Uniform arrays of metallic nanotubes can be prepared with a newly developed electrochemical method. In their Communication on page 6050 ff., W. Lee et al. report the preparation of multisegmented metallic nanotubes with a bimetallic stacking configuration along the nanotube axis. The approach is based on the preferential electrodeposition of metal along the pore walls of anodic alumina membranes in the presence of metallic nanoparticles on the nanochannel surfaces.

Nobel Lectures

Ubiquitin-mediated protein degradation is the focus of this year's Nobel Lectures by Irwin Rose, Avram Hershko, and Aaron Ciechanover. The prizewinners report first-hand in three Reviews on page 5926 ff.

Lithium Hydride

A Li_4H_4 cube coordinated by three bis(amino)alane units is reported by M. Veith et al. in their Communication on page 5968 ff. The compound was isolated and characterized by X-ray crystallographic analysis.
Triple Bonds with Ge

The first compounds with the structural unit {M≡Ge−Ge≡M}, in which a Ge_2 unit is bound between two transition-metal centers through triple bonds, is described by A. C. Filippou et al. on page 5979 ff. The M≡Ge bonds are weakly conjugated within the linear chain.

Protein Breakdown

Protein breakdown is an exact, controlled process in which the protein molecule ubiquitin plays a decisive role by binding to a protein and labeling it for breakdown. The cellular mechanisms of this process are widely known today thanks to the work of the 2004 Nobel Laureates Irwin Rose, Avram Hershko, and Aaron Ciechanover. The Laureates report at first hand in their Nobel Lectures.
Communications

One in seven: A Li_4H_4 unit that is coordinated with three bis(amino)alane units takes the form of a cube; the compound was isolated in molecular form and characterized by X-ray analysis (see molecular structure; pink Li, blue N, gray Al, white H, yellow Si). During the reaction of this molecule with an equimolar amount of water only one of the seven H atoms reacts to give the hydrolysis product $Li_4H_3(OH)[HAl\{N(SiMe_3)\}_2]_3$.
The Lewis acid $TiCl_4$ allows the intermolecular hydroamination of vinylarenes (see scheme). Some of the hydroamination products undergo rearrangements to give *ortho*-alkylated compounds. The catalyst tolerates a range of functional groups ($R' = CF_3$, Cl, CN, F, Br) and provides the products in good yields. This method was also applied to the synthesis of a tetrahydroisoquinoline derivative.
Green light for alkene metathesis: A strong σ-donor ligand L favors the active conformation (green in the scheme) of the carbene ligand in the ruthenium complex and thus leads to high catalytic activity of the second-generation Grubbs catalysts.

1

Going straight: Thermolysis of the germylidyne complexes *trans*-[Cl(depe)$_2$M≡Ge(η^1-Cp*)] (M = Mo, W; depe = Et$_2$PCH$_2$CH$_2$PEt$_2$, Cp* = C$_5$Me$_5$) leads upon cleavage of the Ge–Cp* bond to **1**, the first compounds in which a Ge$_2$ unit is trapped between two transition-metal centers by triple bonds. Quantum chemical analyses suggest a weak conjugation of the M–Ge triple bonds in the linear chain M≡Ge–Ge≡M.

1
A spoonful of sugar ... A carbohydrate-based fully synthetic vaccine **1**, composed of a tumor-associated Tn antigen, a peptide T epitope, and a lipopeptide (see structure), shows potential as a candidate against cancer. Incorporation of the glycolipopeptide into liposomes gave a formulation that was able to elicit a T cell dependent antibody response in mice.
Pro and anti: Recognition of chloride ion and through-membrane H$^+$/Cl$^-$ ion transport ("symport") could account for the biological effects (anticancer activity) of prodigiosin, as inferred from model studies involving pyrrole-based anion receptors designed to mimic the key features of this naturally occurring pigment (see picture).

Expanding our synthetic tool repertoire: The DMP-mediated oxidation of a range of amide substrates has been demonstrated, affording the corresponding imides and *N*-acyl vinylogous carbamates and ureas. Likewise, an array of benzylic and related amines have also been successfully converted into their nitrile counterparts (see scheme; DMP = Dess–Martin periodinane).
Contents

Space program: A general template technique has been developed that enables various Au/Pt nanostructures, such as macroporous 3D films and nanostructures constructed from hollow spheres, to be prepared on silicon wafers and glass substrates (see SEM image). These ordered metallic nanostructures with hierarchical porosity could be useful in industrial applications, including catalytic nanoreactors, sensors, porous electrodes, and fuel cells.
Helpful neighbors: $[Pd\{2\text{-}(OH)C_6H_4\}I(tmeda)]$ reacts at room temperature with excess RCN (R = Me, C_6F_5, $CH_2=CH$) and TlOTf (1 equiv) to give $[Pd\{1\text{-}O\text{-}2\text{-}[C(R)=NH]C_6H_4\text{-}\kappa^2\text{-}O,N\}(tmeda)]OTf$ (see scheme). The proximal OH group plays a crucial role in this first example of the insertion of a nitrile into a late-transition-metal–carbon bond. Tf = trifluoromethanesulfonyl, tmeda = N,N,N',N'-tetramethylethylenediamine.

Selective nucleation of aragonite can be achieved at ambient conditions in water by using block copolymer microgels at a very low concentration (0.1 ppm). One polymer template particle is sufficient to control the nucleation of a ring of aragonite single crystals, which propagate into a sheaf structure (see SEM image). Each aragonite crystal is protected by an outer amorphous layer that results in prolonged stability of the aragonite.
On-again, off-again personality: Superhydrophobic conducting polypyrrole (PPy) films are synthesized through a facile electrochemical process. The PPy films exhibit an extended porous structure with both coarse- and fine-scale roughness (see image). By controlling the electrical potential, PPy films can be switched between the oxidized state and the neutral state, resulting in reversibly switchable superhydrophobic and superhydrophilic properties.
A mosaic pattern: Single virus particle nanoarrays can be made through the positioning and orientation of viral particles on nanotemplate surfaces generated by dip-pen nanolithography. Viral immobilization was characterized with antibody–virus recognition and infrared spectroscopy (an example array of particles is shown in the AFM image).

Heterobimetallic sulfides of composition [LAl(μ-S)$_2$MCp$_2$] (M = Ti, Zr) react smoothly with two equivalents of water by ring opening and chalcogen exchange to form the heterobimetallic oxide–hydroxide–hydrogensulfides [LAl(OH)(μ-O)MCp$_2$(SH)] (Ti derivative shown). The presence of the hydrolysis intermediate [LAl(SH)(μ-O)MCp$_2$(SH)] in the reaction mixture confirms the proposed pathway.
Deprotonative metalation of ferrocene by a lithium zincate reagent was carried out to form the neutral zinc complex [(Fc)$_2$Zn(tmeda)] and the anionic zincate [Li(thf)$_4$][(Fc)$_3$Zn] (see scheme; tmp = 2,2,6,6-tetramethylpiperidine, TMEDA = N,N,N′,N′-tetramethylethylene-diamine). A 1:1:1 mixture of TMEDA, Li(tmp), and nBu$_2$Zn is used to readily prepare the lithium zincate reagent [LinBu$_2$Zn(tmp)(tmeda)] in situ.
Screw top: Photoelectron spectroscopy of doubly charged [FeCp′$_2$] (**1**) and singly charged [Cp′FeCp′H] (**2**; Cp′ = η^5-C$_5$H$_4$CO$_2^-$) shows that strong intramolecular coulomb repulsion keeps **1** in the trans form, with the two CO$_2^-$ groups on the Cp′ ligands oriented opposite to each other, whereas **2** assumes the cis form owing to formation of a strong intramolecular H bond. Fe blue, O red, C gray.

Contents

From linear to dendritic: Glycine is part of the predominant sequence in collagen proteins, and aspartate is similar to the repeating unit of poly(benzyl glutamate)s (PBG)s. Collagen and PBGs are linear peptides that self-organize into fibers and form liquid-crystalline phases and gel solvents. How would a molecule self-assemble if it was built by arranging Gly-Asp units in a dendritic way (see picture)? A dendron as both gelator and liquid crystal?
Gelator? Liquid crystal?
Aminic or iminic: Two tautomeric forms of oxidized guanosine have been produced by chemical radiation methods—by direct oxidation of guanosine or from the protonation of the 8-bromoguanosine electron adduct—and identified. The tautomerization from the iminic to the aminic arrangement has an activation energy of 23.0 kJ mol^{-1} and occurs through a complex transition state (see scheme).

When normal is a surprise: Studies of a ligand-substitution reaction of a Pt^{II} complex (see picture; apa: 2,6-bis(aminomethyl)pyridine) in water, methanol, and the ionic liquid 1-butyl-3-methylimidazolium bis(trifluoromethylsulfonyl)amide reveal that the ionic liquid behaves "normally", that is, as any other solvent. In the ionic liquid, changes in the polarity of the transition state only play a minor role.
$[Pt(apa)Cl]^+ + Nu \longrightarrow [Pt(apa)Nu]^{2+} + Cl^-$
A clever way to clavolonine: The total synthesis of the lycopodium alkaloid clavolonine (**2**) from a linear precursor **1** that contains the complete 16-carbon-atom chain is reported (see scheme). Intramolecular and transannular cascade reaction sequences are explored from both linear and macrocyclic precursors. A variety of polycyclic structures are rapidly constructed from simple acyclic precursors.
Natural product inspired asymmetric catalysis resulted from an effort directed toward colombiasin A and related complex targets. The discovery of highly selective quinone Diels–Alder reactions catalyzed by the new, monomeric [(Schiff base)Cr^{III}] complex **1** was a requisite step in the synthetic endeavor (see scheme; TES = triethylsilyl, DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene).
A made-to-order asymmetric catalytic reaction was applied in the key quinone Diels–Alder step of the total syntheses of the title compounds (see scheme for the synthesis of colombiasin A). The reaction was highly regio- and diastereoselective.

