and/or its more stable rearrangement product $(HO)RB\text{-}RH^+$. The prevalence of alkyl elimination versus alkyl cation formation (hydroxy abstraction) is dependent upon the instability of the proposed alkyl cation. Thus alkyl elimination dominates for short-chain alcohols and ethers capable of alkene elimination. As inferred by the mechanism proposed in Scheme 13, and later confirmed by experiment, compounds unable to eliminate an alkene (i.e. methanol or alkylmethyl ethers) do not undergo dehydration, and collisional activation leads only to methanol dissociation from the borenium ion. Although gas-phase proton-catalyzed dehydration of alcohols is well known, the facile ionic dehydration of alcohol and ether functional groups by borinium ions is notable.

Using these methods and techniques, the reactions of borinium ions, such as $B(OMe)_2^+$, with a variety of organic functional groups have led to the identification of reactivity patterns expected upon complexation of the organic function to the boron cation. The *cis* and *trans* isomers of 1,2-cyclopentane diols have different reactivities[64,72] because of their different geometries. Five-membered acetals and ketals react with the $B(OMe)_2^+$ ion[61] and with the much more electron-rich bis(dimethylamino)borinium cation $(B(NMe_2)_2^+)$[62] to effect *trans*-acetalization by the elimination of, for example, acetone. Similar reactivity patterns have been observed in the reactions of these substrates with phosphonium ions such as $OP^+(OMe)_2$.[73] Kenttämaa and co-workers have also examined the reactivity of borinium ions with carbonyl-containing species such as aldehydes and ketones,[74] Small compounds, such as acetaldehyde, propanal, acetone, and 2-butanone, tend to form stable adducts, while aldehydes and ketones that contain alkyl chains of three or more carbon atoms are subject to abstraction of a smaller aldehydes and/or hydroxy groups by way of C–C bond cleavage. FTICR-MS was also utilized in the study of the reactions of borinium cations with a series of methyl and ethyl carboxylate esters[70,75] and organic amides.[63,76]

The above studies all utilize relatively stable borinium ions containing electron-rich substituents (Me, OMe, NMe_2). The gas-phase behavior of the simplest borinium ion BH_2^+ has long been of interest, but, as previously mentioned, the ability to study the chemistry of the BH_2^+ ion has only recently become possible through the use of new MS techniques. Studies into its reactivity with simple molecules such as H_2 and CH_4 have revealed it to react generally by a mechanism of addition followed by H_2 elimination.[20] Reactions with D_2 revealed an isotope exchange which was calculated to proceed by association of H_2 to boron through a three-center-two-electron (3c–2e) bond to form planar BH_4^+, followed by subsequent rearrangement and dissociation. Similar calculations on the structure of the BH_4^+ ion performed by Olah and co-workers revealed that, although the bulk of the charge remains on boron, a significant amount resides on the 3c–2e H_2 fragment (2×0.19).[77] Existence of the $[BH_2(H_2)]^+$ intermediate, which may be viewed as a borenium ion, was confirmed by experiments run at higher H_2 pressures, the presence of the diadduct boronium ion, $[BH_2(H_2)_2]^+$, was also revealed.

Reactions with methane parallel those of the CH_3^+ ion. However, in contrast, deuterium labeling studies (BD_2^+) have revealed greater selectivity for methane, with the exclusive elimination of HD, rather than the statistical mixture of products observed for CH_3^+ reactions. Reactions with ethane are rapid and involve addition followed by elimination of either H_2 or CH_4. The mechanism of addition followed by H_2 elimination was also observed for other small reagents such as H_2O, H_2S, and NH_3.

Olah and co-workers have further explored the reactivity of the ions BH_2^+ and BCl_2^+ with simple aldehydes and alkenes by means of DFT calculations at the B3LYP/6-311G** level.[78] Aldehydes were found to associate with the borinium ions to form an oxygen-coordinated nonplanar allylic species. While the BH_2^+ adduct can subsequently undergo a hydride shift from the BH_2 group to the carbonyl carbon an analogous chloride shift was calculated to be endothermic. In contrast, association of the borinium ions with ethene was by means of a 3c–2e bond involving the boron atom and two carbon atoms (unsymmetrical for BCl_2^+). Hydride transfer from the BH_2 unit to one of the carbon atoms was less exothermic than that calculated in the case of the homologous aldehydes while calculations of the chloride transfer from the BCl_2 unit were not feasible owing to facile rearrangement to a stable cyclic chloronium structure. Interestingly, reactions of the BH_2^+ and BCl_2^+ ions with propene were found to give unbridged structures and hydride and chloride transfers to the resulting carbocations were endothermic or not found, respectively.



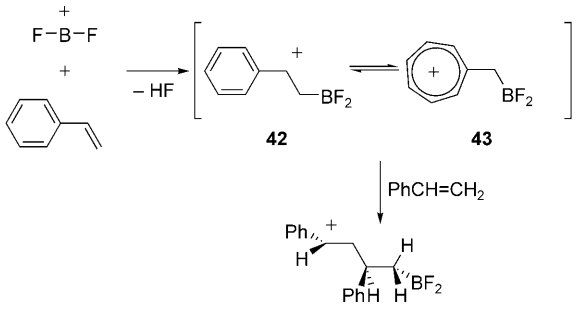
3.1.3 Initiation of Oligomerization of Olefinic Monomers by Gaseous BF_2^+

For olefin polymerization, catalysts that exhibit both coordinative and electronic unsaturation are preferred, as the former provides a binding site for the monomer while the latter is often necessary to support monomer coupling. Two-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

coordinate borinium cations fulfill these requirements and were the first borocations to be tested as olefin polymerization catalysts. Bohme and co-workers were able to observe gas-phase oligomerization of olefinic monomers by BF_2^+.[79,80] These researchers utilized the selected-ion flow tube (SIFT)[81] technique to study the reactions of BF_2^+ (generated by electron impact at 55 to 80 eV from pure BF_3) with ethylene, propylene, isobutene, *cis*-2-butene, and styrene.

Upon introduction of ethylene into the flow-tube, reaction with the borinium ion by means of HF elimination is evidenced by the appearance of a signal that corresponds to a new borinium cation **41** (Scheme 14). As the parent BF_2^+



41

Scheme 14. Initiation of the oligomerization of ethylene by BF_2^+.

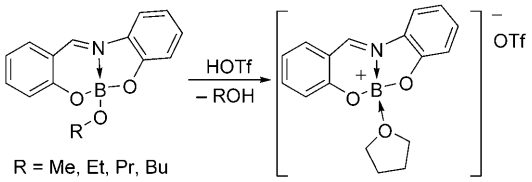
ion is consumed the sequential addition of up to three ethylene units to **41** can be detected, although experimentally calculated rate constants indicate that ethylene addition becomes progressively less efficient as the reaction proceeds.

Calculations at the 6-31G*/6-31G* level of theory predict ethylene addition to BF_2^+ to be exothermic by -58 kcal mol^{-1}. A Mullikan population analysis of the two possible resonance structures (boro- and carbocations) indicate an energetic preference for localization of the cationic charge on boron. This result is further supported by STO-3G level calculations on the subsequent attack of ethylene by **41**, which showed that attack at the boron was 38 kcal mol^{-1} lower in energy than attack at a terminal carbenium center. However, all additional polymerization steps would proceed through terminal carbenium ions. Similar reactivity was observed for the oligomerization of acetylene,[80] while parallel studies with *cis*-2-butene and isobutene were more complex owing to isomerization side reactions.

In contrast to the multiple products obtained from the isomeric butene reagents, the addition of styrene to gaseous BF_2^+ ions yielded only one primary product, believed to be the adduct ion **42**, which may also be in equilibrium with a tropylium-type ring **43**. Experiments only provided evidence for the addition of one further styrene unit (Scheme 15). However, it has been proposed that further polymerization

42 43

Scheme 15. Proposed reaction of BF_2^+ with two equivalents of styrene.

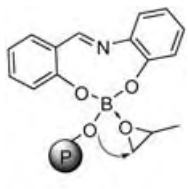


may occur under optimized conditions. Propylene does not exhibit the same reactivity owing to rapid formation of $C_3H_5^+$ followed by termination.

3.2 Synthesis with Condensed-Phase Boron Cations

Since the early studies into condensed-phase cationic boron compounds in 1955,[22] the thrust has been the development of novel structure and bonding motifs for these notoriously unstable species. However, the accumulated data concerning borocations as well as their heavier Group 13 analogues[2] has encouraged investigations into potential applications of these inherently electrophilic species. Recent reports have exploited the properties that make these species so reactive, particularly in condensed phases, in the development of new applications. Thus far, studies in this nascent area have shown borocations to behave as catalysts in polymerization studies (see also section 3.1.3 for gas-phase polymerization studies), as well as enantioselective Lewis acid activators in Diels–Alder reactions.

3.2.1 Polymerization of Propylene Oxide by a Boronium Catalyst

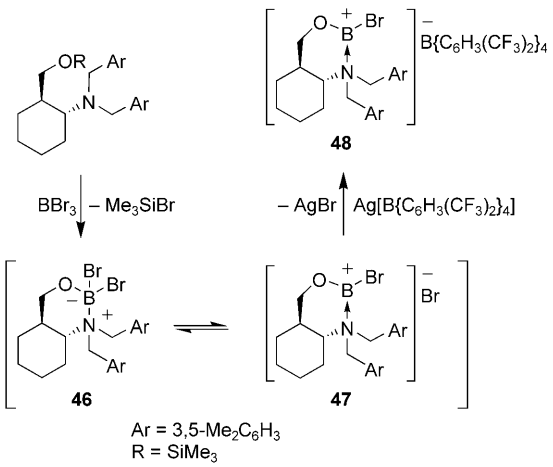


Studies that have shown the successful polymerization of propylene oxide (PO) by aluminum cations[82] have led to the development of analogous borocation systems. Atwood and Wei have used a tridentate O-N-O ligand to prepare a base-coordinated boronium cation and evaluated its capacity to polymerize PO.[83] The boronium salt was prepared by treatment of the parent boronic acid derivative with a strong protic acid to form the corresponding boronium species **44**-OTf, with concomitant loss of alcohol [Eq. (10)].

44 (10)

The signal at $\delta = 3.91$ ppm in the ^{11}B NMR spectrum confirms the presence of a four-coordinate borocation center with a THF donor ligand, the coordination environment about the boron center is believed to be tetrahedral.

Cation **44** was found to polymerize PO at similar rates at room temperature and slightly elevated temperatures, which indicated a moderate efficiency for this reaction. In the proposed mechanism, coordinated PO is activated towards nucleophilic attack by the triflate anion. Subsequent cleavage of the dative B–N bond to provide a vacant coordination site for the incoming PO unit (as in **45**) is implicated. An alternative mechanism would require cleavage of the B–O covalent bond of the polymeric chain, which is substan-



45

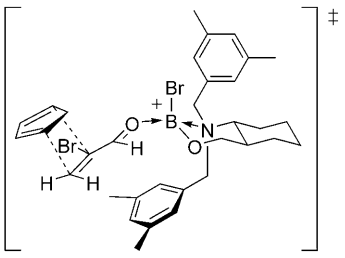
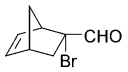
tially stronger than the B–N coordinative bond, and is therefore unlikely.

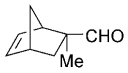
3.2.2 Borocation-Mediated Enantioselective Diels–Alder Reactions

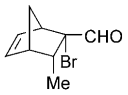


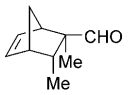
The introduction of Lewis acids, particularly chiral analogues, as catalysts has made Diels–Alder transformations a very powerful tool in organic synthesis. Corey and co-workers[84] designed an enantiopure borenium cation **46** (Scheme 16) and examined its utility for the coupling of

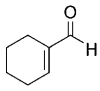
Scheme 16. Synthesis of the borenium-cation catalyst **48**.

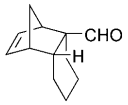












cyclopentadiene with α,β-unsaturated aldehydes. The catalyst exists in equilibrium with the ammonium-borate ylid **47**. The equilibrium can be shifted towards the fully ionic form (**48**) when the reaction of the precursor ligand with BBr_3 is conducted in the presence of $Ag[B\{C_6H_3\text{-}3,5\text{-}(CF_3)_2\}_4]$. Although complete conversion into **48** is never achieved, the activity of the equilibrium mixture is still reasonably good.

A summary of the results obtained from the couplings a series of α,β-unsaturated aldehydes with cyclopentadiene in the presence of 10 mol% of **46**/**47** is outlined in Table 3. *Exo*/*endo* ratios were determined by ^{1}H NMR spectroscopy. The enantioselectivities were extrapolated by a) reduction of the products to the corresponding primary alcohols using $NaBH_4$, b) conversion into the Mosher ester, and c) ^{1}H NMR spectroscopic analysis. A transition state (**49**), in which the bottom face is sterically obstructed by one aryl ring while the other

ring limits the rotational freedom of the incoming cyclopentadiene, was proposed based on these results. An X-ray structure of the hydrochloride salt of the ligand precursor depicts a similar arrangement of the aromatic substituents and supports this proposal.

Since this initial work, Corey and co-workers have reported several similar catalysts that are based on oxaazaborolidines and also function as highly enantioselective catalysts for Diels–Alder condensations.[85] These results indicate the general applicability of such borenium catalysts for enantioselective Diels–Alder condensations and highlight the potential for such species as catalysts for other organic transformations.[86]

4. Summary and Outlook

Cationic boron species were discovered half a century ago, and although activity in the area has been steady, their high Lewis acidity and reactivity has only just begun to be harnessed in useful ways. Advances in ligand design and weakly coordinating anion technology has enhanced our ability to generate and study these elusive species in the condensed phase, while gas-phase experiments using sophisticated mass spectrometric techniques have provided a useful reactivity map to act as a guide for developing applications of these species. As the discussion above indicates, these applications are beginning to appear. Particularly exciting are the potential of well-designed boron cations as Lewis acid catalysts in polymerization reactions and organic transformations. The incorporation of cationic boron centers in organic heterocycles or transition-metal metallocenes is also providing opportunities for the development of new redox active and optical materials. Furthermore, the strategy of preparing cationic compounds based on boron that are isoelectronic with, for example, ammonium-based cations potentially opens up new areas in bioorganic chemistry. These emerging studies indicate that the chemistry of cationic boron com-

pounds is on the cusp of a quantum leap in activity; it is our hope that this review will stimulate further activity in this exciting area of research.

The controlled release of fluorescein from a mesoporous silica/superparamagnetic iron oxide core/shell nanodevice in the presence of an external magnetic field takes place by using cell-produced antioxidants as stimuli. For more information on this promising approach to drug-delivery systems, see the Communication by V. S.-Y. Lin and co-workers on the following pages.

Stimuli-Responsive Controlled-Release Delivery System Based on Mesoporous Silica Nanorods Capped with Magnetic Nanoparticles**

*Supratim Giri, Brian G. Trewyn, Michael P. Stellmaker, and Victor S.-Y. Lin**

Recent reports on surface-functionalized, superparamagnetic iron oxide nanoparticles have demonstrated their feasibility for use in a variety of biological applications such as drug/gene delivery,[1–5] magnetic resonance imaging,[6–9] bioseparation,[10–13] tissue repairing,[14] and thermal tumor therapy.[15–18] In contrast, only a few examples of controlled-release drug-delivery systems based on magnetic nanoparticles have been reported.[19,20] Most of these systems comprise magnetic nanoparticle "cores" coated with organic or inorganic "shell" constituents, and encapsulated within the layers of shells are the pharmaceutical drugs. In the presence of an external magnetic field, these core–shell materials are attracted toward the magnet. This magnetic motor effect is indeed attractive for the development of site-specific drug-delivery systems. However, many important site-selective delivery systems, such as those for highly toxic antitumor drugs, require "zero release" before reaching the targeted cells or tissues. To the best of our knowledge, no controlled-release delivery systems based on magnetic nanoparticles that are stimuli-responsive and capable of "zero premature release" have been reported.

Surface-functionalized mesoporous silica materials have been demonstrated to be excellent hosts of molecules of various sizes, shapes, and functionalities.[21–28] Recent reports[29–33] on the design of capped and gated mesoporous silica derivatives have shown promise in the generation of controlled-release nanodevices. Herein, we report the synthesis of a controlled-release delivery system that is based on MCM-41-type mesoporous silica nanorods (MSNs) capped with superparamagnetic iron oxide nanoparticles and is stimuli-responsive and chemically inert to guest molecules entrapped in the matrix.

The system consists of MSNs functionalized with 3-(propyldisulfanyl)propionic acid to give "linker-MSNs", which have an average particle size of 200 nm × 80 nm (length × width) and an average pore diameter of around 3.0 nm. As a proof of principle, fluorescein was used as the guest molecule to be encapsulated inside the linker-MSN material. By introducing dry linker-MSNs to an aqueous solution of fluorescein, the mesopores of the MSNs behaved like sponges by soaking up fluorescein molecules (Figure 1). Next, the openings of the mesopores of the fluorescein-loaded linker-MSN were covalently capped in situ through amidation[34] of the 3-(propyldisulfanyl)propionic acid functional groups bound at the pore surface with 3-aminopropyltriethoxysilyl-functionalized superparamagnetic iron oxide (APTS-Fe_3O_4) nanoparticles.[35] The disulfide linkages between the MSNs and the Fe_3O_4 nanoparticles are chemically labile and can be cleaved with various cell-produced antioxidants and disulfide reducing agents such as dihydrolipoic acid (DHLA) and dithiothreitol (DTT), respectively. The release of the magnetic nanoparticle caps from the fluorescein-loaded MSNs can be regulated by the concentration of trigger molecules (Figure 1).

The mercaptopropyl-derivatized mesoporous silica nanorods (thiol-MSNs) were initially prepared according to our previously reported co-condensation method.[31,33,36–41] After removal of the surfactant, thiol-MSNs were treated with 2-carboxyethyl-2-pyridyl disulfide to yield the acid-functionalized linker-MSNs. The rod shape, the average particle size, and the MCM-41-type mesoporous structure of the linker-MSNs were confirmed by transmission electron microscopy (TEM). The mesopores (porous channels) are represented by the alternating black and white stripes as shown in Figure 2a. The N_2 sorption isotherms of the material further revealed a BET isotherm typical of an MCM-41 structure (type IV), with a surface area of 1018.0 $m^2 g^{-1}$ and a narrow BJH pore-size distribution (average pore diameter: 3.0 nm).[42]

The superparamagnetic Fe_3O_4 nanoparticles coated with 3-aminopropylsiloxy groups (APTS-Fe_3O_4) were prepared according to a reported procedure.[34] The TEM micrograph (Figure 2b) of the resultant APTS-Fe_3O_4 particles revealed an average diameter of 10 nm for the particles. APTS-Fe_3O_4 nanoparticles (960.00 mg) were treated with the linker-MSNs (80.00 mg) in a solution of fluorescein (3.60 μM) in PBS medium (100.0 mM, pH 7.4). The resulting suspensions were centrifuged, and the Fe_3O_4–MSN-fluorescein material (magnet-MSNs) along with the unreacted APTS-Fe_3O_4 nanoparticles were isolated by filtration. The concentration of fluorescein in the filtrate was determined by UV/Vis spectroscopy to be 1.50 μM. The decrease in the concentration of fluorescein in solution ($\approx$2.10 μM) was attributed to the uptake of 1.68×10^{-8} moles of fluorescein by the MSNs which corresponds to a loading efficiency of approximately 58.3 mol%.

The successful incorporation of APTS-Fe_3O_4 nanoparticles in the MSN matrix was confirmed by various spectroscopic methods. The covalent immobilization of the surface-functionalized Fe_3O_4 nanoparticles to the linker-MSN led to a decrease in intensity of the powder X-ray diffraction (XRD) peaks (Figure 3a). Such a decrease in scattering contrast between the pores and the framework of the MCM-41 materials as a result of pore-filling has been reported previously.[43–46] Furthermore, a small increase was observed in the d_{100} (spacing) value of the Fe_3O_4-capped magnet-MSNs

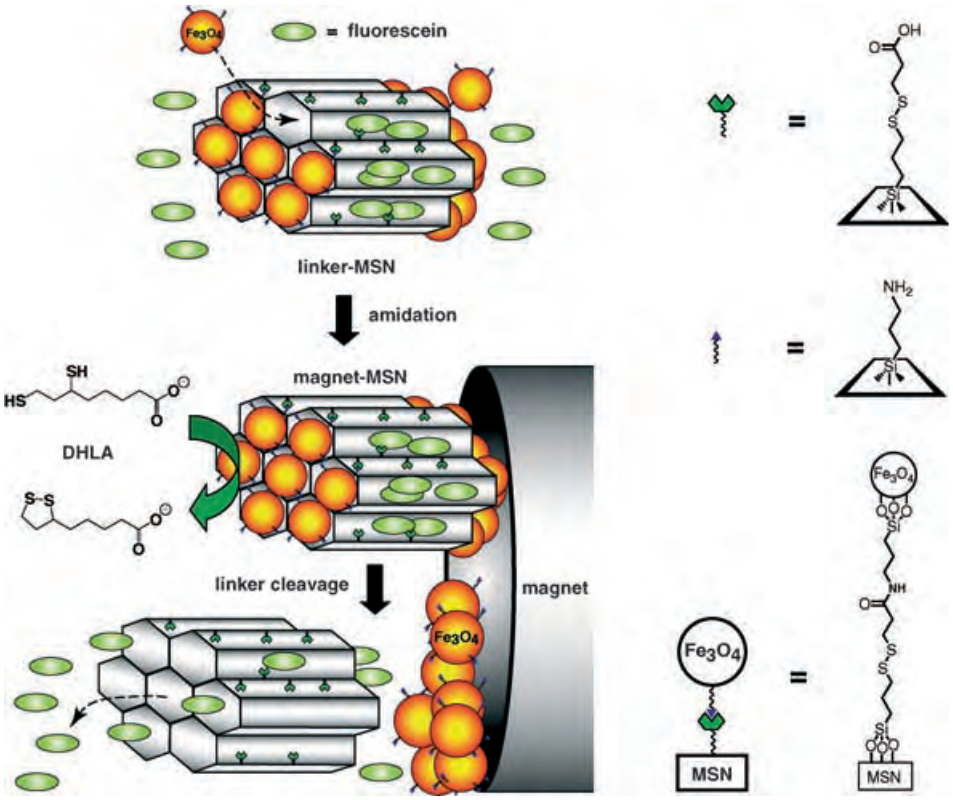

Figure 1. Schematic of the stimuli-responsive delivery system (magnet-MSN) based on mesoporous silica nanorods capped with superparamagnetic iron oxide nanoparticles. The controlled-release mechanism of the system is based on reduction of the disulfide linkage between the Fe_3O_4 nanoparticle caps and the linker-MSN hosts by reducing agents such as DHLA.

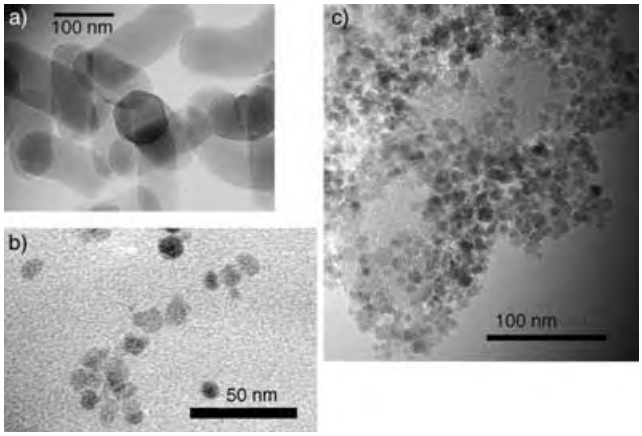

Figure 2. TEM images of a) linker-MSNs, b) APTS-coated Fe_3O_4 nanoparticles, and c) Fe_3O_4-capped magnet-MSNs.

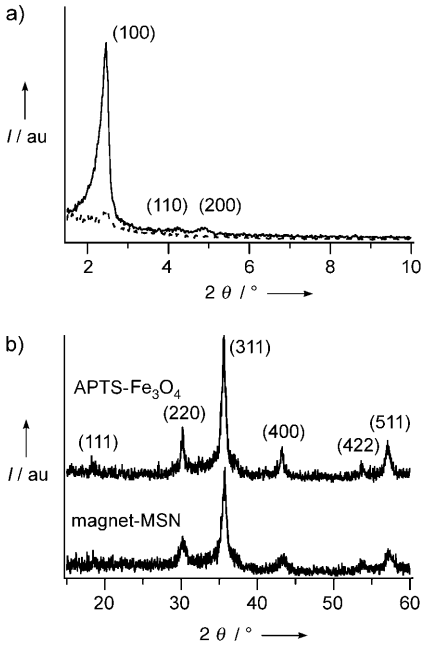

Figure 3. a) Low-angle X-ray diffraction (XRD) patterns of linker-MSN (——) and magnet-MSN (-----) powders. b) High-angle XRD patterns of APTS-coated Fe_3O_4 nanoparticles (top) and magnet-MSN (below).

relative to that of linker-MSN and could also be attributed to the covalent-bond-induced pore-filling effect between the Fe_3O_4 nanoparticles and the mesoporous silica matrix. The high-angle powder XRD patterns of magnet-MSNs matched exactly that of the APTS-Fe_3O_4 nanoparticles (Figure 3b) and confirmed the presence of APTS-Fe_3O_4 on the surface of the linker-MSNs. The pore-filling effect was also confirmed by the N_2 adsorption/desorption isotherms of the Fe_3O_4-capped magnet-MSNs. In contrast to the high surface area ($1018.0\ m^2 g^{-1}$) of linker-MSNs, magnet-MSNs showed a type I BET isotherm typical of nonporous materials, with a surface area of $296.0\ m^2 g^{-1}$.[42] The results indicated that most of the pore openings of the linker-MSN precursor were

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

indeed blocked by Fe_3O_4 nanoparticles. TEM investigations of magnet-MSN also provided direct evidence of the distribution of Fe_3O_4 nanoparticles on the organically functionalized linker-MSN material. The Fe_3O_4 nanoparticles are clearly visible as dark areas on the outside edge of the mesopores (Figure 2c). In contrast to the features observed for Fe_3O_4-capped MSNs, the TEM micrograph of the linker-MSNs (Figure 2a) prior to capping with Fe_3O_4 nanoparticles showed smooth edges and a good contrast between the mesoporous channels and the silica matrix.

As mentioned earlier, the disulfide bonds between the MSNs and the Fe_3O_4 nanoparticles in the magnet-MSNs are labile and can be cleaved with disulfide reducing agents to release the trapped guest molecules from the mesopores. As the entire Fe_3O_4-capped MSN carrier system is magnetic, the system can be magnetically directed to a site of interest from where the release can take place. To demonstrate the release of a drug with the magnet-MSNs under a magnetic field, two cuvettes were charged with fluorescein-loaded magnet-MSNs (50.0 mg each) dispersed in 3.00 mL of PBS solution (100.0 mM, pH 7.4). Both cuvettes were held against the tips of two magnets (magnetic stirrer-bar retrievers). As illustrated in Figure 4a, the magnet-MSNs were attracted to the walls of the cuvettes closest to the tips of the external magnets. Dithiothreitol (DTT, 48.5 mg, 3.15×10^{-4} mol) was added to one of the two cuvettes (left) for the release experiment, while the other cuvette (right) served as a control. After 2 days (Figure 4b), green fluorescence was clearly observed in the solution to which DTT was added whereas no fluorescence could be observed from the control solution. As fluorescein-loaded magnet-MSNs do not fluoresce—Fe_3O_4 nanoparticles quench the fluorescence of fluorescein, as recently described[47]—the result indicates that fluorescein molecules were indeed released from the magnet-MSNs by the introduction of the disulfide-reducing trigger DTT. Note, the color of the accumulated magnet-MSNs near the external magnet changed from black to gray after 4 days following the addition of DTT (Figure 4c). A white precipitate of MSNs was also observed at the bottom of the cuvette. As the black Fe_3O_4 nanoparticles are attracted to the external magnetic field whereas the MSNs are not, it is plausible that the Fe_3O_4 nanoparticle caps from the Fe_3O_4–MSN ensembles were pulled in toward the magnet while the MSNs diffused away from the magnetic field as the disulfide linkage was cleaved by DTT.

Magnet-MSNs exhibited less than 1.0% release of fluorescein in PBS solutions (100.0 mM, pH 7.4) over a period of 132 h in the absence of trigger molecules (Figure 4d). This result suggested a good efficiency of the Fe_3O_4 nanoparticles to retain fluorescein molecules and prevent undesired leaching by capping the mesopores. Addition of 0.1 mM of disulfide reducing agents such as DHLA and DTT to a suspension of magnet-MSNs (13.0 mg) in PBS solution (3.00 mL, 100.0 mM, pH 7.4) triggered a rapid release of the mesopore-entrapped fluorescein. Within 48 h, 85% of the total release of fluorescein (40% of total loading) was attained; the maximum extent of release was achieved after 5 days (Figure 4d). With lipoic acid DHLA, the maximum percentage of

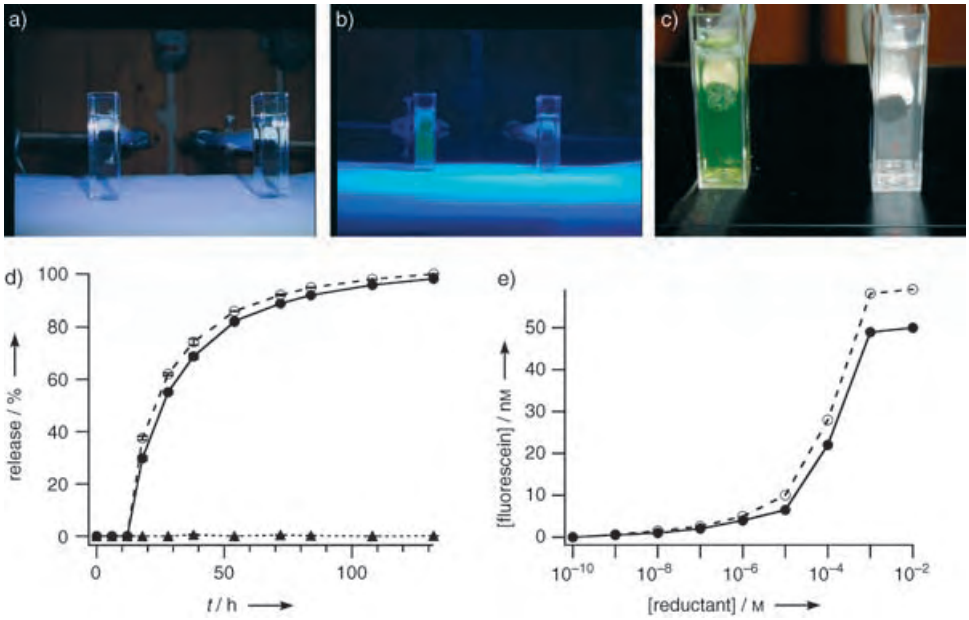

Figure 4. Photographs of two cuvettes charged with fluorescein-loaded magnet-MSNs (50.0 mg each) dispersed in 3.00 mL of PBS solution (100.0 mM, pH 7.4): a) Accumulation of magnet-MSNs on the walls of the cuvettes closest to the tips of the external magnets (magnetic stirrer-bar retrievers shown behind the cuvettes); b) 2 days after the addition of DTT (48.5 mg) to the solution contained in the cuvette on the left, green fluorescence was observed from the sample which signalled the release of encapsulated fluorescein from the matrix; c) 4 days after the addition of DTT, the color of the accumulated magnet-MSNs changed from black to gray. d) Controlled release of fluorescein from magnet-MSNs (13.0 mg) in 3.00 mL of PBS solution (100.0 mM, pH 7.4) triggered by 0.1 mM DHLA (●) or DTT (○). No noticeable release was observed in the absence of a reductant (▲). e) The dependence of the release of fluorescein from magnet-MSNs on the concentration of the reductant, measured 72 h after the addition of DHLA (●) or DTT (○).

fluorescein released was 31.4 % of the total loading. Interestingly, the rates of release of fluorescein by the two different triggers showed similar diffusional kinetic profiles which indicates that the reducing powers of DHLA and DTT are similar. The similarity could be attributed to the fact that DHLA self-oxidizes into a disulfanyl-linked five-membered ring upon reducing the targeted disulfide bond, whereas DTT self-oxidizes into a disulfanyl-linked six-membered ring. The thermodynamic considerations of cyclizations into five- and six-membered rings should be similar. Furthermore, the amount of fluorescein released after 72 h following the addition of DHLA and DTT showed similar dependencies on the concentration of the trigger (Figure 4e) which indicates that the rate of release was dictated by the rate at which the Fe_3O_4 nanoparticle caps were removed.

To investigate the endocytosis and biocompatibility of our system, HeLa (human cervical cancer) cells ($\approx 10^5$ cells mL^{-1}) were incubated overnight with magnet-MSNs (0.2 mg mL^{-1}) to allow the endocytosis of magnet-MSNs.[40] The cells that took up magnet-MSNs were magnetically separated from those that did not. The isolated cells were treated with 0.001 % of 4′,6-diamidino-2-phenylindole (DAPI) dye in PBS solution (100.0 mM, pH 7.4) and placed in a cuvette. DAPI is known to form blue-fluorescent complexes with natural double-stranded DNA and has been widely used as a fluorescent dye for nucleus staining. These DAPI-stained, fluorescent cells were first accumulated to the right side wall of the cuvette by applying an external magnetic field—a commercially available grade N45 neodymium iron boron magnet. When the magnet was moved to the left side of the cuvette, the blue-fluorescent HeLa cells were clearly seen to move across the cuvette toward the magnet (Figure 5a–c) indicating that the magnet-MSNs were indeed endocytosed by HeLa cells. To further confirm the endocytosis of magnet-MSNs, these HeLa cells were examined by confocal fluorescence microscopy. A series of fluorescence images of different cross-sections of magnet-MSN-containing HeLa cells were obtained by changing the focal depth every 1.2 μm vertically (see Supporting Information). Green fluorescence was clearly observed within the cell bodies of these HeLa cells upon excitation at 494 nm (Figure 5d) which strongly indicates that the mesopore-encapsulated fluorescein molecules were released inside the cells. As previously reported by Biaglow et al., cancer cell lines express significant amounts of DHLA.[48] We believe that the efficient intracellular release of fluorescein was triggered by the high intracellular concentration of DHLA. To visualize the locations of the nuclei, the cells were excited at 358 nm (Figure 5e). The appearance of healthy intact nuclei and the visibility of fully grown cells by transmission (Figure 5f) suggested that the magnet-MSNs are biocompatible with HeLa cells in vitro under these experimental conditions.

In conclusion, we have demonstrated that mesoporous silica nanorods capped with superparamagnetic iron oxide nanoparticles—so-called magnet-MSNs— can be used as a stimuli-responsive controlled-release delivery carrier. Guest molecules that are smaller than 3 nm, such as fluorescein, could be encapsulated and released from the magnet-MSN delivery system by using cell-produced antioxidants (e.g. dihydrolipoic acid) as triggers in the presence of an external magnetic field. Furthermore, the biocompatibility and efficiency of intracellular delivery of the magnet-MSN system with human cervical cancer cells offer promising potential in utilization of this system to investigate various inter- and

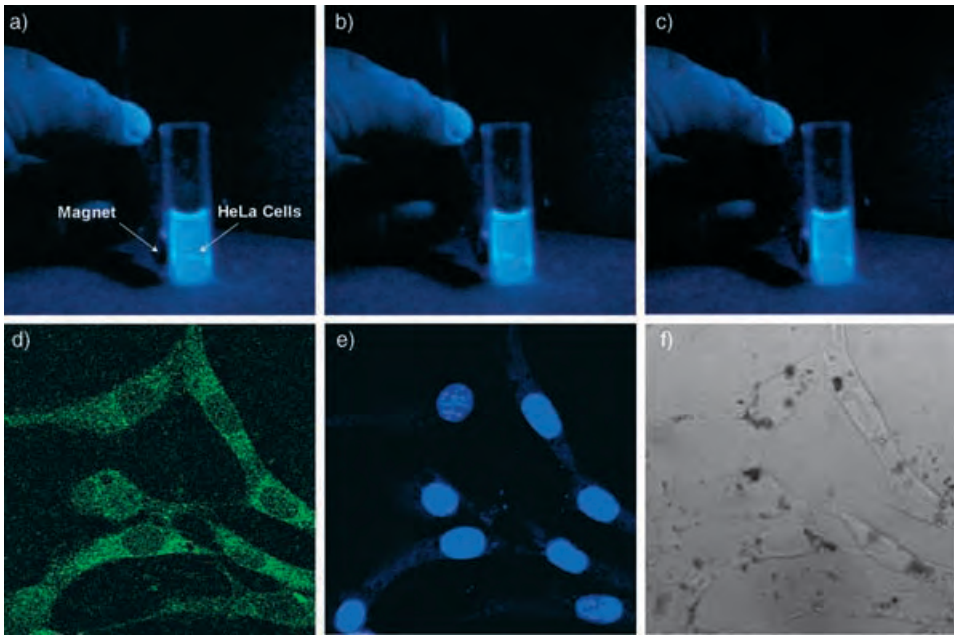

Figure 5. a–c) Single frames of photographs of HeLa cells with Fe_3O_4-capped fluorescein-loaded MSNs traveling across the cuvette, propelled by magnetic force. d–f) Fluorescence confocal micrographs of HeLa cells after 10 h incubation with Fe_3O_4-capped fluorescein-loaded MSNs: d) cells excited at 494 nm; e) cells excited in the UV region; f) a pseudo-brightfield image, where dark aggregations of magnet-MSNs can be clearly observed.

intracellular chemical/neurochemical communications in vitro. We envision that these magnet-MSNs could play a significant role in the development of new generations of site-selective controlled-release delivery devices and interactive sensory nanodevices.

Experimental Section

$FeCl_2 \cdot 4H_2O$, $FeCl_3 \cdot 6H_2O$, 3-aminopropyltriethoxysilane (APTS), 3-mercaptopropionic acid, 2-aldrithiol, 3-mercaptopropyltrimethoxysilane (MPTMS), tetraethylorthosilicate (TEOS), *n*-cetyltrimethylammonium bromide (CTAB), 1-(3-(dimethylamino)propyl)-3-ethylcarbodiimide hydrochloride (EDC), fluorescein, and dithiothreitol (DTT) were purchased from Aldrich and used as received. Dihydrolipoic acid (DHLA) was obtained from Sigma and used without further purification. Nanopure water (18.1 MHz) prepared from a Barnstead E-pure water-purification system was employed throughout. PBS (phosphate-buffered saline) solution (100.0 mM, pH 7.4) was used as the solvent for the loading experiments.

APTS-coated magnetite (Fe_3O_4) nanoparticles: Magnetic nanoparticles were prepared and coated with APTS according to a slightly modified reported procedure[34] (see Supporting Information).

MCM-41-type mesoporous silica nanoparticles functionalized with 3-(propyldisulfanyl)propionic acid (linker-MSN): The thiol-MSN material was prepared according to a slightly modified version of our previously reported procedure[31] (see Supporting Information). The purified thiol-MSNs (1.000 g) were treated with a solution of 2-carboxyethyl-2-pyridyl disulfide (1.340 g, 6.23×10^{-3} mol; prepared according to a reported procedure[49]) in ethanol (80.00 mL) at room temperature for 24 h under vigorous stirring (vortex stirrer) to obtain the desired disulfide bond-exchange reaction. The resulting acid-functionalized MSN was filtered, washed with ethanol, and dried in air. The surface coverage of chemically accessible thiol groups was quantified at 7.01×10^{-4} mol g^{-1}.[38]

Loading of fluorescein into the mesoporous framework of linker-MSN and the capping of the mesopores with APTS coated Fe_3O_4 nanoparticles: The purified linker-MSNs (80.0 mg) was stirred vigorously (vortex stirrer) in a solution of fluorescein (3.6×10^{-6} M) in PBS solution (8.00 mL, 100.0 mM, pH 7.4) for 24 h. Then, APTS-coated Fe_3O_4 nanoparticles (960.0 mg) were added to the suspension followed by 1-(3-(dimethylamino)propyl)-3-ethylcarbodiimide hydrochloride (EDC) (60.0 mg, 3.13×10^{-4} mol). The mixture was stirred vigorously (vortex stirrer) for another 48 h before the precipitate was filtered, washed extensively with buffer, and dried under vacuum. The precipitate (480.0 mg) was stirred vigorously again in PBS solution (10.00 mL, 100.0 mM, pH 7.4) for 48 h, followed by filtration and washing (×7) with PBS solution to remove physisorbed, uncapped fluorescein molecules from the exterior surface of the material. The purification procedure was repeated once more to further remove any physisorbed fluorescein, and the solid material was finally dried into a powder. All the washings were collected, and the loading of fluorescein (2.1×10^{-10} mol mg^{-1} linker-MSN) was calculated from the difference in the concentration of the initial solution of fluorescein and that of the reaction medium combined with the subsequent washings.

Endocytosis of Fe_3O_4-capped MSNs in HeLa cells: Human cervical cancer (HeLa) cell lines were obtained from the American Tissue Culture Collection (ATCC) and were maintained using DMEM (Dulbecco's modified Eagle's medium) supplemented with horse serum (10%), L-glutamine (2.00 mM), penicillin (100 U mL^{-1}), streptomycin (100.0 mg mL^{-1}), and gentamicin (1.0 mg mL^{-1}). HeLa cells were seeded onto 6-well plates (1×10^5 cells in 3.00 mL of growth medium per well) 24 h prior to the experiment. After 24 h, the wells were seeded with Fe_3O_4-capped MSNs (0.2 mg mL^{-1}) in growth medium. After 10 h, the medium was removed and the cells were washed with fresh growth medium. Then, the cells were trypsinized with 0.25% trypsin. A magnet was used to keep the cells associated with the magnetic nanoparticles stationary while the remaining (nonmagnetic) cells were removed. The cells that took up the Fe_3O_4-capped MSNs were centrifuged and resuspended in a solution of 4′,6-diamidino-2-phenylindole (DAPI, 100.0 μg mL^{-1}) in PBS (100.0 mM, pH 7.4).

Phosphonate Ligands Stabilize Mixed-Valent $\{Mn^{III}_{20-x}Mn^{II}_{x}\}$ Clusters with Large Spin and Coercivity**

Shanmugam Maheswaran, Guillaume Chastanet, Simon J. Teat, Talal Mallah, Roberta Sessoli, Wolfgang Wernsdorfer, and Richard E. P. Winpenny**

The discovery that some molecules show a slow relaxation of magnetization below a critical temperature has prompted a large interest in the materials now generally known as "single molecule magnets" (SMMs).[1,2] Investigations have been inspired partly by the idea that SMMs could be used as molecular magnetic storage devices but also because they show unusual phenomena such as quantum-tunneling of magnetization,[3] which can be exchange-biased.[4] The majority of SMMs have been made by Christou and co-workers, and contain Mn^{III} ions;[5–7] the use of Mn^{III} ions has significant advantages as cages containing this ion often have ground states with large spin values and considerable anisotropy derived from the Jahn–Teller distortion common to a d^4 ion.

Phosphonates, such as benzylphosphonate ($PhCH_2PO_3^{2-}$), have only rarely been employed in making transition-metal cages, probably because of the insolubility of metal phosphonates. Recently we showed that the reaction of phosphonates

with preformed trinuclear iron–carboxylate clusters generates a range of new polymetallic complexes.[8] In our search for new SMMs we have extended this work to mixed-valent basic manganese carboxylates such as $[Mn_3O(O_2CR)_6(py)_3]$ (py = pyridyl).

Reaction of equimolar amounts of $H_2O_3PCH_2Ph$ and $[Mn_3O(O_2CCMe_3)_6(py)_3]$ in CH_3CN in the presence of Et_3N gave a dark brown solution from which $[Et_3NH]_2[Mn^{III}_{18}Mn^{II}_2(\mu_4\text{-}O)_8(\mu_3\text{-}O)_4(\mu_3\text{-}OH)_2(O_3PCH_2Ph)_{12}(O_2CCMe_3)_{10}(py)_2]$ (**1**) crystallizes in 40% yield after two days. Structural analysis[9] shows that the μ_3-oxo-centered triangular array of manganese centers in the precursor cage is maintained in the product (for example: Mn1, Mn2, Mn3, and symmetry equivalents; Figure 1); however, **1** is best described as a centrosymmetric cubic-close packed array of Mn sites. Twelve of the manganese centers lie in one plane, which includes the two Mn^{II} sites (Mn6 and Mn6a in Figure 1). Two Mn^{III} triangles (Mn5, Mn8, and Mn10, and the symmetry related ions) lie above and below hexagons of Mn in the central plane and bridged to the central layer by a μ_4-oxide group (Figure 1b). The relative orientation of the two triangles makes the packing ABC, not ABA, hence this is a fragment of a cubic close-packed (ccp) lattice (see Figure 1b). Mn1 lies in the outer plane containing the triangle formed by Mn5, Mn8, and Mn10, and forms a μ_3-oxo-centered triangle with two ions of the central plane (Mn2 and Mn3). The Mn^{II} site is seven-coordinate, while all the Mn^{III} sites are six-coordinate with Jahn–Teller elongations. Valence bond sum analysis confirms the oxidation states, as well as the assignment of two hydroxide and twelve oxide bridges. The Et_3NH cations hydrogen bond to O atoms from phosphonate groups (N–H···O(phos) 2.78 Å). The twelve phosphonate ligands in **1** show three bonding modes: 3.111, 4.211, and 5.221 (Harris notation[8]), with four examples of each mode in the structure.

Two related clusters can be made from mixed-valent $[Mn_3O(O_2CPh)_6(py)_2(H_2O)]$ and homovalent $[Mn_3O(O_2CPh)_6(py)_3]ClO_4$ benzoate triangles: $K_4[Mn^{III}_{16}Mn^{II}_4(\mu_4\text{-}O)_4(\mu_3\text{-}O)_6(PhCH_2PO_3)_{14}(PhCO_2)_{12}(PhCO_2H)_{0.5}(CH_3CN)_2]$ (**2**) and $Na_6[Mn^{III}_{14}Mn^{II}_6(\mu_4\text{-}O)_4(\mu_3\text{-}O)_4(OH)_4(PhCH_2PO_3)_{14}(PhCO_2)_{12}(PhCO_2H)_2(H_2O)_4(CH_3CN)_4]$ (**3**) can be formed, depending on whether K^I or Na^I ions are present. The manganese cores are similar to that in **1**, and the center of symmetry is retained; however, additional Mn^{II} sites are found within the central layer. Mn4 in **2** has been assigned as being in the Mn^{II} oxidation state because of an increase in the average bond length to 2.163 Å (from 2.011 Å in **1**), while the other Mn–O bond lengths remain virtually unchanged. The average bond length to Mn4 in **3** remains long (2.184 Å), but a significant increase is also observed around Mn7 (2.140 Å compared to 2.023 Å for **1** and 2.022 Å for **2**). Mn4 and Mn7 in **3** are thus assigned as Mn^{II} sites. The alkali-metal cations are attached to the periphery of the cages and have no structure-directing role. This result allows us to isolate three different redox states of mixed-valent cages with the same high nuclearity.

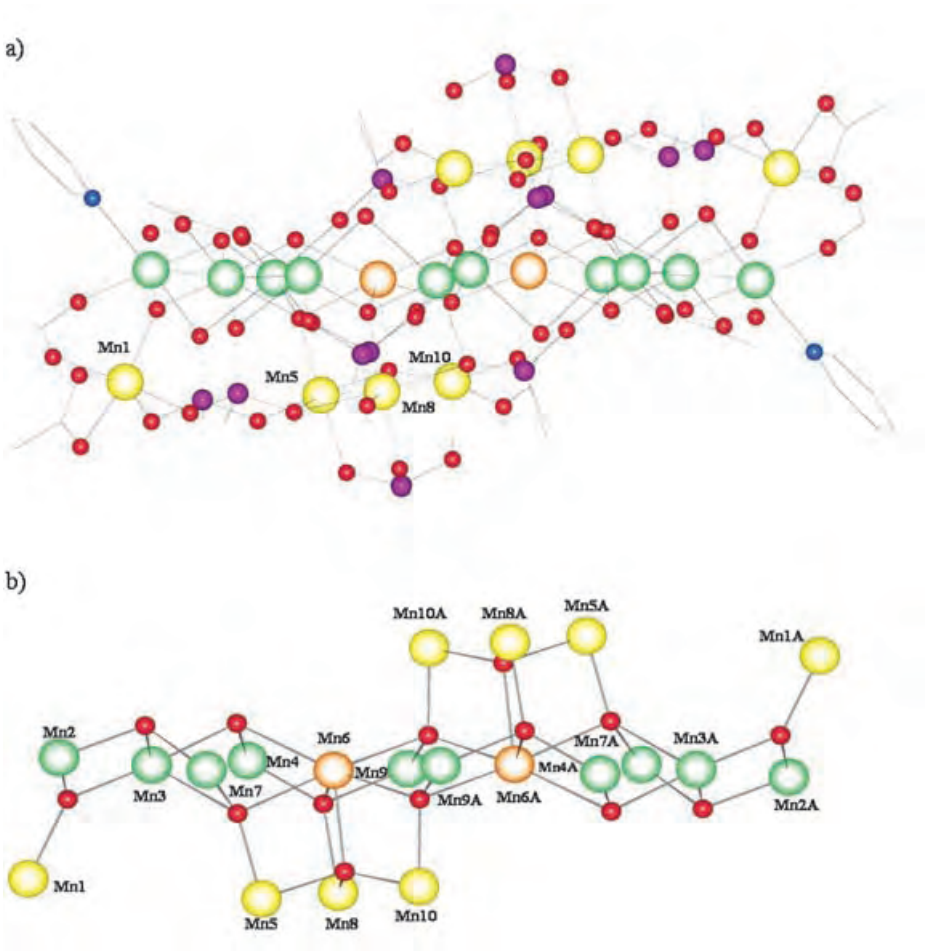

Figure 1. The structure of **1** in the crystal: a) viewed parallel to the central Mn plane (the H and C atoms of the organic side-chains are omitted for clarity), color code: green and yellow, Mn^{III}; orange, Mn^{II}; magenta, P; red, O; blue, N; b) view parallel to the central plane showing the ABC packing of the Mn ions and the bridging oxygen atoms.

The variable-temperature direct current (dc) magnetic susceptibilities measured for the three compounds are shown in Figure 2a. All three compounds show the same type of behavior: the χT value increases from nearly 60 (**1**) and 68 emu K mol^{-1} (**2** and **3**) at room temperature to reach maxima of 210 (**1**), 115 (**2**), and 74 emu K mol^{-1} (**3**). A rapid decrease is observed around 10 K which probably results from zero-field splitting or intermolecular interactions. These curves suggest the three cages have a high-spin ground state: $S = 19 \pm 1$ for **1**, $S =$

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

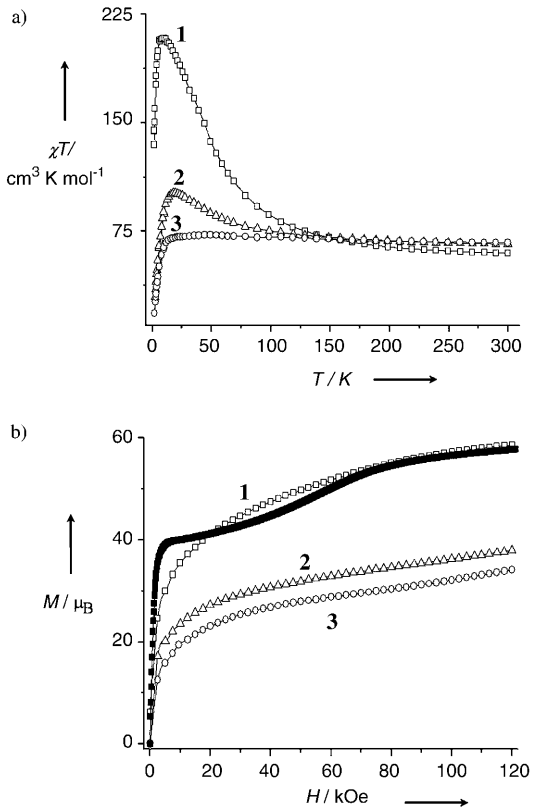

Figure 2. a) Temperature-dependence of the χT value for a polycrystalline sample of **1**, **2**, and **3**; b) magnetization versus field data for **1**, **2**, and **3** recorded at 1.55 K. The filled squares represent the single-crystal magnetization of **1** along the easy axis.

14 ± 1 for **2**, and $S = 11 \pm 1$ for **3**. The magnetization (M) versus magnetic field (H) data are in agreement with the χT plots, and further confirm the large spin values of the ground states. Magnetization measurements were performed on polycrystalline samples at 1.55 K to determine the ground state more accurately (Figure 2b). A two-step curve is obtained for all three compounds, with first a rapid saturation around 40 μ_B (**1**), 30 μ_B (**2**), and 25 μ_B (**3**), followed by a slow increase in the value of M. Single-crystal magnetization measurements performed along the easy axis of the cluster **1** show a pronounced saturation around 40 μ_B at low field, followed by a broad step (Figure 2b).

The further increase in the magnetization is consistent with the presence of excited states close in energy that have a larger spin value. This observation is not surprising when Mn^{II} ions are present as they often lead to weak antiferromagnetic exchange interactions, which can easily be overcome by an external magnetic field. The observed difference in the single-crystal and powder data for **1** suggests that it has a significant magnetic anisotropy which when associated with the large S value ($S = 19 \pm 1$) could lead to slow relaxation of the magnetization.

Alternating current (ac) susceptibility measurements in zero field allows estimation of the energy barrier for the reorientation of the magnetization of superparamagnetic particles or molecules functioning as SMMs.[2] The applied oscillating field probes the dynamics of this reorientation, as the out-of-phase signal (χ'') is maximal when the frequency of the ac field equals the relaxation rate of the magnetization. We monitored the value of χ'' from 1.5 to 10 K at several frequencies between 100 to 20000 Hz. Maxima were observed for compounds **1** and **2** (the data for **1** are shown in Figure 3).

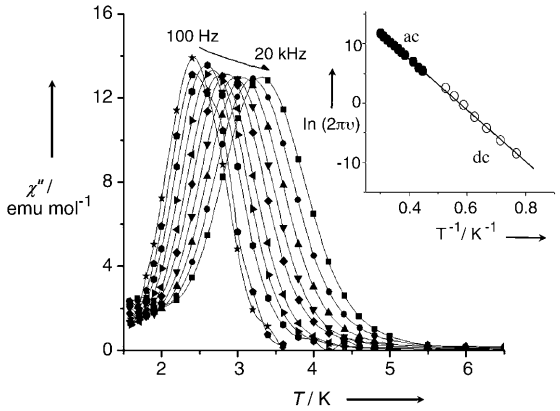

Figure 3. Temperature-dependence of the out-of-phase susceptibility of **1** measured from 100 to 20000 Hz. Inset: the temperature-dependence of the relaxation time extracted from ac measurements and time decay of the magnetization.

In contrast, only a frequency-dependent increase in the value of χ", with no maxima down to 1.5 K, has been observed for **3**. The energy barrier for the relaxation can be derived from the Arrhenius plot[2c] as 43 K ($\tau_0 = 2 \times 10^{-11}$ s) for **1** and 17 K ($\tau_0 = 2 \times 10^{-10}$ s) for **2**, with a moderate distribution of relaxation times. All three compounds are therefore new SMMs, and **1** possesses one of the highest energy barriers known after $\{Mn_{12}\}$ clusters.[2a] It is also one of the highest spin SMMs known.[6,10] It is worth noting that the energy barrier increases from **3** to **1** as the content of anisotropic Mn^{III} ions and the ground spin state of the cluster increases.

The decay of remnant magnetization (see Supporting Information) has been followed on a microcrystal of **1** with a micro-Squid[11] and the relaxation time—extracted as the time delay at which M/M_0 equals $1/e$—is in good agreement with the values extracted from ac measurements (see inset of Figure 3). A square hysteresis loop has been measured that widens on lowering the temperature, with a remarkably high coercive field of 10 kOe below 0.4 K (Figure 4). Previously reported large Mn cages have much narrower hysteresis loops.[6,7] No sudden jumps at $H = 0$ are observed here, which suggests resonant quantum tunneling is not particularly efficient. This proposal is confirmed by the unchanged value of the relaxation time τ extracted from ac susceptibility measurements in zero and under moderate static fields. The shape of the hysteresis is unusual, as it shows small steps around 4 and 9 kOe on the descending field branch. A detailed analysis of the hysteretic behavior of these steps shows that they are not related to dynamic properties but rather that they correspond to a cross-over to a magnetic ground state of higher S value that is induced by the applied field.[12]

The $S = 19 \pm 1$ ground state of **1** in low field can be tentatively rationalized as follows. The strongest antiferro-

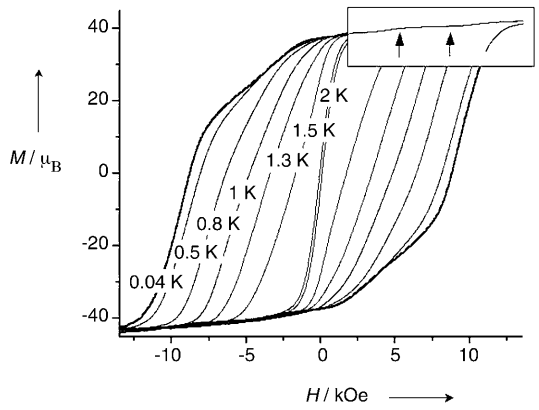

Figure 4. Hysteresis loops measured at a sweep rate of 350 Oe s^{-1} on a crystal of **1** at different temperatures. Steps at 4 and 9 kOe are indicated by arrows.

magnetic interactions are likely to result from μ_3-oxides which are all associated with the triangle Mn1-Mn2-Mn3 and its symmetry equivalent. We assume that these triangles are spin-frustrated and have a low resulting spin.[13]

We can then consider the remaining twelve Mn^{III} and two Mn^{II} sites in the structure; the Mn^{III} sites are bridged by μ_4-oxide and μ_3-hydroxide groups, which can often create ferromagnetic exchange. In contrast, exchange between Mn^{II} and Mn^{III} sites in similar structures is often weak and antiferromagnetic. We can thus propose that the spin of the ground state at low field arises as a consequence of the spin of the twelve Mn^{III} ions ($S = 24$) opposed to the spin of the two Mn^{II} ions ($S = 5$) plus the contribution from the two frustrated triangles. The large change in the ground state S value would then result from the field overcoming the antiferromagnetic exchange between the Mn^{III} and Mn^{II} ions, thus leading to an increase in the S value of 10 and in the M value of 20 μ_B. The observed decrease in the value of S on reduction of Mn^{III} to Mn^{II} confirms the proposed picture, in which the antiparallel aligned spins are associated with Mn^{II} sites. This oversimplified model would, however, predict changes in S of 9 and 18 in going from **1** to **2** and **3**, respectively. The smaller difference observed suggests a more complicated scenario where intermediate spin states are stabilized by competing antiferromagnetic interactions. X-ray magnetic circular dichroism, which is able to distinguish how the two oxidation states contribute to the magnetic moment, thus seems the appropriate technique to investigate the spin structure of these compounds.

The three compounds are therefore very unusual SMMs as shown by the very high spin and high coercivity of **1**, in the immediate availability of three redox forms of the cluster, and finally the observation of a dramatic change in the spin of the ground state.

Experimental Section

All reagents were used as received from Aldrich. $[Mn_3O(O_2CCMe_3)_6(py)_3]$, $[Mn_3O(PhCO_2)_6(py)_2(H_2O)]$, and $[Mn_3O(PhCO_2)_6(py)_3]$ ClO_4 were made by literature procedures.[14]

1: A brown solution of $[Mn_3O(O_2CCMe_3)_6(py)_3]$ (0.58 g, 0.56 mmol) in MeCN (10 mL) was treated with $PhCH_2PO_3H_2$ (0.096 g, 0.56 mmol) and triethylamine (0.14 mL). The resulting solution was stirred for 15 h and then filtered. Very large crystals grew from the filtrate after two days. The crystals were suitable for X-ray studies. Yield: 0.24 g (40 %). Elemental analysis calcd (%) for $C_{156}H_{218}Mn_{20}N_4O_{70}P_{12}\cdot 2\,CH_3CN$: C 39.85, H 4.68, N 1.74, P 7.71; found: C 39.12, H 4.75, N 2.09, 7.73.

2: $[Mn_3O(PhCO_2)_6(py)_2(H_2O)]$ (0.54 g, 0.5 mmol) and $PhCH_2PO_3$ (0.086 g, 0.5 mmol) were mixed in a CH_3CN/EtOH (5:1) mixture (12 mL), and KOMe (0.035 g, 0.5 mmol) was added. The solution was stirred overnight and filtered. Crystals of **2** grew from the filtrate after three days. Yield: 0.21 g (60 %). Elemental analysis (%) calcd for $C_{189.5}H_{167}Mn_{20}N_2K_4O_{77}P_{14}$ (dried): C 42.50, H 3.12, N 0.51, P 8.04; found: C 42.63, H 3.41, N 0.22, P 7.76.

3: $[Mn_3O(PhCO_2)_6(py)_3]ClO_4$ (0.59 g, 0.5 mmol), $PhCH_2PO_3H_2$ (0.086 g, 0.5 mmol), and Et_3N (0.14 mL) were mixed in CH_3CN (10 mL) and the solution stirred for 15 h before being filtered. A solution of $NaClO_4$ (0.24 g) in CH_3CN (2–3 mL) was added to the filtrate and the mixture again filtered before keeping the filtrate for crystallization. After two days dark brown single crystals of **3** grew that were suitable for X-ray analysis. Yield: 0.15 g (30 %). Elemental analysis calcd (%) for $C_{204}H_{194}Mn_{20}N_4Na_6O_{86}P_{14}$ (dried) : C 42.61, H 3.40, N 0.98, P 7.54; found: C 42.98, H 3.81, N 0.98, P 7.72.

Magnetic measurements: The temperature-dependence of the magnetization was measured on polycrystalline powder samples with a Cryogenic S600 SQUID magnetometer at 10 kOe and below 50 K at 1 kOe to avoid saturation. Data have been corrected for the diamagnetic contribution according to Pascal tables. Magnetization curves up to 120 kOe have been obtained by using an Oxford Instruments Vibrating Sample Magnetometer (VSM). Alternating current susceptibility data were obtained by using a home-made probe[15] with an oscillating field of 0.8 Oe. A home-made μ-SQUID magnetometer[11] was used for low-temperature magnetic measurements on single microcrystals of **1**.

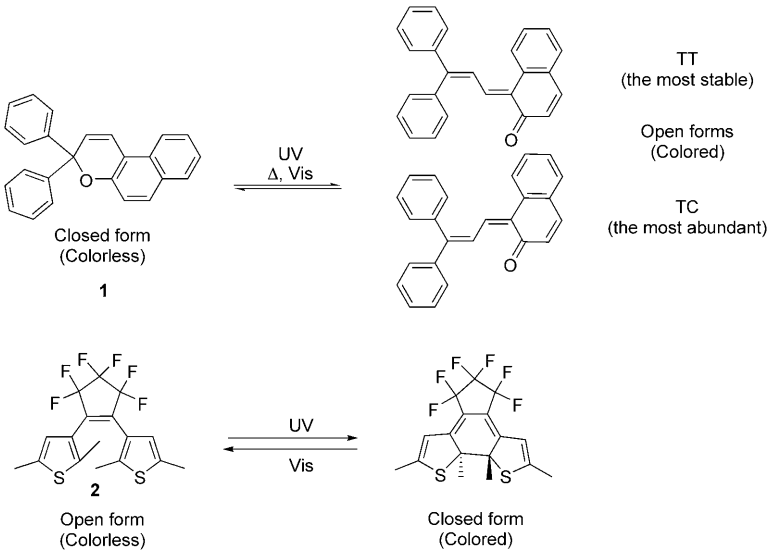
Multiple Addressing in a Hybrid Biphotochromic System

*Michel Frigoli and Georg H. Mehl**

Addressing the optical and electronic properties of organic materials by light is currently a very active research area and such systems are expected to be of great importance for optical computing—as logic gates, as the optical equivalent of field-effect transistors, as high density (3D) data storage systems, as well as for light rectification and harvesting.[1–3] The goal is a miniaturization of functional elements down to the molecular level, or at least close to that, which could result in a markedly increased performance as a consequence of the higher volume density of the functional elements compared to that of current devices.



Irradiation of photochromic systems at selected wavelengths leads to the reversible formation of colored forms as a result of a change of the structure of conjugated π systems. Bistable materials or systems that are dependent on continuous irradiation to maintain the colored (high-energy) form are suitable candidates for such applications. Nanostructured crystalline systems, high-density photochromic polymers, and a range of systems which form anisotropic fluids either as mixtures or as molecular materials in the condensed state, have been reported recently.[4,5]

In this context, biphotochromic systems are particularly attractive, as the controlled sequential interaction of photons in one molecular system promises synergies in the design and electronic properties (for example, a sequential change of the electronic properties would be a precondition for a fully photonic molecular logic gate).[2a,g,3g] Investigations on biphotochromes based on naphthacene–diarylethene, interconnected diarylethenes, and diarylethene–dihydroazulene systems have been reported recently.[6–8] The challenge with biphotochromic systems is both the selective and controlled addressing of individual photochromic units and the conversion of the combined system. In this context, the combination of naphthopyrans and photochemically bistable and very fatigue resistant diarylethene groups (Scheme 1) are particularly interesting, and as yet not investigated.[2b]

Naphthopyrans are currently the most important class of photochromes commercially as a result of their high stability, fatigue resistance, and addressable bleaching kinetics.[9] Herein we report the synthesis and investigation of the photochromic properties of a combined system consisting of a

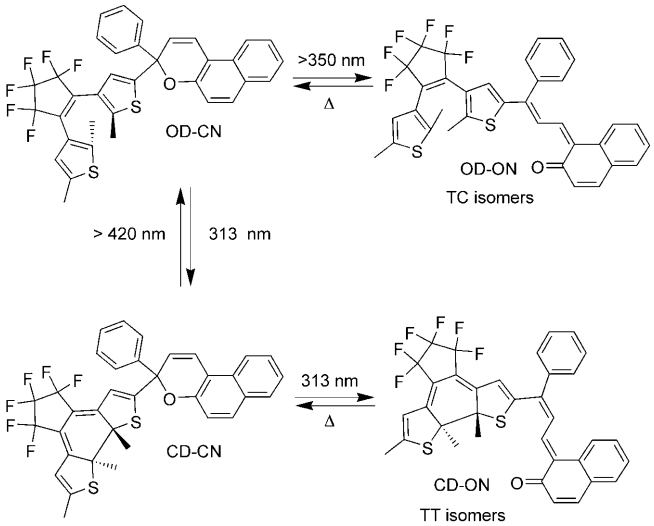
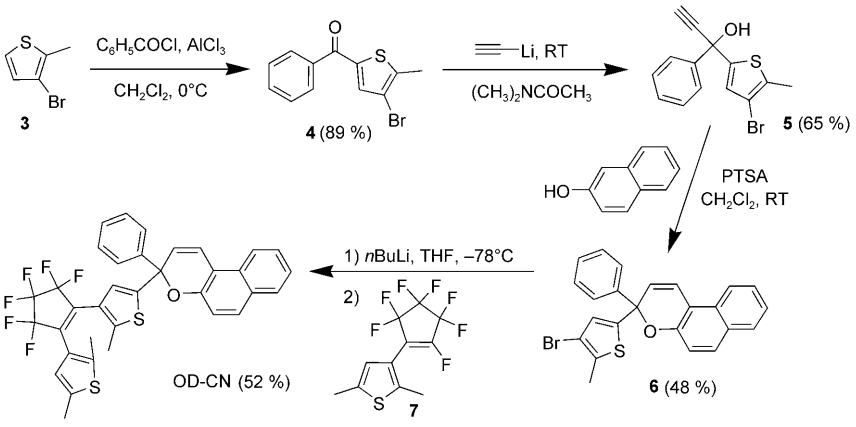


Scheme 1. Photochemical interconversion in the [3*H*]-naphthopyran and dithienylethene series; TT = transoid,*trans*; TC = transoid,*cis*.



naphthopyran unit and a diarylethene group. An important feature in the design of this system is the different absorption behaviors of the naphthopyran (CN) and the diarylethene (OD) groups which are connected through a sp^3-hybrdized carbon center. Only the conversion of the closed naphthopyran (CN) into the open form (ON) leads to conjugation and an electronic connection. Closure of the open diarylethene system (OD to CD) extends the π-electron system over the whole molecule. The different behavior of these two photochromes—diarylethenes are essentially bistable and naphthopyrans open on irradiation to a number of isomers, most of which revert back thermally to the closed forms in the dark—results in a multiaddressable hybrid photochrome.

The synthesis of OD-CN (Scheme 2) starts with the preparation of ketone **4**, which was obtained (89% yield) from the reaction of 2-methyl-3-bromothiophene with benzoyl chloride in the presence of $AlCl_3$. The subsequent condensation of the lithium acetylide diamine complex with **4** resulted in the corresponding propargylic alcohol **5** (65% yield).[10] The intermediate chromene **6** was obtained by a "one-pot reaction" of **5** and 2-naphthol in the presence of a catalytic amount of *para*-toluenesulfonic acid (PTSA; yield 48%).[11] Lithiation of the chromene **6** by bromine/lithium exchange using *n*BuLi in THF at −78°C, followed by quenching of the reaction mixture with **7** afforded the hybrid biphotochrome OD-CN (52% yield).[12a]

The mode of action of the multiaddressable photochromic system OD-CN is illustrated in Scheme 3. The path from OD-CN to CD-ON requires the interaction of OD-CN with two photons. The photochromic properties were investigated by a series of steady-state experiments in which light was either switched on or off (input: 0,1) and spectra were recorded until a photostationary state (PS) was obtained. This sequential approach revealed the formation of four different states with entirely different absorption behaviors, and five addressing modes were investigated.[12b]

Scheme 3. Photochemical reactions of the hybrid OD-CN showing all four photochromic states.

Scheme 2. Synthesis of the biphotochromic hybrid OD-CN.

The associated investigated reaction pathways are: 1) OD-CN→OD-ON, 2) OD-CN→CD-ON (via CD-CN), 3) CD-ON→CD-CN, 4) CD-CN→CD-ON, 5) CD-CN→OD-CN. Our experimental set-up did not allow for the investigation of the potential direct path from OD-ON to CD-ON. Two of the states, OD-CN and CD-CN, are bistable, while OD-ON and CD-ON have to be triggered by irradiation. The absorption spectra of all four forms are shown in Figure 1 and the colored solutions are shown in Figure 2.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

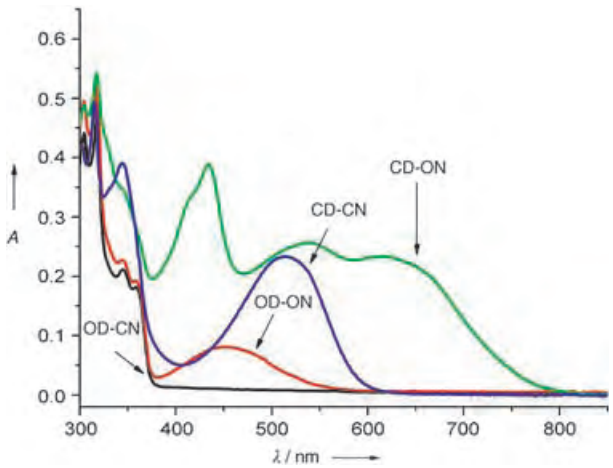


Figure 1. UV/Vis absorption spectra (cylohexane solution, 3.33×10^{-5} M) of the four photochromic states of the system OD-CN, before irradiation (OD-CN), with irradiation at 366 nm (OD-ON), with irradiation at 313 nm (CD-ON), after irradiation at 313 nm then left in the dark (CD-CN).

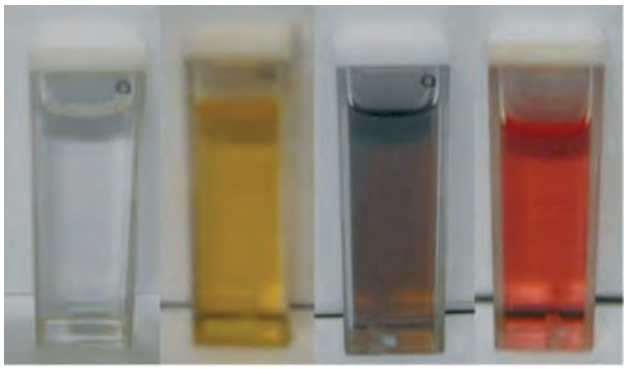

Figure 2. Colors obtained for each stationary state: OD-CN (initial state, colorless), OD-ON (after irradiation at 366 nm, yellow), CD-ON (after irradiation of OD-CN or CD-CN at 313 nm, brown), and CD-CN (from thermal bleaching of OD-ON in the dark, red/pink).

An interesting feature of the OD-CN system is the electronic decoupling of the two photochromic groups connected through a sp^3-hybridized carbon atom. Irradiation above 350 nm transforms the naphthopyran group selectively from the closed (colorless) form of OD-CN to the open form (orange, $\lambda_{max}=456$ nm) of OD-ON (path 1; Figure 1). The thermal bleaching kinetics of the majority of the photoproducts (ca. 81 %) can be described with a monoexponential function ($k_{\Delta}=0.055\ s^{-1}$; Figure 3), with a value for the closure rate similar to that observed for other chromene systems.[13] The residual absorption (ca. 19 %) in the visible region is typical for 2*H*-chromenes and is attributed to the presence of stable isomers; such isomers have been observed with other naphthopyrans.[14] These forms can be converted fully into the closed form by irradiation above 400 nm. In other words, this system has a read-out window between 350 and 380 nm, where the naphthopyran group can be switched selectively without affecting the diarylethene moiety.

Irradiation of OD-CN at 313 nm triggers both the ring-opening reaction of the naphthopyran and also the ring-closing reaction of the diarylethene, as the electronic properties of the ground states of the two photochromic moieties overlap between 300 and 350 nm, which leads initially to the formation of OD-ON and CD-CN. After irradiation for one minute the absorption is centered at 539 nm with a shoulder at 434 nm and also with absorption above 600 nm (Figure 4a). This is, however, not an equilibrium, CD-CN is bistable while OD-ON is not and reverts to OD-CN. Continuing the irradiation leads to an enrichment of CD-CN in the mixture, which is subsequently converted into CD-ON on further irradiation (path 2). The initially colorless solution turns brown, and the UV/Vis spectrum shows absorption up to 800 nm with three absorption maxima at 434, 539, and 618 nm.

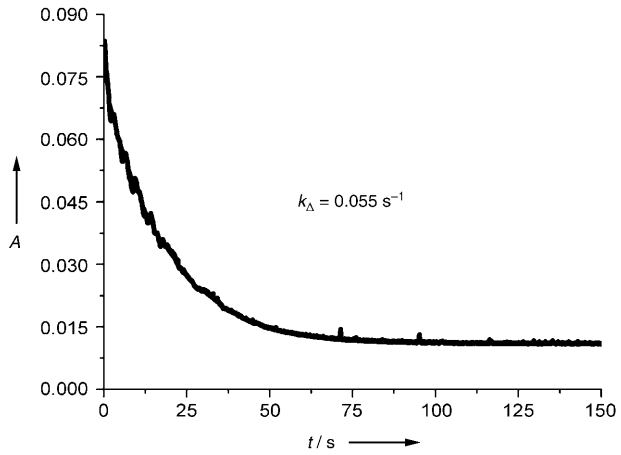

Figure 3. Thermal bleaching of OD-ON monitored at 456 nm.

When the irradiation is stopped, the open forms of the naphthopyran revert back to the closed form CD-CN (see Figure 4b) and the solution turns slowly from brown to pink (the maxima at 434 and 618 nm decrease and a new maximum at 516 nm is observed; path 3). Monitoring the kinetics of the conversion of CD-ON into CD-CN at 680 nm, where only the fully conjugated system absorbs, gives a bleaching rate constant of $1.95\times10^{-3}\ s^{-1}$ (monoexponential; Figure 4d). This comparatively high value indicates that the extension of the π conjugation in the CD-ON isomer stabilizes the open naphthopyran moiety to a large extent.[15]

Two photopathways are possible from the stationary state of CD-CN. Ring opening of the diarylethene to recover the OD-CN starting material (path 4) can be effected quantitatively from CD-CN with visible light (> 420 nm), a behavior typical of dithienylethenes. Irradiation of CD-CN (path 5) at 313 nm (OD-CN and CD-CN have a similar absorption at 313 nm; see Figure 1) induces the formation of CD-ON. The photostationary state (CD-ON) is reached faster from CD-CN than starting from OD-CN (Figure 4c).

The absorption characteristics of CD-ON are the same, regardless of whether the conversion is from OD-CN or CD-CN, which indicates that the naphthopyran group can be selectively opened and closed using UV light without affecting the diarylethene moiety.

In summary, we have investigated a hybrid biphotochromic system based on the thermally reversible naphthopyran

Micheau, G. Vermeersch, *J. Org. Chem.* **2003**, *68*, 8968; c) note: this is typical for 2*H*-chromenes and indicates, in principle, the presence of four photoproducts (CTC, TTC, TTT, and CTC). The isomers differ only in the configuration at the double bond attached to the naphthalene ring and at the position of the aryl group at the terminal double bond. The isomers CTC and TTC are thermoreversible whereas the other two are thermally stable and bleach on exposure to visible light. (TTT = *trans*,transoid, *trans*, CTT = *cis*,transoid,*trans*).
[15] Note: The thermal stability of CD-ON increased about 28 times relative to OD-ON. This result, together with monoexponential bleaching kinetics, might indicate that TT isomers, whose formation is selectively photoinduced by the extended π conjugation throughout the molecule, are formed preferentially.

Multivalent Peptide and Protein Dendrimers Using Native Chemical Ligation**

Ingrid van Baal, Hinke Malda, Silvia A. Synowsky, Joost L. J. van Dongen, Tilman M. Hackeng, Maarten Merkx, and E. W. Meijer**

Multiple, simultaneous interactions are often used in biology to enhance the affinity and specificity of binding, an effect that is known as multivalency.[1] The principle of multivalency has been recognized as an important strategy for the development of (semi)synthetic ligands with high affinity and specificity for biological targets.[1–6] Dendrimers are well-defined, hyperbranched polymers with a high density of functional groups and are therefore attractive scaffolds for multivalent display of natural ligands.[7–9] Dendrimers have been successfully applied in the design of multivalent sugar ligands,[10–12] but much less work has been reported on multivalent peptide and protein dendrimers. Solid-phase peptide synthesis has been used to construct dendritic peptide wedges by condensation of successive generations of lysine residues followed by functionalization of the α and ε amine groups with peptides.[13,14] These so-called multiple antigen peptides (MAPs) typically contain two to eight peptide chains and have been found to be more immunogenic than single

peptides. Dendrimers functionalized with cysteine-reactive chloroacetyl[15] and maleimide[16] groups have been used to conjugate cysteine-containing peptides, but this strategy cannot be applied to peptides and proteins containing functionally important native cysteine residues. Convergent synthesis of peptide dendrimers has also been reported by condensation of ketone-functionalized polyamidoamine (PAMAM) dendrimers with aminooxy-functionalized peptides, but this method is unsuitable for native proteins.[9] The few reports of protein ligation to dendrimers typically involve the coupling of a single protein (for example, an antibody) using nonspecific conjugation chemistry that results in conjugation at multiple sites on the protein. Recently, the preparation of multivalent hemoglobin dendrimers was reported that involved specific conjugation of a fourth generation PAMAM dendrimer to hemoglobin using a hemoglobin-specific cross-linking agent.[17] However, no general synthetic strategy is currently available that allows conjugation of dendrimers with both oligopeptides and recombinant proteins in a chemoselective manner.

Native chemical ligation was first reported by Dawson et al. as a unique method to ligate two unprotected peptide fragments to form a native peptide bond.[18] This chemoselective reaction occurs spontaneously between a peptide with a C-terminal thioester and a peptide with an N-terminal cysteine residue under aqueous conditions at neutral pH. Native chemical ligation has allowed the chemical synthesis of large proteins (by multistep ligation of several peptide fragments), the synthesis of proteins with synthetic moieties such as fluorescent dyes and biotin tags, and the immobilization of peptides and proteins on surfaces.[19–23] The application of native chemical ligation was recently extended to recombinantly expressed proteins by the development of expression systems based on self-cleavable intein domains that generate proteins containing N-terminal cysteine or C-terminal thioester groups.[24,25] Herein we report the application of native chemical ligation as an attractive and general synthetic strategy to conjugate both oligopeptides and recombinantly expressed proteins to dendrimers, thus resulting in multivalent peptide and protein dendrimers.

Dendrimers can either be functionalized with thioester groups or with cysteine residues to allow native chemical ligation. We chose the latter strategy because the synthesis of these cysteine dendrimers is more straightforward. Cysteine dendrimers generations 1–3 (Scheme 1)were synthesized by reaction of the amine end groups of poly(propyleneimine) dendrimers with succinimide-activated and trityl-protected cysteine residues (Scheme 1). Deprotection of the trityl-protected amine and thiol groups using trifluoroacetic acid (TFA) yielded the cysteine-functionalized dendrimers **1**–**3** in good yields. Analysis of **1**–**3** by electrospray ionization mass spectrometry (ESI-MS) showed that the cysteine residues were reduced in the presence of the mild reductant β-mercaptoethanol. Removal of the reductant and addition of

hydrogen peroxide resulted in the immediate formation of dendrimers with two, four, or eight intramolecular disulfide bonds, respectively (see Supporting Information). To assess the reactivity of the cysteine dendrimers in native chemical ligation reactions we performed ligation reactions with several peptides functionalized with an MPAL thioester at their C-terminus.[19] Ligation of **1** with four equivalents of LYRAG, a peptide previously used in studies on native chemical ligation,[19] resulted in the formation of the peptide tetramer **1**-(LYRAG)$_4$ (Figure 1 a). Analysis by liquid chromatography/mass spectrometry (LC-MS) showed that the reaction went to completion as no **1**-(LYRAG)$_{1-3}$ were detected (not shown). Ligation reactions were also performed between LYRAG and dendrimers **2** and **3** to test the efficiency of the ligation reaction for higher generations of cysteine dendrimers. Ligation of **2** with LYRAG again went to completion and yielded the peptide octamer **2**-(LYRAG)$_8$ exclusively (Figure 1 b). The MALDI-TOF spectrum obtained after ligation of **3** with LYRAG showed a signal consistent with the formation of **3**-(LYRAG)$_{16}$, but also contained signals attributable to **3**-(LYRAG)$_{12-15}$. Similar results were obtained for other oligopeptides such as GRGDSGG (Table 1). The RGD sequence present in this peptide is known to bind to various extracellular integrin receptors and can thus be used to attach dendrimers to cell surfaces.

Table 1: Overview of peptide and protein dendrimers obtained by native chemical ligation.

Dendrimer	Observed mass [Da]	Calculated average mass [Da][a]
1-(LYRAG)$_4$	3139.7	3139.8
2-(LYRAG)$_8$	6419.7	6419.9
3-(LYRAG)$_{16}$	12262[b]	12307.6
1-(GRGDSGG)$_4$	3243.2	3243.5
2-(GRGDSGG)$_8$	6627.1	6627.1
1-(GFP)$_1$	28288.6 (0.5)[c]	28291
1-(GFP)$_1$(GRGDSGG)$_3$	30172.5 (0.7)[c]	30177
1-(GFP)$_4$	110971.1 (4.7)[c]	110976

[a] Average masses were calculated assuming the complete reduction of the cysteine groups. [b] In addition to the signal of **3**-(LYRAG)$_{16}$, the MALDI-TOF spectrum showed signals consistent with **3**-(LYRAG)$_{12-15}$. [c] The number between brackets is the experimental error as determined using the program MaxEnt 1.

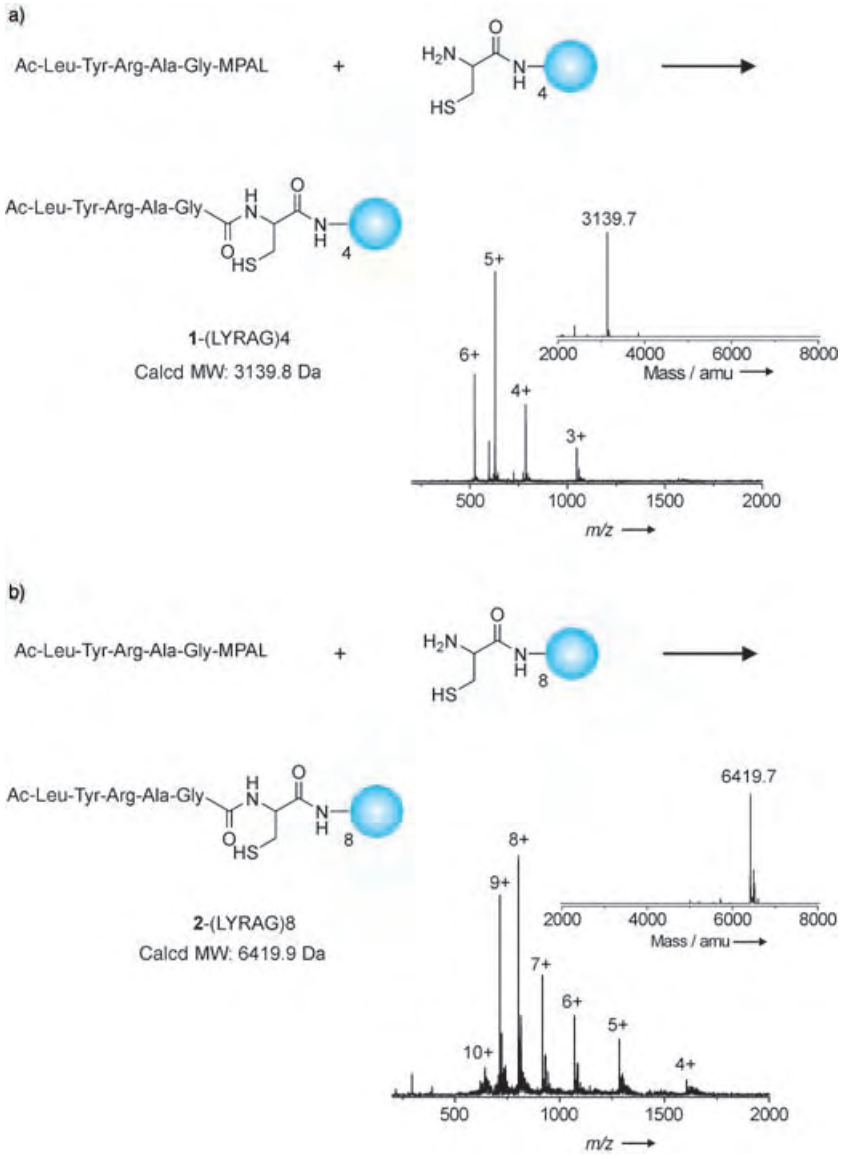

Figure 1. Native chemical ligation of the MPAL-thioester of LYRAG to first (a) and second (b) generation cysteine dendrimers **1** and **2**. Dendrimer was dissolved in 0.1 M Tris, 6 M guanidine, 2% (v/v) thiophenol, and 2% (v/v) benzyl mercaptan pH 7.0–7.5 and treated with four (**1**) or eight equivalents (**2**) of MPAL-peptide for 1 h at 37 °C. The mass spectra were obtained by ESI-MS after removal of the buffer components by RP-HPLC.

Green fluorescent protein (GFP) was chosen as a model protein to study the ligation of folded proteins to cysteine dendrimers. GFP was cloned into the IMPACT vector pTXB1 to yield an *E. coli* expression vector for a fusion protein of GFP with an intein domain and a chitin-binding domain (CBD). The cloning strategy used here meant that the GFP contained eight additional residues at the C-terminus of GFP, that is, NEFLEGSS. Overnight incubation of the GFP-intein-CBD protein bound to the chitin column with MESNA resulted in cleavage of the peptide bond to the GFP and the formation of GFP thioester. ESI-MS analysis showed the presence of a single protein signal with a mass of 27705 Da that is consistent with the MESNA thioester of GFP (theoretical mass: 27703.9 Da). The GFP thioester was first ligated to dendrimer **1** using a large excess of the dendrimer. ESI-MS of the reaction mixture after incubation for 20 h at room temperature showed the clean conversion of GFP thioester to **1**-(GFP)$_1$, with no indication of the presence of the initial GFP thioester or dendrimer with more than one GFP (Figure 2). The large difference in molecular weight between **1**-(GFP)$_1$ and **1** allowed the easy removal of excess of **1** from the ligation mixture by repeated concentration/dilution steps using a centrifugal filter with a 10-kDa molecular-weight cutoff. Subsequently, **1**-(GFP)$_1$ was treated with an

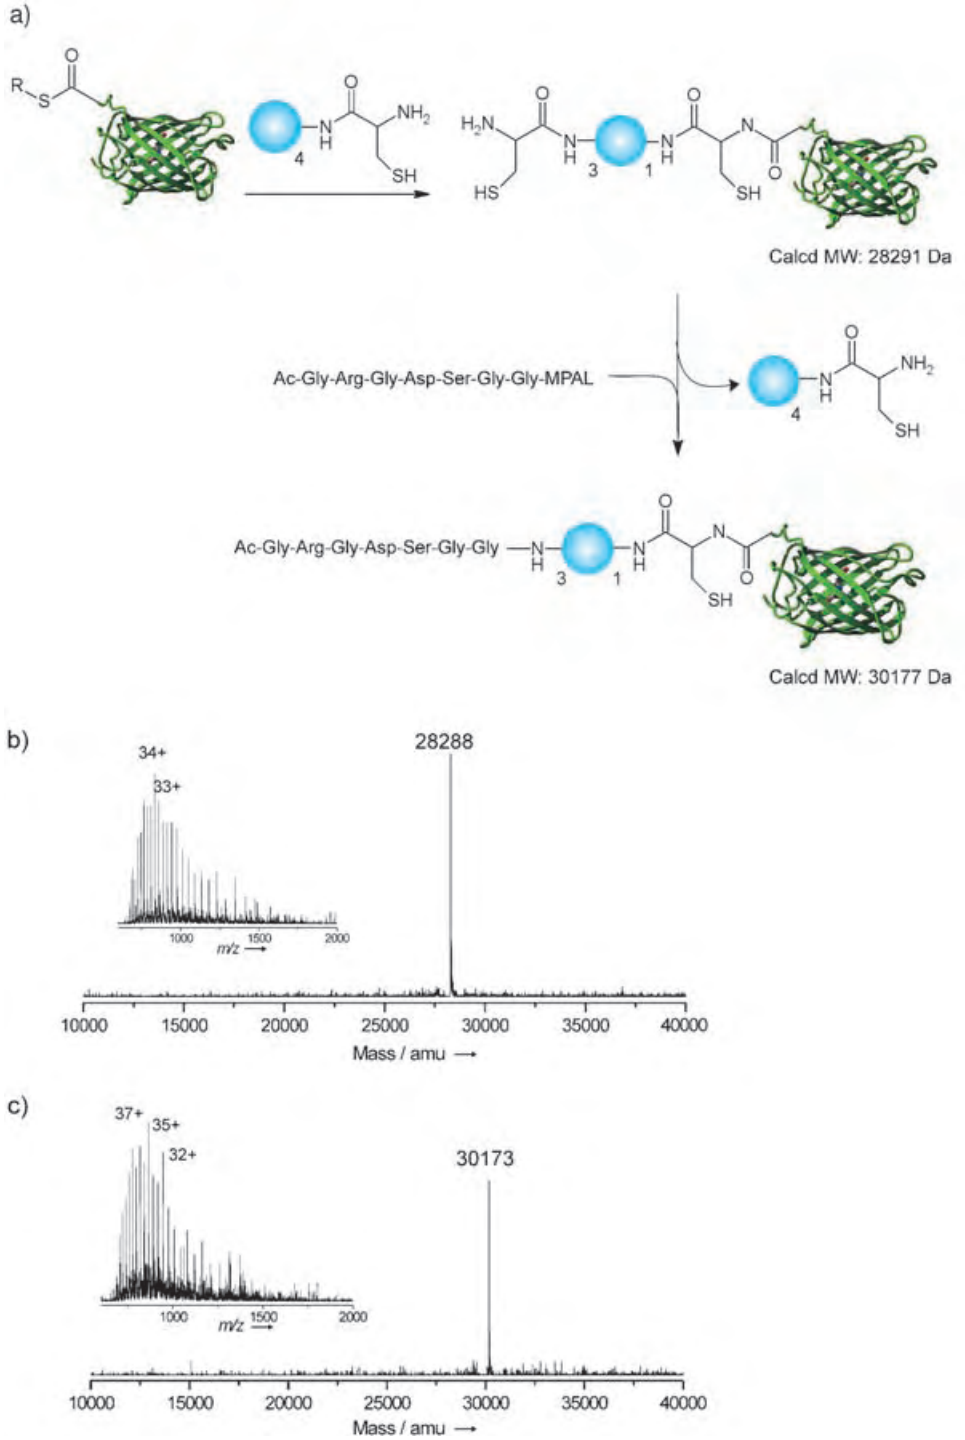

Figure 2. a) Synthesis of a dendrimer containing both protein and peptide end groups. GFP thioester (75 μM) was treated with a large excess of dendrimer **1** (2 mM) for 20 h at 20 °C to yield the monofunctionalized **1**-$(GFP)_1$ exclusively. After removal of remaining dendrimer **1**, **1**-$(GFP)_1$ was treated with excess GRGDSGG-MPAL peptide (375 μM) for 4 h at 20 °C to yield **1**-$(GFP)_1(GRGDSGG)_3$ exclusively. b) Experimental (inset) and deconvoluted ESI-MS of **1**-$(GFP)_1$. c) Experimental (inset) and deconvoluted ESI-MS of **1**-$(GFP)_1(GRGDSGG)_3$.

excess of the MPAL thioester of GRGDSGG. ESI-MS showed the presence of a single, high-molecular-weight signal at 30173 Da, which is exactly the mass expected for **1**-$(GFP)_1(GRGDSGG)_3$ assuming formation of two intramolecular disulfide bonds. This synthetic methodology should be generally applicable to prepare dendrimers with (exactly) one copy of any recombinant protein and multiple copies of any peptide or other synthetic ligand with a thioester functionality.

To test whether our synthetic strategy can be used to obtain multivalent protein dendrimers, a 25 μM solution of dendrimer **1** was incubated with four or eight equivalents of

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

GFP thioester and the ligation reaction was monitored using sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) (Figure 3a). Analysis of the reaction after 20 h showed the presence of four distinct bands at 27, 55, about 120, and about 170 kDa that we attribute, respectively, to GFP thioester and **1**-$(GFP)_1$, **1**-$(GFP)_2$, **1**-$(GFP)_3$, and **1**-$(GFP)_4$. The bands of **1**-$(GFP)_3$ and **1**-$(GFP)_4$ appear at a higher apparent molecular weight than expected, which is probably a consequence of the branched structure of these multivalent proteins. A similar effect of branching on the apparent molecular weight has been reported for ubiquitinated proteins, which are a natural form of branched proteins.[26] The limited solubility of GFP under the conditions suitable for native chemical ligation (100–200 μM GFP thioester) probably makes the ligation of GFP slower than the peptide-ligation reactions that are typically performed at 2–10 mM.[27] A second factor that may prevent the full conversion into **1**-$(GFP)_4$ is increased steric crowding that occurs when attaching four 27-kDa proteins around a 0.7-kDa dendritic core.

The ligation product was further purified using size-exclusion chromatography and analyzed using electrospray ionization time-of-flight mass spectrometry under native conditions to provide definitive evidence for the formation of the GFP tetramer (Figure 3b, c). The spectrum of the first species that elutes from the column shows a limited number of signals that can be deconvoluted to a single mass of 110971 Da. This mass corresponds almost exactly to the average mass calculated for **1**-$(GFP)_4$ with two disulfide bonds (110972 Da). The other detected ions originated from GFP, **1**-$(GFP)_1$, **1**-$(GFP)_2$, and **1**-$(GFP)_3$ and clearly reveal that size-exclusion liquid chromatography coupled to mass spectrometry under native conditions is an ideal analytical tool to separate and analyze these protein mixtures. Moreover, the high m/z values and the narrow charge distribution indicate that the proteins may still be properly folded in **1**-$(GFP)_4$.[28,29]

In summary, we have demonstrated that native chemical ligation is an attractive ligation reaction to functionalize dendrimers with both oligopeptides and recombinantly expressed proteins. Furthermore, dendrimers can be derivatized with exactly one copy of a recombinant protein, and the remaining cysteine residues can then be further functionalized with oligopeptides. Our approach allows chemoselective dendrimer conjugation to the C-terminus of a protein, which is much less likely to interfere with protein function than other less-specific protein-ligation strategies. The modular approach presented here provides access to a wide variety of well-defined multivalent peptides and proteins that are attractive both for understanding the fundamental mecha-

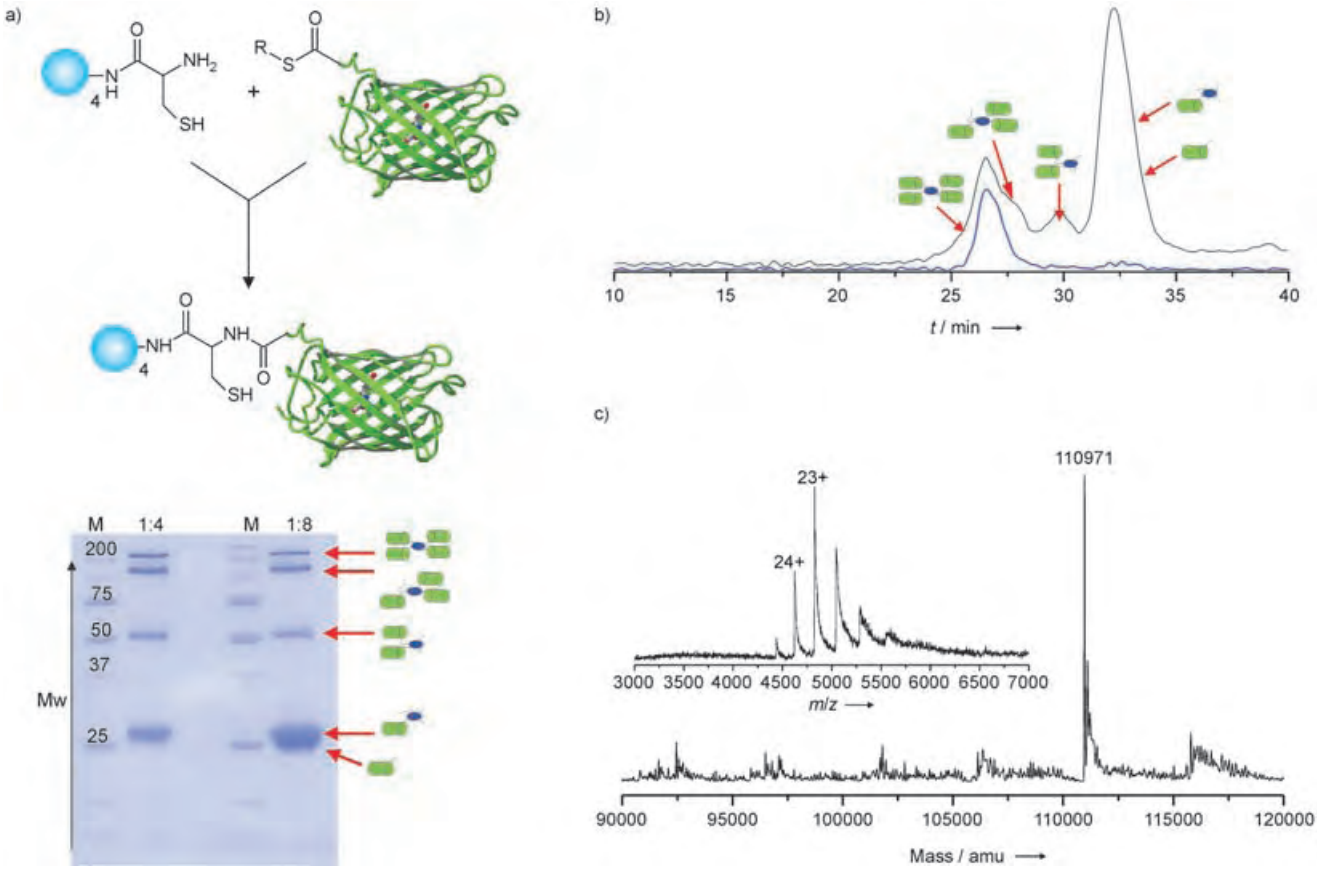

Figure 3. a) Native chemical ligation of dendrimer **1** (25 μM) with four (reaction 1) or eight equivalents (reaction 2) of GFP thioester in 0.1 M sodium phosphate, 2% (v/v) thiophenol, and 2% (v/v) benzyl mercaptan pH 7–7.5 for 20 h at 20°C. b) Size-exclusion chromatogram of the ligation reaction mixture on an analytical Superdex 200 PC 3.2/30 column showing the total ion current (black trace) and the selected ion current for **1**-$(GFP)_4$ (blue trace). c) Experimental (inset) and deconvoluted ESI-MS of **1**-$(GFP)_4$ (fraction that eluted between 25.7 and 27.6 min).

nisms of multivalency in biological interactions and for biomedical applications in targeted drug delivery, molecular imaging, and immunology.

Experimental Section

All peptide ligation experiments were performed in a buffer containing 0.1M tris(hydroxymethyl)aminomethane (tris), 6M guanidine, 2% (v/v) thiophenol, and 2% (v/v) α-toluenethiol (benzyl mercaptan) pH 7.0–7.5. One equivalent of dendrimers **1**, **2**, or **3** was treated with 4, 8, or 16 equivalents of peptide thioester (ca. 10 mg mL^{-1}), respectively, with stirring for 1 h at 37 °C. The ligation products were analyzed by LC-MS. All protein-ligation experiments were performed at 20 °C in a buffer containing 0.1M sodium phosphate, 2% (v/v) thiophenol, and 2% (v/v) benzyl mercaptan pH 7–7.5. Precipitates were removed after the reaction by centrifugation. **1**-$(GFP)_1$ was obtained by ligation of 75 μM GFP thioester with 2 mM dendrimer **1** for 20 h at 20 °C. Remaining dendrimer was removed by repeated concentration and dilution of the reaction mixture using an Amicon Ultra-4 centrifugal concentrator with a 10-kDa cut-off. **1**-$(GFP)_1(GRGDSGG)_3$ was obtained by subsequent ligation with 375 μM GRGDSGG-MPAL for 4 h at 20 °C, followed by analysis using LC-MS.