Bimetallic nanotubes: Uniform arrays of metal nanotubes were prepared by the electrodeposition of a thin metallic film on the pore walls of anodic aluminum oxide membranes decorated with metallic nanoparticles. Multisegmented nanotubes with a bimetallic stacking configuration along the nanotube axis can be fabricated (see picture). The technique is applicable to a wide variety of conducting and semiconducting materials.
A pair to fret about: Biotinylated phosphor nanoparticles that emit upconversion luminescence have been taken with biotinylated Au nanoparticles, which act as energy acceptors, and the pair has been applied to the determination of trace amounts of avidin based on fluorescence resonant energy transfer (FRET; see picture).

Contents
Good to high conversions (70–100 %) into optically active tri- or tetracyclic nitrogen-containing compounds **1** based on 1,2-dihydroisoquinolines and 1,2-dihydro- phthalazines proceed with high diastereoselectivity (d.r. $\geq$ 15:1) and good to excellent enantioselectivity (85–96 % *ee*) in the presence of a chiral amine.
In rare form: Although the structure of the body-centered cubic (bcu) net is commonly found in textbooks, its eight-connected topology is extremely rare in metal–organic frameworks owing to severe geometric requirements. The first example of a highly porous, neutral bcu-type framework (see picture) assembled from a unique eight-connected tricopper cluster and a 5-(4-pyridyl)tetrazolate ligand as linker is reported.
The heavy-atom effect cannot explain the difference in the third-order nonlinear optical properties of the clusters $[Ag_{10}(dcapp)_4](OH)_2 \cdot 12\,H_2O$ (**1**, see structure), $[Zn_4O(dcapp)_3] \cdot 6\,H_2O$ (**2**), and $[Hg_2(dcapp)_2]$ (**3**) (H_2dcapp = 2,6-dicarboxamido-2-pyridylpyridine). Quantum chemical calculations show that the NLO properties of **1** are controlled both by the metal and the ligand, while those of **2** and **3** are controlled by the ligand only.
Tiles go down the tube: A novel method for the preparation of DNA tubes by using the DNA tile system with the assistance of a four-way-branched DNA–porphyrin connector is described (see schematic representation). The detailed DNA tube structures were characterized by atomic force microscopy.

A light switch: The mechanism of transmission of the photoinduced torsional strain along a cyclic peptide, incorporating a biomimetic photochemical switch, is resolved by quantum mechanics/molecular mechanics and molecular dynamics simulations. The excited-state *cis→trans* motion of the switch does not affect the conformation of the peptide which only begins to change after decay to the ground state at a conical intersection (CI; see scheme).

Meeting Reviews

EUCHEM: Nanoscale Surface Self-Assembly**

Helmuth Möhwald*

The last two decades have seen tremendous progress in the controlled self-assembly of molecular organized thin films at the nanometer level. These assemblies offer promise for many applications in optics, electronics, sensors, or biotechnology, and therefore it is important to review the progress in this field, highlight current developments, and discuss future directions. This was the aim of the EUCHEM Conference "Nanoscale Surface Self-Assembly", which was held on June 19–23 at Sigtuna (Sweden). The meeting brought together 100 scientists, of whom many have helped to shape the field over some years, and their younger colleagues, who presented their results through short oral contributions and 60 posters.

Films with probably the best-defined structure control are those formed by chemisorption of silanes or thiols on inorganic surfaces. Through suitable modification of the surface, these can be extended towards multilayers. They can also be laterally structured by various techniques, as presented in original contributions, through locally selective electrochemistry by means of an STM tip (J. Sagiv, Rehovot); through electron-beam-induced polymerization and desorption (M. Grunze, Heidelberg; Figure 1); and through the stamping of

Figure 1. Three-dimensional poly(*N*-isopropyl-acrylamide) micro- and nanostructures can be grown onto various substrates by grafting the polymer brush from an initiator-coated surface. The dependence of the brush height on the density of the initiator (controlled by the electron-beam dose in the chemical lithography process) allows spatially defined polymer patterns with varying heights and unique surface topographies to be created in a single step. Image courtesy of Quiang He, Junbai Li, Alex Küller, and Michael Grunze (University of Heidelberg)

thiols on surfaces (G. Whitesides, Boston; R. Nuzzo, Urbana). This opens up potential applications towards electronics (Nuzzo), microfluidics (Whitesides), and the manipulation of the interactions of biological matter with surfaces. The latter holds for the passivating of surfaces to avoid inflammatory reactions (Grunze) as well as for stimulating cell growth (Montelius, Lund). It was also shown that by varying the composition of surface deposits, gradient films could be prepared which are suitable for lubrication studies at the nanoscopic level (T. Kraus and N. Spencer, Zürich). An interesting new approach to fabricate multifunctional films was introduced by D. Reinhoudt (Twente), who reported the synthesis of molecules with many supramolecular interactions that are able to assemble in well-defined films with a structure that can be manipulated by environmental conditions.

Owing to their ease of fabrication and versatility with regards to selection of the material, polyelectrolyte multilayers have received widespread interest. These films, which are predominantly based on electrostatic interactions, are

structurally controlled only at the nanometer level, but their robustness and high tolerance to imperfections makes them appealing for a variety of applications, including controlled-release surfaces or defined wettability. G. Decher (Strasbourg) presented spray-coating as a simple and efficient way to prepare multilayer films, and A. Rogach (Munich) demonstrated that different components, in this case semiconductor quantum dots, can be introduced with varying composition along the normal to allow an energy-transfer cascade through the film. H. Möhwald (Potsdam, Germany) presented an extension of the polyelectrolyte multilayer assembly technique in which sacrificial colloidal templates have been coated to yield micro- and nanocapsules with well-defined walls and surfaces, and controlled, switchable permeability.

Polyelectrolyte/surfactant assemblies are frequent in nature and are also used in many technical systems. To study them at interfaces, on the one hand, enables one to learn more about their interactions, and on the other hand, enables specific interfacial modifications, for example, in foams (Langevin, Orsay; Thomas, Oxford). Many of these complexes form 3D structures that may be of importance, for example, for gene therapy or conditioners. During the presentations it became clear that not only the rules of the assembly of the multicomponent systems have to be learnt but that also, especially for polymers as components, non-equilibrium states are relevant (Tilton, Pittsburgh).

Inorganic nanoparticles can be inserted into films as stable functional components, and it was shown by E. Hutter and J. Fendler (Potsdam, USA) that the scattering power of gold nanoparticles can be used for the very sensitive detection of interactions including DNA recognition. A new and versatile way of (grafting from) polymerization on nanoparticles that makes them functional building blocks of defined coatings was presented by D. Wang (Potsdam, Germany; Figure 2).

Nature provides us with membranes as multifunctional surfaces and films, and it is intriguing to arrange these on inorganic supports. Whereas the contribution of L. Evans (Leeds) mainly concentrated on solving problems related
Figure 2. The pH-dependent chemical structure of a polymer brush on a nanoparticle surface. With the protonated brush, the nanoparticle is soluble in water; unprotonated, the nanoparticle is soluble in organic solvents. Image courtesy of Dayang Wang and Hongwei Duan (Max Planck Institute of Colloids and Interfaces).

to the coupling of the membrane on a solid support, the contribution of D. Stamou (Copenhagen) demonstrated the fabrication of reaction vessels on micropatterned surfaces.

Progress in the past has been also due to the development of new techniques, and this is expected to continue. T. McMaster (Bristol) demonstrated the applicability of new refinements of scanning force microscopy to probe soft interfaces, and M. Lefenfeld (New York) showed the applicability of high-energy X-ray reflectivity to probe buried interfaces. The latter is also applicable for sum-frequency genera-tion and is especially suited to probe defects and symmetry breaks, as presented by S. Ye (Hokkaido). These techniques first emerged about 10 years ago, but it wasn't until recently that one could extract the quantitative information necessary for a controlled assembly. This is also true for neutron reflectometry, as presented by R. Thomas (Oxford), wherein systematic studies have now revealed a layered arrangement of some polyelectrolytes near interfaces. In a most impressive talk by W. Kern (Stuttgart) based largely on low-temperature scanning tunneling microscopy, the participants realized how much one still has to learn on going from an atom to a supramolecular assembly on a surface. With high-resolution techniques, chiral recognition in assemblies of linear aggregates could be realized, leading to periodic non-close-packed arrays on surfaces.

The program included some free time for informal discussions as well as a "round table" to discuss future perspectives. This developed into a very lively discussion hour, however, without any conclusions. The most evident problems identified from the discussion were as follows:

1) The field is highly multidisciplinary, and as no individual can cover all disciplines in depth, the integration of many specialists is mandatory but highly demanding.