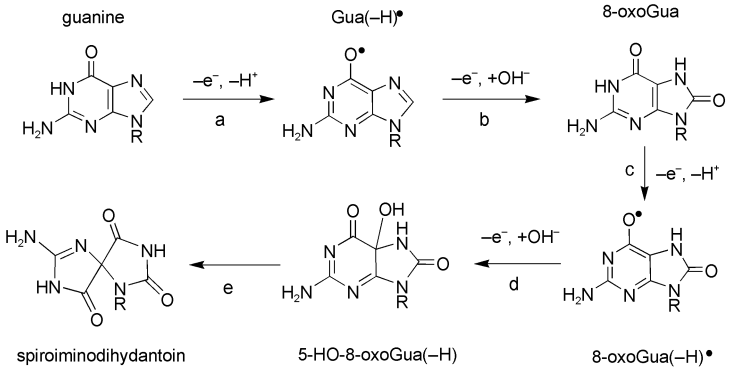
Oxidation of Guanine and 8-oxo-7,8-Dihydroguanine by Carbonate Radical Anions: Insight from Oxygen-18 Labeling Experiments**

*Conor Crean, Nicholas E. Geacintov, and Vladimir Shafirovich**



The carbonate radical anion ($CO_3^{\bullet-}$) is of significant current interest, as it plays an important oxidative role in biological systems.[1] These radical anions arise during the inflammatory response in tissues[2] by the one-electron oxidation of bicarbonate anions in the active site of copper–zinc superoxide dismutase,[3] and the reaction of peroxynitrite with carbon dioxide.[4,5] The $CO_3^{\bullet-}$ radical is a strong one-electron oxidant ($E° = 1.59$ V versus normal hydrogen electrode)[6] which gives rise to the post-translational modification of proteins[7,8] and causes oxidative DNA damage.[2] Guanine is the most susceptible base in DNA toward oxidative damage,[9] and is oxidized by $CO_3^{\bullet-}$ radicals[10,11] predominantly to oxidative end-products such as spiroiminodihydantoin (Sp) lesions,[12] which are highly mutagenic.[13,14] We have shown earlier that 8-oxo-7,8-dihydroguanine, itself the product of a two-electron oxidation of guanine, is an intermediate in the

complex series of reactions that ultimately results in the formation of Sp.[11] The generation of Sp formally requires four electron-transfer steps[12] (Scheme 1) and the transfer of oxygen atoms from either the $CO_3^{\bullet-}$ radical species or water.

Scheme 1. Formation of spiroiminodihydantoin by the consecutive abstraction of four electrons from guanine (a–d) followed by an acyl shift (e) in the 5-HO-8-oxoGua(-H) intermediate.[12]

However, the critical mechanistic aspects of the consecutive four-electron oxidation of G by $CO_3^{\bullet-}$ radicals that culminate in the formation of Sp are still obscure.

Herein, we report the use of a combination of ^{18}O labeling and mass spectrometry to address these questions with 2′,3′,5′-tri-*O*-acetylguanosine (tri-*O*-Ac-Guo) or 2′,3′,5′-tri-*O*-acetyl-8-oxo-7,8-dihydroguanosine (tri-*O*-Ac-8-oxoGuo) derivatives as standard model systems.[12,15] We show that the oxygen atoms incorporated into the Sp end-products formed by the oxidation of either tri-*O*-Ac-Guo or tri-*O*-Ac-8-oxoGuo originate from $CO_3^{\bullet-}$ radicals and not from H_2O. These observations indicate that the intermediate steps occur by the radical–radical combination of $CO_3^{\bullet-}$ with Gua(-H)• and 8-oxoGua(-H)•, and that these reactions can be formally viewed as O^--transfer mechanisms.

The $CO_3^{\bullet-}$ radicals were generated by the laser photolysis method used in our previously reported experiments.[10,11] This method involves the photodissociation of persulfate to sulfate radical anions followed by one-electron oxidation of HCO_3^- anions by $SO_4^{\bullet-}$ radicals. Solutions of tri-*O*-Ac-Guo or tri-*O*-Ac-8-oxoGuo (30 μM), $NaHCO_3$ (0.3 M), and $Na_2S_2O_8$ (0.01 M) containing ≈43% $H_2{}^{18}O$ were equilibrated in air, adjusted to pH 7.5 by NaH_2PO_4 (1 M), and excited by excimer laser pulse train ($\lambda = 308$ nm, 15 mJ pulse^{-1} cm^{-2}, 10 pulse s^{-1}) for ≈10 s. After irradiation, the $Na_2S_2O_8$ was reduced by the addition of a solution of $Na_2S_2O_4$ to quench any further potential oxidation reactions. The Sp nucleoside products, in agreement with our previous experiments,[11] were formed in high yield (40–60%). The Sp products were isolated by reversed-phase HPLC and subjected to ESI MS–MS analysis. The major signals from the Sp molecular ions $[M+H]^+$ were observed at $m/z = 442$; the two additional O atoms in Sp (relative to the parent guanine) are ^{16}O (Figure 1a and c, black traces). The presence of lower-intensity peaks at $m/z =$ 444 in these spectra suggests that some ^{18}O atoms are incorporated into Sp nucleosides. These incorporation pathways could include hydration[12,16–21] of the Gua and 8-oxoGua

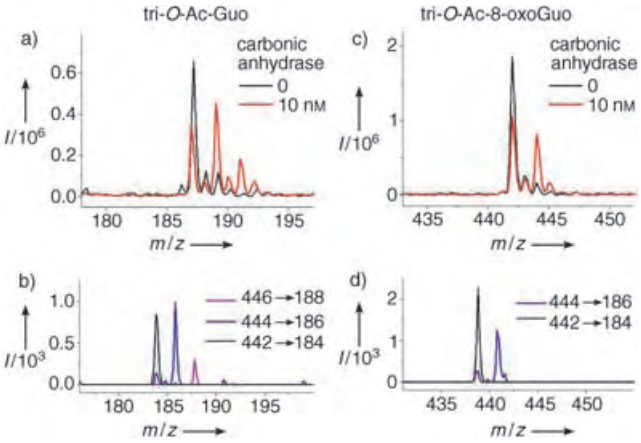

Figure 1. Positive ion spectra of the spiroiminodihydantoin nucleosides prepared by the oxidation of a) tri-*O*-Ac-Guo and c) tri-*O*-Ac-8-oxoGuo by $CO_3^{\bullet-}$ radicals in buffer solutions (pH 7.5) containing $H_2{}^{18}O$ (fraction of ^{18}O atoms $\alpha = 0.43 \pm 0.03$). The reaction mixtures contained either no carbonic anhydrase (black) or carbonic anhydrase at 10 nM to provide a complete exchange of ^{18}O between $HC^{16}O_3^-$ and $H_2{}^{18}O$ (red); Mass spectra obtained by fragmentation of the molecular ion ($[M+H]^+$) at $m/z = 442$ (black), 444 (blue), and 446 (magenta) from b) Sp nucleosides prepared by the oxidation of tri-*O*-Ac-Guo and the oxidation of d) tri-*O*-Ac-8-oxoGuo. In the presence of carbonic anhydrase, the experimentally observed fractions of isotope-labeled Sp nucleosides are 0.37 ± 0.04 for the m/z 442→184 ions, 0.46 ± 0.02 in the case of the m/z 444→186 ions, and 0.17 ± 0.03 for the m/z 446→188 ions. These fractions are close to the expected values of $(1-\alpha)^2 = 0.33 \pm 0.04$ ($^{16}O^{16}O$), $2(1-\alpha)\alpha = 0.49 \pm 0.01$ ($^{16}O^{18}O$), and $\alpha^2 = 0.19 \pm 0.03$ ($^{18}O^{18}O$) for a random transfer of two oxygen atoms from the carbonate radical anions to the Sp products.

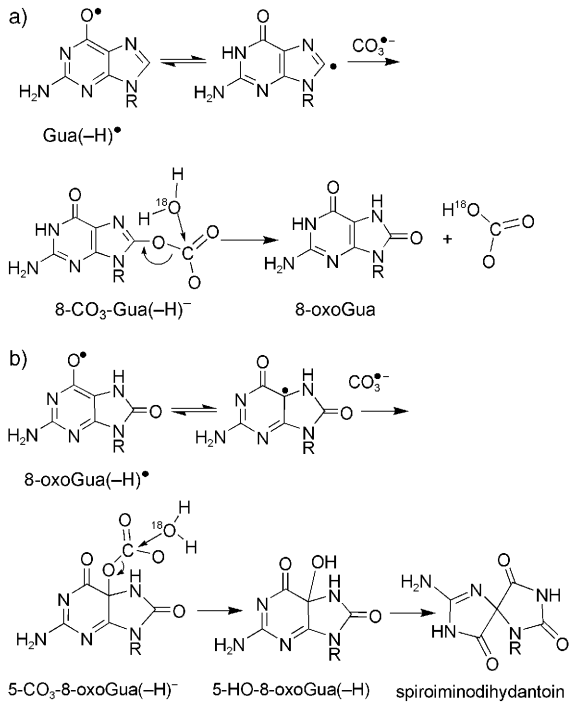
radicals or isotope exchange[22] of $HC^{16}O_3^-$ with $H_2{}^{18}O$ that occurs slowly in the absence of the carbonic anhydrase catalyst[23]. Hence, the O atoms in the Sp nucleosides could have been transferred either from molecular oxygen ($^{16}O_2$) or from $C^{16}O_3^{\bullet-}$ radicals, but not from $H_2{}^{18}O$. In contrast, generation of Sp by the oxidation of tri-*O*-Ac-8-oxoGuo by $IrCl_6^{2-}$ in $H_2{}^{18}O$ solution results in the incorporation of an ^{18}O atom from the heavy water molecules.[12] As Sp can be formed in the absence of oxygen,[11] O_2 can be ruled out as the source of the additional oxygen atoms in Sp, and the $C^{16}O_3^{\bullet-}$ radical can be concluded as the source of ^{16}O.



Normally, isotope exchange between $HC^{16}O_3^-$ and $H_2{}^{18}O$ is slow because it occurs only through the hydration of carbon dioxide in equilibrium with bicarbonate.[22] Therefore, even if the reactions are carried out in heavy water, the isotopic composition of the $CO_3^{\bullet-}$ radicals will be close to that of the parent $HC^{16}O_3^-$ anions, and Sp will contain only ^{16}O. To confirm that the source of the O atoms in Sp are transferred from the carbonate radical anions, the oxidation reactions were conducted in the presence of carbonic anhydrase (Figure 1). This enzyme catalyzes the oxygen isotope exchange between $HC^{16}O_3^-$ and $H_2{}^{18}O$[23] and thus the ^{18}O isotope content in the carbonate radical anions is expected to be the same as that of the water at equilibrium. Indeed, the MS data of the Sp samples prepared by the oxidation of tri-*O*-Ac-Guo in $H_2{}^{18}O/H_2{}^{16}O$ solutions incubated with carbonic anhydrase (≈10 nM) for ≈2 h, are characterized by molecular ions at $m/z = 442$, 444 and 446 (Figure 1a, red trace). The

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

assignment of these molecular ions as the Sp nucleosides was confirmed by monitoring the 442→184, 444→186, and 446→188 transitions (Figure 1b), which correspond to the abstraction of the sugar residues (258 au) from the $^{16}O^{16}O$-, $^{16}O^{18}O$-, and $^{18}O^{18}O$-containing Sp molecular ions.[12] Therefore, these results confirm that both O atoms in the Sp nucleoside derived from the oxidation of tri-*O*-Ac-Guo originate from the $CO_3^{\bullet-}$ radicals.

The MS data of the Sp samples prepared by the oxidation of tri-*O*-Ac-8-oxoGuo in $H_2{}^{18}O/H_2{}^{16}O$ solutions incubated with carbonic anhydrase are characterized by molecular ions at $m/z = 442$ and 444 (Figure 1c, red trace) and their fragmentation patterns at $m/z = 184$ and 186 (Figure 1d). In these spectra, the signals at $m/z = 446$ and 188 were not detected because the first O atom in the Sp nucleoside is derived from a tri-*O*-Ac-8-oxoGuo molecule, and only the second originates from $CO_3^{\bullet-}$ labeled with ^{18}O.

The results of this work suggest that the reaction mechanisms leading to Sp oxidation products involve bimolecular combinations of the $CO_3^{\bullet-}$ radicals with Gua(-H)$^{\bullet}$ or 8-oxoGua(-H)$^{\bullet}$ radicals (Scheme 2). The primary products of

Scheme 2. The O^- transfer mechanism of the combination of $CO_3^{\bullet-}$ radicals with a) Gua(-H)$^{\bullet}$ and b) 8-oxoGua(-H)$^{\bullet}$ radicals.

radical addition can be considered as monoesters of carbonic acid (H_2CO_3). The seminal works of Polanyi,[24] Ingold[25] and co-workers showed that, in the acid–base hydrolysis of esters, the ^{18}O atoms from water are transferred to the acid component and not to the alcohol product. In agreement with this mechanism of ester hydrolysis, the O atoms in Sp originate from the $CO_3^{\bullet-}$ radicals and not from H_2O (Figure 1). Therefore, the combination reactions of $CO_3^{\bullet-}$ radicals with Gua(-H)$^{\bullet}$ and 8-oxoGua(-H)$^{\bullet}$ radicals can be formally considered as a transfer of O^- from $CO_3^{\bullet-}$ to these radicals. The O^--transfer mechanism has been proposed earlier on the basis of the results of pulse radiolysis experiments for the reactions of $CO_3^{\bullet-}$ radicals with inorganic radicals $^{\bullet}NO_2$, $SO_3^{\bullet-}$, and $^{\bullet}NO$, resulting in the formation of CO_2 and the anions NO_3^-, SO_4^{2-}, and NO_2^-.[26,27] In contrast, metal complexes such as $IrCl_6^{2-}$ induce consecutive abstraction of two electrons from 8-oxoGua followed by the addition of water to the carbocation intermediate, and the O atom in the Sp residue originates from water.[12]

These results constitute the first experimental evidence that the combination of carbonate radical anions with organic radicals occurs through the transfer of oxygen atoms from $CO_3^{\bullet-}$ to the target nucleobase radicals, formally corresponding to the transfer of an O^- anion.

Fluorinated TRISPHAT Anions: Spectroscopic Probes for Detailed Asymmetric Ion Pairing Studies**

*Richard Frantz, André Pinto, Samuel Constant, Gérald Bernardinelli, and Jérôme Lacour**

Ion pairing is an important phenomenon, which strongly affects the chemistry of organic, metallo-organic, and organometallic compounds.[1] Many reactions performed with homogeneous cationic transition-metal catalysts are directly influenced by the negative counterion, as the anion plays a critical role for the reaction rate and (enantio)selectivity.[2,3] Recently, detailed structural analyses of ion pairs, experimental[4] and theoretical,[5] have shed new light on the precise nature of salt effects. Much progress has been made using NMR spectroscopy: Homonuclear $^{1}H,^{1}H$-NOESY and heteronuclear $^{1}H,^{19}F$-HOESY experiments have allowed qualitative and quantitative structural investigations on the interactions of cationic moieties and their counterions,[6] and diffusion data from pulse-field gradient spin echo (PGSE) experiments have provided useful information on the average dimensions of salt aggregates in solution.[7]

Many different cationic moieties have been analyzed. In comparison, a relatively limited number of anionic substances have been studied. Only a dozen derivatives possess both NMR-sensitive atoms in their core or periphery as well as the requisite reactivity when associated to a given cation. Typical examples are BF_4^-, BPh_4^-, $BArF^-$,[8] and PF_6^-; this collection of anions is varied enough to allow most ion pairing studies. However, many of the cationic moieties that were studied are chiral and little information regarding asymmetry has been obtained from their interactions with the above-mentioned achiral anions. Here we report on the synthesis and resolution of two novel fluorine-containing, enantiopure, hexacoordinate phosphate anions, named TRISPHAT-F3 and TRISPHAT-F4, which can be used to demonstrate the exact geometry within ion pairs of chiral cations and anions.

Recently, the chemistry of chiral hexacoordinate phosphate anions has been rejuvenated,[9] as anions such as tris(tetrachlorobenzenediolato)phosphate(v) (**1**, TRISPHAT, *Λ* or *Δ* enantiomers) have been shown to be valuable chiral NMR solvating, resolving, and asymmetry-inducing reagents.[10] Effective resolution protocols involving configurationally stable Ru^{II} complexes, in particular $[Ru(4,4'\text{-}Me_2bpy)_3]^{2+}$ (**2**, bpy = 2,2′-bipyridine), have been developed using anion **1**.[9]

Although a high level of chiral recognition was achieved with salts of **1** and **2**, the exact topography within the preferred ion pairs remained uncertain. Monitoring of the addition of enantiopure TRISPHAT salts to racemic D_3-symmetric $[Ru(LL)_3]^{2+}$ complexes by ^{1}H NMR spectroscopy has shown the following: 1) Anions *Δ*-**1** have a stronger influence on homochiral cationic moieties (*ΔΔ* versus *ΔΛ*), and 2) the protons of the cation along the C_3 axis are more strongly perturbed, indicating a preferred approach of the anion in that direction.[11] However, no such qualitative information has been gathered for the chiral anion since the chlorine atoms at the periphery of phosphate **1** are "silent" in NMR spectroscopy. The precise structural geometry within the ion pairs in solution was, overall, a mystery.

To obtain a complete and conclusive image of the situation, we decided to replace the chlorine by fluorine atoms, as these NMR-sensitive atoms are possible probes for selective approaches within the ion pairs. If one considers the D_3 symmetry of **1**, halogen atoms positioned at C3 and C6 ought to be sensitive to approaches along the C_3 axis of the anion, and those at the C4 and C5 positions to the approach of cations along the three C_2 axes (Figure 1). Selective replace-

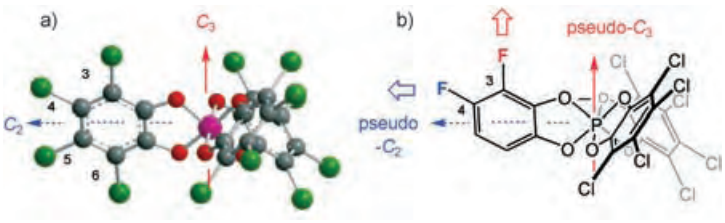

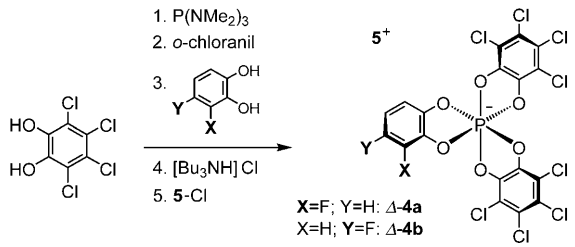

Figure 1. a) Lateral view of *Δ*-**1** and the axes of symmetry. b) Sensing of pseudo-C_3 or pseudo-C_2 approaches by selective positioning of fluorine atoms.

ment of chlorine by fluorine at the C3 and C4 positions would thus generate anions biased towards recognition along the pseudo-C_3 and pseudo-C_2 axes of the derived phosphates, respectively.

To minimize the structural modifications of TRISPHAT, only one of the three tetrachlorocatecholate ligands was exchanged by a fluorine-containing diol. 3-Fluorocatechol (**3a**) and 4-fluorocatechol (**3b**) were selected for their commercial availability. The phosphate anions **4a** and **4b**, namely TRISPHAT-F3 and TRISPHAT-F4, were prepared on a 5-g scale following reported guidelines (Scheme 1):[12]

Scheme 1. Synthesis of phosphate anions **4a** and **4b** and their subsequent resolution using **5**-Cl.

Anhydrous tetrachlorocatechol and $P(NMe_2)_3$ were allowed to react in toluene at reflux. After concentration in vacuo, successive addition in CH_2Cl_2 of *o*-chloranil (3,4,5,6-tetrachloro-3,5-cyclohexadiene-1,2-dione), **3a** or **3b**, and then $[Bu_3NH]Cl$ yielded the desired tri-*n*-butylammonium salts of racemic phosphates **4a** and **4b**. Analytically pure compounds $[Bu_3NH][$**4a**$]$ or $[Bu_3NH][$**4b**$]$ were obtained after chromatography (yield 85%, four consecutive steps).

The resolution of the anions was achieved by the addition of *N*-benzyl-cinchonidinium chloride salt (**5**-Cl, 1.0 equiv) to solutions of $[Bu_3NH][$*rac*-**4a**$]$ or $[Bu_3NH][$*rac*-**4b**$]$ in $CHCl_3$. The diastereomerically pure (−)-[**5**][*Δ*-**4a**] and (−)-[**5**][*Δ*-**4b**] salts were selectively precipitated with good yields (> 45%). X-ray structure determination with the cinchonidinium derivatives (e.g. (−)-[**5**][*Δ*-**4a**], Figure 2) showed an absolute *Δ* configuration for **4a** and **4b**.[13,14] The P–O bond lengths and O-P-O bond angles are virtually identical to those measured for TRISPHAT **1**. The nonracemic anions **4a** and **4b** displayed good chemical and configurational stability, as no evidence of a racemization could be found, for instance, during the ion-exchange metathesis of cation **5** by Bu_4N^+.

The ability of anions **4a** and **4b** to behave as effective chiral auxiliaries for cation **2** was first tested in ^{1}H NMR titration experiments. Various amounts of (−)-$[Bu_4N][$*Δ*-**4a**$]$ or (−)-$[Bu_4N][$*Δ*-**4b**$]$ (0.5–10 equiv) were added to solutions of $[$*rac*-**2**$](PF_6)_2$ in CD_2Cl_2 (see the Supporting Information). In all these experiments, a strong NMR enantiodifferentiation was observed upon addition of the anions (Figure 3a,b);

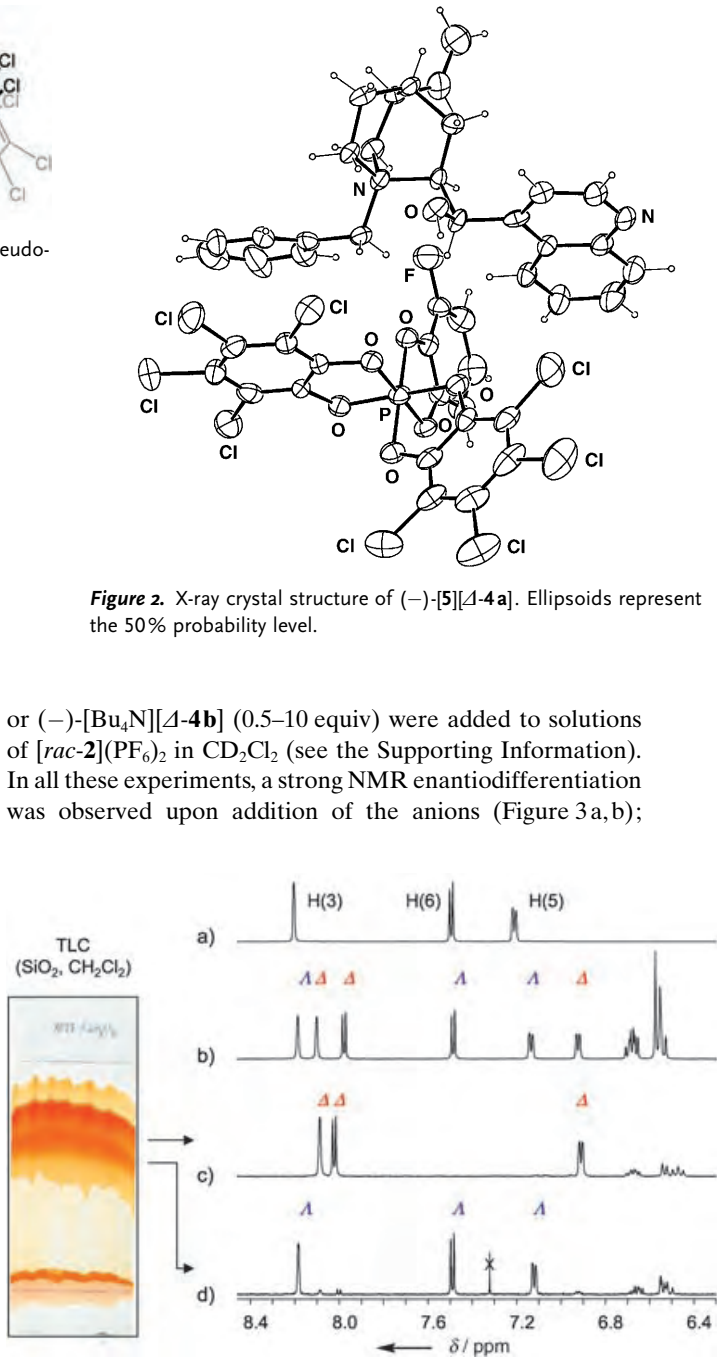

Figure 2. X-ray crystal structure of (−)-[**5**][*Δ*-**4a**]. Ellipsoids represent the 50% probability level.

Figure 3. Left: View of the TLC plate in the separation of the complexes. Right: The corresponding ^{1}H NMR spectra (400 MHz, CD_2Cl_2): a) $[$*rac*-**2**$](PF_6)_2$; b) $[$*rac*-**2**$](PF_6)_2$ + 5.0 equiv of $[Bu_4N][$*Δ*-**4a**$]$; c) [*Δ*-**2**][*Δ*-**4a**]$_2$, d.r. > 48:1; d) [*Λ*-**2**][*Δ*-**4a**]$_2$, d.r. 13.5:1. X = trace of $CHCl_3$.

TRISPHAT-F3 and TRISPHAT-F4 behaved similarly to the original anion **1**. To determine precisely 1) the nature of the preferred association, 2) the effect of the position of the fluorine atom, and 3) the exact topography within the preferred ion pairs, we decided to obtain the enantio- and diastereomerically pure salts [*Δ*-**2**][*Δ*-**4a**]$_2$, [*Λ*-**2**][*Δ*-**4a**]$_2$, [*Δ*-**2**][*Δ*-**4b**]$_2$, and [*Λ*-**2**][*Δ*-**4b**]$_2$.

Chromatographic separation of these complexes was therefore performed.[10c,15] The salts $[$*rac*-**2**$](PF_6)_2$ and [**5**][*Δ*-

4a] or [**5**][*Δ*-**4b**] (2.2 equiv) were mixed, dissolved, and adsorbed on preparative thin-layer chromatographic plates. In each case, elution with CH_2Cl_2 resulted in two well-separated bands (Figure 3, left), which were scraped off the glass surface and stirred in CH_2Cl_2. The resulting suspensions were filtered and concentrated in vacuo. ^{1}H NMR spectroscopy revealed sets of signals corresponding to the separated *Δ* and *Λ* enantiomers of cation **2** (Figure 3 c,d). The circular dichroism analysis indicated that the first and second eluted fractions contained predominantly the cationic complex with absolute *Δ* and *Λ* configurations, respectively (see the Supporting Information).[16] The diastereomeric salts [*Δ*-**2**][*Δ*-**4a**]$_2$/[*Λ*-**2**][*Δ*-**4a**]$_2$ and [*Δ*-**2**][*Δ*-**4b**]$_2$/[*Λ*-**2**][*Δ*-**4b**]$_2$ were thus obtained in decent chemical yields (30–40%, Table 1).

The NMR spectra of the homochiral and heterochiral salts [*Δ*-**2**][*Δ*-**4**]$_2$ and [*Λ*-**2**][*Δ*-**4**]$_2$, respectively, were then compared with those of the PF_6^- and *Δ*-**1** salts. The chemical shifts for the cationic protons of all these compounds are reported in Table 1. Several trends can be observed. Only the *Δ* enantiomer of **2** is strongly perturbed by the presence of the homochiral anions *Δ*-**4a** and *Δ*-**4b**; the *Λ* enantiomer shows a much smaller influence of the anions ($\Delta\delta_{max} = -0.14$ versus 0.53). In the homochiral series, protons H(6,6′) along the C_3 axis are the most efficiently split with a drift towards higher frequencies. For all other signals, upfield shifts result with a decreased influence along the C_2 axes. It had previously been shown that classical anions have preferred contacts with methyl and H(3,3′) protons of cationic 4,4′-Me_2bpy transition-metal complexes.[17] Interestingly, this is not the case with the TRISPHAT family. Anions *Δ*-**4a**, *Δ*-**4b**, and *Δ*-**1** all behave in favor of homochiral associations along the C_3 axis of the cation (Table 1, entries 3, 5, and 7).[11,18]

Nonetheless, detailed quantitative analysis revealed some nuances. Anion *Δ*-**4b** induces weaker variations of proton chemical shifts than do anions *Δ*-**1** and *Δ*-**4a** (e.g., protons H(6,6′): $\Delta\delta = 0.32$, 0.51 and 0.53, respectively). The chemical shifts of the fluorine atom of anion *Δ*-**4b** within its *Δ*-**2** and *Λ*-**2** salts are identical, whereas a difference can be noted for *Δ*-**4a**. Anion *Δ*-**4b** also displays a reduced chromatographic separation of the enantiomers of **2** as compared to *Δ*-**1** and *Δ*-**4a** ($\Delta R_f = 0.19$, 0.27, and 0.30, respectively). The lack of halogen substituent at the C3 or C6 positions of one of the

catecholate ligands apparently has a negative effect (anion **4b**). The presence of Cl or F atoms at the C4 positions cannot compensate the disappearance at C3 and C6.

The positioning of electronegative elements (Cl, F) along the C_3 axis of the anion is thus crucial for both NMR enantiodifferentiation and chiral recognition among the propellers. Only an approach of the cation along this axis can explain the results. As electronegative halogen atoms can participate in charge-assisted C–H···X hydrogen bonds,[19] one can propose that such intermolecular interactions occur upon the alignment of the C_3 axes of the homochiral complexes. The downfield shifts of the H(6,6′) protons is a good indication of the hydrogen-bonding situation with chlorine or fluorine at the C3 positions.

Final and conclusive evidence for this preferred geometry was gathered through $^{1}H,^{19}F$-HOESY NMR experiments (CD_2Cl_2) of salts [*Δ*-**2**][*Δ*-**4a**]$_2$ and [*Δ*-**2**][*Δ*-**4b**]$_2$. In both cases, strong intramolecular interactions between the protons of the anions and the neighboring fluorine atoms were observed. More importantly, selective cross-peaks showing interionic contacts could be determined, from the fluorines at the C3 and C4 positions of *Δ*-**4a** and *Δ*-**4b** towards the H(6,6′) and the methyl protons of cation *Δ*-**2**, respectively (Figure 4).[20,21] These interactions can only be rationalized through an alignment of the propeller ions along their C_3 axes.[22,23]

In conclusion, enantiopure anions **4a** and **4b** can be readily synthesized in two steps from commercially available materials. They display effective NMR discriminating abilities useful for structural determinations of asymmetric ion pairing geometries. Their application in the context of enantioselective homogeneous catalysis is currently in progress.

[20] The ^{1}H,^{19}F-HOESY measurements were carried out on a 500-MHz Bruker DRX spectrometer equipped with a QNP probe; mixing time 700 ms, sample concentration 5 mM, number of scans 96, number of increments in the F1 dimension 256.

[21] The ^{1}H,^{19}F-HOESY NMR experiment on salt [*rac*-**2**](PF$_6$)$_2$ shows cross-peaks of the achiral anions with all the protons of the coordination complex (see the Supporting Information).

[22] The DFT calculations on the preferred geometry of interaction between ions *Δ*-**1** and *Δ*-**2** clearly showed this preferred topography. I. Dance, unpublished results.

[23] Anions **4a** and **4b** also possess H nuclei on the fluorine-containing ligands, which can be equally used for detecting interionic contacts. The results of the ^{1}H,^{1}H-NOESY experiments on salts [*Δ*-**2**][*Δ*-**4a**]$_2$ and [*Δ*-**2**][*Δ*-**4b**]$_2$ are reported in the Supporting Information and confirm the data from the HOESY experiments. These experiments further show that the preferred interaction of the anion with the cation comes indeed from the face containing the fluorine substituent.

Sacrificial Biological Templates for the Formation of Nanostructured Metallic Microshells**

*Emma Kathryn Payne, Nathaniel L. Rosi, Can Xue, and Chad A. Mirkin**

One of the challenges facing chemists and materials scientists is the fabrication of metallic micro- and macroscale materials that exhibit well-defined and controllable nanometer-scale features. Such materials are generally fabricated by using either lithographic or template-mediated approaches and are potentially useful for micro- and nanoelectronics, plasmon optics, and catalysis. In particular, lithographic techniques have proven useful in the generation of surface-confined nanostructured metallic materials.[1] However, fabrication of similarly structured free-standing and isolable metallic materials has proven more difficult. To create these structures, man-made templates have been used,[2] but they generally lack the structural sophistication necessary to yield the intricate details that lithographic methods routinely provide. Microorganism templates such as viruses,[3] bacteria,[4] diatoms,[5] and fungi,[6] on the other hand, offer unique organism- and species-specific details not provided by man-made templates. In this work, diatoms, a form of unicellular algae, were used as sacrificial templates for the formation of 3D metal-coated diatoms and free-standing nanostructured metallic microshells. Herein, we describe their structures and investigate their potential as substrates for surface-enhanced Raman scattering.

Several reports have described and characterized the nanostructure of diatom cell walls (frustules) and the proteins that direct their formation.[7] Of particular interest is the observation that diatom frustules (typically 1–100 μm in size) appear to be composed of fused or aggregated silica nanoparticles[7b] arranged in a manner that imparts species-specific nanometer-scale features including pores and grooves. These unique topological properties are difficult to generate with conventional materials fabrication techniques, which renders diatoms as attractive templates for the formation of new nanostructured metallic materials having potentially interesting optical and catalytic properties.

To produce metal-coated diatom frustules, pure diatom cultures (*Synedra* spp. and *Thalassiosira* spp.), grown in either

freshwater (*Synedra*) or seawater (*Thalassiosira*) silicate-rich growth medium, were first subjected to piranha digestion to remove their organic components (Figure 1). The remaining silica frustules were washed with water and then suspended in ethanol and deposited as a non-overlapping monolayer onto a piranha-cleaned glass substrate. Ti metal (5 nm) and Ag metal (30 nm) were evaporated onto the diatom-coated substrate. Following evaporation, the resulting metal-coated diatoms were isolated by brief sonication in EtOH (Figure 1). SEM images of the 3D products reveal that the silver coating is deposited homogeneously across the diatom surfaces and maintains the morphology and intricate nanometer-scale features of the diatom templates (Figure 2).

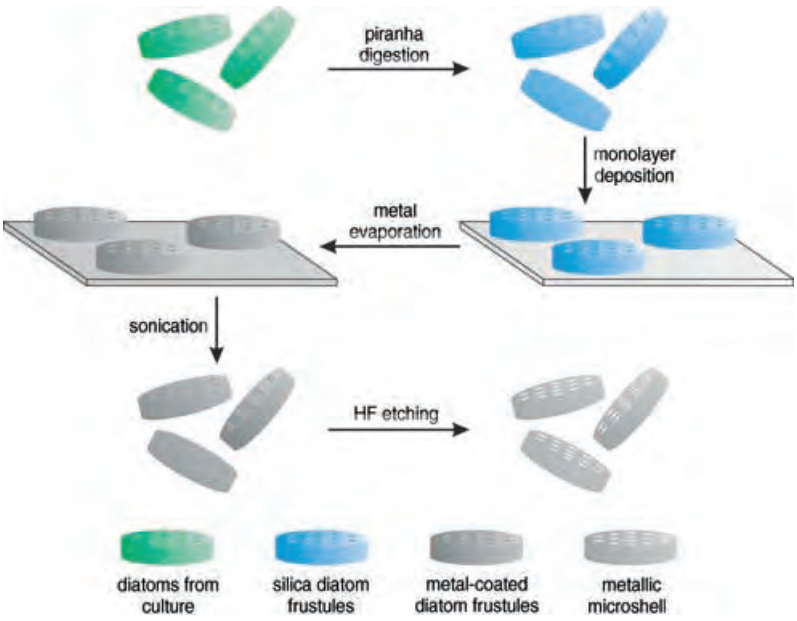

Figure 1. The preparation of metal-coated diatom frustules and the isolation of diatom-templated metallic microshells.

To isolate metallic microshell replicas of the diatoms, the metal-coated diatoms were subjected to HF (1%) etching solutions for 12–15 h which removed the silica shell and the 5-nm Ti layer (Figure 1 and Supporting Information). The resulting metallic materials (Figure 3) are structurally identical to their respective diatom templates in that they retain all of the nanostructural detail present on the diatom surfaces. Moreover, the 30-nm thick silver microshell is robust and remains intact throughout the etching process. This fabrication process is important for a number of reasons. First, thousands of structurally unique diatoms can be chosen as templates,[8] which allows one to choose particular species with topological patterns that best suit their interests. Second, the process is straightforward, high-yielding, easily reproducible, and can be performed with a variety of metals and metal compositions, depending on the desired application. Finally, the resulting 3D free-standing products exhibit nanostructural detail, including regularly patterned sub-200-nm pore sizes (Figure 3b,d). Thus, the diatoms act as sacrificial templates for the formation of 3D nanostructured metallic microshells.

Both the silver-coated diatoms and silver microshell diatom replicas (Figure 2b,d and Figure 3b,d) display pronounced sub-100-nm topological features. Similar features were not observed upon the evaporation of 30 nm Ag onto a glass microscope cover slip, showing that the fused silica particles that constitute the underlying structure of the diatom frustules are responsible for the observed roughness of the resulting metallic materials. As roughened metal surfaces and silver colloids have proven effective as surface-enhanced Raman scattering (SERS) substrates, we hypothesized that the diatom-templated metallic materials could potentially be used as substrates for the optical detection of analytes by using SERS.[9]

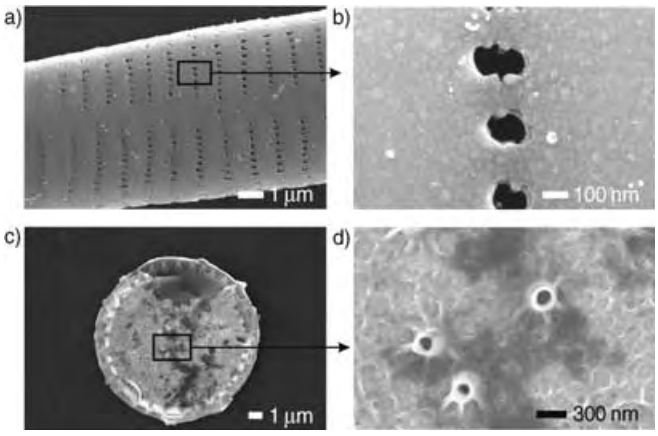

Figure 2. SEM images of the a) and b) *Synedra*, and c) and d) *Thalassiosira* frustules coated with silver (30 nm). The nanometer-scale features of the diatoms are preserved during the coating process.

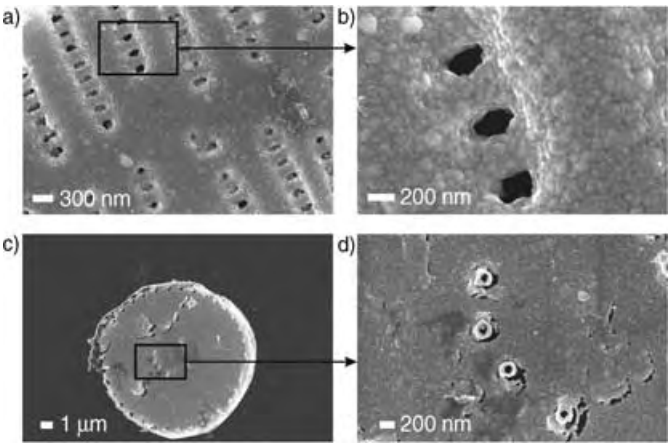

Figure 3. SEM images of silver metallic microshells after HF (1%) etching. The microshells exhibit the nanostructural detail present on the diatom templates.

As a first step in this direction, we began by investigating the SERS activity of the silver-coated diatom frustules. After soaking for four hours in aqueous solutions of rhodamine 6G (R6G) of varying concentration (1 mM, 1 μM, 100 nM), the diatom-templated materials were dispersed onto a piranha-cleaned glass slide and the dye solution was left to evaporate. SERS spectra were collected with a He/Ne laser (633 nm) excitation source with a power of 30 mW. For both *Synedra* and *Thalassiosira*, only the highest R6G concentration (1 mM) resulted in detectable SERS signal (Figure 4). Assuming

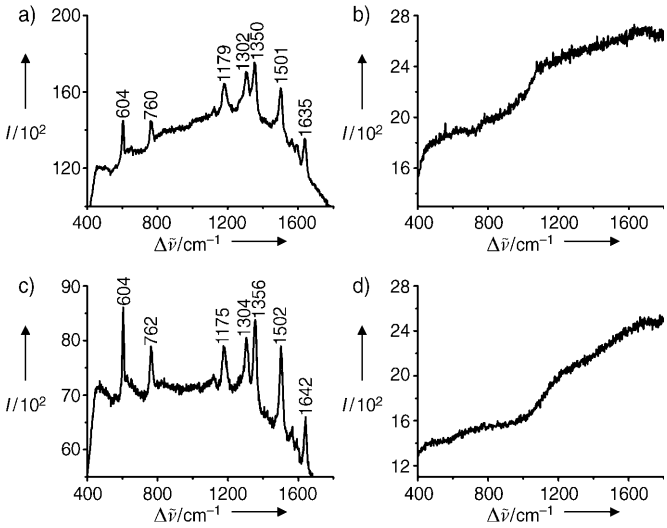

Figure 4. SERS spectra of a) 1-mM R6G and b) 1-μM R6G dye concentrations adsorbed on the silver-coated *Synedra* diatom frustules; c) and d) SERS spectra for 1-mM and 1-μM R6G, respectively, on silver-coated *Thalassiosira* frustules.

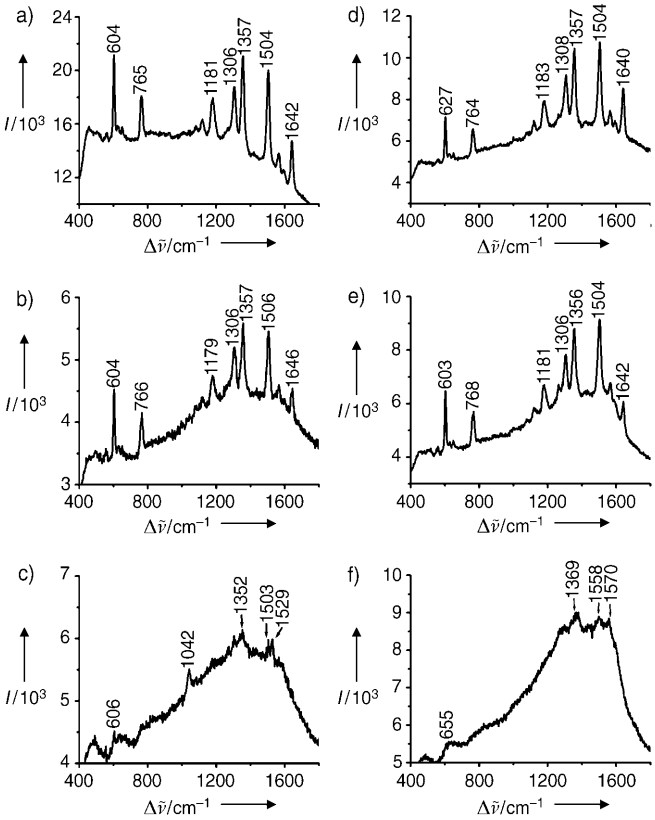

Figure 5. SERS spectra of a) 1-mM R6G, b) 1-μM R6G, and c) 100-nM R6G dye concentrations adsorbed on the silver microshell replicas of the *Synedra* frustules; d), e), and f) SERS spectra for 1-mM, 1-μM, and 100-nM R6G, respectively, on the silver microshell replicas of the *Thalassiosira* frustules.

100% coverage of the dye on the silver-coated diatom substrate, the enhancement factor was calculated to be approximately 4×10^5 for the *Synedra* and 2×10^5 for the *Thalassiosira*.[10]

The SERS signal intensity for the 1-mM solution increased dramatically in identical SERS experiments that were performed on the isolated silver microshells, and significant signal was recorded for both the 1-μM and 100-nM dye solutions (Figure 5). In this case, the enhancement factor was calculated to be 1×10^6 for the *Synedra* and 7×10^5 for *Thalassiosira*. The striking increase in SERS intensity upon template removal can be partially attributed to an increase in the exposed metal surface area onto which the Raman dye can associate, but this does not entirely explain the observed change. It is possible that HF treatment could also impact the SERS signal, as others have reported that mineral acids and anions can result in chemical enhancement of a SERS substrate.[11]

In conclusion, we report a straightforward fabrication method that employs diatoms as templates for the formation of 3D microscale metallic materials that exhibit elaborately detailed and patterned nanometer-scale features. The procedure is general and can be used with a variety of metals and any diatom species to produce a library of structurally unique materials. An important aspect of this work involves the selection of microorganism templates based on specific structural features that may benefit targeted applications. In this regard, we have shown that the nanostructured surfaces of diatom-templated metallic materials, which are inherent to the chosen diatom template, render them useful as SERS substrates.

A Pyrene-Labeled G-Quadruplex Oligonucleotide as a Fluorescent Probe for Potassium Ion Detection in Biological Applications**

*Satoru Nagatoishi, Takahiko Nojima, Bernard Juskowiak, and Shigeori Takenaka**

Alkali metal ions contribute to several physiological functions in living organisms.[1] Fluorescent indicators, particularly for Na^+ and K^+ ions, should permit the continuous or intermittent optical determination of these ions and visualization of their dynamic changes in living cells, extracellular spaces, vesicles, vascular tissue of plants and animals, biological fluids, and environmental samples.[2]

We have focused on fluorescent probes for the potassium ion, which plays a significant role as a transmitter in cells and in the regulation of membrane potential, nerve stimulation, and hormone secretion.[3] Potassium-binding benzofuran isophthalate (PBFI)[4] and coumarin diacid cryptand [2.2.2] (CD222)[5] have been recommended for the fluorimetric detection of K^+ ions in biological fluids, although these indicators show rather poor selectivity against sodium (a 1.5- and 3.4-fold excess of Na^+ ions is tolerated in each case, respectively).[4,5] Therefore, they can only be used for intracellular applications at sufficiently high K^+ concentrations. Other fluorescent probes for K^+ ions have recently been reported,[6] but only some of them are suitable for real-time monitoring applications at high Na^+ concentrations.[6c] Recently, we reported the potassium-sensing oligonucleotide (PSO)[7] as a FRET (fluorescence resonance energy transfer) probe for K^+ ions. It consists of two fluorophores (*N*,*N*,*N*′,*N*′-tetramethyl-6-carboxyrhodamine (TAMRA) and 6-carboxyfluorescein (FAM)) that are attached to the termini of a 21-mer oligonucleotide (human telomeric DNA sequence), which can form stable G-quadruplex complexes with metal cations.[8] Although PSO has been suggested to be useful for the monitoring of K^+ in an excess of Na^+ ions, its application

for real-time K^+ ion monitoring under physiological conditions was rather difficult. Two factors hampered such an application: 1) the binding constant of the potassium complex was too high, resulting in saturation of the probe at a submillimolar concentration of K^+ and 2) FRET for the PSO complex was more efficient with Na^+ than that with PSO/K^+ (apparent quenching).

Herein, we report a novel PSO probe for the facile detection of potassium in the presence of an excess of Na^+ ions, in which these disadvantages are circumvented. The idea behind this new fluorescent probe (termed PSO-py) is to exploit the pyrene excimer emission for the transduction of a cation-binding event. Unlike the FRET system, in which stacking interactions between FRET partners resulted in unwanted quenching phenomena,[7] the pyrene moieties are expected to produce efficient excimer emission when stacked by π interactions.[9] However, potassium and sodium binding preferences were carefully tuned by selection of a quadruplex-forming oligonucleotide. The 15-mer oligonucleotide with the sequence d(GGTTGGTGTGGTTGG), known as a thrombin-binding aptamer (TBA),[10] was chosen for this purpose. TBA forms a chair-type quadruplex structure upon binding to thrombin protein, and this quadruplex incorporates K^+ ions with a 1:1 stoichiometry.[11] Therefore, binding of potassium ions should organize the 5′ and 3′ termini of TBA so that the two attached pyrene moieties are arranged face-to-face (Figure 1). As a result of this spatial orientation

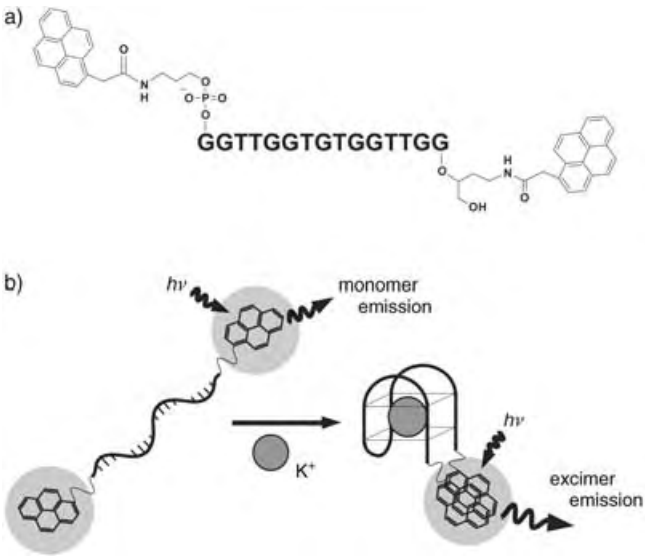

Figure 1. a) Chemical structure of PSO-py and b) the expected quadruplex formation induced by K^+ ions.

of the pyrene rings, the PSO-py/K^+ complex emits only excimer fluorescence, whereas the random-coil structure of PSO-py in the absence of K^+ ions gives only monomer emission. Consequently, PSO-py is expected to exhibit an excimer-emission intensity that depends on the K^+ concentration.[12] The presence of other metal cations is expected to cause minor interferences, as TBA forms weak complexes with Na^+, Mg^{2+}, and Ca^{2+} ions.[11c,13] PSO-py was obtained by modification of the synthetic TBA oligonucleotide termini with the appropriate derivatives of 1-pyrenylacetic acid: the phosphoramidite form for the 5′ end and the succinimidyl ester for the 3′ end. Modification and purification procedures were similar to those described by Fujimoto et al.[9d]

The suitability of PSO-py for the detection of K^+ ions was tested by fluorimetric titration with KCl (Figure 2). The

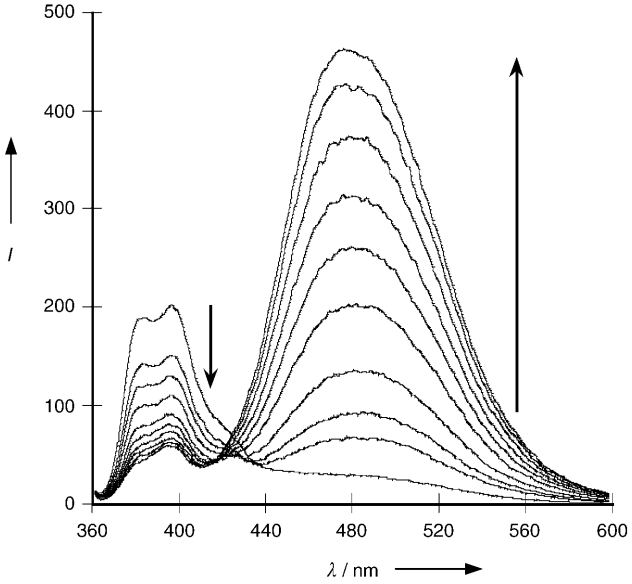

Figure 2. Fluorescence titration spectra of PSO-py (0.2 μM) with KCl (0–200 mM) in Tris·HCl solution (5 mM, pH 7.2) at 25 °C; $\lambda_{ex} = 347$ nm. Tris = tris(hydroxymethyl)aminomethane.

fluorescence spectrum of PSO-py in the absence of K^+ exhibits only a weak monomer band at 390 nm. The addition of K^+ ions results in the appearance of a new broad excimer band around 480 nm,[9] accompanied by quenching of the monomer emission. Interestingly, the weak monomer band at 390 nm lacks the vibronic structure that is probably connected with stacking interactions of the pyrene fluorophore with nucleobases.[9e,f] Notably, there is no clear isoemissive point in the system, which suggests a more complex situation than the simple two-component excimer–monomer equilibrium. Besides excimer emission, an additional fluorescence is most likely present from the excited dimer, for example. Contrary to the classic "dynamic excimer" observed in nonrestricted systems, some pyrene-bridged structures were reported to exhibit a "static excimer" or "fluorescent dimer" emission.[14] Circular dichroism (CD) recorded for PSO-py upon the addition of K^+ ions showed that the excimer fluorescence resulted from a structural change from a random coil to a chair-type quadruplex structure (the negative band near 265 nm and the positive band at 290 nm with an isoelliptic point at 280 nm).[8,13c]

Changes in the excimer fluorescence of PSO-py were also monitored in the presence of Na^+, Mg^{2+}, and Ca^{2+} ions. Excimer emission intensities were plotted against concentration of the tested ions (Figure 3). Only the potassium ion gave a positive response, but excimer emission was detectable for concentrations of Na^+ ions exceeding 100 mM. The small

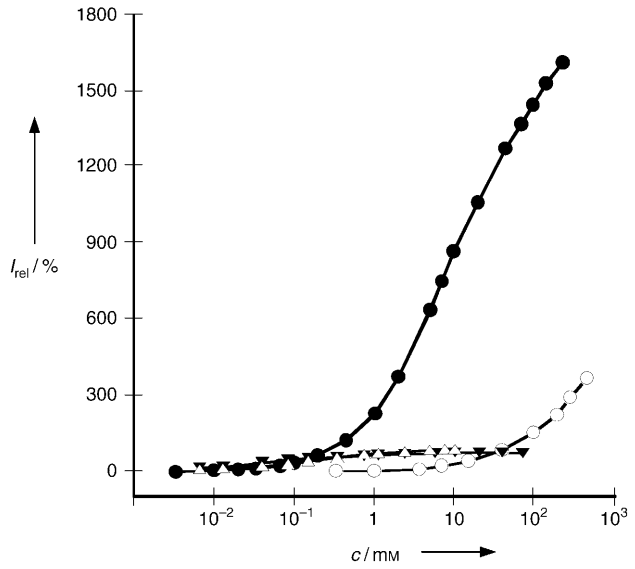

Figure 3. Plots of the relative fluorescence intensity of PSO-py (0.2 μM) against the concentration of KCl (●), NaCl (○), $CaCl_2$ (△), and $MgCl_2$ (▼).

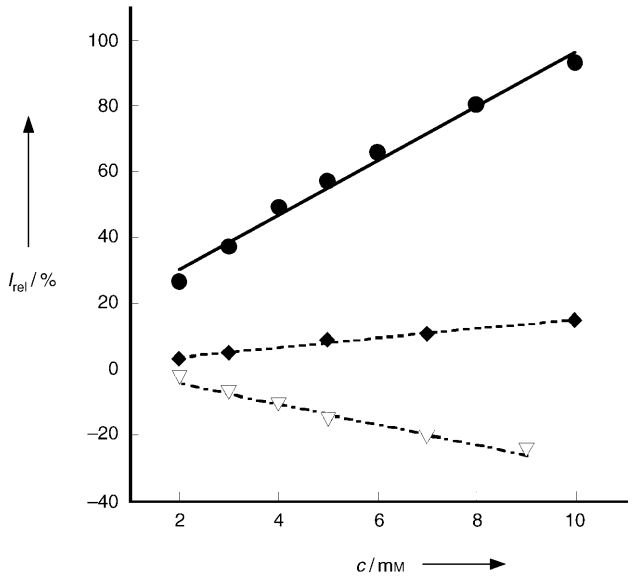

Figure 4. Comparison of the sensitivity of potassium detection for PSO-py (0.2 μM, ●), PBFI (0.2 μM, ◆), and PSO (0.2 μM, ▽) in Tris·HCl (5 mM, pH 7.2) containing 145-mM Na^+, 1.5-mM Mg^{2+}, and 2.5-mM Ca^{2+}.

changes observed in the CD spectra of PSO-py in the presence of Na^+ and Ca^{2+} ions confirmed the low binding affinity of PSO-py toward these cations. The dissociation constants (K_d) of PSO-py complexes were calculated from the plots shown in Figure 3 by fitting experimental data to an equation derived as before,[7] but for a complex with 1:1 stoichiometry. Values of 7.33 and 272 mM were determined for the K^+ and Na^+ complexes, respectively. The selectivity coefficient of 37, obtained from the ratio of sodium and potassium dissociation constants, is much higher than those for PBFI and CD222 (1.5 and 3.4, respectively).[4,5]

Real-time monitoring of the extracellular concentration of K^+ ions (2–10 mM) requires the PSO-py probe to exhibit a sufficiently high response in the presence of a complex matrix containing several ions (Na^+, Mg^{2+}, Ca^{2+}, and Cl^-) at millimolar concentrations. Therefore, the performance of PSO-py was studied by examining the K^+ calibration graph in the presence of a synthetic mixture containing 145-mM Na^+, 1.5-mM Mg^{2+}, and 2.5-mM Ca^{2+}. The increase in excimer emission of PSO-py was observed upon the addition of K^+ ions in the concentration range of 0–200 mM with linear dependence up to 10 mM K^+. The slope of the linear plot was +8.3% per 1 mM K^+, which is an excellent result given the typical physiological level of extracellular potassium. Similar calibration graphs with PBFI and PSO probes were determined for comparison (Figure 4), and these plots exhibit much lower sensitivities of +1.5 and −3.1% per 1 mM K^+, respectively. Undoubtedly, the PSO-py probe exhibits the highest sensitivity for K^+ ions relative to other probes reported so far. The dynamics of the fluorescence response and the reproducibility of excimer emission were also tested for the PSO-py/K^+ system by monitoring fluorescence changes upon subsequent alteration of the K^+ concentration between 5 and 6 mM (sequential dilution of solution and addition of concentrated KCl). The results of this experiment (Figure 5) indicate that the response time to the millimolar

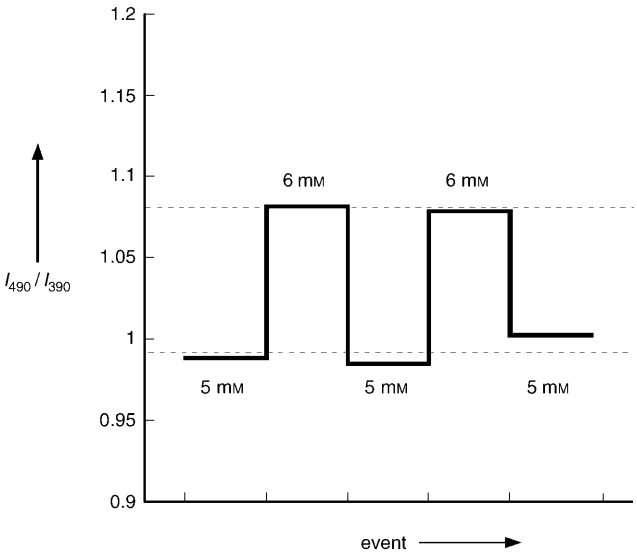

Figure 5. Fluorescence changes of PSO-py (0.2 μM) registered upon the subsequent variation of K^+ concentration between 5 and 6 mM in Tris·HCl (5 mM, pH 7.2).

variation in K^+ concentration is very short (within a few seconds), the excimer fluorescence of PSO-py/K^+ is reversible, and the probe shows reproducibility of the fluorescence signal within 5%.

In conclusion, we have designed the fluorescent probe PSO-py, which can be potentially exploited for the real-time monitoring of K^+ ions under extracellular conditions. The PSO-py ligand possesses the following advantages: 1) it binds potassium with a dissociation constant (K_d) of 7.33 mM, which perfectly matches the expected concentration range for K^+ ions and maximizes sensitivity; 2) it has sufficient discrimination against other ions, especially Na^+ (37-fold, K_d =

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

272 mM), so that variations in the physiological concentration of sodium and other ions have little effect; 3) it shows reasonably good sensitivity (ΔF of +8.3% per 1 mM K^+); 4) its excitation wavelength (>350 nm) avoids the need for expensive quartz optics (microscope) and minimizes light absorption by nucleic acids and aromatic amino acids; and 5) the long wavelength of excimer emission (>450 nm) decreases overlap with tissue autofluorescence. Further studies, including application of the PSO-py probe for K^+ monitoring in biological systems, are in progress.

[12] First, we studied the FRET system containing the TBA sequence with FAM and TAMRA at both termini. However, we did not observe any FRET signal after quadruplex formation with K^+ ions. This effect was probably caused by quenching between dyes, which were prone to direct π-stacking interactions (data not shown). Furthermore, the TBA oligonucleotide carrying FAM and TAMRA showed residual FRET in the absence of K^+ ions.

Supramolecular Stereomutation in Kinetic and Thermodynamic Self-Assembly of Helical Merocyanine Dye Nanorods**

*Andreas Lohr, Marina Lysetska, and Frank Würthner**

In memoriam Rüdiger Wortmann

Self-organization of natural nanostructures controlled by noncovalent interactions is an important topic in biophysics. In most cases, such as protein folding, biological self-assembly is considered to be a kinetically controlled process.[1] On the contrary, most self-assembled artificial systems are formed under thermodynamic control,[2] and only few kinetically controlled processes have been reported, especially for polymeric or metallosupramolecular assemblies.[3–5] Besides self-assembly another key feature of natural structures is the chirality, which is expressed at every level of organization. Hence, it is not surprising that artificial systems with molecular and supramolecular chirality have received increasing attention recently.[6,7]

We are particularly interested in the self-assembly of merocyanine dyes,[8,9] a class of chromophores that is of interest for nonlinear optical and photorefractive applications owing to their outstanding dipolar and polarizability properties.[10] In our earlier work we showed that aggregation of merocyanine dyes into centrosymmetric dimers arises predominantly from dipolar interactions with dimerization constants of $K_{dim} > 10^6\,M^{-1}$ in low-polar solvents.[8a] By utilizing this dipolar aggregation we achieved the self-assembly of the achiral bis(merocyanine) dye **1** into highly defined nanorods through supramolecular polymerization and hierarchical self-organization.[9] Forcefield calculations suggested that these nanorods are formed from six helically intertwined supramolecular single-stranded polymers. The chromophores are organized in a card-pack fashion and helically wound around the long axis of the rods; however, no direct evidence for the helicity of these supramolecular assemblies could be provided by the previously applied methods. Since achiral monomers were used, it was assumed that helices of opposite handedness were formed in equal amounts, that is, a racemic mixture was obtained. To provide evidence for the helicity, we decided to investigate the self-assembly of a chiral bis(merocyanine) derivative **2** bearing two (*R*)-2-octyl side chains at the imide positions. This should lead to the preferential formation of right-handed or left-handed helices. Indeed, pronounced supramolecular and macroscopic chirality effects were observed upon self-assembly of dye **2**, indicating a highly stereoselective self-assembly process. Moreover, a novel phenomenon was observed in the self-assembly of these dyes. Accordingly, herein we report the kinetically controlled self-assembly of merocyanine **2** into helical nanorods that exhibit a supramolecular stereomutation upon subsequent transformation into the thermodynamically stable nanorods, as elucidated by circular dichroism (CD) spectroscopy and atomic force microscopy (AFM).

1: R, R' = *n*-$C_{12}H_{25}$

2: R = *n*-$C_{12}H_{25}$, R' =

The time course of the self-assembly of **2** was studied by UV/Vis and CD spectroscopy, methods that are particularly suited to gain insight into the formation and packing properties of dye aggregates. The starting point for the self-assembly was defined by the addition of methylcyclohexane (MCH) to a stock solution of monomer **2** ($c = 3.33 \times 10^{-5}$ M) in tetrahydrofuran (THF) to provide a 1×10^{-5} M solution in THF/MCH = 30:70 vol%. In the stock solution, bis(merocyanine) **2** is present predominantly in the monomeric form owing to the high polarity of THF ($\varepsilon_r = 7.52$). Upon addition of unpolar MCH ($\varepsilon_r = 2.02$) the monomers instantaneously aggregate into supramolecular polymers and further into H-aggregated species owing to the increased Coulomb forces between the dipolar dyes. The THF/MCH ratio and, thus, the polarity of the solvent affects not only the thermodynamic equilibrium between different self-assembled species,[9b] but also the kinetic rates of the observed self-assembly processes. A 30:70 ratio of THF/MCH was established as the best-suited solvent system for the study of both the kinetic and thermodynamic processes at room temperature on convenient time scales.

Time-dependent UV/Vis spectra (Figure 1, bottom) show the transition from instantaneously formed D-aggregated species to H-aggregated species.[11] The decrease of the D band at 486 nm (assigned to the dimerized chromophores)[8a] and the increase of the hypsochromically shifted sharp H band at 444 nm with increasing time, and the occurrence of a well-defined isosbestic point at 462 nm suggest the conversion between two structurally defined species, which in the following we will refer to as **D** and **H1**, respectively. As the

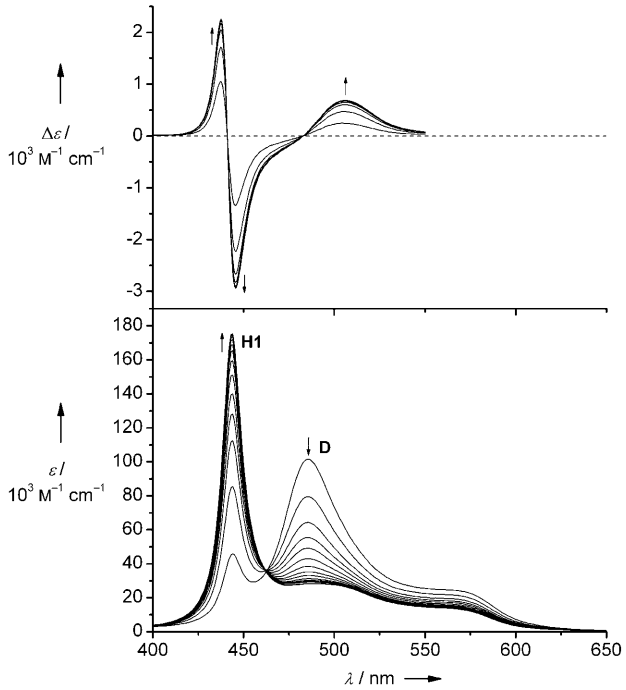

Figure 1. Time-dependent CD (top) and UV/Vis spectra (bottom) showing the transition from the D-aggregated species **D** into the kinetically formed H-aggregated species **H1** for dye **2** in a mixture of THF/MCH = 30:70 vol% at 20°C ($c = 1 \times 10^{-5}$ M). Arrows indicate changes with time (1–53 min).

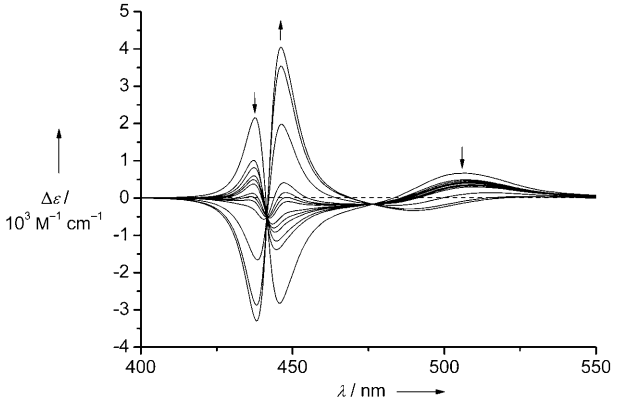

Figure 2. Time-dependent CD spectra showing the transition from the initially formed H-aggregated species **H1** into the thermodynamically more stable H-aggregated species **H2** for dye **2** in a mixture of THF/MCH = 30:70 vol% at 20°C ($c = 1 \times 10^{-5}$ M). Arrows indicate changes with time (96–7050 min).

concentration of **H1** rises, strong induced Cotton effects appear in the CD spectra (Figure 1, top), indicating chiral excitonic coupling of the chromophores in the self-assembled helical nanorods.[12] The CD spectra feature a strong negative bisignate exciton couplet located at the short wavelength absorption band of **H1**. The long wavelength shoulder at around 470 nm (negative) and the band at 506 nm (positive) may be attributed to a second bisignate CD signal with a positive sign, which originates from partly forbidden low-energy transitions of **H1**-aggregated dyes. The formation of the **H1**-aggregated species obeys first-order kinetics with a rate constant of $k = 0.42\ \text{min}^{-1}$ (Supporting Information).

To our surprise we observed a total inversion of this CD spectrum (Figure 2) as the time course of self-assembly progressed, while the UV/Vis spectra remained almost unchanged (Supporting Information). Since the formation of the initial **H1** aggregate is fast and the subsequent inversion is very slow, both processes can be studied independently with good approximation. Two well-defined isodichroic points at 441 nm and 476 nm reveal a transition between **H1** and another H-aggregated species with opposite exciton chirality, which in the following we denote as **H2**.

The UV/Vis and CD spectroscopic data of species **D**, **H1**, and **H2** are summarized in Table 1. The observed spectral changes can be explained in terms of kinetically and thermodynamically controlled self-assembly into two H-aggregated species **H1** and **H2** with opposite exciton chirality.[3a,b] First, the species **H1** is formed in a rapid process by kinetic self-assembly. Subsequently, **H1** is transformed in a much more slower process into the thermodynamic self-assembly product **H2**. It is remarkable that at higher MCH contents (i.e. lower solvent permittivity) this process becomes such slow that the kinetic product (species **H1**) can be trapped for weeks. On the other hand, the self-assembly processes are strongly accelerated at higher temperature.

To gain more insight into the **D**→**H1**→**H2** self-assembly process, we carried out atomic force microscopy (AFM) investigations. Figure 3 illustrates tapping mode AFM images of samples prepared by spin-coating of solutions of monomer **2** ($c = 1 \times 10^{-5}$ M, THF/MCH = 30:70 vol%) onto highly ordered pyrolytic graphite (HOPG) at different time intervals after initiation of the self-assembly process (i.e. addition of MCH into the stock solution in THF). After 1 min (Figure 3a) the height image shows wide disordered "grainy" regions that can be assigned to less structured supramolecular

Table 1: UV/Vis and CD spectroscopic data of species **D**, **H1**, and **H2**, and structural data determined by AFM in tapping mode.

Species	UV/Vis λ [nm]		CD λ [nm] (Δε [M⁻¹cm⁻¹])					AFM[a]

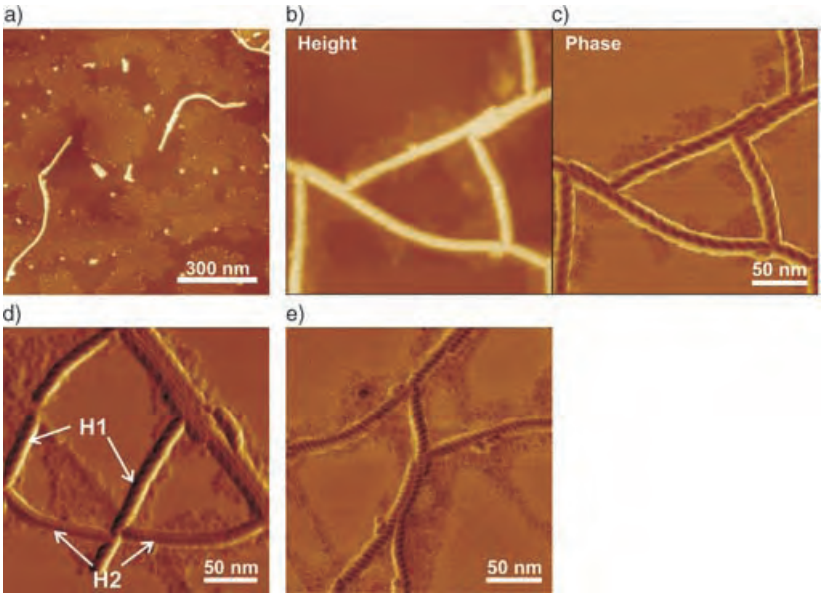

Figure 3. AFM height (a, b) and phase (c–e) images of samples prepared by spin-coating of solutions of bis(merocyanine) dye **2** ($c = 1 \times 10^{-5}$ M, THF/MCH = 30:70 vol%, 20 °C) onto HOPG at different times after initiation of self-assembly: a) 1 min; b,c) 14 min; d) 11 h; e) 22 h. In a and b the *z* scale is 10 nm and in c–e the *z* scale is 30°.

polymers (**D** species), and some short **H1** rods in the initial stage of their formation. After 14 min, when the bisignate CD signal has reached its maximum negative amplitude, the disordered regions have mostly disappeared and much longer **H1** rods are formed. Figure 3b and Figure 3c show the height and the corresponding phase image of the **H1** rods after 14 min in higher resolution. A pronounced right-handed helical (*P*) structure with a pitch of 10.4 ± 0.6 nm can be observed in the phase image (Figure 3c). The **H1** rods have a height of 3.34 ± 0.40 nm. After 11 h the coexistence of the **H2** species is evident (Figure 3d and Supporting Information). The **H2** rods have also right-handed helicity, but now with a helical pitch of only 4.9 ± 0.6 nm, and a height of 3.16 ± 0.25 nm (see Table 1). Subsequently, after 22 h merely the **H2** rods can be observed (Figure 3e). In contrast to the phase images, the corresponding height images do not show the helical morphology, which suggests that regions of different "hardness" render the helical contrast in the phase images. Artefacts caused by sample preparation or measurements can surely be excluded as rods assembled out of the enantiomeric (*S*,*S*)-monomers show opposite left-handed helicity (not shown).

A structural model for the spatial arrangement of the chromophores in the **H1** and **H2** rods is proposed in Figure 4. During the conversion process from **H1** into **H2**, the chromophores are rearranged only slightly as both species are very similar nanorods that contain the chromophores in helically wound stacks (CD, AFM). On the basis of the rod diameter (height values of AFM), a more compact structure is assigned to the thermodynamic **H2** assembly. The induced Cotton effects can be attributed to the H-type interaction of tightly stacked dyes in a slightly twisted antiparallel arrangement. Similar (−/+/−)-shaped CD spectra were observed for natural chlorin dye and artificial cyanine dye J-aggregates and theoretical calculations have revealed that such a spectral shape is a common feature of helical cylindrical dye aggregates.[7h,13] Although we would like to point out that the current model is only preliminary in the absence of theoretical calculations, the CD data strongly suggest a $M \rightarrow P$ change of the helical twist between the closest neighboring chromophores in the helically wound stacks at the **H1**→**H2** transition (Figure 4). Furthermore, our model accounts for the preservation of the right-handed (*P*) macroscopic helical twist in both dye stacks, which is more pronounced in **H2** than in **H1**. This could explain the right-handed helicity of both **H2** and **H1** rods and the smaller helical pitch of **H2** compared to **H1** as observed by AFM. The antiparallel stacking of these dye dipoles with a next closest and a second more distant neighboring dye unit has been established by several crystal structures of dipolar merocyanine dyes.[8a]

To summarize, this work confirms unequivocally the helical nature of self-assembled bis(merocyanine) nanorods and discloses a rare example of a supramolecular stereomutation as visualized spectroscopically by time-dependent CD spectroscopy and, to the best of our knowledge, for the first time microscopically by atomic force microscopy. Our studies reveal a complex transition from an initial kinetic self-assembly into a more stable thermodynamic structure, which is almost undetectable by conventional methods such as UV/Vis spectroscopy. Further investigations on other features of these chiral

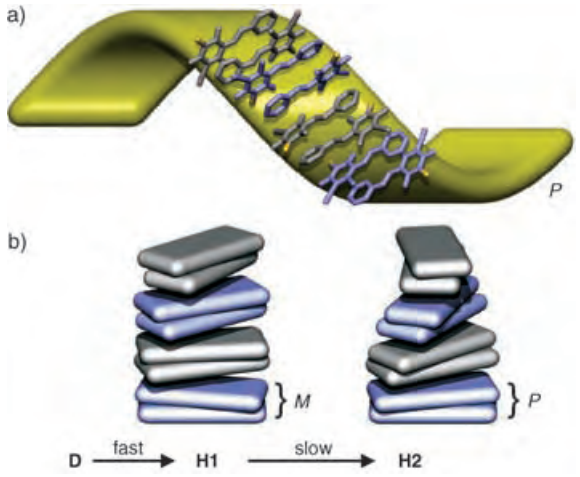

Figure 4. a) Model for right-handed (*P*) helically wound arrangement of the stacked chromophores in the rod aggregates. For the sake of clarity only a section of eight chromophores is shown. For more information on our model see reference [9b]. b) Schematic illustration of the left- to right-handed ($M \rightarrow P$) rearrangement between closest neighboring dyes during the **H1**→**H2** transition. The overall helical twist remains right-handed (*P*) for both **H1** and **H2**, but is more pronounced for **H2** than for **H1**.

merocyanine dye aggregates, for example the "sergeant-and-soldiers" principle and self-assembly behavior of (*R*,*R*)-**2**/(*S*,*S*)-**2** mixtures are underway. Furthermore, such densely packed homochiral assemblies of highly polarizable merocyanine dyes might exhibit pronounced $\chi^{(2)}$ nonlinear optical properties even without electric-field-induced symmetry breaking.[14]

Shape-Persistent Chiral Alleno-Acetylenic Macrocycles and Cyclophanes by Acetylenic Scaffolding with 1,3-Diethynylallenes**

Severin Odermatt, J. Lorenzo Alonso-Gómez, Paul Seiler, M. Magdalena Cid, and François Diederich**

The chemistry of chiral allenes has attracted increasing interest in recent years due to the development of improved syntheses and their emerging use in pharmaceuticals.[1] While strained small-ring allenes have been investigated in greater detail for their theoretical properties and their limits of

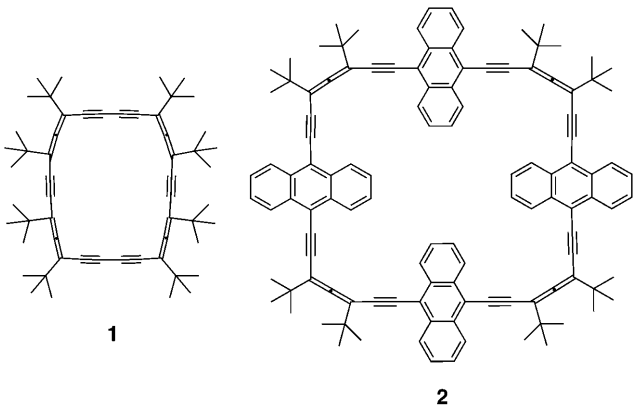
stability and isolability,[2] macrocyclic allenes, in particular shape-persistent ones,[3] are nearly unknown.[4] The only such macrocycle known is a [3$_4$]cyclophane, reported by Krause and co-workers,[5] in which four *para*-phenylene moieties are bridged by four 1,3-dimethylallene-1,3-diyl linkers and which was isolated as a mixture of several stereoisomers. This absence of allenic macrocycles is rather surprising in view of the opportunities for creating new nonplanar, chiral topologies and for developing new chiral host molecules.

The recently described synthesis of the first stable 1,3-diethynylallenes[6] now opens up the way for acetylenic scaffolding, and here we report the preparation of the new chiral, unsaturated macrocycles **1** and **2** (Figure 1). Compound **1** is the first alleno-acetylenic macrocycle without aromatic rings in the backbone. It exists as seven stereoisomers, two pairs of enantiomers and three achiral diastereoisomers, which could be isolated as pure compounds. For one of the enantiomeric pairs, the relative configuration could be assigned unambiguously. Cyclophane **2** was prepared as a mixture of six stereoisomers, two pairs of enantiomers and two achiral diastereoisomers; remarkably, both racemates and the two achiral isomers could all be isolated and their relative configurations assigned.



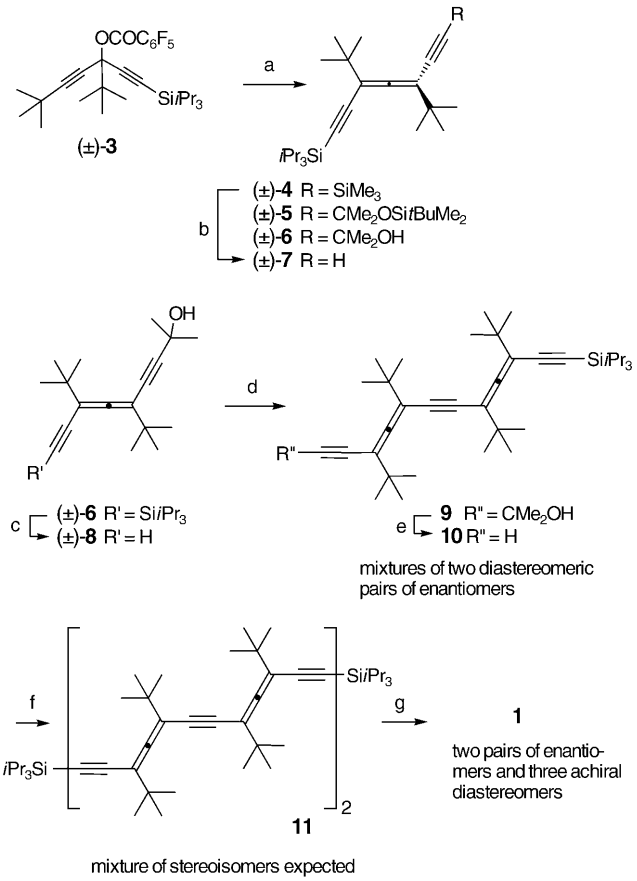


Figure 1. Two pairs of enantiomers and three achiral diastereoisomers are expected for macrocycle **1**; two pairs of enantiomers and two achiral diastereoisomer are expected for cyclophane **2**.

The synthesis of allenes (±)-**4** through (±)-**6** (Scheme 1) by Pd-catalyzed cross-coupling of ester (±)-**3** with the corresponding alkynes followed the previously described protocol;[6] however, a considerable improvement in reaction yields was obtained by using pentafluorobenzoate as the leaving group.[7] Removal of the silyl groups from (±)-**4** and (±)-**6** afforded the free terminal alkynes (±)-**7** and (±)-**8**, respectively. A second cross-coupling of (±)-**3** with (±)-**8** provided diallene **9** in 71% yield as a mixture of two diastereoisomeric pairs of enantiomers as evident from the ^{13}C NMR spectrum (125 MHz, C_6D_6). All attempts to separate the two diastereoisomeric pairs by HPLC failed.[8] The acetonide protecting group in **9** was removed with KOH in hot benzene to give the free alkyne **10**. Subsequent oxidative homocoupling under Hay conditions[17] yielded tetraallene **11** in high yield (91%). The formation of different stereoisomers

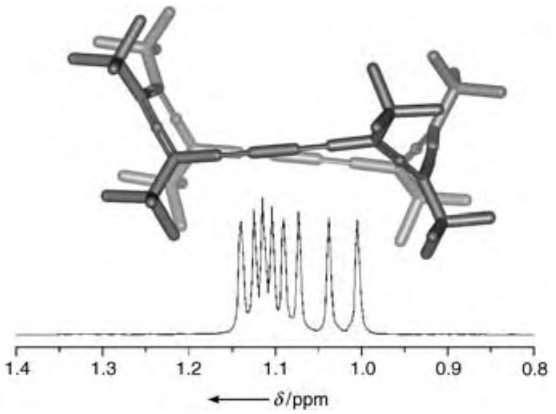
Scheme 1. Synthesis of the allene–alkyne macrocycle **1**. Reagents and conditions: a) R-C≡CH, [Pd(PPh$_3$)$_4$], CuI, *i*Pr$_2$NEt, (CH$_2$Cl)$_2$, 50°C; 74% ((±)-**4**), 53% ((±)-**5**), 69% ((±)-**6**); b) K$_2$CO$_3$, MeOH/THF, 20°C; 90%; c) *n*Bu$_4$NF, THF, 0°C; 67%; d) (±)-**3**, [Pd(PPh$_3$)$_4$], CuI, (CH$_2$Cl)$_2$, Cy$_2$NMe, 60°C; 71%; e) KOH, C$_6$H$_6$, 80°C; 65%; f) CuCl, TMEDA, (CH$_2$Cl)$_2$, 50°C; 91%; g) 1. *n*Bu$_4$NF, *ortho*-nitrophenol, THF, 20°C; 2. CuCl, CuCl$_2$, pyridine, [**11**] ≈ 10^{-4} M; 80% total yield of seven stereoisomers. Cy = cyclohexyl, TMEDA = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine.

was expected, but the spectroscopic data did not give precise information on the composition of the mixture and HPLC analyses showed mainly one peak. Deprotection of **11** with *n*Bu$_4$NF in THF in the presence of *ortho*-nitrophenol provided the crude free terminal bis(alkyne) which, after a filtration through SiO$_2$, was subjected directly to the final ring closure under high dilution (10^{-4} M). The Eglinton–Galbraith conditions[9] proved to be the most effective, providing a total yield of 80% of the macrocyclic tetraallene **1**: higher molecular weight products were not detected by analytical gel permeation chromatography (GPC) after filtration through SiO$_2$ (for experimental details see the Supporting Information).

The individual detection of the expected stereoisomers (two racemates and three achiral diastereoisomers) was possible by analytical HPLC on SiO$_2$ (see the Supporting Information).[10] The increased rigidity of the formed macrocycles **1**, compared to the flexible acyclic precursors **11**, most likely had beneficial effects on the separation. Preparative separation was hampered by the highly apolar nature and the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

reduced solubility (despite the *tert*-butyl groups) of the compounds. The five stereoisomeric products were finally isolated with the aid of two different preparative HPLC separations on "Buckyclutcher 1" and Kromasil columns.[11] The detected ratio of the stereoisomers roughly corresponded to the values of 1:1:4:1:1 expected for an unselective ring closure. The formation of racemic, C_1-symmetric (*M*,*P*,*P*,*P*)/(*P*,*M*,*M*,*M*)-**1** (Figure 2)[12] is statistically favored over the formation of the other isomers.



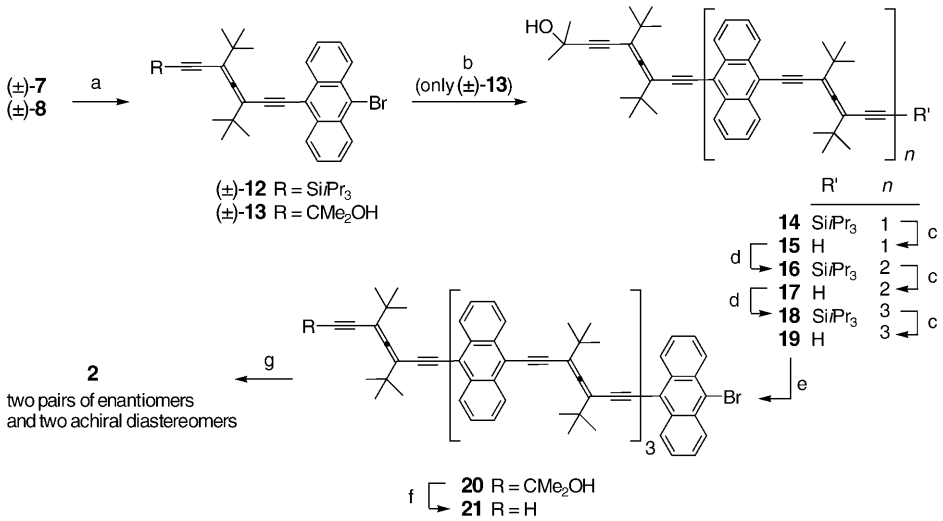


Figure 2. Tube model and ^{1}H NMR spectrum (300 MHz, $C_6D_5CD_3$) of twisted, C_1-symmetric (*M*,*P*,*P*,*P*)/(*P*,*M*,*M*,*M*)-**1**. The conformation of the (*M*,*P*,*P*,*P*) isomer was optimized by AM1 calculations using Spartan Pro.[12]

The assigned relative configuration of (*M*,*P*,*P*,*P*)/(*P*,*M*,*M*,*M*)-**1** was clearly proven spectroscopically. In the ^{1}H NMR spectrum in deuterated benzene or toluene, all eight expected resonances of the eight nonequivalent *tert*-butyl groups were clearly separated (Figure 2). Furthermore, the ^{13}C NMR spectrum showed four signals for the four nonequivalent cumulenic C atoms of the four allene moieties. The relative configuration of the other isolated stereoisomers could not be assigned based on symmetry considerations. For the second racemate, D_2-symmetric (*M*,*M*,*M*,*M*)/(*P*,*P*,*P*,*P*)-**1**, and the three achiral isomers, C_{2h}-symmetric (*M*,*M*,*P*,*P*)-**1** and (*M*,*P*,*P*,*M*)-**1**, and C_{2v}-symmetric (*M*,*P*,*M*,*P*)-**1**, two magnetically different *tert*-butyl groups and one signal for the central C atom of the four allene moieties was expected and observed in the ^{13}C NMR spectra (see the Supporting Information).

The synthesis of anthracenophane **2** started with the Sonogashira cross-coupling[13] of (±)-**7** and (±)-**8** with 9,10-dibromoanthracene to give (±)-**12** and (±)-**13**, respectively (Scheme 2). A series of four Sonogashira cross-couplings alternating with three deprotection steps afforded, after acetonide cleavage, the linear tetraallene , the precursor to cyclophane **2**, as a mixture of stereoisomers (15% overall yield starting from (±)-**13**), which were not separated. Macrocyclization with one equivalent of [Pd(PPh$_3$)$_4$] and CuI provided **2** in 60% yield as a mixture of two racemates and two achiral diastereoisomers, which were separated by preparative HPLC ("Buckyclutcher 1"; for experimental details see the Supporting Information).[11]

In the case of cyclophane **2**, the relative configuration of all the stereoisomers could be assigned. Thanks to its symmetry the major product was identified by ^{1}H NMR spectroscopy (300 MHz, $CDCl_3$) as C_2-symmetric (*M*,*P*,*P*,*P*)/(*P*,*M*,*M*,*M*)-**2** with four magnetically different *tert*-butyl groups (Figure 3a). On the other hand, the spectrum of the achiral C_{2h}-symmetric (*M*,*M*,*P*,*P*)-**2** features only two different *tert*-butyl resonances (Figure 3b). The ^{1}H NMR spectra of the other two products display only one *tert*-butyl signal as expected as a result of their higher symmetry (D_4 and D_{2d}, respectively). Fortunately, the structure of D_4-symmetric (*P*,*P*,*P*,*P*)/(*M*,*M*,*M*,*M*)-**2** could be assigned unambiguously by an X-ray crystal structure analysis of moderate resolution (Figure 3c; for further details of the crystal structure see the

Scheme 2. Synthesis of anthracenophane **2**. Reagents and conditions: a) 9,10-dibromoanthracene, [PdCl$_2$(PPh$_3$)$_2$], CuI, TMEDA, toluene, 110°C; 56% ((±)-**12**), 73% ((±)-**13**); b) (±)-**7**, [PdCl$_2$(PPh$_3$)$_2$], CuI, TMEDA, toluene, 110°C; 83%; c) *n*Bu$_4$NF, THF, 20°C; 95% (**15**); 96% (**17**); 86% (**19**); d) (±)-**12**, [PdCl$_2$(PPh$_3$)$_2$], CuI, TMEDA, toluene, 110°C; 63% (**16**); 65% (**18**); e) 9,10-dibromoanthracene, [PdCl$_2$(PPh$_3$)$_2$], CuI, TMEDA, toluene, 110°C; 64%; f) NaOH, C_6H_6, 90°C, 85%; g) [Pd(PPh$_3$)$_4$], CuI, *i*Pr$_2$NEt, toluene, 110°C, 2 h, then air, CH_2Cl_2, 20°C, 24 h; 60%.

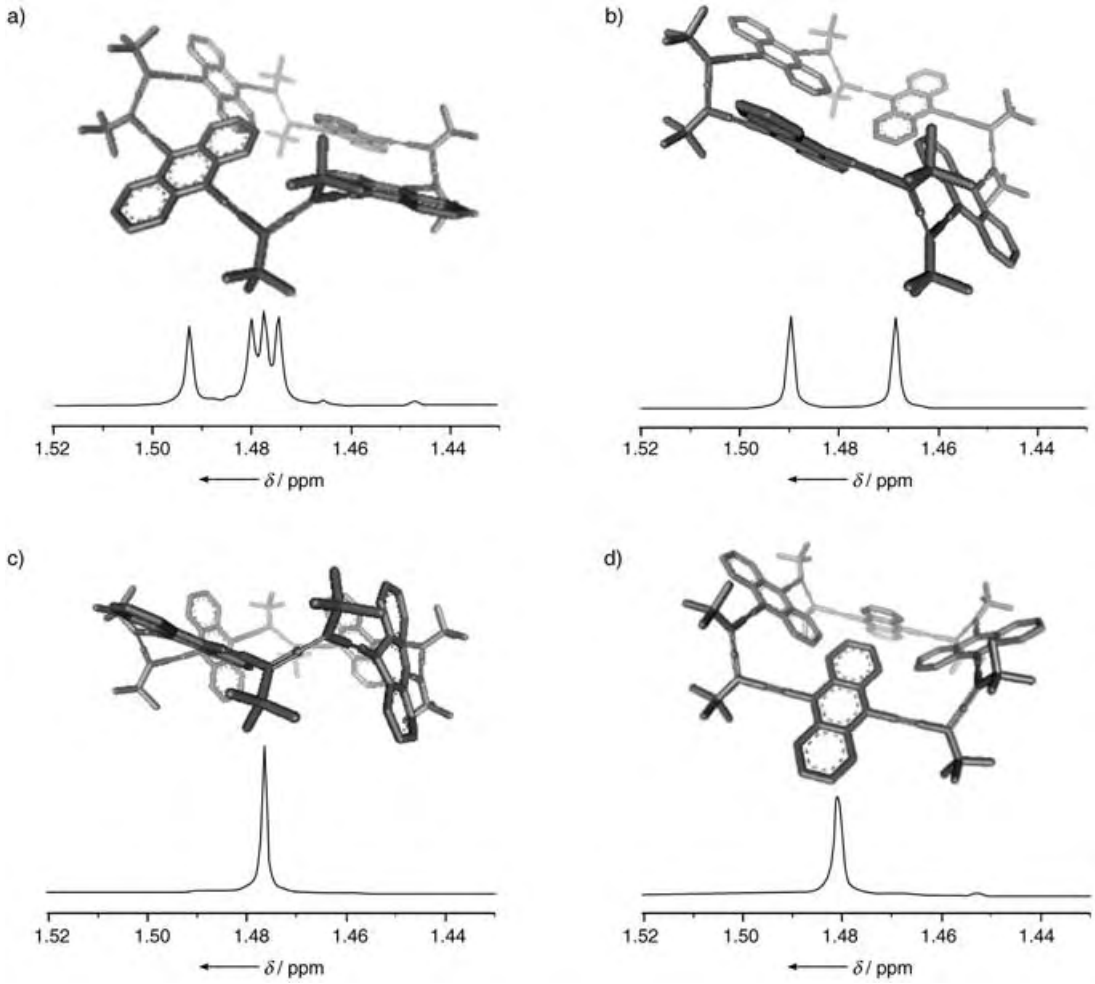

Figure 3. Tube models and ^{1}H NMR spectra of a) C_2-symmetric (*M*,*P*,*P*,*P*)/(*P*,*M*,*M*,*M*)-**2**, ((*P*,*M*,*M*,*M*) isomer shown), b) C_{2h}-symmetric (*M*,*M*,*P*,*P*)-**2**, c) (*P*,*P*,*P*,*P*)/(*M*,*M*,*M*,*M*)-**2**, and d) D_{2d}-symmetric (*M*,*P*,*M*,*P*)-**2**. ^{1}H NMR spectra in $CDCl_3$. The models in (a), (b), and (d) show conformations optimized by AM1 calculations.[12] The X-ray crystal structure of (*M*,*M*,*M*,*M*)-**2** is shown in (c). (Note that in the crystal structure the actual symmetry is C_1 in contrast to the observation from NMR spectroscopy; for further details see the Supporting Information.)

Supporting Information and ref. [14]). Finally, the structure of the last isomer, D_{2d}-symmetric (*M*,*P*,*M*,*P*)-**2**, was assigned by exclusion (Figure 3d).

Macrocycle **1** and cyclophane **2** differ substantially in their properties. While the isomers of **1** are colorless solids, those of **2** are brown-colored. All compounds are stable for weeks upon storage in the air at ambient conditions, when protected from light. The characteristic anthracene bands in the visible region of the electronic absorption spectra of the isomers of **2** are retained but red-shifted by nearly 100 nm (see the Supporting Information). Similar to anthracene, the macrocycles show fluorescence ($\Phi = 0.2$; $\lambda_{max} = 478$–481 and 510–515 nm at $\lambda_{exc} = 315$ nm). The isomers of **2** undergo two reversible $2e^-$ oxidation and one reversible $4e^-$ reduction steps under cyclovoltametric conditions.[15] Whereas the isomers of **1** are stable upon irradiation, photoisomerization of the allene moieties in **2** occurs. The different stereoisomers interconvert slowly upon irradiation (within days under sunlight or within hours under xenon-lamp irradiation, 450 W; $\lambda_{exc} = 300$ nm or 463 nm) to finally reach the photostationary state with an isomeric ratio of 10:5:1:5 (C_2/C_{2h}/D_4/D_{2d}). This ratio differs slightly from the statistically expected ratio of 4:2:1:2. Photoisomerization of **2** but not of **1** is probably a result of the anthracene moieties, which can act as intramolecular sensitizers.[16]

In summary, we have prepared, separated, and characterized the first members of a new class of unsaturated allenoacetylenic macrocycles as well as four new cyclophanes which undergo photoisomerization. The three-dimensional shapes and symmetries of these novel hydrocarbons are intriguing, and the preparation of optically pure derivatives with potentially promising chiroptical properties is being pursued. Furthermore, the host–guest complexation properties of **2** and related macrocycles, which are obtained by Diels–Alder reaction of the anthracene moieties, are now under investigation.

Experimental Section

(*M*,*P*,*P*,*P*)/(*P*,*M*,*M*,*M*)-**1**: A solution of **11** (216 mg, 0.203 mmol) and *ortho*-nitrophenol (43 mg, 0.31 mmol) in THF (100 mL) was treated with nBu$_4$NF (0.30 mL of a 1M solution in THF, 0.30 mmol). After the

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

reaction mixture had been stirred for 1 h at 20 °C, the solvent was removed under reduced pressure. The orange oil was taken up in cyclohexane/CH_2Cl_2 and filtered through a plug of SiO_2 (eluent: cyclohexane/EtOAc 20:1). After concentration, the residue was dissolved in pyridine (0.30 L) and added to a degassed solution of CuCl (1.50 g, 15.1 mmol) and $CuCl_2$ (0.20 g, 1.51 mmol) in pyridine (1.20 L). The green mixture was degassed with Ar and stirred for 3 d at 20 °C. Pyridine was removed under vacuum until a volume of about 100 mL remained, and cyclohexane and toluene were added. The Cu salts were extracted with aq NH_4Cl solution (3×) and aq EDTA (0.2 M) solution. The organic layer was dried over $MgSO_4$ and concentrated. The residual brown solid was filtered twice through SiO_2 and eluted with toluene and cyclohexane successively to give a light brown solid (160 mg). Analytical HPLC analysis (Kromasil, hexane, 1 mL min^{-1}) showed roughly a 1:1:4:1:1 mixture of stereoisomers. Isolation of the most abundant C_1-symmetric isomer (≈60 mg) on preparative scale was successful on a "Buckyclutcher 1" column (eluent: hexane, 10 mL min^{-1}). White solid. M.p. >290 °C (decomp); ^{1}H NMR (300 MHz, $C_6D_5CD_3$): $\delta = 1.007$ (s, 9H), 1.040 (s, 9H), 1.075 (s, 9H), 1.093 (s, 9H), 1.106 (s, 9H), 1.116 (s, 9H), 1.127 (s, 9H), 1.142 ppm (s, 9H); ^{13}C NMR (75 MHz, $C_6D_5CD_3$): $\delta = 29.51$, 29.54, 29.56, 29.62, 29.73, 29.75, 29.80, 29.84, 36.01 (2×), 36.06 (2×), 36.18, 36.21, 36.34, 36.43, 76.43, 76.49 (3×), 78.86, 78.93, 79.11, 79.21, 87.52, 87.64, 88.06, 88.16, 104.04, 104.13, 104.24, 104.44, 105.43, 105.47, 105.60 (2×), 214.56, 215.07, 215.20, 215.46 ppm; UV/Vis (hexane): λ_{max} (ε) = 237 (126700), 266 (sh, 48800), 281 (sh, 32500), 295 (sh, 21300), 321 nm (12800); MALDI-MS (%): $m/z = 783.53$ (19, $[M+K]^+$), 767.55 (34, $[M+Na]^+$), 745.57 (100, $[M+H]^+$), 689.50 (22, $[M+H-t\mathrm{Bu}]^+$); HR-MALDI-MS: $m/z = 745.5694$ ($[M+H]^+$, $C_{56}H_{73}^+$; calcd 745.5707).

Synthesis and Structure Determination of Tellurium Tetracyanide Solvates: Pseudopolymorphism of $Te(CN)_4$ and TeF_4**

Dieter Lentz and Małgorzata Szwak*

Until recently, tellurium dicyanide (**1**), known since 1908,[1] was the only binary cyano compound of tellurium. Its chemistry has remained almost unexplored, and only a few spectroscopic data have been published so far.[2] Very recently, Klapötke et al. reported the crystal structure determination of **1** and the synthesis of an extremely unstable tellurium tetracyanide, which was characterized on the basis of a Raman spectrum and its decomposition into **1** and cyanogens.[3] Extremely explosive tellurium tetraazide was obtained by Klapötke et al.[4] and Christe et al.;[5] again structural data are missing. To the best of our knowledge further homoleptic tellurium(IV) pseudohalides are unknown.

In the course of our studies of pseudohalogen compounds of the chalcogens we have investigated the reaction of tellurium tetrafluoride with trimethylsilyl cyanide in acetonitrile and THF, and have isolated the crystalline solvates of tellurium tetracyanide $[\{Te(CN)_4(CH_3CN)_2\}_n]$ (**2a**) and $[\{Te(CN)_4(thf)_3\}_n]$ (**2b**) [Eq. (1)]. The compounds easily lose

$$n\mathrm{TeF_4} + 4n\ \mathrm{Me_3SiCN} \xrightarrow{\mathrm{CH_3CN}} [\{\mathrm{Te(CN)_4\,(CH_3CN)_2}\}_n] + 4n\ \mathrm{Me_3SiF} \quad \mathbf{2a}$$

$$n\mathrm{TeF_4} + 4n\ \mathrm{Me_3SiCN} \xrightarrow{\mathrm{THF}} [\{\mathrm{Te(CN)_4\,(thf)_3}\}_n] + 4n\ \mathrm{Me_3SiF} \quad \mathbf{2b} \qquad (1)$$

the solvate molecules and decompose readily both as solids and in solution to give **1** ($\delta(^{125}\mathrm{Te}, \mathrm{THF}) = 547$ ppm, $\delta(^{13}\mathrm{C}, \mathrm{THF}) = 86.6$ ppm) and cyanogen ($\nu(\mathrm{CN}, \mathrm{gas}) = 2157\ \mathrm{cm}^{-1}$). Nevertheless, we succeeded in characterizing **2b** and the mixed substituted compounds $TeF_x(CN)_{4-x}$ ($x = 4, 2, 1$) by ^{125}Te, ^{19}F, and ^{13}C NMR spectroscopy at low temperature and in eludicating the structures of **2a** and **2b** by single-crystal X-ray diffraction (Figures 2–4).[6]

The ^{125}Te NMR spectrum (Figure 1) of a mixture of TeF_4 and less than four equivalents of TMSCN at −100 °C exhibits

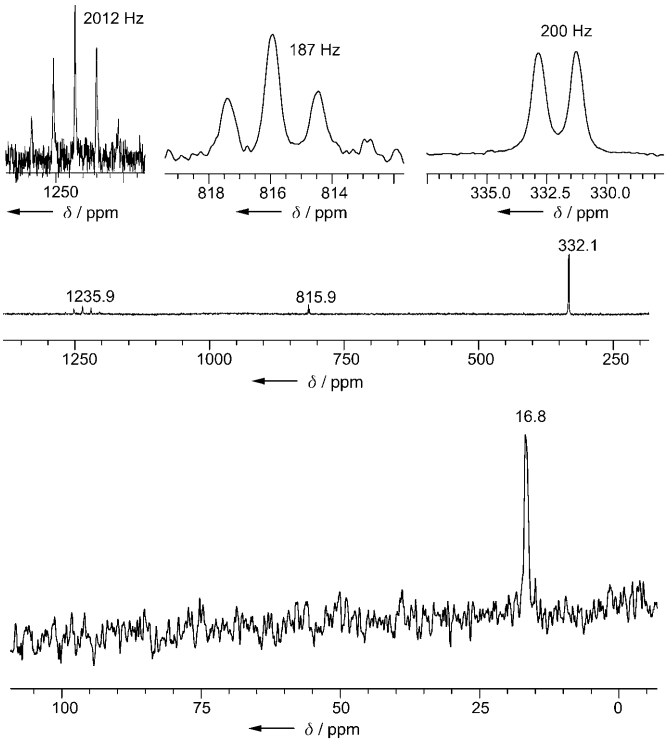

Figure 1. ^{125}Te NMR spectrum of $TeF_x(CN)_{4-x}$ ($x = 4, 2, 1$) at −100 °C (top) and **2b** at −80 °C (bottom) in [D$_8$]THF; dimethyl telluride was used as an external reference.

a quintet at $\delta = 1235.9$ ppm ($^1J(^{125}\mathrm{Te}\text{-}^{19}\mathrm{F}) \approx 2012$ Hz) for TeF_4, a triplet at $\delta = 815.9$ ppm ($^1J(^{125}\mathrm{Te}\text{-}^{19}\mathrm{F}) \approx 187$ Hz) for $TeF_2(CN)_2$, and a doublet at $\delta = 332.1$ ppm ($^1J(^{125}\mathrm{Te}\text{-}^{19}\mathrm{F}) \approx 200$ Hz) for $TeF(CN)_3$. Correspondingly, the ^{19}F NMR spectrum exhibits three resonances with ^{125}Te satellites at $\delta = -45.1$ ppm ($^1J(^{125}\mathrm{Te}\text{-}^{19}\mathrm{F}) \approx 2000$ Hz) for TeF_4, $\delta = -12.8$ ppm ($^1J(^{125}\mathrm{Te}\text{-}^{19}\mathrm{F}) \approx 196$ Hz) for $TeF(CN)_3$, and $\delta = -80.3$ ($^1J(^{125}\mathrm{Te}\text{-}^{19}\mathrm{F}) \approx 182$ Hz) for $TeF_2(CN)_2$, respectively, besides the signal of Me_3SiF. Thus no intermolecular fluoride exchange occurs on the NMR time scale at −100 °C. The small ^{19}F-^{125}Te coupling constants of $TeF_x(CN)_{4-x}$ ($x = 1, 2$) in comparison with those of TeF_4 and $TeF_2(OTeF_5)_2$ ($^1J(^{125}\mathrm{Te^{IV}}\text{-}^{19}\mathrm{F}) = 2812$ Hz)[7] indicate that in these compounds the fluorine atoms occupy the axial positions of the ψ-trigonal-bipyramidal structure as predicted by the VSPER model and as already been observed for $TeF_2(CF_3)_2$[8] ($^1J(^{125}\mathrm{Te}\text{-}^{19}\mathrm{F}) = 234$ Hz). In the case of TeF_4, rapid intramolecular exchange of the fluorine substituents takes place even at −100 °C. On warming, the ^{125}Te-^{19}F scalar coupling disappears as a result of fast intermolecular fluoride exchange. Because of the low solubility of **2b** at −80 °C—a saturated solution contains approximately 25–50 μmol **2b** in 0.7–1.0 mL [D$_8$]THF—it was difficult to obtain the ^{125}Te and ^{13}C NMR spectra. The ^{125}Te NMR spectrum of **2b** at −80 °C exhibits a single resonance at $\delta = 16.8$ ppm which is shifted to $\delta = 45.0$ ppm on warming to −30 °C. The ^{13}C NMR spectrum at −80 °C exhibits two signals at $\delta = 111.6$ and 114.2 ppm, which can be assigned to the CN substituents, besides the resonances of the solvent and trimethylsilyl fluoride. No ^{125}Te satellites could be detected due to the bad signal-to-noise ratio. The low-temperature

Raman spectrum (−80 °C) of **2b** exhibits three bands for the CN stretching modes at 2153 (m), 2178 (w), and 2185 cm^{-1} (w).

In the solid state the structures of **2a** and **2b** are very different from the structure of an isolated $Te(CN)_4$ molecule calculated by ab initio methods[3] which has C_{2v} symmetry (ψ-trigonal-bipyramidal structure including the electron lone pair). Both **2a** and **2b** form a coordination polymer in the shape of bent chains (Figures 2–4). Both compounds have trigonal-pyramidal $\{Te(CN)_3\}$ units as building blocks, which are connected by unsymmetrical CN bridges (TeC < TeN) to form chains and expanding the coordination sphere of tellurium. The Te–C distances to the terminal CN groups range from 2.086 to 2.217 Å. In **2a** two short and one long distance were found, whereas in **2b** one short and two slightly longer distances were observed. The C-Te-C bond angles are between 78 and 87 ° (one small and two larger angles).

The structures of **2a** and **2b** differ in the connection of the $\{Te(CN)_3\}$ units and the coordination of the solvate molecules.

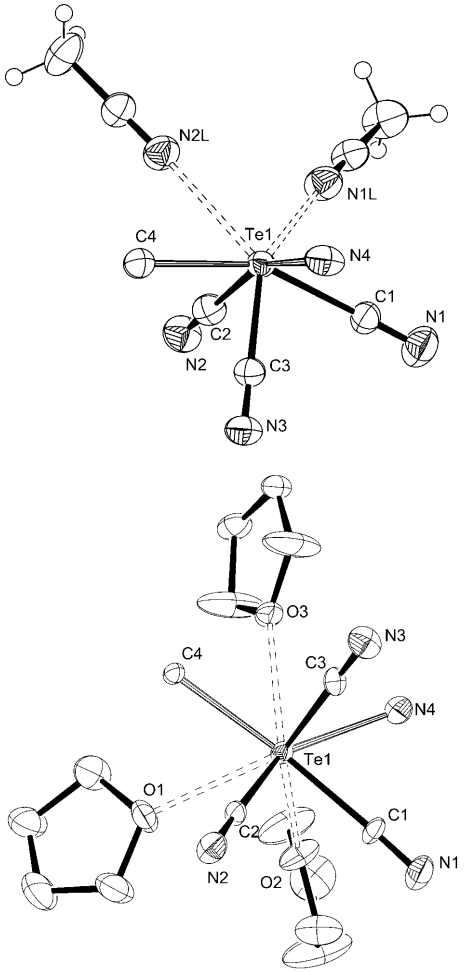

Figure 2. Structure of one monomeric unit of **2a** (ORTEP,[15] 50% ellipsoids, top) and **2b** (ORTEP,[15] 30% ellipsoids, H atoms omitted, bottom). Selected distances [Å] and angles [°] in **2a**/**2b**: Te1–C1 2.217(4)/2.166(7), Te1–C2 2.102(4)/2.157(7), Te1–C3 2.116(4)/2.086(7), Te1–C4 2.397(3)/2.482(7), Te1–N4 2.601(4)/2.567(8); C4-Te1-N4 91.0(1)/128.1(2), C1-Te1-C2 86.9(1)/78.2(3), C1-Te1-C3 79.1(1)/84.4(3), C2-Te1-C3 86.0(1)/86.6(3), C1-Te1-C4 154.3(1)/148.2(3), C2-Te1-N4 158.5(1)/149.1(3).

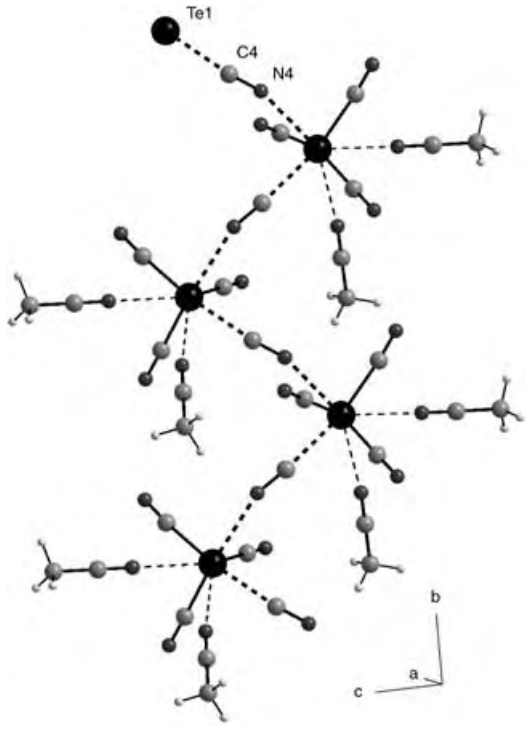

Figure 3. Polymer chain of **2a** (DIAMOND[16]).

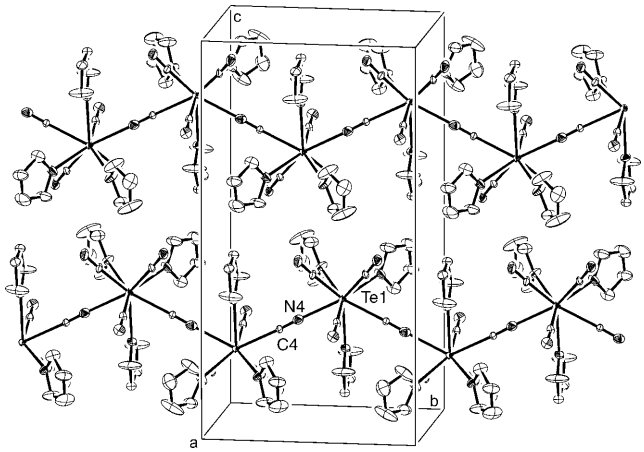

Figure 4. Unit cell of **2b** (ORTEP,[15] 30% ellipsoids, H atoms omitted).

In **2a** the trigonal $[Te(CN)_3]$-pyramid is completed by the bridging ligand atoms C4 ($d_{Te1\text{-}C4} = 2.397(3)$ Å) und N4 ($d_{Te1\text{-}N4} = 2.601(4)$ Å) forming a strongly distorted square pyramid as the coordination polyhedron. Both distances are significantly larger than the sum of covalency radii.[9] The bond angle to the bridging atoms ($\sphericalangle_{C4\text{-}Te1\text{-}N4}$) is 91.0(1)°. Finally the coordination sphere is completed by two acetonitrile molecules which have very large Te–N distances (2.728(4), 2.866(4) Å). The principal coordination in **2b** is rather similar; however, the square pyramid is even more distorted, and the $d_{Te1\text{-}C4}$ (2.482(7) Å) is larger. Furthermore the angle C4-Te1-N4 of 128.1(2) ° is much larger. Three THF molecules are coordinated to the tellurium atom over very large distances (2.700(7)–2.774(7) Å) by dipole interactions.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

In both structures the volume attributed to the lone pair is unoccupied by solvate molecules and ligands. Both compounds **2a** and **2b** can be described as $[Te(CN)_3]CN$ with the ionic character being more pronounced in **2b**.

For comparison, the structures of the previously not characterized solvates $[TeF_4(thf)_2]$ (**3a**)[6] (Figure 5) and

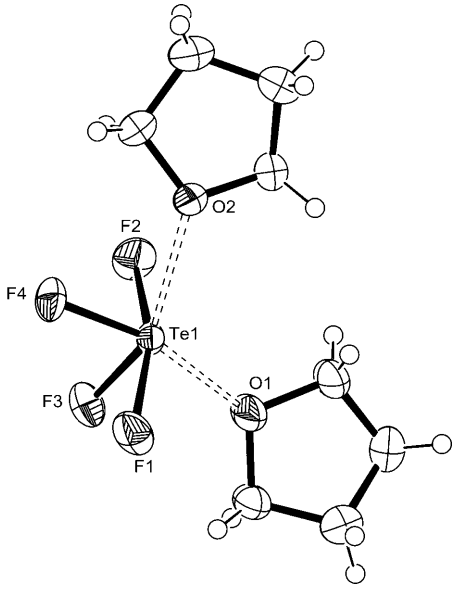

Figure 5. Crystal structure of **3a** (ORTEP,[15] 50% ellipsoids). Selected distances [Å] and angles [°]: Te1–F1 1.966(2), Te1–F2 1.941(2), Te1–F3 1.862(2), Te1–F4 1.867(2), Te1–O1 2.448(2), Te1–O2 2.697; F1-Te1-F2 161.33(7), F3-Te1-F4 86.98(6), F1-Te-F3 80.97(6), F1-Te1-F4 84.74(7), F2-Te1-F3 82.15(7), F2-Te1-F4 86.45, F3-Te1-O2 155.89, F4-Fe1-O1 160.89(7), O1-T1-O2 122.95.

$[\{TeF_4(toluene)\}_n]$ (**3b**)[6] (Figure 6) were elucidated by X-ray crystallography. Unexpectedly, **3a** consists of monomeric C_{2v}-symmetric TeF_4 units in accordance to the ψ-trigonal-bipyramidal geometry expected by the VSEPR model and in contrast to **2a**, **2b**, and **3b**. As expected, the distances to the axial fluorine atoms are about 0.1 Å longer than those to the equatorial ones. Due to the steric influence of the electron lone pair, the angles $\sphericalangle_{F1\text{-}Te1\text{-}F2}$ and $\sphericalangle_{F3\text{-}Te1\text{-}F4}$ are significantly smaller than 180 and 120°, respectively. The distance $d_{Te1\text{-}O1}$, (2.448(2) Å) is shorter than the distance $d_{Te1\text{-}O2}$ (2.697(2) Å) and the comparable Te–O distances in **2b**.

The structures of **2a** and **2b** can be compared to those of **3b** (Figure 6) and tellurium tetrafluoride,[10] in which trigonal-pyramidal TeF_3 units are completed by two bridging fluorine atoms in *cis* position forming a square pyramid. The nearest distances of the aromatic carbon atoms to the tellurium atom range from 3.151(7) to 3.449(7) Å. Thus these distances are shorter than the sum of van der Waals radii (3.8 Å).[11] Tellurium tetrachloride forms a tetramer with a heterocubane structure which is formed by connecting four $TeCl_3$ units with bridging chlorine atoms.[12]

It is surprising that with the same solvate molecule, tetrahydofuran, TeF_4 forms a pseudopolymorphic structure with isolated TeF_4 units, whereas $Te(CN)_4$ forms a coordination polymer that can be better described as $[\{Te(CN)_3(thf)_3\text{-}(\mu\text{-}CN)\}_n]$. Further studies on the influence of solvate molecules on the pseudopolymorphic structures[13] of tellurium halides and pseudohalides are underway in our group.

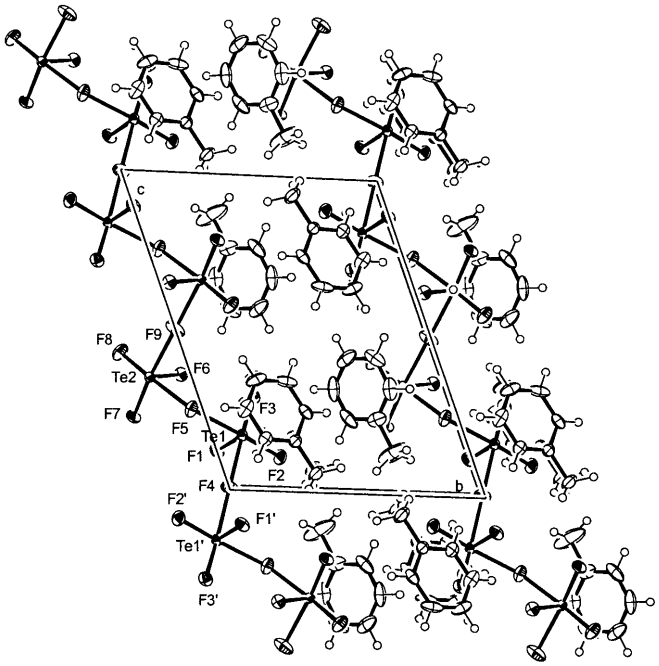

Figure 6. Unit cell of **3b** (ORTEP,[15] 50% ellipsoids, view along $\bar{1}00$). Selected distances [Å] and angles [°]: Te–F(apical) 1.846(3)–1.847(4), Te–F(basal) 1.873(4)–1.886(4), Te–F(Brücke) 2.171(4)–2.23(4), Te1–C-(arom.) 3.151(7)–3.449(7), Te2–C(arom.) 3.202(7)–3.356(7); F5-Te2-F9 95.33(9), F4-Te1-F5 100.39(9).

Experimental Section

All reactions were carried out in carefully dried apparatus under an atmosphere of dry argon or under vacuum. TeF_4 was handled in an automatic drybox. Volatile solvents were carefully dried and condensed into the reaction vessel using a glass vacuum line system.

2a: Acetonitrile (5 mL) was condensed into a 50-mL Schlenk flask containing TeF_4 (0.2 g, 1 mmol), which was dissolved by warming the mixture to ambient temperature. Acetonitrile (4 mL) was condensed into a 50-mL Schlenk flask containing TMSCN (0.45 g, 4.5 mmol). After warming to ambient temperature both solutions were cooled again to −35 °C. After flushing with argon the TeF_4 solution was added to the TMSCN solution by a Teflon tube. The reaction mixture was allowed to warm slowly to −6 °C with stirring. The colorless solution was placed in a refrigerator (−30 °C). After 12 h **2a** was obtained as colorless platelets.

2b: THF (15 mL) was condensed into a 50-mL Schlenk flask containing TeF_4 (0.1 g, 0.5 mmol), which was dissolved by warming the mixture to ambient temperature. THF (20 mL) was condensed into a 100-mL Schlenk flask containing TMSCN (0.25 g, 2.5 mmol), which was dissolved at ambient temperature, and the mixture was cooled to −68 °C. After flushing with argon the TeF_4 solution (−40 °C) was added within 5 min to the stirred TMSCN solution using a Teflon tube. The reaction mixture was warmed slowly to −6 °C (30 min between −10 and −6 °C). Most of the solvent and the trimethylsilyl fluoride (^{19}F NMR, decett at $\delta = -157$ ppm) formed were removed under vacuum at −68 °C. After warming to −8 °C to form a colorless solution, the flask and the cold bath were placed in a refrigerator (−84 °C). Colorless needle-shaped crystals of **2b** formed overnight.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

3a: Crystals of **3a** were first obtained from the attempted reaction of TeF_4 with one equivalent of TMSCN in toluene after crystallization of the nonvolatile residue from THF at −80 °C. The compound can be obtained directly by crystallization of TeF_4 from THF.

3b: Crystals of **3b** were obtained by slowly cooling a solution of TeF_4 (0.1 g, 0.5 mmol) in 1.5 mL of toluene to −84 °C.

NMR spectra: Approximately 5 to 10 mg of TeF_4 was filled into 5-mm NMR tube equipped with a magnetic stirring bar. Using a glass vacuum line 0.5 mL of [D_8]THF was condensed into the tube by cooling with liquid nitrogen. After warming to ambient temperature, the TeF_4 dissolved completely. A further 0.3 mL of THF and approximately 25 mg of TMSCN were condensed by cooling with liquid nitrogen. The reaction mixture was warmed slowly to −6 °C with stirring. The stirring bar was removed from the solution using a magnet; the sample was cooled with liquid nitrogen and sealed under vacuum. The samples were stored at −84 °C before the measurement. NMR spectra were recorded using a JEOL Lambda 400 multinuclear NMR spectrometer at temperatures between −100 and −20 °C.

Stimuli-Responsive Controlled Drug Release from a Hollow Mesoporous Silica Sphere/Polyelectrolyte Multilayer Core–Shell Structure**

Yufang Zhu, Jianlin Shi, Weihua Shen, Xiaoping Dong, Jingwei Feng, Meilin Ruan, and Yongsheng Li*

Recently, there has been increased interest in mesoporous silica materials for use as carriers in controlled drug release, to meet the need for prolonged and better control of drug administration. Amorphous mesoporous silica materials have been investigated as drug supports because of their nontoxic nature, adjustable pore diameter, and very high specific surface area with abundant Si–OH bonds on the pore surface.[1–10] Several research groups have investigated the conventional mesoporous silica materials (such as MCM-41 and SBA-15) used as drug-delivery systems.[1–8] These systems exhibit sustained-release properties, but their drug storage capacity is relatively low, and also the irregular bulk morphology is not perfect for drug delivery. To overcome these disadvantages, one strategy is to synthesize hollow mesoporous silica (HMS) spheres on the nanoscale with pore channels penetrating from the outside to the inner hollow core. Recently, our group has successfully synthesized HMS spheres with a 3D pore-network shell.[11,12] We also investigated the aspirin storage capacity and release properties of these spheres,[13] which indicated that they could store significantly more aspirin molecules than the conventional mesoporous silicas MCM-41 and MCM-48, and also have sustained-release properties.

Compared to the sustained-release system, the stimuli-responsive controlled-release system can achieve a site-selective, controlled-release pattern, which can improve the therapeutic efficacy. Up to now, only two reports have been published about stimuli-responsive controlled drug release from mesoporous silica MCM-41.[9,10] Lin and co-workers reported the stimuli-responsive controlled release of water-soluble drugs from MCM-41 by using chemically removable CdS nanoparticles as caps for mesoporous channels and disulfide bond-reducing molecules as release triggers.[9] Fujiwara and co-workers accomplished, for the first time, the photocontrolled reversible release of drug molecules from coumarin-modified MCM-41.[10] Therefore, it is still a challenge to find more convenient ways to achieve a fully controllable drug-release system under normal physiological pH and NaCl concentrations.

The properties and structure of polyelectrolyte multilayers (PEM) are sensitive to the various physical and chemical conditions of the surrounding medium. The polyelectrolyte pair, which comprises sodium polystyrene sulfonate (PSS) and the polycation poly(allylamine hydrochloride) (PAH), has been widely investigated for hollow microcapsules.[14–24] Möhwald and co-workers prepared hollow PAH/PSS capsules by colloid-templated assembly of polyelectrolytes (layer-by-layer technique),[15] and confirmed the controlled encapsulation and release of several kinds of molecules (such as dyes, enzymes, dextran, and DNA) from the capsules by changing the pH value (or ionic strength) of the release medium.[16–20] However, these hollow capsules are not mechanically strong and about 10% of them easily break in the course of drying and the removal of the colloid templates. In addition, reports on the storage and controlled release of drugs with the freestanding capsules are not found, probably as a result of the relatively low molecular weight of most drugs. Researchers have also tried to directly coat the polyelectrolyte multilayers onto certain drug microcrystals of low molecular weight.[22–24] These systems could prolong the release time to some extent, but unfortunately they did not show the stimuli-responsive controlled release of drug molecules.

It is known that the surface of mesoporous silica is negatively charged above the isoelectric point (pH 2–3),[25] which favors a first-layer coating of the positively charged polycation PAH, followed by the negatively charged PSS. Thus, polyelectrolyte multilayer coatings on mesoporous silica spheres can be prepared. The HMS spheres can be used as a container for drug molecules and the polyelectrolyte multilayer coatings as a stimuli-responsive switch. It is encouraging that with this system one can not only increase the drug-storage capacity, but also achieve stimuli-responsive controlled release of drug molecules and enhance the mechanical strength of the polyelectrolyte multilayers to prevent them from breaking.

Herein, we propose a strategy to combine the advantages of HMS spheres with a 3D pore network and polyelectrolyte multilayers with a stimuli-responsive property. We also report a stimuli-responsive controlled drug-delivery system, which consists of HMS spheres with an average sphere diameter of 300–400 nm and polyelectrolyte multilayer coatings (PAH/PSS) with an average thickness of 14 nm. Prior reports on such a controlled-release system have not been found. In addition, the uncoated HMS sphere drug-release system was used for comparison to investigate the release property.

Figure 1 schematically illustrates two drug-delivery systems, which were designed to demonstrate the stimuli-responsive controlled drug release from PAH/PSS polyelectrolyte multilayer coatings on HMS loaded with ibuprofen (IBU-HMS@PEM) or a simplex sustained-release pattern from the IBU-HMS system. In the former system, the key is to coat the PAH/PSS multilayers on IBU-HMS spheres, which could cap the mesopore channels. During the release process,

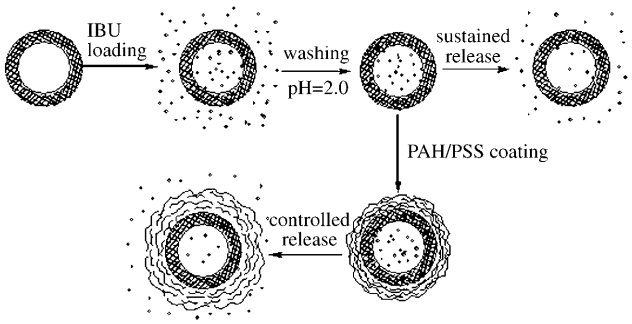

Figure 1. Schematic illustration of two drug-delivery systems which give the different controlled-release patterns.

the loaded drugs need to diffuse subsequently through the mesoporous shell and the PAH/PSS multilayers into the release medium. That is, drug release is doubly controlled by the mesoporous shell and the PAH/PSS multilayers sequentially. The stimuli-responsive controlled drug-release pattern of this system is possible as a consequence of the pH sensitivity and salt-induced responsive property of the PAH/PSS multilayers. For the IBU-HMS system, only the mesoporous shells control drug diffusion, which results in the sustained-release behavior alone.

The detailed synthesis, characterization, and formation mechanism of HMS spheres with a 3D pore network can be found in our recent report.[11] Figure 2a and b show TEM micrographs of spherical mesoporous silica particles with an average diameter of 300–400 nm. The noticeable contrast between the core and the shell of the sphere implies a hollow-core structure. The highly ordered lattice array over the shell suggests that HMS products have a uniform, well-defined mesostructure. Figure 2c shows a TEM micrograph of the HMS sphere after adsorption of IBU molecules (IBU-HMS).

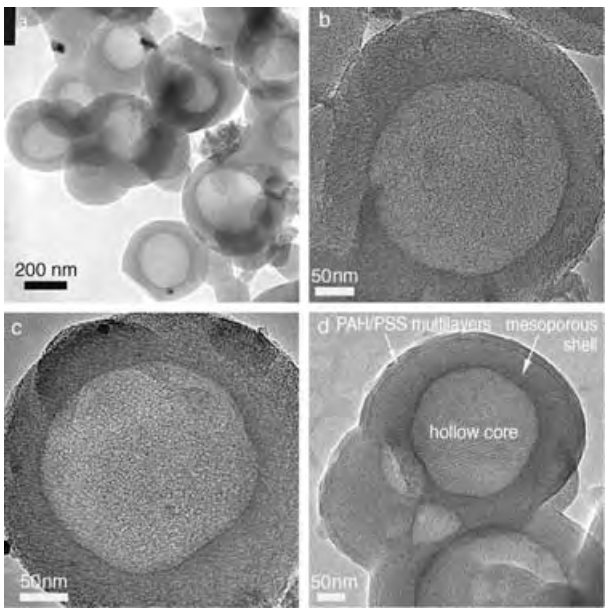

Figure 2. TEM micrographs of HMS (a and b), the IBU-HMS system (c), and the IBU-HMS@PEM system (d).

No apparent difference can be observed compared to HMS, although IBU-HMS contains a large number of IBU molecules. One reason might be that the scattering effects of IBU molecules (which contain carbon, hydrogen, and oxygen) in the hollow core and the pore channels are not strong enough to show the contrast. Figure 2d shows a TEM micrograph of IBU-HMS after being coated with PAH/PSS multilayers (IBU-HMS@PEM). A uniform thin layer with a thickness of around 14 nm exists on the outer surface of the HMS sphere, and the thin layer has coated the whole sphere. Furthermore, the hollow core–mesoporous shell structure still remains intact. Therefore, two controlling layers (mesoporous shell and PAH/PSS multilayers) have been formed in the IBU-HMS@PEM system.

Thermogravimetric analysis (TGA) curves of the IBU-HMS and IBU-HMS@PEM systems are shown in Figure 3,

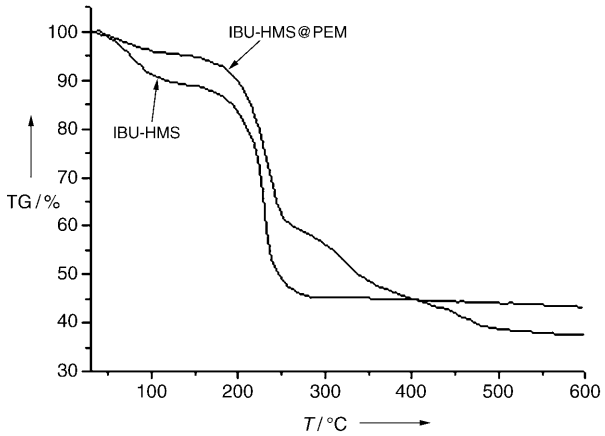

Figure 3. TGA curves of the IBU-HMS and IBU-HMS@PEM systems.

and the results are summarized in Table 1. Both systems showed weight losses below 180 °C that resulted from the physical loss of water. For the IBU-HMS system, another

Table 1: TGA results for the two drug-delivery systems.

	30–180 °C (wt %)	180–280 °C (wt %)	280–500 °C (wt %)	SiO_2 [wt %]	Storage capacity [mg_{IBU}/g_{SiO_2}]
IBU-HMS	13.03	41.64	–	45.33	918.6
IBU-HMS@PEM	7.1	34.60	19.65	39.65	872.6

weight loss (about 41.64 %) occurred between 180 and 280 °C, which demonstrates that the IBU storage capacity of the IBU-HMS system is 41.64 % (918.6 mg_{IBU}/g_{SiO_2}). In the IBU-HMS@PEM system, three weight losses were detected from 180 to 600 °C. The loss of 34.60 % (872.6 mg_{IBU}/g_{SiO_2}) between 180 and 280 °C is attributed to the removal of IBU from the IBU-HMS@PEM system, while the other two weight losses occur by the removal of the PAH/PSS multilayers. Here, the IBU storage capacity in the IBU-HMS@PEM system is a little

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

lower than that in the IBU-HMS system, which may have resulted from the loss of some IBU molecules during the PAH/PSS multilayer coating process. However, this drug storage capacity is almost three times higher than that of the conventional mesoporous material MCM-41.[1–4]

Figure 4 shows the cumulative drug release from the two systems in release media of pH 1.4 (a simulated gastric fluid)

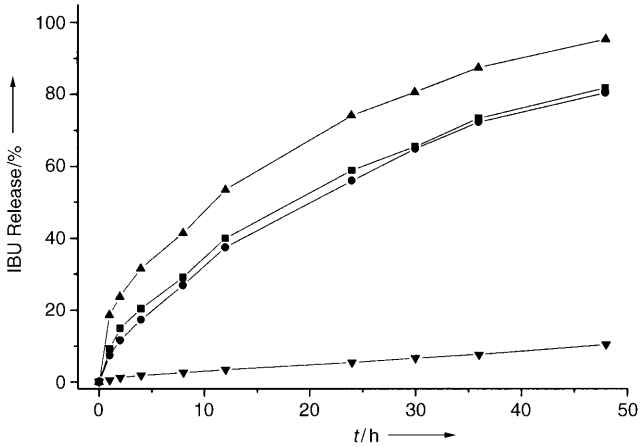

Figure 4. Cumulative drug release from the two systems in release media of different pH values. ■: pH 1.4 from IBU-HMS, ●: pH 1.4 from IBU-HMS@PEM, ▲: pH 8.0 from IBU-HMS, ▼: pH 8.0 from IBU-HMS@PEM.

and pH 8.0 (a simulated intestinal fluid). This diagram clearly proves that both systems exhibit sustained-release properties and that the drug release rates from both systems are very close to each other in the medium of pH 1.4. The amounts released from the two systems reach about 80% in 48 h. This result implies that the PAH/PSS multilayers are incompact and have open pathways in the release medium of pH 1.4, and the incompact wall of the PAH/PSS multilayers could not cap the openings of the mesoporous channels. Therefore, the drug molecules can easily diffuse into the release medium through the mesoporous channels and PAH/PSS multilayers, that is, this system only exhibits the sustained-release property with the IBU-HMS system in acid media. When the pH value of the release medium increases to 8.0, the drug release rates from both systems become apparently different. The IBU-HMS system also exhibits the sustained-release property and the amount released reaches 95% in 48 h; the release rate in the pH 8.0 release medium is higher than that in the pH 1.4 medium. This difference in release rates should mainly be attributed to the different solubility of IBU in release media of different pH values. IBU has limited solubility in low-pH (<7) solutions but is readily soluble in high-pH (>7) solutions. For the IBU-HMS@PEM system the release rate is very low, and the released amount only reaches 10% over a period of 48 h. This finding indicates the good storage and sealing effect of the PAH/PSS multilayer coating on HMS spheres in pH 8.0 solution; that is, the PAH/PSS multilayers are compact and have decreased permeability at the increased pH value, and the compact multilayers could easily cap the openings of the mesoporous channels. It can be concluded that the IBU-HMS@PEM system has a much better controlled drug-release property than the IBU-HMS system and the reported polyelectrolyte multilayer capsule system.[22–24] That is, the IBU-HMS@PEM system can achieve a pH-responsive controlled drug-release pattern by changing the pH value of the release medium.

As we know, the structure and properties of PAH/PSS multilayers are sensitive to the NaCl concentration.[17,26] Therefore, we investigated drug release from the two systems in release media of different NaCl concentration. Sustained releases from both systems are obtained in 10 mM NaCl media (Figure 5) and the release rates are very close to each other,

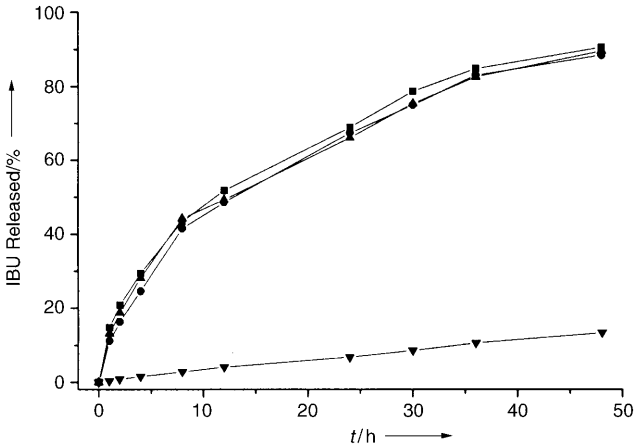

Figure 5. Cumulative drug release from the two systems in release media of different NaCl concentration. ■: 10 mM NaCl from IBU-HMS, ●: 10 mM NaCl from IBU-HMS@PEM, ▲: 0.5 mM NaCl from IBU-HMS, ▼: 0.5 mM NaCl from IBU-HMS@PEM.

which is similar to the result in release media of pH 1.4. In 0.5 mM NaCl media, the amount of drug released from the IBU-HMS system reaches about 90% in 48 h, which is also close to the release rate in 10 mM NaCl media. However, the amount released from the IBU-HMS@PEM system only reaches 13% in 48 h. Therefore, a salt-induced controlled drug-release pattern can be achieved from the IBU-HMS@PEM system. The PAH/PSS multilayers play an important role during the controlled-release process. At the higher salt concentration, the high ionic strength weakens the electrostatic binding between the oppositely charged layers, which results in incompact PAH/PSS multilayers. The multilayers can no longer cap the openings of the mesoporous channels and provide the pathways for drug molecules to diffuse into the release medium. At the lower salt concentration, the electrostatic binding between the oppositely charged layers becomes stronger and the openings of the mesoporous channels are more easily capped by the compact PAH/PSS multilayers. Therefore, the multilayers can play a switch role between the lower and the higher salt concentrations.

In addition, the drug storage and release process does not damage the pore structure (see the Supporting Information). The low-angle XRD patterns show a diffraction peak at $2\theta = 2.2$–$2.5°$ (θ is the Bragg angle) which is unaffected by the drug

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

loading and release. The pore size becomes smaller after drug loading; however, the size distribution and pore volume can mostly recover after drug release from the two systems (see the Supporting Information). Therefore, the two controlled drug-release systems show good stability.

In summary, we have demonstrated a concept to design a novel stimuli-responsive controlled drug-release system by using PAH/PSS multilayers as a coating to cap the mesopore openings of drug-loaded hollow mesoporous silica spheres. The drug storage capacity of this system is three times higher than that of the reported MCM-41 system. Compared with the system without a polyelectrolyte multilayer coating, the reported system can give stimuli-responsive controlled release; for example, it can be designed to release into the stomach instead of the intestine. The drug release rate from the IBU-HMS@PEM system can be well-controlled by changing the pH value (or the salt concentration) of the release medium. Therefore, this system combines the advantages of both high drug storage capacity and the property of stimuli-responsive controlled release, and has potential for applications in drug delivery.

Experimental Section

Materials: Tetrapropylammonium hydroxide (TPAOH, 25% in water) was from Acros. Poly(allylamine hydrochloride) (PAH, $M_w = 15000$) and sodium polystyrene sulfonate (PSS, $M_w = 70000$) were from Aldrich and used without further purification. Ibuprofen (IBU, 99%) was from Shanghai Yuanji Chem. Co. and used as received. Cetyltrimethylammonium bromide (CTAB, 99%), tetraethyl orthosilicate (TEOS, 98%), hydrogen chloride (36–38%), hexane, sodium hydroxide, and aluminum sulfate ($Al_2(SO_4)_3{\cdot}18H_2O$) were purchased from Shanghai Chem. Agents Co. and used without further purification.

Preparation of hollow mesoporous silica spheres and drug-delivery system: HMS spheres were prepared by our method as described in the literature.[11] The drug-storage profile was taken as previously reported.[1–4] IBU was dissolved in hexane at a concentration of 60 mg mL^{-1}. HMS (1.0 g) was added to this solution (50 mL) at room temperature. The vials were sealed to prevent the evaporation of hexane, then the mixture was stirred for 24 h. The HMS with adsorbed IBU was separated by centrifugation and washed several times with a solution of pH 1.4. Finally, the sample was dried under vacuum at 60 °C. This sample is denoted as IBU-HMS.

Preparation of polyelectrolyte multilayer coating: PAH (5 mL) with a monomer concentration of 5 mg mL^{-1} in 0.5 M NaCl was added to a suspension of IBU-HMS (1.0 wt%, 20 mL, pH 6.0). After stirring for 20 min, the suspension was centrifuged three times in water. Gentle shaking followed by ultrasonic treatment for 1 min was used to disperse the particles after centrifugation. Then, oppositely charged PSS (5 mg mL^{-1} in 0.5 M NaCl) was coated on the particles. This coating process was repeated for eight layers and finally a composite of IBU-HMS coated with PAH/PSS multilayers was obtained. This sample is denoted as IBU-HMS@PEM.

In vitro drug-release study: The IBU-HMS (or IBU-HMS@PEM) sample was immersed in release media of different pH values (pH 1.4 and 8.0) or different ionic strength (0.5 and 10 mM NaCl solution) at room temperature, with stirring at a rate of 100 rpm. The release medium (2.0 mL) was removed for analysis at given time intervals with a syringe, and replaced with the same volume of fresh release medium. The extracted medium was diluted to a desired concentration (0.01–0.5 mg mL^{-1}) with release medium, and analyzed by UV/Vis spectroscopy at a wavelength of 264 nm. The samples with released IBU are denoted as IBU-HMS$_R$ and IBU-HMS@PEM$_R$.

Characterization methods: Powder XRD patterns were obtained on a Rigaku D/MAX-2550V diffractometer at 40 kV and 40 mA ($Cu_{K\alpha}$ radiation). TEM analysis was performed using a JEOL 2100F electron microscope operated at 200 kV. The UV/Vis absorbance spectra were measured with a Shimadzu UV-3101PC spectrophotometer. N_2 adsorption–desorption isotherms were obtained on a Micromeritics Tristar 3000 pore analyzer at 77 K under continuous adsorption conditions. Brunauer, Emmett, and Teller (BET) and Barrett, Joyner, and Halenda (BJH) analyses were used to determine the surface area, pore size, and pore volume. Thermogravimetric analysis (TGA) was recorded on an STA-449C thermal analyzer at 10 °C min^{-1} in an N_2 atmosphere.

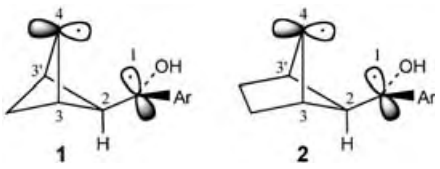
Biradicals



DOI: 10.1002/anie.200500983

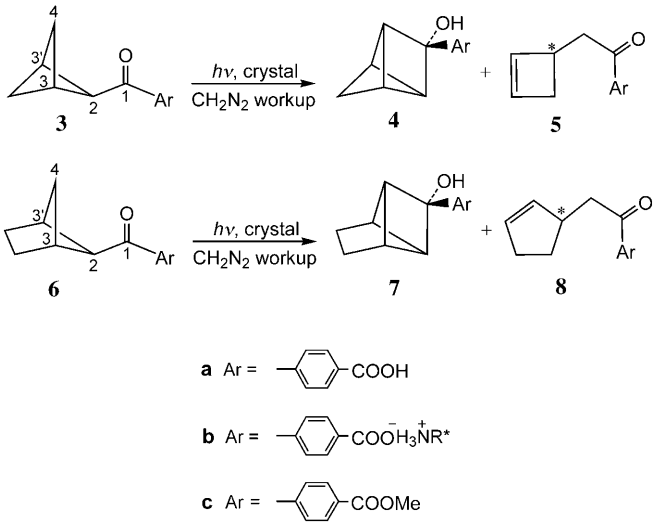
Orbital-Overlap Control of the Reactivity of a Bicyclic 1-Hydroxy-1,4-Biradical**

Chao Yang, Wujiong Xia, John R. Scheffer, Mark Botoshansky, and Menahem Kaftory*

1,4-Biradicals are among the most ubiquitous reactive intermediates in organic chemistry, and are formed or implicated in a variety of reactions including [2+2] photocycloaddition,[1] the Paterno–Büchi reaction (oxetane formation),[2] the Norrish–Yang type II reaction,[3] and the elimination of nitrogen from cyclic azo compounds.[4] Once formed, 1,4-biradicals suffer two main fates: closure to form compounds containing a four-membered ring, and cleavage of the central bond to produce a pair of double-bond-containing fragments.[5] Based on organic intuition backed by semiempirical calculations,[6] and supported by a wide variety of product studies,[1–4] the generally accepted qualitative picture of biradical reactivity is that cleavage is favored when the conformation allows the radical-containing orbitals at positions 1 and 4 to overlap with the sigma bond between positions 2 and 3. Increasing amounts of cyclization are observed as this overlap diminishes, provided that the radical termini are within reasonable bonding distance of one another.

However, quantitative experimental tests of this hypothesis are rare, in part as a result of the difficulty of establishing structure–reactivity relationships for conformationally mobile systems in fluid media. In the case of triplet 1,4-biradicals, the picture is complicated by the likelihood that biradical behavior reflects the geometry in which the singlet biradical is formed by intersystem crossing (isc) from the triplet, which may differ significantly from the geometry of the conformationally equilibrated species.[7] For these reasons, we have elected to work with compounds in the crystalline state, where molecular conformation is fixed and determinable by X-ray crystallography, and where the singlet biradical formed by isc has the same geometry as its triplet precursor. We have shown that 1-hydroxy-1,4-biradicals can be generated conveniently in the solid state by the Norrish–Yang type II reaction, and that because hydrogen-atom transfer occurs with very little movement of the associated heavy atoms, the structure and conformation of the biradicals can be inferred directly from the X-ray crystal structures of their ground-state precursors.[8] Herein, we compare and contrast the behavior of 1-hydroxy-1,4-biradicals of general structures **1** and **2**. These biradicals are interesting because,

unlike the majority of biradicals studied previously, they have only one significant degree of conformational freedom, namely, rotation about the C1–C2 bond. Among the questions we wished to answer about these biradicals were: 1) how does the orientation of the p orbital at the C1 position affect the ratio of cyclization to cleavage; and 2) can we correlate the orientation of the p orbital at C1 with preferential cleavage of either the C2–C3 or C2–C3′ bond? As described below, satisfactory answers to these questions were obtained by generating biradicals **1** and **2** in the crystalline state and correlating their behavior in this medium with their conformations as determined by X-ray crystallography.



We are not the first to study biradicals of types **1** and **2**. The solution-phase behavior of biradical **2** (Ar = Ph) was reported in 1972 by Padwa and Eisenberg and shown to consist of 66% cleavage and 30% cyclization.[9] Similarly, Alexander and Uliana showed in 1976 that, in solution, biradical **1** (Ar = Ph) bearing a phenyl substituent at the C2 position undergoes 100% cyclization.[10] In both cases, the biradicals were formed by a Norrish–Yang type II photoreaction of the corresponding ketone. In the present work, we chose to investigate ketones in which the aryl group bears a carboxylic acid substituent in the *para* position, that is, ketones of general structures **3** and **6** (Scheme 1). This choice was based on the following considerations: previous work from our group had shown that when achiral keto acids such as **3a** and **6a** are treated with optically pure amines, the resulting salts (**3b** and **6b**) crystallize with the carboxylate anions in homochiral conformations.[11] In principle, these salts could react when photolyzed in the solid state to produce, after diazomethane workup, the achiral Yang cyclization products **4c**/**7c** along with the chiral Norrish type II cleavage products **5c**/**8c** (Scheme 1). Cleavage of the

Scheme 1. Ketone reactants and their cyclization/cleavage photoproducts.

C2–C3 bond leads to (*R*)-**5c**/**8c** and cleavage of the C2–C3′ bond leads to (*S*)-**5c**/**8c**. Thus, by determining the absolute configuration of the cleavage product in each case and correlating this information with the absolute conformation of the carboxylate anion obtained by X-ray crystallography, we were able to establish which bond was cleaved and its degree of overlap with the p orbital on C1.

Although a number of different salts were prepared and their solid-state photochemistry investigated, we limit the present discussion to the two salts whose X-ray crystal structures were successfully determined, namely, the (*S*)-(−)-1-phenylethylamine salts of keto acids **3a** and **6a**.[12] Polycrystalline samples of these salts (2–5 mg) were crushed between pyrex microscope slides and the resulting sandwiches taped together, sealed under nitrogen in polyethylene bags, and irradiated (450-W medium-pressure mercury lamp) on both sides at various temperatures for different lengths of time. Even at high conversions, no melting could be detected. After photolysis, the crystals were treated with diazomethane in ether to remove the ionic chiral auxiliaries and form the corresponding methyl esters. The reaction mixtures were then subjected to GC analysis to determine the cyclization-to-cleavage ratios, and to chiral HPLC analysis to measure the enantiomeric excess (*ee*) in which photoproducts **5c** and **8c** were formed. The results are summarized in Table 1.[13]

Table 1: Solid-state photochemistry of (*S*)-(−)-1-phenylethylamine salts of keto acids **3a** and **6a**.

Acid	*T* [°C]	Conversion [%][a]	CY/CL[b]	*ee* [%][c]	α[d]
3a	−20	45	88:10	90	(−)
3a	20	38	87:11	87	(−)
3a	20	72	87:11	70	(−)
6a	−20	85	21:75	98	(−)
6a	20	21	20:79	>98	(−)
6a	20	53	21:77	98	(−)

[a] Determined by GC. [b] Ratio of cyclization (CY) to cleavage (CL). [c] Determined by chiral HPLC. [d] Sign of rotation of major enantiomer at sodium D line.

An independent, enantioselective synthesis of photoproduct **8c** was carried out to determine whether the major enantiomer produced in these photolysis reactions was of *R* or *S* configuration. Optically pure (*S*)-2-cyclopentene-1-acetic acid was prepared by resolution of the racemate with brucine according to the procedure of Mislow and Steinberg.[14] This material was then converted by reduction with lithium aluminum hydride, oxidation with pyridinium chlorochromate (PCC), addition of *p*-carbomethoxyphenylmagnesium iodide, and oxidation with PCC to (*S*)-**8c**, which proved to be dextrorotatory ($[\alpha]_D^{22} = +98.0°$, $c = 0.45$, MeOH). According to the sign of rotation shown in Table 1, this means that compound **8c** formed in the photolysis of the (*S*)-(−)-1-phenylethylamine salt of keto acid **6a** has the *R* absolute configuration. On the basis of the very close structural similarity between photoproducts **8c** and **5c**, we assume that the latter also has the *R*-(−) absolute configuration.

Concomitant with the photochemical and synthetic studies, the X-ray crystal structures of the (*S*)-(−)-1-phenylethylamine salts of keto acids **3a** and **6a** were determined (see Figure 1). A number of important geometric parameters were

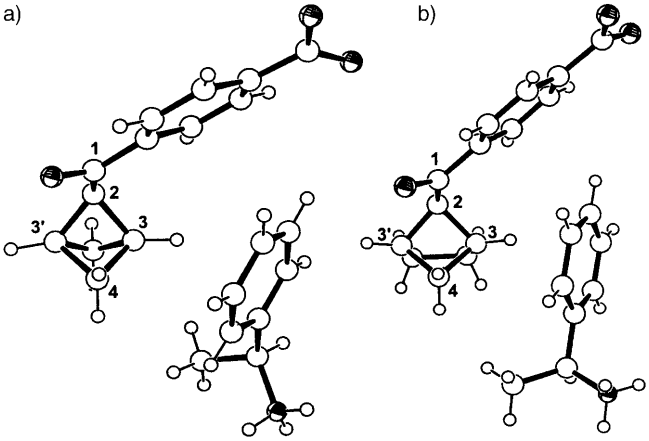

Figure 1. X-ray crystal structures of (*S*)-(−)-1-phenylethylamine salts of keto acids a) **3a** and b) **6a**.

calculated from the crystal structures, including the γ-hydrogen-atom abstraction geometries as well as the geometric relationships relevant to the cyclization and cleavage of the 1-hydroxy-1,4-biradical intermediates (see Table 2).

To begin our discussion of the geometric parameters, we note that the value of d_{O-H4}, the distance between the carbonyl oxygen atom and the γ-hydrogen atom on C4, is similar for both salts and well within the guidelines established by us for

successful Norrish type II hydrogen abstraction in the crystalline state ($d = 2.7 \pm 0.2$ Å).[15] Similarly, the value of d_{C1-C4}, the distance between atoms C1 and C4 in the biradical produced by hydrogen abstraction, is the same for both salts. As a result, distance factors can be excluded as the source of the cyclization-to-cleavage ratio differences. The parameter β, defined as the angle between the p orbital on C1 and the C2–C4 vector, is ideal for cyclization when $\beta = 0°$, that is, when the p orbitals are pointing directly at one another. The values of β in Table 2 indicate that the **3a**-derived biradical is better arranged for cyclization than the **6a**-derived species.

The parameters φ_1 and φ_4 represent the angles formed between the p orbitals on atoms C1 and C4 and the C2–C3 and C2–C3′ bonds (the values of φ_1 and φ_4 for the C2–C3′ bond are shown in parentheses). The best arrangement for cleavage is expected when φ_1 and $\varphi_4 = 0°$, and the data indicate that cleavage of the C2–C3 bond is favored over cleavage of the C2–C3′ bond for both salts. This finding predicts that cleavage photoproducts **5c** and **8c** should have the *R* absolute configuration, a prediction that agrees with the configurational assignment made by independent synthesis of optically pure (*S*)-(+)-**8c**. It is interesting to speculate that the *ee* for **5c** is lower (70–90%) than that for **8c** (98%), because the difference in φ_1 for the former is less ($67-22 = 45°$) than that for the latter ($78-16 = 62°$). Of course, supramolecular factors[16] could contribute to the difference in *ee*, but the fact that the (*S*)-1-phenylethylammonium ion is common to both salts supports the notion that the major determinant of solid-state biradical behavior in these systems is the structure and conformation of the carboxylate anion.

The values of φ_1 and φ_4 also show that the biradical derived from **6a** has a better geometry for cleavage ($\varphi_1 = 16°$, $\varphi_4 = 35°$) than that from **3a** ($\varphi_1 = 22°$, $\varphi_4 = 43°$). Taken together with the earlier conclusion that the biradical from **3a** has a better geometry for cyclization than that from **6a**, the data clearly predict that salts derived from keto acid **3a** should have a higher Norrish–Yang cyclization-to-cleavage ratio than those derived from keto acid **6a**. This prediction is in accordance with the counterintuitive result that Yang photocyclization predominates in the bicyclo[1.1.1]pentane system **3a**, even though the cyclobutanol product in this case is more strained than that formed from the bicyclo-[2.1.1]hexane reactant **6a**.

The work reported herein complements our previous research in this area[8] and highlights, in a quantitative fashion, the fact that relatively small differences in geometry can have a profound effect on 1-hydroxy-1,4-biradical behavior. Furthermore, it demonstrates once again the efficacy of the solid-state ionic chiral auxiliary approach to asymmetric synthesis in organic photochemistry.[17]

Experimental Section

Full experimental details on the synthesis of the starting materials, photolysis of the salts in the crystalline state, the diazomethane workup procedure, and the characterization of the photoproducts are available in the Supporting Information. CCDC 265554 and 265555 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

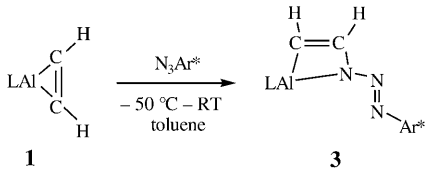
A Stable Aluminacyclopropene LAl(η^2-C_2H_2) and Its End-On Azide Insertion to an Aluminaazacyclobutene**

Hongping Zhu, Jianfang Chai, Hongjun Fan, Herbert W. Roesky, Cheng He, Vojtech Jancik, Hans-Georg Schmidt, Mathias Noltemeyer, William A. Merrill, and Philip P. Power*



Dedicated to Kit Cummins

The MC_2 rings of cyclopropene derivatives substituted with heavier main-group elements have a highly strained structure and indicate a remarkable reactivity. They are often involved in such reactions as ring opening, insertion, substitution, dimerization, and hydrogen [1,2] sigmatropic shifts.[1] Therefore, they are of great interest in syntheses, especially in the preparation of larger heterocycles that contain main-group elements and C–C unsaturated bonds.

Such three-membered heterocyclic compounds with organic substituents at the two olefinic carbon atoms have been reported previously.[1–4] However, species with the simplest M(η^2-C_2H_2) moiety are either discussed on the basis of theoretical calculations,[5] or observed in metal-vapor deposition reactions at 12 K.[6] Among the AlC_2 ring compounds, Et(solvent)Al(η^2-C_2Ph_2) (solvent = Et_2O, THF) and ClAl(η^2-C_2R_2) (R = Me, Et) were assumed to be the respective intermediates in the formation of 1,4-(dialumina)cyclohexadiene and $(ClAl{\cdot}RC{\equiv}CR)_4$.[7] The bulky β-diketiminato ligand L (L = HC(C(Me)NAr)$_2$; Ar = 2,6-*i*Pr$_2$C$_6$H$_3$) was subsequently found to stabilize the ring of the Al(η^2-$C_2R^1R^2$) species (R^1, R^2: $SiMe_3$, Ph). Such compounds have been prepared by the reductive coupling of $LAlI_2$ and potassium in the presence of $R^1C{\equiv}CR^2$.[3] Species with the formula XAl(η^2-C_2H_2) (X = H, Cl) are supported in calculations, yet are considered unstable in comparison with the acyclic isomers.[5d–e] The IR and ESR spectroscopic data on matrix-isolated products from the reaction of AlCl with C_2H_2 confirm the results.[5e] Herein, we show the reaction of the aluminum(I) monomer LAl[8] directly with C_2H_2 in the temperature range from low to room temperature and the successful isolation of the first stable aluminacyclopropene LAl(η^2-C_2H_2) **1**. The subsequent reaction of **1** with C_2H_2 results in the product **2**: LAl(C≡CH)(CH=CH$_2$) (Scheme 1). The reaction of **1** with a large bulky organic azide leads to the unusual aluminaazacyclobutene insertion product **3**: LAl(CH=CHN(N=NAr*)) (Ar* = 2,6-Ar′$_2$C$_6$H$_3$, Ar′ = 2,4,6-Me$_3$C$_6$H$_2$) (Scheme 2).

Scheme 1. The stepwise reaction of LAl with C_2H_2 to **1** and **2**; L = HC(C(Me)NAr)$_2$; Ar = 2,6-*i*Pr$_2$C$_6$H$_3$

Scheme 2. The end-on insertion of N_3Ar* into **1** to form **3**; L = HC(C(Me)NAr)$_2$; Ar = 2,6-*i*Pr$_2$C$_6$H$_3$; Ar* = 2,6-Ar′$_2$C$_6$H$_3$; Ar′ = 2,4,6-Me$_3$C$_6$H$_2$

The reaction of LAl with an excess of carefully dried C_2H_2 in toluene was initially carried out in the temperature range of −78 °C to room temperature. The instant color change of the solution from red to orange and then the slow change to almost colorless was easily observed, and compound **2** was formed. Clearly, the formation of **2** indicates that LAl reacted with two molecules of C_2H_2. When this reaction was controlled in the temperature range between −78 and −50 °C, the red solution only changed to orange (this color change occurred even if the reaction was performed at ≈ −100 °C). By removal of unreacted C_2H_2, the 1:1 adduct LAl(η^2-C_2H_2) **1** was isolated. Notably, when this reaction was continued without the removal of excess C_2H_2, the corresponding ^{1}H NMR spectrum showed the formation of small amounts of **2**, whereas the reaction solution remained orange in color.

Compound **1** was obtained as an orange crystalline solid in quantitative yield and is extremely air-sensitive. Upon exposure to air, the orange color of the solution of **1** immediately becomes colorless. However, **1** is stable in an inert gas atmosphere. It is readily soluble in aromatic solvents and sparingly soluble in nonbranched hydrocarbons. Compound **2** is a colorless crystalline solid and is highly soluble in hydrocarbons. Compounds **1** and **2** were characterized by MS, ^{1}H and ^{13}C NMR spectroscopy, and by X-ray crystallography.[9a–b]

The structural analyses clearly reveal that compound **1** contains the simple Al(η^2-C_2H_2) moiety (Figure 1), whereas **2** contains terminal C≡CH and CH=CH$_2$ groups at the Al cen-

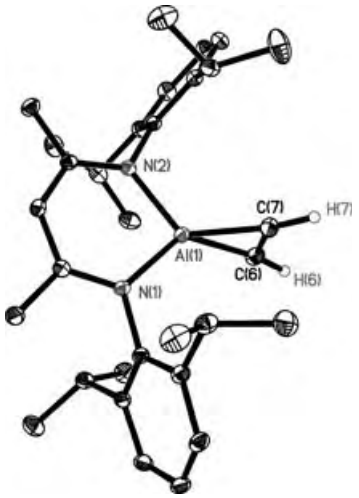

Figure 1. Molecular structure of LAl(η^2-C_2H_2) **1**. Protons in L are omitted for clarity. Selected bond lengths [Å] and angles [°]: Al(1)–N(1) 1.875(1), Al(1)–N(2) 1.884(1), Al(1)–C(6) 1.885(2), Al(1)–C(7) 1.878(2), C(6)–C(7) 1.358(2), C(6)–H(6) 1.000, C(7)–H(7) 1.021; N(1)-Al(1)-N(2) 97.98(5), C(6)-Al(1)-C(7) 42.30(7), Al(1)-C(6)-C(7) 68.57(10), Al(1)-C(7)-C(6) 69.13(10), H(6)-C(6)-C(7) 126.4, H(7)-C(7)-C(6) 127.1.

ter (Figure 2). The latter is the first crystallographically authenticated example of terminal C≡CH and CH=CH_2 groups attached to the same Al center. In **2**, the X-ray reflection data indicate that both CH=CH_2 and C≡CH groups are disordered in two positions (C(6)H(6)C(7)H(7)H(8), C(8)C(9)H(9), 62.2%; C(6A)H(6A)C(7A)H(7A)H(8A), C(8A)C(9A)H(9A), 37.8%). Thus, the central Al ion appears to have a disordered tetrahedral geometry with $\sphericalangle = 96.99(6)°$ for N–Al–N, and $\sphericalangle = 111.6(5)°$ for C–Al–C bond angles (av). The Al–N bond lengths in **1** (1.875(1), 1.884(1) Å) are close to those in **2** (1.895(1), 1.910(2) Å), and are similar to those observed in compounds with four-coordinate β-diketiminato aluminum(III) (1.888(2)–1.935(2) Å).[10] However, they are shorter than the Al–N bonds in LAl (1.957(2) Å) as a result of the Al^I center[8] having a larger radius than that of Al^{III}.

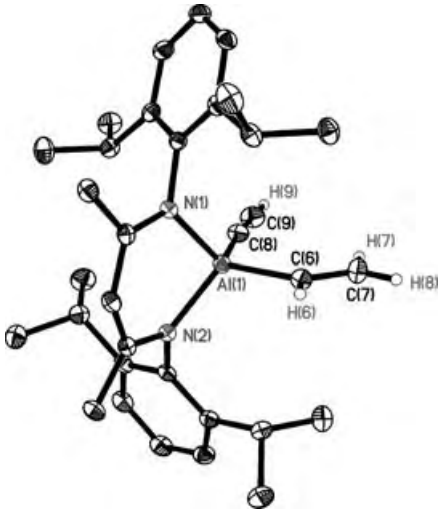

Figure 2. Molecular structure of LAl(C≡CH)(CH=CH_2) **2**, with both C≡CH and CH=CH_2 groups in 62.2% occupation. Protons in L are omitted for clarity. Selected bond lengths [Å] and angles [°]: Al(1)–N(1) 1.910(2), Al(1)–N(2) 1.895(1), Al(1)–C(6) 1.944(11), Al(1)–C(8) 1.962(11), C(6)–C(7) 1.325(17), C(8)–C(9) 1.173(11); N(1)-Al(1)-N(2) 96.99(6), C(6)-Al(1)-C(8) 110.8(4), Al(1)-C(6)-C(7) 124.6(12), Al(1)-C(8)-C(9) 173.9(13).

In **2**, the Al–C bond lengths (Al–$C_{C\equiv C}$ = 1.941(14) Å (av); Al–$C_{C=C}$ = 1.954(14) Å (av)) are similar to those in related compounds $LAlMe_2$ (1.955(4)–1.961(3) Å) and L′$AlMe_2$ (1.958(3)-1.970(3) Å, in which L′ = HC(C(Me)N-*p*-toluene)$_2$).[11] The C≡C (1.170(14) Å (av)) and C=C bond lengths (1.323(18) Å (av)) are indicative of characteristic C-C triple and double bonds, whereas the Al–C≡C (175.4(19)° (av)) and Al–C=C (124.6(14)° (av)) bond angles deviate from the ideal 180° and 120°, respectively.[12] The ^{1}H and ^{13}C NMR spectra of **2** confirm the functional CH=CH_2 and C≡CH groups at the Al center. In the Al–CH=CH_2 moiety, the corresponding protons resonate at $\delta = 5.70$–6.20 ppm; carbon resonances are at $\delta = 125.4$ (=CH_2) and 138.0 ppm (br, Al–*C*H=); both ^{1}H and ^{13}C NMR resonances are within the typical range for alkenyl groups. Furthermore, three groups of double doublets are observed and are indicative for these three protons in a nonequivalent steric environment. The Al–C≡CH group exhibits proton resonance at $\delta = 1.55$ ppm (s) and carbon resonances at $\delta = 94.6$ (br, ≡CH) and 137.3 ppm (br, Al–C≡). The absorptions at 1996 and 3270 cm^{-1} in the IR spectrum of **2** are tentatively assigned to the stretching frequencies of C≡C and ≡C–H bonds.

In **1**, the parameters within the Al(η^2-C_2H_2) moiety (Al–C 1.882(2) Å (av), C–C 1.358(2) Å, C–H 1.010 Å (av); $\sphericalangle$ C–Al–C 42.30(7)°, $\sphericalangle$ Al–C–C 68.85(10)° (av), $\sphericalangle$ H–C–C 126.6° (av)) fit well in comparison with those of Al(η^2-C_2) in LAl(η^2-$C_2R^1R^2$) (R^1 = $SiMe_3$, R^2 = Ph) (Al–C 1.889(2)–1.899(3) Å, C–C 1.356(5)–1.382(4) Å; C–Al–C $\sphericalangle$ 42.02(14)–42.57(11)°, Al–C–C $\sphericalangle$ 68.39(15)–68.80(19)°),[3] and are also much closer to those of the calculated HAl(η^2-C_2H_2) (Al–C 1.844–1.852 Å, C–C 1.362–1.384 Å, C–H 1.076–1.089 Å; H–C–C $\sphericalangle$ 126.8–127.3°).[5d] Notably, in the AlC_2 ring of **1** the average Al–C bond length is shorter than that of **2**, whereas the C–C bond length is longer (standard deviations of 0.072 and 0.036 Å, respectively). This may indicate a conjugated ring system in AlC_2. Furthermore, the ^{1}H and ^{13}C NMR spectra recorded in C_6D_6 show that the proton ($\delta = 8.82$ ppm (s)) and carbon resonances (177.2 ppm (br)) of the Al(η^2-C_2H_2) moiety are in the low-field region characteristic for the alkenyl system. These results indicate a certain aromatic character of the AlC_2 ring in **1**.

The reaction of **1** with a large bulky azide N_3Ar* shows an end-on azide insertion, resulting in the four-membered aluminaazacyclobutene LAl(CH=CHN(N=NAr*)) **3** (Scheme 2). A handful of reactions between monovalent Group 13 compounds and organic azides have been reported.[13] The initial N_2 elimination is generally accepted, and supported by experimental observations.[13e–f] The formation of a five-membered AlN_4 ring in LAl($(NSiMe_3)_2N_2$) was suggested to proceed through a [2+3] cycloaddition of an Al=N intermediate and N_3SiMe_3,[13d] whereas the disubstituted aluminacyclopropene LAl(η^2-$C_2(SiMe_3)_2$) reacted under disassociation and N_2 elimination with a similar bulky

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

azide to an Al=N compound.[3] Accordingly, the end-on N_3Ar^* insertion into the Al–C bond unambiguously reveals the initial interaction between an Al center and the terminal N atom of the azide group. This type of reaction is, to the best of our knowledge, so far unknown. Compound **3** has been well-characterized by spectroscopic, analytical, and X-ray crystallographic measurements.[9c] The molecular structure of **3** is shown in Figure 3.

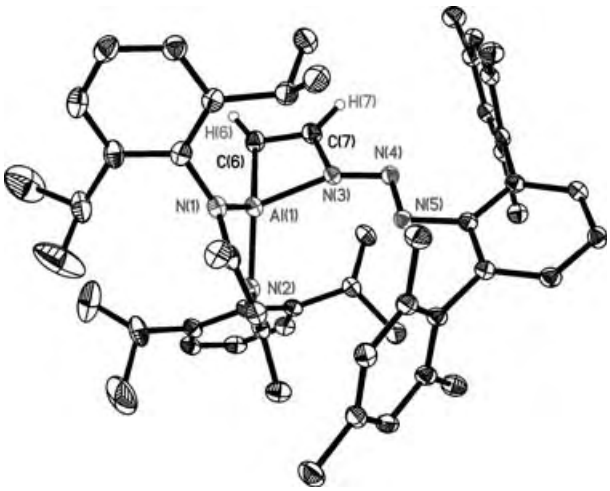

Figure 3. Molecular structure of LAl(CH=CHN(N=NAr*)) (**3**). Protons in L are omitted for clarity. Selected bond lengths [Å] and angles [°]: Al(1)–N(1) 1.866(2), Al(1)–N(2) 1.867(2), Al(1)–N(3) 1.892(2), Al(1)–C(6) 1.932(3), C(6)–C(7) 1.342(4), C(7)–N(3) 1.410(3), N(3)–N(4) 1.320(3), N(4)–N(5) 1.284(3); N(1)-Al(1)-N(2) 99.8(1), C(6)-Al(1)-N(3) 72.6(1), Al(1)-N(3)-C(7) 88.2(2), Al(1)-C(6)-C(7) 88.5(2), C(6)-C(7)-N(3) 110.7(2), N(3)-N(4)-N(5) 112.4(2).

In summary, we have isolated the stable aluminacyclopropene LAl(η^2-C_2H_2) **1** from the reaction of LAl with one equivalent C_2H_2. Further reaction of **1** with another equivalent of C_2H_2 yields LAl(C≡CH)(CH=CH_2) **2**. This may be considered as a prebiotic reaction owing to Al^I species (AlF) and acetylene having been detected spectroscopically in dense interstellar clouds.[14] The crystallographic and NMR spectral data of **1** indicate an electron-delocalized AlC_2 heterocycle, which can be described as a Hückel 2π aromatic system. The Schmidt degradation and Curtius rearrangement of $RC(O)N_3$ to RN=C=O with the elimination of N_2 was described 105 years ago,[15] and the Staudinger reaction in which R_3P interacts with N_3R' via the R_3PNNNR' intermediate to form R_3P=NR′ with the elimination of N_2 was reported in 1919.[16] The reaction of **1** with N_3Ar^* results in an end-on azide insertion to yield an aluminaazacyclobutene LAl(CH=CHN(N=NAr*)) **3**: a novel finding in which degradation or rearrangement of the N_3 moiety is not observed. This reflects the unusual trapping ability of **1**. Current work is focused on experimental confirmation by using **1** to trap small molecules such as NO, N_2O, and CO.

Experimental Section

All manipulations were carried out under a purified nitrogen atmosphere using Schlenk techniques or inside a glove box filled with dry nitrogen in which the calibrated values of O_2 and H_2O were strictly controlled to below 1 ppm.

1: A toluene solution (30 mL) of LAl (0.22 g, 0.5 mmol) at decreased pressure was cooled to −78 °C and exposed to dried C_2H_2. This mixture was kept in the temperature range of −78 °C to −50 °C for 2 h. An instant color change of the solution from red to orange was observed. All volatiles were removed, and an orange crystalline solid of **1** was afforded (> 95 %); m.p. 219 °C; IR (Nujol): $\tilde{\nu}$ = 442.7(w), 529.1(w), 589.8(m), 613.5(w), 647.4(w), 712.7(m), 748.3(w), 758.5(w), 778.2(w), 801.0(s), 867.7(w), 893.9(w), 936.7(w), 1026.0(m), 1055.6(w), 1100.6(m), 1177.4(w), 1260.7(m), 1304.9(w), 1318.7(w), 1410.5(s), 1485.6(s), 1532.8(m), 1653.7(w) cm^{-1}; ^1H NMR (500.13 MHz, [D_6]benzene, 25 °C, TMS): δ = 1.12 (d, ^3J = 6.9 Hz, 4 × 3 H, $CH(CH_3)_2$), 1.46 (d, ^3J = 6.9 Hz, 4 × 3 H, $CH(CH_3)_2$), 1.53 (s, 2 × 3 H, β-CH_3), 3.33 (sept, ^3J = 6.9 Hz, 4 × 1 H, $CH(CH_3)_2$), 4.89 (s, 1 H, γ-CH), 7.02–7.12 (m, 6 H, Ar-*H*), 8.82 ppm (s, 2 × 1 H, Al-η^2-C_2H_2); ^{13}C NMR (125.77 MHz, C_6D_6, 25 °C, TMS): δ = 23.4, 24.4, 24.6, 28.9 ($CH(CH_3)_2$, β-CH_3), 96.5 (γ-*C*), 124.4, 138.8, 143.9 (Ar-*C*), 172.8 (*C*N), 177.2 ppm (broad, Al-η^2-C_2); ^{27}Al NMR (77.13 MHz, C_6D_6, 25 °C, $AlCl_3$): signal too broad to be observed. ^{27}Al NMR (77.13 MHz, [D_8]toluene, −70 °C, $AlCl_3$): signal too broad to be observed. MS: *m*/*z* (%): 469.3 (20) [M^+−1], 455.3 (30) [M^+−Me], 429.3 (100) [M^+−Me−C_2H_2]; elemental analysis (%) calcd for $C_{31}H_{43}AlN_2$ (470.68): C 79.10, H 9.21, N 5.95; found: C 79.43, H 9.18, N 6.03. Single crystals of **1** were obtained by keeping the *n*-hexane/toluene solution of **1** at −26 °C for one week. TMS = tetramethylsilane.

2: The initial procedure (LAl (0.22 g, 0.5 mmol), C_2H_2 (excess), and toluene (30 mL)) is the same as the synthesis of **1**. At −50 °C, the mixture was stirred and warmed to ambient temperature within 48 h, the color of the solution slowly turned to almost colorless. All volatiles were removed in vacuum and the residue was washed with *n*-hexane (2 mL) to afford a colorless crystalline solid of **2** (0.22 g, 90 %); m.p. 163 °C; IR (Nujol): $\tilde{\nu}$ = 1992 (C≡C), 3277 cm^{-1} (≡CH); ^1H NMR (500.13 MHz, [D_8]toluene, 25 °C, TMS): δ = 1.08 (d, ^3J = 6.8 Hz, 2 × 3 H, $CH(CH_3)_2$), 1.25 (d, ^3J = 6.8 Hz, 2 × 3 H, $CH(CH_3)_2$), 1.28 (d, ^3J = 6.8 Hz, 2 × 3 H, $CH(CH_3)_2$), 1.44 (d, ^3J = 6.8 Hz, 2 × 3 H, $CH(CH_3)_2$), 1.55 (s, 2 × 3 H, β-CH_3), 1.73 (s, 1 H, C≡C*H*), 3.23 (sept, ^3J = 6.8 Hz, 2 × 1 H, $CH(CH_3)_2$), 3.81 (sept, ^3J = 6.8 Hz, 2 × 1 H, $CH(CH_3)_2$), 4.91 (s, 1 H, γ-CH), 5.79 (dd, $^3J_{(trans)}$ = 20.9 Hz, ^2J = 6.4 Hz, 1 H), 6.04 (dd, $^3J_{(cis)}$ = 16.5 Hz, ^2J = 6.4 Hz, 1 H), 6.12 (dd, $^3J_{(trans)}$ = 20.9 Hz, $^3J_{(cis)}$ = 16.5 Hz, 1 H), (*CH*=CH_2), 6.97–7.12 ppm (m, 6 H, Ar-*H*); ^{13}C NMR (125.76 MHz, [D_8]toluene, 25 °C, TMS): δ = 23.4, 24.5, 24.7, 24.8, 27.2, 28.2, 28.6 ($CH(CH_3)_2$, β-CH_3), 94.6 (broad, ≡CH), 98.4 (γ-*C*), 124.1, 124.8, 127.5, 128.8, 129.2, 137.1, 140.3, 143.7, 145.4 (Ar-*C*), 125.4, (=CH_2), 137.3 (broad, Al-*C*≡), 138.0 (broad, Al-*C*=), 170.6 ppm (*C*N); MS: *m*/*z* (%): 496.4 (15) [M^+], 469.4 (100) [M^+−CH=CH_2]; elemental analysis (%) calcd for $C_{33}H_{45}AlN_2$ (496.72): C 79.80, H 9.13, N 5.64; found: C 79.26, H 9.18, N 5.56. Single crystals of **2** were grown from the *n*-hexane solution of **2** at 4 °C within one week.

3: Toluene (25 mL) was added to a mixture of **1** (0.24 g, 0.5 mmol) and N_3Ar^* (0.18 g, 0.5 mmol) at −50 °C. The suspension was stirred and allowed to warm to room temperature. After stirring for 12 h, removal of the solvent and washing with *n*-hexane (2 mL) afforded **3** as an orange crystalline solid (0.37 g, 90 %); m.p. 215 °C; ^1H NMR (300.13 MHz, [D_6]benzene, 25 °C, TMS): δ = 1.02 (d, ^3J = 6.8 Hz, 2 × 3 H, $CH(CH_3)_2$), 1.05 (d, ^3J = 6.8 Hz, 2 × 3 H, $CH(CH_3)_2$), 1.16 (d, ^3J = 6.8 Hz, 4 × 3 H, $CH(CH_3)_2$), 1.50 (s, 2 × 3 H, β-CH_3), 2.23 (s, 2 × 3 H), 2.27 (s, 4 × 3 H, *Me*(in Ar′)), 2.83 (sept, ^3J = 6.8 Hz, 2 × 1 H, $CH(CH_3)_2$), 3.03 (sept, ^3J = 6.8 Hz, 2 × 1 H, $CH(CH_3)_2$), 4.92 (s, 1 H, γ-CH), 5.03 (d, $^3J_{(cis)}$ = 7.6 Hz, 1 H), 7.51 (d, $^3J_{(cis)}$ = 7.6 Hz, 1 H), (*HC*=C*H*), 6.83, 6.97–7.12 (m), 7.15 ppm (14 H, Ar-*H*, Ar*-*H*, Ar′-*H*); ^{13}C NMR (75.47 MHz, [D_6]benzene, 25 °C, TMS): δ = 21.3, 22.3, 23.0, 23.2, 24.4, 24.7, 25.0, 25.8, 26.7, 29.1, 31.9 ($CH(CH_3)_2$, β-CH_3, *Me*(Ar′)), 100.5 (γ-*C*), 114.8 (broad, Al-*C*=), 123.5, 123.8, 125.1, 130.9, 134.2, 136.0, 138.5, 141.6, 146.2, 147.3 (Ar-*C*, Ar*-*C*, Ar′-*C*), 162.4 (N-*C*(H)=), 171.9 ppm (*C*N); MS: *m*/*z* (%): 825 (5) [M^+−1], 417 (100) [M^+−N_3Ar^*−C_2H_2−Al]; elemental analysis (%) calcd for $C_{55}H_{68}AlN_5$ (826.17): C 79.96, H 8.30, N 8.48; found: C 79.28,

[9] a) Crystal data for **1**: $C_{31}H_{43}AlN_2$, $M_r = 470.65$, monoclinic, space group $P2_1/n$, $a = 12.199(1)$, $b = 16.932(1)$, $c = 13.974(1)$ Å, $\beta = 103.87(1)°$, $V = 2802(1)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.116$ Mg m^{-3}, $F(000) = 1024$, $\lambda = 0.71073$ Å, $T = 133(2)$ K, $\mu(Mo_{K\alpha}) = 0.093$ mm^{-1}; 29105 measured reflections, 4818 independent ($R_{int} = 0.0486$). The final refinements converged at $R1 = 0.0349$ and $wR2 = 0.0867$ for $I > 2\sigma(I)$ and $R1 = 0.0502$ and $wR2 = 0.0916$ for all data. Fourier synthesis gave a min/max residual electron density $-0.255/+0.263$ e Å^3; b) crystal data for **2**: $C_{33}H_{45}AlN_2$, $M_r = 496.69$, monoclinic, space group $P2_1/n$, $a = 18.844(4)$, $b = 8.732(2)$, $c = 20.080(4)$ Å, $\beta = 112.61(1)°$, $V = 3050(1)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.082$ Mg m^{-3}, $F(000) = 1080$, $\lambda = 0.71073$ Å, $T = 133(2)$ K, $\mu(Mo_{K\alpha}) = 0.089$ mm^{-1}; 14544 measured reflections, 5145 independent ($R_{int} = 0.0394$). The final refinements converged at $R1 = 0.0364$ and $wR2 = 0.0820$ for $I > 2\sigma(I)$ and $R1 = 0.0582$ and $wR2 = 0.0877$ for all data. Fourier synthesis gave a min/max residual electron density $-0.208/+0.163$ e Å^3; c) crystal data for **3**: $C_{58}H_{75}AlN_5$, $M_r = 869.21$, monoclinic, space group $P2_1/c$, $a = 22.289(5)$, $b = 13.057(3)$, $c = 18.765(4)$ Å, $\beta = 109.71(3)°$, $V = 5141(2)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.123$ Mg m^{-3}, $F(000) = 1884$, $\lambda = 0.71073$ Å, $T = 133(2)$ K, $\mu(Mo_{K\alpha}) = 0.081$ mm^{-1}; 53490 measured reflections, 8850 independent ($R_{int} = 0.0825$). The final refinements converged at $R1 = 0.0560$ and $wR2 = 0.1371$ for $I > 2\sigma(I)$ and $R1 = 0.0933$ and $wR2 = 0.1508$ for all data. Fourier synthesis gave a min/max residual electron density $-0.437/+0.589$ e Å^3. The crystallographic data for **1**–**3** were collected on a Stoe IPDS II-array detector system using graphite-monochromated $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å). Intensity measurements were performed on a rapidly cooled crystal with dimensions $0.40 \times 0.40 \times 0.30$ mm^3 in the range $1.92 \le \theta \le 24.83°$ for **1**, with $0.30 \times 0.30 \times 0.30$ mm^3 in $1.89 \le \theta \le 24.82°$ for **2**, and with $0.20 \times 0.10 \times 0.10$ mm^3 in $1.84 \le \theta \le 24.87°$ for **3**. The structures were solved by direct methods (SHELXS-97)[17] and refined with all data by full-least-squares against F^2.[18] The non-hydrogen atoms were located by difference Fourier synthesis and refined anisotropically, in which the C≡CH and CH=CH_2 groups in **2** are both disordered and located in two positions with the same occupation ratio of 0.622/0.378. The hydrogen atoms except for H(6) and H(7) in **1** and **3** were included in geometrically idealized positions with the *U*iso tied to that of the parent atoms and were refined with the riding model. H(6) and H(7) in **1** and **3** were located by difference Fourier synthesis and refined isotropically. CCDC-265784 (**1**), 265785 (**2**), and 265786 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Pd-Catalyzed Stereospecific Azide Substitution of α,β-Unsaturated γ,δ-Epoxy Esters with Double Inversion of Configuration**

Masaaki Miyashita, Taiku Mizutani, Genta Tadano, Yasuhiro Iwata, Masahiro Miyazawa, and Keiji Tanino*

Over recent years, much interest has been focused on the development of not only a stereoselective but also a practical methodology for the synthesis of chiral β-amino alcohols,[1] α-amino acids,[2] and α,α-disubstituted amino acids[2–4] (including natural and unnatural congeners) in the context of medicinal chemistry. Although many synthetic approaches to these biologically important compounds have been reported,[1–4] there is still a need for a new type of methodology that allows the stereospecific synthesis of functionalized amino alcohols and amino acids that bear contiguous chiral centers. We report herein an approach that permits the highly stereoselective synthesis of a variety of amino alcohols, amino acids, and quaternary amino acids, including acyclic and cyclic congeners. This methodology involves the palladium-catalyzed stereospecific azide substitution reaction of α,β-unsaturated γ,δ-epoxy esters with a double inversion of configuration as the key step.

In connection with our recent studies on the palladium-catalyzed stereospecific hydroxy substitution reactions of unsaturated γ,δ-epoxy esters with phenylboronic acid[5] and boric acid[6] with a double inversion of configuration, we anticipated that the palladium-catalyzed azide substitution reaction of α,β-unsaturated γ,δ-epoxy esters with an appropriate azide reagent might occur by a similar π-allyl palladium species to afford an azide substitution product with double inversion of configuration, as shown in Scheme 1. Namely, this new method involves two consecutive S_N2 processes to afford a substitution product with double inversion of configuration in contrast with the normal S_N2 epoxide-opening reactions.[7]

Initially, we chose ethyl *trans*-4,5-epoxy-(2*E*)-octenoate (**1**)[5] as a model substrate and examined its palladium-catalyzed reaction with $TMSN_3$ to confirm whether such a reaction indeed takes place. Thus, first $TMSN_3$ (2 equiv) then

Scheme 1. Pd^0-catalyzed stereospecific azide substitution reaction of unsaturated γ,δ-epoxy esters with double inversion of configuration. TMS = trimethylsilyl, Boc = *tert*-butoxycarbonyl, L = ligand.

a palladium catalyst ($[Pd(PPh_3)_4]$ (10 mol %)) was added to a solution of **1** in THF and the mixture was stirred at room temperature for 20 minutes. The reaction was then quenched with a solution of citric acid in MeOH. The azide substitution reaction of **1** with double inversion of configuration did occur at the γ-position to afford a single *syn* azido alcohol **2** in 90 % yield of the isolated product after purification by chromatography on silica gel (Scheme 2). The configuration of the product was unambiguously determined by NOE interaction studies of its δ-lactone derivative **3**, which was readily derived from **2** by catalytic hydrogenation in the presence of di-*tert*-butyl dicarbonate (Boc_2O)[8] followed by lactonization with PPTS in dichloroethane (Scheme 2). It should be noted that the present palladium-catalyzed azide substitution reaction took place not only in high yield but also with complete stereoselectivity, thus giving rise to the single product with a double inversion of configuration.

Scheme 2. Pd^0-catalyzed azide substitution reaction of ethyl *trans*-4,5-epoxy-(2*E*)-octenoate (**1**): a) $TMSN_3$ (2 equiv), $[Pd(PPh_3)_4]$ (10 mol%), THF, RT, 20 min (90%); b) H_2, PtO_2, Boc_2O, EtOAc, RT, 5 h (84%); c) PPTS, $ClCH_2CH_2Cl$, 90°C, 3 h (96%). Ac = acetate, PPTS = pyridinium *para*-toluenesulfonate, Boc = *tert*-butoxycarbonyl.

These excellent preliminary results led us to examine the scope of the new synthetic methodology with various substrates (Table 1). Thus, the reaction of ethyl 6-benzyloxy-*trans*-4,5-epoxy-(2*E*)-hexenoate (**4**) proceeded cleanly to furnish the *syn* azido alcohol **5** as a single product in 97% yield (Table 1, entry 1). On the other hand, the reaction of a unsaturated *cis* epoxy ester **6** afforded an *anti* azido alcohol **7** in 95% yield (Table 1, entry 2), and a benzyloxy-substituted substrate **8** similarly produced the *anti* isomer **9** in 93% yield with complete stereoselectivity (Table 1, entry 3). Furthermore, a trisubstituted unsaturated epoxy ester **10** containing a methyl group at the γ-position reacted smoothly to produce a *syn tert*-azido alcohol **11** in 93% yield. It is critical to add $TMSN_3$ first to the substrate in solution then the palladium catalyst for a successful reaction. Thus, the palladium-catalyzed azide substitution reaction of acyclic unsaturated γ,δ-epoxy esters was shown to occur stereospecifically at the γ-position with complete stereoselectivity, namely, with double inversion of configuration, regardless of the configuration and substitution pattern of the epoxide substrates.

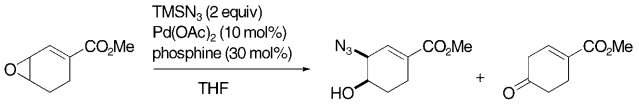

Table 1: Pd^0-catalyzed azide substitution reactions of acyclic α,β-unsaturated γ,δ-epoxy esters with $TMSN_3$ in THF.[a]

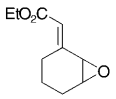
Entry	Substrate		*t*	Product		Yield [%][b]	*syn*/*anti*
1		**4**	20 min		**5**	97	>99:1
2		**6**	1 h		**7**	95	>1:99
3		**8**	2 h		**9**	93	>1:99
4		**10**	8 h		**11**	93	>99:1

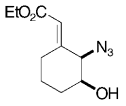
[a] The reaction was carried out with $TMSN_3$ (2 equiv) and $[Pd(PPh_3)_4]$ (10 mol%) in THF at room temperature. [b] Yield of isolated product. Bn = benzyl.

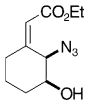
Next, we focused on the azide substitution reaction of cyclic unsaturated epoxy esters, since Tsuda, Saegusa, and coworkers reported that the Pd^0-catalyzed reaction of an α,β-unsaturated γ,δ-epoxy ester containing a cyclohexane ring with nitrogen nucleophiles did not produce the corresponding substitution products at all.[9] To probe the behavior of cyclic substrates, we initially examined the reaction of methyl 3,4-epoxy-1-cylochexenecarboxylate (**12**).[10] Contrary to our expectations, however, the reaction of **12** under the same conditions as those for acyclic substrates was fruitless. Namely, the reaction of **12** with $TMSN_3$ (2 equiv), $Pd(OAc)_2$ (10 mol%), and PPh_3 (30 mol%) in THF afforded ketone **14** as the unexpected major product (61% yield), along with a smaller amount of the desired product **13** (37% yield; Table 2, entry 1). Therefore, we examined in detail the effect of a phosphine ligand on the reaction, and it was found that the azide substitution reaction of **12** was critically dependent on the nature of the phosphine ligand: The use of $PnBu_3$ was totally ineffective, and a large amount of the starting material was recovered (Table 2, entry 2). Similarly, the reaction with a bulky phosphine, such as $P(C_6H_{11})_3$, $P(tolyl)_3$, or $PtBu_3$, merely resulted in the recovery of the starting material. However, the use of $P(OiPr)_3$ gave a similar result to that of PPh_3 (Table 2, entry 3). In contrast to these ligands, P(2-furyl)$_3$ was found to improve this particular reaction dramatically. Thus, the reaction of **12** with $TMSN_3$ (2 equiv), $Pd(OAc)_2$ (10 mol%), and P(2-furyl)$_3$ (30 mol%) in THF produced the desired product **13** in 87% yield along with 13% yield of **14** (Table 2, entry 4). It is noteworthy that the reaction with P(2-furyl)$_3$ was very fast and was completed in 5 minutes at 0°C, thus producing **13** in high yield. The configuration of **13** was determined unambiguously by X-ray crystallographic analysis of its *para*-bromobenzoate derivative. In turn, we examined the stoichiometry in which P(2-furyl)$_3$ was added and the effect of the solvent on the reaction, and it was found eventually that the use of 25 mol% of P(2-furyl)$_3$ in THF gave the best result. Under these conditions, the desired product **13** was obtained in 96% yield of isolated product and the formation of **14** was suppressed to less than 4% (Table 2, entry 5).[11]

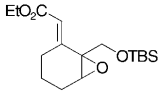
Table 2: Pd^0-catalyzed azide substitution reactions of cyclic unsaturated γ,δ-epoxy ester **12** with $TMSN_3$ in THF.[a]

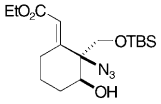
12 **13** **14**











Entry	Phosphine	*T* [°C]	*t*	Yield [%] **13**	**14**
1	PPh_3	RT	5 min	37	61
2	$PnBu_3$	0→50	4 h	<2	10
3	$P(OiPr)_3$	0	5 min	39	57
4	P(2-furyl)$_3$	0	5 min	87	13
5[b]	P(2-furyl)$_3$	0	5 min	96	4

[a] The reaction was carried out by adding a premixed solution of $Pd(OAc)_2$ (5 mol%) and P(2-furyl)$_3$ (30 mol%) in THF. [b] The reaction was carried out with 25 mol% of P(2-furyl)$_3$.

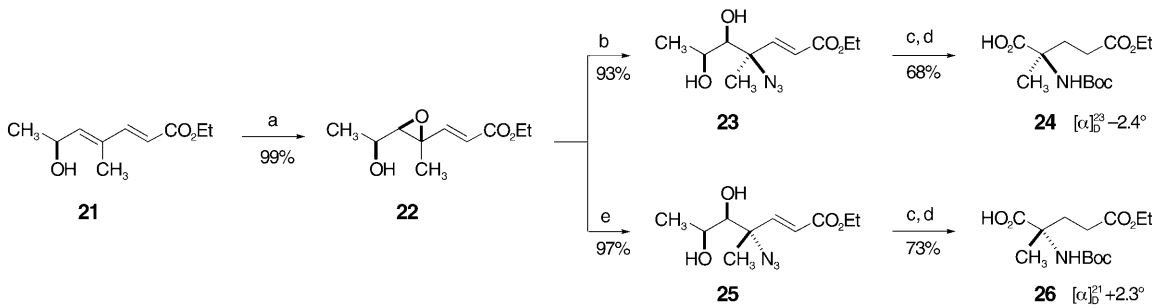
We then applied these optimized conditions to various cyclic substrates (Table 3). Both the *Z*-unsaturated ester **17**[12] and the cyclic *E*-unsaturated γ,δ-epoxy ester **15**[12] (as seen previously) were found to react smoothly under these conditions (Table 3, entries 2 and 1, respectively), thus furnishing the corresponding azide substitution products **18** and **16**, respectively. It should be noted that products **16** and **18** were obtained in remarkably high yields, whereas they had been inaccessible using the previously reported method.[9] Contrary to our expectations, a trisubstituted unsaturated epoxy ester **19**[13] did not react at all under similar conditions and the starting material was recovered (Table 3, entry 3). Fortunately, we found that the reaction of **19** with $TMSN_3$ and $[Pd(PPh_3)_4]$ in *N*,*N*-dimethylformamide (DMF) proceeded smoothly at 50 °C and gave rise to the desired product **20** in 92% yield (Table 3, entry 4).[14] These results demonstrate unambiguously that the palladium-catalyzed azide substitution reaction of unsaturated γ,δ-epoxy esters with acyclic and cyclic substrates occurs stereospecifically at the γ-position with double inversion of configuration, thus producing azido alcohols in high yields regardless of the stereochemistry of the epoxide and unsaturated ester moieties.

Table 3: Pd^0-catalyzed azide substitution reactions of cyclic unsaturated epoxy esters with $TMSN_3$.[a]



Entry	Substrate		Ligand	Solvent	*t* [h]	Product		Yield [%]
1[b]		**15**	$P(2\text{-furyl})_3$	THF	1		**16**	98
2		**17**	$P(2\text{-furyl})_3$	THF	1		**18**	quant.
3		**19**	$P(2\text{-furyl})_3$	THF	4		**20**	trace
4[c]		**19**	PPh_3	DMF	6		**20**	92

[a] The reaction was carried out by adding a mixture of $Pd(OAc)_2$ (5 mol%) and the phosphine (25 mol%) in THF to a solution of each substrate and $TMSN_3$ (2 equiv) in THF at room temperature. [b] After the reaction mixture had been stirred for 50 min at room temperature, $Pd(OAc)_2$ (5 mol%) and the phosphine (25 mol%) were added and then the mixture was stirred for an additional 10 min at room temperature. [c] The reaction was carried out in DMF at 50 °C using $TMSN_3$ (2 equiv) and $[Pd(PPh_3)_4]$ (10 mol%); $[Pd(PPh_3)_4]$ (10 mol%) was added after 2.5 and 4.5 h, respectively. TBS = *tert*-butyldimethylsilyl, quant. = quantitative yield.

To demonstrate the synthetic potential of the current method, we performed a stereospecific synthesis of both (*R*)- and (*S*)-*N*-*tert*-butoxycarbonyl-α-methylglutamic acid γ-ethyl ester (**24** and **26**, respectively; Scheme 3). Thus, treatment of the diene ester **21**, which is readily derived from ethyl (*S*)-lactate, with *meta*-chloroperoxybenzoic acid (*m*CPBA) in CH_2Cl_2 led to unsaturated β-epoxy ester **22** being obtained as a single product in quantitative yield. When the unsaturated epoxy ester **22** was subjected to the palladium-catalyzed azide substitution reaction under the conditions employed for acyclic substrates, azido alcohol **23** was produced exclusively in 93% yield with double inversion of configuration. In contrast, the reaction of **22** with NaN_3 and $[Ti(OEt)_4]$ in DMF under modified Sharpless conditions[15] proceeded through an S_N2 process to afford the single azido alcohol **25** in 97% yield. These products were efficiently transformed into **24** and **26** by the two-step reaction sequence of 1) concomitant hydrogenation of the double bond and the azido group over the Adams catalyst in EtOAc in the presence of Boc_2O[8] and 2) oxidative cleavage of the diol moiety with $RuCl_3$ and $NaIO_4$ in $CCl_4/H_2O/CH_3CN$.[16] The two enantiomers **24** and **26** were efficiently and highly stereoselectively prepared starting from the same compound **21** by applying two contrasting azide substitution reactions.

In summary, we have developed a palladium-catalyzed azide substitution reaction of α,β-unsaturated γ,δ-epoxy esters with $TMSN_3$ that occurs stereospecifically at the γ-position to produce azido alcohols in excellent yields with double inversion of configuration. This new method is widely applicable to various acyclic and cyclic substrates and provides a powerful tool in the synthesis of functionalized β-amino alcohols and α-amino acids, including α,α-disubstituted amino acids. Further investigations into the synthetic applications of this methodology are ongoing.

Control of Differential Inclusion Complexation in the Solid State by Seed Crystals**

Kazuhiro Yoshizawa, Shinji Toyota, Fumio Toda, Spyros Chatziefthimiou, Petros Giastas, Irene M. Mavridis, and Masako Kato*

Simple phenol and naphthol derivatives include various guest compounds through host–guest hydrogen bonds to produce crystalline inclusion complexes.[1] As these inclusion complexation processes occur selectively, separation of isomers and enantiomers can be carried out upon complexation.[2] Of these phenol and naphthol derivatives, 2,2′-dihydroxy-1,1′-binaphthyl (**1**) is the most interesting host compound because of its axel-asymmetric structure. As optically active **1** precisely recognizes the chirality of the guest molecule it includes, enantiomeric separation of the guest can be

performed easily.[3] However, inclusion complexation of guest compounds with racemic **1** has not been extensively studied to date. Herein, we report that differential inclusion complexation between racemic host **1** and simple gaseous guests in the solid state can be controlled by a seed crystal. We also report that inclusion complexation of **1** with gaseous guests in the solid state occurs only in the presence of a seed crystal.

First, inclusion complexes were prepared by recrystallization of **1** from the liquid guests indicated in Table 1. Four types of inclusion patterns are possible according to the host/guest ratio, namely, with 1:2, 1:1, 2:3, and 3:1 stoichiometries. Interestingly, Et_2O formed two types of inclusion complexes with host/guest ratios of 1:2 and 3:1. The 1:2 complex, **2**, loses Et_2O at a relatively lower temperature (40–61 °C) than the 3:1 complex **3** does (87–108 °C). X-ray crystal structural studies showed that **2** has a loose structure (Figure 1), whereas **3** has a more compact and rigid structure (Figure 2). In complex **2**, Et_2O probably evaporates easily through the channel shown in Figure 1. In complex **3**, however, the molecule of Et_2O is trapped tightly, surrounded by three host molecules.

Table 1: Properties of inclusion complexes of **1** with various liquid guests.

Guest	Host/guest ratio[a]	Decomposition temperature [°C]	$\tilde{\nu}$OH [cm^{-1}][b]
Et_2O	3:1	87–108	3419, 3459, 3489
Et_2O	1:2	40–61	3198
	1:2	37–74	3198
THF	2:3	48–106	3173, 3519
	2:3	61–116	3248
MeOAc	3:1	83–108	3403, 3463, 3491
EtOAc	3:1	75–105	3413, 3464, 3490
	1:2	87–128	3366
$Me_2C=O$	1:1	70–98	3036, 3404
	1:1	79–107	3321, 3419
	1:1	87–117	3264, 3417
	1:2	94–121	3199
	1:2	97–141	3198

[a] The ratio was determined by ^1H NMR spectroscopy and thermogravimetric analysis. [b] IR spectra were measured using the ATR (attenuated total reflectance) method.

Interestingly, **2** and **3** could also be prepared by recrystallization of **1** (0.2 g) from 3 and 5 mL of Et_2O to give **3** and **2**, respectively (Scheme 1). The more stable complex **3** ($(\mathbf{1})_3{\cdot}Et_2O$) formed preferentially when the complexation was performed rapidly from a concentrated solution. When the complexation was performed slowly from a diluted solution, the less stable **2** ($\mathbf{1}{\cdot}(Et_2O)_2$) crystallized out. This is the first example of differential inclusion complexation by controlling the concentration of the solution, although differential complexations by controlling the temperature[3] or the type of solvent used for crystallization[4] have also been reported. However, when **1** (0.2 g) was recrystallized from an intermediate volume of Et_2O (4 mL), either **2** or **3** formed

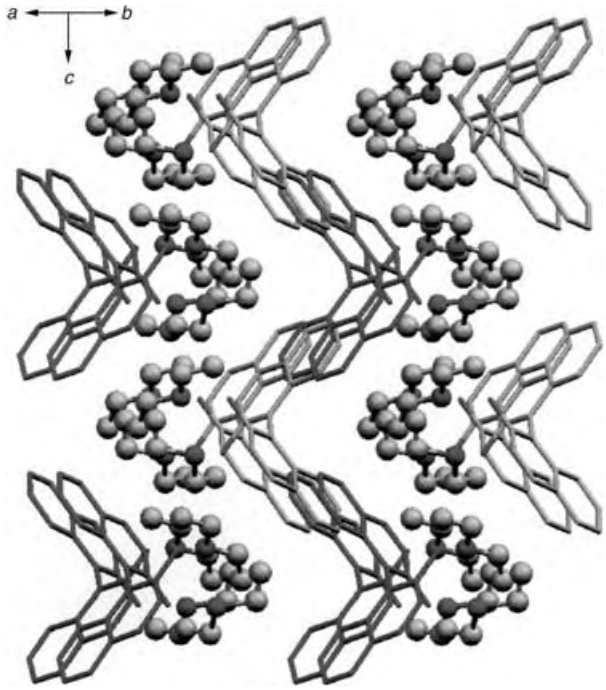

Figure 1. Crystal structure of **2** ($\mathbf{1}{\cdot}(Et_2O)_2$).

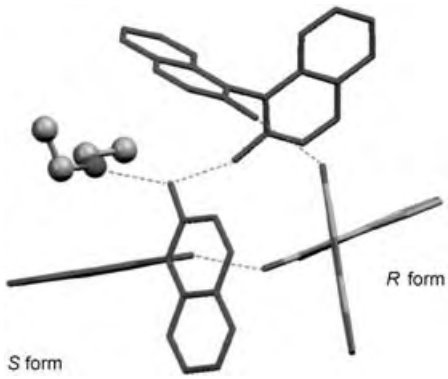

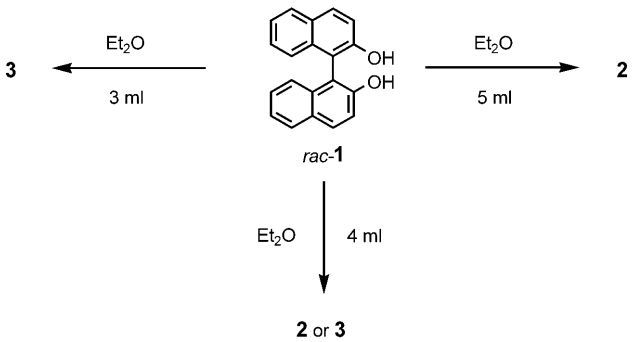

Figure 2. Crystal structure of **3** ($(\mathbf{1})_3{\cdot}Et_2O$).