2) Funding agencies and politicians have received many promises of nanotechnological applications. However, one still has to learn the rules of molecular assembly, and therefore long-term research is required and many promises will not be met in the near future.

3) Most scientists have their personal view on the areas of most promising applications. However, no consensus has been reached, as there have been many examples of unexpected breakthroughs.

These lively, partly chaotic discussions, however, did not affect the extremely friendly spirit of the conference. One could profit from all contributions and discuss with all speakers at length. Much of this is due to the excellent selection and organization by M. Rutland and his team from the Royal Institute of Technology Stockholm and the Swedish Chemical Society. The success of the meeting is probably most clearly expressed in the result of a secret poll of the participants, with 95% rating the conference as very good or excellent. They also expressed a strong wish for a continuation, and hopefully this will be the case on a more regular basis.

THE NOBEL PRIZE
IN CHEMISTRY 2004

In the cell, proteins are being built up and broken down all the time. Unlike in the spontaneous protein breakdown that food undergoes in our intestines, breaking down proteins inside cells requires energy. This was long a research mystery. Thanks to this year's Nobel Laureates, however, we know that this form of breakdown is an extremely detailed control process in which the protein to be destroyed is marked with a special "label" — ubiquitin.

From the Contents

My interest in protein breakdown as a research problem began in l955 at about the time I joined the Biochemistry Department of Yale University. It was known that proteins break down intracellularly in the mature animal.[1,2] In l955 I learned from Melvin Simpson about experiments he had published two years earlier[3] showing that a variety of conditions that should lower the ATP level of liver slices (anaerobiosis, cyanide, 2,4-dinitrophenol) decreased the rate of liberation of labeled methionine from the protein of rat liver slices. Simpson and I had just joined the Biochemistry Department and we had labs down the hall from each other. Simpson's research goal at Yale was to look for an in vitro system that performed protein synthesis rather than protein breakdown. During my Yale years I concentrated on enzyme-mechanism questions relating to the keto-aldose isomerases by using tritium to establish the occurrence of proton transfer,[4] but I kept an eye out for reports in the literature on progress in the field of protein breakdown.

Nothing new was being reported by 1963 when we relocated to the Institute for Cancer Research of Fox Chase, Philadelphia. At that time I began looking for a cell-free system that would show an ATP dependence using the Ehrlich ascites cells that were available from our animal colony. My usual procedure was to label cells in a suspension with an essential amino acid, wash the cells, lyse them by homogenization, and look for acid-soluble counts by adding either ATP or 2-deoxyglucose plus hexokinase to deplete the endogenous ATP.

During 1972, on a half-year sabbatical divided between Oxford (J. Knowles) and Jerusalem (Y. Stein), I was able to do further experiments with tissues supplied by Hans Krebs and by Jacob Mager (Avram Hershko's PhD researsch director at the Hadassah Medical School). Both men were highly supportive, but I was not able to find a cell-free system. At the same time I was often talking to Jacob Bar Tana of the Biochemistry Department and we came up with a "pulse/chase" method that could be used to determine the functionality, binding constant, and rate of dissociation of potential enzyme–substrate complexes.[5]

1. How it All Came Together

Hershko had been with Gordon Tompkins in San Francisco on a post-doctoral fellowship, where he essentially confirmed Simpson's findings but with the tyrosine aminotransferase of cells in cultures. When he returned to Israel to set up his own lab in Haifa he also looked for a cell-free system. I did not meet Avram Hershko until l975, at a Fogerty Conference on Regulation in Bethesda, where we learned of each others interest in protein breakdown. Meanwhile, Tompkins died tragically during a brain tumor operation, and Hershko was looking for a US lab in which to expand his work further during sabbatical years and summers. It is not clear to me why he chose our lab in suburban Philadelphia for this purpose. We had no reputation in protein breakdown, having never published in the field. Our limited expertise was expected to be in mechanistic enzymology. The three American postdocs, Haas, Pickart, and Wilkinson, who

E-mail: irwin@lworld.net

came on board for that reason, could not have anticipated the diversion their research careers were about to take.

In l977, when we joined forces at Fox Chase, Etlinger and Goldberg[6] had done the first successful experiment using a cell-free system with lysates of rabbit reticulocytes. Hershko and his student Aaron Ciechanover[7] had already started fractionating the reticulocyte extract and identified the heat-stable factor (APF-1) before they came to Fox Chase that summer. Their subsequent work, much of which was reported in collaboration with members of my group, is to be found in the following Nobel Lecture by Hershko. The key observation that the 8-kDa APF-1 formed units of a chain linked to the protein targeted for breakdown was the most unexpected and unique aspect of the process.[8]

The identification of APF-1 with ubiquitin was made by three post-docs at Fox Chase: Keith Wilkinson and Arthur Haas from the Rose/Hershko lab and Mike Urban from the neighboring lab. Urban was working with chromatin and knew especially about their interesting components—the histones.[9] The pivotal question asked of Urban was: Do you know any examples of two proteins that are linked covalently. This recalled the small protein of unknown function, ubiquitin, a covalent ligand of histone H2A. The size and amino acid composition of APF-l reported by Hershko and known for ubiquitin were in agreement.

The failure of many cell extracts to give ATP-dependent protein breakdown is probably a consequence of a lysosomal trypsin-like protease that destroys the ubiquitin of the preparation. This was discovered by Haas et al.,[10] who observed the loss of enzyme binding capacity of a ubiquitin affinity column when liver extracts were put through it. Haas was able to show ATP/ubiquitin-dependent protein break-down with liver extracts that were preincubated to inactivate the trypsin-like activity. Ubiquitin was already known to be trypsin-sensitive at the Arg74–Gly75 bond.

2. The Ubiquitin Activating Enzyme

Enzymologists usually study the initial rates of reactions by measuring product formation as a function of substrate concentration or another variable. Cell biologists are more

Irwin Rose received his PhD in 1952 from the University of Chicago in Biochemistry for his work on the conversion of U-^{14}C-cytidine into U-^{14}C-deoxycytidine in the DNA of mouse tissues. In 1955 he joined the Bio-chemistry Institute at Yale Medical School. Here, he learned from Melvin Simpson that protein breakdown was inhibited, not stimulated, under energy-deficient conditions. At Fox Chase (1963–1997), after contributing to enzyme-mechanism research, he was joined by the Hershko/Cienhover team in 1977 who were making progress fractionating reticulocyte extracts. He and his students contributed to studies of the ubiquitin activating enzyme, ubiquitin carrying protein, and ubiquitin C-terminal hydrolase leading to the isolation of ubiquitinaldehyde and an understanding of the hydrolase mechanism.

likely to want to know the effect of a change on the steady-state behavior of a complex system. When the ubiquitin activating enzyme E1 was discovered by Hershko, it could not be studied by the rate of product formation because the enzyme produced a covalently linked end product. In 1982 Art Haas used isotope exchange at equilibrium to establish the reaction sequence and a number of equilibrium and rate constants of E1—the only enzyme of the cell that uses ubiquitin, per se, as a substrate.

The ubiquitin (Ub) activation process is defined by the formation of two equivalents of pyrophosphate (PP_i), one equivalent of bound AMP-Ub, and two exchange reactions: ATP with PP_i and ATP with AMP, as shown in Equations (1)–(3).

$$E1 + ATP + Ub \rightleftharpoons E1 \cdot AMP\text{-}Ub + PP_i \tag{1}$$

$$E1 \cdot AMP\text{-}Ub \rightleftharpoons E1\text{-}S\text{-}Ub + AMP \tag{2}$$

$$E1\text{-}S\text{-}Ub + ATP + Ub \rightleftharpoons E1\text{-}S\text{-}Ub \cdot AMP\text{-}Ub + PP_i \tag{3}$$
AMP-Ub, which is prepared from E1, ATP, and Ub and eluted by denaturing the enzyme, is sensitive to both dithiothreitol (DTT) and hydroxylamine, thus indicating an acyl-P–anhydride linkage. The AMP-Ub could be converted back into ATP upon addition of PP_i and Mg^{2+} ions or to E-S-Ub, which did not require PP_i or Mg^{2+} ions.[11–13] Only the formation of enzyme-bound Ub was inhibited by iodoacet-amide, thus indicating transfer to the cysteine of the enzyme (Ub being cysteine-free). The linkage to Ub had already been established to involve the C-terminal glycine of Ub.[14]

ATP was shown to precede Ub in combining with E1 and with E1-S-Ub (Scheme 1) since inhibition of ATP/PP_i exchange was seen at Ub above 10 μM and inhibition was complete at 400 μM. Addition was not random.[12] Equilibrium constants of the expanded Scheme 1 could be estimated from the influence of varying AMP and PP_i on the concentrations of E1-AMP-Ub and E1-S-Ub, which were determined with tritium-labeled ATP by acid precipitation and labeled Ub by electrophoresis. The affinity for ATP (ca. 40 μM) is higher than the level of ATP in the cell, which ensures that the E1 in the cell will be in the E1-ATP or E1-S-Ub-(ATP) form ready to pick up any free Ub ($K_m = 0.58$ μM). The sensitivity to AMP as an inhibitor ($K_6 = 0.027$ μM) is much higher than ATP as a substrate, which suggests that AMP may be acting as a feedback inhibitor at an allosteric site as well as with E-S-Ub.