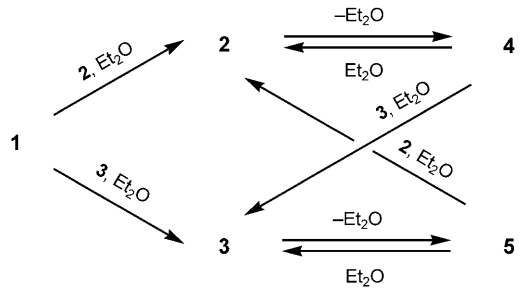

Scheme 1. Inclusion complexation of host **1** and guest Et_2O by recrystallization of **1** from solutions in Et_2O at different concentrations.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

depending on the specific conditions. The pattern of the complexation could be controlled by the seed crystal which formed initially, and this was confirmed by the following seed crystal experiments: Recrystallization of **1** (0.2 g) from 3 and 4 mL of Et_2O by adding one seed crystal of **2** led to formation of **2**; similar recrystallization of **1** (0.2 g) from 3 and 4 mL of Et_2O by adding one seed crystal of **3** led to formation of **3**.

Surprisingly, these seed crystal experiments could also be carried out in the solid state. First, Et_2O (guest)-free hosts **4** and **5** were prepared by evaporation of the guest from **2** and **3**, respectively, by heating at 50 °C under 20 mmHg. Contact of **4** and **5** with Et_2O vapor at room temperature for 12 and 3 h, respectively, gave **2** and **3**, respectively (Scheme 2). These

Scheme 2. Seed crystal experiments in the inclusion complexation between solid host **1** and gaseous guest Et_2O.

data strongly suggest that **4** and **5** "remember" the original inclusion pattern of **2** and **3**, respectively. Nevertheless, no structural differences between **4** and **5** could be observed by IR spectroscopy or X-ray powder diffraction studies. There is a possibility that **4** and **5** still keep a small amount of Et_2O guest molecules in their inclusion cavities and that these inclusion complex lattices play a role as the seed crystal during complexation in the solid state. When a mixture of powdered **4** and a seed crystal of **3** (2 wt %) was exposed to Et_2O vapor for 3 h, **4** was converted into **3** ($(\mathbf{1})_3{\cdot}Et_2O$) in quantitative yield. By similar contact of a powdered mixture of **5** and a seed crystal of **2** (2 wt %) for 12 h, **5** was converted into **2** ($\mathbf{1}{\cdot}(Et_2O)_2$). Furthermore, contact of a powdered mixture of **1** (98 mg, 0.34 mmol) and **2** (2 mg, 4.6 μmol; 2 wt %, 1.35 mol %) with Et_2O vapor for 12 h gave **2** in quantitative yield (Scheme 2). Similar contact of a powdered mixture of **1** (98 mg, 0.34 mmol) and **3** (2 mg, 2.1 μmol; 2 wt %, 0.62 mol %) with Et_2O vapor for 3 h gave **3** in quantitative yield. However, contact of powdered **1** with Et_2O vapor in the absence of a seed crystal for 72 h did not lead to the formation of any inclusion complexes.

Seed crystals were also effective for the inclusion complexation of **1** with some other guests. Contact of powdered **1** with gaseous MeOAc and EtOAc for 3 h in the presence of seed crystals of inclusion complexes $(\mathbf{1})_3{\cdot}$MeOAc and $(\mathbf{1})_3{\cdot}$EtOAc, respectively, led to the corresponding inclusion complexes in quantitative yields. Inclusion complexation of **1** and gaseous cyclopentyl methyl ether (CPME) in the presence of a seed crystal of the 1:2 complex $\mathbf{1}{\cdot}(CPME)_2$ for 12 h gave the same inclusion complex as the complex of the seed crystal in quantitative yield. In all of the cases studied, inclusion complexation did not occur in the absence of the seed crystal.

IR spectral data of inclusion complexes of **1** with different guests but at the same host/guest ratio were similar to each other, and the complexes decomposed at similar temperatures (Table 1). The complexes at the same host/guest ratio also have similar solid-state structures. For example, the crystal structures of **2** ($\mathbf{1}{\cdot}(Et_2O)_2$) and the 1:2 complex of **1** with CPME ($\mathbf{1}{\cdot}(CPME)_2$) are very similar, while the crystal structures of **3** ($(\mathbf{1})_3{\cdot}Et_2O$) and the 3:1 complex of **1** with EtOAc[6] ($(\mathbf{1})_3{\cdot}$EtOAc) are also very similar. However, the crystal structure of a 1:2 complex of **1** with 2-cyclohexenone is completely different to that of **2**, and the structures of 2:3 complexes of **1** with THF and 1,4-dioxane are also different.[7]

These data suggest that a crystal of an inclusion complex is effective as a pseudo seed crystal for the formation of a complex at the same host/guest ratio but with a different guest compound (Table 2). For example, contact of powdered **1**

Table 2: Inclusion complexation of powdered **1** and gaseous guests in the presence of a pseudo seed crystal.

Guest in seed crystal (**1**/guest ratio)	Gaseous guest	Reaction time [h]	Guest in product (**1**/guest ratio)
MeOAc (3:1)	EtOAc	3	EtOAc (3:1)
MeOAc (3:1)	Et_2O	3	Et_2O (3:1)
EtOAc (3:1)	MeOAc	3	MeOAc (3:1)
EtOAc (3:1)	Et_2O	3	Et_2O (3:1)
Et_2O (3:1)	MeOAc	3	MeOAc (3:1)
Et_2O (1:2)	CPME	12	CPME (1:2)
CPME (1:2)	Et_2O	12	Et_2O (1:2)
MeOAc (3:1)	CPME	12	–
Et_2O (3:1)	CPME	12	–

with gaseous EtOAc for 3 h in the presence of seed crystal $(\mathbf{1})_3{\cdot}$MeOAc gave the complex $(\mathbf{1})_3{\cdot}$EtOAc, also in a 3:1 host/guest ratio. Similar contact of **1** with gaseous guests in the presence of seed crystals of complexes with host/guest ratios as anticipated in the products indeed gave quantitative yields of inclusion complexes with the same host/guest ratio as those of the seed. These data clearly show the high efficiency of the pseudo seed crystal. However, contact of **1** with gaseous guests in the presence of seed crystals that have a different host/guest ratio from those of the expected product did not afford any inclusion complexes. In the last two examples shown in Table 2, seed crystals $(\mathbf{1})_3{\cdot}$MeOAc and $(\mathbf{1})_3{\cdot}Et_2O$ did not work as seed crystals for the complexation of **1** with CPME, which forms only the 1:2 host/guest complex. In all the cases studied, 3:1 host/guest complexes were formed more easily than those at a 1:2 ratio.

The efficient role of the seed crystal for inclusion complexation in the solid state is fascinating and has not been reported until now. As far as we are aware, only one report of a seed crystal experiment has been described in which the transformation among three polymorphs of chloramphenicol palmitate in the solid state proceeded two times faster in the presence of a seed crystal.[8] The present findings on the role of seed crystals will become useful in many

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

scientific fields and will give various hints to develop new technologies.

Although the mechanism of the role of seed crystals is interesting, it is not easy to clarify. However, as it has been established that molecules in a crystal move quite easily in the solid state,[9] easy movement of gaseous molecules into the crystal is understandable. Surprisingly, host **1** which has a helical structure with a twofold symmetry axis[10] is converted efficiently into a sheet structure in **2** and a cyclic structure in **3** in the solid state upon contact with Et_2O vapor in the presence of a seed crystal.

Nanoparticle PCR: Nanogold-Assisted PCR with Enhanced Specificity**

Haikuo Li, Jiehuan Huang, Junhong Lv, Hongjie An, Xiaodong Zhang, Zhizhou Zhang, Chunhai Fan,* and Jun Hu**

The polymerase chain reaction (PCR) revolutionized molecular genetics and has become one of the most popular techniques in modern biological and medical sciences.[1] Owing to the exponential amplification ability of PCR, one could start from even a single copy of target DNA to produce large amounts of DNA copies for sequencing, molecular diagnosis, or genetic analysis.[2–4] This remarkable amplification ability is critical in many circumstances, such as early-stage diagnosis of HIV or cancers. Given the rapidly increasing interest in optoelectronic DNA biosensors, the extremely high detection sensitivity of PCR has not been surpassed until now.[5–9] However, the specificity of PCR does not match its unparalleled sensitivity.[10] It is well known that even with sophisticated optimization, PCR specificity is not always satisfactory (e.g. in multiple-round PCR or multiplex PCR).[10] Herein, we report a novel PCR method that employs inexpensive gold nanoparticles to effectively avoid nonspecific PCR reactions.

Gold nanoparticles have found broad and important applications in biology; for example, a variety of ultrasensitive biosensor strategies have been reported which take

advantage of gold nanoparticles.[8,9,11–14] Gold nanoparticles are nontoxic, biocompatible nanomaterials that can be either obtained from commercial sources or conveniently produced in laboratories,[15] and owing to the availability of versatile chemistry for functionalization at their surface as well as their unique optoelectronic properties[9,11] gold nanoparticles provide a particularly useful platform for attachment of biomolecules.[15] However, to the best of our knowledge, the use of gold nanoparticles to improve the performance of PCR has not been reported.

Herein, we employed an error-prone two-round PCR as our model system. Amplification of very low quantities of copies of target genes usually increases the possibility of amplifying nonspecific sequences.[16] In the first round, we amplified a 283-bp sequence using a λ-DNA template with 35 PCR cycles; in the second round PCR, this 283-bp DNA was employed as the template for the other 35-cycle PCR amplification sequence. Nonspecific PCR products tend to accumulate after two rounds of PCR, as manifest by a broad molecular size distribution of amplified products in agarose gel electrophoresis (Figure 1). Strikingly, in the presence of

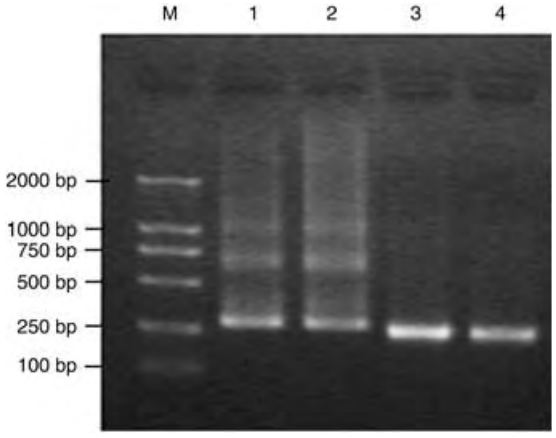

Figure 1. The effect of gold nanoparticles on the specificity of PCR. PCR was performed by employing a 283-bp target sequence from a λ-DNA template, and PCR products were analyzed by agarose gel electrophoresis (1.5%). Lane M is for markers; lanes 1 and 2 show the results of PCR performed in the absence of gold nanoparticles; lanes 3 and 4 show the results of PCR performed with gold nanoparticles (0.4 nM of 10-nm gold nanoparticles). bp = base pair.

0.4-nM gold nanoparticles (10 nm, Sigma) we only observed a single predominant band corresponding to the 283-bp target, and the yield of this target was also much higher in this case (Figure 1). Control experiments show that the high specificity of gold-nanoparticle-assisted PCR (nanoparticle PCR) arises solely because of the effect of gold nanoparticles. We performed nanoparticle PCR by using freshly prepared gold nanoparticles that were free of additives such as tannic acid and sodium azide[17] and observed similar electrophoresis patterns (data not shown). In contrast, we did not observe any improvement by using solely the medium in which the gold nanoparticles were provided (the gold nanoparticles were removed by centrifugation).[18] The concentration of gold nanoparticles is critical for obtaining optimal PCR results. We observed that nonspecific "tailing" bands gradually diminished by increasing the concentration of gold nanoparticles in the range of 0.2–0.8 nM. However, the presence of excess gold nanoparticles (1.0 nM) effectively inhibited the PCR reaction, as manifest by the significantly lowered yield of PCR (Figure 2). This inhibition effect is discussed later.

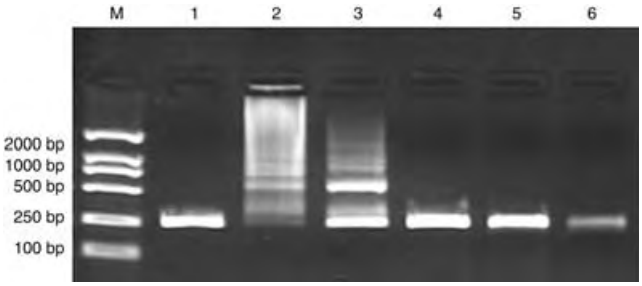

Figure 2. The effect of the concentration of gold nanoparticles on the specificity of PCR: lane M: (markers) 0; lane 1: 0.6 nM; lane 2: 0; lane 3: 0.2 nM; lane 4: 0.4 nM; lane 5: 0.8 nM; lane 6: 1.0 nM.

In conventional PCR, it is essential to find the optimal annealing temperature by the so-called "touchdown" PCR[19] to obtain optimal yields (which requires a lower annealing temperature) and specificity (which requires a higher annealing temperature) of the target. Our nanoparticle PCR strategy allows reliable PCR amplification even at lowered annealing temperatures, obviating time-consuming "touchdown" PCR. As demonstrated in Figure 3, in the presence of 0.4-nM gold nanoparticles we could obtain a single product band at a nonoptimal annealing temperature of 40 °C. We even observed a product band with minor tailing bands at an annealing temperature as low as 25 °C, in sharp contrast to normal PCR in the absence of gold nanoparticles which produces negligible amplified target DNA at this temperature. This specificity could be further improved by using 0.6-nM gold nanoparticles, which produced a single product band at the annealing temperature of 25 °C (Figure 3). Therefore, it is possible to 1) employ gold nanoparticles to perform PCR without the need for sophisticated optimization of annealing temperature and/or 2) to increase PCR yields at lowered annealing temperatures without compromising PCR specificity.

The problems associated with specificity of PCR possibly arise owing to performance of the procedure in vitro. During DNA replication in vivo, DNA polymerase is assisted by a variety of proteins/enzymes, which ensure the specificity of DNA replication.[20] For example, single-stranded DNA-binding protein SSB selectively binds to single-stranded DNA (ssDNA) and not to double-stranded DNA (dsDNA). This selectivity largely minimizes mispairing between primers and templates during DNA replications.[20] Indeed, mimicking Nature's strategy, Nielson et al., among others, successfully employed a thermostable SSB to increase PCR specificity and fidelity.[21–23] Note that the use of thermostable SSB from the *T. thermophilus* strain is critical to withstand the temperature cycles (up to 94 °C) involved in PCR.[23] Here, similarly enhanced PCR specificity is observed for our nanoparticle

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

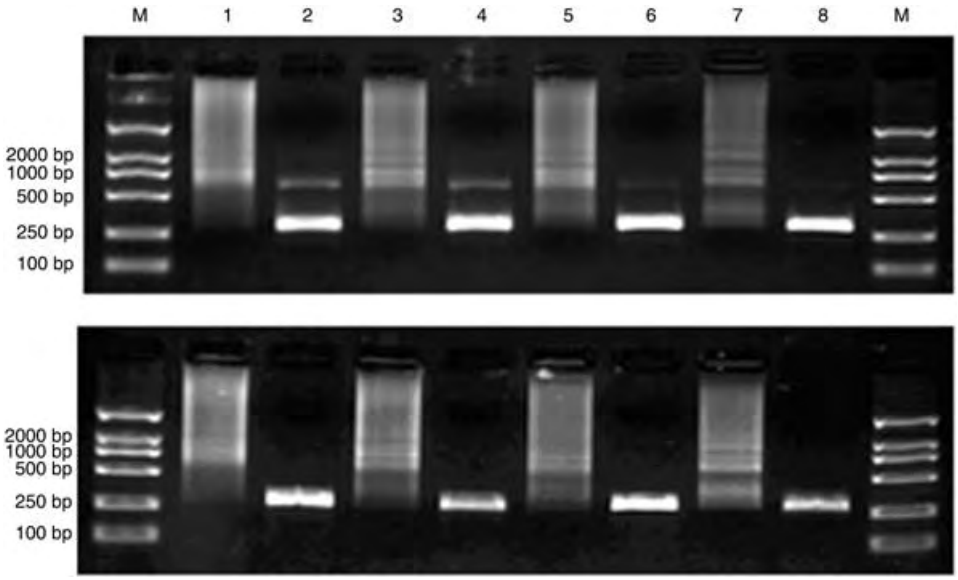

Figure 3. The effect of the annealing temperature on the specificity of PCR: lanes 1, 2: 25 °C; lanes 3, 4: 30 °C; lanes 5, 6: 35 °C; lanes 7, 8: 40 °C; lane M is for markers; lanes 1, 3, 5, and 7 show the results of PCR performed in the absence of gold nanoparticles; lanes 2, 4, 6, and 8 show the results of nanoparticle PCR (the concentration of gold nanoparticles is 0.4 and 0.6 nM in the upper and lower panels, respectively).

PCR system. We reason that this enhancement arises also as a result of a similar mechanism to SSB-assisted PCRs. Indeed, both gold nanoparticles and SSB significantly enhance the specificity of this error-prone two-round PCR (see the Supporting Information). However, in this case, the enhancing effect of gold nanoparticles exceeds that of the commercially available SSB.

Analogous to SSB, gold nanoparticles bind to ssDNA much more strongly than to dsDNA.[8] While not yet fully understood, it is generally recognized that the selectivity of gold nanoparticles for binding to ssDNA arises for various reasons. First, for electrostatic reasons the binding of anionic DNA strands to negatively charged surfaces of citrate-stabilized gold nanoparticles is not favored. Note that dsDNA has a higher surface charge density and thus experiences more repulsion than ssDNA.[6] Second, the four bases—adenine, guanine, thymine, and cytosine (A, G, T, and C)—contain nitrogen atoms that display high affinities to gold.[24,25] Formation of a DNA duplex prevents the exposure of the bases to gold surfaces and thus reduces interactions between the two.[7] Third, the rigidity of dsDNA does not favor the wrapping of dsDNA around gold surfaces, while ssDNA is a "soft", flexible polymer that has a much higher freedom to wrap around gold nanoparticles. (Note that the persistence lengths of ssDNA and dsDNA are approximately 1 and 50 nm, respectively.[26]) However, an excess of gold nanoparticles can significantly reduce PCR yields which suggests that even correctly matched DNA may be adsorbed during PCR amplification (Figure 2). This effect is not unexpected as dsDNA may still bind to gold nanoparticles, although with a much lower affinity relative to ssDNA–gold binding.[27]

An approximate concentration of 10 μM of 1,6-dithiothreitol (DTT) is present in PCR solutions and is required for storage of Taq polymerase, the enzyme that is used to copy DNA. This thiol could self-assemble on gold nanoparticles through Au–S bonds and possibly cross-link them. As DTT-free Taq is not active, we cannot exclude the effect of DTT at present; however, we suggest that its effect is relatively small for the following reasons. First, the concentration of DTT is fairly low. Usually millimolar or higher concentrations of thiols are required for the preparation of densely packed monolayers on gold surfaces.[28] Second, Au–S bonds are labile at elevated temperatures.[29,30] PCR reactions were carried out at a high temperature at which Au–DTT complexes are unstable. Third, the PCR reaction was largely inhibited in the presence of 1.0 nM of gold nanoparticles (Figure 2). If the presence of 10 μM of DTT is enough to cross-link all gold nanoparticles, this inhibition effect could not have occurred. It was mentioned earlier that PCR specificity was enhanced by increasing the concentration of gold nanoparticles in the range of 0.2–0.8 nM. This observation suggests that DTT may cross-link some gold nanoparticles, while the excess gold nanoparticles ensure the enhancing effect. However, the mechanism of nanogold-assisted PCR remains to be explored.

In conclusion, we have developed a highly selective nanoparticle PCR strategy by employing gold nanoparticles. We have demonstrated that in the presence of appropriate concentrations of gold nanoparticles, PCR amplification can be optimized with respect to both yields and specificity. Thus the use of these highly stable, commercially available, and inexpensive inorganic nanomaterials open new opportunities for improving PCR, which is the most important standard method in molecular biology. Besides the two-round PCR employed here, gold nanoparticles may also be applied to many other PCR reactions that require either high specificity or high yields, such as single-molecular, multiplex, and long-distance PCRs. Further investigation into the effect of gold nanoparticles on these PCR reactions is required.

Experimental Section

λ-DNA templates and Ex Taq DNA polymerase were obtained from TaKaRa Bio. Inc. Colloidal gold nanoparticles (10 nm, 0.01% $HAuCl_4$) were either purchased from Sigma or freshly produced in our laboratory following the reported procedure.[31] (Gold nanoparticles from Sigma contain $< 0.01\%$ tannic acid, 0.04% trisodium citrate, 0.26 mM potassium carbonate, and 0.02% sodium azide.) For PCR reactions, final concentrations of primers = 0.1 μM, template = 20 $\mu g L^{-1}$, and deoxynucleotide triphosphates (dNTPs) = 0.5 mM; reaction conditions: 2 min at 94°C for denaturation, followed by 35 cycles of a–c: a) 45 s at 94°C (denaturation), b) 1 min at 50°C (annealing), and c) 1 min at 72°C (elongation). Then after an additional extension step of 72°C for 5 min, PCR tubes were mainatined at 4°C. PCR products were analyzed by agarose gel electrophoresis (1.5%). Aliquots of the solution of gold nanoparticles were added to the PCR reaction system to an appropriate concentration.

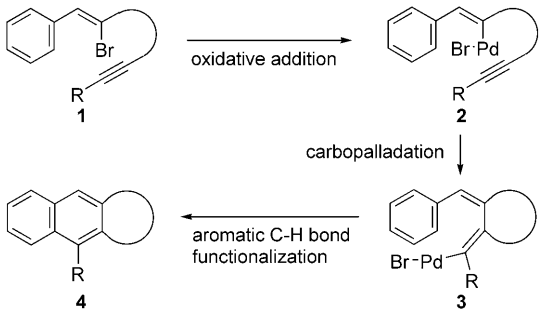
Palladium-Catalyzed Tandem Cyclization of Bromoenynes through Aromatic C–H Bond Functionalization**

Hiroaki Ohno, Mio Yamamoto, Mutsumi Iuchi, and Tetsuaki Tanaka**



Transition-metal-catalyzed cyclization of dienes, diynes, and enynes has received considerable attention in recent years.[1] In contrast, cyclization of this class of compounds through functionalization of a C–H bond of an aromatic ring has scarcely been investigated. We anticipated that tandem cyclization of enynes of type **1** (Scheme 1) could serve as a useful synthetic method for direct construction of tricyclic products such as **4** through the use of a nonfunctionalized aryl group.

Recent investigations in palladium chemistry has revealed that functionalization of a C–H bond of an aromatic group is highly effective for the construction of fused aromatic rings.[2–6] Although tandem cyclization involving C–H bond functionalization that generates two,[7] three,[8] or four carbon–carbon bonds[9] in a one-pot manner and leads to

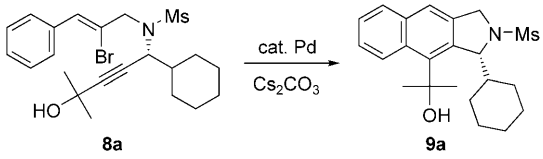
Scheme 1. Palladium-catalyzed tandem cyclization of bromoenynes.

monocyclized products is well documented, the tandem reaction involving a biscyclization process is extremely rare. Grigg et al. reported that an aryl halide bearing a carbon–carbon multiple bond and an additional aryl group undergoes bis- or triscyclization on treatment with a palladium(0) catalyst.[10] More recently, the palladium(0)-catalyzed tandem cyclization of alkyne-substituted phenyl iodide to form condensed aromatic rings[11] and the tandem biscyclization of allenenes with aryl halides[12] were also reported. However, to the best of our knowledge, there has been no report on the successful C–H functionalization of halogenated enynes. Herein we describe a tandem biscyclization of bromoenynes through intramolecular carbopalladation and functionalization of an aromatic C–H bond in the presence of a palladium catalyst.

Benzoisoindole is an important structural motif in medicinal chemistry and exists in many pharmaceutically useful compounds.[13] With a view to synthesizing nitrogen heterocycles, including benzoisoindole derivatives, we prepared enynes **8** as shown in Scheme 2. The chiral propargyl amine



Scheme 2. Synthesis of bromoenynes through the procedure developed by Carreira and co-workers.

derivatives **6** could be prepared with high enantiomeric excess through the asymmetric alkynylation of aldehydes in the presence of zinc triflate and *N*-methylephedrine (NME) developed by Carreira and co-workers,[14] followed by amination of the resulting propargyl alcohols. In some cases, racemic propargylamines which were readily prepared by the reaction of lithium acetylide with aldehydes followed by amination, were used. Condensation of propargyl amines **6** with 3-aryl-2-bromoprop-2-en-1-ols **7** under Mitsunobu conditions gave the desired brominated enynes **8**.

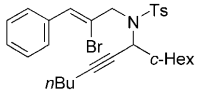
With the requisite brominated enynes in hand, we next investigated the tandem cyclization of bromoenynes under various reaction conditions. After considerable experimentation, we found that bromoenyne **8a** yielded the desired cyclized product **9a** in the presence of a palladium catalyst and Cs_2CO_3 in EtOH (Table 1).[15] Other bases such as

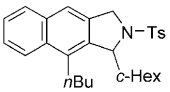
Table 1: Optimization of reaction conditions using bromoenyne **8a**.[a]

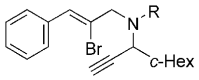
8a **9a**

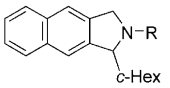
Entry	Catalyst (mol%)	Solvent	*T*	*t* [h]	Yield [%][b]
1	$[Pd(PPh_3)_4]$ (6)	EtOH	reflux	1	26
2	$[Pd_2(dba)_3]\cdot CHCl_3$ (2)	EtOH	reflux	5	59
3	$[Pd(dppf)_2Cl_2]$ (2)	EtOH	reflux	3.5	38
4	$Pd(OAc)_2$ (6)	EtOH	reflux	2.5	74
5	$Pd(OAc)_2$ (2)	EtOH	reflux	7	64
6	$Pd(OAc)_2$ (2)	DMF	100 °C	21	35
7	$Pd(OAc)_2$ (2)	dioxane	reflux	21	27

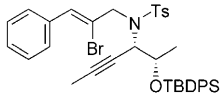
[a] Reactions were carried out with Cs_2CO_3 (2 equiv). [b] Yields of isolated products. dba = dibenzylideneacetone, dppf = 1,1′-bis(diphenylphosphanyl)ferrocene, Ms = methylsulfonyl.

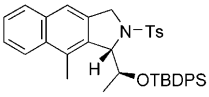


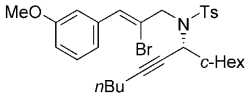


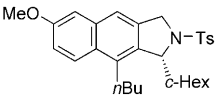


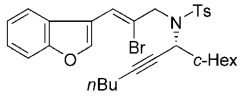


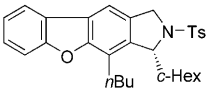


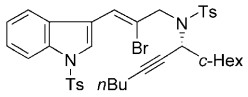


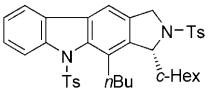






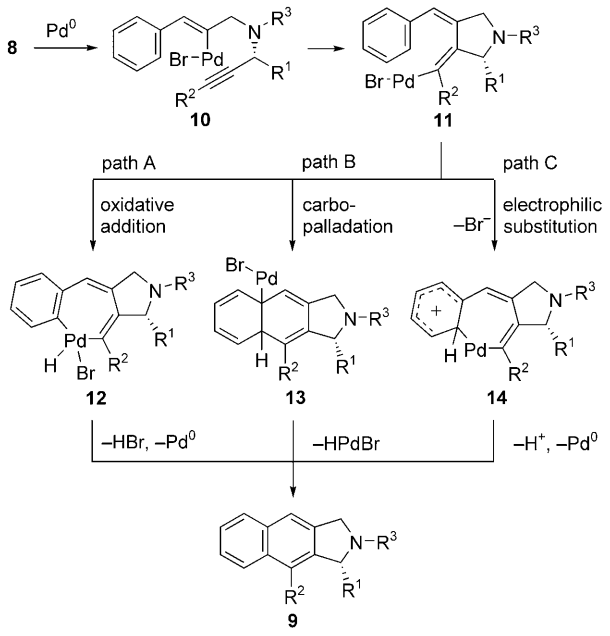






NaOAc were ineffective. Of the palladium catalysts investigated (entries 1–4), palladium acetate most effectively catalyzed the desired conversion (74%, entry 4). Decreased loading of the catalyst (2 mol%) slightly lowered the yield of the tricyclic product **9a** (64%, entry 5). EtOH proved to be a better solvent than DMF or dioxane for the tandem cyclization (entries 6 and 7).

Next we investigated the tandem cyclization of various bromoenynes in the presence of palladium acetate and cesium carbonate in EtOH (Table 2). The cyclization of tosylamide **8b** having an *n*-butyl group on the alkyne terminus gave the desired benzoisoindole **9b** in 79% yield (entry 1). Bromoenyne **8c** (entry 2) and **8d** (entry 3), each with a terminal alkyne, yielded **9c** and **9d**, respectively, in moderate yields (46 and 56%, respectively). The reaction of lactate-derived enyne **8e** with a protected hydroxy group led to functionalized benzoisoindole **9e** (entry 4), although the yield was relatively low. It is noteworthy that bromoenynes having a heteroaromatic ring can also be used for the tandem cyclization involving the functionalization of the aromatic C–H bond. For example, treatment of enyne **8g** bearing a benzofuranyl group with a catalytic amount of palladium acetate and cesium carbonate yielded tetracyclic product **9g** in a shorter reaction time (1 h, entry 6). A similar result was obtained with *N*-tosylindole derivative **8h** in DMF (entry 7).[16]



As shown in Scheme 3, this tandem cyclization could proceed through the oxidative addition of bromoenyne **8** to palladium(0), carbopalladation onto the carbon–carbon triple bond of the intermediate **10**, and functionalization of an aromatic C–H bond of **11**. The final arylation step would be promoted through 1) intramolecular oxidative addition of an aromatic C–H bond to palladium(II) (path A),[2] 2) carbopalladation onto the aryl group in **11** and the subsequent β-hydride elimination (path B),[3] or 3) electrophilic attack by the palladium(II) intermediate **11** to the aromatic carbon atom

4[c]		**8e**	24		**9e**	39
5		**8f**	5		**9f**	57
6		**8g**	1		**9g**	59
7[d]		**8h**	18		**9h**	51

[a] Reactions were carried out with $Pd(OAc)_2$ (2 mol%) and Cs_2CO_3 (2 equiv) in EtOH. [b] Yields of isolated products. [c] An increased amount of $Pd(OAc)_2$ (4 mol%) was used. [d] DMF was used as the solvent. Ts = toluene-4-sulfonnyl, *c*-Hex = cyclohexyl.

Scheme 3. Possible reaction pathways for functionalization of the C–H bond.

followed by deprotonation and reductive elimination (path C).[4] It is difficult to say at present which is the most favorable reaction course, as is also the case in related palladium-catalyzed functionalizations of aromatic C–H bonds.[5]

In conclusion, we have developed a novel tandem cyclization of bromoenynes for the synthesis of tri- and tetracyclic heterocycles. This study has demonstrated for the first time that enynes can undergo a tandem cyclization involving functionalization of C–H bonds of benzene or heteroaromatic rings, such as benzofuran and indole, in the presence of a palladium catalyst. This tandem cyclization in which two carbon–carbon bonds are formed is synthetically useful since complex heterocyclic skeletons can be constructed directly from readily prepared enynes.

Experimental Section

General procedure for condensation of propargylamine derivatives **6** with 3-aryl-2-bromoprop-2-en-1-ols **7**: Diisopropyl azodicarboxylate (DIAD; 2.2 equiv) was added dropwise to a stirred mixture of **6** (1 equiv), **7** (2.2 equiv), and PPh_3 (2.2 equiv) in THF at 0 °C. The mixture was stirred for 4 h at room temperature and concentrated under reduced pressure. The residue was purified by column chromatography on silica gel with an eluent of *n*-hexane/EtOAc to give **8**.

General procedure for the palladium-catalyzed cyclization of bromoenynes **8** (Table 1, entry 5): A mixture of **8a** (124 mg, 0.265 mmol), Cs_2CO_3 (173 mg, 0.531 mmol), and $Pd(OAc)_2$ (1.2 mg, 0.0531 mmol; 2 mol%) in EtOH (1.5 mL) was heated under reflux for 7 h. After cooling the mixture, saturated NH_4Cl was added. The mixture was then extracted with EtOAc and dried over $MgSO_4$. Concentration under reduced pressure gave an oily residue, which was purified by column chromatography on silica gel with *n*-hexane/EtOAc (10:1) to give **9a** (65.7 mg, 64% yield) along with an unidentified minor product (2.5 mg, 3% yield). **9a**: colorless oil; $[\alpha]_D^{28} = +31.4$ ($c = 0.62$, $CHCl_3$); IR (KBr): $\tilde{\nu} = 3545$ (OH), 1336

Correlations between Molecular Numbers and Molecular Masses in an Evanescent Field and Their Applications in Probing Molecular Interactions**

Hongwei Gai, Qi Wang, Yinfa Ma, and Bingcheng Lin**

Single-molecule detection (SMD) technology has made remarkable progress within this decade.[1] It has been demonstrated that it is a unique technique for exploiting the fundamental physical and chemical principles of molecules, down to the single-molecule level, and that it could lead to significant biological and medical applications in the near future. A small probe volume to minimize the background effect is a critical factor for detecting individual molecules in solution. Confocal microscopy[2] or evanescent-wave excitation[3] are two valid techniques to optically confine the excitation volume. An evanescent wave is generated by total internal reflection (TIR) of the light at the interface between two media of different refractive indices, when a parallel beam of light propagates to the interface from a dense medium with a refractive index n_2 to a less dense medium with a refractive index n_1, and the incident angle θ exceeds the critical angle $\theta_c = \arcsin(n_2/n_1)$. The penetration distance z_p away from the interface, located at $z = 0$, is calculated by Equation (1):[4]

$$z_p = \frac{\lambda_0}{4\pi\sqrt{n_2^2 \sin^2\theta - n_1^2}} \quad (1)$$

in which λ_0 is the wavelength of the light. In our experiments, a laser at $\lambda_0 = 488$ nm was focused at an angle of incidence of 40–45° onto a fused silica prism ($n_2 = 1.46$). The laser beam was refracted through the prism at an angle of incidence $\theta =$ 71–74° at the fused silica/water ($n_1 = 1.33$, $\theta_c = 66°$) interface. The penetration distance z_p was 107–89 nm. The scheme for exciting a single fluorophore in an evanescent field has been employed by several research groups. Funatsu et al.[5] used refined TIR fluorescence microscopy to visualize a single fluorophore in a solution and observed adenosine triphosphate turnover reactions. Evanescent-wave excitation[6] was also adopted at the boundary of a cover slip and a polyacrylamide gel for the detection of fluorophores diffusing in and out of the gel. Yeung and co-workers[3] measured the diffusion and photodecomposition of single molecules in solution, and studied the electrostatic trapping and absorption/desorption of protein molecules at a solid/liquid interface. Fang and Tan[7] demonstrated a new fluorescence method for SMD and imaging by using an optical-fiber probe. The fluorophores were excited by the evanescent-wave field that was produced on the core surface of an optical fiber. Gai et al.[8] simultaneously determined the velocities of single molecules flowing near the channel wall and at the center of the channel by using the evanescent-field excitation mode combined with the traditional wide-field microscope.

Heparin consists of repeating disaccharide units of hexuronic acids linked to either N-sulfated or N-acetylated glucosamine units by a (1→4) bond. Both units can be sulfated to a different extent, the hexuronic acid at the C2 carbon atom and the glucosamine at C6.[9] Heparin is known for its interaction with many biologically important proteins such as proinflammatory chemokines, growth factors, extracellular matrix proteins, leukocyte proteinases, and cytokines.[10] The biological activity of heparin is strongly affected by binding to target proteins. Strong binding of heparin to the granulocyte–macrophage colony-stimulating factor (GM-CSF) and fibroblast growth factor (FGF) has been reported in the literature.[11] The granulocyte colony-stimulating factor (G-CSF) is a glycoprotein that can stimulate the proliferation and differentiation of hematopoietic progenitor cells of the neutrophil lineage and also increase the functional activity of fully differentiated neutrophils. The interaction between standard heparin, low-molecular-weight heparin (LMWH), and G-CSF has been studied by Liang et al.[12] with capillary zone electrophoresis.

We designed an experiment to detect fluorescein isothiocyanate (FITC, $M_w = 398$), FITC-deoxythymidine monophosphate (FITC-T, $M_w = 701$), FITC-12-mer oligonucleotides ($M_w = 4358$), FITC-18-mer oligonucleotides ($M_w = 6338$), and FITC-12 bp DNA ($M_w = 8318$) independently in an evanescent field at the single-molecule level and counted their molecular numbers. The numbers of molecules decreased with increasing molecular weight. We then tested a series of single fluorophores of 2-aminoacridone (2-AMAC), oligochitosan labeled with 2-AMAC, and heparin labeled with 2-AMAC, and similar results were obtained. We therefore established, on the basis of these experimental results, a new method for detecting the molecular interactions of heparin and G-CSF as model compounds in a free solution by using a single-molecule fluorescence imaging system.

The imaging system was similar to that used in previous studies,[3] except that an electron-multiplier charge coupled

device (EMCCD) was used instead of an intensified CCD. The detection of single Rhodamine 6G molecules was used to calibrate the system and the results were the same as those in previous reports.[3,7] A series of oligonucleotides of different lengths and labeled with FITC at the 5′ end were used as a model system. A small detection volume and low fluorophore concentration were employed in SMD,[3,7] which was mainly a statistical argument for high confidence in the results. Our experimental data demonstrated that there were excellent linear relationships between the molecular concentrations and the numbers of molecules observed in the images. As shown in Figure 1, the numbers of bright spots were proportional to the concentrations of FITC, FITC-T, FITC-12-mer oligonucleotides, FITC-18-mer oligonucleotides, and FITC-12 bp DNA. Based on these five linear fits, we quantitatively calculated the molecular numbers in the evanescent field for each individual solution at a concentration of 1000 nM (Figure 2). The expected numbers of molecules of the test compounds detected in the evanescent field should be undifferentiated, with the same concentration of fluorophores under the same fluorescence imaging conditions. The experimental results, however, indicated that the numbers of molecules that were detected in the evanescent field decreased with increasing molecular weight. We also counted the molecule numbers of real samples (at 1000 nM) and compared them with the calculated values (Figure 2); the two groups of molecule numbers are almost the same. This unexpected result indicates that, as a consequence of steric hindrance, larger molecules labeled with a single fluorophore cannot be completely immersed in the 100-nm-deep evanescent field near the surface. Although the number of molecules detected in the evanescent field was constant for each specified molecule at a given concentration, the numbers of molecules detected under the same conditions can be different for different molecules because of the variations in molecular masses and/or structures.

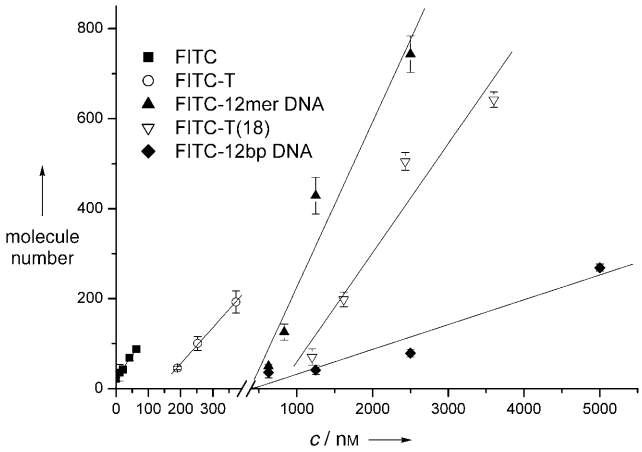

Figure 1. The linear relationships between the numbers of molecules of FITC, FITC-T, FITC-12-mer oligonucleotides, FITC-18-mer oligonucleotides, and FITC-12 bp DNA and different concentrations of each type of molecule. Samples (3 μL) were placed on the surface of the prism. The results were obtained from 128×128 pixel subframe images that were acquired by excitation with a 488-nm Ar^+ laser (100× NA 1.3 objective). The laser power was measured at about 25 mW before reaching the prism. Each pixel represents a square with 0.16-μm edges, as calibrated by the microscope stage micrometer. The excitation depth was about 100 nm (see text) and the volume of each pixel was 2.56×10^{-18} L. The EMCCD was maintained at −60 °C; the gain and exposure time were set at 255 and 100 ms, respectively. A mechanical shutter with 3-s closure was used to minimize photobleaching by blocking the laser beam when data were not being collected.

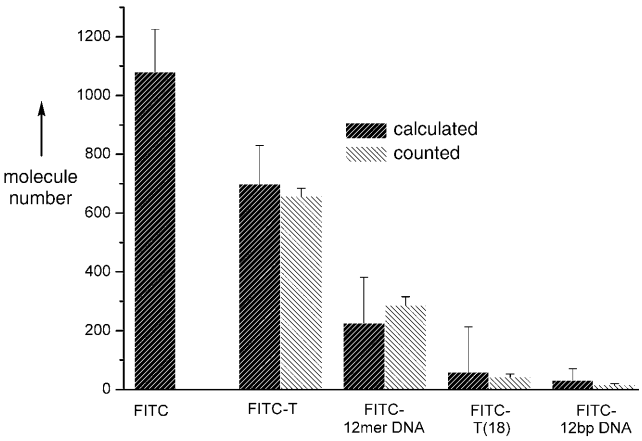

Figure 2. Comparison of the experimental and calculated numbers of individual molecules of FITC, FITC-T, FITC-12-mer oligonucleotides, FITC-18-mer oligonucleotides, and FITC-12 bp DNA at the same fluorophore concentration (1000 nM). All other experimental conditions were the same as those in Figure 1.

Oligochitosan and heparin molecules were derivatized with 2-AMAC according to the literature.[13] The 2-AMAC-glycan derivatives were produced by a "one-pot" Schiff reaction at the reducing end (the *N*-acetylglucosamine residues) followed by reduction, and one carbohydrate molecule was labeled with one fluorophore. After four extraction steps with tetrahydrofuran, free 2-AMAC dye was totally removed from the 2-AMAC-labeled oligochitosan and heparin solution. The fluorescence concentration and purity of the derivatives were determined by fluorescence spectrometry and high-performance thin-layer chromatography.

As shown in Figure 3a, the numbers of molecules were proportional to the concentrations of 2-AMAC, 2-AMAC-oligochitosan, and 2-AMAC-heparin. Similarly, the calculated molecular numbers for each individual solution (Figure 3b) decreased with an increase in molecular weight.

Oligochitosan is a mixture of chitosan oligomers with a degree of polymerization of 3–10,[14] obtained by the enzymatic hydrolysis of chitosan. Its average molecular weight was about 1800 according to mass spectrometry (data not shown). Heparin is a glycosaminoglycan with an average molecular mass of about 14000. Oligochitosan and heparin molecules were both derivatized with 2-AMAC. All of the bright spots in the fluorescence images corresponded to the 2-AMAC-derivatized molecules.

The two series of correlated experimental data allow us to hypothesize that the interaction of molecules can be probed in a mixture without separation, based on the decreased numbers of product molecules in the probed area after

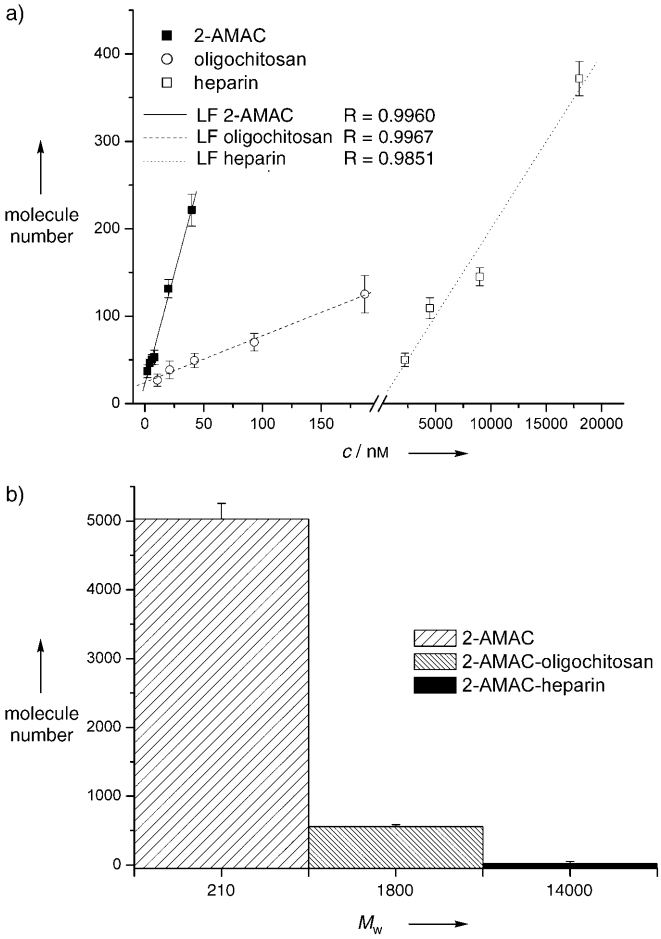

Figure 3. a) The linear relationships between the numbers of molecules of 2-AMAC (■), 2-AMAC-oligochitosan (○), and 2-AMAC-heparin (□) and different concentrations of each type of molecule. LF = linear fit. b) Comparison of the numbers of individual molecules of 2-AMAC, 2-AMAC-oligochitosan, and 2-AMAC-heparin at the same fluorophore concentration (1000 nM). All other experimental conditions were the same as those in Figure 1.

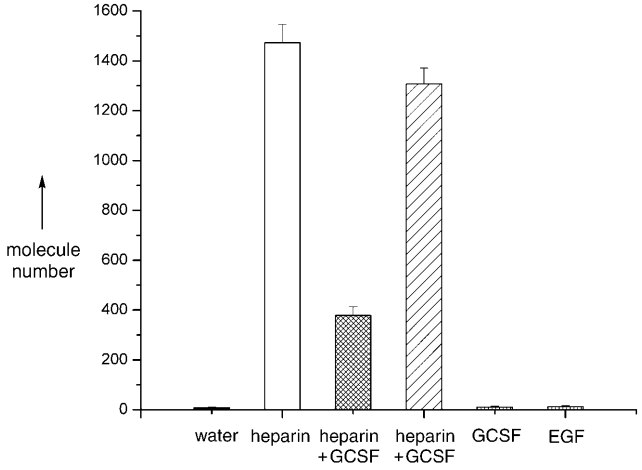

Figure 4. The numbers of molecules counted in purified water, heparin (73 μM), a mixture of heparin (73 μM) with G-CSF (6.5 μM), a mixture of heparin (73 μM) with EGF (34.72 μM), G-CSF (6.5 μM), and EGF (34.72 μM). The experimental conditions were the same as those indicated in Figure 1.

reaction relative to the numbers of reactant molecules. To test this hypothesis, the complex of heparin with G-CSF was studied as a model.

The binding of heparin with G-CSF was demonstrated by Liang et al.[12] with capillary zone electrophoresis. The heparin-G-CSF complex has a higher molecular mass (M_w = 14000 + 18987) than heparin itself (M_w = 14000), and therefore the number of heparin-G-CSF complex molecules observed in the evanescent field should be less than that of the heparin molecules. The imaging results fully supported our hypothesis (see Figure 4). Furthermore, we imaged a mixture of heparin and epidermal growth factor (EGF) to confirm that the decrease in the number of heparin-G-CSF complex molecules was not a result of the co-existing protein molecules. EGF is an ideal negative control for the formation of heparin-G-CSF complex because EGF molecules do not bind to heparin at all.[15] At EGF concentrations up to 34.72 μM, the number of heparin molecules counted in the evanescent field was about the same as the number counted for the solution that did not contain EGF. The G-CSF and EGF molecules were also counted separately to determine whether their fluorescence backgrounds were comparable with that of water, as both of these proteins had no fluorescence. This step was to ensure that the numbers of extra G-CSF molecules in solution did not contribute to the count of the heparin-G-CSF complexes when using this technique. The results in Figure 4 confirm that the existence of G-CSF and EGF molecules at this concentration level does not significantly increase the background signal. The findings support our hypothesis that the formation of a macromolecular complex changes the number of molecules detected in the evanescent field, which means that the interaction of macromolecules can be probed with this technique. Conversely, the data prove that the number of molecules decreases with an increase of molecular weight in the evanescent field.

In summary, with our single-molecule fluorescence imaging technique we discovered that the numbers of molecules probed in the evanescent field decreased with an increase of molecular weight as a consequence of steric hindrance. Our results suggest that this technique and phenomenon could be potentially useful for screening undefined molecular interactions at extremely low concentrations without any separation, for which other methods may not be applicable. This finding could be especially useful for studying the interactions of biological molecules. Future investigations will focus on quantitative measurements of the relationship between molecule numbers and molecular mass, quantitative determination of binding constants, and exploration of the effects of binding constants on the numbers of molecules detected in a probed area.

C_2-Symmetrical Thiodigalactoside Bis-Benzamido Derivatives as High-Affinity Inhibitors of Galectin-3: Efficient Lectin Inhibition through Double Arginine–Arene Interactions**

*Ian Cumpstey, Anders Sundin, Hakon Leffler, and Ulf J. Nilsson**

Galectin-3 is a β-galactoside-binding protein[1] that has been implicated as playing an important role in cancer and inflammation processes.[2] Recently, a dominant negative C-terminal fragment of galectin-3 was shown to slow the growth of breast cancer in mice by blocking galectin-3 endogenous ligands.[3] Although many intriguing biological activities have been demonstrated,[2] the precise mode of action of galectin-3 remains unknown. The synthesis of potent, low-molecular-weight inhibitors of galectin-3 is therefore an important goal, as such molecules could be used both as tools to investigate the molecular biology of the protein and as lead compounds for drugs.

The β-galactoside binding site (termed subsite C in Ref. [1b]) is highly conserved across the galectins, whereas the neighboring sites on either side of the Gal group (B, toward the nonreducing terminus; D, toward the reducing terminus) are more variable, albeit important, contributors to the interaction. *N*-Acetyllactosamine (LacNAc, **1**), which binds in subsites C and D, is the best natural disaccharide ligand for galectin-3 (Figure 1a). We have previously reported the synthesis of potent inhibitors of galectin-3 based on modification of LacNAc at C3 of galactose to target subsite B.[5] The best inhibitors were aromatic amides of general structure **2** (Figure 1c) and according to the crystal structure of an inhibitor–galectin-3 complex, the increase in binding affinity results from particularly favorable interactions of the aromatic amide moiety with an arginine side chain (Arg 144).[5b] Arene–guanidinium interactions[6] have attracted considerable interest in recent years, as they can be as strong as cation–anion interactions[6c] and up to 70% of all arginine side chains are involved in such interactions.[6b]

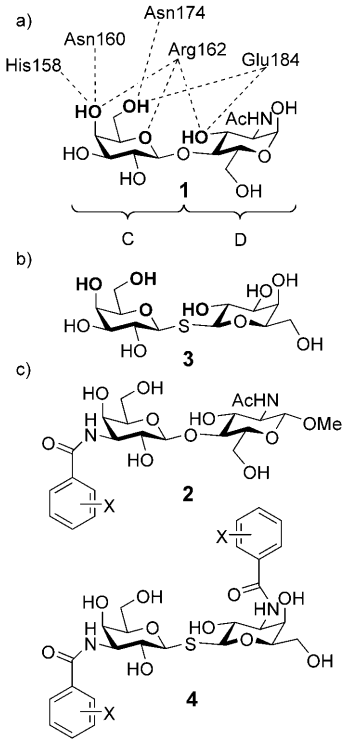

Figure 1. a) Representation of the complex of *N*-acetyllactosamine **1** with galectin-3 in which dashed lines represent hydrogen bonds.[4] The areas known as subsites C and D are indicated, and the key polar interacting groups on the saccharide are shown in bold.[1b] b) Thiodigalactoside **3** with key polar groups for interaction with galectin-1 shown in bold.[8b] c) Lactosamine-based galectin inhibitors **2** and proposed thiodigalactoside-based inhibitors **4**, showing the similarity in structure and conformation.

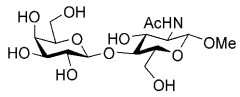
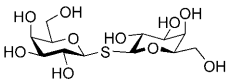
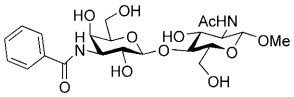
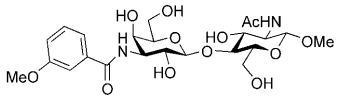
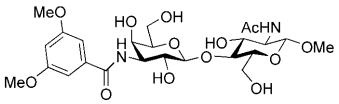
The guanidinium ion is positively charged, has a π system, and is poorly solvated in water,[7] which makes it ideal for interactions with aromatic π systems. Consequently, the targeting of protein arginine residues with aromatic structures is emerging as an attractive strategy for protein inhibitor development.

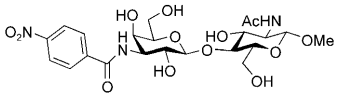


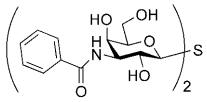


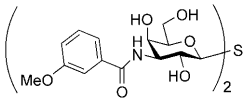


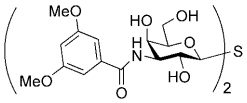


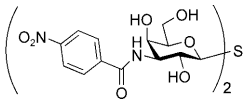












Thiodigalactoside **3** has been shown to bind to galectins with about the same affinity as LacNAc,[8] and it was hypothesized that it bound in a mode similar to that of LacNAc,[8a] that is, in subsites C and D, with a similar conformation and hydrogen-bonding network (Figure 1b). This notion has recently been confirmed for galectin-1, for which X-ray structures have been solved both with LacNAc **1** and with thiodigalactoside **3** as ligands.[8b] The galactose residues bind identically in subsite C for the two disaccharides, and in subsite D, the Gal of thiodigalactoside and GlcNAc of LacNAc show identical patterns of interaction with the protein.

We reasoned that derivatization with aromatic amides at C3 of galactose in thiodigalactoside, as for **2**, could increase the affinity for galectin-3 through favorable interactions with Arg144 in subsite B. Furthermore, similar derivatization at the second galactose C3 of **2** would give an amide that could interact with an arginine residue (Arg186) in subsite D (Figure 1c). The resulting molecules **4** are C_2-symmetrical, which simplifies the synthesis and could also lead to interesting thermodynamic properties as there are two degenerate binding modes.

Computer modeling[9] of the complex of galectin-3 with a thiodigalactoside bis-benzamido derivative **4a** (Table 1), which was performed by starting from the reported crystal structure of galectin-3 complexed with a C3-benzamido LacNAc-based inhibitor,[5b] gave an energy minimum with the two galactose units bound in subsites C and D (Figure 2). Moreover, the two aromatic rings of the benzamides were involved in stacking interactions with the two arginine residues, Arg144 and Arg186.

To test the potential of 3,3′-bis-amide-derivatized thiodigalactosides as inhibitors of galectin-3, we synthesized a selection of these compounds. The amide structures were

Table 1: K_d values for the inhibitors **4a–d** established by fluorescence polarization.[11]

	Compound	K_d [nM]	Relative activity[a]
9		69000[5b]	1
3		43000	1.6
2a		6700[5b]	10
2b		2500[5b]	28
2c		1100[5b]	63
2d		950[5b]	73
4a		3000	23
4b		61	1130
4c		50	1380
4d		33	2090

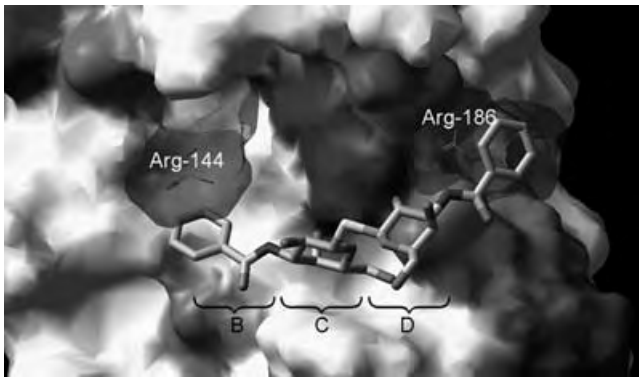

Figure 2. Molecular model of **4a** bound in the galectin-3 active site, energy-minimized by using MacroModel MMFF/water. The two arginine residues, Arg144 and Arg186, in subsites B and D, respectively, are stacked against the two aromatic rings of the amide groups.

chosen based on the best results from our investigation into C3-benzamido LacNAc derivatives **2**.[5] Consequently, the bis-amide structures **4a–d** were synthesized starting from the known 1,2,4,6-tetra-*O*-acetyl-3-azido-3-deoxy-D-galactopyranose[10] (Supporting Information).

Bis-amides **4a–d** were tested for binding to galectin-3 with a fluorescence polarization assay[11] (Table 1). Pleasingly, our strategy was successful; bis-amides **4a–d** all have dissociation constant values ($K_d = 33$–3000 nM) significantly better than those of nonderivatized thiodigalactoside **3** and the methyl β-glycoside of *N*-acetyllactosamine **9**, both of which were included in the test as reference compounds. The substituted benzamides **4b–d** bind much better than the unsubstituted benzamide **4a**, as would be expected if the thiodigalactoside derivatives **4** bound in the galactose binding site of galectin-3 (subsite C) similarly to the LacNAc-derived amides **2**.[5b] Furthermore, these thiodigalactosides **4** have much higher affinities than the corresponding LacNAc derivatives **2** (compare **2a–d** and **4a–d**), and it is logical to conclude that this finding is the consequence of a favorable interaction between the second aromatic amide and Arg186, as suggested by our docking experiments (Figure 2). An alternative interpretation would be that compounds **4a–d** cross-link by binding to subsites B and C of two galectin-3 molecules. However, such a binding mode is unlikely as, for steric reasons, it would require a much longer galactose–galactose distance than that present in **4a–d**.

In conclusion, the targeting of arginine side chains with aromatic structures has been demonstrated as an efficient approach toward the discovery of monovalent high-affinity lectin inhibitors. The 3,3′-bis-benzamido-thiodigalactosides **4a–d** are the best monovalent galectin-3 inhibitors reported to date and, as such, constitute promising lead structures for the development of galectin-targeting drugs. In general, the targeting of arginine–arene interactions may be underexploited in drug design relative to targeting, for example, hydrogen-bonding and ionic interactions. Our observation that both of the arginine–arene interactions between galectin-3 and the inhibitors **4a–d** provide substantial affinity enhancements implies that systematic targeting of such interactions could find wider use in drug design.

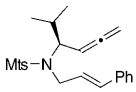
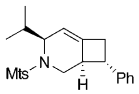
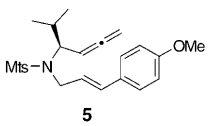
Thermal Intramolecular [2+2] Cycloaddition of Allenenes and Allenynes: Diastereoselective Access to Bicyclic Nitrogen Heterocycles**

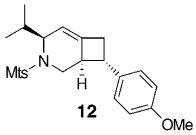
Hiroaki Ohno, Tsuyoshi Mizutani, Yoichi Kadoh, Kumiko Miyamura, and Tetsuaki Tanaka**

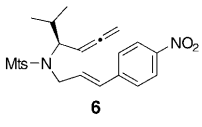
Cycloaddition reactions that occur without the use of reagents or catalysts and without creating any waste have attracted much attention in recent years as an ideal process in terms of atom economy.[1] Considerable research efforts have been particularly focused on the development of cycloaddition of allenes,[2] on account of the current interest in the reactions of allenes with an additional multiple bond, including transition-metal-catalyzed carbocyclizations.[3,4] The [2+2] cycloaddition reactions[5] between allenes and alkenes are extremely useful for the synthesis of methylenecyclobutane derivatives.[6] Especially, intramolecular cycloaddition constitutes a versatile method for the stereoselective synthesis of a variety of bicyclic compounds having a strained bicyclo[*n*.2.0] framework (Scheme 1).[7] In most reported intramolecular [2+2]

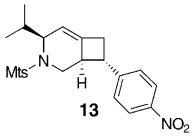


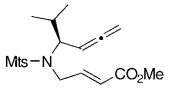


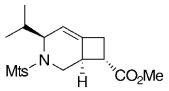


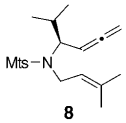


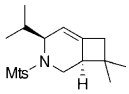


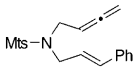


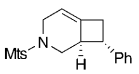


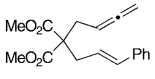


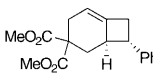












Scheme 1. Intramolecular [2+2] cycloaddition of allenenes.

cycloaddition reactions of simple unactivated allenes, the proximal 2π component of the allene moiety participates in the cycloaddition to form bicyclic products **2**.[2] Only limited examples of the intramolecular [2+2] reaction of the distal allenic double bond to give **3** have been reported to date, which used a special class of allenes such as allene carboxylates,[8] allenyl sulfones,[9] difluoroallenes,[10] β-lactam-tethered allenes,[11] or diyne-diallenes.[12]

In the course of our efforts toward the development of a new methodology for the synthesis of heterocyclic compounds by the transition-metal-catalyzed cyclization of allenes,[4,13] we found that the thermal cycloaddition of simple allenes with an additional multiple bond proceeds by simply heating the allenenes or allenynes in the absence of any catalyst. Herein, we present an intramolecular [2+2] cycloaddition of unactivated allenes to form distal adducts of type **3**, which constitute an important class of compounds in synthetic[14] and natural product chemistry.[15]

Various allenenes **4**–**10** (Table 1) were prepared according to the reported procedure[4d] and their thermal cycloaddition reaction was investigated. First, the [2+2] cycloaddition of

heteronuclear multiple quantum correlation (HMQC) and NOESY analysis of the corresponding hydrogenated derivatives. The reaction in dioxane under reflux was rather slow (Table 1, entry 1), and therefore the cycloaddition of the other allenenes **5**–**10** was conducted in DMF. All the allenenes were successfully converted into the corresponding bicyclic products in good to excellent yields, with complete regioselectivity. The reaction of the allenene **5** bearing an electron-donating aryl group gave **12** in relatively low yield (71%, Table 1, entry 3), whereas the allenene **6** with an electron-withdrawing group afforded **13** in 93% yield within a shorter reaction time (1 h, Table 1, entry 4). Allene **7** with an α,β-unsaturated ester group showed sufficient reactivity to give the cycloadduct **14** in 73% yield. Allenene **8** with a geminal dimethyl group on the olefinic carbon atom (Table 1, entry 6), α-unsubstituted allene derived substrate **9** (Table 1, entry 7), and dimethyl malonate derived allenene **10** (Table 1, entry 8) gave the distal cycloadducts **15**–**17** in 68–82% yields, although prolonged reaction times were required.

Next, the thermal cycloaddition of allenynes **18**–**23** (Table 2) was investigated, which were easily prepared by the N-arylpropargylation of known amino allenes. In contrast to the cycloaddition of allenenes **4** (Table 1, entries 1 and 2), the reaction of the allenyne **18** was complete within 2 h in dioxane under reflux conditions to give 3-azabicyclo-[4.2.0]octa-1(8),5-diene derivative **24** in 92% yield (Table 2, entry 1). In the reaction of N-tosylated allenyne derivatives **19**–**21**, the effect of the electron-donating and -withdrawing aryl group on the reactivity was not dramatic (Table 2, entries 2–4). More important is the α substituent of the allene: the reaction of the allenyne **22** bearing a smaller substituent at the α position was complete in 8 h, whereas the cycloaddition of α-unsubstituted allene derivative **23** required a prolonged reaction time (117 h) to give **29** in 94% yield.

The related [2+2] thermal reactions of allenes are thought to proceed by a two-step mechanism, that is, via a diradical intermediate.[2, 9b,c, 16] In the present [2+2] cyclization of simple allenenes and allenynes, the substituent on the double or triple bond, which effectively stabilizes the radical intermediate, is essential for successful conversion: the corresponding allenenes or allenynes without the radical-stabilizing group were completely inert to the thermal [2+2] cycloaddition. This experimental result supports the diradical mechanism; however, further study is necessary to elucidate the reaction mechanism.

In conclusion, a stereoselective route to bicyclo-[4.2.0]octane derivatives has been developed by using thermal [2+2] cycloaddition of allenes with an additional multiple bond. This study first demonstrated that unactivated allenenes and allenynes can regioselectively undergo intramolecular [2+2] cycloaddition of the distal double bond of the allene moiety. This simple and environmentally benign process would extend the potential application of fused bicyclic cyclobutane derivatives in synthetic and medicinal chemistry.

Table 2: Thermal [2+2] cycloaddition of allenynes.[a]

Entry	Substrate	*t* [h]	Product	Yield [%][b]

The Fabrication and Switchable Superhydrophobicity of TiO_2 Nanorod Films**

*Xinjian Feng, Jin Zhai, and Lei Jiang**

Titanium dioxide (TiO_2) is an important material that is used in many industrial applications related to photo-splitting of water,[1] photocatalysis,[2] photovoltaic devices,[3] etc. Since the discovery[4] of photoinduced superhydrophilicity (water contact angle (CA) $< 10°$) on a hydrophilic TiO_2 surface in 1997, many research efforts[5–8] have been devoted to exploring this photosensitive mechanism with the aim of manipulating the surface wettability to a larger extent in virtue of the good light, thermal, and chemical stability and better biocompatibility of TiO_2 than of other organic or inorganic materials. However, its wettability has only been tuned in a limited region thus far.

In the past several years, inspired by the surface-topography-induced superhydrophobicity of lotus leaves[9,10] and water striders' legs,[11] various films that exhibit superhydrophobic properties have been fabricated.[12–19] On the other hand, superhydrophilic surfaces have been realized by taking advantage of a 2D[4] or 3D[20] capillary effect. Very recently, several stimuli-responsive, smart, interfacial materials that can be switched between superhydrophilicity and superhydrophobicity by combining the geometrical morphology of

the surface with a change of surface chemistry have been reported.[21–23] Herein, we report on the creation of superhydrophobic surfaces consisting of inorganic nanorods fabricated from hydrophilic TiO_2, and further demonstrate that their wettability can be reversibly switched between superhydrophobicity and superhydrophilicity. The mechanism involves the cooperation of the micro- and nanoscale hierarchical surface structures, the orientation of the crystal planes, and the surface photosensitivity.

The TiO_2 nanorod films were deposited on glass substrates by a low-temperature hydrothermal approach. Typically, aqueous solutions of titanium trichloride supersaturated with NaCl were heated to 160 °C for 2 h. The films deposited on glass wafers used as substrate were rinsed thoroughly with deionized water and ethanol, dried at room temperature, and stored in the dark for two weeks. Figure 1 a shows a typical

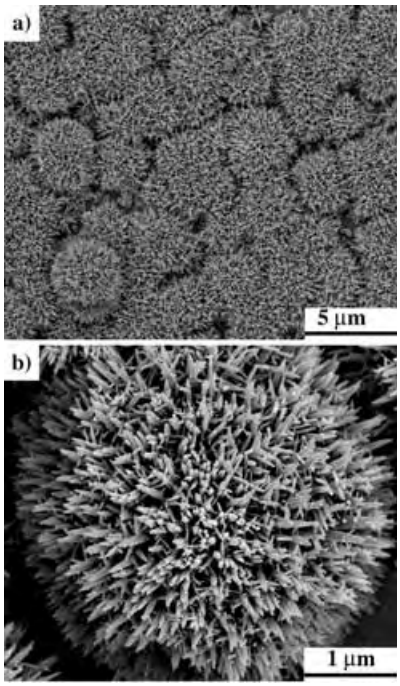

Figure 1. a) Low-magnification FE-SEM image of a TiO_2 nanorod film deposited on a glass wafer; b) morphology of a single papilla at high magnification.

field emission scanning electron microscopy (FE-SEM) image of the as-synthesized nanorod films. Many papillae can be found on the surface in a random pattern with diameters ranging from 2 to 6 μm. Each of these papillae is composed of nanorods with uniform diameters of 30 to 60 nm. As can be seen from the magnified image of a single papilla (Figure 1 b), the nanorods grow radial to the substrate and are self-assembled into micro- and nanoscale hierarchical structures.

According to the X-ray diffraction (XRD) pattern of the as-prepared TiO_2 films, the nanorods can be classified as having a standard tetragonal rutile structure (space group $P4_2/mnm$; JCPDS file no. 21-1276). The peaks are relatively broad compared with those of the bulk material, thus corroborating the small crystal size. In contrast to the standard pattern, the XRD profiles clearly exhibit an enhanced peak for the (110) reflection and a comparatively low diffraction intensity for (101) and (111) (see Supporting Information), which indicates that the growth of the nanorods has a preferred orientation. The samples were then dispersed onto a transmission electron microscopy (TEM) grid for further detailed structure analysis. Figures 2 b and c show the high-resolution TEM images of the

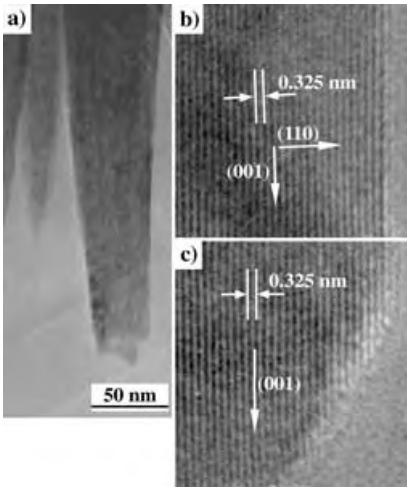

Figure 2. TEM image of a single TiO_2 nanorod (a). High-resolution TEM images of a nanorod wall at the side surface (b) and at the top surface (c) of the nanorod.

side and top surfaces, respectively, of the nanorod wall shown in Figure 2 a at low magnification. It can be seen that the nanorod is well crystallized with clear lattice fringes parallel to the wall. The inter-plane distance of 0.325 nm for the (110) planes perpendicular to the rod axis can be readily resolved. Combined with the XRD data and SEM images, such features imply that the nanorods grow along the (110) crystal plane with a preferred orientation in the (001) direction.

The wettability of the films was evaluated by contact angle (CA) measurements. The rutile form of TiO_2 is a hydrophilic material with a water CA of 72 and 74° on smooth single crystal (110) and (001) surfaces, respectively.[6] As shown in Figure 3 a (left), the water CA of the as-prepared rough TiO_2 nanorod films is large ($(154 \pm 1.3)°$), that is, the as-prepared films show superhydrophobicity. This result indicates that the surface structure strongly affects the wetting behavior. There are two equations in the literature that describe the water CA on rough surfaces. One is Wenzel's law,[24] $cos\theta_f = r\cos\theta_w$, where θ_f and θ_w are, respectively, the water CA on a rough and smooth surface and r is the surface roughness. For $\theta_w < 90°$, it can be seen that an increase of r will result in a smaller CA, and water will fill the grooves below the droplet. However, the high water CA of the as-prepared films indicates that the water droplet does not penetrate the trough but is suspended on the sharp nanorod films, and that an air pocket might be formed on the surface.

The apparent contact angle θ_f can be described by another equation, first formulated by Cassie and Baxter,[25] which is generally valid for heterogeneous surfaces composed of air and a solid with superhydrophobicity, $\cos\theta_f = f_s\cos\theta_w - f_v$,

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

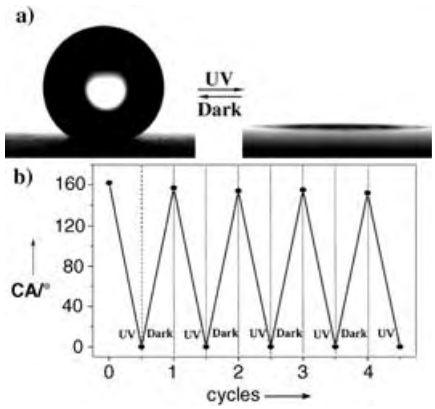

Figure 3. a) Photographs of a spherical water droplet with a CA of (154 ± 1.3)° (left) and a flat water film with a CA of 0° (right) before and after the films were exposed to UV illumination, respectively; b) reversible superhydrophobicity/superhydrophilicity transition of the as-prepared films by alternating UV irradiation and storage in the dark.

where f_s and f_v are the area fractions of the projecting solid and air on the surface, respectively ($f_s + f_v = 1$). The large fraction of air trapped in the films forms a cushion at the film–water interface that prevents the penetration of the water droplet into the grooves. All these results indicate that the preferred orientation of the (001) crystal plane of TiO_2 nanorods and the micro- and nanoscale hierarchical surface structures result in a significant change of the wetting behavior from hydrophilic to superhydrophobic.

When the as-prepared films were exposed to UV light, their surface superhydrophobicity transformed into superhydrophilicity; this remarkable surface wettability transition can be tuned reversibly. Figure 3a shows the change of the water CA when the films are irradiated with UV light (obtained from a 500-W high-pressure Hg lamp with a filter centered at (365 ± 10) nm) for 2 h. The spherical water droplet spreads out on the film with a CA of about 0°. After the UV-irradiated films were placed in the dark for two weeks, their superhydrophobicity was obtained again. This process was repeated for several cycles; a good reversibility of the surface wettability was observed (Figure 3b). TiO_2 is a photosensitive material,[5] and when the film is irradiated with UV light the photogenerated hole reacts with lattice oxygen to form surface oxygen vacancies, to which water molecules kinetically coordinate. This improves the surface hydrophilicity greatly. For the as-prepared multiscale rough surface, the water droplet will fill the grooves along the nanorods and replace the trapped air. This results in a water CA of about 0°. After the hydroxy group adsorption, the surface transforms into an energetically metastable state, and the adsorbed hydroxy groups can gradually be replaced by atmospheric oxygen[6] when the films are placed in the dark. Subsequently, the surface evolves back to its original state, and the surface wettability converts from superhydrophilic to superhydrophobic again.

In conclusion, TiO_2 nanorod films with special micro- and nanoscale hierarchical surface structures have been prepared. A remarkable, controllable surface wettability that shows reversible superhydrophobicity/superhydrophilicity, which is a challenge in surface chemistry, is observed on this inorganic oxide nanorod film. The cooperation of the hierarchical surface microstructures, the orientation of the crystal planes, and the surface photosensitivity are considered to be responsible for this behavior.

Experimental Section

The films were synthesized by hydrothermal treatment of an aqueous titanium trichloride (0.15 M) solution supersaturated with NaCl. The solution was placed in a Teflon-lined autoclave. Thoroughly cleaned glass wafers were used as substrates and immersed in the solution. The mixture was then heated to (160 ± 2) °C for 2 h. The as-deposited films were rinsed with deionized water and ethanol, dried at room temperature, and stored in the dark. The structure and morphology of the product was investigated by FE-SEM (JSM-6700F, Japan), HRTEM (Tecnai F30, Japan), and powder XRD (diffractometer D/max2500 using $Cu_{K\alpha}$ radiation). Water CAs were measured with an OCA20 (DataPhysics, Germany) at ambient temperature.

A Tiny Excited-State Barrier Can Induce a Multiexponential Decay of the Retinal Chromophore: A Quantum Dynamics Investigation**

Massimo Olivucci, Alessandro Lami, and Fabrizio Santoro**

The *N*-alkyl protonated Schiff base of retinal (PSBR) is the chromophore of rhodopsin proteins,[1–3] a large class of transmembrane photoreceptors comprising the human retina visual pigment rhodopsin (Rh) and the bacterial proton pump bacteriorhodopsin (bR). In these receptors, PSBR undergoes an efficient *cis–trans* photoisomerization (e.g., the 11-*cis* to all-*trans* isomerization marked with a curved arrow in Scheme 1) which, ultimately, triggers a conformational change of the protein. It has been established that in solution the excited-state decay of PSBR is multiexponential and shows a fast (subpicosecond to picosecond) and a slow (picosecond) component, whose values depend on the type of signal recorded, the probing wavelength, and the nature of the solvent.[4–7] More recently, evidence for multiexponential excited-state decay has also been reported for Rh[8,9] and bR.[10]

The precise origin of the observed PSBR multiexponential decay is unknown. Several models have been proposed such as the existence of competing excited-state isomerization paths[7] (for example, one reactive and one nonreactive path as demonstrated in ref. [9]) or the occurrence of an isomerization path splitting,[8] or the generation of a vibrationally hot photoproduct followed by cooling.[11] The possibility that a multiexponential decay arises from dynamics along a single coordinate has also been discussed.[12] Herein, we present an investigation on a different origin of multiexponential decay: the dynamics prompted by the specific shape of the excited-state potential-energy surface.

Ab initio CASPT2//CASSCF calculations on the reaction path of different isolated PSBR models,[13–16] and more recently on Rh,[17] have invariably shown that the isomerization path on the excited state (S_1) involves mainly two nuclear modes. The process begins with the relaxation of the Franck–Condon (FC) structure along a collective C–C stretching (double-bond expansion and single-bond contraction) mode of the chromophore backbone. It then proceeds along the torsion corresponding to the change from *cis* to *trans*; this torsion leads to a conical intersection (CI) between the S_1 and the ground-state (S_0) potential-energy surfaces. The essential features of the calculated surface, which are in line with the indication of time-resolved experiments,[18–24] are reproduced by the simple analytical potential V^C [Eq. (1)]

$$V^C(x_s,y_t) = a_s x_s^2 - b_t(x_s/x_{seq})y_t^2 \qquad (1)$$

with $b_t > 0$.[25] As illustrated in Figure 1a, a vibrational wave packet released at FC initially evolves along the stretching coordinate x_s. V^C is bound along y_t when $x_s < 0$, but it is unbound (i.e., gives the wave packet an acceleration towards large y_t values) when $x_s > 0$ (Figure 1b). This anharmonic feature creates a shallow valley around the origin (SP) and, for $x_s > 0$, a decay channel along y_t, whose existence has been documented by mapping the minimum-energy path for realistic PSBR models.[16] V^C does not describe the region of the conical intersection, which must be thought somewhere along the channels. Below, we assume that once the wave packet is entered into the decay channels, it will irreversibly proceed towards the CI and decay to S_0.

Because of its low dimensionality V^C provides an attractive model for the study of the quantum dynamics of the photoinduced wave packet. While we do not try to reproduce experimental data, we show that the peculiar topology of the S_1 energy surface of PSBR may be responsible for biexponential decay. In particular, we show that such a decay regime

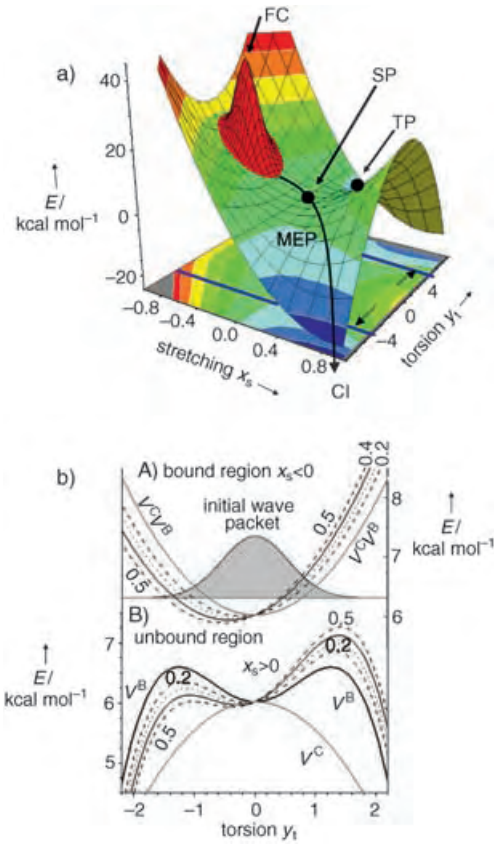

Figure 1. a) 3D plot of the potential V^C; the initial wave packet at $t=0$ is superimposed. x_s and y_t are given in atomic units. Two lines on the $x_s y_t$ plane mark the borders of the NR region (-4 au $\le y_t \le 4$ au). The curved arrow indicates the minimum-energy path (labeled MEP) towards negative values of y_t (an equivalent MEP develops towards positive values of y_t). b) Profiles of the potential with no barrier (V^C), with a symmetric barrier (V^B), and with an asymmetric barrier (asymmetry parameter c_t: 0.2, 0.3, 0.4, 0.5 kcal mol^{-1} bohr^{-1}). A) $x_s = -0.475$ au (FC); the larger c_t the more shifted the minimum is towards negative y_t values. The cross section of the initial wave packet is given as a gray Gaussian. B) $x_s = 0.475$ au (TP); the larger c_t the higher the barrier for positive y_t and the lower the barrier for negative y_t.

is induced by the presence of a flat energy ridge located between the SP and CI regions.

We begin by looking at a barrierless potential. The parameters of Equation (1) are fixed by assuming typical values for pure stretching ($\omega_s = 1500$ cm^{-1}, $a_s = 1/2\, m_s \omega_s^2$, $m_s = 1$ u; u = atomic mass unit, $\omega = \tilde{\nu}$) and torsional frequencies ($\omega_t = 200$ cm^{-1}, $b_t = 1/2\, m_t \omega_t^2$, $m_t = 1$ u). The FC point is located at $x_s(0) = x_{seq} = -0.475$ au by imposing an energy gap of 6 kcal mol^{-1} between the points FC and SP, which is consistent with the results of ab initio calculations.[15] To study how the wave packet moves along the SP→CI channel, we monitor $P_{NR}(t)$, which describes the population in the nonreactive (NR) region comprising FC and SP (see Figure 1a) or, in other words, the transient S_1 population of PSBR. The results (see the thick gray line in Figure 2a, b) demonstrate that after an induction time of about 50 fs there is a substantial monoexponential decay of $P_{NR}(t)$ with a time constant of about 150 fs (see the Supporting Information for a table with the exponential fits of $P_{NR}(t)$ for the S_1 potential).

The presence of a barrier < 1 kcal mol^{-1} on the S_1 surface has been detected experimentally[6] and is consistent with CASPT2//CASSCF calculations on a realistic PSBR model.[16] We now show that energy ridges (Figure 2c, dotted lines)—which start at $x_s = 0$ and $y_t = \pm 1.26$ au, increase linearly for $x_s > 0$ (along the stretching), and impose a tiny torsional barrier (B^{max} of 0.6 kcal mol^{-1} at the turning-point (TP) level (see V^B Figure 1b, plot B)—have a drastic effect on the decay dynamics. Naming V^B the potential with a barrier (see the Supporting Information for mathematical details), we report in Figures 2a and b the $P_{NR}(t)$ function. As apparent from an inspection of the graphs, the barrier switches the S_1 population decay from monoexponential to biexponential with time constants of 257 fs (19% of the population) and 2110 fs (81% of the population). The appearance of the biexponential decay does not depend on a specific choice of the V^B parameters; for example, the biexponential decay persists if the barrier is moved along y_t between 0.8 and 1.5 au and its height is fixed to the value of 0.6 kcal mol^{-1} (the time constants and the populations of the fast and slow components vary significantly). Furthermore, the extension of the ridge to negative x_s values, which creates a barrier along the MEP, should prompt the biexponential regime more readily.

Figure 2c provides a mechanistic interpretation of the biexponential regime. The tiny barrier in the region of the

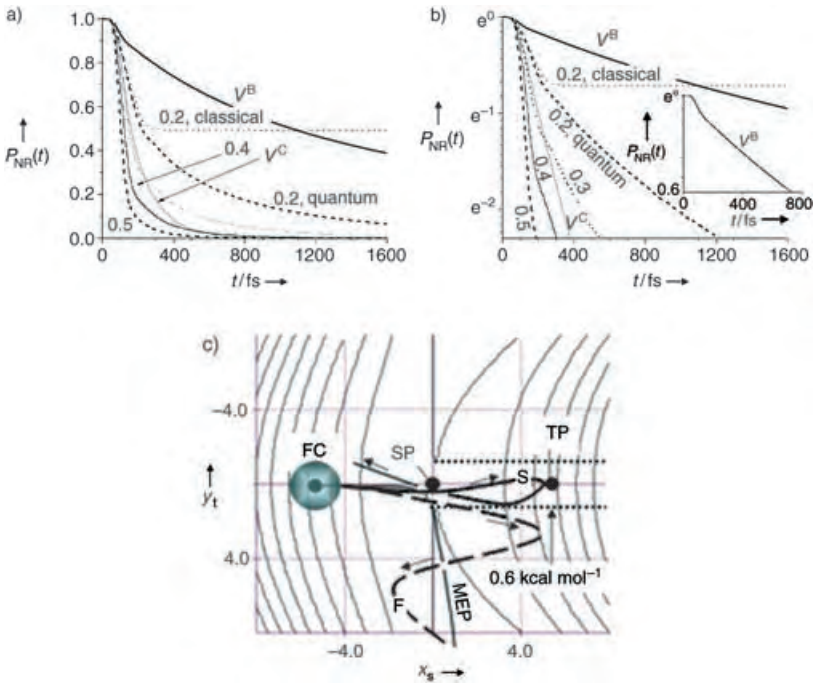

Figure 2. Decay of the quantum NR population, $P_{NR}(t)$: a) linear scale; b) semilogarithmic scale. Potentials V^C (thick gray line), V^B (solid line), and $V^B + c_t y_t$ (curves marked by the c_t values 0.2, 0.3, 0.4, 0.5 kcal mol^{-1} bohr^{-1}; for $c_t = 0.2$ the classical result is also given). Notice that the larger c_t the faster the decay. Inset: detail of the decay for V^B. c) Schematic representation of a fast (F) and slow (S) trajectory on a contour plot of V^C. turning point restrains the decay of a large subset of trajectories that temporarily remain in the NR region (S trajectory) rather than evolve immediately along the SP→CI channel (F trajectory). However, the introduction of a barrier does not cause an "isomerization path splitting". In fact, the wave packet oscillates along the stretching mode in the SP region without splitting. What actually happens is a progressive loss of population of the NR region that enters the SP→CI channel of no return (for an analysis of the flow of the population in the SP→CI channel as a function of the stretching x_s see the Supporting Information).

The investigation of the origin of the biexponential decay in the protein environment (e.g., in Rh[8,9] or bR[10]) requires the detailed understanding of the PSBR V^B topology in these systems. While this is outside the scope of the present work, we can easily introduce in V^B the zero-order effect of the chiral protein cavity, that is, the breaking of the mirror symmetry of the torsional potential. This is done through an additional term, $c_t y_t$, which shifts the equilibrium position along y_t, removes the symmetry of the barriers for positive torsion values (B_+^{max}) and for negative torsion values (B_-^{max}), and decreases the size of the SP valley (see Figure 1b and the Supporting Information).

In Figure 2a,b, we report the changes of $P_{NR}(t)$ as a function of the increase of the asymmetry parameter c_t. It is apparent that even when c_t induces a limited symmetry breaking (see Figure 1b and the Supporting Information), both time constants of the biexponential fit decrease (i.e., the overall decay is faster) and more remarkably the population decay with the faster kinetic increases while the population decay with the slower kinetic decreases (for $c_t = 0.2$ kcal mol^{-1} bohr^{-1} these are 62% for the fast decay and 38% for the slow decay). When $c_t = 0.5$ kcal mol^{-1} bohr^{-1} the slow component disappears and the biexponential fit collapses into the monoexponential one with a time constant of 72 fs. These results show that, according to our basic model, the symmetry breaking induced by the protein cavity would decrease the multiexponential character of the decay, which would ultimately lead to a monoexponential behavior due to the removal of the plateau around SP and the decrease of the barrier along one sense of rotation ($B_-^{max} < B_+^{max}$ in Figure 1b).

The comparison between quantum and classical $P_{NR}(t)$ for the case $c_t = 0.2$ kcal mol^{-1} bohr^{-1} (see Figures 2a,b) demonstrates that quantum effects, like tunneling, are essential for the correct description of the slower decay of the NR population. In fact, classical trajectories (see the Supporting Information) do not reproduce the behavior described above but predict that after the fast decay, a part of the wave packet remains unreactive and is permanently trapped on the SP valley.

In conclusion, exploratory quantum dynamics on a two-dimensional analytical potential that mimics the PSBR S_1 potential derived through ab initio quantum chemical calculations provides a novel explanation for the observed biexponential decay of the excited-state population. Such an explanation may be proposed for other systems featuring a biexponential decay with a fast component in the subpicosecond regime. The motion of the wave packet is strongly affected by the existence of a tiny barrier along the channel leading to the conical intersection. This phenomenon is general (as an example it still survives for $\omega_s \approx 700$ cm^{-1} and $\omega_s \approx 500$ cm^{-1}) and depends on the topology of the S_1 surface. The sensitivity of the quantum dynamics of the wave packet to the precise features of the potential is also reflected by the chaotic behavior found for classical trajectories released on V^C. This fact and other details of the investigation reported above will be documented in a forthcoming publication.

Experimental Procedure

Quantum dynamical calculations were performed assuming the simple kinetic operator $T = (2m_s)^{-1}\partial^2/\partial x_s^2 + (2m_t)^{-1}\partial^2/\partial y_t^2$ ($m_s = m_t = 1$ u) by adopting the Fourier method,[26] and propagating the wave packet through an orthogonalized Lanczos algorithm.[27,28] We assume an FC excitation from the ground (harmonic) vibrational state of the S_0 surface to S_1 and equal frequencies on the S_0 (ω_s', ω_t'') and S_1(ω_s, ω_t) surfaces ($\omega_s' = \omega_s$, $\omega_t' = \omega_t$). An initial thermal distribution of the torsional states increases, moderately, the population of the fast component of the biexponential decay.

Supporting Information includes: Computational details; a mathematical expression for the V^B potential; a table of the exponential fits of quantum $P_{NR}(t)$ for different values of the S_1 potential; a table reporting the positions and heights of the barriers for the different potentials considered and the comparison between mono- and biexponential fits; further discussion of the reaction mechanism through the analysis of snapshots of the wave packet and through the study of the $P_{NR}(t)$ decay as a function of x_s.

Nanotrench Arrays Reveal Insight into Graphite Electrochemistry**

*Trevor J. Davies, Michael E. Hyde, and Richard G. Compton**

Over the past few decades the popularity of carbon as an electrode material has increased dramatically. The fact that so many different types of carbon materials are commercially available has led to their use in a wide range of applications.[1] However, despite the large amount of research conducted with carbon electrodes, there still remains uncertainty about the individual roles of the edge-plane and basal-plane regions in the electrochemical response of a graphite surface. Herein, we address this fundamental problem and introduce a novel approach to investigate the source of the electrochemical reactivity of graphite.

A good way to understand the electrochemical properties of graphite electrodes is to study the voltammetry of well-defined graphite surfaces. For this reason, basal-plane highly ordered pyrolytic graphite (HOPG) is an attractive material; the surface consists of atomically flat basal-plane graphite terraces separated by steps and defects which expose extremely thin bands (multiples of 0.335 nm) of edge-plane graphite.[1,2] Accordingly, the voltammetric characteristics of basal-plane HOPG electrodes in simple redox couples are well-documented.[1,3,4] HOPG cyclic voltammograms provide relatively poor fits to linear diffusion simulations and display an increased peak-to-peak separation, indicative of slow electron-transfer kinetics relative to other electrode materials.[1,3–5] These characteristics become more pronounced if fewer defects are present on the surface.[6–8]

With the aid of a 2D simulation approach that allowed us to take the actual size and separation of surface defects into account, we recently demonstrated that the characteristics of HOPG cyclic voltammograms are consistent with the voltammetry of a macroarray of nanobands (edge-plane steps).[9,10] In other words, for the range of redox couples considered, the basal plane was effectively inert (Supporting Information). Given that edge-plane steps can make up less than 0.5% of the total electrode area, and heterogeneous electron-transfer electrons are known to occur at basal-plane terraces as well as edge-plane steps,[11,15] the suggestion that basal-plane graphite makes no contribution to HOPG voltammograms is quite controversial.

For the work reported herein, we sought to prove beyond any doubt that the cyclic voltammetry response of basal-plane HOPG is solely due to the edge-plane steps present as defects on the electrode surface by selectively blocking the basal-plane terraces to leave only the edge-plane defects uncovered; covering the basal-plane terraces with inert material should make no difference to the observed voltammetry. Although heterogeneous electron-transfer reactions occur at basal-plane terraces, a combination of nonlinear diffusion and the large difference in reactivity between basal- and edge-plane graphite gives cyclic voltammograms in which the basal-plane terraces appear to be inert. For example, a previous study in which we compared experimental and simulated cyclic voltammograms for the oxidation of ferrocyanide at an HOPG electrode produced results suggesting that the electron-transfer rate constant for the edge-plane oxidation was $0.022\ cm\,s^{-1}$, whereas that for the basal-plane reaction was less than $10^{-9}\ cm\,s^{-1}$. Furthermore, as all graphite electrodes are made from essentially the same building blocks (graphene sheets) we can expand our conclusions to other carbon materials such as pyrolytic graphite, carbon fibers, and even carbon nanotubes.[10]

To generate an HOPG surface upon which the basal plane is selectively covered, we employ a three-stage method that involves the initial "protection" of the edge-plane steps, followed by "passivation" of the remaining carbon, and then the re-exposure of the edge-plane sites. This results in the formation of "nanotrenches" (relatively long grooves in the electrode surface with nanometer-scale dimensions in width and depth) which we identify by using AFM. The contribution of edge-plane steps to basal-plane HOPG voltammograms can then be assessed by comparing the cyclic voltammetry of the nanotrench arrays with that of the freshly cleaved basal-plane HOPG.

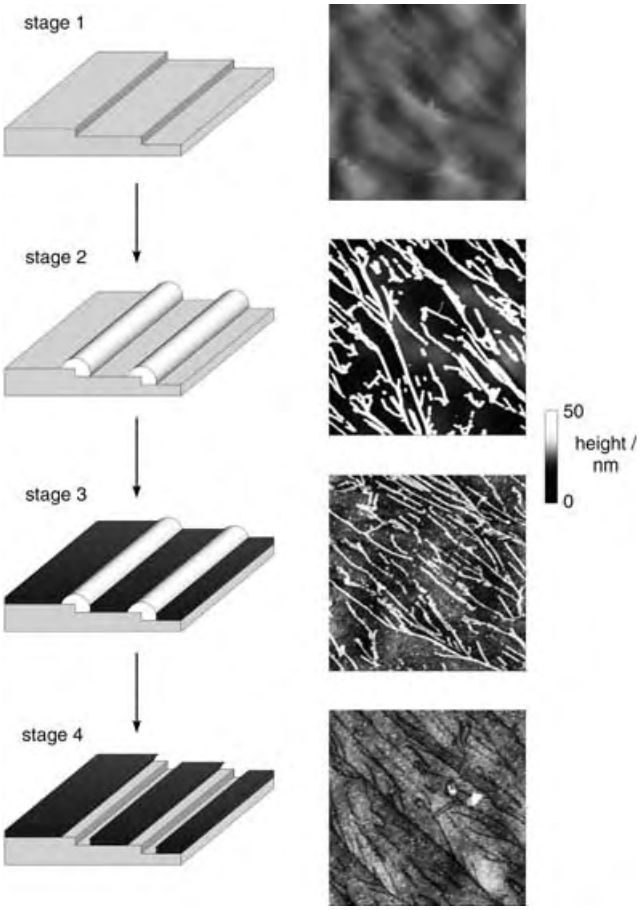

Figure 1. Schematic diagram and corresponding AFM images ($5 \times 5 \mu m^2$ each) of the four stages involved in nanotrench fabrication.

Figure 1 outlines the stages involved in nanotrench formation, along with the corresponding AFM images ($5 \times 5\ \mu m^2$ each). Initially, a HOPG slab of the highest quality ($10 \times 10 \times 2\ mm^3$, SPI 1 grade, equivalent to ZYA grade of Union Carbide[12]) was adhesively cleaved to produce a fresh surface, as illustrated in Figure 1, stage 1 (only relatively large edge-plane steps are resolved owing to the resolution limits of the AFM scanner used). The following electrochemical experiments with the HOPG slab were conducted with the HOPG housing previously described, which resulted in an exposed electrode area of 0.32 cm^2.[13]

Recently, Penner and co-workers reported that the electrodeposition of MoO_2 (by Equation (1)) at a basal-

$$MoO_4^{2-} + 2\,H_2O + 2\,e^- \rightarrow MoO_2 + 4\,OH^- \quad (1)$$

plane HOPG surface occurs exclusively at edge-plane sites (at the appropriate deposition potential) resulting in the formation of MoO_2 nanowires along the edge-plane steps.[14–16]

Following the procedure of Penner and co-workers, MoO_2 nanowires were electrodeposited on HOPG from a solution of sodium molybdate (1.1 mM) in sodium chloride (1M) and ammonium hydroxide (1M) adjusted to pH 8.5 with sodium hydroxide. The AFM image in Figure 1 for stage 2 was recorded immediately after nanowire deposition at −1.0 V versus standard calomel electrode (SCE) for 130 s, and illustrates an ensemble of nanowires $\approx$50 nm in diameter (the average thickness has been shown to depend on the deposition time, which permits the preparation of specific diameters[15]). Further experiments confirmed that the wires were indeed on edge-plane steps. Experiments at short deposition times produced incomplete nanowires for which it was possible to see the edge-plane steps emerging from the ends of the nanowires (that is, these further experiments confirmed the wires had been formed along the edge-plane steps).

With the edge-plane sites covered, the HOPG surface was effectively passivated by nitrophenyl radicals, formed from the electrochemical reduction of 4-nitrobenzenediazonium cations. Savéant and co-workers demonstrated that the reduction of diazonium salts yields N_2 and a radical, which aggressively chemisorbs to both the edge and basal planes of graphite.[17–18] Stage 3 in Figure 1 illustrates the HOPG surface after electroreduction at −0.5 V versus SCE for 30 s in a stirred solution containing 4-nitrobenzenediazonium tetrafluoroborate (1.2 mM) and tetrabutylammonium perchlorate (0.1M) in acetonitrile. The AFM image displays a clear change in texture of the material surrounding the nanowires (the basal-plane terraces) consistent with the formation of a thin film. Because the nanowires are composed of MoO_2 (an electrically conductive metal oxide), chemisorption of the nitrophenyl radicals to the nanowire surface should not be possible. Furthermore, comparison of the images for stages 2 and 3 in Figure 1 reveals that the surface surrounding the nanowires is relatively higher after treatment with diazonium salt. Thus the nanowires are not as prominent after the modification which also suggests the presence of a thin film formed over the basal-plane terraces.

In the final stage, the nanowires are removed by placing the HOPG surface in a stirred solution of hydrochloric acid (1M) for 300 s.[19] As observed for stage 4 in Figure 1, this results in the formation of nanotrenches along which the edge-plane steps reside. Figure 2 illustrates more AFM images of these nanotrenches at various scan ranges. Similar nanotrenches were observed on a large number of different sections of the HOPG surface which confirms that the acid treatment only removed the nanowires and not the basal-plane coating. As observed from the inset section analysis, the depth of the nanotrenches is $\approx$8 nm, which is significantly deeper than expected from a monolayer coverage. Given that

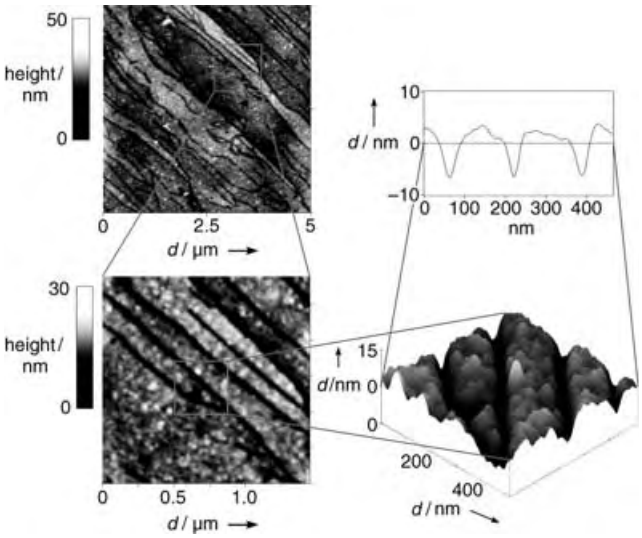

Figure 2. AFM images of nanotrenches at various scan ranges and perspectives.

the length of a nitrophenyl group is ≈5 Å,[20] the walls of the nanotrenches correspond to approximately 15 monolayers. Previous work by more than one research group has concluded that a monolayer is formed when diazonium salts are reduced at carbon electrodes.[17,18,21,22] However, our system is slightly different in that the nitrophenyl radicals should not chemisorb to the MoO_2 nanowires. This allows more nitrophenyl radicals to be generated than would be on a pure graphite surface. The AFM images provide clear evidence of a "multilayer" film which could be caused by the attack of nitrophenyl radicals on an already modified surface. Indeed, for experiments in which no MoO_2 was present, no evidence was found of a multilayer film after reduction of the diazonium salt. Alternatively, the nitrophenyl radicals could induce a polymerization reaction that forms a thin polymer film over the electrode surface rather than a chemisorbed multilayer.

Having developed an experimental method that selectively blocks the basal-plane terraces, we were next able to turn our attention to identifying the role of edge-plane defects in HOPG cyclic voltammetry. Figure 3 illustrates four cyclic voltammograms taken with an HOPG electrode in $[Ru(NH_3)_6]^{3+}$ (1.1 mM) at each of the four stages of nanotrench synthesis. Figure 3a illustrates a cyclic voltammogram with a freshly cleaved HOPG electrode taken at $2.0\,V\,s^{-1}$. Overlaid as a dashed curve is the corresponding response from an edge-plane pyrolytic graphite electrode 5 mm in diameter (in this case, the difference in surface area between the two electrodes required that the y axis be represented by I/I_p instead of I). Analysis of the edge-plane experimental data with DigiSim gave $D_{[Ru(NH_3)_6]^{3+}} = 8.0\times10^{-6}\,cm^2\,s^{-1}$ and $k^\circ_{edge} = 0.4\,cm\,s^{-1}$ for the $[Ru(NH_3)_6]^{3+}/[Ru(NH_3)_6]^{2+}$ system. The corresponding fit of the HOPG voltammogram to DigiSim gives the effective electron transfer rate constant: $k^\circ_{eff} = 0.018\,cm\,s^{-1}$. The term "effective electron transfer rate constant" is used rather than k°_{basal} because the surface is electrochemically heterogeneous, and its response is clearly dependent on the population of defects.[9] If our previous conclusion is correct, then the HOPG voltammogram in Figure 3a is solely the result of the tiny amount of edge-plane defects on the HOPG surface.[9] By using the method outlined in reference [9], the coverage of edge-plane defects can be approximated as: $\Theta_{edge} = \frac{k^\circ_{eff}}{k^\circ_{edge}} = 0.045$. Thus, 4.5 % of the surface is edge-plane graphite, which agrees well with the appropriate STM studies of Bard and Chang.[2] It follows that selective blockage of the basal-plane terraces should have no effect on the voltammetry.