3. Ubiquitin-Carboxy-Terminal Hydrolase: Discovery and Mechanism

It was observed that the usual one-turnover assay of E1 used ATP well beyond expectation when glutathione was included in the assay. The explanation: The ubiquitin of E1-S-Ub is readily transferred nonenzymatically to mild nucleophiles such as glutathione, DTT, and hydroxylamine. By itself, this would increase the consumption of ATP to the amount of Ub present in the assay. However, much more was taken up. Were the Ub derivatives unstable? None of the expected Ub-S-DTT from an incubation of AMP-Ub and DTT could be isolated on a covalently bound Hg$^+$ column unless great care was taken in the conversion. Most revealingly, the yield was increased if urea was added immediately after the reaction. This result indicated that an enzyme carried over with the AMP-Ub from the E1 preparation was regenerating the Ub. These two observations—the transfer of Ub from E1-S-Ub to mild nucleophiles and an enzyme contaminating E1 that would restore free Ub—were needed to explain why much more ATP was consumed than could have been expected in the E1 assay.[15] The combined action of E1, glutathione, and the hydrolase results in a futile cycle converting ATP into AMP + PP$_i$ (Scheme 2). AMP-Ub is normally too tightly bound to E1 to lead to a futile cycle of its own in the presence of an active nucleophile.
Scheme 2.

Amides of ubiquitin were not available to test as substrates of the new ubiquitin thioesterase until their synthesis was made possible by Cecile Pickart through the action of E1 + E2 on primary amines.[16] This research was of great interest because the enzymes required for recovery of Ub from conjugation in the newly emerging Ub system were believed to be isopeptidases. An E1·E2-S-Ub complex normally transfers Ub to the ε-NH$_2$ group of lysine in proteins. To determine the substrate specificity of this system, Dr. Pickart found that a variety of small primary amines at much higher concentration are also very good Ub acceptors. The Ub amides were good substrates for the previously purified Ub thioesterase which henceforth has been known as ubiquitin-carboxy-terminal hydrolase (UCH).

The pure enzyme ($M_w = 29$ kDa) was readily prepared from mature human red cells (ca. 0.1 units per mL of packed cells). Its turnover rate is quite high, almost diffusion limited, and its V_{max} value is approximately 10 s^{-1}. Ubiquitin conjugated to glutathione or to a polyamine in cells with such activity should be negligible.

The rate of the E1·E2/UCH/amine system can be determined by measuring ATP consumption in a futile cycle similar to that of Scheme 2, where the rate can be used to test the activity or the specificity of the component present in a rate-determining amount. UCH enzymes are limited in the size of the substrate they will act upon. Any role in the deubiquitination of polyubiquitin chains is doubtful. This activity is given over to much larger deubiquitinating enzymes (DUBs).

Considerations of the mechanism of UCH start with the observation that these enzymes are inactivated by iodoacetamide, protected by Ub, and therefore should have an active-site thiol group and possibly a ubiquitin thiolester intermediate. We found that inactivation of UCH was brought about by borohydride if ubiquitin was also present.[17] Both the tritium from the borohydride and the label from Ub were tightly fixed to the inactive enzyme. Both isotopes were released upon mild acid denaturation, whereby tritium traveled with the Ub. The released product was about 1000 times more inhibitory than Ub in an assay using [^{3}H]-butanol-4-NH$_2$-Ub as a substrate. This effect was lost with borohydride addition to the inhibitor, which was protected from reduction if enzyme was added first. We concluded that the acid-liberated inhibitor must be the C-terminal aldehyde form of Ub (Ubal). This was shown with [^{3}H]-NaBH$_4$, and by isolation of [^{3}H]-ethanolamine among the acid-hydrolysis products. The basis for the protection of the Ubal by the enzyme must be the formation of a strong complex that shields the aldehyde group. A combination of chemical and physical forces would result from the addition of the active-site SH to the carbonyl group, a thiolhemiacetal on the one hand and multiple protein–protein interactions between the active site and the remainder of the Ubal. Additional stabilization may come from the resemblance of the thiohemiacetal to the tetrahedral intermediates and transition states in the amidase reaction, as would be drawn for papain and cathepsin B (Scheme 3).

This interpretation of the mechanism of action of Ubal has been confirmed and extended by X-ray crystallographic studies of Ubal complexed with the UCH of yeast Yuh 1 by Johnston et al.[18] and with the 352-residue UCH domain that was cut out of the 1102-residue-long HAUSP (herpes virus preassociated ubiquitin-specific protease) deubiquitinating enzyme by Hu et al.[19] In both cases, Ubal caused significant distance and angle rearrangements in the catalytic triad regions compared with structures obtained without Ubal,[19,20] respectively, as well as placement of H-bonding residues to accommodate the expected oxyanion hole of a thiohemiacetal–Ub adduct.

The large DUBs, about 80 of which have been identified, serve to reverse the lengthening of the polyubiquitin chains that leads to the destruction of the targeted protein at the proteasome. HUASP is also known as a tumor-suppressor co-protein because deubiquitinating p53 (the tumor suppressor
Scheme 3.

transcription factor of tissues) should raise its steady-state level. The large size of DUBs is consistent with high specificity and signal control. The roles of the UCHs are not yet clear. The size of the Ub extension that can be removed by these smaller enzymes is smaller than a Ub molecule so that Ub–Ub cleavage intermediates, if they arise in the deubiquitination process, will not be further degraded by a UCH.

4. Unresolved Issues

● Current discussions of the E1-E2-E3 system often ignore the potential of E1-AMP-Ub to transport Ub units between the solvent and E1-SH to E2 without dissociation of the E1·E2 complex. This possibility should be easily evaluated by pulse/chase experiments using heavy-isotope-labeled Ub in the pulse, unlabeled Ub in the chase, and analyzing the product by mass spectrometric sequencing.

● This approach may fail if the E2·E3–protein interactions are weak. In addition, the experiment should give information about the processivity of the system, namely, how many Ub moleculess can be added in succession.

● This approach should also answer the question of whether when Ubs are added to the growing chain they are added to the distally located end of the chain as is often stated, but which seems unreasonable as the chain-length increases.

● An interesting problem stems from the observation by Cecile Pickart[16,17] that hydroxylamine at $K_m \approx 1$ mM inactivates the C-terminal hydrolase of erythrocytes, and possibly all UCHs, in the presence of Ub. Using the hydroxamate of Ub as a substrate, complete inactivation requires about 2000 turnovers of the enzyme. Labeled Ub is not found on the re-isolated enzyme, nor is activity recovered. Unless hydroxylamine has some unexplored way of reacting with the S- of the Ub-thiolester-enzyme intermediate, the classical reaction products should be Ub-hydroxamate and active enzyme. In view of the important role of the deubiquitinating enzymes and a

practical interest in their inactivation, it will be useful to know how hydroxylamine works.

The Ubiquitin System for Protein Degradation and Some of Its Roles in the Control of the Cell-Division Cycle (Nobel Lecture)**

*Avram Hershko**

From the Contents

1. Biographical Notes

I was born on December 31, 1937, in Karcag, Hungary. Karcag is a small town of around 25000 inhabitants, about 150 kilometers east of Budapest. It had a Jewish community of nearly one thousand people. My father, Moshe Hershko, was a schoolteacher in the Jewish elementary school in Karcag; most of the Jewish children in that town were his students. His former students from Hungary, and later from Israel, described him with admiration as an inspiring teacher and a role-model educator. My mother Shoshana/Margit ("Manci") was an educated and musically gifted woman. She gave some English and piano lessons to children in Karcag. My older brother Chaim was born in 1936, less than two years before me. My mother wanted very much to also have a baby girl, but the times were the eve of World War II, Hitler's screams could be frequently heard on the radio, my parents became apprehensive of the future and thus did not try to have more children. Still, my recollections of my early childhood are of very happy times, with loving and supporting parents, growing up in a nice house with a beautiful garden, created by my father who was also an amateur (but avid) gardener. A family picture from these times, with my parents, my brother, and I as an infant, shows well the warmth of my family (Figure 1).

This early paradise was lost rapidly and brutally. World War II broke out, and soon Hungary joined in as an ally of Nazi Germany. In 1942, my father was taken by the Hungarian Army to serve as a forced laborer, with companies of other Jewish men. They were sent to the Russian front, where most of them perished. Luckily for my father, the Soviet Army advanced so rapidly after Stalingrad that he was captured by the Soviets before the Nazis could kill him. Then, he was used by the Soviets as a forced laborer. He was

released only in 1946, so we did not know for four years whether or not he was alive.

In the spring of 1944, Hungary's dictator Horthy understood that Germany was losing the war, and planned to desert. The Germans sensed this and quickly occupied Hungary. This was followed by the rapid extermination of much of the Jewish population of Hungary. In May/June 1944, most Jewish people were concentrated in ghettos and then transported to death camps in Poland. I was six years old at that time. We were in a ghetto on the outskirts of Karcag for a couple of weeks and then were transferred to a terribly crowded ghetto in Szolnok, which is a larger city in the same district. From there, Jews from the entire district were transported further on freight trains. They were told that they were being sent to work, but after the war we learned that most of the trains were headed for Auschwitz. By some random event, my family and I were put on one of the few trains that headed for Austria, where Jews were actually used for labor. This group included my mother with us two children, my paternal grandparents, and my three aunts. In Austria we were in a small village near Vienna, where adults worked in the fields and in a factory. We were liberated by the Soviet Army in the spring of 1945. My maternal grandparents perished in the Holocaust, along with 360 000 Hungarian Jews and almost two-thirds of the Jewish people of Karcag. Following our reunion with my father in 1946, the family lived for three years in Budapest, where my father found a job as a schoolteacher. The family emigrated to Israel in 1950.