Figure 3b illustrates the voltammogram recorded at $0.2\,V\,s^{-1}$ immediately after stage 2 of the nanotrench fabrication process, in which MoO_2 was deposited along edge-plane steps. Overlaid is the corresponding voltammogram from stage 1, that is, the freshly cleaved HOPG surface at $0.2\,V\,s^{-1}$. As observed, the HOPG with MoO_2 nanowires instead of edge-plane steps gives a response with a larger peak-to-peak separation (ΔE_p) than the freshly cleaved HOPG. This indicates slower electrode kinetics and agrees with the hypothesis that the HOPG response is that of a nanoband array.[9] Although MoO_2 is electrically conductive, one might

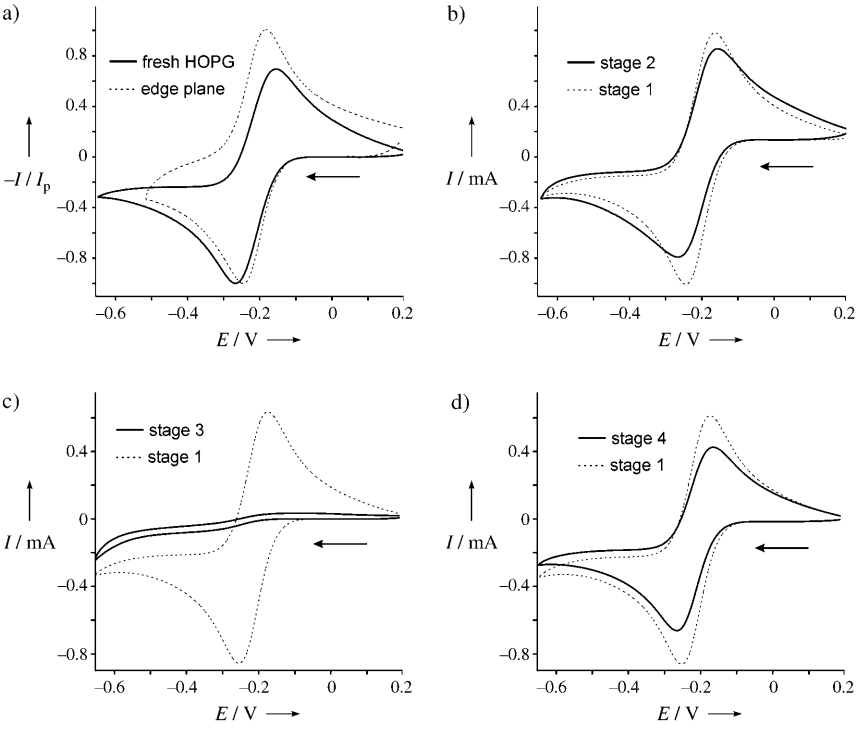

Figure 3. Cyclic voltammograms for the reduction of 1.1 mM $[Ru(NH_3)_6]^{3+}$ at a HOPG electrode (versus SCE) after each stage of nanotrench fabrication (——): a) stage 1, b) stage 2, c) stage 3, d) stage 4. The voltammogram ----- in a) was obtained from the same experiment with an edge-plane pyrolytic graphite electrode. Voltammograms ----- in b)–d) were obtained after stage 1 of nanotrench fabrication; experimental details are given in the text.

expect an MoO_2 electrode to display slower electrode kinetics than that of a noble metal, for example. For a random array of nano- or microbands in which the surface coverage is Θ, the peak-to-peak separation is approximately that expected for a cyclic voltammogram in the same system at a macroelectrode with an electron transfer rate constant of Θk°_{mat}, in which k°_{mat} is the electron transfer rate constant of the nano- or microband material.[9,23] Therefore, as k°_{edge} is expected to be greater than $k^{\circ}_{MoO_2}$, the increased ΔE_p is easily explained. The decrease in peak current was a general characteristic observed after each stage of the process and is probably due to relatively large defects created as a result of adhesive cleaving,[2] and thus becoming inactive or separated from the surface.

Figure 3c illustrates the cyclic voltammogram recorded immediately after stage 3, in which the scan rate is $0.2\ V\,s^{-1}$. As before, the corresponding voltammogram obtained from a freshly cleaved HOPG surface is overlaid (-----). The reduction of the diazonium salt appears to have passivated the entire surface (both the MoO_2 nanowires and basal-plane terraces), with only a tiny response from the modified electrode. As discussed above, nitrophenyl radicals are not expected to chemisorb to MoO_2. This suggests a more plausible result of generating nitrophenyl radicals in the absence of edge-plane graphite through a polymerization reaction which effectively blocks the entire surface. Although this may be unexpected, it does show that the surface is sufficiently blocked by the generation of nitrophenyl radicals.

Figure 3d shows the cyclic voltammogram obtained immediately after the final stage, along with the corresponding response obtained at stage 1 (freshly cleaved HOPG). As observed, the two voltammograms are almost identical, with the small difference in ΔE_p probably the result of a slight loss in activity of the edge-plane sites caused by the preceding treatments. In the case of the modified electrode, only the edge-plane steps located along the bottom of the nanotrenches are exposed to the solution (that is, we have effectively created an array of nanobands).[24] Thus, as predicted for a simple redox couple, the cyclic voltammetric response of a basal-plane HOPG electrode is solely due to the edge-plane defects, no matter how small their coverage may be (which can be as low as 0.2%[11]). The basal-plane graphite terraces have no influence on the voltammetry and are effectively inert; blocking the basal-plane sites results in no overall change to the observed voltammetry.

Cyclic voltammetry with the nanotrench arrays was performed in other redox couples and gave exactly the same results. Figure 4 shows the voltammetric response at $200\ mV\,s^{-1}$ taken at stage 1 (-----) and stage 4 (——) for the oxidation of a) 2,3,5,6-tetramethyl-1,4-phenylenediamine (TMPD, 1.1 mM) and b) ferrocyanide (1.1 mM) for which the background electrolyte is KCl (0.1M) in both cases. Figures 4a and b clearly show that the ensemble of nanotrenches gives almost identical *I*-*E* signals to the freshly cleaved HOPG.

In conclusion, performing cyclic voltammetry with our nanotrench arrays has answered and raised some fundamental questions. For example, we now know categorically that edge-plane sites are responsible for the cyclic voltammetric response of a basal-plane HOPG electrode; there is no reason

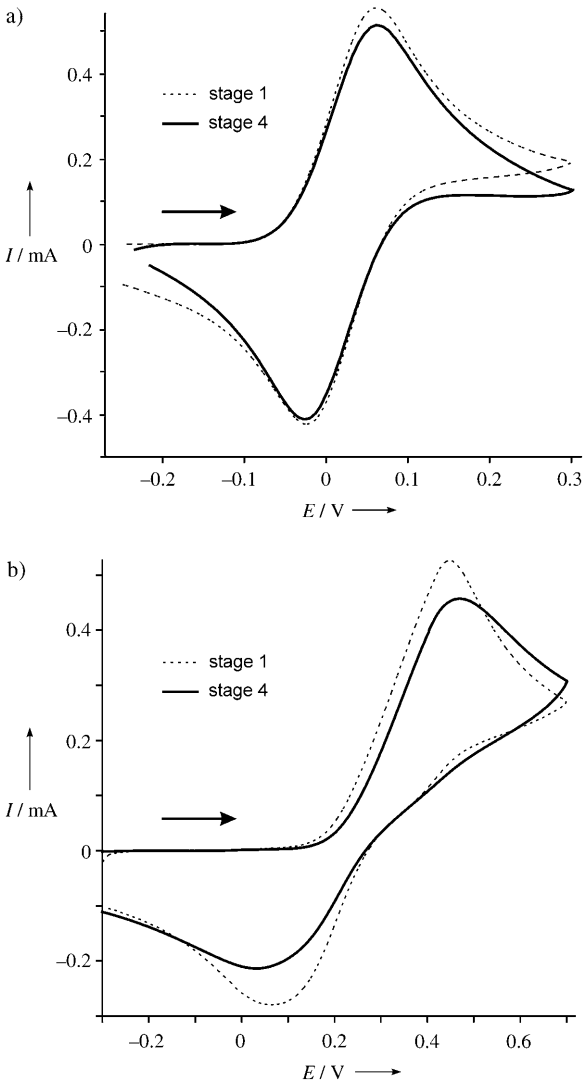

Figure 4. Cyclic voltammograms (versus SCE) taken at stage 1 (-----) and stage 4 (——) of nanotrench fabrication for the oxidation of a) TMPD (1.1 mM) and b) ferrocyanide (1.1 mM); experimental details are given in the text.

why these findings cannot be applied to other carbon materials such as carbon nanotubes (which are effectively rolled-up graphene sheets).[10,25] Furthermore, our nanotrenches could have major applications for the synthesis of nanowires, which is currently under investigation. What, however, are the implications for basal-plane graphite? The results of electrodeposition experiments demonstrate that basal-plane graphite cannot be electrochemically inert.[15] Conversely, our simulations show that k°_{basal} is significantly smaller than k°_{edge}. Otherwise, we would observe strange voltammetric characteristics.[9] The value of k°_{basal} could be determined by performing the inverse of this experiment and selectively blocking the edge-plane steps. This is currently under investigation. However, an important question to consider is why there is such a large difference in electrochemical reactivity between basal and edge-plane graphite.

To answer this question one must attempt to link electrochemical activity with electronic structure.[4] Theoretical

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

calculations predict graphite to have both semiconductor and metallic properties, in that the density of states (DOS) at the Fermi Level, E_f, is smaller than that of a metal, but there is no band gap.[26,27] The problem to consider is how the 3D pristine graphite DOS relates to our HOPG electrode surface.

In a differential capacitance study on basal-plane HOPG, Gerischer and co-workers determined the DOS around E_f to be both qualitatively and quantitatively similar to the most popular theoretical models for graphite.[28] It can therefore be inferred that the theoretical calculations for graphite are relevant to basal-plane terraces. This is not surprising; the major contribution to the DOS diagram for graphite comes from orbital overlap in the planes of individual graphene sheets, so exposing the basal plane should not have a significant effect. (Indeed, the DOS diagrams for a 2D graphene sheet and 3D graphite are similar.[27]) In addition to well-established parameters such as reorganization energy, the rate of electron transfer (reflected in the value of $k°$) also depends on the surface concentration of electrons. The electron-transfer reaction proceeds by electron tunneling; the more electrons present, the more likely it is that a tunneling event will occur.[4,29]

For metals such as gold, the DOS at E_f is relatively large, and the rates of electron transfer depend on the properties of the redox system with the electrode band structure having no limiting effect.[4,30] However, redox reactions for which the DOS at E_f is much smaller (or even zero) are limited by the low surface concentrations of electrons.[4,29] Basal-plane graphite appears to fall into this category, effectively behaving like a semiconductor with zero band gap, in agreement with the DOS diagram for graphite.

McCreery and co-workers have shown edge-plane graphite to have a capacitance over 30-fold that of basal-plane graphite.[7] Furthermore, electrochemical reactions at edge-plane pyrolytic graphite electrodes for a wide range of redox couples possess similar $k°$ values to those conducted at metal electrodes. Therefore, electron surface concentration is not a limiting factor for edge-plane graphite, and the theoretical calculations for pristine graphite are clearly not relevant. Indeed, exposed edge-plane graphite is expected to have a far different electronic structure than 3D pristine graphite, with the "cut-off" along the surface severely disrupting the main orbital interactions.

There is notable overlap between the conclusions reported herein and those of Gerischer et al.[28] In a differential capacitance study, the experimentally observed capacitance (C_{obs}) for the HOPG surface is expected to scale with the relative areas of edge-plane and basal-plane graphite, as expressed in Equation (2) in which C_i is the capacitance of the

$$C_{obs} = \frac{A_{basal}}{A_{HOPG}} C_{basal} + \frac{A_{edge}}{A_{HOPG}} C_{edge} \quad (2)$$

given electrode material, A_{HOPG} is the total area of the HOPG electrode, and A_i is the total surface area of the given electrode material. Therefore, by using high quality basal-plane HOPG, Gerischer and co-workers were able to minimize the contribution of edge-plane graphite and obtain experimental data attributable to basal-plane graphite.

In the case of cyclic voltammetry, the experimental observation is an $I-E$ response, $I-E$(HOPG). Owing to the depleting effects of nonlinear diffusion, the individual contributions of edge and basal-plane graphite do not scale with relative areas; Equation (3) is thus a more appropriate description in which

$$I-E_{HOPG} = \beta[I-E_{basal}] + \varepsilon[I-E_{edge}] \quad (3)$$

$I-E_i$ is the cyclic voltammetry response for the given electrode material and β and ε are complicated functions that take into account the relative areas and sizes of the two electrode materials as well as nonlinear diffusion. For HOPG cyclic voltammetry at scan rates of $\approx 1\ V s^{-1}$ and diffusion coefficients greater than $\approx 10^{-6}\ cm^2 s^{-1}$, $\beta = 0$, so there is no contribution from the basal-plane terraces as evidenced by the work reported herein. This means that unlike the results of Gerischer et al.,[28] the use of HOPG in cyclic voltammetry experiments (with the aforementioned parameters) will not provide experimental results that are attributable to basal-plane graphite. The same can be said for all other types of graphite electrodes. Therefore, to obtain a response from which kinetic parameters for basal-plane graphite could be determined would require setting ε to zero (by selectively blocking edge-plane sites) or by making $\beta > 0$. This approach is currently under investigation.

Previously, researchers described anomalously slow kinetics for basal-plane HOPG electrodes relative to their edge-plane counterparts. Our work herein shows that edge-plane defects are responsible for the voltammetric response at basal-plane HOPG electrodes, with the basal plane being effectively inert. A $k°_{basal}$ value significantly less than that of a metal (that is, $k°_{edge}$) agrees with the extensive amount of theoretical work on the electronic structure of graphite.[26,31–33] Therefore, we suggest the more appropriate perception that *electrochemical reactions at edge-plane graphite are anomalously fast*. Whatever the reason for this, the fact that massive changes in electronic structure occur over the traverse of a basal-plane HOPG surface is quite fascinating.

Alternate Isotope-Coded Derivatization Assay: An Isotope Dilution Method Applied to the Quantification of Zearalenone in Maize Flour**

Stefano Sforza, Chiara Dall'Asta, Alessandra Moseriti, Gianni Galaverna, Arnaldo Dossena, and Rosangela Marchelli*

The chromatographic quantification of analytes in complex matrices such as food or feed can be problematic as a result of the possible presence of interfering agents. The application of liquid chromatography coupled to mass spectrometric detection (LC–MS) is particularly helpful in these cases given the high selectivity of mass detectors. However, the response of a given amount of analyte at atmospheric pressure interfaces is quite variable, as ionization and evaporation depend on the different eluent mixtures used and small instrumental variations. They are also affected by the co-elution of interfering agents, which may result in ion-suppressive effects.[1] Moreover, serious recovery problems may arise from the extraction procedures performed to concentrate the analytes. The best way to handle these problems, given the ability of MS to detect simultaneously different isotopes of the same molecule, is to use the isotope dilution approach, in which the same analyte containing with stable isotopes is used as an internal standard.[2] The evident drawback, however, is that stable, isotope-labeled analogues of most analytes are either not available, not completely labeled, or are very costly.

Herein, we present an innovative approach for the application of isotope dilution methods to the quantification of analytes for which stable isotope-labeled analogues are not available. We were inspired by the isotope-coded affinity tagging (ICAT) method, which is widely used for the detection of differential protein expression in living systems:[3] isotope-labeled molecules can be obtained by using isotope-labeled derivatizing reagents starting either from standards or samples. The purpose of this method is to determine a suitable derivative of the analyte that is obtained by derivatization with reagents that are available in two pure isotopic forms, "light" and "heavy" (for example, protonated or deuterated). In the approach proposed herein, two standard analyte solutions containing the same amount of standard are used in two derivatization reactions, one with the "light" derivatizing reagent and the other with the "heavy"

reagent. The derivatized products are added to the matrix in two portions, with the "light" derivatized standard added to one half and the "heavy" derivatized standard to the other half. The derivatization procedure is then repeated on both matrices, thereby derivatizing the part containing the "heavy" derivatized standard with the "light" derivatizing reagent and the part containing the "light" derivatized standard with the "heavy" derivatizing reagent. Both mixtures are then extracted by conventional methods and analyzed by LC–MS, monitoring the "light"- and the "heavy"-derivatized analytes with the former as standard for the latter in one case, and vice versa in the other (Figure 1).

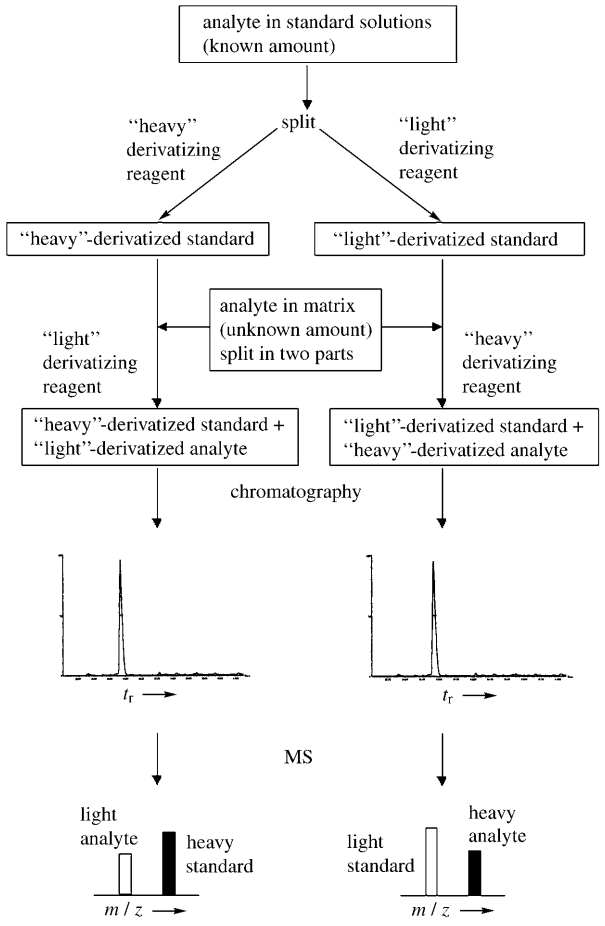

Figure 1. Procedure for the application of the AIDA method.

In this way, two independent quantifications can be carried out on the same sample. We therefore termed this method the alternate isotope-coded derivatization assay (AIDA). The addition of the derivatized internal standard before the extraction procedure permits corrections for the recovery. In the LC–MS analysis, both derivatives, which are isotopomers are expected to have almost the same retention times. They will therefore experience the same instrumental and matrix conditions, thus allowing accurate results. This procedure may allow the adoption of a fast and simplified sample preparation technique that avoids loss of analytes, as any matrix interference during LC analysis will be corrected by the use of the isotopic internal standard. Indeed, the most important self-correction of the analytical data obtained in this way comes from the use of a double determination ("light" standard and "heavy" analyte and vice versa), which allows the determination of the relative response factor (the ratio of the response factor of the analyte to that of the standard) directly on the sample analyzed, without the need to calculate it from a calibration curve or by checking the linearity range.

The theoretical background is derived directly from the following simple calculations: for the analysis of molecule **A** in the presence of an internal standard **B**, quantitative data are given by Equation (1):

$$q_A = (R_{fA}/R_{fB}) \times (A_A/A_B^S) \times q_B^S \quad (1)$$

(q : quantity; R_f : response factor; A : area; the superscript S indicates the use as internal standard)

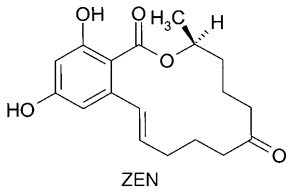
The relative response factor $R_r = (R_{fA}/R_{fB})$ usually must be calculated previously from a calibration curve. According to our AIDA method, **A** and **B** are isotopomers, and **B** is used as a standard for **A** in one case, and **A** as a standard for **B** in the other. In the latter case, Equation (1) can be written as Equation (2):

$$q_B = (R_{fB}/R_{fA}) \times (A_B/A_A^S) \times q_A^S \quad (2)$$

Dividing the two equations gives Equation (3):

$$q_A/q_{B=}(R_{fA}/R_{fB})^2 \times (A_A/A_B^S) \times (A_A^S/A_B) \times (q_B^S/q_A^S) \quad (3)$$

Clearly, $q_A/q_B = 1$, as this value should always be the same regardless of whether the analyte has been treated with the "heavy" or the "light" derivatizing reagent. Moreover, also $q_B^S/q_A^S = 1$ if the "light" and "heavy" derivatized standards are used in the same amounts. Accordingly, Equation (4) can be derived from Equation (3), thus allowing the calculation of R_r.



$$(R_{fA}/R_{fB})^2 = (A_B^S/A_A) \times (A_B/A_A^S) \quad (4)$$

It is therefore possible to calculate the relative response factor directly from the area ratios **A**/**B** obtained from the two different determinations, in which **A** and **B** are alternatively used as analyte and internal standard. The quantitative data obtained can then be corrected according to the relative response factors ($R_{fA}/R_{fB} = R_r$ and $R_{fB}/R_{fA} = 1/R_r$). It is very important to ensure that the reaction gives the same conversion both for the matrix and the standard solution to avoid inaccurate results. Moreover, for the same reasons, both "light" and "heavy" derivatizing agents should also give the same conversion. Both these conditions appear to be easily achievable.

To test the applicability of the method, we addressed the quantification of the mycotoxin Zearalenone (ZEN) in food and feed. ZEN is a fungal toxin that is mainly produced by several *Fusarium* species, such as *F. culmorum, F. graminearum*, and *F. sporotrichioides*, which are known to colonize maize, barley, wheat, oats, and sorghum in both warm and temperate climates.[4] ZEN consists of a resorcinol moiety

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

fused to a 14-membered macrocyclic lactone ring that includes a *trans* double bond, a ketone, and a methyl substituent on a stereogenic center. The structure is flexible

ZEN

enough to allow ZEN to adopt a conformation that is able to bind to the mammalian estrogen receptor; ZEN can therefore act as an endocrine disrupter.[5] The analysis of ZEN is commonly performed by applying a clean-up step with immunoaffinity chromatography (IAC) after extraction, followed by HPLC with fluorescence detection that takes advantage of the native fluorescence of this mycotoxin.[6] As an alternative to fluorescence detection, several LC–MS methods have been developed with various interfaces.[7] In all cases, however, quantification was hampered by the choice of an appropriate standard.

To apply the AIDA method to the ZEN molecule, we chose as derivatizing reagent a compound that can easily react with the hydroxy functional groups, and which is commonly available in two isotopic forms: acetic anhydride and its deuterated [D_6] analogue. A standard solution of ZEN was derivatized either with [H_6]- or [D_6]acetic anhydride,[8] and LC–MS analysis[9] revealed only the presence of the [H_6]- or [D_6]bisacetylated compound, respectively, with no chromatographic peaks attributable to nonderivatized or monoacetylated toxin (Figure 2). NaCl was added to the eluent to enhance detection of the sodiated compounds according to a method recently published by our research group[10]: infusion experiments of ZEN and bisacetylated ZEN performed by adding NaCl to the solvent confirmed that, under these conditions, only the sodiated molecular ion is present; LC–MS experiments performed with and without NaCl added to the eluent showed an average 20-fold increase of the chromatographic peak intensity for the former relative to the latter case (data not shown).

The derivatization reaction was also repeated in food matrices by spiking several toxin-free maize flour samples with ZEN. The samples were blended and the toxins extracted in a 1:4 water/acetonitrile mixture, filtered, evaporated to dryness, and derivatized with acetic anhydride.[11] Again, only the bisacetylated compounds were observed by LC–MS both with [H_6]- and [D_6]acetic anhydride (Figure 2). To ensure that the AIDA method gives no artifacts, some important controls were performed. The most important was the stability of the acetyl groups during the derivatization reaction. As after the addition of the [D_6]bisacetylated standard to the food matrix, a second acetylation with [H_6]acetic anhydride is carried out (or vice versa), it is essential that the acetyl groups do not undergo exchange with each other. This control can be done rapidly in the case of ZEN: if an exchange does occur, it would be possible to detect bisacetylated molecules that bear one [H_3]acetyl group and one [D_3]acetyl group. As shown in

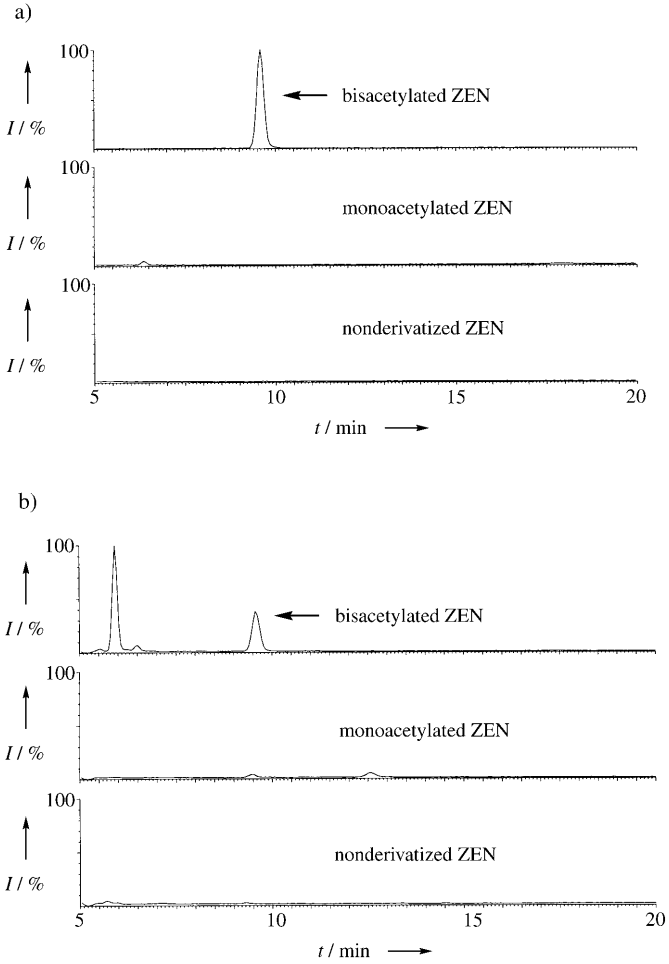


Figure 2. LC–MS chromatograms (single-ion mode acquisition of sodiated molecular ions) of the acetylation reaction in a) standard solution and b) with spiked flour. Bisacetylated, monoacetylated, and nonderivatized ZEN were monitored, thus confirming that in both cases only the bisacetylated compound was present.

Figure 3, no species of this type were detected after the derivatization reaction. Full-scan MS data of the [D_6]bisacetylated ZEN also confirmed that the protons on the acetyl groups do not exchange with the solvent, as the molecule shows only minimal traces of a [D_5H]compound that was already present in the starting [D_6]acetic anhydride preparation and no sign of other [$D_{6-x}H_x$]derivatives.

The above method was then applied to the determination of ZEN in several spiked maize flours by LC–MS.[11] The limits of detection (S/N = 3:1) and quantification (S/N = 10:1) of the method were determined by spiking toxin-free flour samples at the appropriate level and were found to be 5 ppb (absolute amount injected: 100 pg) and 10 ppb (absolute amount injected: 200 pg), respectively. Notably, a calibration curve was not calculated before the analyses, and six independent determinations (three with the deuterated standard and three with the protonated standard) were run for every sample. The chromatographic peak areas were then measured for both isotopes by extracting the chromatograms given by the corresponding sodiated ions. The response-factor ratios were calculated from Equation (4) and the amounts

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

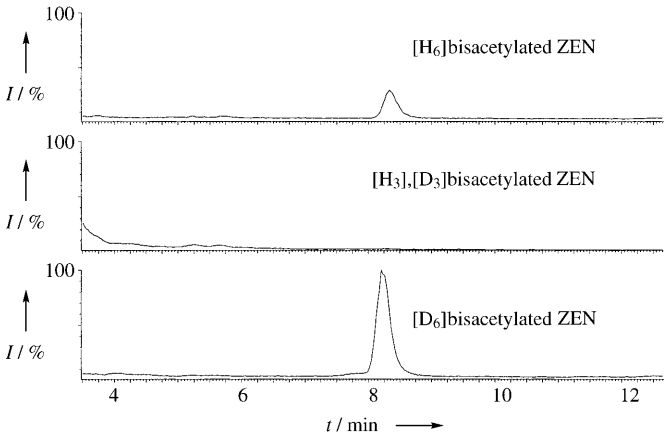

Figure 3. LC–MS chromatograms (single-ion mode acquisition of sodiated molecular ions) of a flour preparation spiked with [D_6]bisacetylated ZEN and derivatized with [H_6]acetic anhydride. [D_3],[H_3]bisacetylated ZEN was not detected, thus indicating the absence of acetyl group exchange.

were then calculated from Equations (1) and (2). The true results were taken as the average of these six determinations. The data are reported in Table 1, together with the results for

Table 1: Determination of ZEN in spiked samples and in a FAPAS-certified reference material.

Quantity spiked [ppb]	Quantity detected [ppb]	Average response factor ratio [H_6]Ac_2-ZEN/ [D_6]Ac_2-ZEN
10	13 ± 3	1.20 ± 0.14
50	48 ± 7	1.20 ± 0.17
100	104 ± 5	1.26 ± 0.05
500	516 ± 58	1.34 ± 0.05
1000	1039 ± 72	1.41 ± 0.02
certified flour (648 ± 140)	709 ± 24	1.07 ± 0.04

a FAPAS-certified reference material (FAPAS = food analysis performance assessment scheme). The results are quite outstanding, considering that no calibration curve or linearity tests were performed. The response ratio between protonated and deuterated compounds was calculated in every sample analyzed and are also reported in Table 1. These ratios always appear to be slightly, yet significantly, different from unity, which implies that the methodology proposed herein must be followed with the subsequent response-factor correction for the results to be accurate. These data constitute definitive proof of the validity of the AIDA concept. The chromatograms of the FAPAS-certified reference material corresponding to the two cases ([H_6]acetylated ZEN as standard with [D_6]acetylated ZEN as analyte and [D_6]acetylated ZEN as standard with [H_6]acetylated ZEN as analyte) are shown in Figure 4. Notably, in all these cases, no IAC purification was carried out before the LC–MS analyses, which is usually performed before ZEN analysis by LC-FLD (FLD = fluorescence detection), which demonstrates that the acetylation procedure used is also suitable for the detection of ZEN in

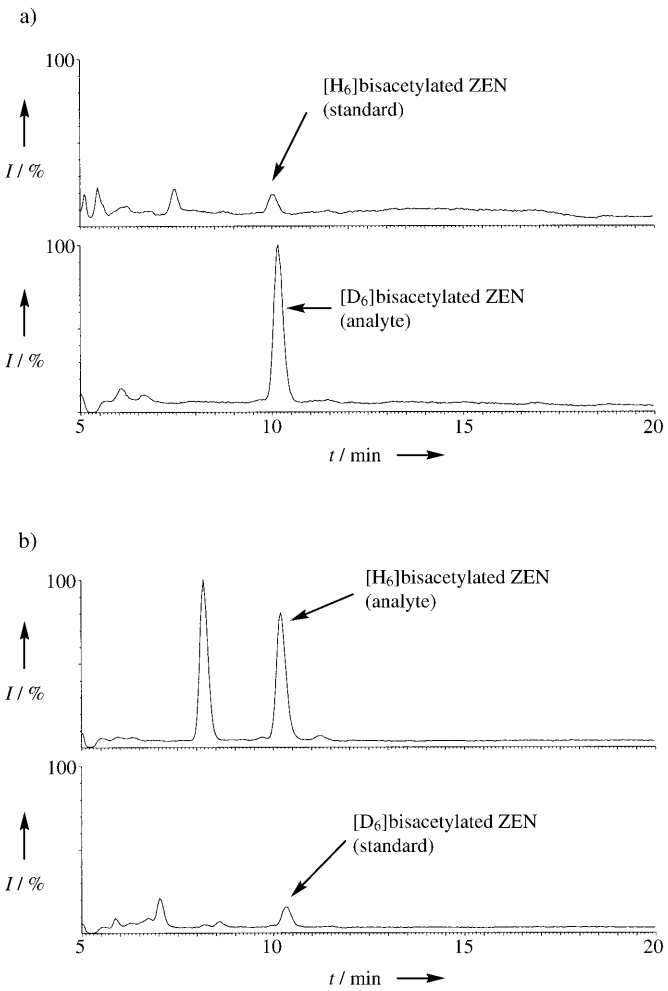

Figure 4. LC–MS chromatograms (single-ion mode acquisition of sodiated molecular ions) of a) the FAPAS-certified flour with added [H_6]bisacetylated ZEN (standard, 100 ppb) and derivatized with [D_6]acetic anhydride and b) the same sample with added [D_6]bisacetylated ZEN (standard, 100 ppb) and derivatized with [H_6]acetic anhydride.

natural samples by using raw extracts. This allows one to avoid the cumbersome and expensive IAC clean-up procedure that can also prevent a full recovery of the analyte.

The data presented herein on the quantification of ZEN in flour samples demonstrate how the AIDA method may be applied for the accurate quantification of analytes in complex matrices, such as food or feed, by LC–MS. This method avoids errors due to instrumental and matrix effects, yields accurate results with minimal sample preparation, and exploits all the advantages of isotope dilution methods in a low-cost, easy-to-perform procedure, although two independent experiments have to be performed for each sample analyzed. This procedure is currently being extended to the detection of other mycotoxins in food samples.

[8] Procedure for the preparation of derivatized standards: 100 μL of a 10-ppm standard solution of ZEN in dry acetonitrile was added to 35 μL triethylamine, 270 μL dry acetonitrile, and 95 μL either [H_6]- or [D_6]acetic anhydride. The mixture was left at room temperature for 60 min, then evaporated to dryness and redissolved in 1 mL water/acetonitrile (1:4) to be added to the food/feed samples or directly analyzed by LC–MS.
[9] LC–MS conditions: C18 column (Waters, 250 × 4.6, 5 μm) on a Waters Alliance 2695 separation module, isocratic elution with 0.2 mM aqueous NaCl/CH_3OH (35:65); flow: 1 mL min^{-1}. Injected volume: 10 μL. A Micromass ZMD mass spectrometer equipped with an ESI interface was used as MS detector by splitting 90% of the flow with a T-valve before the probe. Acquisition in positive ion mode; capillary voltage: 3.5 kV (pos); cone voltage: 30 V (pos); source temperature: 80 °C; desolvation temperature: 150 °C; cone gas (N_2): 100 L h^{-1}; desolvation gas (N_2): 400 L h^{-1}. Acquisition in single-ion monitoring: $m/z = 425.3$ for sodiated [H_6]bisacetylated ZEN and 431.3 for sodiated [D_6]bisacetylated ZEN; dwell time: 0.5 s; span: 0.2. Acquisition in full scan: range: 150–1000; scan time: 3 s; inter-scan delay: 0.1 s.
[10] C. Dall'Asta, S. Sforza, G. Galaverna, A. Dossena, R. Marchelli, *J. Chromatogr. A* **2004**, *1054*, 389–395.
[11] Sample preparation: 10 g flour was mixed with 39 mL water/acetonitrile (1:4) and 1 mL of a water/acetonitrile (1:4) solution containing 1 μg of [H_6]- or [D_6]bisacetylated ZEN, prepared as reported in Ref. [8]. The mixture was blended for 2 min in a high-speed blender. After filtration through paper filters, the filtrate (4 mL) was dried under a nitrogen stream. The residue was redissolved in 35 μL triethylamine, 370 μL dry acetonitrile, and 95 μL [H_6]acetic anhydride (in the case of [D_6]bisacetylated standard) or [D_6]acetic anhydride (in the case of [H_6]bisacetylated standard). For acidic food matrices, which may give incomplete derivatization, the amount of triethylamine was doubled. The mixture was left at room temperature for 60 min, then evaporated to dryness and redissolved in 500 μL water/acetonitrile (1:4) to be analyzed by LC–MS.

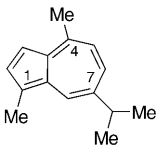
Approach to the Blues: A Highly Flexible Route to the Azulenes**



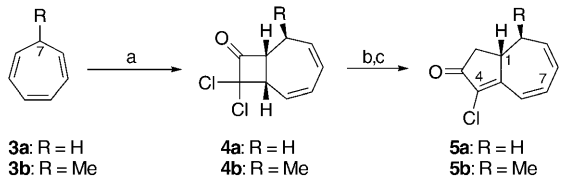
*Sébastien Carret, Aurélien Blanc, Yoann Coquerel, Mikaël Berthod, Andrew E. Greene, and Jean-Pierre Deprés**

Dedicated to Dr. Jean-Louis Luche on the occasion of his retirement

Nearly a century and a half ago, Septimus Piesse applied the descriptive name azulene to azure-blue distillates from various sources, such as chamomile, yarrow, and wormwood.[1] However, it was only in 1937 that Placidus Plattner and Alexander Pfau successfully carried out the first synthesis of azulene (**1**),[2] the appellation given to the parent compound

Azulene (**1**)

Guaiazulene (**2**)



of the family of bicyclo[5.3.0]decapentaenes, which are now collectively referred to as the azulenes. Since this historical event, additional syntheses of the parent azulene and preparations of various other azulenes, such as guaiazulene (**2**), which is the archetype of the major azulene class, have been reported.[3] Although the approaches to these fascinating and electronically unique compounds are often ingenious, they suffer for the most part from being excessively long, low yielding, or lacking in generality. Many substitution patterns of the azulenes are still difficult to access, if they can be accessed at all.[3]

We have found that chlorotrienones **5a** and **5b** are readily prepared from cycloheptatriene and 7-methylcycloheptatriene, respectively, through a doubly regioselective cycloaddition of dichloroketene, a regioselective ring expansion with ethereal diazomethane, and dehydrochlorination in dimethylformamide (DMF; Scheme 1).[4]

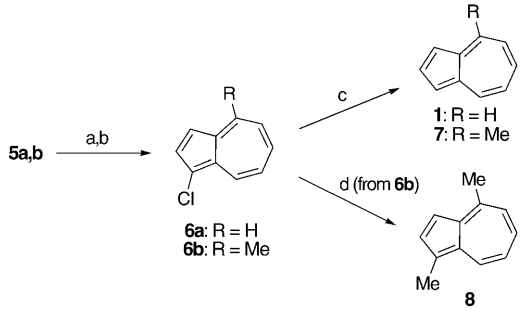
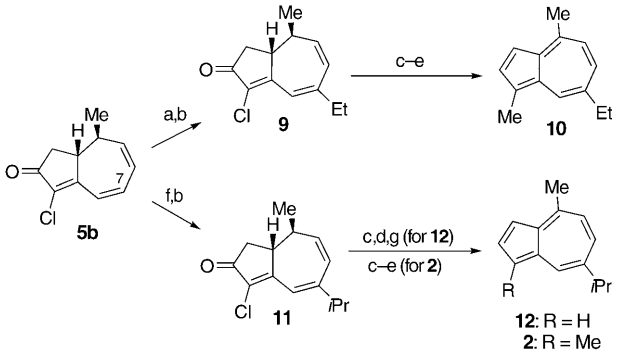


Scheme 1. Preparation of chlorotrienones **5a** and **5b**: a) Zn/Cu, $POCl_3$, CCl_3COCl, Et_2O, 20 °C, 20 h; b) CH_2N_2, MeOH/Et_2O (5:95), 0→20 °C, 35 min; c) DMF, 20 °C, 12 h (44–45 % yield, 3 steps).

As other C7-substituted cycloheptatrienes and diazoalkane reagents are also readily available[4a,5] for use in this sequence, it appeared to us that a broad approach to the azulenes might now be possible if 1) the oxygen atom at C3 could be excised, 2) the fused rings could be dehydrogenated to aromaticity, 3) the chlorine atom at C4 could be replaced, and 4) additional substituents could be regioselectively introduced into the trienones, particularly at C7. Herein, we disclose an efficient and exceptionally versatile preparation of azulenes, which are compounds of considerable interest for use in cosmetics,[6a] pharmaceutical preparations,[6b] and new molecular materials,[6c] through effective resolution of these concerns.

Azulene itself was targeted initially so that the first three critical points could be addressed at the outset. It was pleasing to find, after a number of failed attempts, that sequential treatment of **5a** with $NaBH_4/CeCl_3$, the Burgess reagent,[7] and *p*-chloranil could transform **5a** into chloroazulene **6a** in 45 % overall yield (Scheme 2).[8] Azulene could then be obtained from **6a** in 92 % yield through modification of the reduction recently described by Rahaim and Maleczkza.[9] Analogously, 4-methylazulene (**7**)[2,10] was readily prepared from **5b** in a slightly higher overall yield.

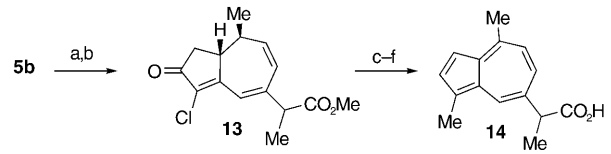


As most naturally occurring azulenes have methyl groups at C1 and C4, the discovery that **6b** could also be methylated by reaction with methylboronic acid, dpdb, and K_3PO_4[11] to give 1,4-dimethylazulene (**8**)[12a] in 98 % yield was welcomed

Scheme 2. Preparation of azulene (**1**), 4-methylazulene (**7**), and 1,4-dimethylazulene (**8**): a) $NaBH_4$, MeOH/$CeCl_3$, 0 °C, 1.5 h (from **5a**: 96 %; from **5b**: 98 %); b) the Burgess reagent, THF, 0→20 °C, 1 h; *p*-chloranil, 20 °C, 24 h (from **6a**: 47 %; from **6b**: 52 %); c) PMHS, $Pd(OAc)_2$, dpdb, K_3PO_4, THF, 80 °C, 12 h (**1**: 92 %; **7**: 91 %); d) $MeB(OH)_2$, $Pd(OAc)_2$, dpdb, K_3PO_4, PhMe, 100 °C, 24 h (98 %). Burgess reagent = (methoxycarbonylsulfamoyl)triethylammonium hydroxide inner salt, *p*-chloranil = tetrachloro-1,4-benzoquinone, PMHS = poly(methylhydrosiloxane), dpdb = dicyclohexylphosphano-2′,6′-dimethoxybiphenyl.

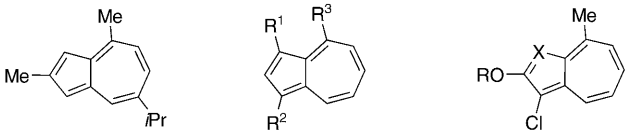
and augured well for the application of this approach to many other naturally occurring azulenes.[12b]

Considerable study was required to resolve point (4) satisfactorily. Although several different types of organometallic reagents did indeed add regio- (and stereo-)selectively to **5b** at C7, the yields were modest and, furthermore, aromatization of the resultant dienones proved difficult to achieve efficiently. We were, therefore, pleased to find that organozinc reagents, in the presence of CuOTf (cat.) and TMSCl,[13] were highly effective in transforming **5b** into the corresponding 1,6-conjugate addition products: Me, 91 %; Et, 98 %; *i*Pr, 71 %. Even better, it was discovered that simply by adding PhSeCl to the reaction mixture and then effecting oxidative (H_2O_2) elimination, the chlorotrienone system could be smoothly regenerated (Scheme 3).[14] Thus, chloro-



Scheme 3. Preparation of chamazulene (**10**), 7-isopropyl-4-methylazulene (**12**), and guaiazulene (**2**): a) 1. Et_2Zn, CuOTf, HMPA, TMSCl, −50 °C, 6 h; 2. PhSeCl, −50→0 °C, 2 h; b) H_2O_2, pyridine, 0 °C, 1 h (**9**: 71 %, 2 steps; **11**: 62 %, 2 steps); c) $NaBH_4$, MeOH/$CeCl_3$, 0 °C, 1.5 h (97 %); d) 1. Burgess reagent, THF, 0 °C, 1 h; 2. *p*-chloranil, 20 °C, 24 h (58–59 %); e) $MeB(OH)_2$, $Pd(OAc)_2$, dpdb, K_3PO_4, PhMe, 100 °C, 24 h (**10**: 89 %; **2**: 94 %); f) 1. iPr_2Zn, CuOTf, HMPA, TMSCl, −100 °C, 6 h; 2. PhSeCl, −50→0 °C, 2 h; g) PMHS, $Pd(OAc)_2$, dpdb, K_3PO_4, THF, 80 °C, 12 h (95 %). Tf = trifluoromethanesulfonyl, HMPA = hexamethylphosphoramide, TMSCl = trimethylsilyl chloride.

trienones **9** and **11** were prepared in 71 and 62 % yields, respectively. The former, through application of the above chemistry, provided chamazulene (**10**), and the latter, 7-isopropyl-4-methylazulene (**12**) and guaiazulene (**2**).[15]



Ketene acetals can also be employed for 1,6-conjugate addition, thus adding to the synthetic possibilities: the treatment of **5b** with the *tert*-butyldimethylsilyl (TBDMS) ketene acetal, derived from methyl propionate, in the presence of lithium perchlorate[16] readily generated the 1,6-conjugate addition product, which on successive treatment with PhSeCl and H_2O_2 afforded chlorotrienone **13** (Scheme 4). Aromatization, methylation, and saponification then provided chamazulenecarboxylic acid (**14**).[17]

The attractiveness of the present approach resides, in part, in the diversity of structures that can readily be accessed with total regiocontrol, a feature that few other approaches enjoy. To further illustrate this point, regiochemically pure 7-isopropyl-2,4-dimethylazulene (**15**)[18a] (a naturally occurring isomer of guaiazulene (**2**)),[15b] 1-chloro-3-methylazulene (**16a**),[18b] and the phenylazulenes **16b**[18c] and **16c**[18d] have

Scheme 4. Preparation of (±)-chamazulenecarboxylic acid (**14**): a) 1. MeCH=C(OMe)OTBDMS, $LiClO_4$, CH_2Cl_2, 20 °C, 12 h; 2. PhSeCl, −50→0 °C, 2 h; b) H_2O_2, pyridine, 0 °C, 1 h (46%, 2 steps); c) $NaBH_4$, MeOH/$CeCl_3$, 0 °C, 1.5 h (92%); d) 1. Burgess reagent, THF, 0 °C, 1 h; 2. *p*-chloranil, 20 °C, 24 h (55%); e) $MeB(OH)_2$, $Pd(OAc)_2$, dpdb, K_3PO_4, PhMe, 100 °C, 24 h (99%); f) LiOH, THF, H_2O, 20 °C, 12 h (94%).

15

16a: R^1 = Me, R^2 = Cl, R^3 = H
16b: R^1 = H, R^2 = Cl, R^3 = Ph
16c: R^1 = H, R^2 = Ph, R^3 = Me

17a: R = Ac, X = CH
17b: R = Me, X = N

also been efficiently prepared, thereby demonstrating four distinctly different substitution options as well. Finally, acetoxy and aza derivatives **17a**[18e] and **17b**[18f] are examples of novel azulenes that are readily prepared with this methodology.

In conclusion, modern chemistry has been applied to the long-standing problem of azulene synthesis and an efficient, highly flexible approach has resulted. Our approach allows controlled access to a wide variety of substituents and substitution arrays and should prove to be among the most broadly useful methods to prepare these important compounds.

Experimental Section

Experimental procedure for the preparation of **6b** from **5b**: $NaBH_4$ (43 mg, 1.13 mmol) was added to a stirred solution of **5b** (200 mg, 1.03 mmol) in MeOH/$CeCl_3$ (2.80 mL, 0.40 M, 1.12 mmol) at 0 °C. The reaction mixture was stirred for 1.5 h at 0 °C and then treated with a saturated solution of aqueous NaH_2PO_4. The crude product was isolated with EtOAc/pentane (1:1) in the usual manner and purified by column chromatography on dry silica gel with diethyl ether/pentane (40:60) to afford 198 mg (98%) of the *trans* alcohol as a white solid. M.p. 67–68 °C; ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.17 (d, J = 7.1 Hz, 3H), 1.38–1.48 (m, 1H), 2.16–2.24 (m, 2H), 2.33 (pseudo q, $J\cong$7.3 Hz, 1H), 2.68–2.77 (m, 1H), 4.57 (pseudo t, $J\cong$7.2 Hz, 1H), 5.66 (dd, J = 11.4, 3.3 Hz, 1H), 5.85–5.94 (m, 1H), 6.01 (dd, J = 11.5, 6.9 Hz, 1H), 6.51 ppm (d, J = 11.5 Hz, 1H); ^{13}C NMR (75.5 MHz, $CDCl_3$): δ = 19.2, 38.9, 40.3, 46.6, 74.6, 123.7, 125.3, 127.7, 133.6, 139.6, 141.5 ppm; FTIR: $\tilde{\nu}$ = 3360, 3016, 1700 cm^{-1}. A solution of the Burgess reagent (347 mg, 1.46 mmol) in dry THF (5 mL) was added to a stirred solution of the above alcohol (198 mg, 1.01 mmol) in dry THF (6.0 mL) at 0 °C. The reaction mixture was allowed to warm to 20 °C and stirred for 1 h, whereupon *p*-chloranil (745 mg, 3.03 mmol) was added and the resulting mixture was stirred for a further 24 h. The crude product was isolated with pentane in the usual way and purified by column chromatography on dry silica gel with pentane to give 92 mg (52%) of chloroazulene **6b** as a blue solid. M.p. 36 °C; ^{1}H NMR (300 MHz, $CDCl_3$): δ = 2.86 (s, 3H), 7.13 (d, J = 10.3 Hz, 1H), 7.14 (pseudo t (dd), $J\cong$9.5 Hz, 1H), 7.30 (d, J = 4.2 Hz, 1H), 7.53 (pseudo t (dd), $J\cong$10.3 Hz, 1H), 7.67 (d, J = 4.2, 1H), 8.40 ppm (d, J = 9.5 Hz, 1H); ^{13}C NMR (75.5 MHz, $CDCl_3$): δ = 24.1, 113.4, 117.1, 122.0, 127.2, 133.3, 133.5, 134.8, 136.7, 137.8, 148.0 ppm; FTIR: $\tilde{\nu}$ = 3085, 3021, 2957, 2923, 2853, 1591, 1560, 1487, 1419, 1389, 1358, 906, 772, 743 cm^{-1}; MS (DCI): m/z: 177 $[M+H]^+$; HRMS calcd for $[C_{11}H_9Cl+H]^+$: 177.0471; found: 177.0484; elemental analysis (%) calcd for $C_{11}H_9Cl$: C 74.79, H 5.14; found: C 74.84, H 5.18.

Data for selected compounds: **2**: M.p. 31–32 °C; ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.36 (d, J = 6.9 Hz, 6H), 2.66 (s, 3H), 2.83 (s, 3H), 3.08 (sept, J = 6.9 Hz, 1H), 7.01 (d, J = 10.7 Hz, 1H), 7.22 (d, J = 3.7 Hz, 1H), 7.42 (dd, J = 10.7, 1.8 Hz, 1H), 7.62 (d, J = 3.7 Hz, 1H), 8.19 ppm (d, J = 1.8 Hz, 1H); ^{13}C NMR (75.5 MHz, $CDCl_3$): δ = 13.0, 24.2, 24.9, 38.4, 112.9, 125.2, 125.3, 133.5, 135.0, 136.2, 136.4, 137.4, 140.0, 144.4 ppm; FTIR: $\tilde{\nu}$ = 3095, 3064, 2958, 2924, 2854, 1554, 1527, 1462, 1420, 1387, 1367, 772 cm^{-1}; MS (DCI): m/z: 199 $[M+H]^+$; HRMS calcd for $[C_{15}H_{19}+H]^+$: 199.1487; found: 199.1482.

10: ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.34 (t, J = 7.6 Hz, 3H), 2.65 (s, 3H), 2.82 (s, 3H), 2.83 (q, J = 7.6 Hz, 2H), 6.98 (d, J = 10.5 Hz, 1H), 7.21 (br s, 1H), 7.38 (dd, J = 10.5, 1.9 Hz, 1H), 7.61 (br s, 1H), 8.15 ppm (d, J = 1.9 Hz, 1H); ^{13}C NMR (75.5 MHz, $CDCl_3$): δ = 13.0, 17.5, 24.2, 34.0, 112.9, 125.1, 125.2, 134.8, 135.9, 136.3, 136.4, 136.5, 137.5, 144.4 ppm; FTIR: $\tilde{\nu}$ = 3098, 3063, 2960, 2926, 2866, 1555, 1561, 1526, 1452, 1422, 1364, 772 cm^{-1}; MS (DCI): m/z: 185 $[M+H]^+$; HRMS calcd for $[C_{14}H_{16}+H]^+$: 185.1330; found: 185.1334; elemental analysis (%) calcd for $C_{14}H_{16}$: C 91.25, H 8.75; found: C 91.44, H 8.86.

12: ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.35 (d, J = 6.8 Hz, 6H), 2.88 (s, 3H), 3.07 (sept, J = 6.8 Hz, 1H), 7.11 (d, J = 10.6 Hz, 1H), 7.29 (d, J = 3.8 Hz, 1H), 7.31 (d, J = 3.8 Hz, 1H), 7.46 (dd, J = 10.6, 2.0 Hz, 1H), 7.80 (pseudo t (dd), $J\cong$3.8 Hz, 1H), 8.31 ppm (d, J = 2.0 Hz, 1H); ^{13}C NMR (75.5 MHz, $CDCl_3$): δ = 24.3, 24.7, 38.2, 114.7, 118.0, 126.0, 135.3, 135.4, 136.6, 137.4, 140.2, 141.8, 145.2 ppm; FTIR: $\tilde{\nu}$ = 3093, 3064, 2958, 2924, 1556, 1529, 1461, 1422, 1389, 1362, 749 cm^{-1}; MS (DCI): m/z: 185 $[M+H]^+$; HRMS calcd for $[C_{14}H_{16}]^+$: 184.1252; found: 184.1259.

14: M.p. 86–87 °C; ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.61 (d, J = 7.2 Hz, 3H), 2.65 (s, 3H), 2.83 (s, 3H), 3.88 (q, J = 7.2 Hz, 1H), 7.00 (d, J = 10.7 Hz, 1H), 7.28 (d, J = 3.8 Hz, 1H), 7.44 (dd, J = 10.7, 1.9 Hz, 1H), 7.64 (d, J = 3.8 Hz, 1H), 8.22 ppm (d, J = 1.9 Hz, 1H); ^{13}C NMR (75.5 MHz, $CDCl_3$): δ = 13.0, 19.2, 24.2, 48.8, 114.3, 125.1, 127.1, 130.9, 133.9, 135.7, 135.8, 136.9, 137.6, 145.6 ppm; FTIR: $\tilde{\nu}$ = 3585, 3103, 3065, 2961, 2923, 2853, 1704, 1556, 1454, 1261, 1023, 774 cm^{-1}; MS (DCI): m/z: 229 $[M+H]^+$.

Through-Space (Cofacial) π-Delocalization among Multiple Aromatic Centers: Toroidal Conjugation in Hexaphenylbenzene-like Radical Cations**

*Duoli Sun, Sergiy V. Rosokha, and Jay K. Kochi**

Strong (nonbonded) π-to-π interactions were first recognized by the appearance of characteristic near-IR absorption bands and doubled hyperfine lines in the electronic and ESR spectra of various intermolecular dimer cations formed upon electron ejection from stacked aromatic donors, as in $\mathbf{I} \rightarrow \mathbf{I}^{+\cdot} + e^-$.[1,2] Equivalent spectral changes are also observed in the corresponding intramolecular assembly derived from tethering the same aromatic dyad, as in **II** (Do = electron donating functional group).[3,4] Indeed, such a spectral (NIR, ESR) equivalence relates to the common π-electronic transition from the filled HOMO to the singly occupied LUMO that are

I **II**

Supporting information for this article (synthesis, characterization, and X-ray data for the hexaarylbenzene donors **1**–**3**, spectral (Vis-NIR) characterization of their radical cations, and Mulliken–Hush (six-state) analysis of the radical cation of **1**) is available on the WWW under http://www.angewandte.org or from the author.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

more or less equally disposed in **I** and **II**. This HOMO–LUMO or charge-transfer (intervalence) transition is well accommodated by Mulliken–Hush theory to provide the important connection between the experimental NIR spectrum and the electronic coupling energy (H_{DA}) that binds such cofacial moieties.[5]

In broader context, the further applicability of Mulliken–Hush theory to extended aromatic (stacking) arrays that are inherent to molecular conductors and wires for organic materials science,[6] depends first on the stepwise extension of the dyad structure **II** to the closed-loop hexad structure **III**,[7] in which extensive π-electron delocalization would result in complete toroidal conjugation **IV** in the limit of

strong interactions among the six (Do-phenyl) centers.[8] To this end, we now report the synthesis and structural characterization of the hexadonor **1** (see the Supporting Information for structure) which is an analogue of **III** containing six electron-rich anilinyl groups with the six donor groups Do being *N*,*N*-diethylamino or *N*-methyl-*N*-ethylamino. Compound **1** has highly unusual redox properties in two important ways: First, the linear-sweep voltammogram of the hexaanilinylbenzene **1** (Figure 1 A) shows a reversible one-electron-

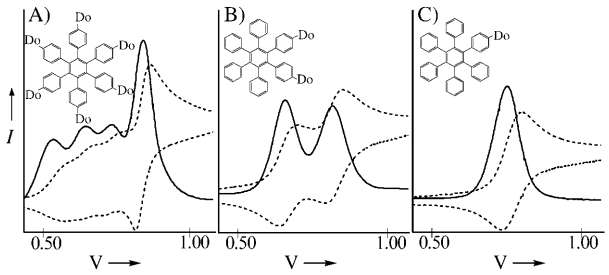

Figure 1. CV (dotted line) and Osteryoung square-wave voltammetry (OSWV; solid line) in V versus SCE of A) hexadonor **1**, B) bidonor **2**, and C) monodonor **3**.

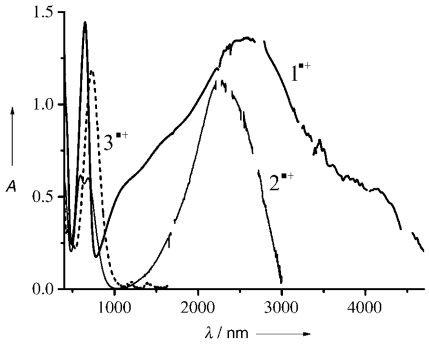
oxidation wave at $E_{1/2} = 0.51$ V (versus saturated calomel electrode (SCE)) which is strongly (negative) shifted relative to those of the bis and monoanilinyl analogues **2** and **3** (Figure 1 B and C). Indeed, the voltammetry of **1** shows four separate anodic waves at 0.51, 0.64, 0.74, and 0.86 V; and controlled-potential coulommetry reveals each of the first three waves to correspond to reversible one-electron changes and the fourth a composite three-electron process.

The wide separation of the potentials of the redox events in **1** allow the radical cation (**1**$^{\bullet+}$) to be quantitatively prepared either by controlled-potential anodic oxidation or by chemical oxidation with dodecamethylcarboranyl (B$^{\bullet}$).[3b] In the latter case, the blue polycrystalline solid is isolated in excellent yields and quantitatively analyzed as **1**$^{\bullet+}$B$^-$.

The second unusual redox property of **1** is detected in the electronic spectrum of **1**$^{\bullet+}$, generated by either method. This spectrum shows the highly distinctive low-energy absorption (Figure 2) that stretches continuously from the visible (red)



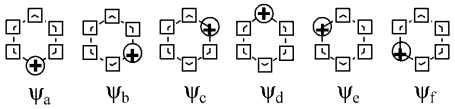


Figure 2. Electronic spectrum of hexadonor radical cation **1**$^{\bullet+}$ in comparison with its bidonor **2**$^{\bullet+}$ and monodonor **3**$^{\bullet+}$ models.

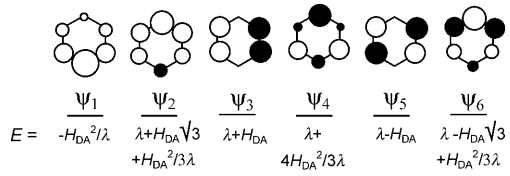
region all the way to the infrared region beyond 4000 nm (with $\lambda_{max} = 2570$ nm, $\varepsilon = 3300\ M^{-1}cm^{-1}$). By comparison, the bidonor analogue **2**$^{\bullet+}$ merely exhibits a single near-Gaussian[9] band in the NIR region with $\lambda_{max} = 2300$ nm ($\varepsilon = 2800\ M^{-1}cm^{-1}$); and the monodonor **3**$^{\bullet+}$ is completely transparent in the region beyond 1000 nm. Indeed, such characteristic low-energy optical behaviors in **1**$^{\bullet+}$ and **2**$^{\bullet+}$ are diagnostic of intervalence transitions as observed in both organic and inorganic mixed-valence systems.[3,5,10]

To account for the spectral and electrochemical properties of the radical cation **1**$^{\bullet+}$, we extend the Mulliken–Hush (two-state) model to the redox system with six equivalent (anilinyl) centers. The diabatic (non-interacting) states $\psi_a - \psi_f$ with the hole localized on different centers in the hexagonal array are presented pictorially in Scheme 1 (hole = ⊕) and the adiabatic wave functions ($\Psi_1 - \Psi_6$) of **1**$^{\bullet+}$ are given in Equation (1).

$$\Psi_i = a_i\,\psi_a + b_i\,\psi_a + c_i\,\psi_c + d_i\,\psi_d + e_i\,\psi_e + f_i\,\psi_f \qquad (1)$$



Scheme 1.

To evaluate the adiabatic states, we follow Lambert–Noll[7b] and take into account only equivalent interactions (H_{DA}) between neighboring groups (neglecting other interactions), and set the diabatic state ψ_a with relaxed nuclear geometry of all six centers as the zero point of reaction coordinate (i.e., $H_{aa} = 0$ at $X = 0$). As such, the energy of the other diabatic states at the same point on the nuclear reaction coordinate (Franck–Condon excitation) are equal to the reorganization energy λ; and the secular determinant is expressed as Equation (2).

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

$$\begin{vmatrix} -E & H_{DA} & 0 & 0 & 0 & H_{DA} \\ H_{DA} & \lambda-E & H_{DA} & 0 & 0 & 0 \\ 0 & H_{DA} & \lambda-E & H_{DA} & 0 & 0 \\ 0 & 0 & H_{DA} & \lambda-E & H_{DA} & 0 \\ 0 & 0 & 0 & H_{DA} & \lambda-E & H_{DA} \\ H_{DA} & 0 & 0 & 0 & H_{DA} & \lambda-E \end{vmatrix} = 0 \quad (2)$$

The resulting energy levels of the adiabatic states (truncated to the second order) and their pictorial representations are shown in Scheme 2 (exact eigenvalues and

Scheme 2.

coefficients a_i–f_i in terms of H_{DA} and λ are given in the Supporting Information). In contrast to bidonor **2**$^{\bullet+}$ with one intervalence transition (i.e., $\nu_{IV}=\lambda$), the absorption band of **1**$^{\bullet+}$ contains five optical transitions with energies determined as differences between ground state Ψ_1 and excited states Ψ_2 to Ψ_6. The intensities of the transitions are related to the corresponding transition moments which can be expressed (according to Mulliken–Hush theory[5]) as Equation (3), in which $i=2$ to 6, and μ_a to μ_f are moments of diabatic states a to f within the arbitrarily chosen coordinate system.

$$\mu_{oi} = \int \Psi_1 \mu \Psi_i = \int (a_1\psi_a + \ldots + f_1\psi_f)\mu(a_i\psi_a + \ldots + f_i\psi_f) \approx (a_1 a_i \mu_a + \ldots + f_1 f_i \mu_f) \quad (3)$$

When the coupling element is small ($H_{DA}\approx 0$), all optical transitions ($\Psi_1 \rightarrow \Psi_i$, $i=2$–6) are essentially degenerate (i.e., $\nu_{IV}\approx\lambda$), however significant electronic coupling between the redox sites leads to broadening of the intervalence absorption and splitting into individual components with the energy difference between the highest and lowest transition given by $\nu_5-\nu_1=2H_{DA}\sqrt{3}$. Indeed, the broad intervalence NIR absorption of **1**$^{\bullet+}$ in Figure 2 (with several partially resolved components) points to a significant value of H_{DA}, and digital deconvolution into Gaussian bands (see Supporting Information Figure S2) leads to $\lambda = 5400\pm600\ cm^{-1}$ and $H_{DA}=1600\pm400\ cm^{-1}$ (see Supporting Information for details). The coefficients (a_1 to f_6) and transition moments are calculated from λ and H_{DA} (see Supporting Information Table S2), and the results in Table 1 demonstrate how the energies and intensities of the optical transitions based on the Mulliken–Hush (six-state) model agree with those obtained by deconvolution of the experimental (intervalence transfer) spectrum.

In conclusion, the compounds **1**–**3**, which are closely related to **III**, have been prepared and studied. The Mulliken–Hush (MH) quantification of λ and H_{DA} confirms for the first time the substantial stabilization allowed in the one-electron oxidized hexadonor system **III** since the resonance energy of $\Delta G_r = -2H_{DA}^2/\lambda \approx -3.5\ kcal\,mol^{-1}$ shows the extensive intra-annular (electron) delocalization in **1**$^{\bullet+}$ relative to the localized **3**$^{\bullet+}$. Furthermore, the MH treatment of the experimental spectral behavior correctly predicts the potential shift of $\Delta E_{ox}=0.21$ V (for the first anodic wave of **1** relative to **3**) which is close to the experimental value of $\Delta E_{ox}=0.23$ V when the entropy contribution is taken into account. Finally, the attractive interaction in **1**$^{\bullet+}$ with $H_{DA}=5.3\ kcal\,mol^{-1}$ is almost sufficient to offset the reorganization penalty of $\lambda/2=8.0\ kcal\,mol^{-1}$ and predicts a low barrier for hole (electron) hopping between six (contiguous) anilinyl sites (Scheme 1). Indeed, the value of $\Delta G^{\ddagger}=0.5\ kcal\,mol^{-1}$ evaluated from H_{DA} and λ[11] is at the threshold of the thermal barrier, and implies that **1**$^{\bullet+}$ has borderline Robin–Day Class II/III behavior.[9,10] As such, we hope that our search for other redox systems will reveal complete toroidal delocalization (i.e., Robin–Day Class III behavior) as in **IV**—of practical interest for the new design of molecular "motors."

Table 1: Energies[a] and relative intensities[b] of intervalence optical transitions in radical cation **1**$^{\bullet+}$.

	$\Psi_1\rightarrow\Psi_2$	$\Psi_1\rightarrow\Psi_3$	$\Psi_1\rightarrow\Psi_4$	$\Psi_1\rightarrow\Psi_5$	$\Psi_1\rightarrow\Psi_6$
Theoretical (MH)[c]	3.7(0.30)	4.8(0.50)	7.5(0.07)	8.6(0.12)	10.2(≈0)
Spectral[d]	3.7(0.25)	4.8(0.52)	7.4(0.10)	8.6(0.13)	10.1(0.01)

[a] In $10^3\ cm^{-1}$. [b] In parenthesis, normalized intensities. [c] MH = Mulliken–Hush model. Calculated according to MH with $\lambda=5500\ cm^{-1}$ and $H_{DA}=1900\ cm^{-1}$. [d] From Gaussian deconvolution of the intervalence absorption.

Experimental Section

Solvents and chemicals were prepared and handled as described earlier.[3] Hexaanilinylbenzene donors (**1**) were obtained by trimerization of bis(*N*,*N*-diethyl or methylethylanilinyl)acetylene with dicobalt octacarbonyl catalyst.[7b,12a] Bidonor (**2**) and monodonor (**3**) models were synthesized by Diels–Alder addition of tetraphenylcyclopentadienone to the appropriate anilinylacetylene and subsequent decarbonylation.[12b] Electronic spectra were measured on Varian Cary 5 spectrometer, IR spectra measured with a Nexus 470 FT-IR (Thermo Nicolet), and structural studies were carried out with Siemens SMART APEX diffractometer. Cyclic voltammetry (CV) and Osteryoung square wave voltammetry (OSWV) were performed on BAS 100A Electrochemical Analyzer, as described previously.[3] For full experimental and analytical details see the Supporting Information.

[8] a) Toroidal conjugation occurring through π-faces is to be distinguished from the usual planar conjugation occurring at π-edges of aromatic moieties; b) A reviewer has kindly pointed out an earlier study[8c] of hexaiodobenzene dication as a stable σ-delocalized or (Hückel) σ-aromatic species. Such extensive conjugation is essentially circular since it occurs among six iodo atoms in a single plane. This contrasts with electron delocalization among six anilinyl faces (each involving multiple π-centers), which is thus enveloped by a toroid-shaped surface. As such, the concept of toroidal conjugation also extends to enlarged systems including perarylnaphthalenes, anthracenes, and to various other polyacenes (in general), as well as to more flexible perarylated polyacetylenes; c) D. Polyoxovanadometalate-Catalyzed Selective Epoxidation of Alkenes with Hydrogen Peroxide**

*Yoshinao Nakagawa, Keigo Kamata, Miyuki Kotani, Kazuya Yamaguchi, and Noritaka Mizuno**

Vanadium is an important element in biology, inorganic chemistry, and organic syntheses,[1–8] and can heterogeneously or homogenously catalyze selective oxidation reactions of alkanes, alkenes, aromatic compounds, alcohols, halides, etc.[1–4,7–14] While homogenous oxidation catalysis by mono- and divanadium complexes has extensively been studied, the oxidation catalysis by bis(μ-hydroxo)-bridged divanadium compounds is scarcely known.[1–8,15,16] In addition, even monovanadium complexes cannot efficiently catalyze the epoxidation of alkenes by a green oxidant such as H_2O_2 because of a contribution from the radical mechanism; for example, the oxidation of cyclohexene by H_2O_2 in the presence of vanadium-based catalysts proceeds mainly at the allylic position.[9–14] Moreover, the efficiency of H_2O_2 utilization is intrinsically low.[9–14] Therefore the vanadium-catalyzed, H_2O_2-based epoxidation of alkenes with high selectivity to the epoxide and high efficiency of H_2O_2 utilization is currently not possible, although it is well known that other transition metals such as tungsten, manganese, and iron show high activity and selectivity.[17–20]

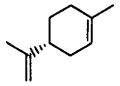
The catalytic function of polyoxometalates has attracted much attention because the ability to design catalytically active sites means that their redox and acidic properties can be controlled at the atomic or molecular levels.[21–28] Recently, various efficient catalytic systems for H_2O_2-based epoxidation by polyoxometalates have been developed with peroxotungstates or -molybdates as catalyst precursors or with transition-metal-substituted polyoxometalates. However, these require either an excess of H_2O_2 with respect to the alkene or an excess of alkene with respect to H_2O_2 to attain a high yield of epoxide or high efficiency of H_2O_2 utilization.[29] Herein, we report that $[\gamma\text{-}1,2\text{-}H_2SiV_2W_{10}O_{40}]^{4-}$ (**1**), which has a {VO-(μ-$OH)_2$-VO} core, can catalyze the epoxidation of alkenes in the presence of only one equivalent of H_2O_2 with a high yield of epoxide and high efficiency of H_2O_2 use. Notably, this system shows unique stereospecificity, diastereoselectivity, and regioselectivity that are quite different from those reported for the epoxidation systems based on $[\gamma\text{-}SiW_{10}O_{34}(H_2O)_2]^{4-}$.[30,31] Furthermore, we have investigated the active site of **1** and the active species for the present epoxidation on the basis of various physicochemical characterizations.

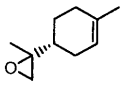
First, we examined the scope of the present epoxidation with the tetra-*n*-butylammonium salt of **1** (TBA-**1**), various kinds of alkenes, and with only one equivalent of H_2O_2 (except for gaseous alkenes; Table 1). Under the present reaction conditions, the amounts of allylic oxidation products and glycols produced by hydrolysis were negligible in all cases. The epoxidation did not proceed at all in the absence of catalyst, and no epoxidation was observed with *tert*-butylhydroperoxide (TBHP) as the oxidant. Nonactivated aliphatic terminal C_3–C_{10} alkenes, including propene, could be transformed into the corresponding epoxides with $\geq 99\,\%$ selectivity and $\geq 87\,\%$ efficiency of H_2O_2 utilization. A larger-scale reaction (50-fold scale-up) for 1-octene showed the same results as the small-scale experiments (99 % selectivity to 1,2-epoxyoctane, 93 % yield determined by GC, and 86 % yield of isolated product). The reaction rate increased with an increase in the reaction temperature, and the TOF reached as high as 38 h^{-1} at 313 K whilst maintaining the selectivity for 1,2-epoxyoctane as high as $> 99\,\%$, although the efficiency of H_2O_2 utilization decreased slightly from 93 % (293 K) to 85 % (313 K). Acid-sensitive styrene was epoxidized to give styrene oxide as the sole product. Also, the catalytic epoxidation of cyclic alkenes such as cyclohexene and cyclooctene proceeded efficiently to afford the corresponding epoxides in high yields.

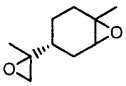
Table 1: Epoxidation of various monoalkenes catalyzed by TBA-**1**.[a]

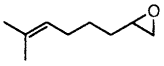
Substrate	Product	Yield [%]	Selectivity [%]	E_{ox} [%][b]
[c]		87	99	87
[d]		91	99	91
		92	99	92
		93	99	93
		90	99 (only *cis*)	90
		88	98	90
		93	99	93
		88	99	88
		90	99	92
		93	99	93
		91	97 (*syn*/*anti* = 5/95)	91
OH	OH	87	95 (*syn*/*anti* = 12/88)	91

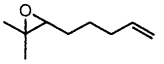
[a] Reaction conditions: alkene (33.3 mM), TBA-**1** (1.67 mM), H_2O_2 (30 % aq., 33.3 mM), and CH_3CN/*t*BuOH (1.5/1.5 mL) at 293 K for 24 h. Yields and selectivities were determined by gas chromatography or ^{1}H NMR spectroscopy using an internal standard technique and are based on alkenes. [b] E_{ox}(H_2O_2 efficiency) = [products (mol)/consumed H_2O_2-(mol)] × 100. [c] Propene pressure 6 atm. [d] 1-Butene pressure 3 atm.

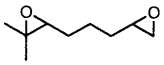












The epoxidation of *cis*- and *trans*-2-octene gave *cis*-2,3-epoxyoctane (90 % yield; Table 1) and *trans*-2,3-epoxyoctane (6 % yield), respectively; the configuration around the C=C moieties is retained in these epoxides. Moreover, for the competitive epoxidation of *cis*- and *trans*-2-octenes (100 μmol each, the other conditions were the same as in Table 1), the initial rates for the epoxidation were 0.32 and 0.001 mM min^{-1}, respectively. The ratio of the formation rate of *cis*-2,3-epoxyoctane to that of the *trans* isomer is more than 3×10^2, which is much larger than the ratios (1.3–11.5) reported for other stereospecific epoxidation systems (see Supporting Information). For competitive epoxidation of *cis*- and *trans*-2-octenes, the yields of *cis*-2,3-epoxyoctane and the *trans* isomer (based on H_2O_2), even after 24 h, were 91 and 2 %, respectively. The epoxidation of 3-substituted cyclohexenes, such as 3-methyl-1-cyclohexene and 2-cyclohexen-1-ol, showed an unusual diastereoselectivity: the corresponding epoxides are formed highly diastereoselectively with the oxirane ring *trans* to the substituents (*anti* configuration; Table 1 and Tables S2 and S3 in the Supporting Information).

Further, the more accessible, but less nucleophilic double bonds in nonconjugated dienes such as *trans*-1,4-hexadiene, (*R*)-(+)-limonene, 7-methyl-1,6-octadiene, and 1-methyl-1,4-cyclohexadiene were epoxidized in high yields in a highly regioselective manner, as shown in Table 2. The values of [less-substituted epoxide]/[total epoxides] (≥ 0.88) are much higher than those reported for the other epoxidation systems (Tables S4–S7 in the Supporting Information). As far as we know, such unique stereospecificity, diastereoselectivity, and regioselectivity have never been reported for **1**.

The relative reactivity (rate) of a series of C_8 alkenes decreased in the order of 2-methyl-1-heptene (1.1) > 1-octene (1.0 taken as unity) > *cis*-2-octene (0.87) > 2-methyl-2-heptene (0.03) > *trans*-2-octene (< 0.01) (see Table S8 in the Supporting Information). This order is not consistent with that of the π(C=C) HOMO energies of C_8 alkenes because they decrease with an increase in the number of alkyl substituents in alkenes, as reported previously.[30] Therefore, the inconsistency between the ordering of the π(C=C)

HOMO energies and the reactivities should be caused by the steric constraints of the active site of **1**, that is, an active oxygen species formed by the reaction of **1** with H_2O_2 is embedded in the polyoxometalate framework and thus a sterically hindered C=C double bond cannot easily approach the site.

The mono- and trivanadium-substituted compounds [α-$SiVW_{11}O_{40}]^{5-}$ and [α-1,2,3-$SiV_3W_9O_{40}]^{7-}$ are inactive for the epoxidation under the present conditions, which suggests that the V–O–W and V=O centers are not the active sites. The fully occupied silicotungstate [γ-$SiW_{12}O_{40}]^{4-}$, which has the same structure as **1**, is also inactive, which suggests that the tungsten atoms in **1** are not the active sites. The regioselectivity of the catalytic epoxidation of nonconjugated dienes by **1** is quite different from that by [γ-$SiW_{10}O_{34}(H_2O)_2]^{4-}$ (Tables S4–S7 in the Supporting Information), which shows that the catalytically active site (species) of **1** is different from that of [γ-$SiW_{10}O_{34}(H_2O)_2]^{4-}$.

In addition, we confirmed by in situ IR and NMR measurements that tungstate compounds such as [γ-$SiW_{10}O_{34}(H_2O)_2]^{4-}$ and $[W_2O_3(O_2)_4(H_2O)_2]^{2-}$ are not formed during the catalysis. The ^{51}V NMR spectrum of the recovered catalyst in CD_3CN shows a line at $\delta = -564$ ppm ($\Delta\nu_{1/2} = 125$ Hz) and the ^{183}W NMR spectrum in CD_3CN shows three lines at $\delta = -84$ ($\Delta\nu_{1/2} = 9.9$ Hz), -97 ($\Delta\nu_{1/2} = 2.3$ Hz), and -131 ppm ($\Delta\nu_{1/2} = 1.6$ Hz) with an integrated intensity ratio of 2:1:2, in agreement with the γ-Keggin framework. Signals due to tungstate compounds such as [α-$SiW_{12}O_{40}]^{4-}$, [γ-$SiW_{10}O_{34}(H_2O)_2]^{4-}$, $[W_2O_3(O_2)_4(H_2O)_2]^{2-}$, and $[H_nWO_2(O_2)_2]^{(2-n)-}$ were not observed. The IR and UV/Vis spectra of the catalyst recovered after the completion of the epoxidation were the same as those of the fresh one, which also suggests the maintenance of the γ-Keggin framework of **1**.

All these facts strongly indicate that the {VO-(μ-$OH)_2$-VO} core is preserved in the cluster framework of **1** during the catalytic process and that tungstate compounds are not the true catalytically active species in the present epoxidation. The fact that the regioselectivities for nonconjugated dienes with **1** are different from those with [γ-$SiW_{10}O_{34}(H_2O)_2]^{4-}$ and $[W_2O_3(O_2)_4(H_2O)_2]^{2-}$ also support this idea.

Next, the reactivity of **1** with H_2O_2 was investigated. The cold-spray ionization mass spectrum (CSI-MS) of TBA-**1** in 1,2-$C_2H_4Cl_2$ shows the most intense parent-ion peak (centered at m/z 3337.9) with an isotopic distribution (Figure 1a and Supporting Information) that agrees with the pattern calculated for $[(TBA)_3H_2SiV_2W_{10}O_{40}]^-$ (Figure 1b and Supporting Information). Upon the addition of 350 equiv of H_2O_2, a new peak centered at m/z (3337.9 + 16) appeared (Figure 1c) which agrees with the pattern calculated for $[(TBA)_3HSiV_2W_{10}O_{39}(OOH)]^-$ (Figure 1d).

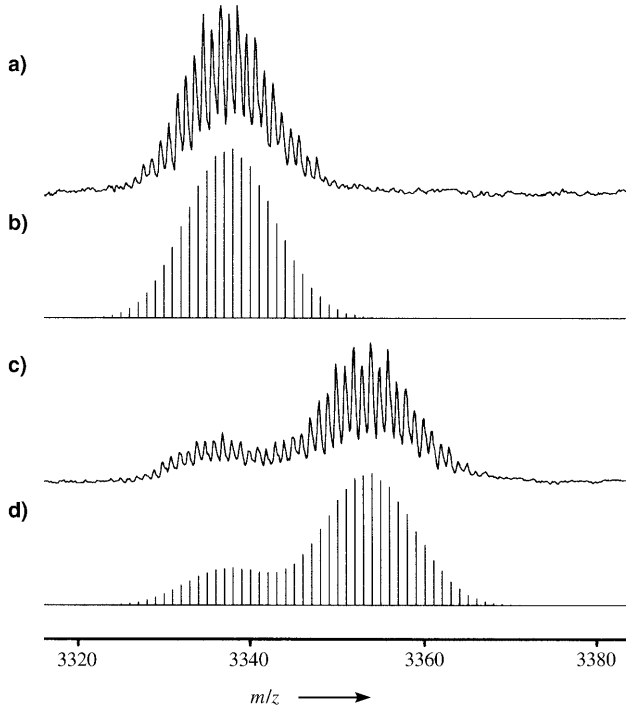

Figure 1. CSI-MS (anion mode, m/z 3300–3400) of a) TBA-**1** (0.14 mM) in 1,2-$C_2H_4Cl_2$ and c) TBA-**1** (0.14 mM) in 1,2-$C_2H_4Cl_2$ treated with 350 equiv of H_2O_2 (96% aqueous solution) with respect to TBA-**1** (253 K, 2 h). The lines in (b) are the pattern calculated for $[(TBA)_3H_2SiV_2W_{10}O_{40}]^-$ and the lines in (d) are the pattern calculated for a mixture of $[(TBA)_3H_2SiV_2W_{10}O_{40}]^-$ (22%) and $[(TBA)_3HSiV_2W_{10}O_{39}(OOH)]^-$ (78%). The small increase in the content of $[(TBA)_3H_2SiV_2W_{10}O_{40}]^-$ in comparison with those of Figures 2–4 is probably caused by a slight increase in the temperature at the inlet of the injection port of the spectrometer.

The ^{1}H NMR spectrum of **1** (2.5 mM) in 1,2-$C_2D_4Cl_2$ at 253 K shows a signal at $\delta = 4.80$ ppm due to the hydroxy proton of the {VO-(μ-$OH)_2$-VO} core in **1**. Upon the addition of 20 equiv of H_2O_2, two signals appear at $\delta = 5.10$ and

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

9.45 ppm with an intensity ratio of 1:1, and the intensity of the signal at $\delta = 4.80$ ppm has greatly decreased (by $(93 \pm 1)\%$) after 2 h, although the sum of the three signal intensities remains almost constant (Figure 2). A similar lower-field shift

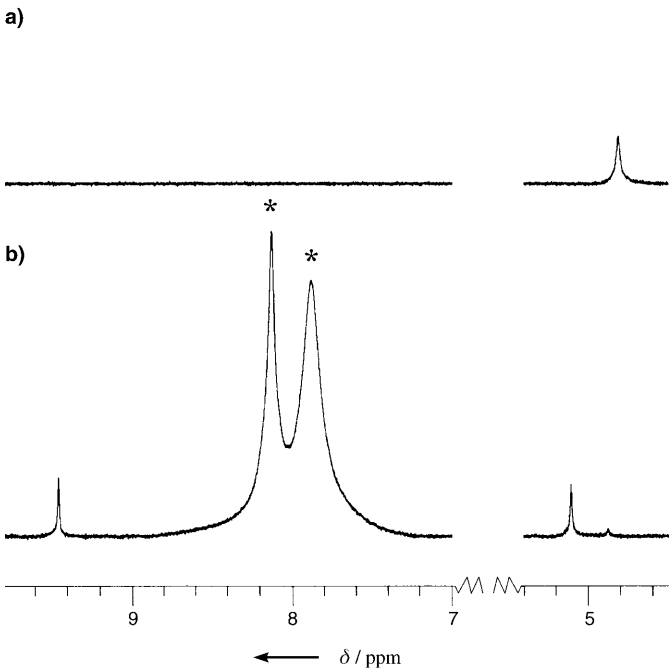

Figure 2. ^{1}H NMR spectra of a) TBA-**1** (2.5 mM) in 1,2-$C_2D_4Cl_2$ and b) TBA-**1** (2.5 mM) in 1,2-$C_2D_4Cl_2$ treated with 20 equiv of H_2O_2 (95% aqueous solution) with respect to TBA-**1** at 253 K for 2 h. The asterisks indicate the signals of H_2O_2 in the organic and aqueous phases.

of the hydroxy proton signal from $\delta = 5.10$ to $\delta = 5.18$ ppm has been observed upon the formation of $[\gamma\text{-}1,2\text{-}SiV_2W_{10}O_{38}(\mu\text{-}OH)(\mu\text{-}OCH_3)]^{4-}$ in CD_3CN.[32] The chemical shift of $\delta = 9.45$ ppm is close to those of other hydroperoxide species such as H_2O_2 ($\delta = 8.74$ ppm), *t*BuOOH ($\delta = 8.84$ ppm), and $PhC(CH_3)_2OOH$ ($\delta = 8.95$ ppm).

One new ^{51}V NMR signal appears at $\delta = -530$ ppm in 1,2-$C_2D_4Cl_2$ upon the addition of H_2O_2, and the intensity of the signal of **1** at $\delta = -562$ ppm has greatly decreased (by $(93 \pm 1)\%$) after 2 h, although, again, the sum of the two signal intensities remains almost constant (Figure 3). Six new ^{183}W NMR signals appear at $\delta = -79$, -83, -92, -104, -127, and -132 ppm with an intensity ratio of 2:2:1:1:2:2, in 1,2-$C_2D_4Cl_2$ upon the addition of 15 equiv of H_2O_2, and the signals at $\delta = -81$, -95, and -128 ppm due to **1** have almost completely disappeared after 2 h, although the sum of the nine signal intensities remains almost constant (Figure 4). A quantitative analysis of the ^{1}H, ^{51}V, and ^{183}W NMR data gives an atomic ratio of H(δ=5.10 ppm):H(9.45):V(-530):W(-79):W(-83):W(-92):W(-104):W(-127):W(-132) of 1:1:2:2:2:1:1:2:2.

The ^{183}W NMR spectral pattern depends on the structure and symmetry of the anion. The anion **1** has C_{2v} symmetry and shows three signals with intensities of 2:1:2. The reaction of **1** with H_2O_2 lowers or does not change the symmetry of the anion, and there are five possibilities for the symmetry of the resulting compound: 1) C_2, 2) C_s with a symmetry plane containing two vanadium atoms, 3) C_s with a symmetry plane

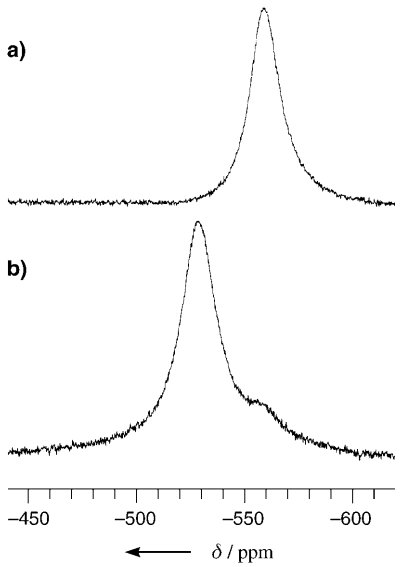

Figure 3. ^{51}V NMR spectra of the same samples as for Figure 2.

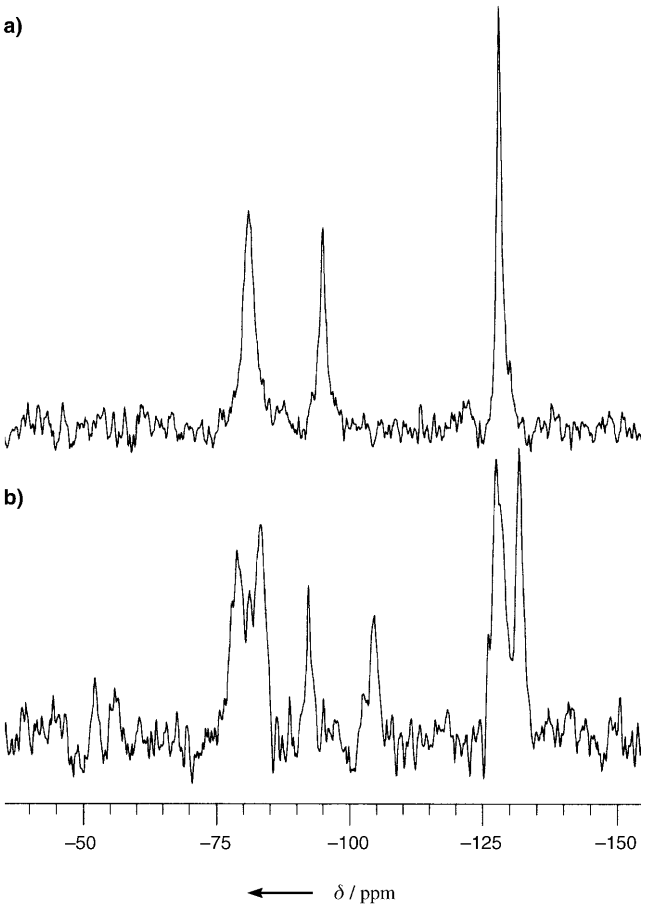

Figure 4. ^{183}W NMR spectra of a) TDA-**1** (0.1 M) in 1,2-$C_2D_4Cl_2$ and (b) TDA-**1** (0.1 M) in 1,2-$C_2D_4Cl_2$ treated with 15 equiv of H_2O_2 (95% aqueous solution) with respect to TDA-**1** at 253 K for 2 h. TDA = *n*-decylammonium.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

containing two V–O–V bridging oxygen atoms, 4) C_1, and 5) C_{2v}. After the treatment of **1** with H_2O_2, six ^{183}W NMR signals are observed with an intensity ratio of 2:2:1:1:2:2; only case (3) can explain the observed ^{183}W NMR spectrum.[33] The ^1H NMR spectrum shows two signals at $\delta = 5.14$ (1H) and 9.45 ppm (1H). These two protons must exist in the symmetry plane, which favors the C_s symmetry. The ^{51}V NMR spectrum shows one signal. Therefore, the NMR data indicate the formation of a {VO-(μ-OH)(μ-OOH)-VO} species.

The chemical shifts of the ^{51}V and ^{183}W NMR signals are also in agreement with this idea: the oxo→peroxo transformation for complexes of ^{51}V, ^{95}Mo, and ^{183}W leads to significant upfield shifts in the NMR signals (see Table S11 in the Supporting Information). On the other hand, the oxo→hydroperoxo transformation from $H_xMoO_2(O_2)_2^{(2-x)-}$ ($0 \le x \le 1$) to $[MoO(O_2)_2OOH]_2^{2-}$ produces a 15–30 ppm downfield shift in the ^{95}Mo signals;[34] no ^{51}V NMR data have been reported for the oxo→hydroperoxo transformation as far as we know. In the present case, a downfield shift of 32 ppm is observed for the ^{51}V NMR signal after the treatment of **1** with H_2O_2. Such a downfield shift is in accordance with the oxo→hydroperoxo transformation. These NMR and CSI-MS data strongly suggest that the {VO-(μ-OH)$_2$-VO} core in **1** reacts with H_2O_2 to form a {VO-(μ-OH)(μ-OOH)-VO} species.

The methanol monoester of **1** (**2**) was easily formed by the dehydrative condensation between the hydroxy group in **1** and methanol (equilibrium constant 75).[32] No diester was formed even in the presence of an excess of methanol. The anionic cluster **2** retains the γ-Keggin structure with the two vanadium atoms bridged by one protonated oxygen atom and one methoxy group.[32] Therefore, the dehydrative condensation between **1** and H_2O_2 to form the hydroperoxo complex should proceed as reported for bis(μ-hydroxo) complexes of the first row transition metals.[35] When one proton in the {VO-(μ-OH)$_2$-VO} site in **1** was removed by titration with 1 equivalent of nBu_4NOH with respect to **1**, neither esterification of **1** with methanol nor its epoxidation with H_2O_2 proceeded. All these results indicate that the {VO-(μ-OH)$_2$-VO} core in **1** is the active site that forms {VO-(μ-OH)(μ-OOH)-VO} species for the epoxidation of olefins with H_2O_2, according to Equation (1) with R = OH, CH_3.

$$[\gamma\text{-}1,2\text{-}H_2SiV_2W_{10}O_{40}]^{4-} + ROH \rightarrow [\gamma\text{-}1,2\text{-}SiV_2W_{10}O_{38}(\mu\text{-}OH)(\mu\text{-}OR)]^{4-} + H_2O \quad (1)$$

As has been reported previously,[32] the esterification of the {VO-(μ-OH)$_2$-VO} core in **1** with alcohols is sterically controlled: the esters of primary alcohols with a bulky substituent, such as neopentyl alcohol, or of secondary and tertiary alcohols are hardly formed (equilibrium constant < 0.02) because of the steric repulsion from the polyoxometalate framework. For the same reason, no reaction of **1** with TBHP occurs. Thus, the hydroperoxo group in the possible intermediate $[\gamma\text{-}1,2\text{-}SiV_2W_{10}O_{38}(\mu\text{-}OH)(\mu\text{-}OOH)]^{4-}$ may also be sterically hindered, which could explain the unique stereospecificity, diastereoselectivity, and regioselectivity in the epoxidation catalysis (Figure S3 in the Supporting Information).

Experimental Section

An aqueous solution of $[\gamma\text{-}1,2\text{-}H_2SiV_2W_{10}O_{40}]^{4-}$ was prepared according to reference [36], and the anion was isolated as the tetra-*n*-butylammonium salt (TBA-**1**): $K_8[\gamma\text{-}SiW_{10}O_{36}]\cdot 12H_2O$[37] (8 g, 2.7 mmol) was quickly dissolved in 1M HCl (28 mL), $NaVO_3$ (0.5M, 11 mL, 5.5 mmol) was added, and the mixture was gently stirred for 5 min. The solution was filtered and $[(n\text{-}C_4H_9)_4N]Br$ (8 g, 25 mmol) added in a single step. The resulting yellow precipitate was collected by filtration and then washed with a large amount of water (300 mL). The crude product was purified twice by precipitation (addition of 1 L of H_2O to an acetonitrile solution of TBA-**1** (50 mL)). Analytically pure TBA-**1** was obtained as a pale-yellow powder. Yield: 7.43 g (76%). Anal. calcd. for $[(C_4H_9)_4N]_4[\gamma\text{-}1,2\text{-}H_2SiV_2W_{10}O_{40}]\cdot H_2O$: C 21.4, H 4.15, N 1.56, Si 0.78, V 2.83, W 51.1, H_2O 0.50; found: C 21.4, H 3.91, N 1.59, Si 0.79, V 2.88, W 51.2, H_2O 0.50. ^{51}V NMR (CD_3CN): An intense signal at $\delta = -563.6$ ppm ($\Delta\nu_{1/2} = 133$ Hz) attributed to two equivalent vanadium atoms is observed. ^{183}W NMR (CD_3CN): $\delta = -82.2$ ($\Delta\nu_{1/2} = 9.6$ Hz), -95.6 ($\Delta\nu_{1/2} = 2.5$ Hz), and -129.7 ppm ($\Delta\nu_{1/2} = 2.9$ Hz) with an integrated intensity ratio of 2:1:2. ^{29}Si NMR (CD_3CN): $\delta = -84.0$ ppm ($\Delta\nu_{1/2} = 2.0$ Hz). The UV/Vis spectrum (in CH_3CN) shows shoulder bands at 240 ($\varepsilon = 36000\ M^{-1}cm^{-1}$), 285 (24000), and 350 nm (5900), characteristic of the γ-Keggin structure.[38,39] IR (KBr): $\tilde{\nu} = 1151, 1106, 1057, 1004, 995, 966, 915, 904, 875, 840, 790, 691, 550, 519, 482, 457, 405\ cm^{-1}$.

The epoxidation of gaseous substrates (propene and 1-butene) was carried out in a Teflon-coated autoclave; a glass-tube reactor was used for the other substrates. The epoxidation was carried out as follows: catalyst (1.67 mM), CH_3CN/*t*BuOH (1.5/1.5 mL), H_2O_2 (30% aq., 33.3 mM), and substrate (propene, 6 atm; 1-butene, 1 atm; others, 33.3 mM) were charged in the reaction vessel. The reaction was carried out at (293 ± 0.2) K. The reaction solution was sampled periodically and analyzed by GC in combination with mass spectrometry. The products were identified by comparing their mass and NMR spectra with those of authentic samples. The carbon balance in each experiment was in the range of 95–100%. The amount of H_2O_2 remaining after the reaction was analyzed by Ce^{4+}/Ce^{3+} titration.[40] After the reaction, the catalyst was recovered by evaporating the reaction mixture to dryness, followed by washing with *t*BuOH and *n*-hexane. TOF values were estimated from the initial rates below 10% conversion of H_2O_2.

Mapping Protein–Protein Interfaces on the Basis of Proton Density Difference**

*Xiaogang Sui, Yingqi Xu, Janel L. Giovannelli, Nancy T. Ho, Chien Ho, and Daiwen Yang**

A protein normally functions through interacting with its partners. In order to understand the molecular basis for biochemical and biological processes, it is important to identify the contact surfaces of interacting molecules or even to characterize the structures of protein complexes. Since it is much easier and faster to define interacting surfaces by NMR spectroscopy than to determine the full structures, a number of methods have been developed to map protein interactions.[1] The traditional approach based on chemical-shift perturbation is easy to do,[2] but its precision is low. In cases where the entire protein changes conformation, this approach fails as a mapping device but can indicate the presence of allosteric processes.[3] It cannot be applied to map the intersubunit interface of oligomeric proteins in which the monomeric form is unstable. There exist methods based on the paramagnetic line-broadening effect with the use of site-specific spin labeling[4] or paramagnetic ions,[5] but they are applicable only to systems in which spin labeling is available or conformation change upon forming a complex does not increase relaxation protection from paramagnetic ions.

Amide-proton exchange has also been used to map protein interfaces,[6] but it is not a reliable tool because the change of exchange rates depends on local and global structural changes upon the formation of the complexes. Intermolecular NOESY analysis can be used to map the interactions, but it is difficult to completely suppress intra-moleuclar NOEs.[7] A more sophisticated method based on saturation transfer from an acceptor to a reporting protein, called cross-saturation,[8] has been proposed. It provides more reliable information about the binding interface, but highly

deuterated ^{15}N-labeled protein is required for the suppression of spin diffusion in the reporting protein. Incomplete deuteration of the reporting protein may result in the identification of false interaction sites. In addition, to reduce spin diffusion among amide protons, especially for α-helical proteins, it is necessary to do experiments in a solvent mixture of $H_2O/^2H_2O$ with $<30\%$ H_2O. This is equivalent to lowering the effective sample concentration by a factor of about three or more. Thus, this technique may not work for proteins with moderate solubility or that are difficult to obtain fully deuterated.

Herein, we propose a novel strategy to map amino acid residues involved in protein–protein interactions at interfaces on the basis of the dependence of NMR relaxation on proton density, by using two moderately deuterated samples in which the reporting protein in a protein–protein complex is ^{2}H,^{15}N-labeled while the acceptor protein is either unlabeled or ^{2}H-labeled. Figure 1 shows the pulse scheme used to measure

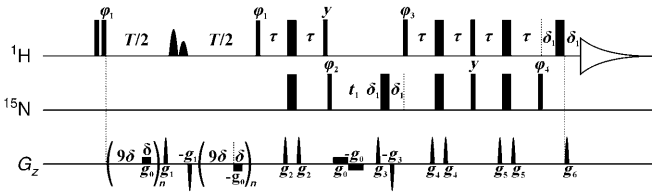

Figure 1. Pulse scheme used; all narrow (wide) bars represent 90° (180°) rectangular pulses. The first shaped 180° pulse (1 ms, REBURP, centered at 9.1 ppm) selectively inverts the signals of amide protons, the second shaped 180° pulse (2 ms, rectangle) that of H_2O (G_z represents pulsed field z gradients). The delays used are: $\tau = 2.3$ ms, $\delta = 0.5$ ms, and $\delta_1 = 1.1$ ms. Radiation damping during the relaxation delay T is suppressed by gradient g_0. The phase cycling employed is: $\varphi_1 = x,x,-x,-x$; $\varphi_2 = x,-x$; $\varphi_3 = y$; $\varphi_4 = x$; rec $= x,-x$. The durations and strengths of the sine-shaped gradients are: $g_1 = 2$ ms, 20 G cm^{-1}; $g_2 = 1$ ms, 17.5 G cm^{-1}; $g_3 = 1$ ms, 40 G cm^{-1}; $g_4 = 1$ ms, 22.5 G cm^{-1}; $g_5 = 1$ ms, 35 G cm^{-1}; and $g_6 = 1$ ms, 8 G cm^{-1}. The strength of g_0 is 1.5 G cm^{-1}. Quadrature detection in F_1 uses the enhanced sensitivity pulse gradient method, where for each t_1 separate data sets are recorded for (g_6, φ_3, φ_4) and ($-g_6$, φ_3+180°, φ_4+180.

selective longitudinal relaxation rates of amide protons in a deuterated reporting protein A, which binds to its acceptor protein B. The effect of phase alternation of φ_1 is to alternately store magnetization along the $-Z$ axis and the $+Z$ axis at the very beginning of the relaxation period so that the longitudinal magnetization relaxes as $\exp(-RT)$.[9] In this way, the measurement of relaxation rates will be independent of the interscan delay. Suppression of cross-relaxation between amide and aliphatic protons is achieved by selective inversion of only amide and aromatic protons, while reduction of amide magnetization loss due to exchange with H_2O is achieved by maintaining the proton magnetization of the amide and H_2O along the same direction during the entire relaxation period. A single scan TROSY scheme[10] is used to obtain TROSY-HSQC data.