In Israel we settled in Jerusalem and I started a new and very different life. Of course, there were initial difficulties in being new immigrants. We had to learn a new language, Hebrew. This was not too difficult for children (I was less than 13 at that time), but it was more difficult for my parents. Still, my father studied Hebrew and soon started to work, again as a schoolteacher. (Later he taught at a teachers' seminary and authored mathematics textbooks, which were very popular in Israel.) As always, education of their children was my parents' highest priority. Although we were quite poor immigrants at that time, my brother and I were sent to an expensive private school in Jerusalem. I suspect that most of the salary of my father was spent on our tuition fees.

At school I was received well by the other children. These were times of massive immigration to Israel, so a new immigrant child with a Hungarian accent did not stand out too much (I am told that I still have some Hungarian accent, especially in English, though my Hungarian language is quite poor now). I was a good student, and learned easily different subjects, such as mathematics, physics, literature, history, and even Talmud! That became a problem when I finished high school; I was interested in too many subjects, so it was difficult for me to decide how to continue. I chose to study medicine, probably by default, because my brother Chaim was already a medical student, so I could inherit his books for free! Chaim always wanted to be a physician, and he is now a very well-known hematologist and an authority on iron metabolism.

In 1956, I started to study at the Hebrew University–Hadassah Medical School in Jerusalem, which was the only medical school in Israel at that time (there are now four). In the basic science part of my medical studies, I fell in love with biochemistry. I studied biochemistry in three different courses: organic chemistry, basic biochemistry, and a course called "physiological chemistry", which was medically oriented biochemistry. I was very fortunate to have outstanding teachers in all three courses. Organic chemistry was taught by Yeshayahu Leibowitz, a legendary person in Israel, a highly original thinker whose knowledge encompassed philosophy, political science, Bible, Talmud, medicine, chemistry, and more. He was probably my best teacher, it was an intellectual feast to listen to him. Leibowitz loved biochemistry, and he sneaked biochemistry into his lectures on organic chemistry whenever he could, which was often. Basic biochemistry was taught by Shlomo Hestrin, also an inspiring teacher who had a special talent to transfer his enthusiasm of science to the students. Physiological chemistry was taught by Ernst Wertheimer, a professor of German Jewish origin whom we had some difficulty to understand because of his heavy German accent, but who had an excellent perspective of integrating metabolism at the level of the total body and of physiological contexts of biochemistry. Another part of the same course was taught by Jacob Mager. Mager was an outstanding biochemist and a man of encyclopedic knowledge. However, he was very shy and quite a bad classroom teacher (although an excellent teacher in the laboratory, as I learned later). Most of his lectures were delivered while he was writing whole metabolic pathways on the blackboard, without any notes, with his face to the blackboard and his back directed to the class. Still, I was so much impressed by the depth and breadth of his knowledge of biochemistry that I decided to ask Mager if I could do some research in his laboratory (Figure 2).

I started to work in Mager's laboratory in 1960. At that time, there was no formal MD/PhD program at the Hebrew University, but it was possible to do a year of research between the preclinical and the clinical years of medical studies. I did that, and although I completed medical studies later on, I already knew by the end of that year that I was going to do research, rather than clinical practice. I was very fortunate to have had Jacob Mager as my mentor and tutor of biochemical research. He was a scientist of incredible scope of interests and knowledge. He was interested in every subject in

Figure 2. Jacob Mager.

biomedicine, he knew almost everything about every subject and he worked simultaneously on three to four completely different research projects. This undoubtedly caused fragmentation of his contributions to science, but provided his students with a broad experience in different areas of biochemistry in a single, relatively small laboratory. In a period of a few years I worked with Mager on subjects as different as the effects of polyamines on protein synthesis in vitro, glucose-6-phosphate dehydrogenase deficiency, and a variety of aspects of purine nucleotide metabolism, including enzymology and regulation. During this time, I also finished my medical studies, did my military service as a physician (1965–1967), and then returned for two more years to Mager's laboratory to finish my PhD thesis (1967–1969). I received not just a broad view of biochemistry from Mager, but also a very solid basis. He was a very rigorous experimentalist, every experiment had to be done with all possible positive and negative controls, all experiments were carried out in duplicate, and every significant new finding had to be repeated several times to make it sufficiently credible. I owe a lot to Jacob Mager for a strong background in rigorous biochemistry.

I met Judith (née Leibowitz) in 1963, and we married at the end of the same year. Judy was born and raised in Switzerland. After her studies in biology, she decided to spend a year in Israel. During this year, she worked in the hematology laboratory of the Hadassah hospital in Jerusalem. One day, I walked over to the hematology laboratory to get a blood sample that I needed for my research, and we literarily bumped into each other. This collision caused her to stay in Israel for more than one year, and now we have been married for over 41 years. We have three sons: Dan (1964), Yair (1968), and Oded (1975). Dan is a surgeon, Yair is a computer engineer, and Oded is a medical student. We have now six grandchildren: Maya (1994), Lee, (1997), Roni (1998), Ela (2000), Ori (2002), and Shahar (2004). Needless to say, both

Judy and I are crazy about all our grandchildren. During all our years together, I got tremendous support from Judy. Although she came from one of world's most peaceful countries to one of the least, and from a very comfortable and pampering environment to quite primitive surroundings, she stood ground with a lot of energy, courage, and cheerful optimism. She always took care of all my possible needs, as well as the needs of our children and grandchildren. Judy is not only a very beautiful woman, but she also radiates a lot of caring, love, and compassion. In addition to providing so much support at home, she also helped me a lot in the laboratory, over a period of more than 15 years. The ubiquitin system was helped by Judy in more than one way (Figures 3 and 4).

In 1969 to 1971 I was a postdoctoral fellow with Gordon Tomkins at the Department of Biochemistry and Biophysics of the University of California in San Francisco. I met Gordon the previous year, when he gave some lectures in Israel. He was very different from Mager: outgoing, vivacious, bursting with original ideas (Figure 5). Unlike Mager, Gordon did not

care much about controls or experimental detail, but he was a volcano of a man, constantly erupting with great ideas and he was a wonderful stimulator of many other researchers' work as well. Many distinguished scientists who knew Gordon Tomkins at that time (unfortunately, he died at an early age) still speak of him with great admiration. He exuded a great personal charm and I liked him instantly. I thought that Gordon may add some new dimensions to my development in science and this indeed was the case. I got a lot of stimulation and biological perspective from Gordon, while I continued to use what I learned from Mager about rigorous controls. As described in the main text, I learned about protein degradation and got fascinated with this process while I was working with Gordon Tomkins.

I returned from San Francisco to Israel in 1971. Originally, I planned to return to the Hebrew University in Jerusalem, but a new medical school opened in Haifa and I was offered the opportunity of being its Chairman of Biochemistry. This sounded very challenging and I agreed, but later it turned out to be a very minute unit of Biochemistry in a very small Faculty of Medicine of the Technion, so at the beginning I chaired mainly myself. One initial reason for its being so small was that there was not enough space to house much faculty. The whole Faculty of Medicine was housed, on a temporary basis, in an old two-floor monastery (Figure 6). This "temporary" situation lasted for more than 15 years, until the new building of the Faculty of Medicine was completed in 1987. However, I had great times in that old monastery, and much of the discovery of the ubiquitin system was done right there. Isolation may at times lead to creativity, since one is not bothered by what others are doing and does not feel compelled to work on currently popular, "fashionable" subjects. I was very fortunate to assemble there a highly devoted research team, which included at the beginning Hanna Heller and Dvora Ganoth, and later, at different times, Ety Eytan, my wife Judy, Sarah Elias, and Clara Segal. Dvora and Ety still work with me. My first graduate students were
David Epstein, Yaacov Hod, and Michael Aviram. For a number of years, we tried to establish a cell-free system that reproduces energy-dependent protein degradation in the test tube, essential for the biochemical analysis of this system. For this purpose, we tried different sources, such as liver homogenates and extracts from cultured cells, and even from bacteria. We did not have any success in any of these attempts. I remember that a biochemist friend from Jerusalem visited my laboratory and at the end of the visit she told me that I should not have most of my laboratory working on a hopeless subject. However, I was very obstinate and was obsessed with the idea that it would be possible to find out how proteins are degraded only with a biochemically analyzable cell-free system. Maybe I was lucky to work in such a remote and small place; in a larger institution, my graduate students and research assistants may have deserted me for some less frustrating research. Finally we used the reticulocyte cell-free system established in the Goldberg laboratory for the biochemical fractionation (see Lecture). At that time, Aaron Ciechanover joined my laboratory for a DSc thesis, after completing his medical studies and Army service. Aaron was the most incredibly hard-working graduate student that I ever had. With his huge energies, he contributed a lot to the discovery of the ubiquitin system. He was also a natural manager, already as a graduate student. I recall that at the end of my sabbatical year in Philadelphia in 1978 (see below), after telling Ernie Rose how small Israeli research grants were, Ernie suggested that I should apply for a foreign research grant from the NIH to support my work in Israel. I was inclined to do a couple more experiments instead of writing a grant application, but Aaron pushed me into a chair and commanded: "now write the NIH grant application!". I wrote it and got the grant, the first of five consecutive grant periods supported by the NIH. It saved the situation in the Haifa lab at a very critical time. I am very grateful to the NIH for supporting my work and also to Aaron for forcing me to write the initial grant application.