The initial relaxation rate of an amide proton ($R^1(H_Z^N)$) under selective inversion is dominated by dipolar interactions with its surrounding aliphatic protons and it can be approximated as shown in Equation (1), where τ_c is the molecular

$$R^1(H_Z^N) \approx 0.1\,\tau_c \left(\frac{\mu_0 \hbar \gamma_H^2}{4\pi}\right)^2 \left\{ \sum_{j=1}^{m} \frac{S_j^2}{r_{HHAj}^6} + \sum_{k=1}^{n} \frac{S_k^2}{r_{HHBk}^6} \right\} + R_{ex} \qquad (1)$$

tumbling time; μ_0 is the permeability in vacuum; $\hbar = h/2\pi$ and h is Planck's constant; γ_H is the proton gyromagnetic ratio; r_{HHAj} is the distance between the amide proton and the jth residual aliphatic proton in protein A; r_{HHBk} is the distance between the amide proton and the kth residual aliphatic proton in protein B; S_j^2 and S_k^2 are the order parameters describing the motional amplitude of an H–H$_j$ and an H–H$_k$ vector, respectively; m and n are the total numbers of the respective aliphatic protons in proteins A and B interacting with the amide proton; and R_{ex} is the relaxation contribution from the unsuppressed NH–H_2O exchange effect, which is minimized by preventing radiation damping and keeping H_Z^N and H_2O magnetization parallel.

If protein A is perdeuterated (that is, $m = 0$), amide protons located at the binding interface have larger R^1 values than other amide protons since they are much closer to the protons in protein B. In principle, amino acid residues in the interacting region can be identified based on R^1 values by using a single sample consisting of a perdeuterated reporting protein and an unlabeled acceptor. However, incomplete deuteration in aliphatic protons and the unsuppressed NH–H_2O exchange effect (R_{ex}) can lead to the incorrect identification of interacting sites. In order to overcome this drawback, we propose herein the use of two samples in $H_2O/^2H_2O$ (95:5) solution: 1) ^{15}N,^{2}H-labeled protein A complexed with unlabeled protein B and 2) ^{15}N,^{2}H-labeled protein A complexed with ^{2}H-labeled protein B. The difference of R^1 values for a given amide proton in the two samples [Eq. (2), in which n_1 and n_2 are the numbers of aliphatic

$$\Delta R^1 \propto \sum_{k=1}^{n_1} S_k^2 r_{HHBk}^{-6} - \sum_{j=1}^{n_2} S_j^2 r_{HHBj}^{-6} \qquad (2)$$

protons in protein B in samples 1 and 2, respectively] is mainly determined by the location of the amide (that is, r_{HHBk}) but is independent of the deuteration percentage of protein A (m) and the R_{ex} value. Although incomplete deuteration of protein B in the second sample affects the amplitude of ΔR^1, it cannot result in false binding sites. With the assumption that $S^2 = 1$ and of perdeuteration of protein B in sample 2 (that is, $n_2 = 0$), the ΔR^1 value can be used to estimate an upper limit of the effective distance between an amide proton in protein A and its proximal protons in protein B (r_{eff}) [Eq. (3)]. Even in the case of 85% deuteration of protein B

$$r_{eff} = [\sum r_{HHBk}^{-6}]^{-1/6} \qquad (3)$$

and $S^2 = 0.3$, the actual r_{eff} is $\approx 25\%$ shorter than its upper limit, a fact implying that effects of the local dynamics and deuteration rate of protein B can be neglected (see Figure S1 in the Supporting Information). On the basis of r_{eff} values, one can model the structure of a protein complex, provided that individual structures are known.

We have applied the above-mentioned strategy to map the intersubunit interface of recombinant human adult hemoglobin in the carbonmonoxide form (rHbCO A, 1 mM, pH 7.0)

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

on an 800 MHz NMR spectrometer. Here, proteins A and B correspond to the α and β chains, respectively, and the α chain is ^{15}N,^{2}H-labeled. The average deuteration percentage was ≈85% for both chains. As expected, the decay of H_Z^N often follows a multiexponential form due to strong cross-relaxation among amide protons.[11] Nevertheless, it is possible to obtain initial relaxation rates for both samples and then to calculate ΔR^1 values. Since we are interested in only the ΔR^1 value, an alternative way to obtain it is from the dependence of the intensity ratio of a given proton in two samples ($I_1(t)$/$I_2(t)$) on the relaxation delay (which is shown by numerical simulations; see Figure S1 in the Supporting Information), for which $I_1(t)$ ($I_2(t)$) is the relative intensity at time t with respect to that at the first delay for sample 1 with unlabeled β chains (sample 2 with ^{2}H-labeled β chains).

Figure 2 shows the decays of a number of representative amide protons. Amides not involved in subunit contacts have shown no dependence of I_1/I_2 on the relaxation delay. Amides involved in weak contacts display nearly monoexponential profiles during a period of 500 ms, while those located in close-contact regions show nearly monoexponential profiles within the first 150 ms. Amide protons that involve weak or no direct subunit contact but that are close to the amides with strong subunit interactions display slower decay or no decay in the initial period and then faster decay in the later stage (F36 in Figure 2). This is due to the two-step "spin-diffusion" process. Fortunately, the spin-diffusion effect decreases dramatically with the steps and it has been found to be negligible for multistep processes for rHbCO A within a relaxation delay of up to 400 ms.

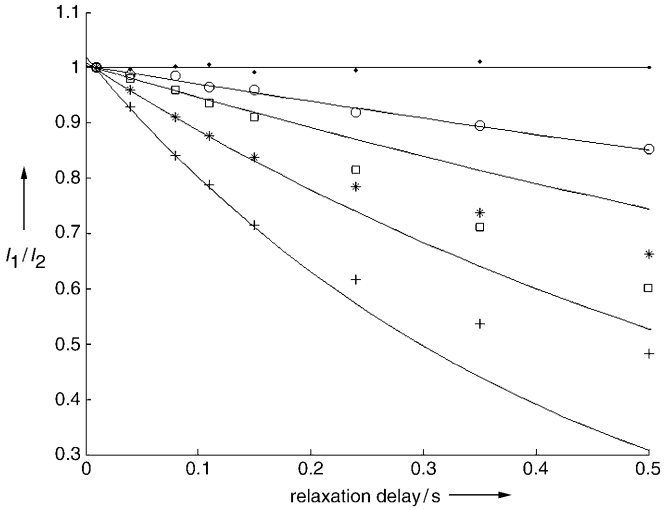

Figure 2. The dependence of the intensity ratio of normalized peak intensities in two samples (I_1/I_2) on the relaxation delay for a number of representative residues of rHbCO A (K60, ◆; V96, ○; F36, □; R31, *; A123, +). The normalized intensity for a given amide in one sample ($I(t)$) was obtained by taking the ratio of the peak intensities at delay t and the first delay (10 ms). Experimental data and initial decay profiles are indicated by symbols and solid lines, respectively. The total experimental time was ≈22 h.

Amino acid residues involved in subunit contacts can be simply identified from the ratios of normalized peak intensities (I_1/I_2) at one desired delay (for example, 250 ms; Figure 3a). Alternatively, they can be identified more confidently from ΔR^1 values (Figure 3b). The difference in the initial rate (ΔR^1) of an amide proton was estimated by fitting I_1/I_2 to a monoexponential equation in three steps: 1) calculation of the relaxation rate with all data points; 2) removal of the point with the longest delay in the existing data; and 3) repetition of step 2 until the absolute difference of the relaxation rates obtained with m+1 and m data points is smaller than the sum of the fitting errors of these two fittings, where m is the number of data points and $m > 3$. The fitting error was determined by using the Jackknife method.[12] The relaxation rate and fitting error obtained with m+1 points were reported. Amide protons in the α chain with a ΔR^1 value smaller than 0.7 times the average ΔR^1 value (≈0.1 s^{-1}, the noise level) are considered to have no interaction with the β chain. The results are consistent with the contact sites derived from the crystal structure of the R2 state of human normal adult hemoglobin (PDB entry 1BBB). With the use of a cross-saturation experiment on sample 1 in H_2O/$^{2}H_2O$ (30:70) solution, many residues in the contact region were also identified.

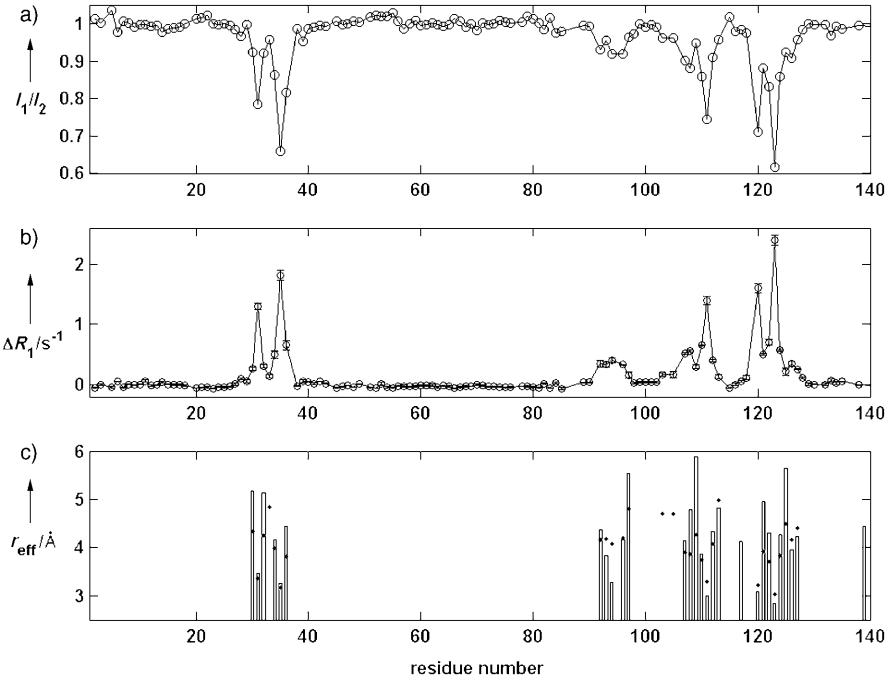

Figure 3. a) Peak intensity ratios of amides in two samples (I_1/I_2) against the residue number of the α chain of human normal adult hemoglobin; desired delay: 250 ms; first delay: 10 ms. b) Difference of initial relaxation rates (ΔR^1) between samples 1 and 2. Errors are indicated with vertical bars. c) Comparison of effective distances derived from the ΔR^1 values (◆) and from the crystal structure of the R2 state of rHbCO A (bar). The r_{eff} value is set to zero when it is larger than 5 and 6 Å for the NMR-derived data and the crystal-structure-based data, respectively.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

However, the $\alpha_1\beta_2$ interface (residues 92–97) cannot be identified because of the strong noise level caused by spin diffusion among many residual protons in the α chain (see Figure S2 in the Supporting Information).

Figure 3c shows the upper limits of effective distances (r_{eff}) estimated from the ΔR^1 values and a τ_c value of 32 ns (τ_c was established from ^{15}N relaxation times). The distances agree well with those calculated from the R2 structure except for a few residues (see Table S1 in the Supporting Information). The r_{eff} value for α94D estimated from the ΔR^1 value (4.07 Å) is significantly larger than that from the R2 crystal structure (3.28 Å) because the $\alpha_1\beta_2$ interface is more dynamic in solution than in the crystal state. The dynamics of this region has been shown previously by a relaxation study of β37W which is in contact with α94D.[13] The discrepancy for α117F (in a loop) and α139K (in the C terminus) is also due to different mobility in the solution and crystal states. The effective distances for α33F, α103H, and α105L are significantly shorter from the present method than from the crystal structure. This can be explained by a slight difference in subunit arrangement and side-chain packing in the solution and crystal states. The slight difference of the $\alpha_1\beta_1$ interface in solution and in the crystal state has previously been evidenced by the different solvent exchange rates of side-chain protons of α103H and α122H in the T and R states.[14]

Although the experiment proposed here requires deuteration of both the reporting protein and its binding partner, only moderate deuteration that is easily achievable is required. Residues located in the protein–protein interface can be mapped out simply from the ratios of normalized amide peak intensities at one desired delay in two samples. The effect of protein-concentration difference in the two samples is removed by normalizing the peak intensities of each sample at the desired delay with respect to those at a very short delay (for example, 10 ms). In order to obtain upper limits of effective distances for the amides at contact sites, one can measure the initial relaxation rate differences (ΔR^1) in the two samples. The distance information together with other experimental data such as residual dipolar couplings can be used to model protein complex structures with docking techniques.[2,15]

The selective hydrogenation of unsaturated aldehydes such as propenal on a Pt(111) surface, as shown in the cover picture, is an example of a heterogeneous catalysis reaction that yields two competitive products: propenol and propanal. The selectivity of this reaction is controlled by the balance between the surface hydrogenation steps and the desorption of the product. D. Loffreda et al. describe on page 5279 ff. the use of density functional theory and a microkinetic model to investigate the reaction pathways.

Electrophilic Reagents
N-Acylhydrazones are stable imine equivalents that can combine with a variety of nucleophiles to yield many useful synthetic building blocks. S. Kobayashi and M. Sugiura present the latest developments in this area in their Minireview on page 5176 ff.

Organic Azides
Despite the fact that they are often difficult to handle, organic azides have established a niche in organic synthesis. In their Review on page 5188 ff., S. Bräse and co-workers discuss fundamental reactions and new developments in organoazide chemistry.

Cluster Chemistry
In their Communication on page 5242 ff., D. Fenske et al. detail the synthesis and structural characterization of spherical cluster complexes that comprise an ordered shell of {AgS*t*Bu} groups and a disordered $\{(Ag_2S)_n\}$ core.

Supramolecular Assembly of Nanoparticles at Liquid–Liquid Interfaces

At the interface: The supramolecular organization of nanometer-scale objects is of great interest in the field of applied nanotechnology. Liquid–liquid interfaces can provide an alternative to current methods for the formation of highly ordered structures through the self-assembly of nanoparticles, nanocrystals, and even viruses (see picture). The concept is generally applicable and can be transferred to other interfaces, such as those of polymers.

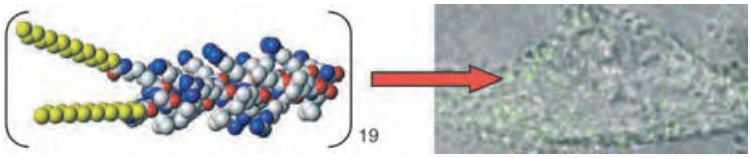
Mutations in the transcription factor p53 enhance one's predisposition to cancer. Mutational studies show that double salt bridges are key elements for the dimerization of p53, its cooperative binding to DNA, and thus its proper function as a tumor suppressor (see picture). This might explain certain germ-line mutations found in patients with Li–Fraumeni syndrome.



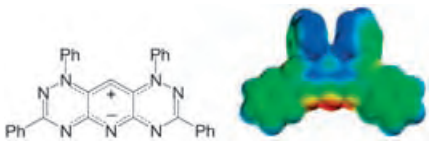
Protein Structures

A. Dehner, C. Klein, S. Hansen, L. Müller, J. Buchner, M. Schwaiger, H. Kessler* ——— **5247 – 5251**

Cooperative Binding of p53 to DNA: Regulation by Protein–Protein Interactions through a Double Salt Bridge

---

Detergent activity is conferred upon a cell-penetrating peptide by dipalmitoylation, and the peptide can incorporate large amounts of phospholipid into supramolecular particles with unique physicochemical properties. These nanocarriers combine the advantages of both liposomes and micelles as they offer a membrane-like environment in spite of their small size, thus preserving the biofunctionality of the vector peptide and affording efficient internalization into live cells.



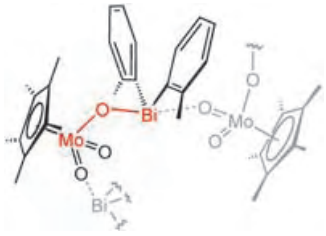
Drug Delivery

S. Keller,* I. Sauer, H. Strauss, K. Gast, M. Dathe, M. Bienert ——— **5252 – 5255**

Membrane-Mimetic Nanocarriers Formed by a Dipalmitoylated Cell-Penetrating Peptide

---

Zwitterionic structures with very low lying triplet states are the dominant characteristics of the first hexaazaacridine, 3,5,7,9-tetraphenylhexaazaacridine (TPH-acridine, see picture), and the analogous TPH-anthracene. The structure and spectroscopic properties were studied experimentally and by DFT calculations and analysis of nucleus-independent chemical shifts.



Antiaromatic Species

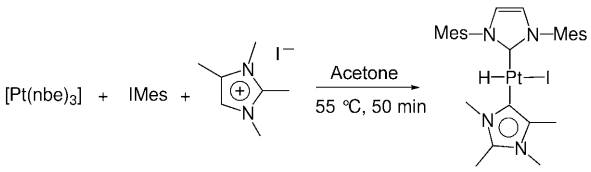
Homogeneous Catalysis

S. Ma,* P. Lu, L. Lu, H. Hou, J. Wei, Q. He, Z. Gu, X. Jiang, X. Jin ——— **5275 – 5278**

What Can a Metal Catalyst Do with Allenes? One-Step Formation of Steroid Scaffolds from Readily Available Starting Materials

The beauty and power of transition-metal-catalyzed reactions has been demonstrated by the one-step synthesis of steroid scaffolds from readily available allenes. The best results (57–73% yield) were obtained using *trans*-[RhCl(CO)(PPh$_3$)$_2$] as the catalyst in toluene (see scheme; E = CN, CO$_2$Me, SO$_2$Ph, Ts = toluene-4-sulfonyl).

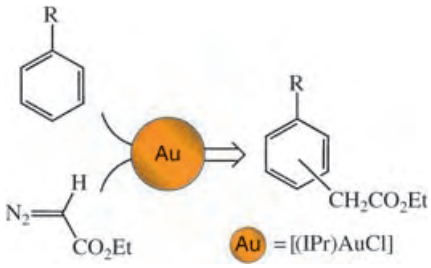


Heterogeneous Catalysis

D. Loffreda,* F. Delbecq, F. Vigné, P. Sautet ——— **5279 – 5282**

Catalytic Hydrogenation of Unsaturated Aldehydes on Pt(111): Understanding the Selectivity from First-Principles Calculations

Coordinating the attack: A theoretical approach based on first-principles calculations and a kinetic model has shown that the partial hydrogenation of the C=O or C=C bonds in acrolein on a Pt(111) catalyst is controlled by the balance between the hydrogenation steps on the surface and the desorption of the partially hydrogenated products. The scheme shows the four possible surface intermediates and the two products.



Carbene Ligands

D. Bacciu, K. J. Cavell,* I. A. Fallis, L.-l. Ooi ——— **5282 – 5284**

Platinum-Mediated Oxidative Addition and Reductive Elimination of Imidazolium Salts at C4 and C5

Wrong way round: Imidazolium salts blocked at C2 undergo oxidative addition to a Pt^0 center at C4/C5 (see scheme; nbe = norbornene, IMes = 1,3-bis(2,4,6-trimethylphenyl)imidazolin-2-ylidene). The resulting carbene ligands, which are bound the "wrong way" are susceptible, in common with their "normal" counterparts, to reductive elimination reactions to regenerate Pt^0 complexes and imidazolium salts.

Carbene Chemistry

M. R. Fructos, T. R. Belderrain, P. de Frémont, N. M. Scott, S. P. Nolan,* M. M. Díaz-Requejo,* P. J. Pérez* ——— **5284 – 5288**

A Gold Catalyst for Carbene-Transfer Reactions from Ethyl Diazoacetate

Approaching El Dorado: A gold catalyst has been discovered that transfers a carbene unit from ethyl diazoacetate to aromatic substrates (see scheme) as well as olefins, amines, and alcohols. The insertion of carbene units into the C–H bonds of the aromatic ring of benzene, toluene, and styrene is a novel reaction. R = H, CH$_3$, CH=CH$_2$; IPr = 1,3-bis(diisopropylphenyl)imidazol-2-ylidene.

Kaleidoscope of Catalysis: Heidelberg Forum of Molecular Catalysis 2005**

Martin Oestreich*

The Heidelberg Forum of Molecular Catalysis (HFMC) originated from the Georg Wittig Lectureship in 1999 and continues as a one-day symposium that has been held biennially ever since. The event is sponsored by the BASF corporation which reflects the considerable importance this company sees in academic research and innovation. In the tradition of the forum, the BASF Catalysis Award is presented to an outstanding young researcher in recognition of her or his significant contributions to the thriving field of molecular catalysis. Frank Glorius (University of Marburg, Germany) is the recipient of this year's award, which includes prize money of €10000.

As in preceding years, the program attracted well over 500 junior and senior scientists from academia and industry. In addition to four plenary lectures (three invited and one by the prize winner), a strong poster session with more than 100 contributions rounded off the scientific program. The chairman of the local collaborative research center, Peter Hofmann (University of Heidelberg, Germany), moderated the symposium.

The scientific program commenced with a talk by David W. C. MacMillan (California Institute of Technology) on state-of-the-art asymmetric organocatalysis, which is hinged on two distinct strategies for the reversible activation of carbonyl groups by amines: activation through lowering the lowest unoccupied molecular orbital (iminium catalysis) and activation through raising the highest occupied molecular orbital (enamine catalysis). Starting with a brief outline of the evolution of suitable chiral catalysts based on the imidazolidinone framework, MacMillan presented an impressive number of applications, sometimes outshining classic asymmetric Lewis acid catalysis. Some of the recent accomplishments of his research group include heteroconjugate addition reactions with one amine as the catalyst and a second amine as the reactant, unusual *exo*-selective Diels–Alder reactions, aldehyde–aldehyde direct aldol reactions (enabling rapid access to orthogonally protected carbohydrates), and α-halogenations of carbonyl compounds. Another part of his talk was devoted to a formidable challenge in organic synthesis: the asymmetric construction of quaternary carbons. The core architecture ("the heart of the beast") of diazonamide A (and likewise, of pyrroloindoline alkaloids) was elegantly assembled by Friedel–Crafts-type conjugate additions of indoles to α,β-unsaturated aldehydes coupled with the cyclization of a pendant heteroatom donor. The fireworks ended with an alternative organocatalytic concept for complex molecule synthesis. The efficiency of a synthetic process decreases exponentially with an increase in the number of sequential operations; tandem catalysis provides a strategic foundation to bypass this disadvantage. A highly stereoselective tandem iminium–enamine–enamine one-pot process carried out for the first time has already demonstrated promise for facilitating asymmetric syntheses.

In his ceremonial address, Stefan Marcinowski (BASF) introduced the prizewinner, Frank Glorius, to the audience with a comprehensive summary of his academic background and a list of his significant scientific achievements. This was followed by a lecture given by the prizewinner himself. Glorius presented a blend of novel homogeneous and heterogeneous catalytic processes. Within the theme of homogeneous catalysis, part of his research program is directed toward the synthesis and application of N-heterocyclic carbenes. His research group devised a new family of sterically demanding carbene ligands (IBiox) with restricted flexibility and applied them in transition-metal catalysis. The unique feature of flexible steric constraints enables these ligands to adapt to the changing requirements of the catalytic cycle, thereby allowing the intricate preparation of tetra-*ortho*-substituted biaryl compounds by Suzuki–Miyaura cross-coupling of aryl chlorides. An additional research area for Glorius is the use of carbenes in organocatalysis; thus α,β-unsaturated aldehydes can be transformed into homoenolate equivalents upon reaction with N-heterocyclic carbenes. Through this organocatalytic conjugate Umpolung and the subsequent reaction with an aldehyde, several γ-butyrolactones were made accessible in one step. Within the theme of heterogeneous catalysis, Glorius reported on a highly diastereoselective hydrogenation of oxazolidinone-substituted pyridines accompanied by the "traceless" cleavage of the chiral auxiliary. This single synthetic operation affords highly enantiomerically enriched piperidine derivatives with up to three stereocenters!

The afternoon session opened with a talk by Amir H. Hoveyda (Boston College) about the quest for ligand–metal combinations of broad utility in asymmetric synthesis. With a catalyst system for the asymmetric alkylation of alkenes as a starting point, Hoveyda nicely delineated the subtle and unforeseeable influences of incidental additives ("impurities") as well as the substrate itself on reaction efficiency and selectivity. The targeted design of general chiral ligands is an attractive alternative to the painstaking search for the right substrate for a given ligand, and Hoveyda has addressed this challenge by using peptide-based ligands. These ligands provide multiple sites for steric and electronic alterations, and libraries of considerable size are easily accessible by

parallel synthesis on solid support. With a plethora of ligands and reasonable mechanistic models at hand, several transformations, such as titanium-catalyzed Strecker reactions, copper-catalyzed conjugate addition and allylic substitution reactions, and aluminum-catalyzed alkylation reactions, were carried out with excellent enantioselectivity. Application of the asymmetric Strecker reaction to the synthesis of non-natural α-amino acids led to the total synthesis and stereochemical assignment of members of the complestatin family of natural products. Hoveyda closed his lecture with the presentation of a novel silver-based chiral N-heterocyclic carbene complex that has already been successfully applied toward enantioselective ruthenium-catalyzed alkene metatheses and copper-catalyzed allylic substitutions.

The scientific program ended with a guided tour by Gregory C. Fu (Massachusetts Institute of Technology) through palladium- and nickel-catalyzed coupling reactions. Equipped with a profound understanding of the importance of electron-rich (facilitating oxidative addition) and sterically demanding (facilitating reductive elimination) ligands at the transition-metal center, Fu introduced broadly applicable tricyclohexylphosphine and tri-*tert*-butylphosphine ligands. These afford unusually active catalysts, which assist in a number of cross-coupling reactions (Suzuki, Stille, Negishi, and Heck reactions) of aryl and vinyl chlorides under exceptionally mild reaction conditions ($C(sp^2)$–Cl bonds appeared to be more reactive than $C(sp^2)$–OSO_2CF_3 bonds). Careful mechanistic investigations revealed the pivotal influence of the base in the resting state of the catalytic cycle. Another focus of his research is the development of capricious $C(sp^3)$–$C(sp^3)$ cross-coupling reactions, which are often thwarted by facile β-hydride elimination. Nevertheless, Fu reported powerful reaction protocols including elucidation of the stereochemical course of the oxidative addition at $C(sp^3)$–$OSO_2C_6H_4CH_3$. This final part culminated in the development of catalytic enantioselective Negishi couplings of racemic secondary benzylic bromides and alkyl zinc reagents.

The well-balanced content of these four plenary lectures provided an excellent up-to-date overview of some first-rate facets of modern molecular catalysis. Interlacing the talks with poster sessions created a relaxed atmosphere in which there was ample time for mutual scientific and personal exchange. The afternoon session ended with a social get-together including complimentary dinner for all participants. All those infected with the "catalysis virus" will have the opportunity to meet again in two years at the 4th Heidelberg Forum of Molecular Catalysis!

Supramolecular Assembly of Nanoparticles at Liquid–Liquid Interfaces**

*Wolfgang H. Binder**

Keywords:
interfaces · nanoparticles · polymers · self-assembly · supramolecular chemistry

The supramolecular organization of nanoparticles, nanocrystals and other nanometer-sized objects (NPs) is an important prerequisite for permanent applications in the field of nano-(bio)technology.[1] There is an intense search for a simple and general strategy to organize NPs on interfaces through self-assembly processes, as NPs exhibit a wide range of size-dependent physical effects (optical, electrical, magnetic, etc.).[2] Such processes require adequate stabilization of the NP at interfaces with a high degree of organizational selectivity. Sufficient dynamic freedom is necessary in the course of the ordering process and once completed, the assembly must be stabilized. Three different approaches are currently explored to effect ordering of NPs by the self-assembly processes (Figure 1):

a) Crystallization of nanoparticles[1a,2a,2b,3] leads to a 3D ordering to produce so-called "colloidal crystals", in which high levels of order are possible through sedimentation and precipitation processes. An advantage of this process is the high level of order within the materials obtained. A main disadvantage lies in the low rate of sedimentation, which may require weeks to generate the ordered materials.

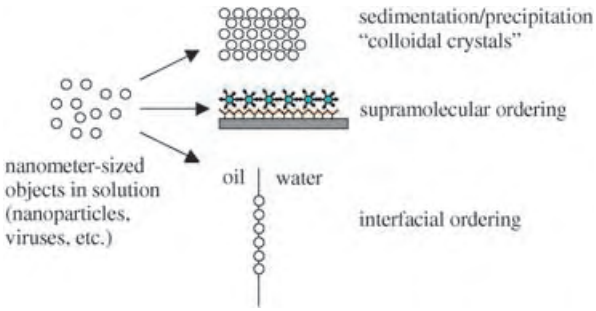

Figure 1. Strategies for the self-assembly of nanoparticles.

b) Another type of self-assembly process uses directed supramolecular interactions between a surface and the NP (for example: electrostatic interactions,[4] oligonucleotides,[5] metal complexes,[6] directed hydrogen bonds,[7] and hydrophobic forces[8]). This technique is usually carried out by a wet-deposition processes. A general disadvantage of using direct supramolecular interactions for assembly lies in the formation of irregular arrays that result from initially strong attachments, which usually do not allow the correction of errors or mismatches during the assembly process.

c) Liquid–liquid interfaces offer an important alternative scaffold for the organization of nanometer-sized objects. For example, interfacial ordering effects[9] can be used for the self-assembly of NPs and viruses. Of key importance is the assembly of NPs at an oil–water interface where the interfacial tension is high. In this process, the assembly is highly dynamic, which enables errors to be corrected rapidly. At the macroscopic level, such processes have been known for over 100 years as "Pickering emulsions",[10] in which large particles ($d > 1$ μm) stabilize emulsions efficiently by adsorption to the liquid–liquid interface.

The theory of the self-assembly of NPs and other nanometer-sized objects at liquid–liquid interfaces was developed initially by Binks et al.[11] (Figure 2). The high interfacial energy between oil and water can be decreased by the assembly of the NPs at the interface. This decrease in surface energy favors the formation of a monolayer of NPs located at the interface. Clearly this process is counterbalanced by the kinetic energy of the NPs in solution. The energetics of the assembly process can be calculated from several parameters according to the equation outlined in Figure 2. The placement of one NP at the interface leads to a decrease in the interfacial energy, which

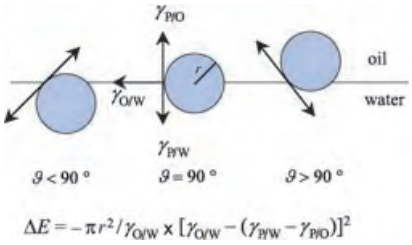

Figure 2. Energy balance (ΔE) of particle assembly at interfaces; adapted from ref. [9a]; γ: interfacial energy, P: particle, W: water, O: oil, r: effective NP radius.

is expressed as the difference between the energies of the oil–water ($\gamma_{O/W}$), the particle–water ($\gamma_{P/W}$), and the particle–oil ($\gamma_{P/O}$) interfaces, in which R is the effective radius of the nanoparticle. Three parameters influence the energy of the assembly process:

a) Simple surface modification of the NPs can be used to modulate the interfacial energies $\gamma_{P/O}$ and $\gamma_{P/W}$; either covalently bound or adsorbed ligands may be used for this. An important aspect of NP surface modification is the influence of the ligand on the properties of the NP core which may limit the range of feasible surface modifications.
b) The nature of the oil–water interface (modification of $\gamma_{O/W}$).
c) The effective radius (R) of the nanoparticles. According to this theory, smaller NPs should adsorb more weakly to the interface than larger NPs.

All three parameters can be used to control the exact location of the NPs; only if the contact angle is exactly 90° will the particle be located exactly at the middle of the oil–water interface (that is, positioned equally between the oil and water phases). In all other cases, the oil or the water will be favored as an adsorption site. The energy of the adsorption process can be determined in the following way: based on known values[12b] ($\gamma_{O/W} = 35.7\ mN\,m^{-1}$; $\gamma_{P/O} = 15\ mN\,m^{-1}$; $\gamma_{P/W} = 40\ mN\,m^{-1}$) the energy is strongly dependent on NP size. A particle with $d \approx 1\ \mu m$ yields a stabilizing interfacial energy of $\Delta E \approx 10^7\ k_B T$, which leads to an almost irreversible adsorption at this interface. Particles with smaller radii adsorb with smaller energy values, as ΔE is proportional to r^2 (for $d = 100$ nm, $\Delta E \approx 10^5\ k_B T$; $d = 10$ nm, $\Delta E \approx 10^3\ k_B T$, $d = 1$ nm, $\Delta E \approx 10^1\ k_B T$).

So much for theory—but what is theory without proof? Russell and co-workers[12] (Figure 3a) recently investigated the assembly of CdSe nanoparticles of two different radii (2.7 nm and 4.6 nm) by competitive adsorption, stabilized with phosphinoxide ligands. Discrimination in adsorption can be followed by taking advantage of the size-dependent fluorescence (F) of the CdSe NPs: the initial fluorescence of adsorption of the smaller particles ($r = 2.7$ nm, $\lambda_F = 525$ nm) at a toluene–water interface was followed by a change at $\lambda = 610$ nm, which indicates the interfacial adsorption of the larger particles added subsequently. This not only gives proof to the theory that larger particles may win the adsorption process in competition with smaller NPs, but also allows determination of the time constant of the selective adsorption process. The particles are mobile (in a fluid phase) at the interface without the formation of ordered arrays. Extending this concept yields isolable films after evaporation of the solvent. Furthermore, charged gold NPs[9c] and voltage-induced processes[13] effect the same type of assembly at interfaces. A related concept developed by Möhwald and co-workers[9a] (Figure 3b) uses Au, Ag or γ-Fe_2O_3 NPs that have been surface-modified with a 2-bromo-2-methylpropionate ligand. The contact angle of these particles has a value close to 90°, resulting in the assembly of the particles exactly in the middle of a toluene–water interface. The formation of a thin film (transferable by Langmuir–Blodgett techniques) with metallic gold reflectance and blue transmittance demonstrates the formation of closely packed NP layers. "Nanoalloys", controlled mixtures of different nanoparticles (assemblies of Ag and Au NPs, for example), can also be formed at the interface given that the NP size and packing permits the formation of matching lattices.

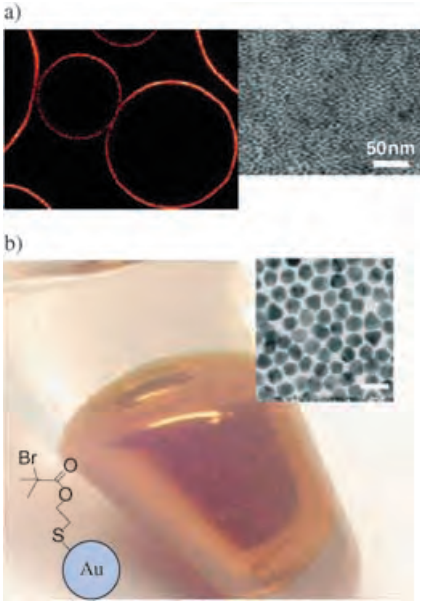

Figure 3. a) Left: fluorescence confocal microscope image of CdSe-particle-coated water droplets dispersed in toluene; right: TEM image of a dried film; from ref. [12a]. b) Photograph of self-assembled Au nanoparticles ($d = 12$ nm) covered with 2,2′-dithiobis(1-(2-bromo-2-methylpropionyloxy)ethane) at a toluene–water interface. Inset: HRTEM image of the film (scale bar = 25 nm); from ref. [9a].

The method is not restricted to metallic, siliceous or semiconductive NPs.[14] Regular biological objects are as important for the formation of thin films and nanometer-sized membranes as are NPs. A recent example of viral assembly (with $r = 33$ nm) was demonstrated by Russell and co-workers[15] with Cowpea Mosaic Virus (CPMV) at a perfluorodecaline–water interface. The virus offers an excellent system, as it is stable in organic solvents and is easily isolated in large quantities from infected black-eyed pea plants. Detection was assisted by chemical labeling with a fluorescent dye (rhodamine). Cross-linking of the CPMV particles at the interface was carried out with glutaraldehyde or biotin groups (Figure 4). Noncovalent cross-linking with the biotin–avidin interaction was superior to chemical cross-linking with glutaraldehyde, as stable and ultrathin membranes consisting of the assembled viruses were obtained. This proves the assembly concept proposed by Whitesides and Boncheva,[16] that a self-assembling system needs a sufficient degree of reversibility to form highly ordered arrays. Otherwise, disordered (glassy) arrays are produced. Thus interfaces not only provide a scaffold for the facile assembly of NPs, but also retain sufficient flexibility to rapidly correct errors during the assembly process, leading to a high degree of order with a rapid process.

The assembly of NPs at polymeric surfaces[17] demonstrates the broad applicability of the interfacial assembly concept. The interface of immiscible block-copolymer micelles provide an environment in which the surface energy in a nonaqueous system (block-copolymer micelles formed in a selective solvent for one block) is comparable to the interfacial energy of oil–water interfaces. Thus Au NPs (with $r = 5.4$ nm) can be assembled within micelles composed of polystyrene-*block*-poly(4-vinylpyridine) (PS-PVP) in toluene—a selective

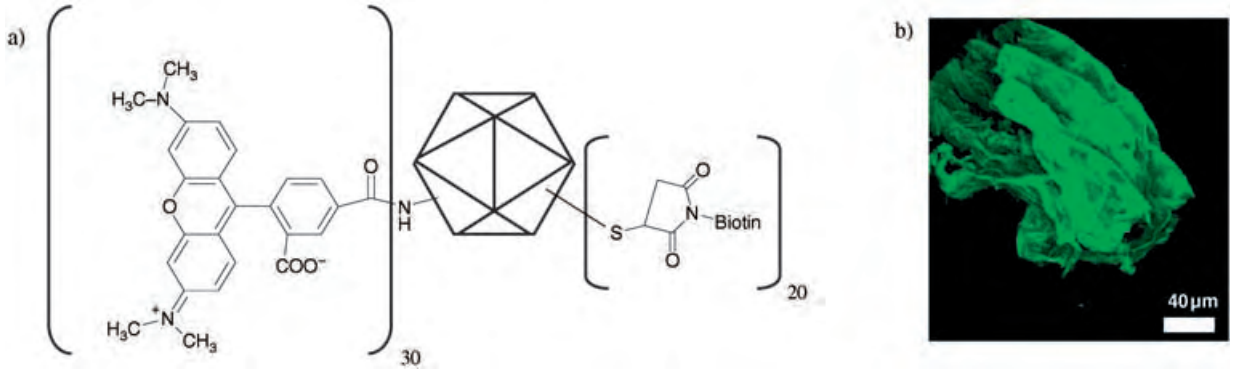

Figure 4. a) CPMV particles modified with rhodamine and biotin. b) Optical micrograph of a CPMV membrane after self-assembly and cross-linking; from ref. [15a].

solvent for the PS block (Figure 5a). Subsequent spin coating leads to an ultrathin film that concentrates the nanoparticles at the interface between the micellar core and corona in a hexagonal pattern ($d \approx 40$ nm per hexagon).[18] An extension of this concept relies on the formation of "honeycomb-patterns"[19] from a homopolymer (polystyrene) under humid conditions from a solution containing CdSe nanoparticles (Figure 5b,c).[20] During evaporation, the CdSe NPs assemble at the interface between $CHCl_3$ and water, leaving behind the micrometer-sized honeycomb pattern of the polymer with the CdSe NPs concentrated at the former location of the evaporated water droplet.

The interfaces can also be used as a medium for chemical reactions in the synthesis of heterodimeric nanoparticles.[21] For example, preassembled Fe_3O_4 nanoparticles ($d = 8$ nm) can be assembled at the interface of a dichloromethane droplet and water (Figure 6). Owing to the high density and stability of the assembly, these particles can act as seeds for the subsequent nucleation of Ag NPs ($d = 5.5$ nm) only on the outside of the Fe_3O_4 assemblies. This is an elegant approach to heterodimeric nanoparticles, consisting of two different materials.

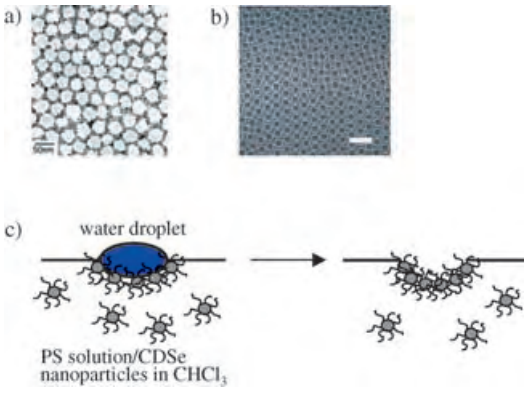

Figure 5. a) Assembly of Au nanoparticles at a polymer interface (*block*-copolymer micelles); from ref. [18a]. b) Optical fluorescence image of CdSe nanoparticles ($d = 4$ nm) of a sample obtained from solvent casting a polystyrene film from chloroform with CdSe nanoparticles under humid conditions (scale bar = 16 µm); from ref. [20]. c) Mechanism of pattern formation and concomitant particle assembly at the water–chloroform interface; from ref. [20].

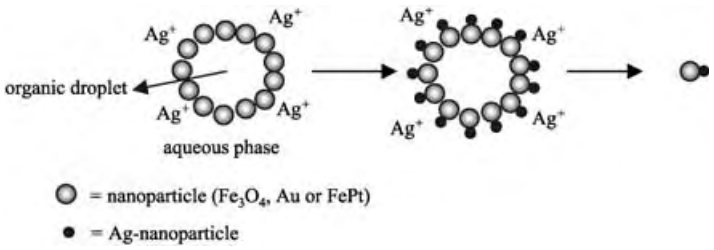

Figure 6. Formation of heterodimeric nanoparticles through the assembly of Fe_3O_4 nanoparticles on a liquid–liquid interface and subsequent seeding of Ag nanoparticles on the outside of the Fe_3O_4 nanoparticles; adapted from ref. [21].

In summary, interfaces are ubiquitous in nature and can be used broadly as ideal means for the self-assembly of nanoparticles. The ease and speed of this approach make it an excellent method for large-scale use and potentially valuable for industrial application. Especially in the area of thin-membrane generation, the functionalization and modification of nanometer-scale objects at specific positions, the size selection of nanometer-sized objects, and the controlled mixing of nanoparticles all give this method great potential for future applications in the field of nanotechnology.

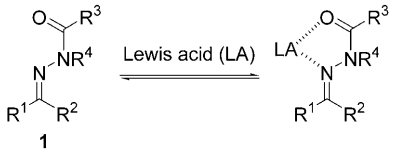
Electrophilic Reagents

N-Acylhydrazones as Versatile Electrophiles for the Synthesis of Nitrogen-Containing Compounds



*Masaharu Sugiura and Shū Kobayashi**

Keywords:
allylation · cyanation · cycloaddition · Mannich reaction · *N*-acylhydrazones

The use of N-acylhydrazones as electrophiles in reactions with nucleophiles has recently made some important advances. N-Acylhydrazones, which can be readily prepared and stored, act as stable imine surrogates in these reactions. The hydrazide products are useful, often chiral building blocks which can be transformed into various nitrogen-containing compounds by cleavage of the N–N bond. The N-acyl groups often play important roles as templates for metal catalysis in controlling stereochemistry. This Minireview summarizes the most recent results of N-acylhydrazone chemistry, and provides an overview of current developments in this field.

1. Introduction

N-Acylhydrazones **1**, which are readily obtained by the condensation of aldehydes or ketones and acylhydrazines[1] in the presence of an acid catalyst, represent a class of azomethine compounds (Scheme 1). They are often crystalline, can be purified by simple recrystallization, and have

1

Scheme 1. The chelation effect of *N*-acylhydrazones toward metal catalysts.

therefore been used for the identification and purification of carbonyl compounds.[2] However, organic chemists have only quite recently focused on their utility as electrophiles for the synthesis of nitrogen-containing compounds. *N*-Acylhydrazones serve as storable, stable imine equivalents which can react with various nucleophiles. A variety of *N*-acylhydrazones can be prepared from enolizable, sterically hindered (α- or β-branched), water-soluble, and/or chiral α-substituted aldehydes or ketones (Scheme 2). Even aqueous solutions of aldehydes or ketones such as glyceraldehyde and chloral can be used. Various *N*-acyl groups ($-COR^3$) can be installed and often play an important role in the control of reactivity and selectivity. The *N*-acylhydrazone structure provides a suitable template for the chelation of Lewis acids, which activate the imino carbon atom as a target for nucleophilic attack (Scheme 1). This Minireview summarizes recent developments in the chemistry of *N*-acylhydrazones as electrophiles (Scheme 2).

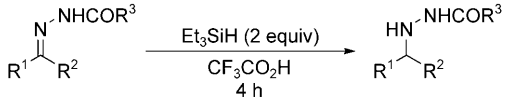
2. Reductions



Reductions of *N*-acylhydrazones to *N*′-alkyl-*N*-acylhydrazines have been accomplished with catalytic hydrogenation,[3] reducing metals,[4] and boron,[5] silicon,[6] or tin[7] reagents. For example, triethylsilane reduces aldehyde- or ketone-derived *N*-acylhydrazones in trifluoroacetic acid (Scheme 3).[6] Whereas aldehyde-derived *N*-acylhydrazones are readily reduced at 0 °C, higher temperatures are needed for the ketone derivatives.

Recently, Qin and Friestad reported that *N*-acylhydrazones **1** derived from ketones and a chiral *N*-aminooxazolidinone were diastereoselectively reduced by tributyltin hydride in the presence of boron trifluoride etherate, whereas the use of triethylsilane as reducing agent resulted only in recovery of the starting material (Scheme 4).[7] Diastereomeric ratios of the products corresponded to the *E*/*Z* ratios of

compound **1**. The observed stereochemistry was explained through a nonchelation model in which the *N*-acyl oxygen lies *anti* with respect to the BF_3 group coordinated to the imino nitrogen atom (Figure 1).

In 1992, Burk and co-workers reported pioneering work on catalytic asymmetric hydrogenation of *N*-acylhydrazones (Scheme 5).[3] The concept of substrate chelation in the highly enantioselective hydrogenation of enamides or enol acetates led them to apply hydrazones with *N*-acyl groups as secondary donors. The best results were obtained with cationic rhodium-DuPhos complexes as catalysts, an alcohol as solvent, conjugatively electron-donating *N*-acyl groups (R^3: 4-$Me_2NC_6H_4$ > 4-$MeOC_6H_4$ > Ph > 2-furyl > 2-$MeOC_6H_4$ > Me > 4-$O_2NC_6H_4$), and electron-withdrawing groups on R^1 ($R^1 = p$-XC_6H_4, X = $NO_2 \approx CO_2Et$ > Br > H > $SiMe_3$ > OMe; R^2 = Me). The high electron-donating ability of the *N*-acyl group and strong π-backbonding from the metal to the electron-deficient C=N bonds have been suggested to be responsible for the decrease in conformational mobility of the substrate in the transition state, leading to high enantioselectivity. Notably, high chemoselectivity was observed in this hydrogenation; only the C=N bonds of hydrazones were reduced in the presence of other functional groups (ketones, aldehydes, esters, nitriles, imines, halogens, nitro groups, alkenes and alkynes). Even chalcon-derived *N*-benzoylhydrazone showed complete chemoselectivity in the same molecule to afford homoallylic hydrazide, although enantio-

Masaharu Sugiura was born in 1970 in Tokyo and received his PhD at the Tokyo Institute of Technology in 1997 under the supervision of Professor Takeshi Nakai. After postdoctoral work at Sagami Chemical Research Center (Dr. Shiro Terashima) and at Florida State University (Professor Marie E. Krafft), he joined the research group of Professor Kobayashi as a JST postdoctoral fellow in 2000. He was appointed assistant professor in 2004, and lecturer in 2005 at the Graduate School of Pharmaceutical Sciences of the University of Tokyo. His research interests include the development of new synthetic methods and novel catalysts.

Shū Kobayashi was born in Tokyo in 1959. He received his PhD in 1988 under the direction of Professor T. Mukaiyama at the University of Tokyo. After eleven years at Science University of Tokyo, he moved to the Graduate School of Pharmaceutical Sciences of the University of Tokyo in 1998. His research interests include development of new synthetic methods and novel catalysts, organic reactions in water, solid-phase synthesis, total synthesis of biologically interesting compounds, and organometallic chemistry. His honors include the Springer Award in Organometallic Chemistry (1997), the IBM Science Award (2001), and the Organic Reactions Lecturer Award (2002).

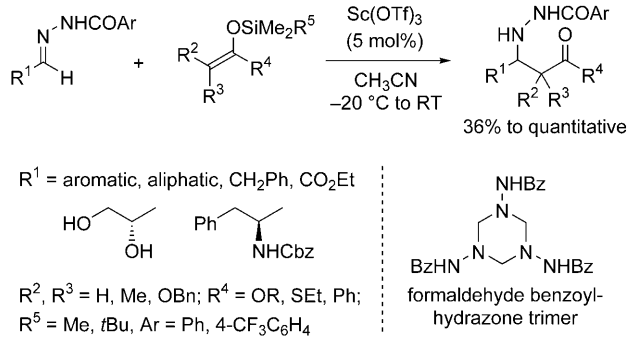
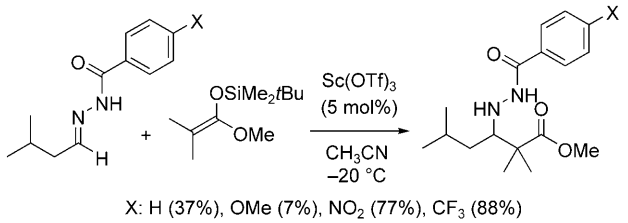
Scheme 5. Asymmetric catalytic hydrogenation of *N*-acylhydrazones.



selectivity in this case was low. High chemoselectivity can be attributed to two effects: 1) capture of the catalyst by substrate chelation by the *N*-acyl group; 2) product inhibition by *N*-acylhydrazine (Scheme 5). With regards to the second effect, it has been established that the Rh-DuPhos catalyst can reduce aldehydes, alkenes, and alkynes, but the presence of *N*-acylhydrazine inhibits the reduction of these functional groups. Furthermore, *N*-acylhydrazone coordinates to the catalyst with higher affinity than does *N*-acylhydrazine, allowing catalytic turnover.

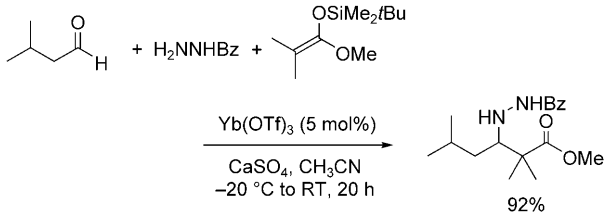
Burk and co-workers also developed a new method for the cleavage of the N–N bond in *N*-acylhydrazine. Treatment with samarium(II) iodide (2.2–3.0 equiv) at 20 °C in MeOH/THF gave primary amines almost instantaneously without loss of enantiomeric purity.



3. Mannich Reactions

Mannich reactions are among the most powerful tools for the preparation of β-amino carbonyl compounds. In particular, the last two decades have witnessed significant developments, including asymmetric catalytic Mannich reactions with preformed imines and/or enolates.[8]

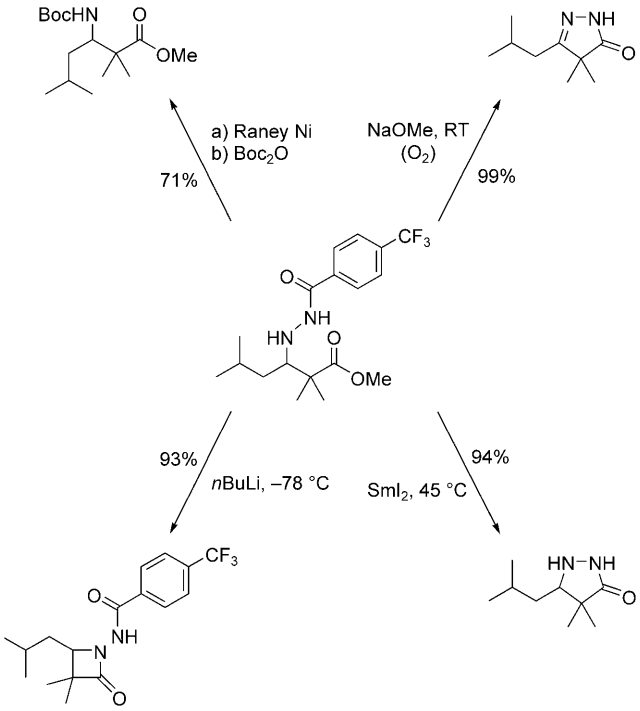
In 1998, our research group found that *N*-acylhydrazones can be efficiently activated by a catalytic amount of a Lewis acid such as $Sc(OTf)_3$ or $Yb(OTf)_3$ to react with silicon enolates (Scheme 6).[9] Various types of *N*-acylhydrazones (aromatic, aliphatic, α,β-unsaturated, α-oxy and α-aza aldehydes, as well as glyoxylate and formaldehyde) and silicon enolates (ester, thioester, and ketone derivatives) readily gave rise to β-*N*′-acylhydrazinocarbonyl compounds in high yield. In contrast to $Sc(OTf)_3$ and $Yb(OTf)_3$, typical Lewis acids such as titanium tetrachloride, tin tetrachloride, and boron trifluoride were not effective. The effect of *N*-acyl groups on reactivity was examined in the $Sc(OTf)_3$-catalyzed reaction of isovaleraldehyde-derived *N*-aroylhydrazones with a silicon enolate (Scheme 7). Among the *para*-substituted



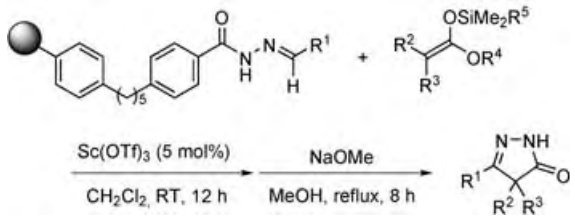
Scheme 6. Lewis acid catalyzed Mannich reactions with *N*-acylhydrazones. Cbz = benzyloxycarbonyl, Bz = benzoyl.

Scheme 7. Effect of *N*-acyl groups on Lewis acid catalyzed Mannich reactions.

benzoyl groups tested, electron-withdrawing groups such as CF_3 were found to be the most reactive. A three-component reaction of isovaleraldehyde, benzhydrazide and the silicon enolate shown in Scheme 7 was also found to proceed smoothly with high yield in the presence of $Yb(OTf)_3$ and $CaSO_4$ (Scheme 8).



Scheme 8. Three-component Mannich reaction.



β-*N*′-Acylhydrazinocarbonyl compounds produced by Mannich reaction can undergo further transformations as shown in Scheme 9. Reductive cleavage of the N–N-bond with Raney nickel under a hydrogen atmosphere provided β-amino esters, whereas reactions with *n*-butyl lithium, sodium methoxide, and samarium (II) iodide, gave β-lactam, pyrazolone, and pyrazolidinone derivatives, respectively. Polymer-supported *N*-acylhydrazones were also developed, and their reactions with silicon enolates in the presence of $Sc(OTf)_3$ followed by treatment of sodium methoxide gave various pyrazolone derivatives (Scheme 10).[9c]

Catalytic asymmetric Mannich reactions of *N*-acylhydrazones have also been performed with a chiral zirconium catalyst prepared from zirconium(IV) *tert*-butoxide and (*R*)-3,3′-dibromo-2,2′-dihydroxy-1,1′-dinaphthyl (Scheme 11).[10] 4-Trifluoromethylbenzoyl hydrazones reacted with silicon enolates to afford the corresponding adducts in good yield and with high enantiomeric excess. The products were

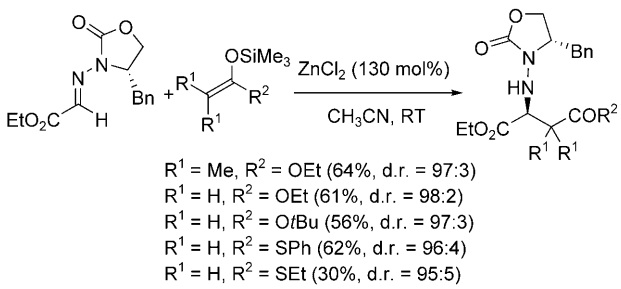


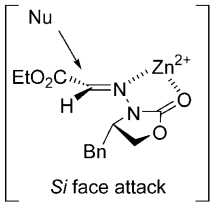
Scheme 10. Solid-phase synthesis of pyrazolone.

Scheme 11. Asymmetric catalytic Mannich reaction.

transformed into β-amino esters, β-lactams or pyrazolidinones without loss of enantiomeric purity.

Mannich reactions of chiral *N*-aminooxazolidinone-derived acylhydrazones with silicon enolates proceeded in the presence of zinc(II) chloride (130 mol%) with high diastereofacial selectivity (Scheme 12).[11] A catalytic amount of $Sc(OTf)_3$ was also effective in some cases, whereas an attack of the nucleophile on the ester group to some extent was observed in other cases. The diastereofacial selectivity can be explained by a selective chelation of Zn^{II} between the imino nitrogen atom and the *N*-acyl oxygen atom. The nucleophile attacks from the *Si* face, as the *Re* face is blocked by the benzyl group (Figure 2).

Scheme 12. Diastereoselective Mannich reaction.



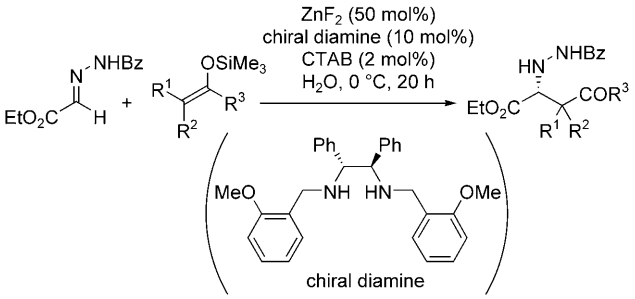


Figure 2. Proposed transition state of the diastereofacial Mannich reaction shown in Scheme 12.

Catalytic asymmetric Mannich reactions in aqueous media were carried out for the first time by the use of *N*-acylhydrazono esters, taking advantage of the tolerance *N*-acylhydrazines have toward water (Scheme 13).[12] It was found that a complex of zinc(II) fluoride with chiral 1,2-phenylethylene diamine effectively catalyzed the reactions of hydrazono esters with silicon enolates to afford Mannich adducts with high enantio- and diastereoselectivity. Reactions proceeded smoothly in water as the sole solvent (mostly in the presence of cetyltrimethylammonium bromide (CTAB), a cationic surfactant). Both diastereomers were obtained with high selectivity by choosing geometrical isomers of silicon enolates. Notably, the use of water as a solvent is a key to obtain high yields and selectivities.

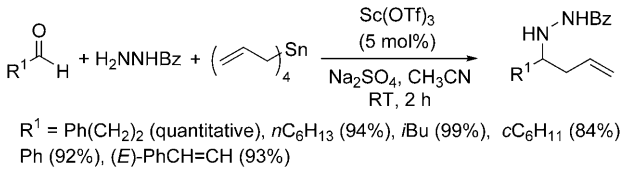
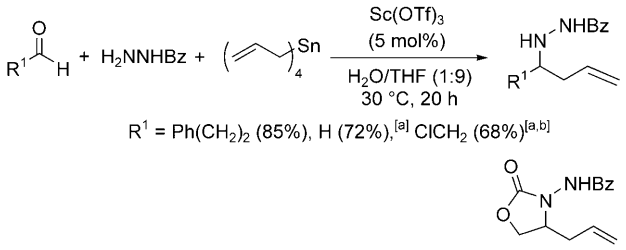
4. Allylation



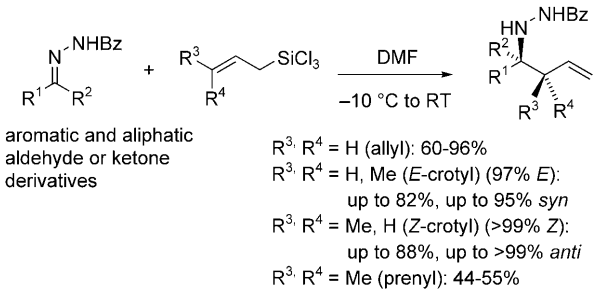
The addition of allyl metal compounds to azomethines provides synthetically useful homoallylic amine derivatives.[13] In contrast to the allylation of carbonyl compounds, the stereoselective allylation of azomethines has undergone very little study.

A variety of *N*-acylhydrazones can be allylated by tetraallyltin in the presence of a Lewis acid catalyst (Scheme 14).[9b,14] The reaction is tolerant to many functional



Scheme 14. Lewis acid catalyzed allylation of *N*-acylhydrazones.

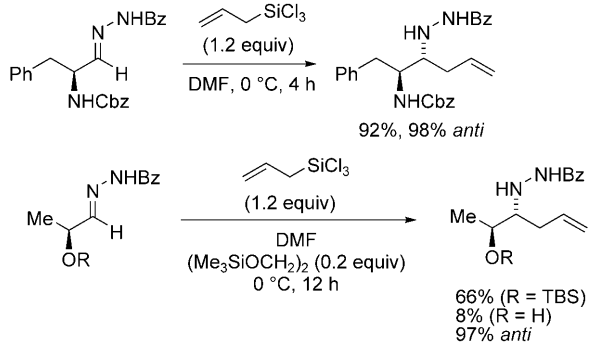
groups, and homoallylic hydrazides were obtained in high yield. Furthermore, it was possible to use *N*-acylhydrazones prepared in situ without isolation (Scheme 15). It was re-



Scheme 15. Three-component allylation with in situ formation of *N*-acylhydrazones.

vealed in a subsequent study that three-component reactions of aldehydes, *N*-acylhydrazines, and tetraallyltin also proceeds well in an aqueous medium (Scheme 16).[14b]

Scheme 16. Allylation in an aqueous medium. [a] A commercial aqueous solution of the aldehyde was used. [b] The oxazolidin-2-one shown at right was obtained in 75% yield if the reaction was treated directly with saturated aqueous $NaHCO_3$.

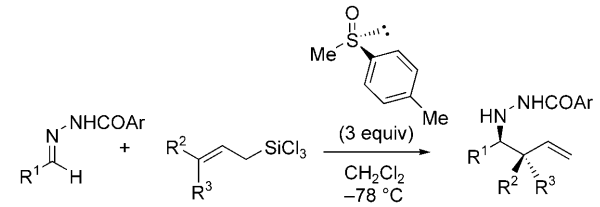


The stereospecific allylation of *N*-acylhydrazones with allyltrichlorosilanes as allylation agents is possible upon the use of *N*,*N*-dimethylformamide (DMF) as a solvent (Scheme 17).[15] *Syn*-crotylated products were obtained from

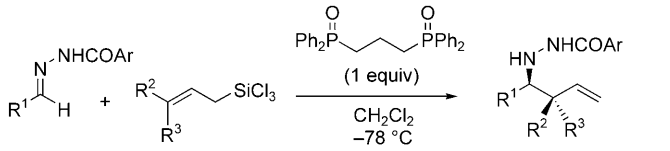
Scheme 17. Stereoselective allylation of *N*-acylhydrazones with allyltrichlorosilanes in DMF.

(*E*)-crotyltrichlorosilane with high diastereoselectivity, whereas (*Z*)-crotyltrichlorosilane stereoselectively afforded *anti*-crotylated products. *N*,*N*-Dimethylformamide is proposed to coordinate allyltrichlorosilanes to form hypervalent silicon species, which then undergo nucleophilic attack to afford *N*-acylhydrazone products *via* six-membered chair-like transition states. We defined such Lewis base catalysts as neutral coordinate organocatalysts (NCOs). Notably, even sterically demanding ketone-derived *N*-acylhydrazones underwent highly diastereoselective crotylation.[15c]

Reactions of α-chiral *N*-acylhydrazones with allyltrichlorosilane in DMF showed high diastereofacial selectivity (Scheme 18). The Felkin–Anh model could explain



Scheme 18. Diastereofacial selective allylation of chiral *N*-acylhydrazones. TBS = *tert*-butyldimethylsilyl.



the observed *anti*-selectivity.[15b] A search for further effective NCOs revealed that a stoichiometric amount of a sulfoxide species promoted the reaction (Scheme 19).[16] Importantly, enantioselective allylation was accomplished for the first time by the use of simple, optically active (*R*)-methyl *p*-tolylsulfoxide. High stereoselectivity was observed not only in allylation but also in crotylation.

In an effort to decrease the amount of NCOs needed, a bidentate propylene-tethered bis(phosphine) dioxide emerged as a more efficient catalyst (Scheme 20),[17] with

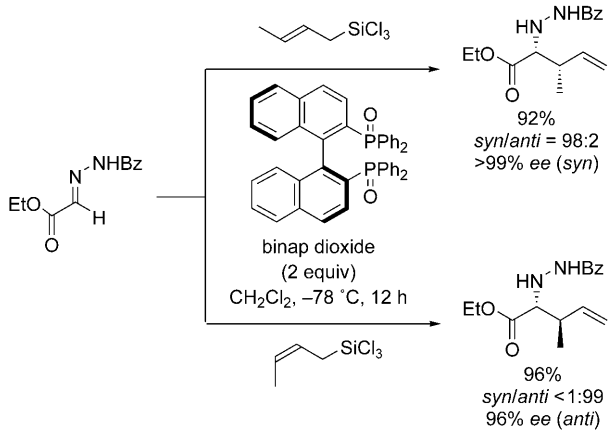
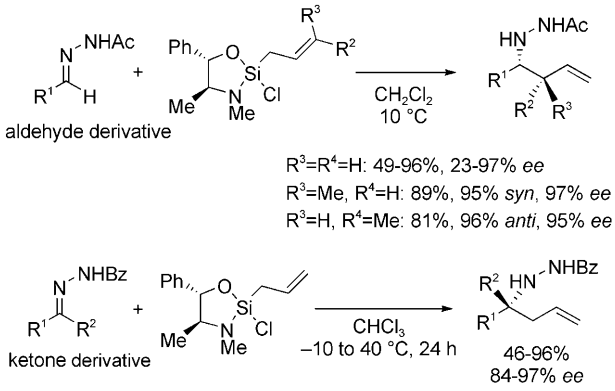
Scheme 20. A bis(phosphine) dioxide as an NCO for allylation.

which the less-reactive aromatic *N*-acylhydrazones were found to react well. Furthermore, a polymer-supported phosphine oxide was also developed as a recoverable and



Scheme 21. A polymer-supported phosphine oxide as an NCO for allylation.



reusable NCO (Scheme 21). This polymer-bound catalyst exhibited a higher activity than a polymer-supported formamide, which was effective for the allylation of aldehydes with allyltrichlorosilane.

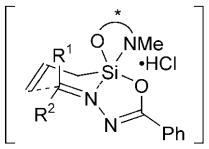
Meanwhile, the highly stereoselective asymmetric allylation of a hydrazino ester was carried out with (*S*)-binap dioxide as a chiral NCO (Scheme 22).[17b] The synthetic utility of this system was demonstrated by the highly enantio- and diastereoselective syntheses of α- and β-chiral amino acid derivatives, such as D-alloisoleucine.

Leighton and co-workers reported related reactions with ephedrine-derived chiral allylchlorosilanes (Scheme 23).[18] It is significant that even sterically encumbered ketone-derived *N*-acylhydrazones underwent highly enantioselective allylation. The chlorine atom of the allylsilane is important for reactivity, and *N*-methylated *N*-acylhydrazone is unreactive;

Scheme 22. Enantioselective allylation of an *N*-acylhydrazono ester with binap dioxide; binap = 2,2′-bis(diphenylphosphino)-1,1′-binaphthyl.

Scheme 23. Enantioselective allylation with a chiral allylsilane.

these two points suggest that the reaction proceeds by the formation of a covalent Si–O bond between the silane reactant and the acyl oxygen atom of the *N*-acylhydrazone with the liberation of hydrogen chloride (Figure 3).



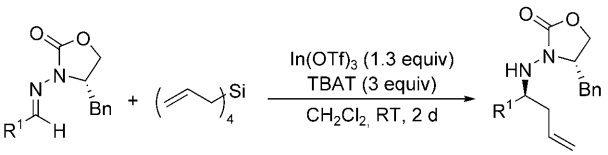


Figure 3. Proposed transition state of the allylation shown in Scheme 23.

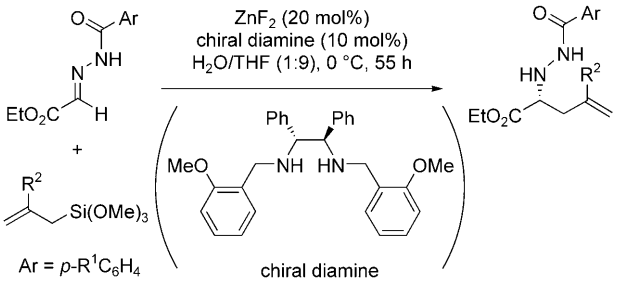
Friestad and Ding reported the diastereoselective reaction of *N*-acylhydrazones derived from a chiral *N*-aminooxazolidinone with allylsilanes in the presence of a stoichiometric amount of indium triflate and tetrabutylammonium triphenyldifluorosilicate (TBAT) (Scheme 24).[19] Among the allylsilanes tested, allyltrimethylsilane, allyl(diisopropylamino)dimethylsilane, and tetraallylsilane (in increasing order of reactivity) were found to be effective as



R1 = Ph (78%, d.r. > 99:1), *p*-MeC6H4 (94%, d.r. = 98:2), *m*-O2NC6H4 (71%, d.r. > 99:1), 2-naphthyl (82%, d.r. = 98:2), 2-furyl (58%, d.r. = 96:4), (*E*)-PhCH=CH (60%, d.r. = 95:5), Et (51%, d.r. = 82:18)

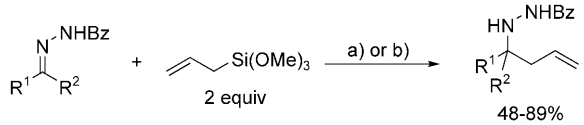
allylating agents, whereas triphenyl-, trimethoxy-, and chlorinated allylsilanes were ineffective. It was suggested that the reaction proceeded through the addition of a hypervalent silicate to the Lewis acid complexed hydrazone.



The first catalytic asymmetric allylation of *N*-acylhydrazono esters in an aqueous medium was performed with allyltrimethoxysilanes as allylating agents and zinc(II) fluoride in combination with a chiral 1,2-phenylethylenediamine

derivative as catalyst (Scheme 25).[20] The Zn(OH)F/chiral diamine was catalytically inactive, yet following the addition of $(EtO)_3SiF$ to this system, similar yield and selectivity to those of the reaction with ZnF_2/chiral diamine were observed. This is indicative of the regeneration of ZnF_2 from Zn(OH)F and the fluorosilane by-product, leading to catalytic turnover of the fluoride anion. The methoxy groups of the chiral diamine ligand play an essential role in attaining high yields and selectivities. Improvement of the yield was also observed upon the use of 4-alkoxybenzoylhydrazones. Importantly, water was indispensable for the promotion of this reaction.

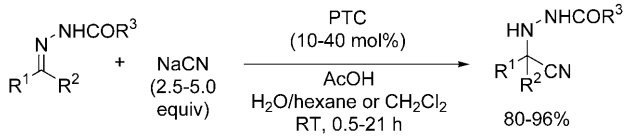
b) TBAT (20 mol%), *t*BuOH (2 equiv), DMF, RT, 17-72 h

Scheme 26. Catalytic allylation under various reaction conditions; dppe = 1,2-bis(diphenylphosphino)ethane



More recently, Ding and Friestad reported the reaction of *N*-acylhydrazones with allyltrimethoxysilane under two possible conditions (Scheme 26).[21] One case is closely related to the conditions reported by Shibasaki and co-workers,[22] in which CuCl, TBAT, and a phosphorous ligand are used in the presence of *t*BuOH as a proton source. The other set of conditions involves a catalytic amount of TBAT and two equivalents of *t*BuOH. Control experiments supported the hypothesis that reactions under these conditions proceed through distinctly different mechanisms. A Cu-containing allyl nucleophile was suggested for the former case, whereas an autocatalytic and/or alkoxide-catalytic mechanism was proposed for the latter (Scheme 27).

5. Cyanation

The hydrocyanation of *N*-acylhydrazones enables a practical access to α-hyrazino acids and related chiral building blocks.[23] It was reported in 1990 that the addition of hydrogen cyanide generated in situ to *N*-acyl or *N*-tosylhydrazones in a biphasic system takes place efficiently in the presence of a phase-transfer catalyst (Scheme 28).[24] More recently, the Lewis acid hafnium(IV) triflate was found to

catalyze the addition of trimethylsilyl cyanide to functionalized *N*-acylhydrazones in acetonitrile (Scheme 29).[9b]

Keith and Jacobsen reported the first asymmetric catalytic hydrocyanation of *N*-acylhydrazones (Scheme 30),[25] in which

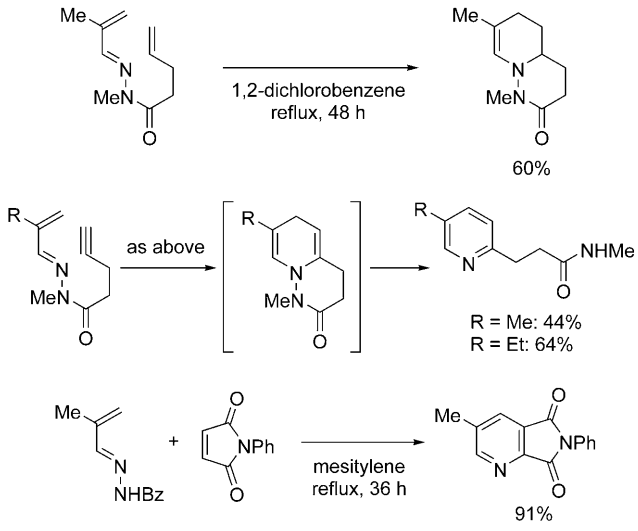
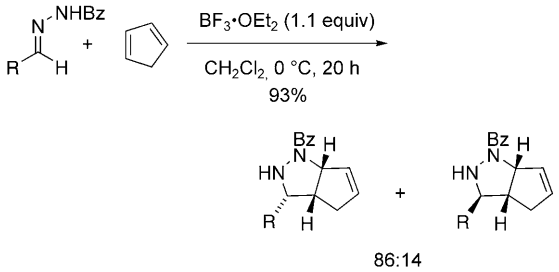
Scheme 29. Lewis acid catalyzed cyanation.



Scheme 30. Asymmetric Lewis acid catalyzed hydrocyanation.

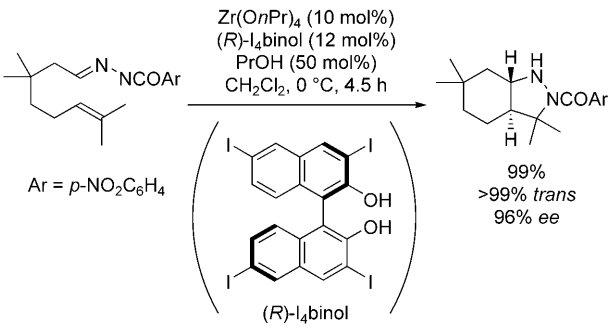
a $EuCl_3$/pybox complex was found to be an efficient enantioselective catalyst. Although long reaction times were required, high enantioselectivities were observed. The best results were obtained with aromatic hydrazones bearing electron-rich substituents; electron-deficient substrates gave very poor reactivity. This suggests that the formation of a complex between the hydrazone and the Lewis acid catalyst may be the rate-limiting step in this process.



6. Cycloaddition

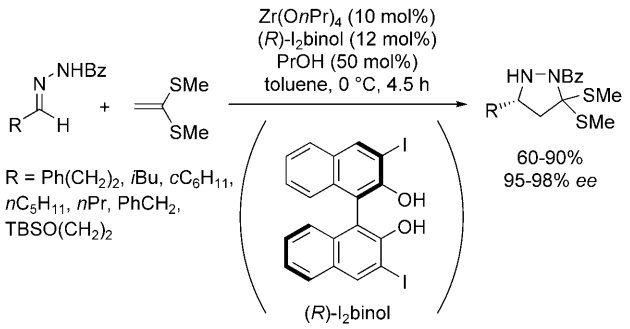
N-Acylhydrazones can serve as azadienes in aza-Diels–Alder reactions (Scheme 31).[26] Methacrolein or ethylacrolein-derived hydrazones can undergo both intra- and intermolecular [4+2] cycloadditions at high temperatures (> 140 °C) to afford pyridopyridazines or pyridines. Pyridines were formed by the elimination of the carbamoyl groups (followed by air oxidation in the case of reactions with *N*-phenylmaleimide). The reaction of phenylhydrazone with *N*-phenylmaleimide is appreciably faster than that of *N*-acyl or *N*-tosylhydrazones.

Scheme 31. Aza-Diels–Alder reactions with *N*-acylhydrazones.



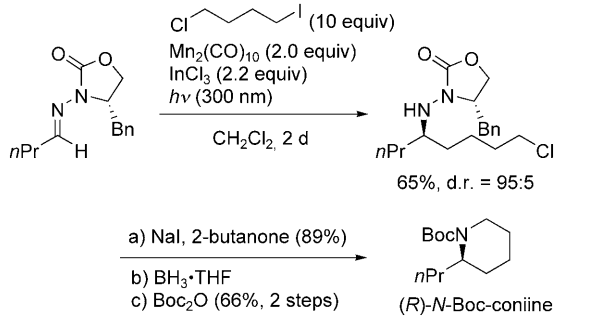
It is also known that hydrazones can serve as 1,3-dipolar agents in [3+2] cycloadditions with olefins. Hesse first reported in 1971 that three-component reactions of *N*-phenyl or *N*-acetylhydrazine, aldehydes, and olefins in acetic acid in the presence of a stoichiometric amount of sulfuric acid can provide pyrazolines in good yield.[27] Protonated hydrazones were suggested to be the active species. Since that time, several examples of [3+2] cycloadditions of *N*-acylhydrazones and alkenes under thermal conditions have been reported.[28] We recently found that Lewis acids also promote this transformation (Scheme 32).[29] *N*-Benzoylhydrazones

Scheme 32. Lewis acid catalyzed [3+2] cycloaddition.



derived from 3-phenylpropanal, benzaldehyde, and ethyl glyoxylate in reaction with conjugated dienes in the presence of a stoichiometric amount of $BF_3{\cdot}OEt_2$ or a catalytic amount of $Zr(OTf)_4$ and $Hf(OTf)_4$ afford the corresponding pyrazolidine derivatives.

Asymmetric cycloadditions of this type have also been carried out in our research group. Both intra- and intermolecular [3+2] cycloaddition reactions proceeded smoothly in the presence of a catalytic amount of $Zr(OPr)_4$/binol derivatives to afford pyrazolidine products in high yield with high enantioselectivity (example reactions shown in Schemes 33 and 34).[30] In the case of intermolecular reaction



Scheme 33. Asymmetric catalytic intramolecular [3+2] cycloaddition.

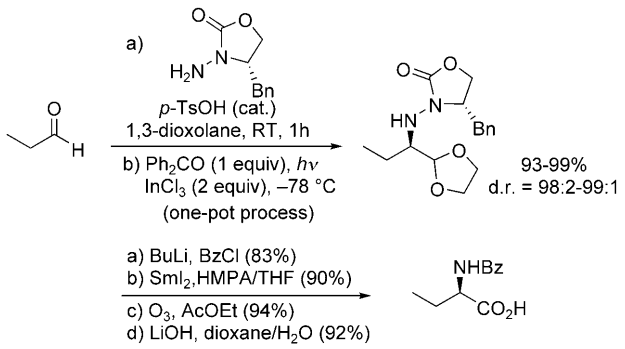
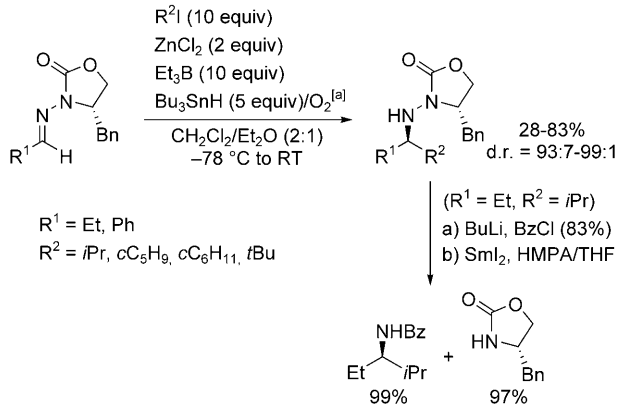
Scheme 34. Asymmetric catalytic intermolecular [3+2] cycloaddition.

Scheme 36. Diastereoselective addition of a primary alkyl radical to an *N*-acylhydrazone.



(Scheme 34), vinyl ethers such as propyl vinyl ether can be used. Enantiomeric excess of the major and minor diastereomers were different in this case, although no epimerization between the diastereomers occurred during the course of the reaction. If the reaction were to proceed by a stepwise mechanism, the enantioselectivity of both diastereomers would be expected to be the same; this suggests that the reaction proceeds by a concerted mechanism.

7. Radical Addition

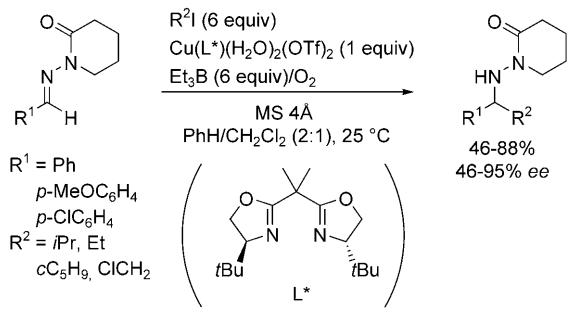


As a result of the lower electron density of their C=N bonds, hydrazones are better radical acceptors than imines.[31] Three-electron π-bond interactions could also stabilize a transition state leading to an aminyl radical adduct.

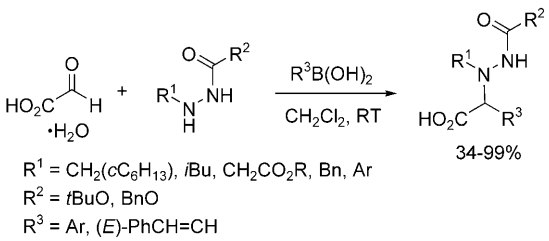
Friestad and Qin reported the diastereoselective reaction of chiral *N*-acylhydrazones with secondary and tertiary alkyl radicals in the presence of a stoichiometric amount of zinc chloride as an activator and tributylstannane as a radical mediator (Scheme 35).[32] Adducts were obtained with high diastereoselectivity and could be transformed into optically active benzamides without epimerization through treatment with BuLi/benzoyl chloride and SmI_2. It was also discovered that primary alkyl radicals react with chiral *N*-acylhydrazones if $InCl_3$ is employed as a Lewis acid with $[Mn_2(CO)_{10}]$ as a radical mediator under irradiation (Scheme 36).[33] In these reactions, high diastereofacial selectivity similar to that of the previous system was observed. Photolytic Mn–Mn homolysis facilitated formation of primary alkyl radicals, thus allowing the use of toxic tin reagents to be avoided. Reaction of the radical species [·Mn(CO)$_5$] with primary halides was more efficient than that with secondary and tertiary halides.

More recently, Fernández and Alonso discovered that α-oxygenated carbon radicals, generated from methanol, 2-propanol, or 1,3-dioxolane under irradiation in the presence of benzophenone, can react with the chiral hydrazones reported by Friestad (Scheme 37).[34] In this case as well,

Scheme 37. Diastereoselective addition of a 1,3-dioxolanyl radical.



Scheme 35. Diastereoselective addition of secondary and tertiary alkyl radicals to *N*-acylhydrazones; HMPA = hexamethylphosphoramide. [a] Added by syringe pump.



$InCl_3$ was effective for the control of diastereofacial selectivity; the selectivity was also largely dependent on the aldehyde source for the formation of hydrazones. Hydrazone formation and radical addition could be performed in a one-pot process to improve yield and selectivity, and in one case, the product was transformed into an α-amino acid derivative.

Friestad et al. also reported enantioselective radical addition (Scheme 38).[35] Although their initial attempts with prochiral oxazolidione-derived *N*-acylhydrazones resulted in insignificant enantioselectivity, dramatic improvement was observed with valerolactam-derived *N*-acylhydrazones. Further optimization of Lewis acids and chiral ligands revealed that a combination of $Cu(OTf)_2$ and a chiral *tert*-leucinol-derived bis(oxazoline) ligand gave high enantioselectivity in a less-polar reaction medium (benzene/CH_2Cl_2). Notably, with the catalyst present at 10 mol% (R^1 = Ph, R^2 = *i*Pr), the product was obtained in 74% yield with 46% *ee*, whereas

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 38. Enantioselective addition of alkyl radicals to *N*-acylhydrazones.

Scheme 39. Three-component reaction of glyoxylic acid, hydrazides and boronic acids.

slightly lower yield (66%) and much higher enantiomeric excess (95% *ee*) were observed with the catalyst at 100 mol%.

8. Transformation of Products

A valuable range of nitrogen-containing compounds with N–N bonds, for example *N*-carbamoyl-β-lactam, pyrazolidinone, pyrazolone, and pyrazolidine derivatives (see Schemes 9, 10, 31–34)[9,10,27–30] are available from *N*-acylhydrazine products. Cleavage of the N–N bond can convert *N*-acylhydrazines into further interesting derivatives. This transformation is enabled by hydrogenolysis (with palladium, platinum or Raney nickel), reduction with dissolved metals, and hydroboration.[36] Reductive cleavage with samarium(II) iodide,[3] has gained increased attention in recent studies.[9d,10,11,12a,14a,15,18b,19,20,30a,32,34] Indeed, Friestad and Ding recently reported a dramatic improvement of SmI_2-mediated N–N bond cleavage by the *N*′-benzoylation or *N*′-trifluoroacetylation of *N*-acylhydrazines.[37] Benzoyl groups have been suggested to decrease the reducing potential of the N–N bond, while chelation of SmI_2 between the amide oxygen atom and the fluorine atom of the trifluoroacetyl group (Figure 4) is proposed to enhance the rate of reduction.

Figure 4. Proposed transition state that explains the rate enhancement of SmI_2-mediated N–N-bond cleavage by the trifluoroacetyl group.

9. Other Reactions

The addition of an ethyl Grignard reagent to an *N*-formylhydrazone[38] and Friedel–Crafts reactions of *N*-acylhydrazonium ions[39] have also been reported. Furthermore, it has been found that Petasis three-component reactions of glyoxylic acid, *N*-(alkoxycarbonyl)hydrazines, and aryl or styryl boronic acids afford α-hydrazinocarboxylic acids efficiently (Scheme 39).[40] Interestingly, the reaction of an unsubstituted hydrazine ($R^1 = H$, $R^2 = t$BuO) with pMeO$C_6H_4B(OH)_2$ gave a complex mixture, whereas reactions of the preformed *N*-acylhydrazone BocNHN=$CHCO_2H$ provided the adduct in 71% yield. However, other reactions with substituted hydrazones ($R^1 \neq H$) cannot involve *N*-acylhydrazones, but presumably *N*-acylhydrazonium ions.

10. Summary and Outlook

N-Acylhydrazones as versatile electrophiles have attracted increasing attention not only because they are readily prepared, storable, and stable imine surrogates, but also because the *N*-acyl groups act as good templates for metal catalysts which facilitate stereochemical control. Chiral hydrazide products can be used as chiral building blocks and can also be transformed into a variety of nitrogen-containing compounds through cleavage of the N–N bond. It is expected that new stereoselective reactions that take advantage of *N*-acylhydrazones will be developed, and that the use of *N*-acylhydrazones as imine equivalents will be expanded to the chemical and pharmaceutical industries.[41]

Since the discovery of organic azides by Peter Grieß more than 140 years ago, numerous syntheses of these energy-rich molecules have been developed. In more recent times in particular, completely new perspectives have been developed for their use in peptide chemistry, combinatorial chemistry, and heterocyclic synthesis. Organic azides have assumed an important position at the interface between chemistry, biology, medicine, and materials science. In this Review, the fundamental characteristics of azide chemistry and current developments are presented. The focus will be placed on cycloadditions (Huisgen reaction), aza ylide chemistry, and the synthesis of heterocycles. Further reactions such as the aza-Wittig reaction, the Sundberg rearrangement, the Staudinger ligation, the Boyer and Boyer–Aubé rearrangements, the Curtius rearrangement, the Schmidt rearrangement, and the Hemetsberger rearrangement bear witness to the versatility of modern azide chemistry.

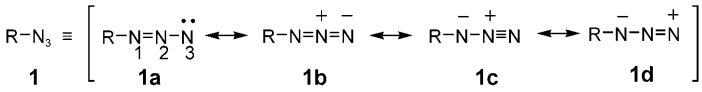
6. Summary and Outlook 5227

1. Introduction

Since the preparation of the first organic azide, phenyl azide, by Peter Grieß in 1864 these energy-rich and flexible intermediates have enjoyed considerable interest.[1,2] A few years later Curtius developed hydrogen azide and discovered the rearrangement of acyl azides to the corresponding isocyanates (Curtius rearrangement).[3] The organic azides received considerable attention in the 1950s and 1960s[4,5] with new applications in the chemistry of the acyl, aryl, and alkyl azides. Industrial interest in organic azide compounds began with the use of azides for the synthesis of heterocycles such as triazoles and tetrazoles as well as with their use as blowing agents and as functional groups in pharmaceuticals. Thus, for example, azidonucleosides attract international interest in the treatment of AIDS.[6]

Like hydrogen azide most other azides are also explosive substances that decompose with the release of nitrogen through the slightest input of external energy, for example pressure, impact, or heat. The heavy-metal azides are used, for example, in explosives technology, in which they serve as detonators. Sodium azide is applied in airbags. The organic azides, particularly methyl azide, often decompose explosively.

However, in spite of their explosive properties, organic azides are valuable intermediates in organic synthesis.[7,8] Thus they are used in cycloadditions, the synthesis of anilines and *N*-alkyl-substituted anilines,[9] as well as precursors for nitrenes. In this Review, which is not meant to be a comprehensive overview,[10] the fundamental characteristics of organoazide chemistry with its "explosive" diversity in modern synthetic chemistry will be illustrated. In this context, inorganic azides, purely main-group azides (such as $Te(N_3)_5$[11]), and purely structural-chemical aspects will not be discussed. After the section on their properties, the synthetic opportunities and applications of organoazides will be illustrated.



2. Physicochemical Properties of Organic Azides

The structural determination of azides originates from the initial postulation of Curtius and Hantzsch, who had suggested a cyclic 1*H*-triazirine structure [3,12,13], that was, however, rapidly revised in favor of the linear structure.

1-phenyl-1*H*-triazirine

A basis for the chemical diversity of azides comes from the physicochemical properties of azides. Some of the physicochemical properties of the organic azides can be explained by a consideration of polar mesomeric structures.[1] Aromatic azides are stabilized by

conjugation with the aromatic system. The dipolar structures of type **1c**,**d** (proposed by Pauling[14]) also compellingly explained the facile decomposition into the corresponding nitrene and dinitrogen (see Section 4.2) as well as the reactivity as a 1,3-dipole. The regioselectivity of their reactions with electrophiles and nucleophiles is explained

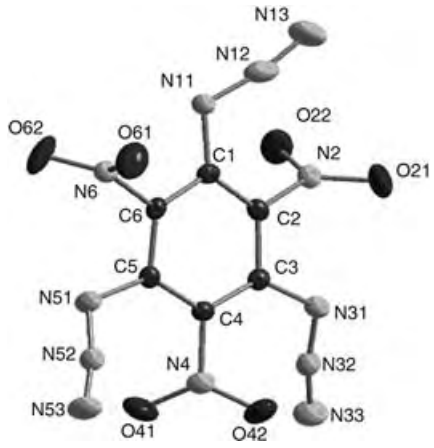
on the basis of the mesomeric structure **1d** (attack on N^3 by nucleophiles, whereas electrophiles are attacked by N^1).

The angles $R–N^1–N^2N^3$ and $RN^1–N^2–N^3$ are approximately 115.2° and 172.5°, respectively (calculated for methyl azide, $R = CH_3$[15]). The bond lengths in methyl azide were determined as $d(R–N^1) = 1.472$, $d(N^1–N^2) = 1.244$, and $d(N^2–N^3) = 1.162$ Å; slightly shorter $N^2–N^3$ bond lengths are observed with aromatic azides. Thus an almost linear azide structure is present, with sp^2 hybridization at N^1 and a bond order of ≈ 2.5 between N^3 and N^2 and ≈ 1.5 between N^2 and N^1. Figure 1 is an example of the molecular structure of an aromatic azide.

The polar resonance structures **1b**,**c** explain the strong IR absorption at $\approx 2114\ cm^{-1}$ (for phenyl azide),[17] the UV absorption (287 nm and 216 nm for alkyl azides), the weak dipole moment (1.44 D for phenyl azide), and the acidity of aliphatic azides (e.g. see Scheme 12).[18] The azide ion is regarded as a pseudohalide[19] and organic azides are similar in certain respects to organic halogen compounds. The Hammett parameters for arenes with azide groups in the *meta* and *para* positions are 0.35 and 0.10, respectively, which are comparable with those of fluoroarenes. In aromatic substitution reactions the azide group acts as an *ortho*- and *para*-directing substituent.

Whereas ionic azides such as sodium azide are relatively stable (see box), covalently bound and heavy-metal azides are thermally decomposable and in part explosive classes of compounds. For organic azides to be manipulable or non-explosive, the rule is that the number of nitrogen atoms must not exceed that of carbon and that $(N_C + N_O)/N_N \geq 3$ ($N =$ number of atoms; Smith[20]). Synthesized but potentially explosive compounds include hexakis(azidomethyl)benzene (**2**),[16] triazidotrinitrobenzene (**3**),[21] azidotetrazole (**4**) (88 %



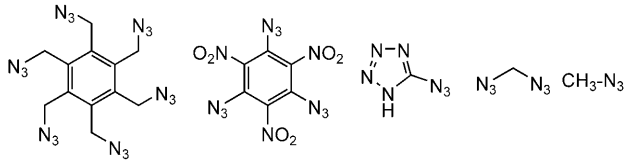


Figure 1. ORTEP representation of 1,3,5-triazido-2,4,6-trinitrobenzene with the ellipsoids of the C, N, and O atoms drawn at the 50% probability level.[16b]

Stefan Bräse was born in Kiel in 1967 and studied at Göttingen, Marseille (France), and Bangor (Wales) (PhD: Prof. Armin de Meijere). After periods of research in Uppsala (Sweden) and La Jolla (USA) he completed his Habilitation at the RWTH Aachen (Prof. Dieter Enders). In the same year he was appointed C3 professor at Bonn University. He was guest professor in Madison (USA) before taking up his current professorship at the Universität Karlsruhe (TH) in 2003. His research interests combine asymmetric catalysis, the synthesis of natural products, combinatorial chemistry, and medicinal chemistry.

Carmen Gil was born in Talavera de la Reina, Spain in 1972. She studied at the Complutense University of Madrid and received her PhD in 2001 at the Medicinal Chemistry Institute in Madrid (Prof. Ana Martínez). After a postdoctoral appointment at Bonn University (Prof. Stefan Bräse) as a Marie-Curie fellow, she joined the Medicinal Chemistry Institute in Madrid in 2004. Her research interests includes combinatorial chemistry applied to the synthesis of bioactive molecules.

Viktor Zimmermann studied chemistry at the universities of Nowosibirsk, Göttingen, and the RWTH Aachen. He completed his Diploma at the RWTH Aachen in 2002. Since then he has been working for his PhD at Bonn University (Prof. Stefan Bräse). The main topic of his research is carrier-supported combinatorial synthesis of benzotriazoles and azides.

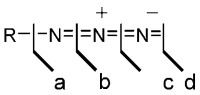
Kerstin Knepper was born in Dortmund, Germany in 1976 and studied chemistry at the University of Dortmund. In 2001, she obtained her Diploma in chemistry (Prof. Norbert Krause). She received her PhD in 2004 at the University of Bonn (Prof. Stefan Bräse). She is currently a postdoctoral fellow with Prof. N. Winssinger (Université Louis Pasteur, Strasbourg, France). Her research interests include the solid-phase synthesis of benzannelated heterocycles, methods of organometallic chemistry, and the combinatorial synthesis of natural product analogues.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

nitrogen!),[22] and azidomethane (**6**). Diazidomethane (**5**) is prepared from sodium azide and dichloromethane.[23] Certain low-molecular-weight azides, which in practice have proved to be nonreactive, can still decompose under unexplained circumstances so that special care is needed.

Safety in the Handling of Sodium Azide and other Azides

Sodium azide is toxic (LD_{50} oral (rats) = 27 mg kg^{-1}) and can be absorbed through the skin. It decomposes explosively upon heating to above 275 °C; hence its use in airbags in the automotive industry).



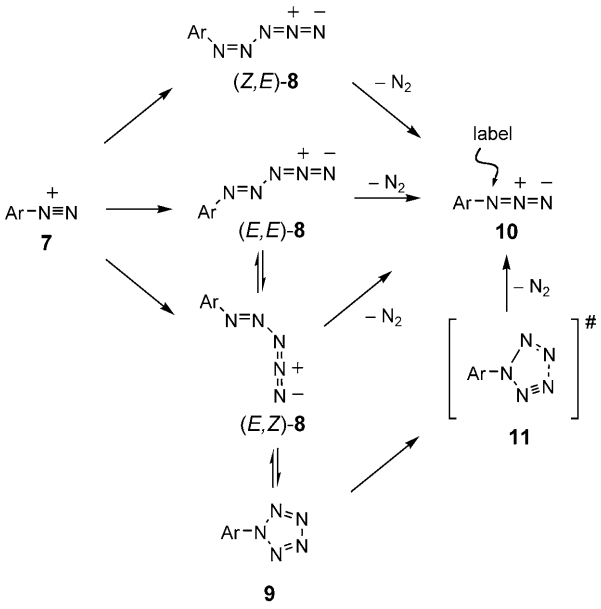
Sodium azide reacts vigorously with CS_2, bromine, nitric acid, dimethyl sulfate, and a series of heavy metals, including copper and lead. In reaction with water or Brønsted acids the highly toxic and explosive hydrogen azide is released. It has been reported that sodium azide and polymer-bound azide reagents form explosive di- and triazidomethane with CH_2Cl_2 and $CHCl_3$, respectively.[23a]

Heavy-metal azides that are highly explosive under pressure or shock are formed when solutions of NaN_3 or HN_3 vapors come into contact with heavy metals or their salts. Heavy-metal azides can accumulate under certain circumstances, for example, in metal pipelines and on the metal components of diverse equipment (rotary evaporators, freeze-drying equipment, cooling traps, water baths, waste pipes), and thus lead to violent explosions.

Some organic and other covalent azides are classified as toxic[24] and highly explosive[25], and appropriate safety measures must be taken at all times.

3. Synthesis of Organic Azides

In principle, organic azides may be prepared through five different methods: a) insertion of the N_3 group (substitution or addition), b) insertion of an N_2 group (diazo transfer), c) insertion of a nitrogen atom (diazotization), d) cleavage of triazines and analogous compounds, and e) rearrangement of azides. As the properties and the synthesis of aromatic and aliphatic azides vary considerably, the two classes of compounds will be discussed separately.[26]



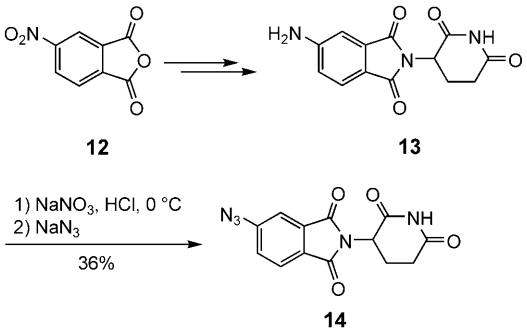
3.1. Aryl Azides

Because of their relatively high stability, aryl azides[27,28] have found biological and industrial use as photoaffinity labels,[29] as cross-linkers in photoresistors,[30] for conducting polymers,[31] and for light-induced activation of polymer surfaces[32] and are important intermediates in organic chemistry. Classic aromatic chemistry is usually the access of choice.

3.1.1. Aryl Azides from Diazonium Compounds

The older preparative methods for aryl azides are based on the reaction of diazonium salts with hydrazine[33] or *O*-benzylhydroxylamine hydrochloride.[34] The reaction of arene diazonium perbromides with ammonia also leads to aryl azides and is the oldest method for the preparation of azides.[2,34,35]

In the meantime, however, more convenient conversions of diazonium salts into aryl azides are known. Thus, aryl diazonium salts react directly with azide ions without catalysts directly to the corresponding aryl azides.[36] Alkali azides or trimethylsilyl azide act as source.[37] The latter compound is especially suitable because of its solubility in organic solvents (see Section 3.5.1). Unlike the Sandmeyer reaction, this reaction does not take place with cleavage of the C–heteroatom bond but occurs with attack of the azide on the diazonium ion with formation of aryl pentazoles and its subsequent products.[38] This reaction is sufficiently rapid even at low temperatures; *p*-chlorophenyldiazonium chloride reacts with azide ion even at −80 °C. The mechanism of this reaction (whether it occurs through a concerted [3+2] mechanism or takes place stepwise) and the nature of the intermediates have been the subject of controversial discussions since its discovery. There is a general consensus that the intermediate pentazenes and pentazoles lose dinitrogen. The corresponding azides are obtained at low reaction temperatures.[39] A pentazole structure was established for the first time by X-ray crystal-structure analysis in 1983.[40a] A British group investigated this reaction spectroscopically by ^{1}H and ^{15}N NMR spectroscopy (Scheme 1)[39] and established that



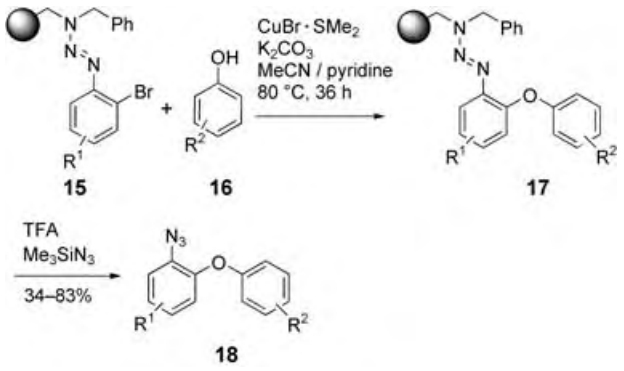
Scheme 1. Mechanism of the conversion of diazonium ions into azides.[39]

three isomeric aryl pentazenes **8**, namely the (*Z*,*E*), (*E*,*E*), and (*E*,*Z*) isomers, were formed by the attack of the azide ion at the β nitrogen atom of the diazonium ion **7**, as already postulated by Huisgen.[41] Whereas (*E*,*Z*)-**8** produces the 1-aryl pentazole **9**, (*Z*,*E*)-**8** forms the aryl azide directly by cleavage and does not rearrange to the *E* isomer. The *Z*,*E*-**8** isomer is considered to be the stereoelectronically favored product. This mechanism also explains the isotope labeling of the aryl azides found during the decomposition of labeled

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

diazonium ions.[39c] Besides the isolated diazonium salts, other precursors such as benzotriazinones[42] may be used for the synthesis of aryl azides according to this scheme.

A more recent example of the decomposition of diazonium salts into the corresponding aryl azides is illustrated by the synthesis of azidothalidomide (**14**; Scheme 2).[43] The

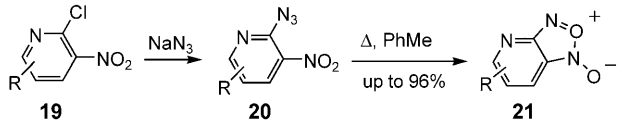


Scheme 2. Synthesis of azido-thalidomide (**14**).[43]

heterocycle was formed from nitrophthalic anhydride (**12**) by classic procedures, and the amino group in **13** was obtained by reduction. Diazotization and its subsequent reaction with sodium azide gave **14**. This compound is more active than thalidomide in the inhibition of the proliferation of human microvascular endothelial cells (HMEC) both in the presence and absence of vascular endothelial growth factors (VEGF). It was possible to demonstrate that the effect on endothelial cell growth by introduction of the azide group did not influence the affinity for the thalidomide-binding domains negatively.

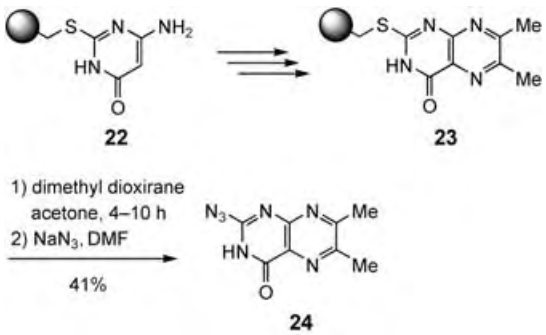
A combinatorial access to aryl azides **18** is provided by the cleavage of polymer-bound aryl triazenes **15**. These aryl triazenes can be modified on the polymer support in a number of different reactions, for example, the Ullmann–Nicolaou reaction (Scheme 3). The cleavage of the resulting aryl triazenes **17** to azides **18** is then carried out in good yields in the presence of trimethylsilyl azide.[44,45]

Although the conversion of diazonium salts into aryl azides represents one of the most important reactions of this class of compounds, the need to prepare the diazonium salts is



Scheme 3. Solid-phase synthesis of aryl azides **18** after a successful Ullmann–Nicolaou reaction.[44]

a severe limitation, so that in a few cases they may be synthesized only with difficulty if at all.

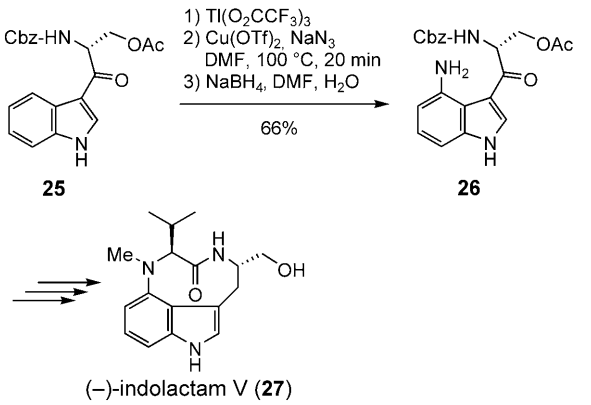


3.1.2. *Nucleophilic Aromatic Substitution: S_NAr Reactions*

Activated aromatic systems such as fluoro- and chloronitro arenes[46a] and a few heteroaromatic systems[46b] can undergo nucleophilic substitution by azide ions. They are generally sufficiently nucleophilic to produce aryl azides in good yields. The *ortho*-nitroazidoarenes formed react further at elevated temperatures with loss of nitrogen and formation of benzofurozane derivatives. Analogous reactivity is exhibited by the corresponding azidonitropyridine **20**, which may be prepared from chloronitropyridine **19** and sodium azide. (Scheme 4).[47]

Scheme 4. Aromatic substitution to give aryl azides.[47]

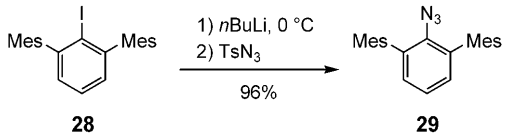
Heteroaryl sulfones are also cleaved regioselectively by azide ions. They can be used for the functionalizing cleavage of heteroaryl azides from polymeric supports, in which case the sulfur linker is first activated by oxidation to the sulfone with dimethyldioxirane (Scheme 5).[48]



Scheme 5. Functionalizing cleavage to give heteroaryl azides.[48]

If aromatic systems are provided with appropriate leaving groups, such as thallium substituents, the nucleophilic substitution can be carried out with electron-rich arenes. This aromatic substitution has been used in the total synthesis of indolactam V (**27**; Scheme 6),[49a] an indole alkaloid isolated from *Streptomyces blasmyceticum*. Alternatively, activated and deactivated aryl iodides can be converted into aryl azides under mild conditions with sodium azide in the presence of proline and copper(I) iodide.[49b]

3.1.3. *Aryl Azides from Organometallic Reagents*

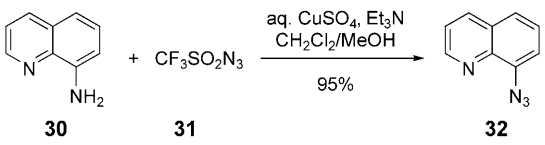


Over the last decades, numerous methods for the preparation of aryl azides with organometallic reagents have been developed. For example, tosyl azide reacts with Grignard or

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 6. Total synthesis of indolactam according to Kogan et al.[49a] Cbz = benzyloxycarbonyl; Tf = trifluoromethanesulfonyl.

lithium reagents—depending on the corresponding aryl halide—to form novel aryl azides (see also Section 3.5.2).[50] One example is the preparation of aryl azide **29** (Scheme 7).

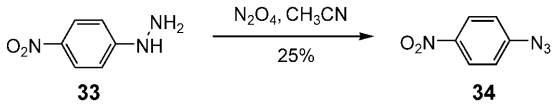


Scheme 7. Aryl azides according to Tilley and co-workers.[51] Mes = mesityl; Ts = *para*-toluenesulfonyl.

2,6-Dimesitylphenyl iodide (**28**) was initially treated with *n*-butyllithium at 0°C, and the resulting lithium salt reacted with *p*-toluenesulfonyl azide to form **29** in 96% yield.[51] Similarly, aryl amide salts (generated from the corresponding anilines and strong bases) react with tosyl azide to form the desired aryl azides.[52]

3.1.4. Aryl Azides by Diazo Transfer

In analogy to aliphatic amines (see Section 3.3.6), aryl azides and heteroaryl azides may be prepared by the reaction of anilines with triflyl azide (**31**).[53] The mild reaction conditions and very high yields make these transformations the method of choice for the preparation of numerous aromatic azides. In the typical reaction (Scheme 8) freshly prepared **31** is treated with 8-aminoquinoline (**30**) at room temperature in a mixture of dichloromethane and methanol in the presence of triethylamine and copper sulfate. The reaction produces 8-azidoquinoline (**32**) in almost quantitative yield.

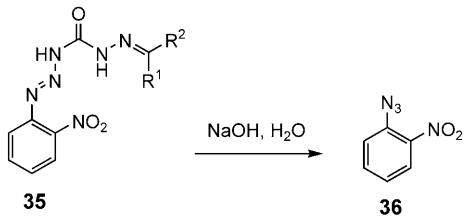


Scheme 8. Conversion of aromatic amines **30** into aryl azides **32** according to Tor and co-workers.[53]

3.1.5. Aryl Azides from Nitrosoarenes

The reaction of nitrosoarenes with hydrogen azide leads to aryl azides in good yields.[54] However, the diazonium ions must first be formed and then treated with azide ions as the second step: Thus, 2 equivalents of the explosive acid are required.

3.1.6. Diazotization of Hydrazines

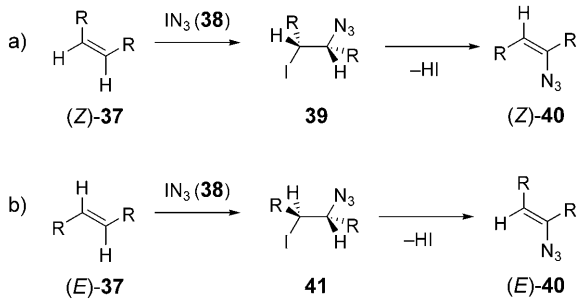


A well-established procedure that is equally suitable for the preparation of different classes of compounds such as aromatic and aliphatic azides, acyl azides, and sulfonyl azides is the reaction of hydrazines with nitrosyl ions or their precursors. N_2O_4,[55] mixtures of nitrogen oxide/oxygen,[56] nitrosyl salts,[57] and sodium nitrite[58] are particularly suitable (Scheme 9). The use of hydrazones[59] or 1-*tert*-butyl-1-aryl hydrazines,[60] which are cleaved under the reaction conditions used, is also a possibility.

Scheme 9. Conversion of the aromatic hydrazine **33** into aryl azide **34** according to Kim et al.[55,57]

3.1.7. Modification of Triazenes and Related Compounds

An older method for the preparation of azides is based on the rearrangement of triazenes into azides.[61] In particular, the base-induced cleavage of semicarbazones **35** can be used for the preparation of azides **36** (Scheme 10).[61a]



Scheme 10. Synthesis of the aryl azide **36** from the semicarbazone **35**.[61a]

3.2. Alkenyl Azides

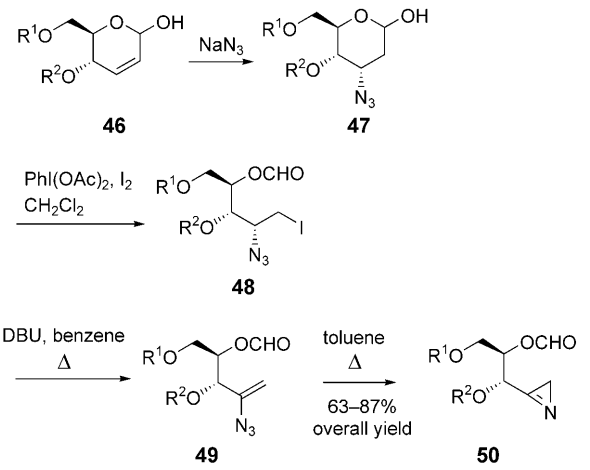
Alkenyl azides are important as precursors for alkenyl nitrenes[62,63] and hence for the rearrangement to 2*H*-azirines.[64] A general synthetic route for alkenyl azides was developed by Hassner and co-workers.[63] In this method, the addition of iodine azide (**38**) to the double bond and the subsequent elimination of hydrogen iodide (base induced) occurs with a high degree of stereospecificity. On the one hand, exclusively vinyl azides and no allyl azides are formed from the 2-azido-3-iodoalkanes **39** and **41** formed as intermediates (with the exception of cyclopentene and cyclo-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

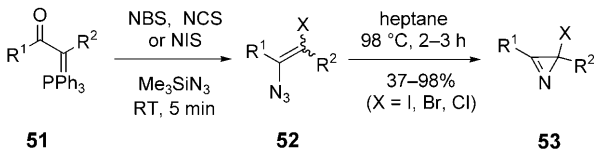
hexene adducts). On the other, the product configuration is determined by that of the starting material (Scheme 11).

Scheme 11. General synthesis of alkenyl azides **40** according to Hassner et al.[63]

An interesting access to 3-aryl-2-azidopropenoates is provided by the Knoevenagel reaction of aldehydes (e.g. **42**) and azidoacetate (e.g. **43**; Scheme 12, see also Scheme 77).[65] The subsequent thermolysis then gives the corresponding indoles or pyrroles. This reaction sequence was first described by Hemetsberger and co-workers.[66]



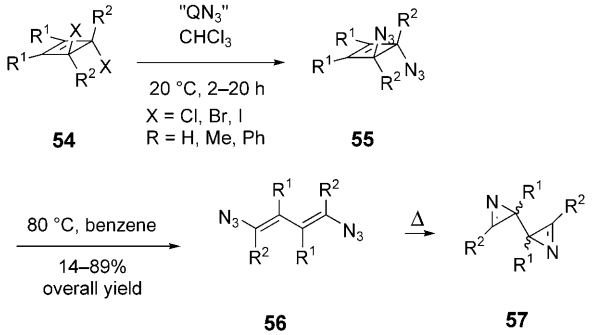
Scheme 12. Synthetic steps in the synthesis of the alkaloid varioline (**45**) and its analogues according to Molina et al.[65]



A new possibility for the synthesis of vinyl azides lies in the fragmentation of azide-substituted alkoxy radicals,[67] which are readily available from 3-azido-2,3-didesoxyhexopyranoses[68] **47** and consequently from glycals **46** and sodium azide. In the presence of an iodine source; the fragmentation initially results in vicinal iodoazides **48**, which then undergo elimination under mild conditions to the azidoalkenes **49**. This reaction sequence was used for the synthesis of 2*H*-azirines **50** (Scheme 13).

Alkenyl azides may also be prepared by conjugative addition of azide ions to activated alkynes or allenes.[69] A very convenient synthesis of 2-azidoacrylates is provided by the reaction of α,β-dibromopropanoic acid derivatives with sodium azide (see Scheme 64).[70,71]

Halogenated alkenyl azides can be formed from, among others, α-oxophosphonium ylides by reaction with *N*-halosuccinimides and trimethylsilyl azide. These haloalkenyl azides can be transformed into the corresponding 2-halo-2*H*-azirines **53** by heating to 98 °C (Scheme 14).[72]

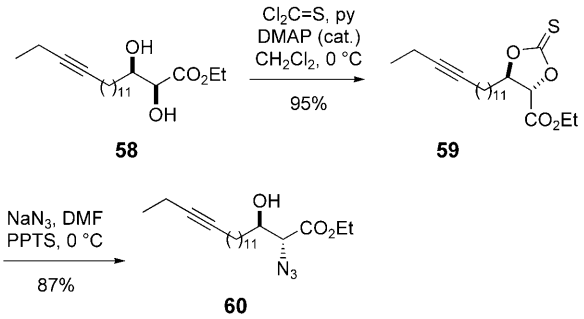


Scheme 13. Fragmentation of alkoxy radicals in the synthesis of alkenyl azides **49**.[67] DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene.

Scheme 14. Synthesis of 2-halo-2*H*-azirines **53** via haloalkenyl azides **52**.[72] NBS = *N*-bromosuccinimide, NCS = *N*-chlorosuccinimide, NIS = *N*-iodosuccinimide.

1,4-Diazido-1,§-dienes **56** serve as precursors for biazirinyls **57** (see Scheme 65). They may be prepared in acceptable yields only by conrotatory opening of *trans*-diazidocyclobutanes **55** (Scheme 15). The latter are accessible by reaction of the *trans*-dihalocyclobutanes **54** with tributylhexadecylphosphonium azide ("QN_3").[73]

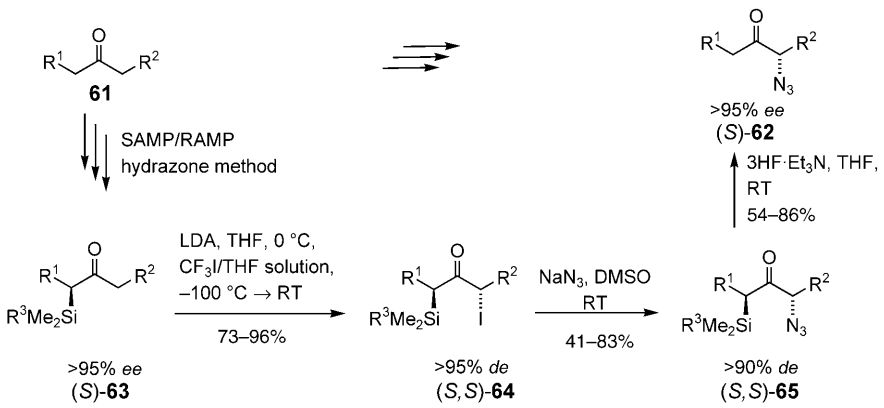
Scheme 15. Synthesis of 1,4-diazido-1,3-dienes **56** and biazirinyls **57**.[73]



3.3. Alkyl Azides

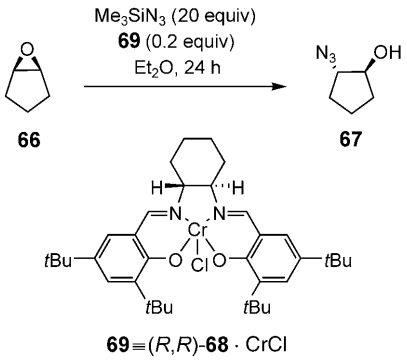
Alkyl azides were first discovered by Curtius and, after aryl azides, represent the second most important class of azide compounds. In most cases, classic nucleophilic substitution is the method of choice.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



3.3.1. Classic Nucleophilic Substitution

Aliphatic azides are compounds readily accessible by nucleophilic substitution (S_N2 type) with the highly nucleophilic azide ion. Sodium azide is most commonly used as the azide source, although other alkali azides, tetraalkylammonium azides, polymer-bound azides,[74] or (as in the classic variant) the highly explosive silver azide[3] are also used. In most cases halides,[75] carboxylates,[76] and (cyclic) sulfonates[77] as well as mesylates,[78] nosylates,[79a] and triflates[79b,80] are chosen as leaving groups,[81,82] although sulfonium salts are possible substrates.[83] Besides the classic variants with DMF as solvent under thermal conditions, ionic liquids,[84] supercritical carbon dioxide,[85] or microwave radiation[86] can be used. A regioselective azide substitution at the α position of α,β-dihydroxy ester **58** via a cyclic thiocarbonate intermediate **59** was described by Bittman and co-workers in 2000 (Scheme 16).[87]



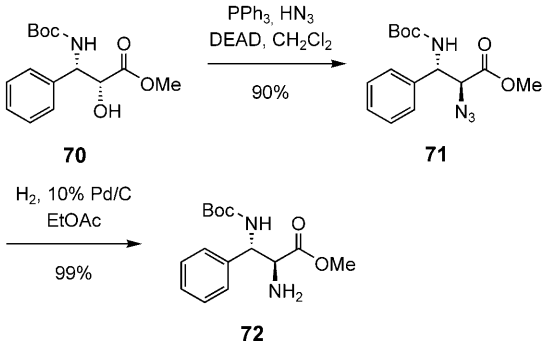
Scheme 16. Synthesis of α-azido-β-hydroxy ester **60** via a cyclic thiocarbonate intermediate **59**[87] DMAP = 4-dimethylaminopyridine, py = pyridine, PPTS = pyridinium *para*-toluenesulfonate.

The asymmetric synthesis of α-azidoketones **62** was described by Enders and Klein in 1999.[88] The key step in this reaction is a diastereoselective nucleophilic substitution of the iodine substituent in α-silylated-α′-iodoketones **64** with sodium azide. The necessary iodoketones **64** were prepared by the well-established SAMP technique. The α-azidoketones **62** are useful intermediates in the synthesis of protected and unprotected α-aminoketones (Scheme 17).

Scheme 17. Asymmetric synthesis of α-azidoketones **62** according to Enders et al.[88]

A further possibility for the synthesis of organic azides is the ring opening of epoxides by azide ions.[18] This useful reaction, which leads to α-azidoalcohols **67** and thus potentially to α-aminoalcohols and aziridines,[18] can also be carried out enantioselectively on the corresponding *meso*-epoxides **66** (Scheme 18).[89,90] A kinetic racemate separation is also possible.[91] Catalysts of choice are salen complexes **69** (salen = *N*,*N*′-bis(salicylidene)ethylenediamine, **68**)[92] with chromium as the central metal.[93] A monomeric salen structure is the reactive species with the participation of a bimetallic intermediate,[94] although macrocyclic and linear oligomer variants are significantly more active then their monomeric analogues.[95] The tolerance of biological systems towards azides also allows kinetic racemate separation of styrene epoxides with halohydrin dehalogenase from *Agrobacterium radiobacter*. The products (the *S* epoxide and the *R* azidoalcohol) were formed with excellent enantiomeric excesses.[96]

Scheme 18. Asymmetric synthesis of α-azidoalcohols **67** according to Jacobsen and co-workers.[89]



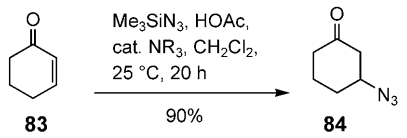
Sodium azide, either zeolite-bound[97a] or in the presence of molecular sieves,[97b] has also been used for the organic transformation of epoxides into organic azides. Glycidols, which can be readily obtained by the Sharpless epoxidation of allyl alcohols, can be opened regioselectively with titanium reagents such as $Ti(OiPr)_2(N_3)_2$.[98] In contrast, a reverse regioselectivity to Markovnikow products is achieved with aluminum reagents such as diethylaluminum azide.[99] The analogous ring opening of aziridines[100]—preferably in the presence of cerium[101] or copper[102] ions—leads to valuable 1,2-diaminoalkanes.[103–105]

S_N1 reactions are also frequently observed. Azide ions react especially readily with oxonium cations, such as are formed in the reaction of glycosyl cations. In this way thioacetals and other precursors can be transformed with azide ions in the presence of Lewis acids.[106] A stereoselective synthesis of anomeric organic azides involves the opening of oxazolines by trimethylsilyl azide and a fluoride source as described by DeShong and co-workers.[107a]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

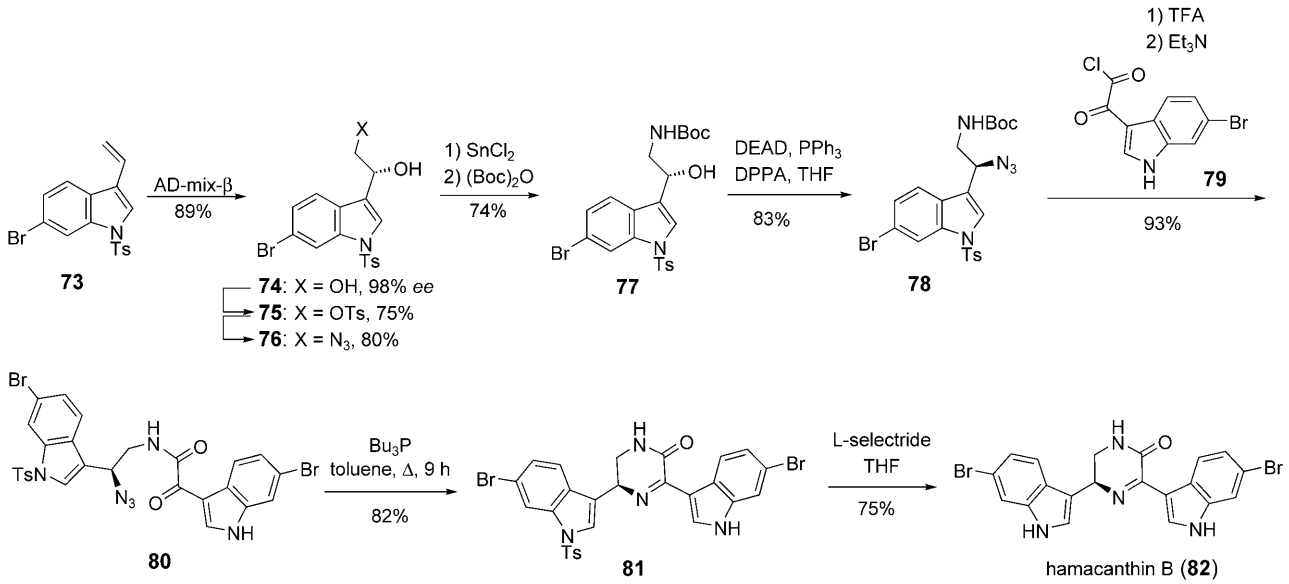
3.3.2. The Mitsunobu Reaction

A derivation of the Mitsunobu reaction published in 1967[108] provides a simple access to organic azides from alcohols.[109,110] Primary and secondary alcohols react with hydrogen azide, triphenylphosphane, and diethyl azodicarboxylate (DEAD). Secondary alcohols are of considerable interest as substrates because they react with inversion of stereochemistry. Lee et al. used this reaction as the key step in the synthesis of 2,3-diamino-3-phenylpropanoic acid derivatives **72** (Scheme 19), which are important structural elements of many biologically active compounds such as antibiotics.[111]



Scheme 19. Application of the Mitsunobu reaction to the asymmetric synthesis of 2,3-diamino-3-phenylpropanoic acid derivates.[111] Boc = *tert*-butoxycarbonyl.

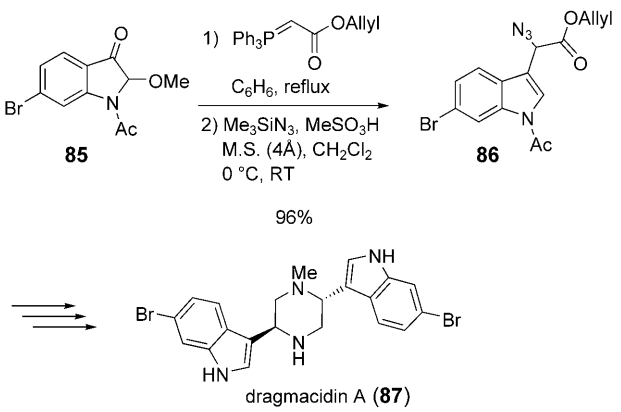
Diphenylphosphoryl azide (DPPA) in the liquid phase[112–115] or immobilized on polymeric supports (see Scheme 125)[116] can also be used successfully in place of the explosive hydrogen azide. In 2002, Jiang et al. published the enantioselective total synthesis of hamacanthine B (**82**) in which this variant of the Mitsunobu reaction was a key reaction (Scheme 20).[117] The central chiral pyrazinone ring was formed in a Staudinger/aza-Wittig sequence (Section 4.3.3). Another Mitsunobu azide source is zinc azide.[118]Alkyl azides can also be prepared by the reaction of alcohols with a reagent combination of tetrabromomethane, triphenylphosphane, and sodium azide—comparable with the classic Appel reaction—as shown in a formal synthesis of mappicin.[119] Homada and co-workers used the Mitsunobu reaction for the preparation of biologically active peptides.[120] The substitution of hydroxy groups under Mitsunobu conditions has been carried out in the solid phase with DPPA.[121,122] In Scheme 32 (Section 3.3.8), the key step of the preparation of a sarcodictyin library by Nicolaou and coworkers is illustrated as an example.[122]



3.3.3. Polar 1,2- and 1,4-Addition Reactions

α,β-Unsaturated carbonyl compounds react with azide ions in 1,4-additions—unlike organic azides, which form triazoles. One example of this valuable method for the synthesis of alkyl azides was described by Miller and coworkers in 1999 for 2-cyclohexenone (**83**).[123,124] The source for the azide ion in this Michael-like reaction is an equimolecular mixture of trimethylsilyl azide and acetic acid, while tertiary amines as Lewis bases catalyze the reaction (Scheme 21). Other suitable Michael acceptors are glycals

Scheme 21. Conjugate addition of azide ions to cyclohexenone **83**.[123]



(Scheme 13) or quinones.[125] However, in the presence of Lewis acids (aluminum), azide ions react differently with α,β-unsaturated ketones: triazoles are formed after a hydride

Scheme 20. Enantioselective synthesis of the marine indole alkaloid hamacanthin B (**82**).[117] L-Selectride = lithium tri(*sec*-butyl)borohydride.

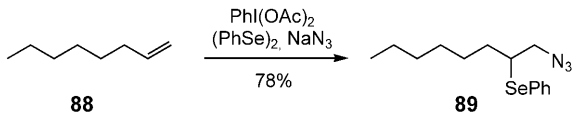
shift.[126] Kawasaki et al. used the 1,4-addition of azides to an indolenium intermediate as key step in the total synthesis of dragmacidin A (**87**; Scheme 22).[127]

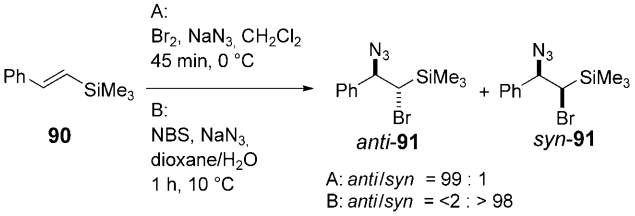


Scheme 22. Synthesis of dragmacidin A according to Kawasaki and co-workers.[127]

3.3.4. 1,2-Addition to Non-Activated Double Bonds

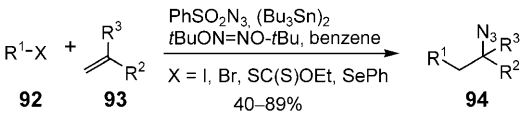
The addition of halogen azides to olefins was first described by Hassner and Levy in 1965.[63] This reaction eventually permitted wide access to vinyl azides (see Section 3.2).

In recent years, single- and multistep radical syntheses have become increasingly important.[128] 1,2-Addition to non-activated double bonds with azide sources can involve a radical reaction since the azidyl radical behaves as a pseudohalogen radical. The reaction of olefins with diphenyldiselenium, diacetoxyiodobenzene, and sodium azide is a radical azidoselenation (Scheme 23).[129,130b] The unusual



Scheme 23. Radical 1,2-addition to non-activated double bonds.[130b]

regiochemistry—the azide group is inserted at the least-substituted position—is an indication of the radical nature of this reaction. Recently Klapötke and co-workers isolated a stabilized aryl selenium azide,[131] a member of the class of selenium azides whose existence had been postulated in a number of reactions.[132] The radical azidoselenation has found interesting applications in sugar chemistry.[133]

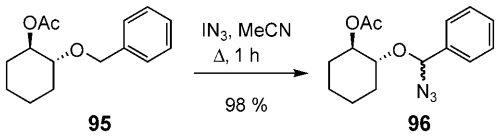


In contrast, the addition of bromoazide to alkenes by pre-electrophiles (Br_2, NBS) and azide ions is mostly polar in nature. The choice of the pre-electrophile and the substrate allows control of the stereochemistry, as shown in Scheme 24 (see also Scheme 11).[134,135]

In 2001, Renaud and co-workers described an efficient carbon–nitrogen bond formation in the reaction of radicals with sulfonyl azides.[136] In 2002, they extended this to the intermolecular addition of radicals to non-activated alkenes

Scheme 24. Polar 1,2-addition to non-activated double bonds.[134,135]

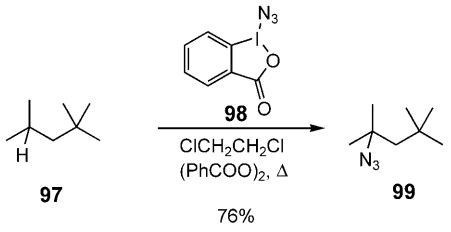
with subsequent azidation. This reaction sequence formally represents a carboazidation of alkenes and is a key step in the three-component syntheses of pyrrolidone, pyrrolizidinone, and indolizinone derivatives.[137] One example is the reaction of the terminal alkenes **93** with different radical precursors (Scheme 25).



Scheme 25. Radical azide insertion according to Renaud et al.[137]

Kirschning and co-workers elegantly showed that iodoazide can be used as a polymer-bound reagent and in this way were able to convert a series of alkenes into vicinal iodoazides.[138–140] Furthermore, alkenes can be converted into β-azido alkyl mercury compounds by hydrogen azide in the presence of azide ions.[141a] Glycals can be converted into 2-desoxyglycosyl azides by the action of trimethylsilyl azide in the presence of catalytic amounts of trimethylsilyl nitrate.[141b]

3.3.5. C–H Activation



The activation of C–H bonds can also be carried out with azides. The radical azidation in the benzyl position of benzyl ethers **95** with iodoazide[25] was recently described by Viuf and Bols.[142] This reaction takes place in very good yields (74–98%) and relatively short reaction times with a number of substrates (Scheme 26). Related to this reaction is the open-

Scheme 26. Radical azidation of the benzyl position with iodoazide.[142]

ing of benzal acetals with the formation of β-azidobenzoates (azido-Hanessian reaction).[143] A domino radical iodoazide cyclization strategy was used as a key step in the formal total synthesis of (±)-aspidospermidine.[144] Hydrocarbons can also undergo radical azidation at high temperatures with the somewhat more stable hypervalent iodo reagent **98** (Scheme 27).[145]

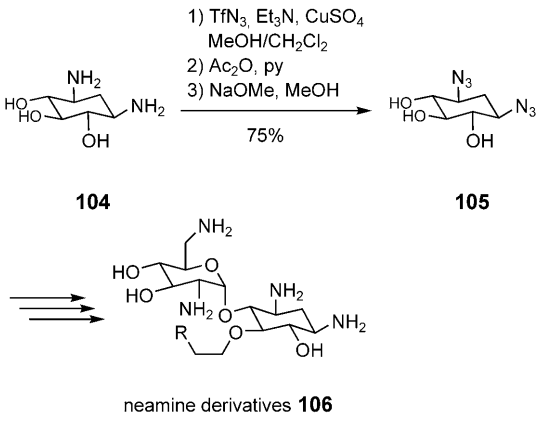
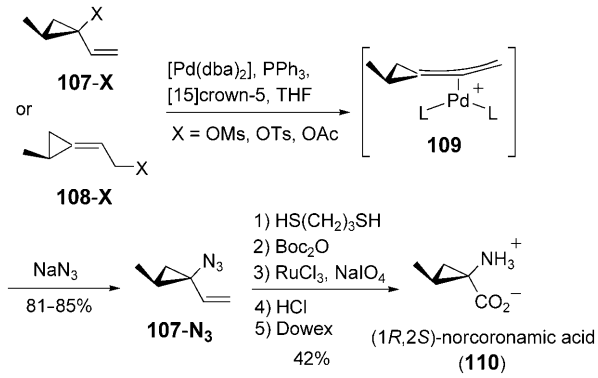


Scheme 27. Activation of the C–H bond by azidoiodinane **98** according to Zhdankin et al.[145]

3.3.6. *Diazo Transfer: A Simple Synthesis of Alkyl Azides from Amines*

Primary aliphatic amines may be converted into the corresponding azides by diazo transfer. In this way, the step involving sensitive aliphatic diazonium ions can be circumvented.[146,147] The reagent of choice for this transformation is triflyl azide (**31**), which can be prepared from trifluoromethanesulfonic anhydride and sodium azide. Aliphatic primary amines **100** give the azides **101** in the presence of a copper catalyst in exceptionally good yields.[148–150] The azides can then be converted, for example, into 1,2,3-triazoles **103** with different alkynes (Scheme 28; see Section 4.1.1). These methods were also used in the syntheses of aminoglycosides, an important group of antibiotics.[151,152] The synthesis of neamine derivatives **106** by Wong and co-workers is shown here as an example (Scheme 29).[152]

Scheme 28. Diazo transfer to primary amines and subsequent triazole synthesis according to Ghadiri and co-workers.[150] Fmoc = fluorenylmethoxycarbonyl.

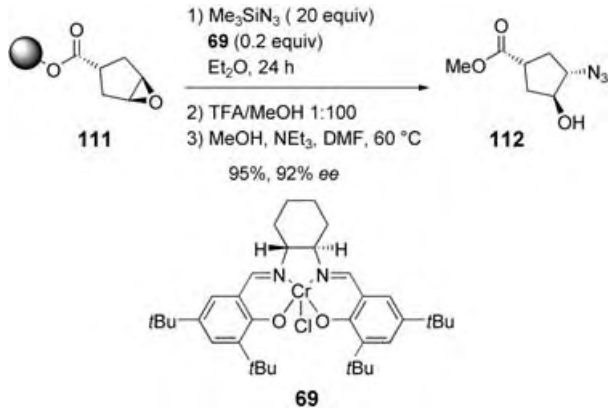


neamine derivates **106**

Scheme 29. Synthesis of neamine derivates **106** according to Wong and co-workers.[152]

3.3.7. *Azide Addition to Palladium Complexes: Synthesis of Allyl Azides*

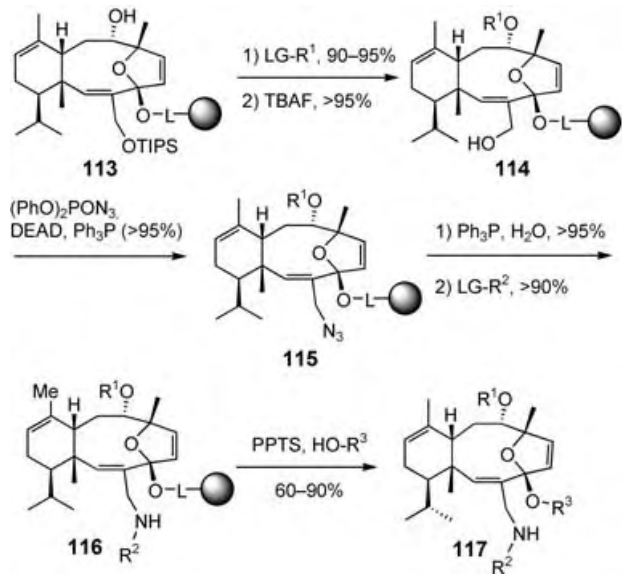
The addition of azide ions to 1,1-substituted π-allylpalladium complexes has been used by de Meijere, Salaün, and coworkers in the synthesis of aminocyclopropanoic acids. π-Allyl palladium compounds are formed from allyl acetates **107**-OAc, **108**-OAc, or similar compounds in the presence of palladium(0) complexes and are then treated with sodium azide.[153–155] Whereas normally the addition of nucleophiles occurs at the unsubstituted end with formation of the thermodynamically less stable methylenecyclopropanes, in the case of 1,1-ethanoallylpalladium complexes **109**, azide ions give the corresponding alkenylcyclopropanes. A subsequent [3,3] rearrangement may also have occurred (Section 4.8) after the initial formation of methylenecyclopropane derivatives. The azidocyclopropane **107**-N_3 formed stereoselectively could then be transformed into (−)-(1*R*,2*S*)-norcoronamic acid (**110**) in a sequence comprising a reduction (Section 4.4.2) and an oxidative cleavage of the double bond (Scheme 30).[156] 1-Aminocyclopropanecarboxylic acid was also prepared in this way.[157] Structurally demanding π-allyl palladium complexes, which are formed according to Grigg and co-workers [158] in a cascade cyclization or by arylation of allenes,[159] could also be converted regioselectively into the corresponding allyl azides. A special feature is the fact that π-allyl complexes can also be transformed into enantiomerically pure allyl azides by the action of chiral ligands.



Scheme 30. Synthesis of (−)-(1*R*,2*S*)-norcoronamic acid (**110**) according to de Meijere, Salaün, and co-workers.[156] dba = Dibenzylideneacetone.

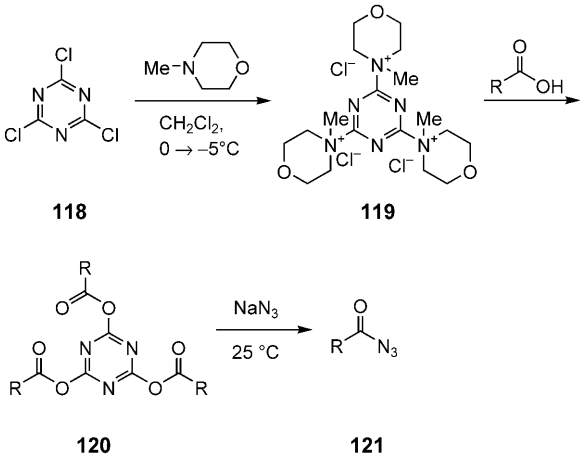
According to Yamamoto and co-workers π-allyl palladium complexes also play a role in the reaction of allyl carbonates, trimethylsilyl azide, and alkynyl aryl isocyanides to give indoles.[160] Allyl azides that bear a leaving group such as nitrite in the 1-position can readily fragment with the loss of this leaving group to form α,β-unsaturated nitriles.[161]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



3.3.8. Solid-Phase Synthesis of Aliphatic Azides

Aliphatic azides have already been frequently synthesized on solid supports. In each case a start was made from a polymer-bound electrophile, which reacted with the corresponding azide-transfer reagent. The substitution of alkyl halides and alkyl alcohols was carried out with sodium azide[162,163] or tetra-*N*-butylammonium azide.[164] The ring opening of epoxides was carried out with sodium azide.[165,166] Jacobsen and co-workers used trimethylsilyl azide for the asymmetric ring opening of *meso*-epoxides in the solid-phase synthesis of cyclic azidoalcohols (Scheme 31).[167]

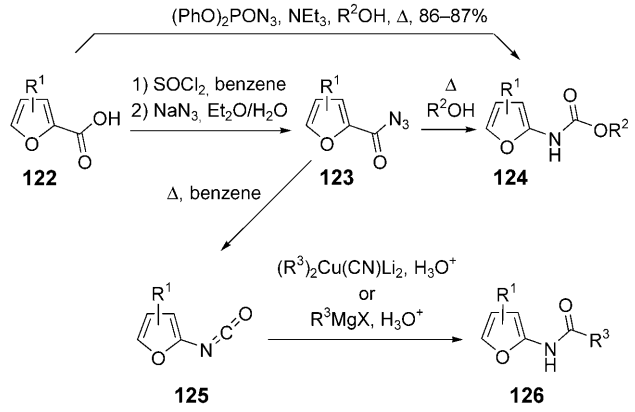


Scheme 31. Asymmetric epoxide opening on solid supports.[167] TFA = trifluoroacetic acid.

The substitution of hydroxy groups on solid-supports can be carried out under Mitsunobu conditions with DPPA[121,122,168] or under classic conditions.[169] In 1998, Nicolaou and co-workers reported the solid-phase synthesis of a sarcodictyin library with three points of diversity (Scheme 32) in which the Mitsunobu reaction played an important role.[122]

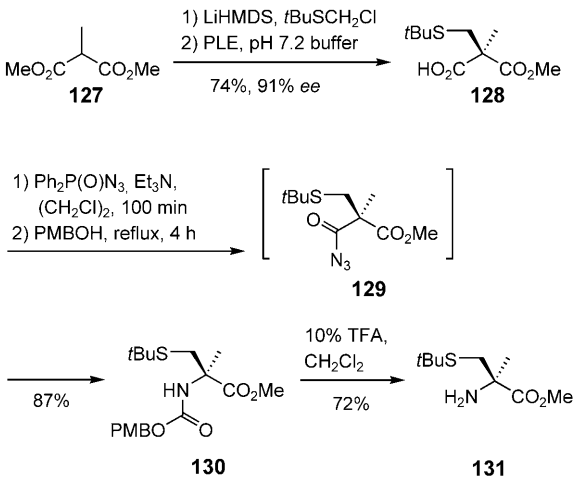
Scheme 32. Solid-phase synthesis of sarcodictyin analogues by Nicolaou and co-workers.[122] L = linker, TIPS = triisopropylsilyl, LG = leaving group, TBAF = tetrabutylammonium fluoride.

Scheme 33. Synthesis of acyl azides **121** from cyanurtrichloride **118**.[171]



3.4. Acyl Azides

Acyl azides are widespread, highly reactive reagents in organic chemistry and are used for the preparation of amides and heterocycles. Acyl azides are normally prepared from acid derivatives such as acyl chlorides or mixed anhydrides[170] with azide ions or by reaction of acyl hydrazines with nitrosyl precursors. A very mild and efficient method for the preparation of acyl azides without subsequent Curtius rearrangement (see Section 4.5.1), which would lead to the isocyanate, was described by Banddgar and Pandit in 2002 (Scheme 33).[171] In this case, different aryl, heteroaryl, alkyl aryl, and alkyl carboxylic acids are converted into the respective acyl azides **121** under mild conditions with cyanurtrichloride (**118**) in the presence of sodium azide and *N*-methylmorpholine.



Padwa et al. used the synthesis of acyl azides **123** in the preparation of substituted furans.[172] The free acids **122** are first converted into the corresponding acid chloride with thionyl chloride and then into the corresponding acyl azide **123** with sodium azide. Formation of the isocyanates **125** under Curtius conditions and subsequent reaction leads to amidofurans **126**. If the acyl azides **123** are heated in the presence of alcohols, furanamino carboxylates **124** are formed. The latter can also be prepared directly from the carboxylic acids by reaction with DPPA and alcohols in the presence of triethylamine (Scheme 34). The reaction of carboxylic acids with DPPA and subsequent Curtius rearrangement can also be used for the conversion of malonic ester derivatives **127** into α-amino acid esters **131**. In particular, the enantioselective, enzymatic desymmetrization with pig liver esterases (PLE) leads to the enantiomerically pure amino acids (Scheme 35).[173]

Enamides were prepared by Kitahara and co-workers by rearrangement of α,β-unsaturated acyl azides to alkenyl isocyanates **133** and subsequent addition of nucleo-

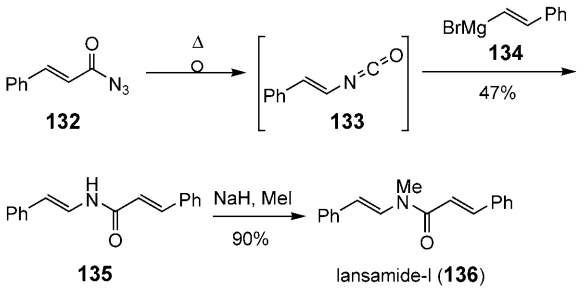
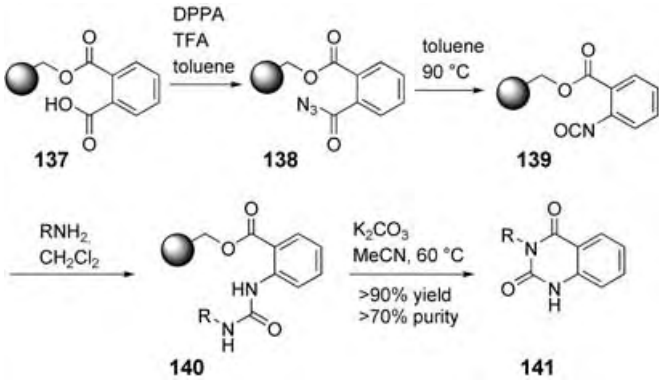


Scheme 34. Derivatization of furoic acids **122** according to Padwa et al.[172]

Scheme 35. Asymmetric conversion of the dimethyl malonate derivate **127** into α-amino acid ester **131**.[173] LiHMDS = lithium hexamethyldisilazide; PMB = *para*-methoxybenzyl.

philes.[174,175] The reaction sequence was used for the preparation of a series of natural products such as the lansiumamides A–C and lansamide-I (**136**; Scheme 36),[176] coscinamide, chondriamide, igziamide,[174] salicylihalamide,[177] apicularen A,[178] and others.[179]



The synthesis of (poly)peptides can also be carried out with the highly reactive acyl azides[180] that are formed

Scheme 36. Total synthesis of lansamide-I (**136**) according to Taylor and co-workers.[176]

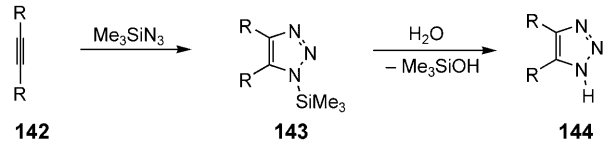
directly, for example, from DPPA and carboxylic acids. The azide unit with its ability to activate the acid group can then be replaced by nucleophiles—as already found by Curtius. Lucente and co-workers used the synthesis of acyl azides for the preparation of ergopeptides,[181] while Larsen and co-workers prepared β-1,3-glycosidically bound aminomonocarbodisaccharides.[182]

One application was described by Castelhano and co-workers in 1998 with the solid-phase synthesis of quinazoline-2,4-diones **141**.[183] Phthalic acid was first immobilized on a PEG4-PS resin and then converted into the acyl azide with DPPA in the presence of trifluoroacetic acid in toluene. Rearrangement to the isocyanate followed by reaction with a primary amine and subsequent base-catalyzed cleavage with ring closure gave the heterocycles in good yields with excellent purity (Scheme 37).

Scheme 37. Solid-phase synthesis of quinazoline-2,4-diones **141** with the generation of an acyl azide synthesis as a key step.[183]

A new variant for the preparation of acyl azides was described by Bols and co-workers. Aldehydes react with iodoazide[25] at room temperature, presumably in a radical mechanism.[184] If this reaction is carried out at elevated temperatures the acyl azides rearrange and the resulting isocyanates are captured with the formation of carbamoyl azides. Unlike acyl azides, *C*-azidoimines rearrange to tetrazoles (Scheme 145).

3.5. Heteroazides and Azide Reagents



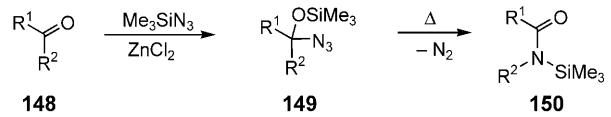
Besides organoazides, in which the azide function is connected directly to the carbon atom, different heteroazides are of importance in organic synthesis and are briefly mentioned here.

3.5.1. Silyl azides

Silyl azides are valuable reagents in organic synthesis,[185,186] because, unlike sodium azide and hydrogen azide, they have no immediate explosive properties.[187] However, they hydrolyze in the long term to the volatile, toxic, and explosive hydrogen azide and therefore must be stored in the absence of moisture and acids. Trimethylsilyl azide (bp.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

95 °C), which is also commercially available, can be prepared by photolysis of tetrakis(trimethylsilyl)-2-tetrazene[188] or by reaction of tris(trimethylsilyl)phosphate with sodium azide.[189] Most conveniently, however, it is formed from trimethylsilyl chloride by reaction with sodium azide in diglyme.[190] The higher thermal stability of trimethylsilyl azide relative to hydrazoic acid[191] can be used in the preparation of 1,2,3-triazoles from trimethylsilyl azide and acetylenes (Scheme 38).[192]

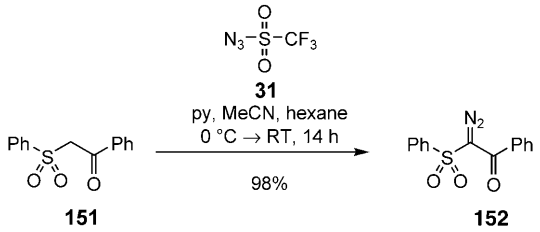


Scheme 38. Cycloadditions with trimethylsilyl azide.[192]

The facile cleavage of the Si–N bond governed the success of the synthesis of trialkyl- and triarylphosphinimines **147** from the corresponding phosphines **145** and trimethylsilyl azide (Scheme 39).[193] This reaction is significantly simpler than the reaction of phosphines with chloramine.[194]

Scheme 39. Synthesis of triaryl phosphinimines.[194]

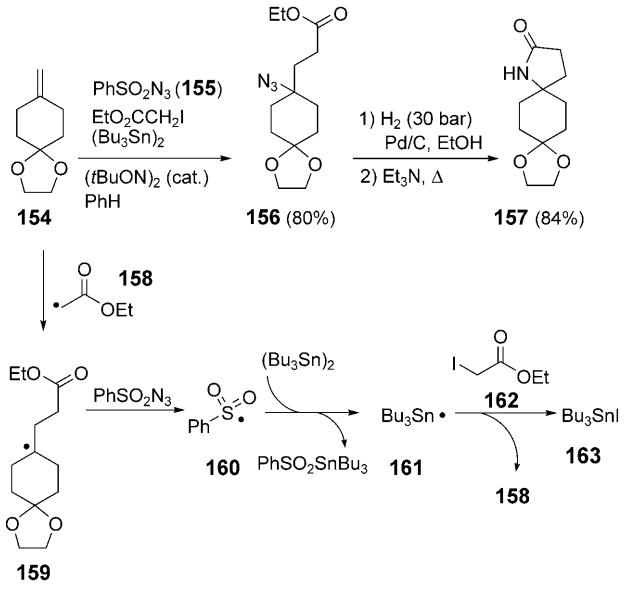
Trimethylsilyl azide reacts with aldehydes or ketones **148** and their enol ethers with the formation of trimethylsilyloxy azides **149**, which can be transformed thermally[195a] or photochemically[195b] in a Schmidt rearrangement into *N*-trimethylsilyl amides **150** (Scheme 40) or the respective protiodesilylated amides. This reaction sequence is superior to the Schmidt reaction at least for a few derivatives because of the higher yields.[195b]



Scheme 40. Conversion of ketones into *N*-trimethylsilylamides.[195]

It was reported recently that trimethylsilyl azide can be immobilized in the solid phase as a reagent.[196]

3.5.2. *Sulfonyl Azides*



Sulfonyl azides[197] can be prepared from the corresponding sulfonyl chlorides by reaction with sodium azide in acetone.[198] These useful but sensitive[199] reagents are also available as shock-resistant solid-phase variants.[200]

The sulfonyl azides are used for diazo transfer[201] to CH-acid compounds, especially activated esters, β-ketoesters, and ketosulfones.[198,202] The enolate or enol attacks the organoazide with formation of a triazene, which after tautomerization reacts to form the diazo compound and the sulfonamide. Trifluoromethanesulfonyl azide (triflyl azide, **31**) was proposed by Charette and co-workers as a highly electrophilic diazo-transfer reagent that gives good results with activated acetic acid esters and ketones, particularly with pyridine as base (Scheme 41).[203,204]

Scheme 41. Diazo transfer with sulfonyl azide **153**.[203]

An interesting application of *p*-toluenesulfonyl azide (tosyl azide, **153**) is the proline-mediated enantioselective α-amination of aldehydes (see Scheme 46).[226] Recently sulfonyl azides, including pyridine-3-sulfonyl azide,[205] were successfully used in the azidation of nucleophilic radicals.[206] This reaction can also be used for intra- or intermolecular carboazidation of olefins. Renaud and co-workers demonstrated the use of this method in the synthesis of the spirolactam **157** (Scheme 42). The radical **158**, produced from ethyl iodoacetate, reacts with the olefin **154**, and the newly generated (nucleophilic) tertiary radical **159** extracts the azide group from phenylsulfonyl azide (**155**). The electrophilic radical **158** is, in contrast, unable to react with the sulfonyl azide. Tin-free methods are being intensively investigated, and triethyl borane appears to be a useful alternative.[207]

Scheme 42. Synthesis of spirolactam **157** by radical-induced carboazidation of olefins according to Renaud et al.[206]

Furthermore, sulfonyl azides (especially triisopropylbenzenesulfonyl azide)[208] have been used in the electrophilic (diastereoselective) α azidation[208b] of the harder amide enolates of the Evans type[208] and ester enolates (Scheme 146)[134] for the synthesis of α-amino acid derivatives (Section 3.1.3, Scheme 7, Section 3.3.4, Scheme 25, Section 3.3.6).

Other important azides are iodoazide,[25,63,138–140,209] phosphoryl azides such as DPPA,[210] tributylhexadecylphosphonium azide ("QN_3"),[211] and *tert*-butoxycarbonyl azide (Boc azide), a transfer reagent for the *tert*-butoxycarbonyl group onto amines. The Zhdankin reagent (a stable azidoiodinone) was used for the direct azidation of hydrocarbons (see Scheme 27).[145] An important reagent is tetramethylguanidinium azide introduced by Papa[212] which has been used for the synthesis of vinyl azides,[69] among others (Section 3.2) and is advantageous for safety reasons.[213]

4. Reactions of Organic Azides

Azides can react very differently under different reaction conditions. In principle, they react with electron-deficient compounds (electrophiles) at N^1 (Section 4.6; Figure 2) and

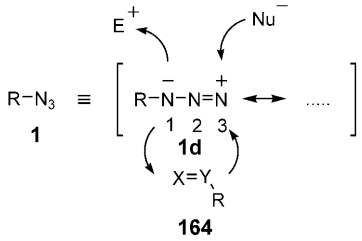

Figure 2. Reactivity of organic azides.[1]

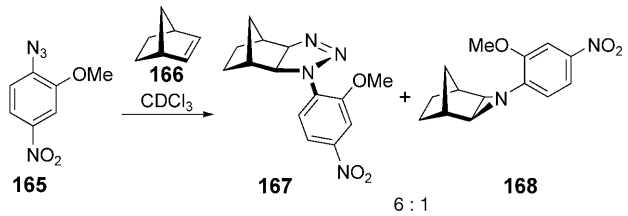
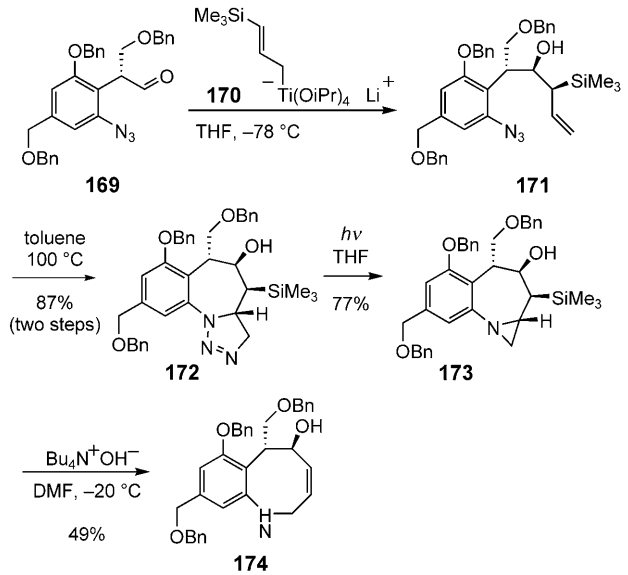
electron-rich compounds (nucleophiles) at N^3 (Sections 4.3 and 4.4; Figure 2). There can be retention of the azide unit, but also cleavage of the nitrogen–nitrogen single bond, as in the case of nitrene chemistry. The simplest case mechanistically—an addition—has been used extensively in cycloaddition reactions.



4.1. "Clicked": Cycloadditions Newly Discovered

The Huisgen reaction[214]—the cycloaddition of dipoles to dipolarophiles—also succeeds with azides as dipoles,[215] and selected dipolarophiles can be used.

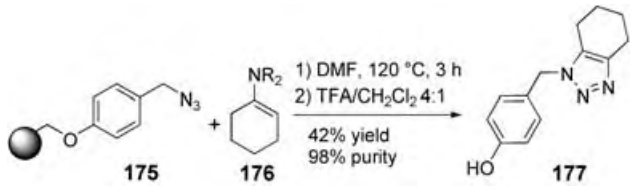
4.1.1. 1H-Trazoles and Δ^2-1,2,3-Triazolines Made Simple



The uncatalyzed thermal cycloaddition of organic azides to alkynes and olefins allows the synthesis of 1*H*-triazoles and Δ^2-1,2,3-triazolines.[74,216,217] The addition takes place at different rates depending on the dipolarophile. Whereas strained olefins or alkynes such as norbornene and cyclooctyne[218] react readily, terminal alkenes react extremely slowly.[217b] In principle, suitable dipolarophiles include both electron-deficient and electron-rich alkenes (enol ethers such as glycans,[216f] enamines,[219a,b]; see Scheme 45) as well as magnesium acetylides.[216e] Many olefins are so unreactive, however, that intramolecular reaction control or the use of microwaves is necessary.[220]

The reaction of organoazides with alkenes is illustrated with a number of examples.[221,222] The aryl azide **165**, prepared as part of a combinatorial approach, reacted with norbornene **166** at 40 °C within 18 h and a conversion of ≈75 % with the formation of the Δ^2-1,2,3-triazoline **167** and the aziridine derivative **168** in a ratio of 6:1.[45] This ratio is temperature-dependent as the primarily formed Δ^2-1,2,3-triazoline **167** can react further to furnish the aziridine derivative **168** (Scheme 43).

Scheme 43. Cycloaddition of aryl azide **165** to norbornene.[45]

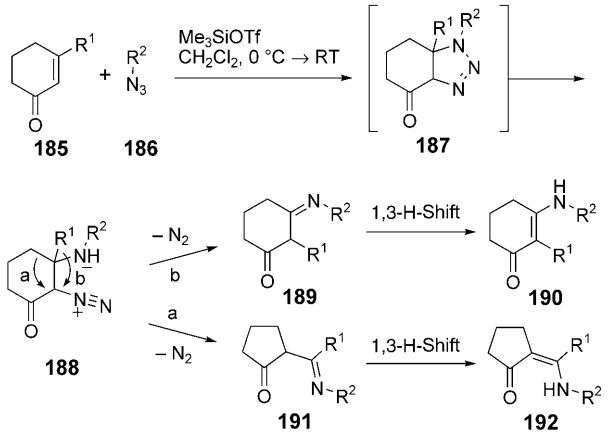


Ciufolini and co-workers demonstrated the use of intramolecular cycloadditions in their total synthesis of FR66979. After a selective Cram allylmetal addition of the titanium allyl compound **170** to an aldehyde **169** with an azide moiety through a Zimmerman–Traxler transition state, diastereoselective 1,3-dipolar cycloaddition gave the tricycle **172**. After photochemical nitrogen extrusion from the Δ^2-1,2,3-triazoline **172** and ring contraction to the aziridine **173**, an anionically induced azacyclopropylmethyl-azahomoallyl rearrangement took place (Scheme 44).[223]

Scheme 44. Part of the total synthesis of FR66979 according to Ciufolini and co-workers.[223] Bn = benzyl.

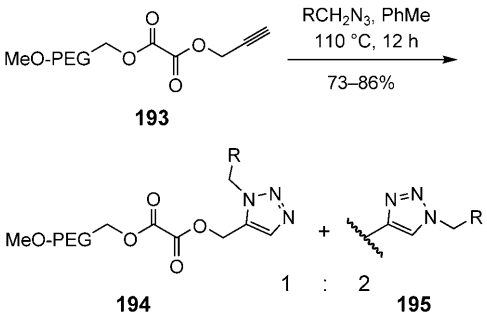
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

If the alkene bears a suitable leaving group, the initially formed Δ^2-1,2,3-trazoline aromatizes to the 1*H*-triazole.[224] In the case of enamines **176**, cycloaddition with organoazides **175** is usually followed by elimination of the amine group so that 1,2,3-triazoles **177** are formed (Scheme 45).[219] In a few cases, these and the analogous enol ether adducts rearrange to form β-lactams.[225]



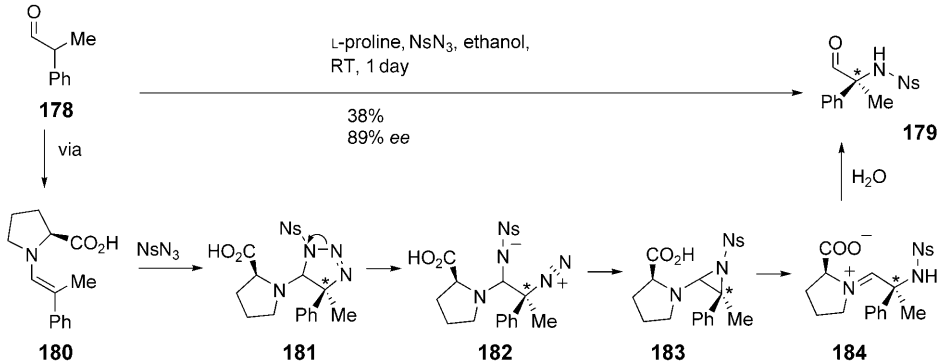
Scheme 45. Synthesis of 1,2,3-triazoles on a polymer support according to Harju et al.[219]

The enamine **180**, which is formed in a proline-mediated enantioselective α sulfamidation of 2-phenylpropanal (**178**), reacts with nosyl azide in moderate yield via the triazoline **181** to give *N*-nosyl-2-amino-2-phenylpropanal (**179**) with 89% *ee* (Scheme 46).[226] Compound **182** and the aziridine **183** are presumed to be intermediates; the latter undergoes ring opening to **184** by participation of the proline nitrogen atom to form **179** after hydrolysis.



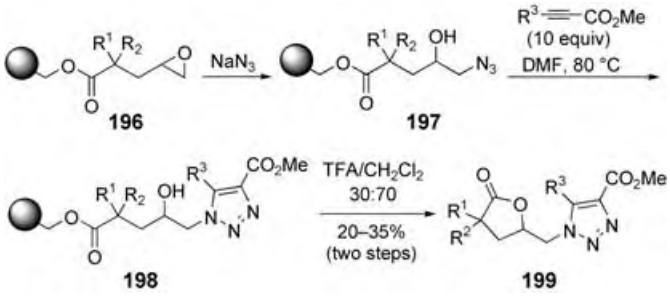
The assumed reaction mechanism is supported by work from Benati et al.[227] and Zhu et al.[228]

A series of α,β-unsaturated ketones **185** react with alkyl azides **186** under Lewis acid catalysis in a similar mechanism, as determined by Aubé and co-workers (Scheme 47).[229] Unlike the known rearrangements of this type,[230] the Lewis acid catalyzed variant takes place at low temperatures. The Δ^2-1,2,3-triazolines **187** are indeed first formed. However, they are not stable under the prevailing reaction conditions. It is a case of nonstabilized triazenes.[231] In the presence of Lewis acids, they open to amidodiazonium betaines **188**, which according to the structure of the addition product either rearrange with migration of the substituents (path b) or ring contraction occurs (path a). Endo- or exocyclic enaminones **190**/**192** are formed. Cyclohexenones usually form the (*Z*)-configured ring contraction product **192**. Cyclopentenones, in contrast, usually give aminocyclopentenones. Aziridines can also be formed.



Scheme 47. Cycloaddition of alkyl azides to α,β-unsaturated ketones according to Aubé et al.[229]

Related to this reaction are the additions of arynes to azides, which lead to benzotriazoles, as Huisgen and co-workers were able to show quite early.[215,232,233] Trimethylsilylacetylene[234] and a number of strained or electronically activated alkynes react with organoazides at room temperature or below, whereas with many other alkynes the reaction must be carried out at elevated temperatures in the absence of catalysts. The cycloaddition of immobilized alkynes with organic azides has also been carried out on soluble polymers[235] (Scheme 48) and on polystyrene resins.[236,237] Furthermore, other solid-phase variants of this reaction with immobilized azide have been used for the preparation of

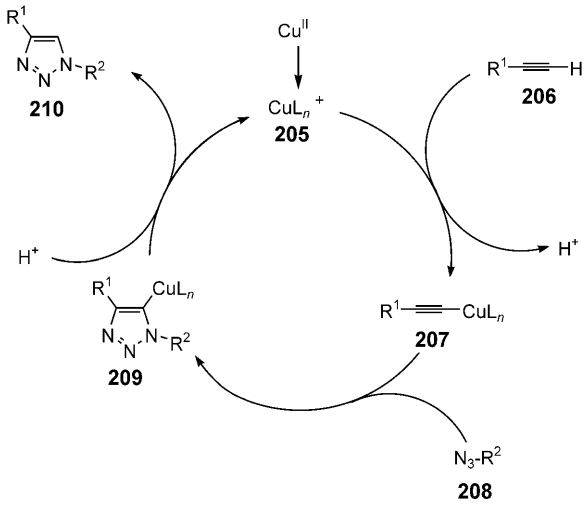


Scheme 48. Synthesis of 1,2,3-triazoles on a soluble polymer according to Norris et al.[235]

Scheme 46. Enantioselective α sulfamidation of 2-phenylpropanal (**178**) with tosyl azide.[226]

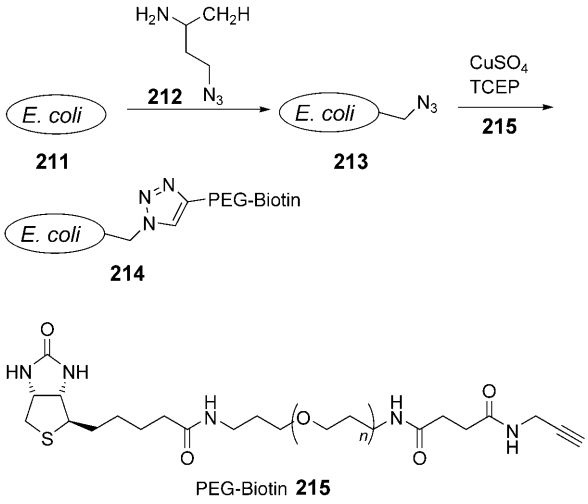
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

substituted 1,2,3-triazoles.[237,238] In the example shown in Scheme 49, the final product **199** is obtained by subsequent cleavage and cyclization.



Scheme 49. Synthesis of 1,2,3-triazoles **199** on a polystyrene support according to David and co-workers.[237]

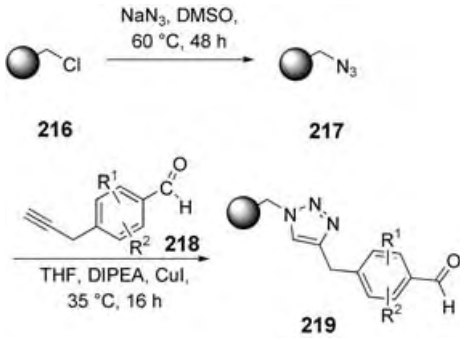
The intramolecular 1,3-dipolar cycloaddition[239] of cinchona azides to a C10–C11 alkyne and a C10–C11 alkene was demonstrated recently by Hoffmann and co-workers (Scheme 50).[240] Thus, *O*-mesylcinchonidine **200** and NaN_3 reacted to form the triazole **201** and the ring-expanded derivative **202**. Both triazoles **201** and **202** were formed with retention of configuration at C9 and C3. The 1-azabicyclo[3.2.2] rearrangement is clearly reversible.



Scheme 50. Substitution, rearrangement, and cycloadditions to cinchona alkaloids according to Hoffmann and co-workers.[240] Ms = methanesulfonyl.

A breakthrough in triazole chemistry occurred with the independent observations by the groups of Meldal[241] and Sharpless[242] that the reaction of aliphatic azides **208** with terminal alkynes **206** is accelerated by copper ions, and their regioselectivity is improved (Scheme 51).[243–247] These reactions have been used frequently in recent years[248] and are also considered as a contribution to "click chemistry"[249]

Scheme 51. Possible catalytic cycle for the copper-catalyzed triazole synthesis.

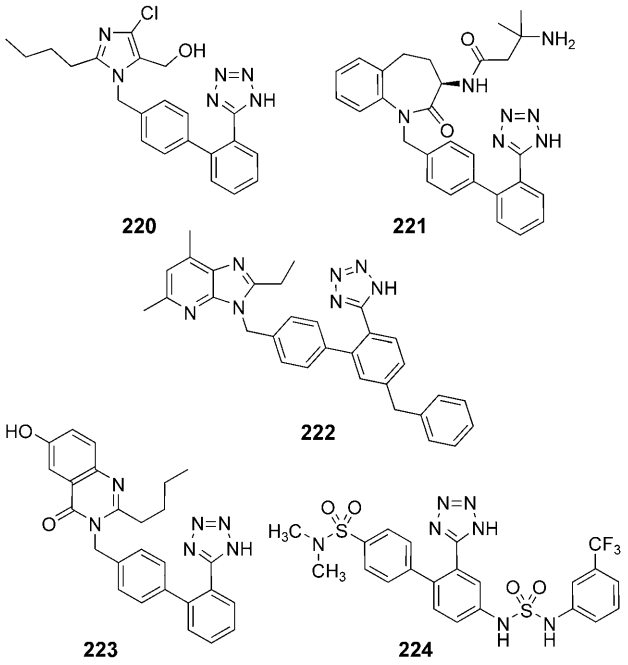


because they take place under mild conditions and form complex structures. The special feature of this reaction is that it is biocompatible[250,251] and takes place particularly well in aqueous media. They can also be carried out very efficiently in organic solvents in the presence of a copper complex with appropriate ligands.[247] The sensitivity of the reaction towards copper catalysts is so high that even copper wire is sufficient to maintain the corresponding copper ion concentration. Thus it was possible, for example, to label the surface of *Escherichia coli* cells. Azidohomoalanine (**212**) was incorporated metabolically into the outer membrane protein C (OmpC), one of the most common membrane porines of *Escherichia coli*. Selective modification of the azide functionality was possible by copper-mediated [3+2] azide–alkyne cycloaddition with an alkyne **215** that carries a biotin marker (Scheme 52). The specificity of this reaction was demonstrated by Western blotting and continuous-flow cytometry.[252]

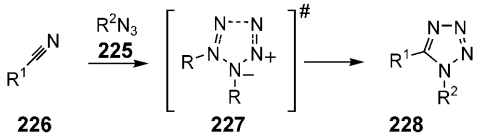
Scheme 52. Labeling of bacteria by cycloadditions.[252] TCEP = tris(2-carboxyethyl)phosphane.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

A copper-catalyzed 1,3-dipolar cycloaddition with an alkyl azide **217** in the solid phase that was synthesized starting with Merrifield resin was reported recently by Gmeiner and co-workers.[253] Based on this concept, aldehydes **218** can be immobilized to generate amides in subsequent steps (Scheme 53).



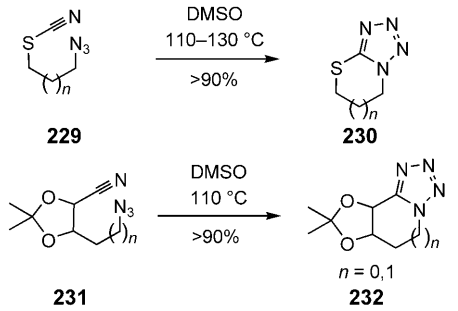
Scheme 53. Synthesis of a new family of SPOS resins by 1,3-dipolar cycloaddition through a click linker.[253] SPOS = solid-phase organic synthesis, DIPEA = diisopropylethylamine.



A new three-component reaction of azides, alkynes, and allyl carbonates leads to 2-allyl-1,2,3-triazoles.[254] A more recent and preparatively interesting preparation of 1,2,3-triazoles takes place through the less stable allenyl azides **586** formed from propargyl azides **585** in a [3,3] sigmatropic shift of the azide group (see Section 4.8, Scheme 144).[255]

4.1.2. *Tetrazoles*

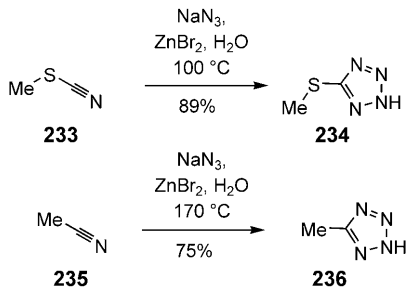
Because of their stability towards acids and bases and oxidative and reducing conditions[256] tetrazoles are interesting building blocks and target structures in organic synthesis.[257] They are lipophilic, metabolically stable compounds,[257] carboxylic acid bioisosteres[258] and *cis*-amide isosteres in peptide chemistry,[259] and are used frequently in different pharmaceuticals such as losartan[260] and in materials science.[261] Suitably substituted biphenyltetrazoles, in particular, are potent and selective ligands for different proteins such as G protein-coupled receptors, enzymes, and ion channels. Besides their well-known antihypertensive property in pharmaceuticals such as losartan (**220**),[260] biphenyltetrazoles stimulate the release of growth hormones (e.g. **221**).[262] Furthermore, they inhibit metalloproteases (e.g. **222**, **223**)[263,264] and are chloride-channel effectors (e.g. **224**).[265]



Tetrazoles **227** can be synthesized directly by a [3+2] dipolar cycloaddition between an organoazide **225** and a nitrile **226** (Scheme 54).[266] This reaction occurs through a concerted[266] and regioselective[267] [3+2] cycloaddition between an organic azide and an organic nitrile with formation of the 1,5-disubstituted product.[268] However, it only takes place sufficiently rapidly if electron-withdrawing groups are present on the nitrile,[269] or the reaction is intramolecular.[268,270] Polycyclic tetrazoles are formed in very good yields. This reaction could be improved further by the introduction of further heteroatoms such as oxygen, nitrogen, and sulfur at the nitrile terminal (thiocyanate,

Scheme 54. [3+2] Cycloaddition of nitriles **226** and organoazides **225** to give tetrazoles **228**.[266]

cyanate) (Scheme 55).[271] The spectrum of suitable azidonitriles for these intramolecular [3+2] cycloadditions is considerable, the second ring thus formed can be unsaturated or



Scheme 55. Intramolecular synthesis of tetrazoles.[271,273]

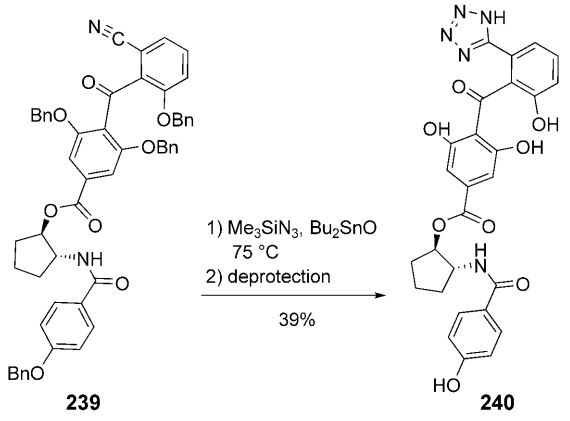
contain heteroatoms. If the necessary reaction temperature is taken as a measure of the reactivity, cyanates are more reactive in zinc-catalyzed reactions than simple nitriles. In the absence of the catalyst, however, this reactivity is reversed.[272]

If azide ions or hydrogen cyanide are used as dipoles, 1*H*-tetrazoles are formed in high yields,[274] as demonstrated by Hantzsch and Vagt more than 100 years ago.[275] The addition

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

of azide ions to nitriles is accelerated by microwaves[276] or by catalysis with zinc salts (Scheme 56).[277,278] This latter discovery was used for the synthesis of, among others, chiral, enantiomerically pure tetrazoles **238** under relatively mild conditions (Scheme 57).[279]

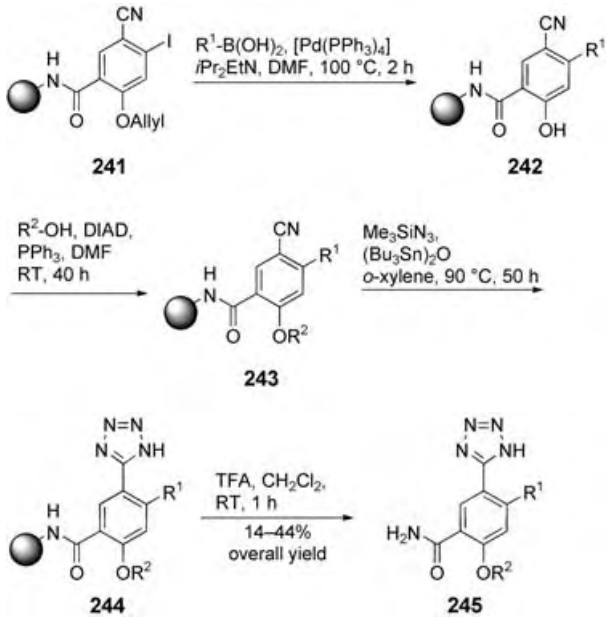
233 **234** **235** **236**



Scheme 56. [3+2] Cycloaddition of thiocyanates **233** and nitriles **235** with azide ions.[278]

237 **238**

Scheme 57. Synthesis of tetrazoles **238** according to Sharpless et al.[279]



Trimethysilyl azide (in the presence of catalytic amounts of tin oxides,[280a,b] or tetrabutylammonium fluoride)[280c] and trialkyl stannyl azides[258] can act as surrogates for azide ions. They are not only more soluble in organic solvents but are probably less toxic. The tetrazoles obtained may be readily deprotected. The synthesis of the balanol analogue **240**, which has a high affinity for protein kinases A and C, is shown as an example (Scheme 58).[281]

239 **240**

Scheme 58. Synthesis of tetrazoles **240** according to Lampe et al.[281]

A solid-phase synthesis of biphenyltetrazoles was described recently.[282a] The formation of the tetrazole ring from polymer-bound nitriles **243** (which were prepared in two stages on the support from the iodides **241**) was achieved with Me_3SiN_3 and catalytic amounts of n-Bu_2SnO within 50 h at 90 °C in o-xylene and gave the solid-phase-bound biphenyltetrazoles **244**. Cleavage from the support with TFA/CH_2Cl_2 gave the tetrazoles **245** in good purity (Scheme 59).

Scheme 59. Synthesis of tetrazoles **245** on a polystyrene support according to Kivrakidou et al.[282] DIAD = azodicarboxylic acid diisopropyl ester.

4.1.3. Reactions of Organoazides with Other Dipolarophiles

Other π systems such as allyl cations also react with organoazides, as demonstrated by the Lewis acid induced intramolecular reaction of hydroxyazidoalkenes.[283] Thus far, however, this reaction has found little use in the synthesis of dihydrotriazines. One interesting application is the cycloaddition of aliphatic azides **248** to 2-oxyallyl systems **247** that were prepared from cyclopropanone derivatives **246** (Scheme 60).[284] The regioselective dihydrotriazines **249** formed initially fragment to give α-diazoketones **250**. The

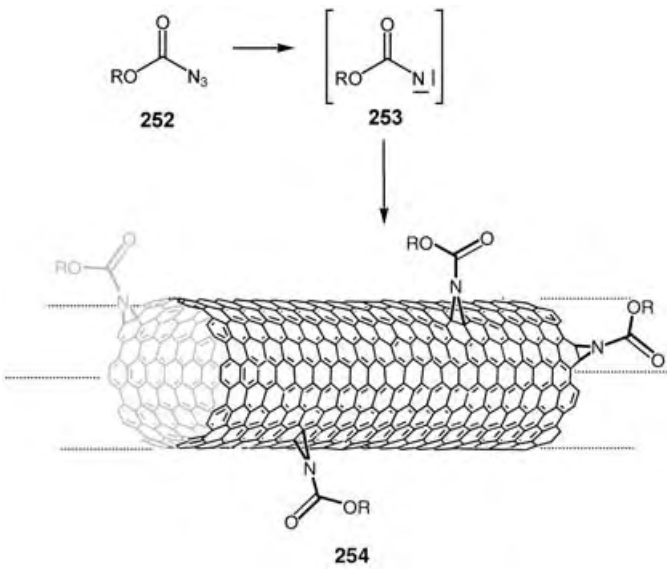
Scheme 60. Synthesis of α-diazoketones according to Desai and Aubé.[284] TES = triethylsilyl.

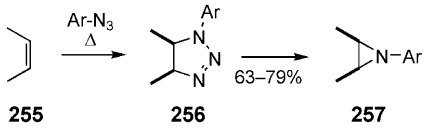
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



latter can be transformed into the azetidinones **251**, which otherwise only occur as by-products, in very good yields with catalytic amounts of rhodium acetate.

4.2. Nitrene Chemistry

The chemistry of aryl azides (and the postulate by Tiemann[285] of nitrenes during the decomposition of azides) has a long history that stretches back to the 19th century. However, targeted photochemical rearrangements with aryl nitrenes is a relatively new area of research. Both the complexity of the possible products and the diverse applications makes this area of research of special interest. In general, nitrenes are formed either thermally or photochemically.[27d,286,287] Nitrenes are related to carbenes but have different properties.[28] A difference is drawn between singlet and triplet nitrenes, and it has been possible to detect the latter by matrix isolation experiments.[288,289] The reactions of nitrenes stretch from cycloaddition, to rearrangements, to insertion reactions. Reference is made here to the cited review articles[1] and monographs[7] for an exhaustive treatment of the very broad spectrum.

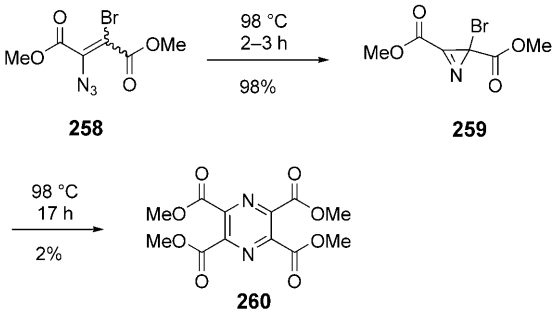


4.2.1. Intermolecular Cycloadditions of Nitrenes

The intermolecular cycloaddition of thermochemically or photolytically generated nitrenes to alkenes gives aziridines. This reaction is stereospecific as long as it occurs through singlet nitrene and can be catalyzed by metal ions. In this context, enantioselective variants have been developed which use the photolysis of aryl sulfonyl azides in the presence of copper ions.[290] Whereas acylnitrenes react in a secondary reaction to form isocyanates through a Curtius rearrangement (Section 4.5.1),[291] ethyl azidoformate usually gives the corresponding aziridines in good yields.[222] This reaction can also be used, for example, for the functionalization of carbon nanotubes (Scheme 61)[292,293]

Scheme 61. Functionalization of carbon nanotubes according to Holzinger et al.[293]

However, the cycloaddition of organoazides to alkenes is not necessarily a direct nitrene addition, as Δ^2-1,2,3-triazolines **256** can be formed which then react in a further step to aziridines **257** (Scheme 62). Both (strained) alkyl-substituted alkenes and electron-deficient or -rich alkenes such as fullerenes[294] can act as dipolarophiles.[295]

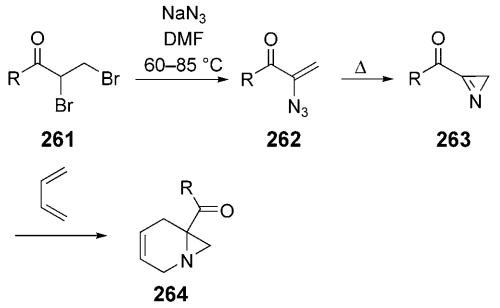


Scheme 62. Intermolecular synthesis of aziridines **257** via Δ^2-1,2,3-triazolines **256**.[295]

4.2.2. Intramolecular Cycloadditions of Nitrenes

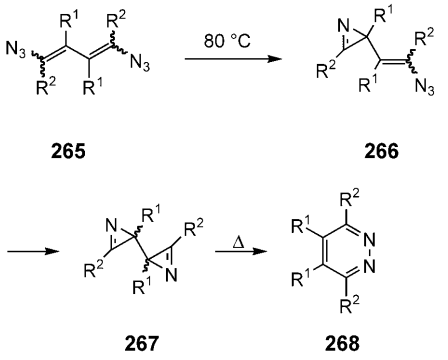
4.2.2.1. Intramolecular Cycloadditions of Alkenyl Nitrenes

The (reversible) transformation of alkenyl nitrenes, which are formed by thermal or photolytic decomposition of alkenyl azides into the corresponding 2*H*-azirines,[62c,296] is a very frequently used reaction.[62,64] Recently, further reaction of the photolabile azirines has been suppressed by the use of microwaves[297] or brief heating at 150 °C in closed vessels.[70] The preparation of 2-halo-2*H*-azirines **53** was carried out with the method of Pinho e Melo et al. by heating haloazidoalkenes **52** to 100 °C (Scheme 14).[72] According to Hassner et al., 2*H*-azirines are formed from 3-monoalkylalkenylazides under thermolysis conditions.[298] The 2*H*-azirines formed react further, sometimes rapidly, with the formation of, for example, indoles (Scheme 76). Frequently found by-products are the corresponding nitriles (Scheme 93, Scheme 95)[299] or occasionally isonitriles.[300] 2-Halo-2*H*-azirines **259** with electron-withdrawing groups at C3 decompose after a few days at room temperature. Heating to ≈100 °C leads to the formation of small amounts of substituted pyrazines **260** (Scheme 63).



Recently, activated 2*H*-azirines **263** with electron-withdrawing substituents have proved to be particularly good dienophiles in *endo*-selective Diels–Alder reactions with electron-rich dienes. This was demonstrated recently in

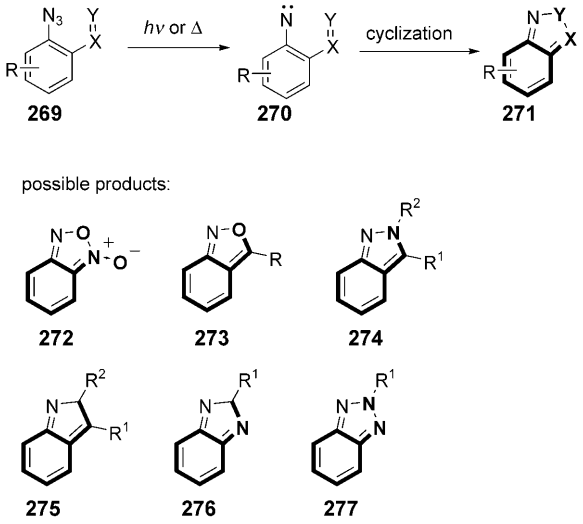
Scheme 63. Synthesis and decomposition of 2-halo-2*H*-azirines.[72]



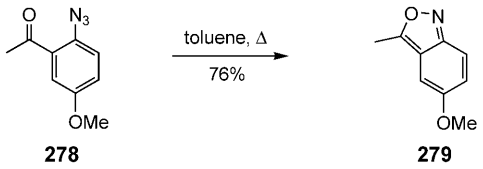
© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

particular by Gilchrist and co-workers[301] and by Somfai and Timen[302] in the synthesis of bridged aziridines **264** (Scheme 64). The use of chiral 2*H*-azirines, chiral dienophiles, or chiral Lewis acids allows the asymmetric synthesis of such ring systems.

Scheme 64. Synthesis and Diels–Alder reactions of 2*H*-azirines.[301,302]



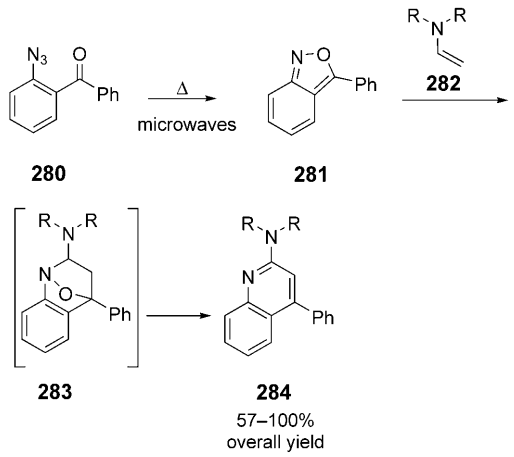
Interesting biazirinyls **267** were synthesized from 1,4-diazido-1,3-dienes **265** via 2-alkenyl-2*H*-azirines **266** intermediates (see Scheme 15). The pyridazines **268** are formed as by-products into which the biazirinyls **267** can also be converted upon heating for longer periods of time (Scheme 65).[73]



Scheme 65. Synthesis of biazirinyls.[73]

4.2.2.2. *Intramolecular Cycloadditions of Alkyl, Acyl, and Aryl Nitrenes to C=X Double Bonds*

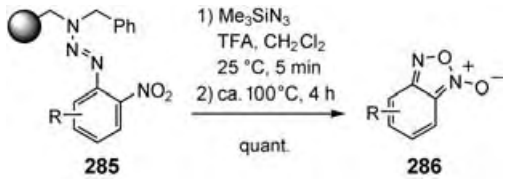
Aryl azides with a suitable double bond in the *ortho* position decompose photochemically or thermally to form the corresponding heterocycle with loss of dinitrogen. Indazoles **274**,[303,304] benzofuroxanes **272**,[305,306] benzisoxazoles **273**,[307–311] and other heterocycles (Schemes 66 and 67) are formed amongst others. This reaction sequence was demonstrated nearly 100 years ago.[309] An electrocyclic mechanism is assumed[306b,308] in which, in a few cases, subsequent aromatization occurs through an H or alkyl shift. This applies especially to the 2*H*-indoles and 2*H*-benzimidazoles. As this latter reaction represents a formal insertion into a C–H bond, it is discussed in more detail in Section 4.2.3.1.



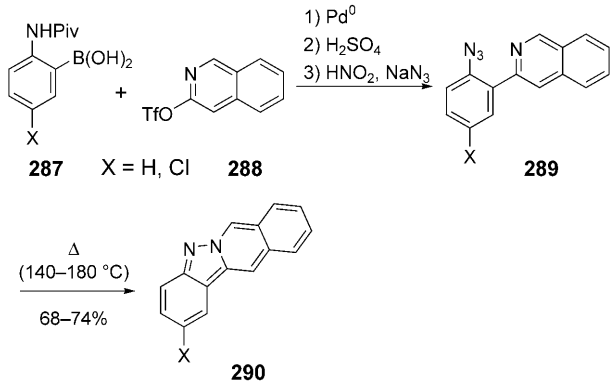
Scheme 66. Cyclization of substituted aryl azides.

Scheme 67. Thermal cyclization of *ortho*-acylaryl azides.[310]

These cycloaddition-derived heterocycles can in turn also react as reactive intermediates with further substrates, as shown in the microwave-induced synthesis of 2-aminoquinolines **284**.[312] In this synthesis, 3-aryl benzo[*c*]isoxazoles **281** react with enamines **282** to form the tricycles **283**, which then lose water. The quinolines **284** formed were isolated in good yields and with high purity after solid-phase extraction (Scheme 68).



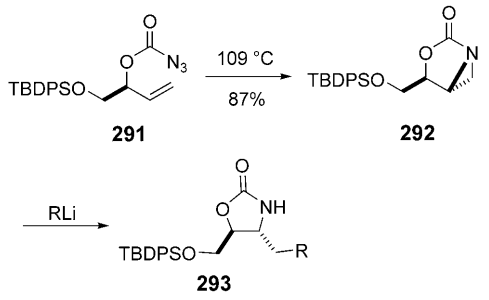
One application, the synthesis of benzofuroxanes **286**, could be demonstrated with *ortho*-nitro resins **285**. The azides formed after displacement cyclize at approximately 70 °C to



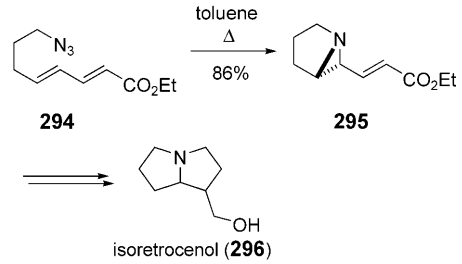
Scheme 68. Synthesis of aminoquinolines **284** by cycloaddition of intermediate benzoisoxazoles **281**.[312]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

give the benzofuroxanes **286** (Scheme 69).[45a] Benzofuroxanes are biologically active compounds with considerable synthetic potential.[313] Complex heterocyclic structures can also be prepared in this way, as shown by the synthesis of indazolo[2,3-b]isoquinolines **290** (Scheme 70).[314]

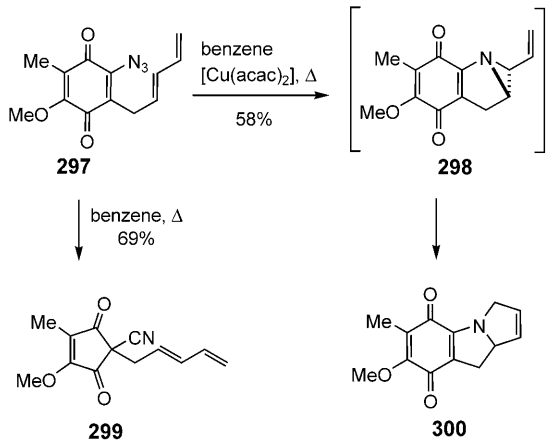


Scheme 69. Preparation of benzofuroxans **286** according to Bräse et al.[45a]



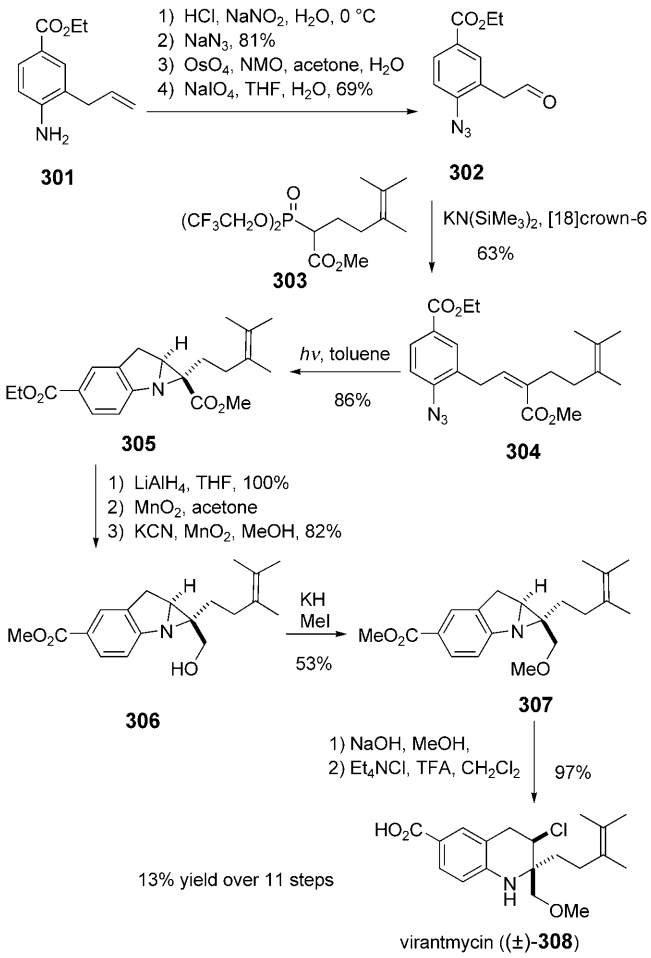
Scheme 70. Synthesis of indazolo[2,3-*b*]isoquinolines **290** according to Hajós and co-workers.[314] Piv = pivaloyl.

4.2.2.3. *Intramolecular Cycloaddition of Nitrenes to C=X Double Bonds*



In the presence of a double bond in the nitrene precursor, which allows the formation of a relatively unstrained bicyclic system, intramolecular cycloaddition occurs with the formation of aziridine systems. This is particularly the case with the azabicyclo[3.1.0]hexane systems **292**, which can be opened regioselectively by nucleophiles (Scheme 71).[315] This reaction finds further application in the synthesis of pyrrolizidines, which can then react further to give isoretrocenol (**296**) as described by Hudlicky et al. (Scheme 72).[316] This formal nitrene–diene cycloaddition can also be carried out directly, as demonstrated in the synthesis of the tricyclic system **300** (Scheme 73).[317] In the absence of copper ions, the quinoyl nitrene rearranges to form a nitrilocyclopentenedione **299** (see also Scheme 95).

Scheme 71. Intramolecular aziridines synthesis and subsequent nucleophilic ring opening.[315] TBDPS = *tert*-butyldiphenylsilyl.



Scheme 72. Synthetic pathway for the preparation of isoretrocenol (**296**).[316]

Scheme 73. Intramolecular [4+1] cycloaddition.[317] acac = acetylacetonate.

An application of intramolecular cycloadditions of nitrenes to alkenes was demonstrated by the total synthesis of the natural product (−)-virantmycin (**308**), which was first isolated in 1981 by Ōmura and co-workers in the fermentation broth of the bacterial culture *Streptomyces nitrosporeus*, strain AM-2722.[318] This tetrahydroquinoline derivative is characterized by extremely high antiviral action against a series of different RNA and DNA viruses, although its antifungal activity is much weaker. In the 11-step total synthesis optimized by Morimoto et al.,[319c,d] the aryl azide **304** was obtained from ethyl 3-allyl-4-aminobenzoate (**301**) in a stereoselective *trans* olefination by reaction with the Still–Gennari phosphonate **303** (Scheme 74). Subsequent stereospecific photochemical nitrene addition gave the tricyclic aziridine derivative **305**, which was transformed into the methyl benzoate derivative **306** by reduction of the ester group and subsequent chemoselective oxidation to the benzaldehyde derivative. In subsequent synthetic steps, the primary alcohol **306** was converted into the corresponding methyl ether **307**. This aziridine derivative **307** was trans-

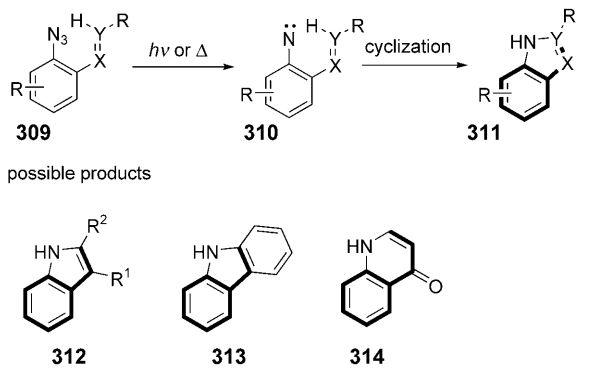
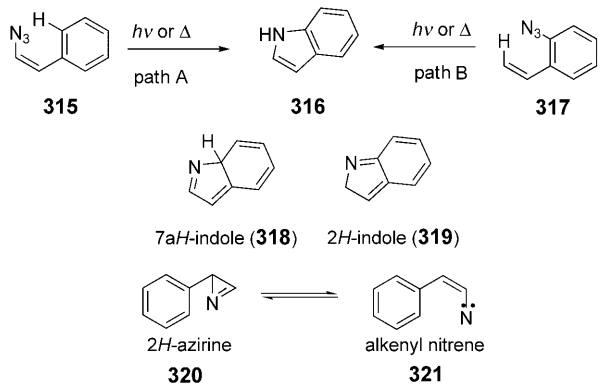
Scheme 74. Total synthesis of (±)-virantmycin (**308**) according to Morimoto et al.[319] NMO = *N*-methylmorpholine-*N*-oxide.



formed regioselectively and stereoselectively into (±)-virantmycin (**308**) under basic conditions. The overall yield in this total synthesis was 13% over 11 steps.

4.2.3. Insertion into C–H Bonds

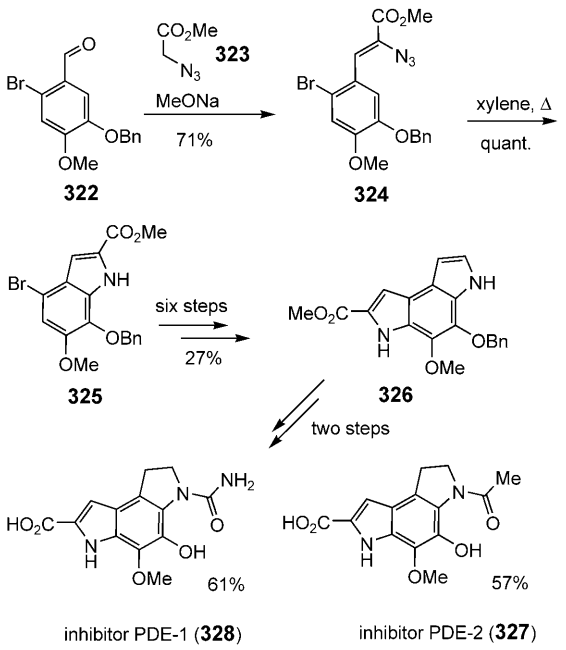


4.2.3.1. Insertion into C(sp^2)–H Bonds

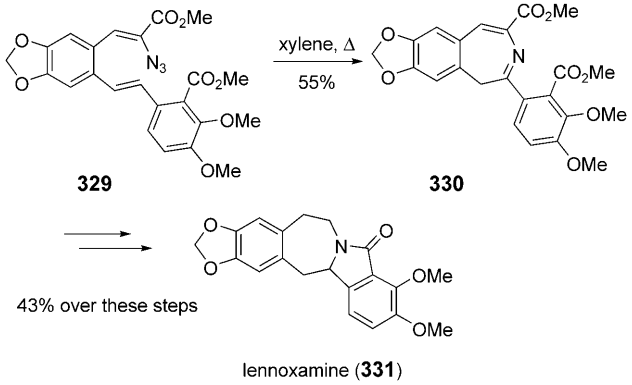
The cycloadditions of nitrenes described earlier are related to insertion reactions. In particular, the formal insertion into C(sp^2)–H bonds is a frequently used reaction, which in part also follows the cycloaddition principle (Section 4.2.2.2). Thus indoles **312**,[303] carbazoles **313**,[268] and other heterocycles can be formed (Scheme 75). Early mechanistic investigations showed that the nitrogen atom in the product originates from the probable nitrene precursor.[320]

Indoles in particular are readily accessible by this reaction, and two strategies are conceivable. Either the cyclization of (*Z*)-2-aryl alkenyl nitrenes (path A) (Scheme 76) or the cyclization of 2-alkenyl aryl nitrenes (path B) can be used. 7a*H*-Indoles (path A) or 2*H*-indoles (path B) may be formulated as reactive intermediates. Viewed mechanistically, the cyclization of (*Z*)-2-aryl alkenyl nitrenes (path A) presumably involves prior intramolecular 2*H*-azirine formation, which follows reversible alkenyl

Scheme 75. Cyclization possibilities of substituted aryl azides: insertion reactions.