The story of the discovery of the ubiquitin system is described in my lecture, and here I add only some anecdotal

episodes from these times. The fractionation of reticulocyte lysates into fractions 1 and 2 was based on a trick that I learned from Mager in the purification of enzymes of purine nucleotide metabolism from erythrocytes. Hemoglobin constitutes about 80–90 % of the total protein of erythrocytes and reticulocytes, and therefore the first task in the purification of any enzyme from these cells is to get rid of the great mass of hemoglobin. This is most conveniently done by using the anion-exchange resin DEAE-cellulose, which binds most nonhemoglobin proteins, but not hemoglobin. In our case this procedure resulted in loss of activity, which could be recovered by adding back fraction 1 that contained not only hemoglobin but also ubiquitin. In fact, in our laboratory jargon we called ubiquitin for some time "Red", because of the red color of hemoglobin in this fraction. After we found that the factor in this fraction (that is, ubiquitin) remains active after boiling for 30 minutes, we consulted a protein expert at the Technion who told us that our factor cannot be a protein. We found, however, that it is a protein, based on its sensitivity to the action of proteinases. Maybe the lesson from this story is that it is dangerous to consult experts.

After working for six years at the Technion, I had a sabbatical year due in 1977/1978. I had a problem in choosing a person with whom I would spend my sabbatical year. I knew the people in the (then) small protein-degradation field, and I was not very enthusiastic. Many people in the field had their pet theories about the cause for the high selectivity of intracellular protein degradation, without much (or any) experimental evidence. Once again, I was lucky. In 1976, I attended a Fogarty meeting on a quite general subject at the National Institutes of Health. Irwin Rose also attended this meeting, and one morning I joined him at the breakfast table. Ernie was well known for his work on enzyme mechanisms. In the course of our conversation I asked Ernie in what else he was interested, and his reply was: "protein degradation". I was a bit taken aback and told him that I never saw anything published by him on protein degradation. His reply was: "there is nothing worth publishing on protein degradation"! I liked his critical attitude and Ernie being such a character, and therefore I asked him if I could spend my sabbatical year in his laboratory (Figure 7). It turned out that Ernie Rose was really interested in protein degradation. When he had been a young faculty member in the fifties at the Department of Biochemistry of Yale University, he talked to Melvin Simpson, another young faculty member there, and Simpson told him about his experiments on the energy-dependence of the liberation of amino acids from proteins in liver slices (see Lecture). This aroused Ernie's interest, and from time to time he did experiments trying to understand the energy-dependence of protein degradation. He did not make any significant progress in these experiments, and therefore he did not publish anything on protein degradation.

Ernie Rose is the third person, in addition to Mager and Tomkins, who had a great influence on my scientific life. He is very different from both Mager and from Tomkins. He likes problem solving, and his attitude to science is highly analytical. I am more intuitive, so we complemented each other very well. He is so brilliant that people do not always

Figure 7. Irwin Rose at Fox Chase Cancer Center in 1992.

understand his ideas and are a little afraid of him. People are also often apprehensive of him because he can be very critical, and does not hesitate to voice his criticisms. We got along very well over a period of 20 years, which included several sabbaticals and many summer visits in his laboratory at Fox Chase Cancer Center in Philadelphia. Our only disputes were when he refused to be co-author of work to which he actually made significant contributions. In the case of the few papers on which he is co-author, I had to force him to agree. He was most unselfish in our joint work, a rare phenomenon in today's science. I asked him once why does he keep inviting me back to his laboratory, and his answer was: "I like the excitement". Ernie always downplayed his contributions to the ubiquitin field. He wrote an autobiographical article for *Protein Science* in 1995, and the word "ubiquitin" is not mentioned in this recollections paper. In our conversations he always described his role in the ubiquitin story as being merely supportive, but this is certainly not true. Although on occasions when I worked in his laboratory, he was adsorbed with some problem in enzyme mechanisms, he would forget about my existence for a week or two, but then suddenly he would come up with a bright suggestion about my current work. I can state that Ernie's input of ideas, inspiration, and helpful criticism were essential for the discovery of the ubiquitin system and for the delineation of some of the main enzymatic reactions in this pathway.

The rest of my story is a lot of more work, but also a lot of more scientific excitement and fun. I continued to be obstinate, and continued to do what many considered to be old-fashioned biochemistry in the eighties, when the powerful technologies of molecular biology became available. This biochemical work resulted in the discovery of the three types of enzymes involved in ubiquitin–protein ligation (E1, E2, and E3), and of some further enzymes of this system. Subsequently, I became interested in the roles of ubiquitin-mediated protein degradation in the cell division cycle. This led me to the Marine Biological Laboratory (MBL) at Woods Hole, due to the availability of a clam oocyte cell-free

system, which faithfully reproduces cell-cycle-related events in the test tube. This system was important for the discovery of the cyclosome/anaphase-promoting complex, as described in the Lecture. In the past decade, I have spent my summers at the MBL for the same reason that I spent my summers previously at Fox Chase Cancer Center—to be able to devote almost all my time to doing experiments in a tranquil environment. Benchwork is my great hobby; I also do benchwork in Haifa, but on a more part-time basis. I have always loved to do experiments with my own hands, both for peace of mind and for excitement. Also, my own experiments were important for almost every significant progress made in my laboratory. One cannot have a more beautiful place than the MBL for doing experiments: the great natural beauty of the surroundings, the tranquility and outstanding scientific environment all combine to make the MBL a great place for doing summer research.

When I look back at my life until now, I am amazed how fortunate I have been in both my personal and my scientific life. After escaping the Holocaust, both my parents lived in Israel to a good old age. I am very happy with my wife, children, and grandchildren. I was very fortunate to have outstanding mentors in science, and then to be able to use the knowledge gained for a significant contribution. If only there were some peace in the world, including between Israel and its neighbors—I would be completely satisfied.

2. Introduction

All living cells contain many thousands of different proteins, each of which carries out a specific chemical or physical process. Due to the importance of proteins in basic cellular functions, there has been a great interest in the problem of how proteins are synthesized. In the fifties and sixties of the 20th century, the discovery of the double-helical structure of DNA and the cracking of the genetic code focused attention on the mechanisms by which the order of bases in DNA determines the sequence of amino acids in proteins, and on further molecular mechanisms that regulate the expression of specific genes. Because of the intensive research activity on protein synthesis, little attention was paid at that time to the fact that many proteins are rapidly degraded to amino acids. This dynamic turnover of cellular proteins had been previously known by the pioneering work of Schoenheimer et al., who were among the first to introduce the use of isotopically labeled compounds to biological studies. They administered ^{15}N-labeled L-leucine to adult rats, and the distribution of the isotope in body tissues and in excreta was examined. It was observed that less than one-third of the isotope was excreted in the urine, and most of it was incorporated into tissue proteins.[1] Since the weight of the animals did not change during the experiment, it could be assumed that the mass and composition of body proteins also did not change. It was concluded that newly incorporated amino acids must have replaced those in tissue proteins in a process of dynamic protein turnover.[1] Schoenheimer's studies on the dynamic state of proteins and of some other body constituents were published in a small booklet in 1942, soon after his untimely death (ref. [2], see Figure 8).

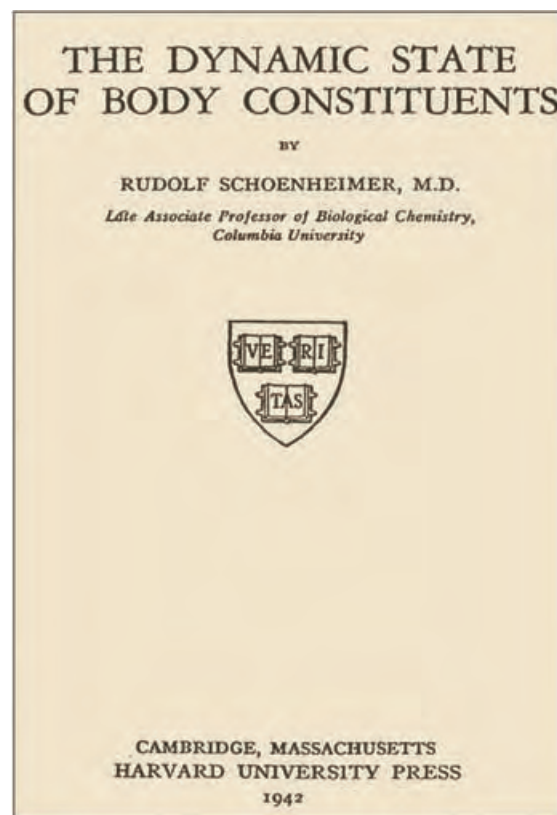
In the subsequent decades, research on protein degradation was neglected, mainly because of the great interest in the mechanisms of protein synthesis, as described above. However, experimental evidence gradually accumulated which indicated that intracellular protein degradation is extensive, selective, and has basically important cellular functions. It was observed that abnormal proteins produced by the incorporation of some amino acid analogues are selectively recognized and are rapidly degraded in cells.[3] However, intracellular protein degradation was not thought to be merely a "garbage disposal" system for the elimination of abnormal or damaged proteins. By the late sixties, it became apparent that normal proteins are also degraded in a highly selective fashion. The half-life times of different proteins ranged from several minutes to many days, and rapidly degraded proteins usually had important regulatory functions. These properties of intracellular protein degradation and the role of this process in the regulation of the levels of specific proteins were summarized in an excellent review by Schimke and Doyle in 1970.[4] Thus, it was known at that time that protein degradation has important functions, but it was not known


Figure 8. Front page of Schoenheimer's collected lectures, edited by his colleagues soon after his death.

what is the biochemical system that carries out this process at such a high degree of selectivity and sophistication.