Scheme 76. Syntheses of indoles from organoazides.



nitrene formation and determines the necessary stereochemistry. The required azidocinnamic esters are readily formed by condensation of azidoacetic esters and aryl aldehydes (Scheme 12). This reaction, named after Isomura, Hemetsberger, and Rees,[321–323] is one of the most important indole syntheses[324,325] and was used with success in a number of natural products syntheses such as murrayquinone,[326] discorhabdin C, makaluvamine D,[327] and varioline (**45**)[65] (Scheme 12). Furthermore, this reaction is used in the synthesis of phosphodiesterase inhibitors PDE-1 (**328**) and PDE-2 (**327**), which are related to the antibiotic CC-1065 (Scheme 77).[328] The choice of the correct solvent, which also influences the thermolysis temperature, is pivotal for success. 2*H*-Azirines can otherwise occur as by-products. Dimerization can also give pyrazines.[329] The Hemetsberger reaction can also be used for the synthesis of pyrroles from αβ-unsaturated aldehydes.[330] If another accessible double bond is present in the molecule, a competitive addition to this double bond can occur which can even be the main reaction. This was used by Moody and co-workers in their total synthesis of lennoxamine (**331**) (Scheme 78).[349]

Ortho-alkenyl aryl azides also rearrange to indoles upon heating. This reaction, known as the Sundberg cyclization,[331,332] takes place by direct attack at the β-carbon atom and not after insertion into the C–H bond.[332] This reaction was recently applied to the synthesis of complex indoles

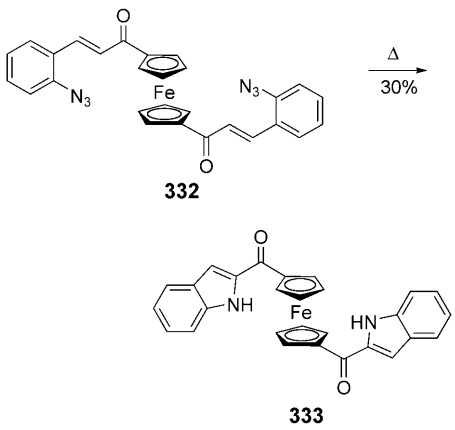
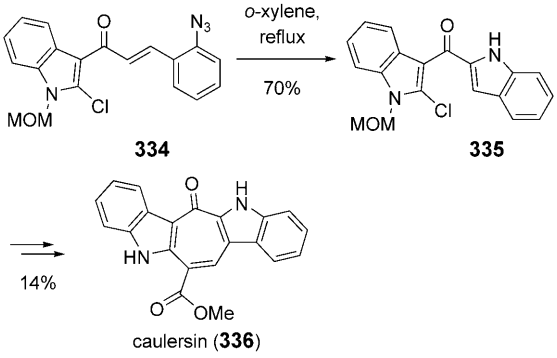
Scheme 77. Synthesis and conversion of the alkenyl azide **324** into indoles **327** and **328**.[328]



Scheme 78. Synthesis of lennoxamine (**331**) according to Moody et al.[349]

(Scheme 79).[333–335] As an alternative to thermolysis or photolysis this cyclization can also be carried out by protonation or by the action of Lewis acids with the formation of electrophilic nitrenium ions (see also Section 4.6.3).[336]



The first synthesis of the marine bisindole alkaloid caulersin (**336**) in seven steps was reported by Molina and co-workers in 1999 (Scheme 80).[337] The key step is the conversion of the azide **334** into the bisindole ketone **335** upon heating.

Other recent natural products syntheses that use this reaction pathway have been published, for example, those of the indole alkaloid meridianine from the fungus *Aplidium meridianum*,[338] novel indolecarboxylic acids related to the plant hormone indolylacetic acid,[325] and (±)-*cis*- and (±)-*trans*-trikentrin A.[339]

conventional UV lamps has been known for some time in the synthesis of carbazoles such as **338**, but this reaction has been carried out with only a few examples of substituted compounds and yields different by-products, such as the corresponding azo compounds (Scheme 81).[28,340] The use of laser

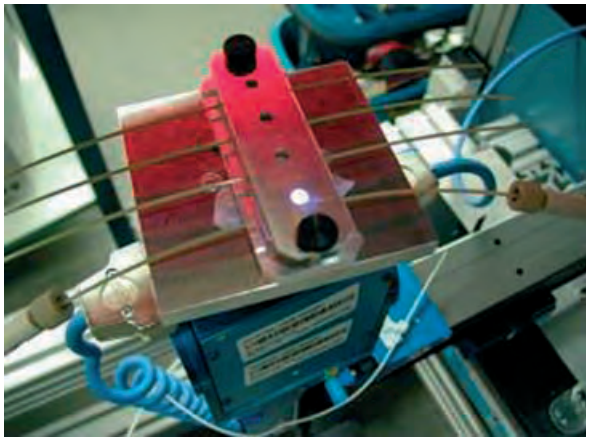
Scheme 81. Synthesis of carbazoles **338** by photolysis.[340]

light not only significantly accelerates the reaction, but also improves the selectivity of this preparatively important and extensively investigated process (Scheme 82). A further

Scheme 82. Laser-induced preparation of carbazoles **340** according to Bremus-Köbberling et al.[341]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

improvement is its execution in miniaturized photoreactors (Figure 3) which gave a greater turnover of photolysis products.[341]



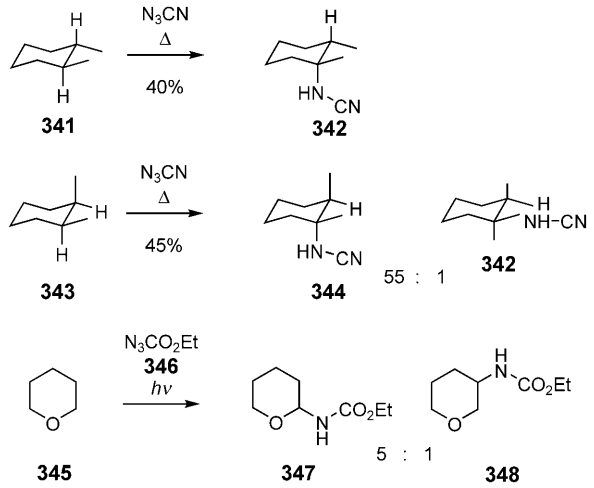


Figure 3. A miniphotoreactor for the photolysis of aryl azides. Picture reprinted with kind permission from the Fraunhofer-ILT, Aachen (Germany).[341]

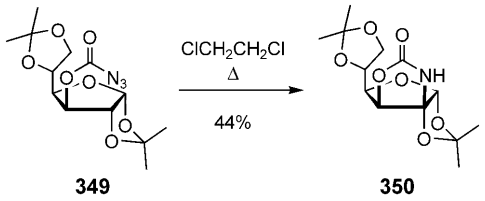
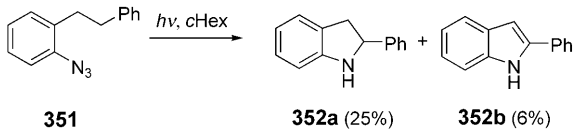


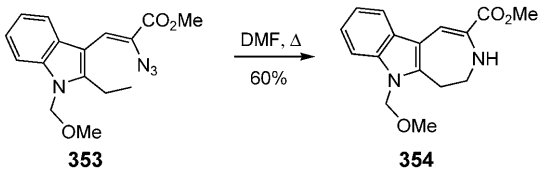
4.2.3.2. *Insertion into sp^3 C–H Bonds*

Nitrenes also undergo insertion into sp^3 C–H bonds. The selectivity of the insertion decreases from tertiary and finally to secondary to primary species. Thus statistically corrected reactivities of 25:10:1 were determined for the insertion of ethoxycarbonyl nitrene into the C–H bonds of 2-methylbutane.[342] This reaction can be both intramolecular[343] and intermolecular. These insertions usually take place with retention of configuration and regioselectively α to the oxygen atoms (Scheme 83).[345] In a few cases suitable metal catalysts have been found, although metal–nitrene complexes are not necessarily formed because these species undergo intermolecular reactions to form azoarenes.[344] An example of an intramolecular insertion of an acyl azide is the functionalization of furanose derivatives **349**

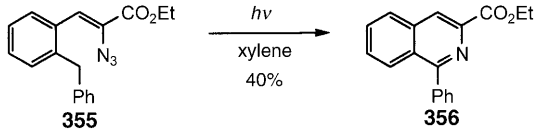


Scheme 83. Stereoselective and regioselective azide addition.[345]

(Scheme 84).[346] The newly formed rings are mostly five- or six-membered, of which the smaller rings are formed more readily. In 1995 Tomioka and co-workers synthesized 2-phenylindoline (**352a**) in this way (Scheme 85).[347] The



Scheme 84. Functionalization of furanose derivates.[346]

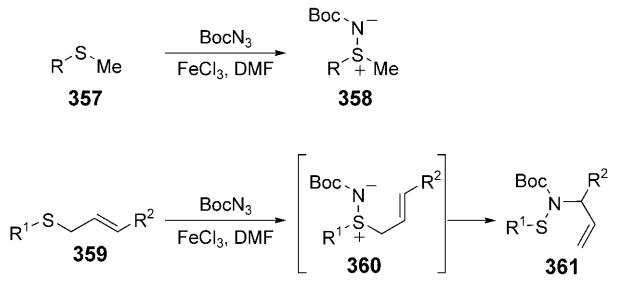


Scheme 85. Synthesis of 2-phenylindoline (**352a**) according to Tomioka et al.[347] *c*Hex = cyclohexane.

thermal decomposition of azidoacrylates **353** in refluxing DMF produces the pharmacologically important azepino[4,5-*b*]indoles **354** (Scheme 86).[348] The synthesis of isoquinolines

Scheme 86. Synthesis of azepino-[4,5-*b*]indole **354** according to Moody et al.[348]

by insertion into sp^3 C–H bonds has also been extensively investigated by Moody and co-workers.[349] In this case, the nitrene inserts into the benzhydrylic C–H bond, and the isoquinoline **356** is formed after aromatization (Scheme 87)[350]. In the case of *ortho* substituents (methyl or similar), a hydrogen atom is extracted and an imidoquinone methide is formed.[287,350]



Scheme 87. Synthesis of isoquinoline **356** according to Moody et al.[350]

4.2.4. *Addition of Nitrenes to Heteroatoms*

Nitrenes that are formed from azides react with electron-rich heteroatoms (nitrogen,[27c,351,352] sulfur, phosphorus) to form the corresponding ylides. The reaction of phosphorus compounds to form aza ylides is discussed in Section 4.3.

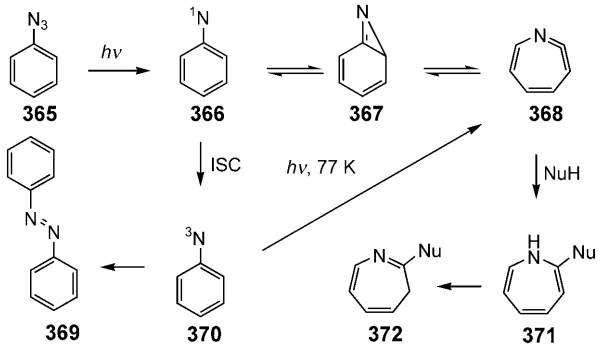
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Different organoazides can be converted into sulfur ylides **358** by reaction with sulfides **357**. Bach and co-workers reported an iron-catalyzed reaction of Boc azide with organic methyl sulfides (Scheme 88).[353] These authors also showed that allyl thioethers **359** undergo a [2,3] sigmatropic shift to give α-branched allylamines **361**.[354] This reaction was extended by Van Vranken and co-workers to propargyl thioethers, which form *N*-allenylsulfenimides.[355]

Scheme 88. Azide additions according to Bach and Körber.[353,354]

A ruthenium–salen-catalyzed, highly enantioselective variant of this reaction of alkyl aryl sulfides with arylsulfonyl azides and alkoxycarbonyl azides was reported recently by Katsuki and co-workers (Scheme 89).[356] The electron-deficient and sterically demanding reagent $Cl_3C(tBu)_2COCON_3$ proved to be especially useful in the case of alkoxycarbonyl azides, which produce somewhat more readily deprotected alkoxycarbonyl aziridines. This asymmetric synthesis can be carried out with allyl sulfides in the synthesis of chiral allylamines.[357]

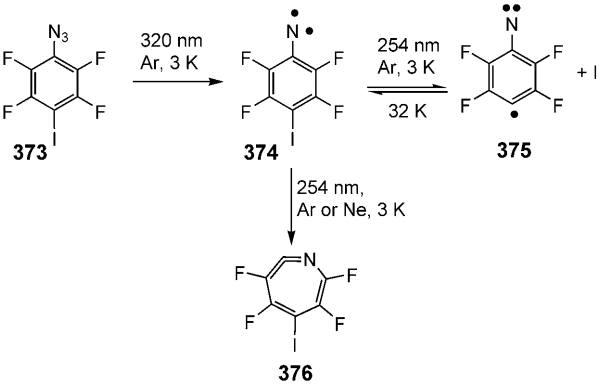
Scheme 89. Synthesis of enantiomerically pure sulfur ylides.[356]



4.2.5. *Rearrangement of Nitrenes*

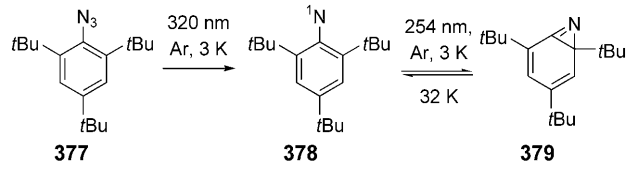
4.2.5.1. *Rearrangement of Acyl Nitrenes and Alkyl Nitrenes*

The rearrangement of acyl azide to isocyanates through the corresponding nitrene is well known as the Curtius rearrangement (see Section 4.5.1), whereas the general rearrangement of alkyl nitrenes is usually known as the Schmidt rearrangement (see Section 4.5.2). In the case of methyl azide (**6**) photolysis leads to methanimine, which is formed by simultaneous cleavage of dinitrogen and a 1,2-H shift.[15]



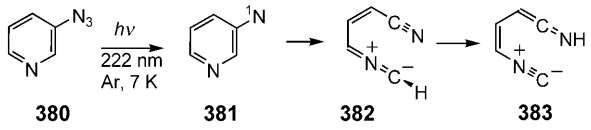
4.2.5.2. *Rearrangement of Aryl Nitrenes*

The rearrangement of aryl nitrenes by the photolysis of aryl azides leads to a broad spectrum of possible products.[358–363] As the large number of published examples would extend beyond the scope of this article, this section will be restricted to current examples. The work of Platz and co-workers in particular has helped greatly to explain the complex mechanism. In-depth analysis of reaction mixtures with matrix-isolation spectroscopy, laser flash photolysis (LFP), and modern molecular-orbital theory (MO) have all contributed to this understanding. In the photolysis of phenyl azide, various reactive intermediates are formed, of which the singlet phenyl nitrene **366** is the key molecule (Scheme 90). Intersystem crossing next gives the triplet nitrene **370**, which dimerizes to **369**. A special feature is the ring expansion of the benzazirine **367** to form the highly strained azepine derivative **368** and its subsequent products.[364] In a few cases, ring contraction to form cyanocyclopentadienes is observed.



Scheme 90. Rearrangement of aryl nitrenes.[364]

An application example was provided by Wenk and Sander in 2002 with the synthesis of 2,3,5,6-tetrafluorophenylnitren-4-yl (**375**). The intermediate **374** can also undergo iodine transfer to give dehydro-2,3,5,6-tetrafluoro-4-iodo-1*H*-azepine (**376**; Scheme 91).[365] Aryl azides with bulky *ortho* substituents react somewhat slower; the resulting benzazirines are stable for a few nanoseconds and can be detected spectroscopically (Scheme 92).[366]



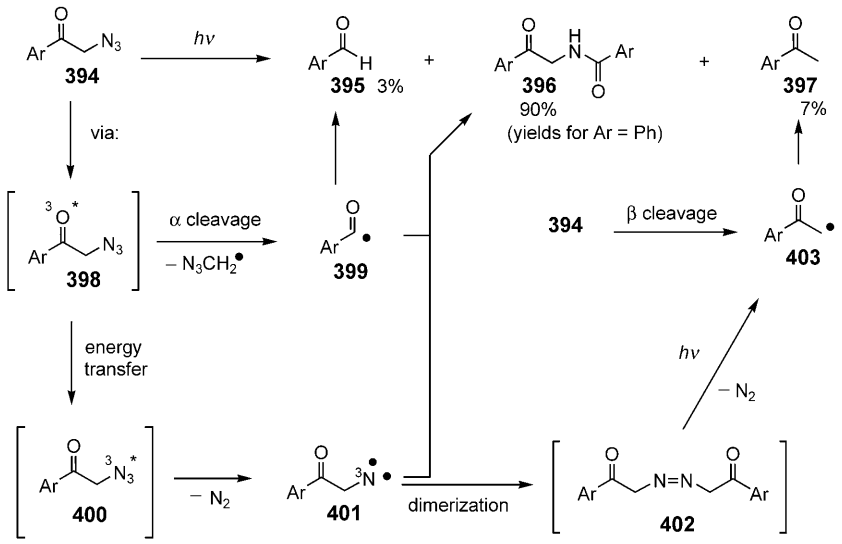
Scheme 91. Synthesis of **375** according to Wenk und Sander.[365]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 92. Synthesis of stabilized benzazirines according to Platz et al.[366]

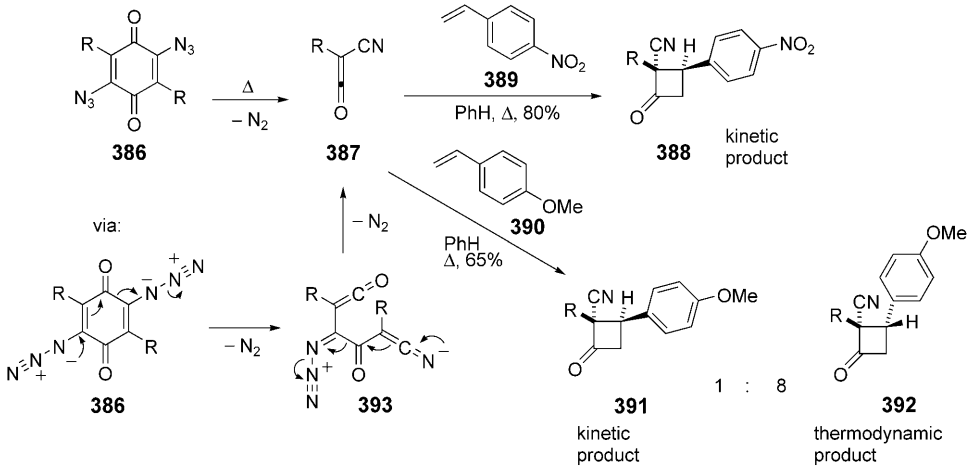
Scheme 93. Rearrangement of pyridylnitrenes **381**.[372]

Scheme 94. Synthesis of azepinones **385** according to Knepper and Bräse.[373a]



Functionalized aryl azides[367] and a few other azidopyridines[368] (see reference [369]) also rearrange under photolytic conditions in accord with this scheme. Another feature of aryl nitrenes is a reversible rearrangement between phenylnitrene and 2-pyridyl carbene, and 3-pyridyl carbene and 4-pyridyl carbene.[28,370] Furthermore, a coarctate ring opening[371] of 3-pyridyl nitrene with formation of a cyanovinylnitrile ylide complicates the reaction (Scheme 93).[372]

In the presence of water, alkenylaryl azides **384** provide access to substituted azepinones **385** by ring expansion (Scheme 94), as previously demonstrated by Scriven and co-workers.[373]



As a special case, azidoquinones usually rearrange to form nitriles (see also Scheme 73). However, 2,5-diazidoquinone (**386**) gives rise to the Moore ketene **387**, which reacts stereoselectively, for example, with styrenes **389** and **390** in intermolecular [2+2] cycloadditions to cyclobutanones **388** and **391**/**392**, respectively. Different reaction control is observed with the electron-rich styrene **390**, which gives predominantly **392** (Scheme 95).[374]

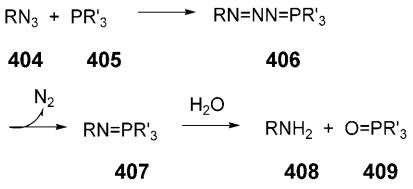
4.2.5.3. ***Fragmentation of Nitrenes***

Besides nitrene formation, alkyl azides with a photosensitive group in the α position (e.g. phenacyl azides **394**) can also react by α cleavage under radiation (Scheme 96).[375] This arises from the fact that with the supply of light the carbonyl group is first excited to the triplet state **398**. This can react either through the excited azide triplet state **400** to the triplet nitrenes **401**, or directly (by α cleavage)

Scheme 96. Fragmentation of phenacyl azides **394**.[375]

Scheme 95. Fragmentation of 2,6-diazidoquinones **386** according to Moore and synthesis of the corresponding cyclobutanone.[374]

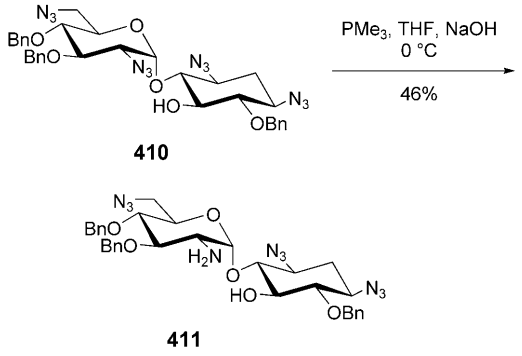
 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



to the benzoyl radicals **399**. The benzoyl radicals **399** react predominantly with the triplet nitrenes **401** to give ketoamides **396**. Benzaldehydes **395** are formed to a small extent by H extraction. Acetophenones **397** also occur as by-products and are presumably formed by dimerization of the nitrene **401** to the azo compound **402**; direct β cleavage of **394** is also conceivable.

4.3. Nucleophilic Addition to Organoazides: Aza Ylides

As already discussed, organoazides react readily with nucleophiles. One of the most frequent applications is the attack by phosphorus nucleophiles.

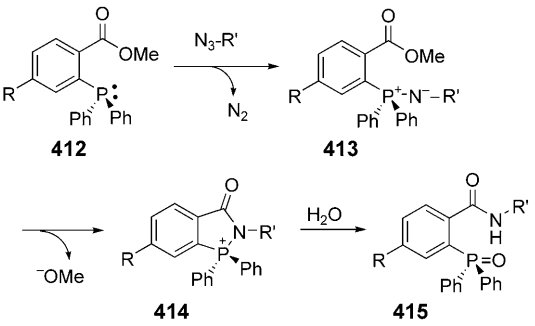


4.3.1. Azides as Amine Surrogates: The Staudinger Reduction

The Staudinger reduction was developed in 1919 by Staudinger and Meyer[376,377] as a procedure for the reduction of organoazides. This reaction involves the formation of a phosphazine intermediate **406** by nucleophilic attack of the phosphorus atom of a trialkyl or triaryl phosphine at the terminal nitrogen atom of the organoazide, which immediately loses nitrogen to form the iminophosphorane **407**.[378,379] These iminophosphoranes **407** are important reagents and intermediates in organic synthesis.[380,381] In the presence of water, the iminophosphorane **407** is spontaneously hydrolyzed to a primary amine **408** and to the corresponding phosphine oxide **409** (Staudinger reduction; Scheme 97).

Scheme 97. The Staudinger reduction.

If trimethylphosphane is used at low temperature, the organoazide—depending on its electronic properties—can be reduced chemoselectively in moderate yields in a modification of the Staudinger reaction (Scheme 98).[382]



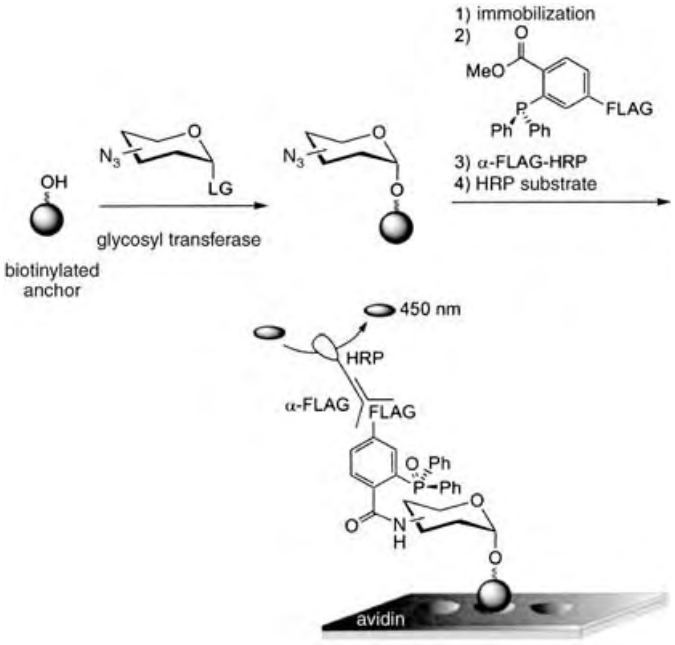
Scheme 98. Chemoselective reduction of organoazides.[382]

The Staudinger reaction between phosphines and organoazides has been used recently in the synthesis of dendrimers,[383] long-chain acyclic phosphazenes,[384] P-stereogenic phosphine oxides,[385] amides, [386] and glycosidated peptides,[387] as well as in the solid-phase synthesis of 3,5-disubstituted oxazolidine-2-ones.[388] A general Staudinger protocol has been developed for the liquid-phase parallel synthesis with fluoroalkyl-chain-modified triphenylphosphines which permits an extraction of the otherwise relatively poorly separable triphenylphosphane oxide into an organofluorous phase.[389]

4.3.2. The Staudinger Ligation

The intermediate in the Staudinger reaction is an iminophosphorane with a nucleophilic nitrogen atom. Vilarrasa and co-workers showed that this nitrogen atom can attack an acyl donor in an intermolecular or intramolecular reaction.[390] The amide is obtained as the final product after hydrolysis of the amidophosphonium salt. Thioamides can also be prepared by a coupling of thiocarboxylic acids and alkyl azides with triarylphosphines.[391]

Saxon and Bertozzi reported a modification of the Staudinger reaction for the first time in 2000—the intramolecular Staudinger ligation.[392,393] This generates an amide bond starting from organoazides and specifically functionalized phosphines.[393] This reaction takes place by nucleophilic attack at the organoazide to form an aza-ylide intermediate. A methoxycarbonyl group on one of the aryl rings of the phosphine traps the aza-ylide **413** to yield, after hydrolysis, an amidic phosphine oxide **415** (Scheme 99).[394] The reaction is



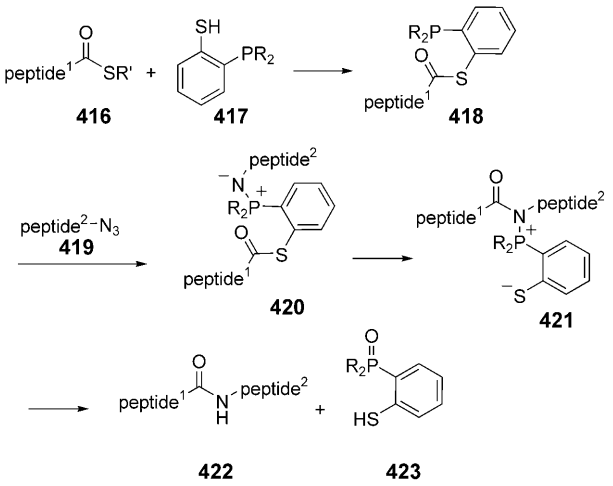
Scheme 99. The Staudinger ligation according to Saxon and Bertozzi.[393]

compatible with a large number of functional groups and therefore has various uses in organic synthesis and biological chemistry. The reaction has already been used in the investigation of cellular metabolism of synthetic azidosugars,[395] for biological labeling,[396,397] and for immobilization of substrates to surfaces.[398,399] The Staudinger ligation has been used successfully by Bertozzi and co-workers even on living organisms such as a mouse.[396b]

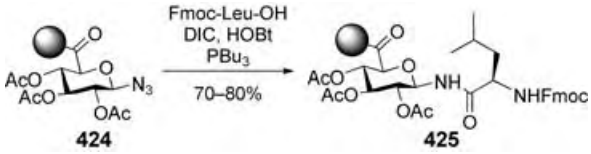
Bertozzi and co-workers recently reported an ELISA (enzyme-coupled immunosorbent assay) based on the Staudinger ligation (azido-ELISA).[398] A potential substrate, in this case a sugar, is equipped with an azide functionality and a

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

biotin anchor by an enzyme-induced coupling. This allows binding to an avidine-coated surface. The Staudinger reaction with a α-phosphinylbenzoic acid ester that bears a short peptide chain forms a conjugate. The short peptide chain (FLAG) can then be recognized by a specific monoclonal antibody (α-FLAG) to which a horseradish peroxidase is attached (α-FLAG-HRP). A substrate for this peroxidase then gives a signal at 450 nm. This system allows rapid screening of different glycosyl transferases, but should also be transferable to other systems (Scheme 100).

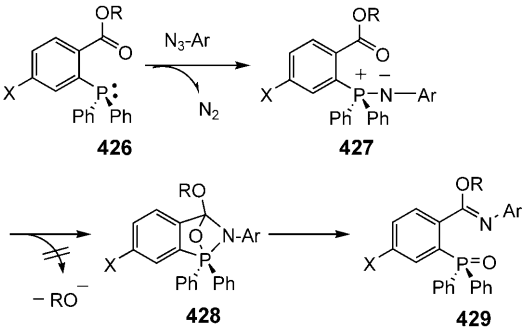


Scheme 100. Azido-ELISA according to Bertozzi and co-workers.[398]



The Staudinger ligation was applied to peptide synthesis by Raines, Kiessling, and co-workers. In this case, an amide bond is formed between a peptide fragment with a C-terminal phosphinylthioester **418** and a further peptide fragment **419** with N-terminal azide functionality (Scheme 101).[400] The reaction can be used to obtain dipeptides in high yields with retention at the α carbon atom[401,402] and is useful for the preparation of tetra- and pentapeptides.[403] The solid-phase synthesis of peptides and proteins under the conditions depicted was recently described in detail.[404]

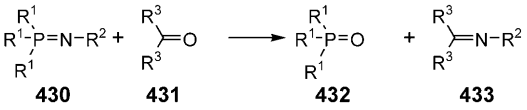
Modified Staudinger reactions with activated carboxylic acids are applied in the liquid- and solid-phase synthesis of glycosyl amides **425** (Scheme 102);[405a] stereoselective methods are also known.[405b] The reaction conditions are compatible with Boc and Fmoc protecting-group strategies, which are common in solid-phase synthesis and may be used in the synthesis of glycopeptides.



This reaction can also be applied to aryl azides and, in particular, to purinyl azides to obtain ligated material. The main product from this ligation contains a relatively stable imidate compound. *O*-Alkoxycarbonyltriaryl phosphines react somewhat differently with aryl azides. After Staudinger ligation, they form *O*-alkyl imidates **429** (Scheme 103).[406]

Scheme 101. Peptide synthesis by Staudinger ligation.[400]

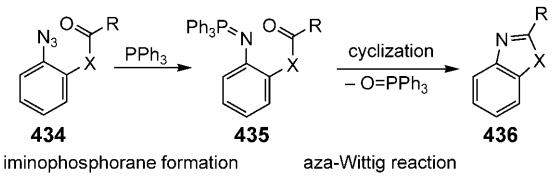
Scheme 102. Coupling of amino acids to glycosyl azides **424** by Staudinger ligation for the preparation of glycoamino acids **425**.[405] DIC = diisopropylcarbodiimide, HOBt = 1-hydroxy-1*H*-benzotriazole.



Scheme 103. Staudinger ligation with aryl azides.[406]

The intramolecular Staudinger ligation is a particularly efficient ring-closing reaction for the formation of medium-sized lactams that are difficult to prepare by other methods.[407]

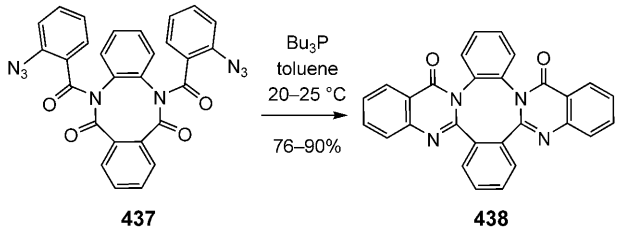
4.3.3. The Aza-Wittig Reaction in a New Light



As described, the azide functionality is very useful for the synthesis of other nitrogen compounds. The reaction of iminophosphoranes **430**[381]—obtainable by Staudinger reaction from organic azides and phosphorus(III) reagents—with carbonyl compounds **431** has frequently been used for the synthesis of imines **433** by the aza-Wittig reaction (Scheme 104).[76,380,381,408–410]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

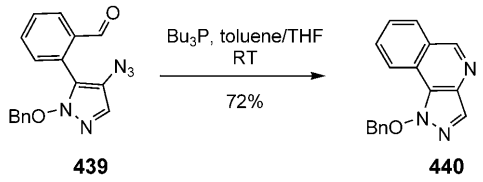
Scheme 104. Aza-Wittig reaction.



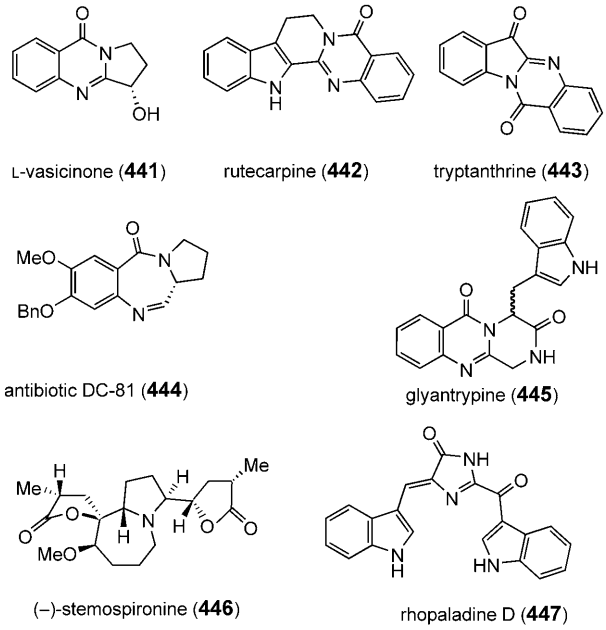
Because of its high synthetic potential, the intramolecular version of this reaction[408] is often the method of choice for the preparation of nitrogen heterocycles[411] such as isoxazolines[412] and for the synthesis of five-,[411] six-, and seven-membered nitrogen heterocycles, among others (Scheme 105).[411,413–416] A series of natural products syntheses

Scheme 105. Intramolecular aza-Wittig reaction.

uses precisely this reaction as the key step. The reactivity of the precursors is controlled by several factors: chain length, substituents at the phosphorus and nitrogen atoms of the iminophosphorane, and the chemical nature of the carbonyl group. Ester carbonyl groups are normally unreactive in the intermolecular aza-Wittig reaction, but they react in intramolecular versions and form the corresponding imino cyclization products.[76]



According to Eguchi et al. the reactivity of amidic carbonyl groups in intramolecular aza-Wittig reactions gives access to iminolactams.[417] Lactams can also act as substrates and give the corresponding annelated quinazolinones (for an alternative, see Section 4.6.2, Scheme 134).[413,415] This reaction can also be carried out twice, as demonstrated in the synthesis of the polyazamacrocycle **438** (Scheme 106).[418]

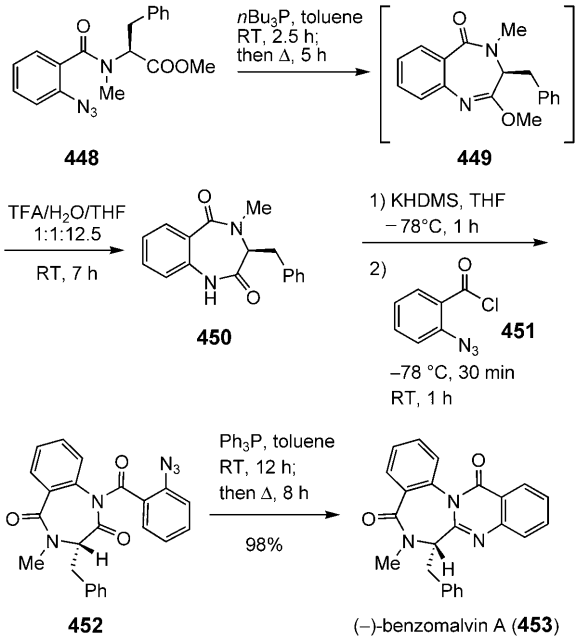


Scheme 106. Synthesis of the benzanellated polyazamacrocycle **438**.[418]

The pyridine ring of pyrazoloisoquinoline **440** was formed by a Staudinger/aza-Wittig cyclization of a formyl group with the azide group of a 4-azido-1-(benzyloxy)-5-(2-formylphenyl)pyrazole (**439**; Scheme 107).[419] Oxazoles are available from β-(acyloxy)vinyl azides and triethylphosphane.[420]

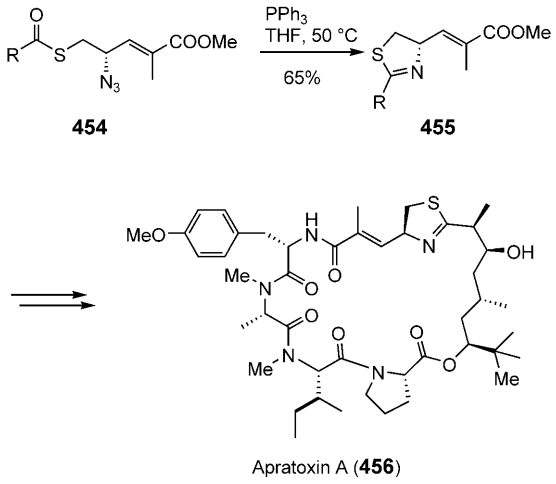
Efficient access to quinazolines by Eguchi et al. allows the synthesis of natural products in a domino Staudinger–intramolecular aza-Wittig reaction, for example, vasicinon (**441**),[421] desoxyvasicinon,[414] rutecarpin (**442**),[422] and tryp-

Scheme 107. Preparation of pyrazoloisoquinoline **440** by aza-Wittig reaction.[419]



tanthrin (**443**).[422] This methodology is particularly suitable for the synthesis of seven-membered nitrogen heterocycles such as the antitumor antibiotic DC-81 (**444**),[423–425] and for the synthesis of trifluoromethylated nitrogen heterocycles.[426] Furthermore, studies on the total synthesis of the marine alkaloids of the chartellamide group[427] and pinnatoxin A[428] by aza-Wittig reactions have been reported. Other successful examples are glyantrypine (**445**),[429] (−)-stemospironine (**446**),[430] rhopaladine (**447**),[431] ardeemin,[432] and hamacanthin A[433] and B (**82**; Scheme 20).[117]

The first total synthesis of (−)-benzomalvin A (**453**), which bears both a quinazoline-4(3*H*)-one and a 1,4-benzodiazepine-5-one unit, was reported by Eguchi and co-workers.[434,435] Both heterocycle frameworks were prepared by an aza-Wittig reaction as the key step (Scheme 108).



Enantiomerically pure 2,4-disubstituted thiazolines **455** can also be prepared efficiently from thioesters **454** in a mild Staudinger/aza-Wittig process,[436] as demonstrated in the total synthesis of apratoxin (**456**) (Scheme 109).[437]

The intramolecular aza-Wittig reaction can also be used in the synthesis of nonnatural products, as demonstrated by the synthesis of novel heterocycles based on ferrocenophanes that are used as ligands for metal ions (Scheme 110).[438] A new class of orthoacylimine-derived chiral auxiliaries have been synthesized by the reaction of the corresponding

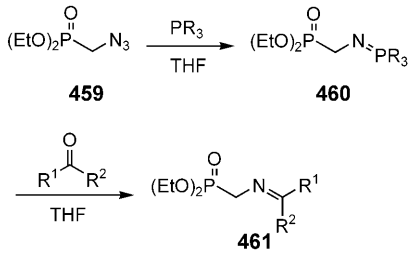
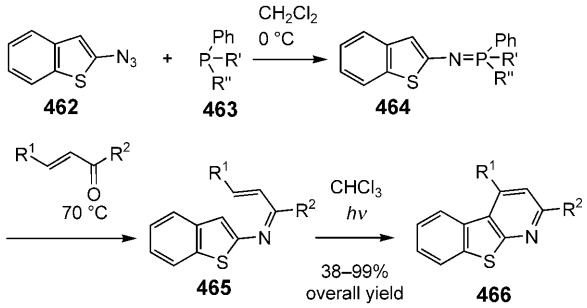
Scheme 108. Synthesis of (−)-benzomalvin A (**453**).[435]



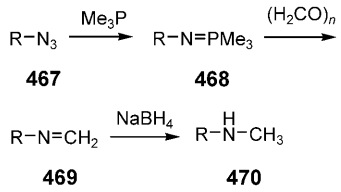
Scheme 109. Thiazole synthesis by aza-Wittig reactions in the total synthesis of apratoxin A.[437]

Scheme 110. Conversion of a ferrocenophane into the ligand **458**.[438]



orthoacyl azides and a series of aldehydes in the presence of trialkylphosphines.[408]

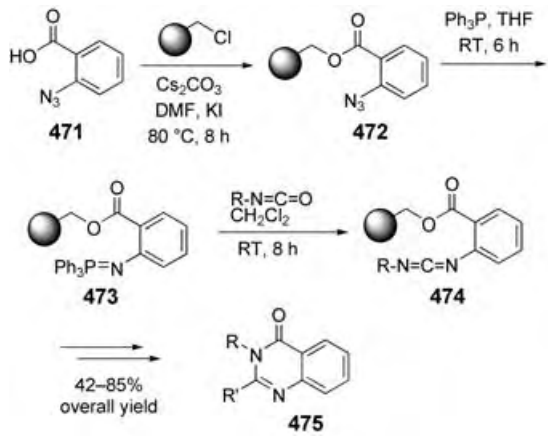
The aza-Wittig reaction can thus be used for the introduction of imine units, for example, to prepare iminophosphonates **461** (Scheme 111),[439] or in keto acids for the preparation of imino acids.[440]



Scheme 111. Synthesis of functionalized imines **461**.[439]

The preparation of pharmacologically important benzothieno[2,3-*b*]pyridines **466** takes place by an intermolecular aza-Wittig reaction of iminophosphoranes **464** with various unsaturated aldehydes and ketones and subsequent photocyclization (Scheme 112).[441]

Scheme 112. Synthesis of benzothienopyridines **466**.[441]



A one-pot synthesis of *N*-monomethylamines **470** from organoazides **467** by Suzuki and co-workers[442] uses an aza-Wittig reaction with paraformaldehyde. The resulting imine **469** is then reduced with $NaBH_4$ to give the corresponding *N*-monomethylamine **470** (Scheme 113). Although a frequent structural motif in natural products, the *N*-monomethylamine group is at times difficult to insert without the formation of by-products.

Scheme 113. Synthesis of *N*-monomethylamines from organoazides.[442]

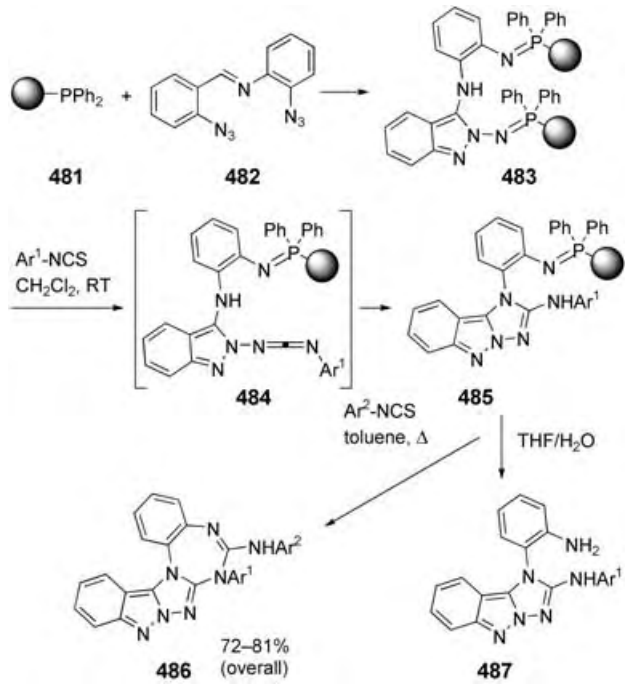
Owing to the potential of iminophosphoranes in the mild and neutral synthesis of nitrogen heterocycles, different solid-phase variants have been developed. Either the triarylphosphine in the aza-Wittig reaction or the substrate is immobilized on the support. The solid-phase synthesis of 1,4-benzodiazepine-2,5-diones,[443] trisubstituted guanidines,[162] oligomeric guanidines,[444] and 3*H*-quinazolin-4-ones (**475**; Scheme 114)[445] has been carried out with aza-Wittig reac-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

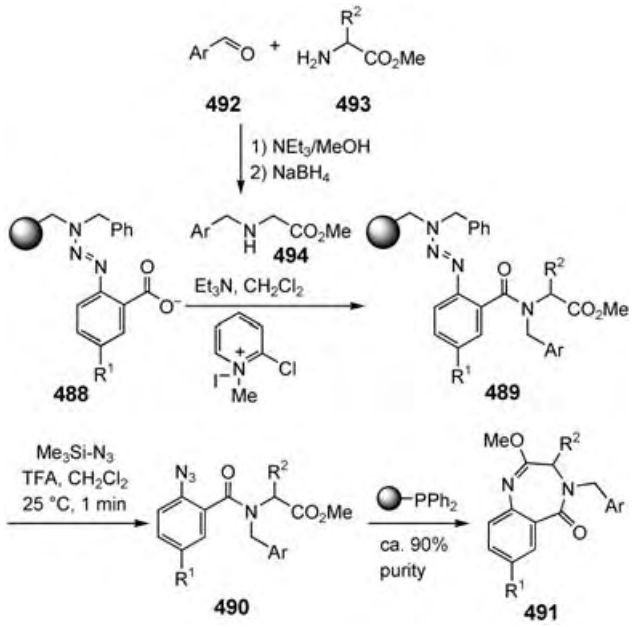
Scheme 114. Solid-phase synthesis of 3*H*-quinazolin-4-ones **475**.[445]

tions and permitted the synthesis of libraries of these classes of compounds.

The use of the commercially available, polymer-bound diphenylphosphine (**477**) combines the advantages of solid phase synthesis with the use of polymer-bound reagents. The usual Wittig by-product triphenylphosphane oxide is normally difficult to separate from polar products, but in this way it can be readily removed as the polymer-bound diphenylphosphane oxide (**479**) by filtration (Scheme 115).[446] Owing to the high cost of the reagent **477**, it is occasionally



Scheme 115. Aza-Wittig reaction with polymer-bound diphenylphosphane.

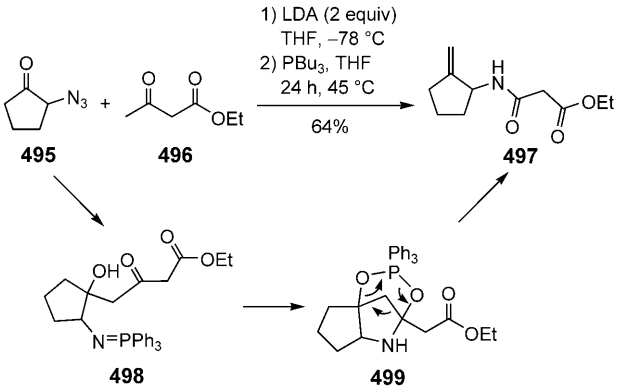


recovered, usually by reduction with trichlorosilane. In particular, the fact that the iminophosphorane **478** is polymer-bound in the first step the purification of the final product is simplified, as excess organoazide **476** can be removed before the aza-Wittig reaction.

This strategy has been used in the synthesis of condensed indazolobis(guanidines) **486** (Scheme 116),[447] amines,[448] pyrrolo[2,1-*c*][1,4]benzodiazepines such as the natural product DC-81 (**444**),[424b] pyrido[1,2-*c*]pyrimidines,[449] non-anomeric glycosidyl isothiocyanates,[450] the antitumor-active phloeodictin A1,[451] and libraries of benzodiazepine–quinaxolinone alkaloids of the circumdatin type.[452]

A combined solid-phase strategy for the synthesis of benzodiazepinones **491** starts from substituted triazene resins **488**, which were first treated with a series of *N*-benzyl amino acid esters. The latter are readily prepared by reductive amination of aryl aldehydes **492** with amino acid esters **493**. The cleavage of the resulting amide **489** in the presence of trimethylsilyl azide gave the highly functionalized aryl azides **490**. The intramolecular aza-Wittig reaction with polymer-bound triphenylphosphane then gave **491** in good yields (Scheme 117).[453]

Scheme 116. Solid-phase synthesis of condensed indazolo-bis(guanidines) **486**.[447]



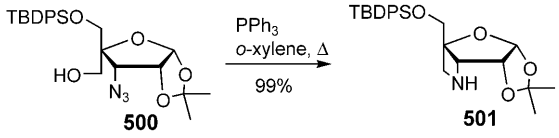
Scheme 117. Solid-phase synthesis of benzodiazepinones **491**.[453]

Soluble and easily separable triphenylphosphane reagents have been prepared from noncrosslinked polystyrene (NCPS)[454] or through perfluoroalkyl-substituted triphenylphosphane[455] and are also used in the Staudinger/aza-Wittig reaction.

A new reaction sequence that includes iminophosphoranes was recently reported by Langer and co-workers. α-Azidoketones **495** are converted into allyl amides **497** with enolizable β-carbonyl compounds in a sequence of Stau-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

dinger–aza-Wittig–1,5-phosphonium rearrangement–fragmentation sequence (Scheme 118).[456] This reaction differs from a related reaction,[457] such that the iminophosphorane does not cyclize to the pyrrole under aza-Wittig conditions,



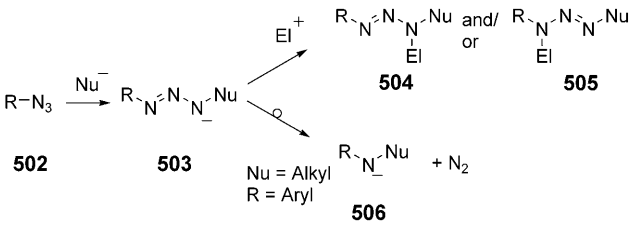
Scheme 118. A rearrangement cascade for the synthesis of allyl amides **497**.[456]

but first attacks the ketone and forms compound **499**. Ring opening of intermediate **499** and fragmentation of the resulting phosphonium oxide gives the allyl amide in a retro-Prins reaction with elimination of triphenylphosphane oxide.

At this point it must not be overlooked that alternative substrates and reagents for imine syntheses from organoazides and carbonyl compounds or their derivatives have recently been published (Section 4.6.2).

4.3.4. Reaction of Iminophosphoranes with other Electrophiles

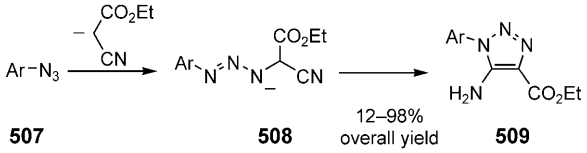
Iminophosphoranes also react with other electrophiles, for example, epoxides or activated carbon electrophiles.[458] These intramolecular reactions take place with the formation of aziridines.[18,381] Recently, a new bridged nucleic acid monomer **501** was successfully synthesized by azetidine formation under Staudinger conditions (Scheme 119).[458a]



Scheme 119. Synthesis of azetidine-condensed nucleoside analogues.[458a]

4.4. Other Reactions of Organoazides with Nucleophiles

4.4.1. Reactions of Carbanions: Synthesis of Triazenes



Stabilized and nonstabilized carbanions react with organoazides **502** (Scheme 120) to form triazenyl anions **503**, which can then be trapped with electrophiles—under certain circumstances regioselectively. (For the reaction with sulfonyl azides see Section 3.1.3.) This reaction is particularly useful for the preparation of the corresponding aliphatic triazenes,

Scheme 120. Synthesis of triazenes and secondary amides **506** from organoazides **502**.[9,460]

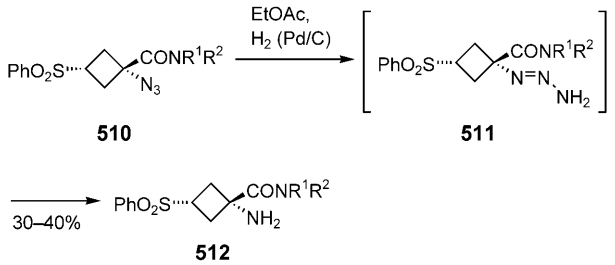
as other possible precursors (aliphatic diazonium ions) are not stable. The addition of nucleophiles to organoazides can also be used for diazo transfer[459] or for electrophilic amination of carbanions as found by Trost, Kabalka, and others,[460] because the triazenes cleave under mildly acidic conditions. However, triazenyl anions **503** that are formed by attack of aliphatic Grignard reagents on aromatic azides, are in a few cases not stable and lead to formal *N*-alkylation (Scheme 120).[9]The recently reported indium-induced Barbier synthesis of *N*-allylamines from allyl bromides and azides also probably follows a similar pattern.[461]

More than 100 years ago it was shown that in the presence of an internal electrophile the triazenyl anions **508** cyclize, for example, to triazoles **509** (Dimroth cyclization; Scheme 121).[58] Malonic, cyanoacetic, and related esters can be used.

Scheme 121. Synthesis of triazoles **509** from azides **507**.[58a]

4.4.2. Reduction of Azides to Amines

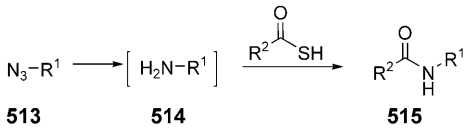
The reduction of azides[462] to the corresponding amines has been carried out with hydrogen in the presence of catalysts such as Lindlar catalyst,[78] with thiols,[463,464] complex hydrides, boranes, and phosphanes (see Section 4.3.1, Staudinger reduction).[122,409a,465–467]



Thioethers R_2S are often used in catalytic amounts; different boranes[468,469] or borohydrides[470] function as stoichiometric reducing agents. The high reactivity of the reducing agent $BHCl_2{\cdot}SMe_2$ is exploited in the selective reduction of azides in the presence of double bonds. With $BH_3{\cdot}SMe_2$, hydroboration is preferred to reduction.[469] The reduction also takes place in good yields with various metals in the presence of Lewis[471] or Brønsted acids.[472] Acyl azides can be reduced to the corresponding primary amines with lithium/DTBB (di-*tert*-butylbiphenyl) at room temperature.[473] One mild reducing agent is *N*,*N*-dimethylhydrazine, which requires the presence of catalytic amounts of iron(III) chloride.[474] A further reducing agent is SmI_2, which transforms aliphatic, aromatic, and benzoyl azides smoothly into the corresponding amines under mild conditions.[475] Analo-

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

gously, the reduction also takes place with zinc borohydride,[476] sodium borohydride under Cu(II) or Co(II) catalysis,[477] sulfur-modified calcium or barium borohydrides $M^{II}(BH_2S_3)$,[478] lithium aminoborohydrides (aliphatic and benzylic azides),[479] as well as classically with lithium aluminum hydride.[480]

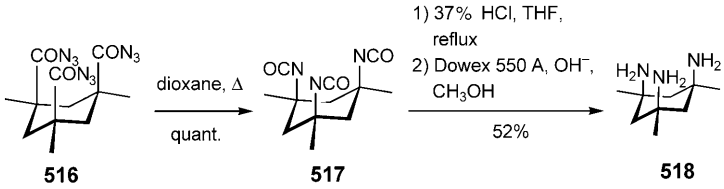


Iron(II) salts under basic conditions are also suitable reducing agents,[481] as are tetrathiomolybdates.[482] Very powerful yet selective reducing agents are the thioaryl-substituted Sn(II) complexes $Sn(SAr)_3^-$ (Bartra reagent).[483–485] Bu_3SnH is also used as reducing agent, sometimes with Ni(II) catalysis,[486,487] although a radical mechanism is assumed here.[486] Aliphatic, aromatic, and benzoyl azides can be reduced to the corresponding amines or amides by the action of trimethylchlorosilane.[488] The direct conversion of organazides into Boc-protected amines,[465,489] which provides elegant access to orthogonally protected diamines, is very attractive. The selective reduction of an azide group on an anomeric carbon atom of a saccharide by tetrathiomolybdates has also been reported, while the azide groups at other sites of the sugar were not attacked.[490] Enzymatic reductions of azides with baker's yeast[491] and lipases[491d] are also known.

The classic heterogeneous catalytic hydrogenation of aliphatic, aromatic, and sulfonyl azides with palladium on charcoal[492] as catalyst can also be carried out with other supports such as molecular sieves.[493] An interesting reduction of tertiary azides **510** to stable, monosubstituted triazenes **511** has been reported by Gaoni (Scheme 122).[494] At this point it has to be speculated whether most of the aforementioned reductions occur through triazenes.

Scheme 122. Reduction of organoazides **510** via triazene intermediate **511** according to Gaoni.[494]

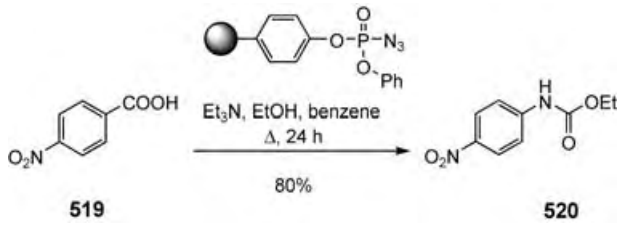
A highly promising reaction is the transformation of thioacids with azides **513**, which leads directly to amides **515** (Scheme 123). Since this reaction takes place in water, it is suitable for aqueous peptide syntheses. Alkyl, acyl, and sulfonyl azides react equally well, and the amine **514** is formed in situ.[495,496]



Scheme 123. Acylation of azides **513** with thiocarboxylic acids.[495]

4.5. The Curtius Rearrangement and Related Reactions

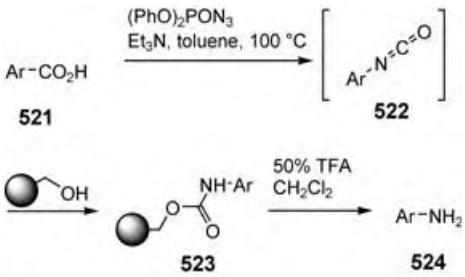
4.5.1. Curtius Rearrangement



The Curtius rearrangement is a widely applicable reaction for the preparation of isocyanates and their secondary products.[497] Acid azides are photolytically decomposed to nitrenes, which in a further reaction at room temperature are converted into the isocyanates.[498] In principle, this reaction can be regarded as an aminating decarboxylation. The potential was demonstrated in a series of syntheses of complex natural products.[174,499,500] Owing to the widespread use of this reaction,[170,173,184,501,502] only a few selected examples are described here. Menger and co-workers recently reported the synthesis of 1,3,5-triaminocyclohexane **518** (in which the three amino groups adopt an axial disposition) from the Kemp triacid (Scheme 124).[503] The stereospecific triple

Scheme 124. Preparation of 1,3,5-triaminocyclohexane **518** according to Menger et al.[503]

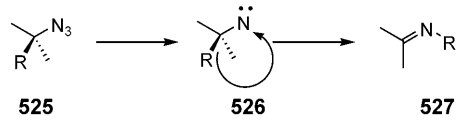
Curtius rearrangement occurs with complete conversion in refluxing dioxane or toluene. The subsequent hydrolysis gave the triamine **518** in good yield.



Carboxylic acids and their derivatives can also be transformed directly into the corresponding amines through a Curtius rearrangement. Thus monoesters of dicarboxylic acids can be converted into amino acids.[170] Usually diphenylphosphoryl azide (DPPA) is used as the reagent; however, its use is severely restricted owing to its high toxicity. Recently Taylor prepared and successfully used a solid-phase-bound phosphoryl azide in a Curtius rearrangement (Scheme 125).[116]

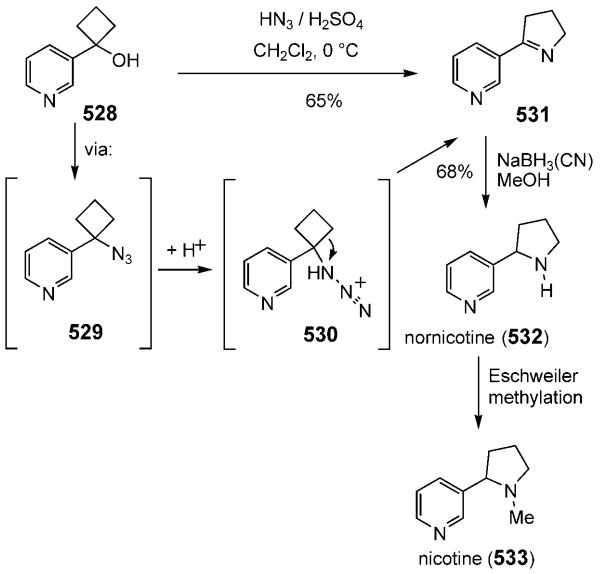
Scheme 125. Curtius rearrangement with immobilized phosphoryl azide according Taylor and Lu.[116]

The Curtius rearrangement is a key step in the total synthesis of (+)-zamoanolide, a tumor-growth inhibitor.[500] Solid-phase Curtius rearrangements have also been described for the amine[504] or carboxylic acid[505] immobilized on the solid phase. The isocyanate **522** is first formed as an intermediate in a Curtius rearrangement before further transformation (Scheme 126).



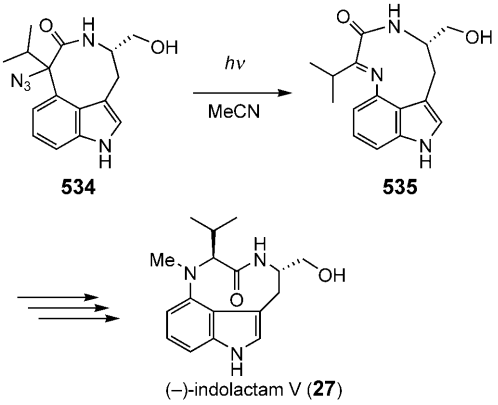
© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Scheme 126. Solid-phase synthesis of amines **524** according to Morishima and co-workers.[505]



4.5.2. *The Schmidt Rearrangement*

The Schmidt rearrangement has been somewhat less extensively investigated than the Curtius rearrangement and usually takes place under pyrolysis or thermolysis conditions (Scheme 127).[506] An alkyl azide is either converted into a nitrene and further rearranges into an imine, or the rearrangement and loss of nitrogen takes place in a concerted manner.



Scheme 127. Gas-phase pyrolysis of alkyl azides according to Bock et al.[506]

Andrieux and co-workers prepared tobacco alkaloids such as nicotine (**533**) with a Schmidt reaction as a key step. The intermediate in the nicotine synthesis is a cyclobutyl azide **529** (Scheme 128).[507]

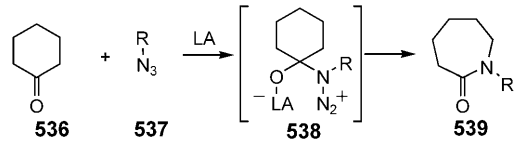
Scheme 128. Synthesis of tobacco alkaloids according to Andrieux and co-workers.[507]

Another application of this rearrangement is the total synthesis of indolactam V (**27**) reported by Moody and Mascal in 1988 (Scheme 129).[508] The preparation is based on a photocyclization reaction of *N*-haloacetyltryptophan, also described by Moody and co-workers[509] and uses the α,α-dichloroisovaleryl amide of tryptophanol as starting material.

Scheme 129. Total synthesis of indolactam **27**.[508]

Further applications are found in the rearrangement of azidocubanes[147] and the synthesis of tetrazoles from fatty acids,[510] and the total synthesis of stenine.[511] In a series of examples, the Schmidt reaction takes place in the presence of Brønsted or Lewis acids. In a few of these cases, for example, in the reaction with aldehydes or ketones, the intermediate imine reacts either in an intermolecular or intramolecular fashion with a further equivalent of azide to form tetrazoles.[512]

4.6. *Reactions of Azides with Electrophiles*



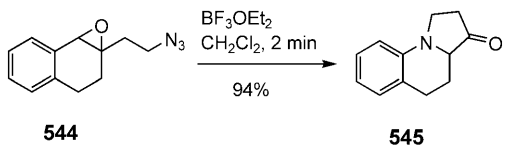
Suitable electrophiles (carbon electrophiles, protons, boranes) normally react with organoazides at N^1, mostly to form initially an amine-substituted diazonium ion, which loses nitrogen. The electron-deficient nitrenium ion usually rearranges or reacts with nucleophiles.

4.6.1. *Boyer Reaction*

In the presence of Lewis acids, organoazides react with carbon electrophiles with framework expansion in analogy to the Schmidt reaction. Suitable (pre)electrophiles include ketones (Aubé[513]), epoxides, or carbenium ions, which can be obtained from alkenes or alcohols through protonation (Pearson[514]) or mercuration.[515] The aminodiazonium ion formed initially loses dinitrogen with simultaneous migration of the alkyl residue to the electron-deficient nitrogen atom. The reaction of aliphatic azides with ketones in the presence of Brønsted acids—the Boyer reaction[516]—occurs in good yields to form *N*-alkylated amides or lactams,[517] but is limited to aliphatic ketones. An improvement was brought about by the observation by Aubé and co-workers that Lewis acids can

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

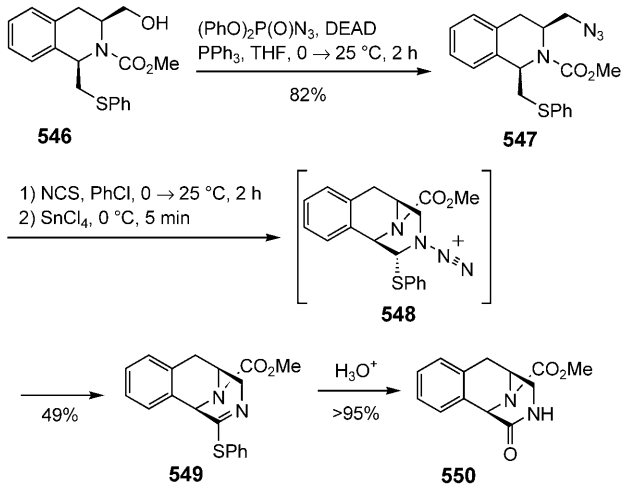
also accelerate this reaction (Scheme 130). α,β-Unsaturated ketones react through another reaction pathway (Scheme 47).



Scheme 130. Boyer reaction according to Aubé and co-workers.[513] LA = Lewis acid.

The asymmetric variant of this Boyer rearrangement was also developed by Aubé and co-workers.[518,519] Prochiral cycloalkanones **540** react with chiral 3-hydroxyalkyl azides **541** in the presence of Lewis acids and yield ring-expanded *N*-alkyl lactams **543** with high diastereoselectivity. Prior to the antiperiplanar migration, the phenyl ring in the intermediate **542** adopts an axial disposition, and the methyl group is arranged equatorially (Scheme 131). The cause of this otherwise unusual behavior lies in the interaction of the phenyl group with the electron-deficient diazonium unit.[519,520]

Scheme 131. The asymmetric Boyer reaction according to Aubé and co-workers.[518]



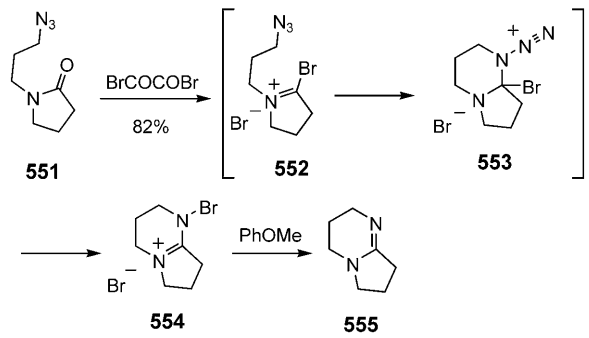
Alternatively, besides ketones, azidoalkyl-substituted epoxides such as **544** can be transformed in an intramolecular reaction (Scheme 132).[521,522] The benzylic nature of the nitrenium ion formed allows the migration of the aromatic residue, and an amino-substituted aromatic system is formed (see Scheme 136).

Scheme 132. The azido-Schmidt reaction with epoxides **544**.[522]

4.6.2. *New Electrophiles for the Synthesis of Imines from Azides: Alternatives to the Aza-Wittig Reaction*

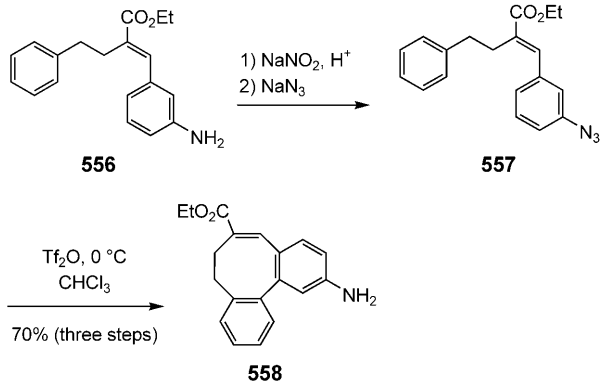
A reaction sequence, the first stage of which is related to the organoazide Schmidt reaction, was reported by Magnus and co-workers in 2003.[523] An α-chlorinated thioether acts as the electrophile, which undergoes intramolecular attack by an alkyl azide with loss of a chloride ion. Unlike the Schmidt reaction, however, both a proton and dinitrogen are lost. The resulting thioimine **549** then releases an amide functionality under hydrolytic conditions. The overall reaction sequence thus corresponds to an aza-Wittig reaction (Scheme 133).

Scheme 133. Intramolecular alkylation of azides according to Magnus and co-workers.[523]



A related reaction sequence for the preparation of imines from azides was reported recently by Shibasaki and co-workers.[524] They observed that a number of azidoalkyl lactams **551** reacted only slowly, if at all, under Staudinger–aza-Wittig conditions with formation of the corresponding amidines. A search for suitable reagents led to oxalyl bromide/anisole as an efficient reagent combination. A bromoaminium ion is probably formed which acts as an electrophile and attacks the azide group. The resulting aminodiazonium ion **553** loses dinitrogen with migration of the bromine atom to the nitrogen atom. A dipolar mechanism has been proposed as an alternative. In any case, anisole then removes the electrophilic bromine, leading finally to the amidine **555** (Scheme 134).

4.6.3. *Nitrenium Ions by Protonation of Organoazides*



According to Bamberger, the protonation of organoazides with strong acids (e.g. TFA) gives aryl or alkyl nitrenium ions that are analogous to carbocations.[525–527] Aryl nitrenium ions are highly reactive intermediates, which react as electrophiles in either inter- or intramolecular[336] reactions with aromatic groups (Scheme 135).[526,528] The high reactivity is an argument for the carcinogenicity of such compounds.[529]

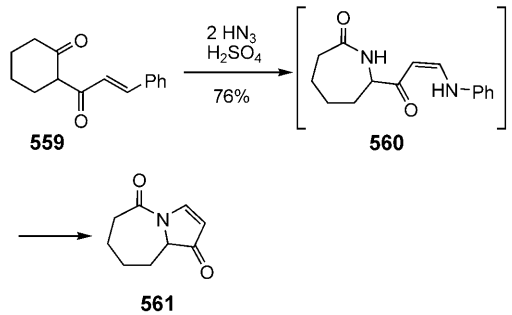
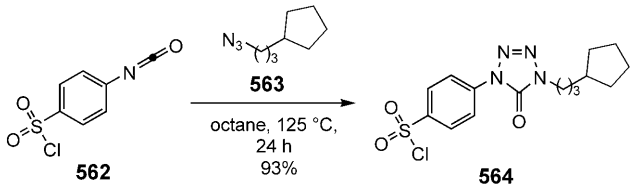


Scheme 134. Intramolecular synthesis of amidine **555** according to Shibasaki and co-workers.[524]

Scheme 135. Intramolecular cyclization of aryl nitrenium ions.[526]

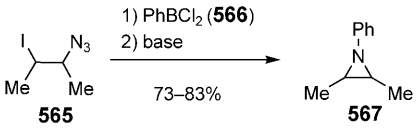


Boyer addition, also involves the participation of nitrenium ions.[532] This rearrangement takes place through an intramolecular electrophilic substitution and subsequent ring opening of the resulting aziridine to form an iminium ion. Hydrolysis then gives the aniline derivative. In the case of cyclohexanone-substituted ketones of type **559**, insertion of nitrogen atoms from 2 equivalents of HN_3 leads to the enamine **560**, and cyclization produces the unsaturated lactams **561** (Scheme 136).[533]

Scheme 136. Double rearrangement of the Schmidt type according to Casey et al.[533]

4.6.4. ***Reaction of Organoazides with Heterocumulenes***

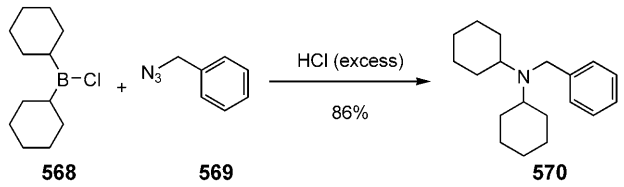
The reaction of organic azides with aryl isocyanates takes place rapidly and in the presence of excess azide gives 1,4-disubstituted Δ^2-tetrazoline-5-ones in very good yields.[534,186] The addition is largely chemoselective, so that even sensitive functions such as the sulfonyl chloride group are not attacked (Scheme 137).[535] Alkoxycarbonyl isocyanates, sulfonyl isocyanates, and isothiocyanates react with organic azides in the same manner to form Δ^2-tetrazoline-5-ones.[536]



Scheme 137. Selective addition of alkyl azide **563** to 4-isocyanatobenzenesulfonyl chloride (**562**).[535]

4.6.5. ***Reaction of Organoazides with Boron Compounds***

According to an early observation by Brown et al., trialkyl boranes react with aromatic and aliphatic azides to form secondary amines.[537] The formation of nitrogen follows second-order kinetics so that a mechanism that proceeds via a nitrene intermediate is excluded. The organoboranes react reversibly with the organoazides, which subsequently react further with loss of nitrogen and simultaneous migration of the alkyl groups from the boron to the nitrogen. This reaction follows a similar but relatively older observation of Paetzold and Habereder on the decomposition of azidoboranes.[538]

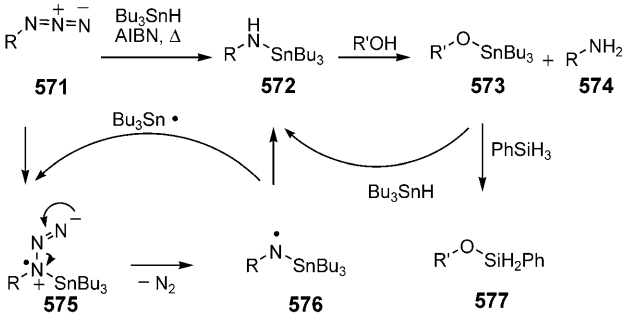


As the steric demand of the alkyl residue increases, the reaction slows down significantly, and the yields decrease. Haloboranes such as monochloro-,[539] dichloro-,[540,541] and difluoroboranes[542] or their precursors such as aminoboranes in the presence of anhydrous HCl[543] can be used likewise and even advantageously[469,539] because they are more reactive. Only dibromoboranes react differently, with simultaneous formation of tetraazaborolines.[544] In the presence of alkylating agents, subsequent alkylation occurs, as in the synthesis of the aziridines **567** (Scheme 138).[539]

Scheme 138. Arylation of organoazides with boranes and subsequent intramolecular alkylation.[539]

As dichloroboranes can be prepared readily in enantiomerically pure form by diastereoselective hydroboration and subsequent transformation, α-chiral amines are readily accessible.[545] This reaction sequence also proceeds in an intramolecular fashion with the synthesis of chiral cyclic amines.[542] Under certain conditions, two alkyl groups can be transferred (Scheme 139).[543]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim



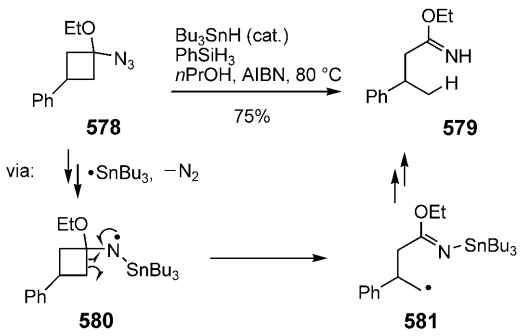
Scheme 139. Alkylation of organoazides with boranes.[543]

4.6.6. Reaction of Organoazides with Heteroelectrophiles

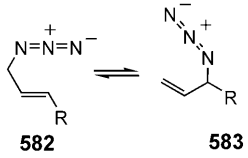
The reaction of aliphatic and aromatic azides with HOF/CH_3CN leads to an immediate oxidation with formation of nitro compounds. Initially, the electrophilic oxygen atom in HOF is attacked with concomitant loss of HF and dinitrogen. The nitroso compound is thus formed and reacts further to form the nitro compound. This single-step reaction is simpler than other variants.[546]

4.7. Radical Additions to Organoazides

The addition of tributyltin radicals to organoazides **571** leads initially to triazenyl radicals **575**. Loss of nitrogen leads to amine radicals **576**, which finally react with tributyltin hydride to give **572** (Scheme 140).[486a] The latter are transformed into the amines **574** with phenylsilyl hydride in the presence of alcohols. Tributyltin hydride is regenerated so that only catalytic amounts are needed.



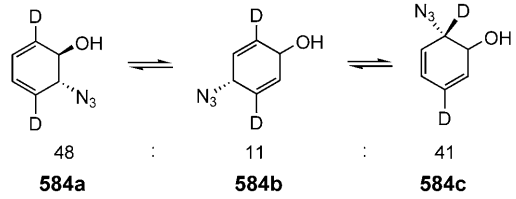
Scheme 140. Reduction of organoazides with phenylsilyl hydride under tributyltin hydride catalysis.[486] AIBN = 2,2′-azobis(isobutyronitrile).



The radical reaction mechanism is confirmed by the conversion of cyclobutane azide **578** which proceeds through ring opening (Scheme 141). A few synthetically very useful azide-transfer reactions also proceed through a radical mechanism (see Scheme 27, Scheme 42).[145,206]

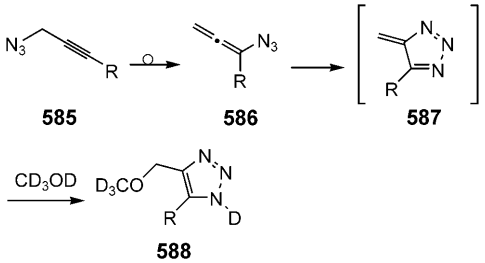
4.8. [3,3] Sigmatropic Rearrangements and Electrocyclizations of Organoazides

The rearrangement of allyl azides (Scheme 142) was first reported by Gagneux, Winstein, and Young in 1960, and has since then been observed with different substrates, including



Scheme 141. Ring opening of azidocyclobutanes **578**.[486,547]

Scheme 142. Sigmatropic rearrangement of allyl azides.[549]



substituted cyclopropene azides.[548–551] This [3,3] sigmatropic rearrangement takes place even at low temperatures.

In the case of azidocyclohexadienes, all possible products are in thermal equilibrium (Scheme 143).[548] In some cases, a mixture of all possible products is also formed in the synthesis of allyl azides.[552]

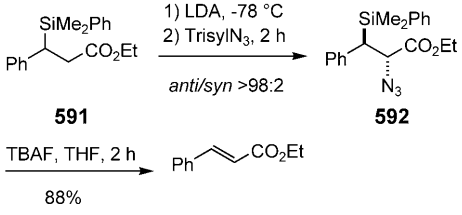
Scheme 143. Consecutive sigmatropic rearrangements of cyclohexadienyl azides **584**.[548]

The propargyl azides **585** rearrange to the less stable allenyl azides **586** (Banert cascade, Scheme 144).[255] The short-lived allenyl azides **586** cyclize rapidly to the triazafulvenes **587**, which in the presence of a nucleophilic trapping reagent (e.g. $[D_4]$MeOH) form the corresponding 1,2,3-triazoles **588** quantitatively. In the absence of a nucleophilic trapping reagent, the allenyl azides polymerize.

Scheme 144. Preparation of 1,2,3-triazoles from allenyl azides.[255]

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

C-Azidoimines **589** can form tetrazoles **590** in a reversible electrocyclic reaction (Scheme 145).[553] These *C*-azidoimines **589** are formed, for example, in a Mitsunobu reaction of amides with trimethylsilyl azide and in most cases, rearrange directly to the tetrazoles **590**. This reaction is complementary to the cycloaddition of organoazides with nitriles.[554]



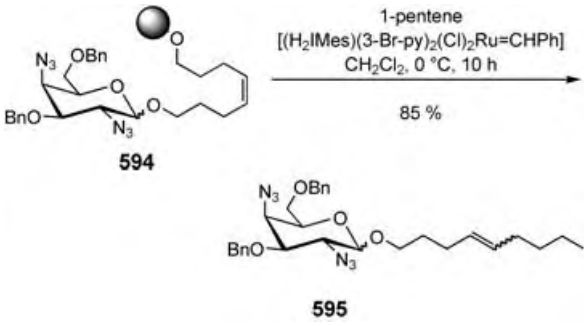
589 **590**

Scheme 145. Electrocyclization of *C*-azidoimines **589** to tetrazoles **590**.[553]

4.9. Azide Ions as Leaving Groups

Aliphatic azides can be either eliminated or substituted by suitable organic bases or nucleophiles. In this case, the property of the azide as pseudohalogen comes to the fore. Thus β-silyl azides **592** undergo *anti* elimination stereoselectively in the presence of fluoride ions to give the olefins **593**.[134] The corresponding silanes **591** are readily accessible either through haloazidation of silylalkanes (Scheme 24) or by electrophilic azidation of enolates (Scheme 146). Whereas sterically unhindered aliphatic azides are reduced smoothly to amines with Ni(II)/Bu_3SnH (see Section 4.4.2), this reagent effects substitution of the azide group by hydride with benzylic azides.[486a]

591 **592** **593**



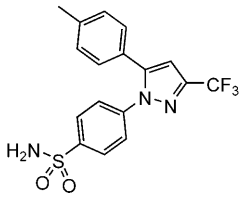
Scheme 146. Synthesis and elimination of β-silyl azides **592**.[134] Trisyl = 2,4,6-triisopropylbenzenesulfonyl.

5. Applications of Azides

5.1. Use as Protecting Groups

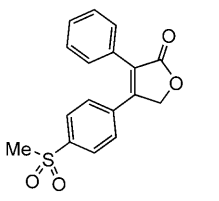
The azide function provides a good possibility to protect coordinating primary amines, especially in sensitive substrates such as oligosaccharides, aminoglycoside antibiotics,[152,155] glycosoaminoglycans such as heparin[556] and peptidonucleic acids (PNA).[557] Furthermore, the azide group is stable in osmium-[558] and ruthenium-induced[559] dihydroxylations or alkylations (see Scheme 44).

The protection of the amino function is carried out with, for example, triflyl azide (see Schemes 28 and 29). A more recent example of the stability of alkyl azides towards organometallic catalysts in this context was provided by Seeberger and co-workers, who demonstrated the compatibility of the azido group in cleaving alkene metathesis of saccharides (Scheme 147).[560]



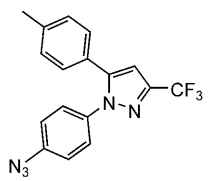
594 **595**

Scheme 147. Cleavage metathesis of organoazides.[560]



In addition to its use as a protecting group, the azide function provides other creative possibilities, for example, in the aza-Wittig reaction.

5.2. Azides as Biologically Active Compounds and in Natural Products Synthesis



A number of syntheses for the preparation of natural products have been described in the text,[78,80,114b,386,514f,517,561] (see Schemes 6, 20, 22, 30, 36, 44, 74, 78, and 108). Although no natural products are (yet) known with an azide functionality, there is a series of potentially active compounds with this functionality. The high activity can be seen in bioisosteric comparisons of the azide group with other functional groups (see also Section 4.1.2).[562] Parallels have been drawn between the methylsulfonyl and aminosulfonyl groups. The relatively smaller azide group is slightly more lipophilic than these two groups, and, for example, interacts better with arginine units than with sulfonyl functions. Azide derivatives (such as **598**) of the COX-2 inhibitors colecoxib (**596**) and rofecoxib (**597**) are also more potent than the corresponding sulfone derivatives.[563] Comparisons between a 1,1-dichloroethyl group (as in chloramphenicol) and the azidomethyl group have shown that they exhibit similar behavior. A well-

celecoxib (**596**)

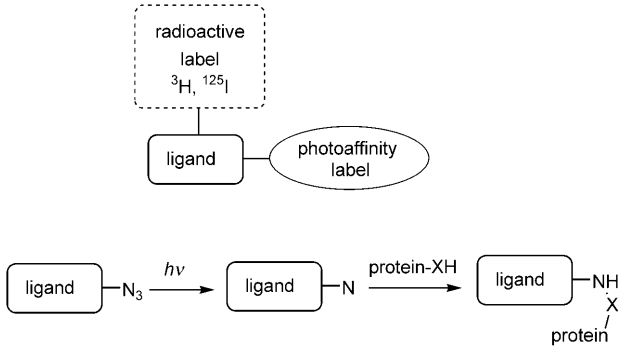
599

known example is the anti-HIV medication AZT (**599**; 3′-azido-2′,3′-didesoxythymidine).[564,565]

5.3. *Photoaffinity Labeling*

The labeling of receptor compounds and ligands with the azide functionality is used in photoaffinity labeling.[566,567] The ligand is equipped with this nitrene precursor at a position (for thalidomide see Scheme 2) that does not distort its affinity for the receptor, but yet is close enough to its target protein. The azide group is particularly suitable for this labeling since after photolysis the organoazide can be inserted into many carbon, nitrogen, oxygen, or sulfur compounds by the formation of nitrenes. An additional radioactive label can also be used to identify the ligand–protein complex (Figure 4).



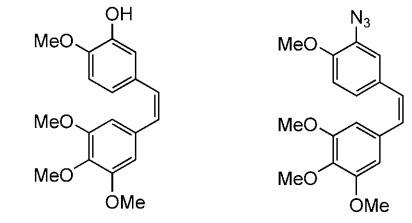


Figure 4. The principle of photoaffinity labeling.

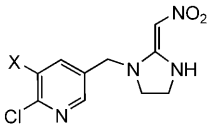
This principle was used, for example, in the synthesis of combrestatin analogues as molecular probes for tubulin polymerization (Figure 5).[568] Furthermore, there have recently been a number of applications in medicinal chemistry.[569]



combrestatin A-4 (**600**)

azide-analogous combrestatin A-4 (**601**)

Figure 5. Aryl azides as molecular probes according to Pinney et al.[568]

This process has also been used in modern plant protection research to analyze, for example, the interaction of proteins with insecticides, as in the neonicotinoids (e.g. imidacloprid (**607**), Figure 6).[570] In this connection it was important that the biological properties of the labeled compounds differ only little from the starting compound. The lipophilicity of organic azides has a direct advantage here.

X = H: imidacloprid (**602**)
X = N_3: 5-azidoimidacloprid (**603**)

Figure 6. Heteroaryl azides as molecular probes according to Zhang and co-workers.[570]

Not only can the interaction of small molecules with proteins[571] be investigated by photolabeling with organoazides but also protein–protein [572] and protein–nucleic acid interactions.[573]

The photoaffinity labeling can also be carried out in an intramolecular fashion, which leads to crosslinking. One current example is the covalent bonding of an RNA duplex strand with an internally attached aryl azide (**606**) by photolysis. It was crucial that a hydroxy group occupied the 3-position of the aryl azide **606**, for in this way the evidence was obtained that a ketene imine or a corresponding sequential product as active species leads to the crosslink under nucleophilic attack by the antisense strand (Figure 7).[574]

6. Summary and Outlook

Organic azides have in recent times enjoyed much popularity in synthetic organic chemistry. In spite of—or perhaps because of—their partly less attractive properties (explosiveness, toxicity), a plethora of new applications has been published. In the area of cycloadditions, in particular, the discovery of new reaction conditions has led to a true "explosion" of new applications. It remains to be seen how organic azides will find use in chemical biology or in materials science.

Addendum (April 7, 2005)

Since the submission of this Review, the number of articles on organic azides has continued to increase tremendously—on average, there are more than 1000 publications a year. We refer to some of the excellent papers that have appeared most recently.[575]

Organic azides were used as flexible building blocks in the partial synthesis of some very complex natural products;[576] modern techniques in gene technology have even allowed the incorporation of biochemically modified amino acids as "proteogenes" in peptides.[577]

The 1,3-dipolar cycloaddition of alkynes with azides, an application of the Huisgen reaction in the field of "click chemistry", was discussed several times in review articles.[578] The number of applications of this useful reaction is steadily increasing.[579] The reaction has been optimized considerably, especially in biochemical applications,[580] such that larger biomolecules can also participate in this type of reaction.

 © 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

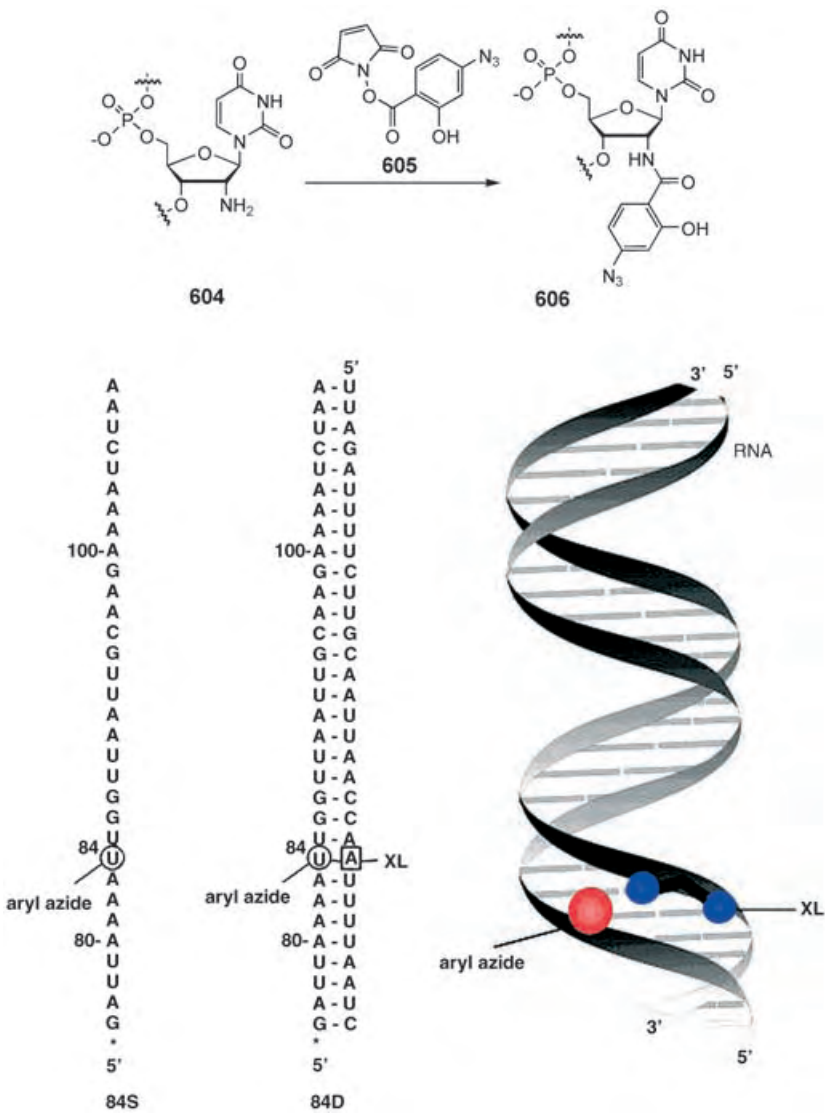


Figure 7. 3-Hydroxyaryl azides as crosslinkers according to Platz, Weeks et al.[574] *: Position of a radioactive ^{32}P label, XL = crosslinking.

Furthermore, this reaction can even take place in enzyme pockets.[581] Consequently, the mechanism of the 1,3-dipolar cycloaddition of alkynes with azides has been investigated in depth.[582] Moreover, polymers can also be prepared in this manner.[583] Azides have also been employed in other cycloadditions.[584]

The Staudinger reaction[585,586] and its application as a ligation method for the conjugation of biomolecules has been widely popular among bioorganic chemists[587] and was used in the synthesis of complex structures.[588] Investigations into the mechanism of this reaction have also been carried out.[589]

Further applications include radical reactions,[590] multicomponent reactions,[591] rearrangements,[592] and several well-known reactions such as the Curtius,[593] Hemetsberger–Knittel,[594] Schmidt,[595] Mitsunobu,[596] and Wittig (aza-Wittig)[597] reactions. Diazido iodinate (formed in situ or polymer-bound) was used in a safe azidation of aldehydes and benzyl ethers.[598] Organic azides are also important structural motifs in the field of high-energy materials, for example, in the synthesis of tetrazolylazide[599] and as precursors in materials research.[600] The rearrangement of organic azides has been investigated within organic cavitands[601] as well as spectroscopically.[602]

We thank G. Bucher, R. Breinbauer, A. Hirsch, T. M. Klapötke, J. Podlech, and J. L. Radkiewicz for the availability of preprints, schemes, and comments, and B. Lesch and S. Vanderheiden for their critical reading of the manuscript. We thank the referees for critical suggestions for improvement. Our work was supported by the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, and the European Union (Marie-Curie-Fellowship (Program "Improving Human Research Potential and the Socio-Economic Knowledge Base) to C.G.).

[10] According to a Chemical Abstracts search, an average of over 1000 publications a year have been published on the topic of azides over the last few years.
[11] a) T. M. Klapötke, B. Krumm, P. Mayer, I. Schwab, *Angew. Chem.* **2003**, *115*, 6024–6026; *Angew. Chem. Int. Ed.* **2003**, *42*, 5843–5846; b) R. Haiges, J. A. Boatz, A. Vij, M. Gerken, S. Schneider, T. Schroer, K. O. Christe, *Angew. Chem.* **2003**, *115*, 6027–6031; *Angew. Chem. Int. Ed.* **2003**, *42*, 5847–5851.
[12] 1*H*-Triazirines have not been observed previously,[13] but N_3H should have less strain energy (198.3 kJ mol^{-1}) than the homologous cyclopropenes: M. N. Glukhovtsev, R. D. Bach, L. Laiter, *Int. J. Quantum Chem.* **1997**, *62*, 373–384. A CAS search also gave no results; in a few publications the saturated heterocycle (triaziridine) has been called triazirine.

Silver carboxylates react with silylated sulfur compounds to yield the cluster complexes $[Ag_{123}S_{35}(StBu)_{50}]$ and $[Ag_{344}S_{124}(StBu)_{96}]$. The nanoscopic clusters have an ordered outer shell that comprises {AgS*t*Bu} groups, while the $\{(Ag_2S)_n\}$ core is disordered. For more information, see the Communication by D. Fenske et al. on the following pages.

Syntheses and Crystal Structures of $[Ag_{123}S_{35}(StBu)_{50}]$ and $[Ag_{344}S_{124}(StBu)_{96}]$**

Dieter Fenske, Christopher E. Anson, Andreas Eichhöfer, Olaf Fuhr, Arnd Ingendoh, Claudia Persau, and Clemens Richert*

Dedicated to Professor Malcolm H. Chisholm on the occasion of his 60th birthday

We have recently reported the syntheses of metal-rich silver chalcogenide clusters.[1] Examples of these are $[Ag_{70}S_{16}(SPh)_{34}(PhCO_2)_4(triphos)_4]$, $[Ag_{70}S_{20}(SPh)_{28}(dppm)_{20}](CF_3CO_2)_2$, $[Ag_{188}S_{94}(PnPr_3)_{20}]$, and $[Ag_{262}S_{100}(StBu)_{62}(dppb)_6]$ (triphos = 1,1,1-tris(diphenylphosphinomethyl)-ethane, dppm = bis(diphenylphosphino)methane, dppb = 1,4-bis(diphenylphosphino)butane). These compounds are formed in high yield by the reaction of silylated sulfur compounds with silver salts. The reaction of $AgCF_3CO_2$ with $PnPr_3$ and $S(SiMe_3)_2$ yields $[Ag_{188}S_{94}(PnPr_3)_{20}]$, whereas $[Ag_{262}S_{100}(StBu)_{62}(dppb)_6]$ is formed from the reaction of $AgPhCO_2$ and dppb with a mixture of $S(tBu)SiMe_3$ and $S(SiMe_3)_2$ in THF.[1] Both compounds contain unusual sections of the structure of binary silver sulfide;[2–4] these Ag–S cluster cores are surrounded by tertiary phosphines or S*t*Bu groups. Such compounds can be regarded as intermediary stages in the formation of Ag_2S, in which phosphine and S*t*Bu ligands have inhibited further growth of the cluster core towards crystalline Ag_2S. A striking feature of these structures is the tendency to disorder shown by the anions and cations. In this respect the molecules already possess to a large extent the properties of the binary Ag_2S phase.[2–4] $[Ag_{188}S_{94}(PnPr_3)_{20}]$ is a spheroidal molecule which has a Ag_2S core with a diameter of 1.9 nm. In $[Ag_{262}S_{100}(StBu)_{62}(dppb)_6]$ the molecules have the form of oblate ellipsoids, in which the Ag–S cluster has a maximum diameter of 2.6 nm. In the course of studying size-dependent properties, such as the conductivity of electrons and Ag^+ ions, which could also possibly be studied in single molecules, we have attempted to synthesize further examples of this class of molecules.

To prepare $[Ag_{123}S_{35}(StBu)_{50}]$ (**1**), a suspension of $AgCH_3CO_2$ and 1,4-bis(diphenylphosphinomethyl)benzene (dppxy) in toluene is treated with a mixture of $S(tBu)SiMe_3$ and $S(SiMe_3)_2$. A red solution results, from which, over a few days, dark brown crystals of **1** are formed [Eq. (1)].

$$AgCH_3CO_2 + 0.9\,S(tBu)SiMe_3 + 0.5\,S(SiMe_3)_2 \xrightarrow[\text{toluene}]{0.25\,\text{dppxy}} \mathbf{1} \quad (1)$$

$[Ag_{344}S_{124}(StBu)_{96}]$ (**2**) is formed by the analogous reaction of $AgPhCO_2$, dppxy, $S(tBu)SiMe_3$, and $S(SiMe_3)_2$ in toluene [Eq. (2)]. It can also be prepared by treating AgS*t*Bu with $S(SiMe_3)_2$ in toluene [Eq. (3)]. In both cases, a red solution forms initially, which darkens after a few days. After several weeks, black crystals of **2** form. The formation of **1** and **2** apparently occur via an intermediate, as red crystals appear in the red solution and later dissolve. However, the structures of these red compounds have so far not been determined.

$$AgPhCO_2 + S(tBu)SiMe_3 + 0.5\,S(SiMe_3)_2 \xrightarrow[\text{toluene}]{0.25\,\text{dppxy}} \mathbf{2} \quad (2)$$

$$AgStBu + 0.5\,S(SiMe_3)_2 \xrightarrow[\text{toluene}]{0.25\,\text{dppxy}} \mathbf{2} \quad (3)$$

In contrast to the above-mentioned Ag_{188} and Ag_{262} clusters, which are formed under similar conditions, **1** and **2** do not contain phosphine ligands. Apparently dppxy is necessary for the formation of these compounds, because otherwise a mixture of Ag_2S and AgS*t*Bu is obtained. The formation of **2** from the reaction of AgS*t*Bu with $S(SiMe_3)_2$ in the presence of dppxy is not understood; possibly $S(tBu)SiMe_3$ is formed as a leaving group.

A crystal structure analysis[5] shows that **1** crystallizes in the space group $R\bar{3}c$ with six molecules per unit cell and 15 toluene molecules per formula unit. Assuming the presence of a cluster molecule with the formula $[Ag_{123}S_{35}(StBu)_{50}]$, then cluster should be a cation with a charge of 3+. However, a close inspection of the structure did not reveal the presence of $CH_3CO_2^-$ counterions. It is therefore assumed that there is a nonstoichiometric Ag:S ratio, as has been found in other metal chalcogenide clusters.[1,11] This situation is not surprising, because this effect is also observed in solid Ag_2S.[3]

From Figure 1, it can be seen that the sulfur atoms of the S*t*Bu groups act either as μ_2- or μ_3-ligands (μ_2: Ag–S (S1, S2, S4): 2.400–2.439(5) Å; μ_3 Ag–S: (S3, S5–S9): 2.211–2.686(4) Å).[5] The S^{2-} ions show a range of bonding modes. S11 is a μ_4-ligand with Ag–S distances of 2.392–2.576(3) Å. In contrast, S10 and S12–S14 are bonded as μ_5-ligands and S15 and S16 as μ_7-ligands ((μ_5-S)-Ag: 2.346–2.953(3) Å; (μ_7-S)-Ag: 2.585–2.937(5) Å).

The silver atoms Ag2, Ag5, Ag8–Ag10, Ag12, Ag13, Ag16, and Ag18–Ag20 are coordinated by two sulfur atoms in a nearly linear arrangement (Ag–S: 2.387–2.594(5) Å; S-Ag-S: 131.2–172.5(1)°). The Ag atoms Ag1, Ag4, Ag5, Ag7, Ag11, Ag14, Ag17, Ag21, and Ag23 (Ag–S: 2.211–2.960(4) Å) are each linked to three sulfur atoms in a quasiplanar environment. Ag6 has a distorted tetrahedral coordination of four sulfur atoms (Ag–S: 2.529–2.687(3) Å),