3. My First Encounter with Protein Degradation

I became interested in the problem of how proteins are degraded in cells when I was a postdoctoral fellow in the laboratory of Gordon Tomkins in 1969–1971 at the University of California, San Francisco. At that time, Gordon was mainly interested in the mechanisms by which steroid hormones induce the synthesis of specific proteins. His model system for this purpose was the synthesis of the enzyme tyrosine aminotransferase (TAT) in cultured hepatoma cells. When I arrived there I saw that it was a large laboratory, with many postdoctoral fellows working on different aspects of the synthesis of TAT. I thought that this was a bit too crowded and I asked Gordon for a different project. He suggested that I should study the degradation of TAT, a process that also regulates the level of this enzyme. This was how I became involved in protein degradation, a problem on which I have been working ever since.

Figure 9 shows one of the first experiments that I did as a postdoctoral fellow in the Tomkins lab. It was quite easy to follow the degradation of TAT: first hepatoma cells were
Figure 9. Energy-dependence of the degradation of tyrosine amino-transferase; from ref. [5].

incubated with a steroid hormone, which caused a great increase in the level of this protein. Then the hormone was removed by changing the culture medium, and a rapid decline in the level of this protein, due to its degradation, could be observed. As with other regulatory proteins, this protein also had a relatively rapid rate of degradation, with a half-life time of about 2–3 h. I found then that the degradation of TAT was completely arrested by potassium fluoride, an inhibitor of cellular energy production (ref. [5] and Figure 9). The effect was not specific to fluoride, because I got similar results with

other inhibitors of cellular energy production. These results confirmed and extended earlier findings of Simpson[6] on the energy-dependence of the liberation of amino acids from proteins in liver slices. This observation was later dismissed as being indirect, and that energy is needed to keep the acidic pH value inside the lysosomes (described in ref. [7]). However, in the case of TAT, energy was needed for the selective degradation of a specific enzyme, and it did not seem reasonable to assume that engulfment into lysosomes could be responsible for the highly selective degradation of specific cellular proteins. Since ATP depletion also prevented the inactivation of the enzymatic activity of TAT, it was concluded that energy is required at an early step in the process of protein degradation.[5]

I was very much intrigued by the energy-dependence of intracellular protein degradation. Energy is usually needed to synthesize a chemical bond, and not to break a chemical bond. Thus, the action of extracellular proteinases of the digestive system is an exergonic process, that is, it actually releases energy. This suggested that within cells a novel, as yet unknown proteolytic system exists, that presumably uses energy to attain the high selectivity of the degradation of cellular proteins.

4. Discovery of the Role of Ubiquitin in Protein Degradation

Parts of the story of the discovery of the ubiquitin system have been described previously.[7–9] Following my return to Israel and setting up my own laboratory at the Technion in Haifa, I continued to pursue this problem of how proteins are degraded in cells, and why energy is required for this process. It was clear to me that the only way to find out how a completely novel system works is that of classical biochemistry. This consists of using a cell-free system that faithfully reproduces the process in the test tube, fractionation to separate its different components, purification and characterization of each component, and reconstitution of the system from isolated and purified components. A cell-free ATP-dependent proteolytic system from reticulocyte lysates was first established by Etlinger and Goldberg.[10] Subsequently, my laboratory subjected this system to biochemical fractionation, with the aim of the isolation of its components and the characterization of their mode of action. A great part of this work was done by Aaron Ciechanover, who was my graduate student at that time (1976–1981). This work has also received a lot of support, great advice, and helpful criticism from Irwin Rose, in whose laboratory at Fox Chase Cancer Center I worked in a sabbatical year in 1977/1978 and in many summers afterwards.

In the initial experiments, we resolved reticulocyte lysates on DEAE-cellulose into two crude fractions: fraction 1, which contained proteins not adsorbed to the resin, and fraction 2, which contained all proteins adsorbed on the resin and eluted with concentrated salt solution. The original aim of this fractionation was to get rid of hemoglobin, which was known to be in fraction 1, while most nonhemoglobin proteins of reticulocytes were known to be in fraction 2. We found that

neither fraction was active by itself, but ATP-dependent protein degradation could be reconstituted by the combination of the two fractions.[11] The active component in fraction 1 was a small, heat-stable protein; we have exploited its stability to heat treatment for its purification to near homogeneity. We termed this protein at that time APF-1, for ATP-dependent proteolysis factor 1. The identity of APF-1 with ubiquitin was established later by Wilkinson et al.,[12] subsequent to our discovery of its covalent ligation to protein substrates, as described below. Ubiquitin was originally isolated by Goldstein et al. in a search for hormones of the thymus, but was subsequently found to be present in all tissues and eukaryotic organisms, hence its name.[13] The functions of ubiquitin were not known, though it was discovered by Goldknopf and Busch that ubiquitin was conjugated to histone 2A by an isopeptide linkage.[14]

The purification of APF-1/ubiquitin from fraction 1 was the key to the elucidation of the mode of its action in the proteolytic system. It looked smaller than most enzymes, so at first we thought that it might be a regulatory subunit of some enzyme (such as a protein kinase or an ATP-dependent protease) present in faction 2. To test this notion, we looked for the association of APF-1/ubiquitin with some protein in fraction 2. For this purpose, purified radiolabeled APF-1/ubiquitin was incubated with fraction 2 in the presence or absence of ATP, and was subjected to gel-filtration chromatography. A marked ATP-dependent association of APF-1/ubiquitin with high-molecular-weight material was observed.[15] It was very surprising to find, however, that ubiquitin was bound by a covalent amide linkage, as indicated by the resistance of high-molecular-weight derivative to alkali, hydroxylamine, and boiling with SDS (sodium dodecylsulfate) in the presence of mercaptoethanol.[15] The analysis of reaction products by SDS-polyacrylamide gel electrophoresis showed that ubiquitin was ligated to a great number of endogenous proteins. Since crude fraction 2 from reticulocytes contained not only enzymes, but also endogenous substrates of the proteolytic system, we began to suspect that ubiquitin may be linked to protein substrates, rather than to an enzyme. We indeed found that proteins that are good (though artificial) substrates of the ATP-dependent proteolytic system, such as lysozyme, are conjugated to ubiquitin.[16] The original experiment is shown in Figure 10. We found that similar high-molecular-weight derivatives were formed when ^{125}I-labeled ubiquitin was incubated with unlabeled lysozyme (Figure 10, lanes 3–5), or when ^{125}I-labeled lysozyme was incubated with unlabeled ubiquitin in the presence of ATP (Figure 10, lane 7). Based on these observations, we proposed that proteins are targeted for degradation by covalent ligation to APF-1/ubiquitin.[16] The original hypothesis from 1980, formulated jointly with Irwin Rose, is shown in Figure 11a. We proposed that a putative enzyme, which we called "APF-1-protein amide synthetase", ligates multiple molecules of ubiquitin to the protein substrate (step 1) and then some other enzyme degrades proteins which are linked to several molecules of ubiquitin (step 3), and finally free and reutilizable ubiquitin is released (step 4). According to this proposal, ubiquitin is essentially a tag, which when attached to a protein, dooms this protein to be degraded.

Figure 11. The ubiquitin system then and now. a) Original proposal of the sequence of events in protein degradation. See the text for more information; from ref. [16]. b) Our current view of the main enzymatic reactions in ubiquitin-mediated protein degradation. See the text for more information. Ub, ubiquitin; DUB, deubiquitylating enzyme; UCH, ubiquitin carboxyl-terminal hydrolase.

5. Identification of Enzymes of the Ubiquitin-Mediated Proteolytic System

In subsequent work, we tried to isolate and characterize enzymes of the ubiquitin pathway, by using the same biochemical fractionation/reconstitution approach. The original proposal of the mechanism (Figure 11 a) was found to be essentially correct, but much important detail was added. Our present knowledge of the main enzymatic steps in the

ubiquitin-mediated proteolytic pathway is shown in Figure 11b (reviewed in ref. [17]). This scheme summarizes about 10 years of our work (1980–1990), as well as that of some other researchers. Thus, we found that ubiquitin is ligated to proteins not by one enzyme, but by the sequential action of three enzymes. These are the ubiquitin activating enzyme E1,[18] a ubiquitin carrier protein E2,[19] and a ubiquitin protein ligase E3.[19] E1 carries out the ATP-dependent activation of the carboxy-terminal glycine residue of ubiquitin[20] by the formation of ubiquitin adenylate, followed by the transfer of activated ubiquitin to a thiol site of E1 with the formation of a thiolester linkage.[18,21] Activated ubiquitin is transferred to a thiol site of E2 by transacylation, and is then further transferred to an amino group of the protein substrate in a reaction that requires E3.[19] We found that the role of E3 is to bind specific protein substrates.[22] Based on this observation, it was proposed that the selectivity of ubiquitin-mediated protein degradation is mainly determined by the substrate specificity of different E3 enzymes.[23] This notion was verified by subsequent work in many laboratories on the selective action of a large number of different E3 enzymes on their specific protein substrates. Proteins ligated to polyubiquitin chains are degraded by a large 26S proteasome complex (discovered by other investigators) and free ubiquitin is released by the action of ubiquitin-C-terminal hydrolases or isopeptidases (reviewed in ref. [17]).

6. Mechanisms of the Degradation of Cyclin B: Discovery of the Cyclosome/Anaphase-Promoting Complex

All our studies on the basic biochemistry of the ubiquitin pathway were carried out with the reticulocyte system, using artificial model protein substrates. Though many gaps remained in our understanding of the basic biochemical processes of the ubiquitin system, at around 1990 I thought that it was important to turn to the question of how the degradation of specific cellular proteins is carried out by the ubiquitin system in a selective and regulated fashion. This is how I became interested in the roles of the ubiquitin system in the cell-division cycle, because the levels of many cell-cycle regulatory proteins oscillate in the cell cycle. I first worked on the biochemical mechanisms of the degradation of cyclin B in the early embryonic cell cycle. Cyclin B was discovered by Hunt and co-workers to be a protein that is degraded at the end of each mitosis.[24] It was subsequently found that it is a positive regulatory subunit of protein kinase Cdc2/Cdk1 (cyclin-dependent kinase 1; reviewed in ref. [25]). In the early embryonic cell cycles, cyclin B is synthesized during the interphase and then is rapidly degraded in the metaphase–anaphase transition. The active protein kinase Cdk1-cyclin B (also called MPF or M phase-promoting factor) is formed at the beginning of mitosis and promotes entry of cells into mitosis. The inactivation of MPF, caused by the degradation of cyclin B, is required for exit from mitosis. Our question was: what is the system that degrades cyclin B and why does it act only at the end of mitosis?

I approached this problem again by biochemistry, and here the quest for a cell-free system led me to marine biology and to the surf clam *Spisula solidissima* (Figure 12). This is a large clam that produces large numbers of oocytes. Luca and
Figure 12. The North Atlantic surf clam *Spisula solidissima*.

Ruderman[26] established a cell-free system from fertilized clam oocytes that faithfully reproduced cell-cycle stage-specific degradation of mitotic cyclins. In this work, I was greatly helped first by Robert Palazzo and Leonard Cohen, and then by collaboration with Joan Ruderman. Initial fractionation of the system[27] showed that in addition to E1, two novel components were required for the ligation of cyclin B to ubiquitin: these were a specific E2 called E2-C and an E3-like activity, which in clam extracts was associated with particulate material. We solubilized the E3-like activity and found it to be a large (ca. 1500 kDa) complex that has ubiquitin ligase activity on mitotic cyclins. The activity of this enzyme is regulated in the cell cycle: it is inactive in the interphase and becomes active at the end of mitosis, an event that requires the action of Cdk1/cyclin B.[28] We called this ubiquitin ligase complex the cyclosome, to denote its large size and important roles in cell-cycle regulation.[28] A similar complex was isolated at about the same time from extracts of *Xenopus* eggs by the Kirschner laboratory and was called the anaphase-promoting complex.[29] Parallel genetic work in yeast by the Nasmyth group identified several subunits of the anaphase-promoting complex/cyclosome (or APC/C, as it is now called) as products of genes required for exit from mitosis.[30] Thus, the discovery of APC/C was due to the convergence of biochemical and genetic work. Subsequent work by other investigators showed that the APC/C is also involved in the degradation of several other important cell-cycle regulators, such as securin, an inhibitor of anaphase onset (reviewed in refs. [31,32]). In addition, APC/C is the target of the spindle assembly checkpoint system, an important surveillance mechanism that allows the separation of sister chromatids only after they are all properly attached to the mitotic spindle (reviewed in ref. [33]).

7. Role of Scf^SKP2 Ubiquitin Ligase in the Degradation of the Cdk Inhibitor P27^Kip1

Another problem on which I have been working recently, in collaboration with Michele Pagano, is the mode of the degradation of the mammalian Cdk inhibitor p27^Kip1. This inhibitor is present at high levels in G0/G1, preventing the action of Cdk2/cyclin E and Cdk2/cyclin A to drive cells into the S-phase. Following growth stimulation by mitogenic agents, p27 is rapidly degraded, allowing the action of these kinases to promote entry into the S-phase (reviewed in ref. [34]). It has been shown that p27 is degraded by the ubiquitin system.[35] We have tried to identify the ubiquitin ligase system that targets p27 for degradation. It was first found that the process of p27–ubiquitin ligation can be faithfully reproduced in vitro in extracts of HeLa cells. Thus, the rate of ligation of p27 to ubiquitin was much greater in extracts from growing cells than in extracts from G1-arrested cells. It was also found that the phosphorylation of p27 on T187 by Cdk2/cyclin E is required for p27–ubiquitin ligation in vitro,[36] as is the case in vivo.[37] Having established that the cell-free system accurately reflects the characteristics of p27 ubiquitylation in cells, we then proceeded to utilize this cell-free system to identify the ubiquitin ligase (E3 enzyme) involved in this process. Because of the requirement for the phosphorylation of the p27 substrate, we suspected that an SCF-type (Skp1-cullin1-F-box protein) ubiquitin ligase might be involved. SCF complexes comprise a large family of ubiquitin–protein ligases, whose variable F-box protein subunits recognize a variety of phosphorylated protein substrates (reviewed in ref. [38]). We have identified Skp2 (S-phase kinase-associated protein 2) as the specific F-box protein component of an SCF complex that ubiquitylates p27, based on the following biochemical evidence: 1) Immunodepletion of extracts from proliferating cells with an antibody directed against Skp2 abolished p27–ubiquitin ligation activity; 2) addition of recombinant, purified Skp2 to such immunodepleted extracts completely restored p27–ubiquitin ligation; 3) specific binding of p27 to Skp2, dependent upon phosphorylation of p27 on T187, could be demonstrated in vitro. Combined with further in vivo evidence from the Pagano group, Skp2 was identified as the specific and rate-limiting component of an SCF complex that targets p27 for degradation.[39] It is notable that levels of Skp2 also oscillate in the cell cycle, being very low in G1, increasing upon entry of cells into the S-phase, and declining again later on.[40] These fluctuations in Skp2 levels provide an important mechanism for cell-cycle, stage-specific regulation of p27 degradation.

We next tried to reconstitute the SCF^Skp2 system that ligates p27 to ubiquitin from purified components. We found that in addition to the known components (cullin 1, Skp1, Skp2, Roc1, Cdk2/cyclin E, E1, and the E2 enzyme Cdc34), an additional protein factor is required for this reaction. We have purified the missing factor from extracts of HeLa cells and have identified it as Cks1 (cyclin kinase subunit 1), both by mass spectrometry sequencing and by functional reconstitution with recombinant Cks1 protein.[41] Cks1 belongs to the highly conserved Suc1/Cks family of proteins, which bind to some cyclin-dependent kinases and to phosphorylated proteins, and are essential for several cell-cycle transitions.[42] Human Cks1, but not other members of this protein family, reconstituted p27–ubiquitin ligation in a completely purified system. While all members of the Suc1/Cks protein family have Cdk-binding and anion-binding sites, only mammalian Cks1 binds to Skp2 and promotes the association of Skp2 with p27 phosphorylated on T187.[41] Similar results were independently obtained by another research group.[43] More recently, we have mapped the Skp2 binding site of Cks1 by site-directed mutagenesis and found that it is located on a region that includes the α2 and α1 helices, well separated from the other two binding sites of Cks1. All three binding sites of Cks1 are required for its action to promote p27–ubiquitin ligation and for the association of Skp2 with T-187-phosphorylated p27.[44] Based on these and on further observations a model was proposed, according to which Cks1 serves as an adaptor necessary for enzyme–substrate interaction: the Skp2–Cks1 complex binds to phosphorylated p27, a process which requires the anion-binding site of Cks1. The affinity of Skp2 to the substrate is then further strengthened by the association of the Cdk binding site of Cks1 with Cdk2/cyclin E, to which phosphorylated p27 is tightly bound.[44] It is notable that the expression of Cks1 also oscillates in the cell cycle,[45,46] providing an additional mechanism for the regulation of p27 degradation.

8. Concluding Remarks

The ubiquitin system has come a long way since its humble beginnings described here. Ubiquitin-mediated degradation of positively or negatively acting regulatory proteins is involved in a variety of cellular processes such as the control of cell division, signal transduction, transcriptional regulation, immune and inflammatory responses, embryonic development, apoptosis, and circadian clocks, to mention but a few. The involvement of malfunction of ubiquitin-mediated processes in diseases such as certain cancers, and the therapeutic implications of this knowledge, are also beginning to emerge. I am quite certain that we are still seeing only the tip of the iceberg of the multitude of functions of the ubiquitin system in health and disease. The main lesson from the story of the discovery of the ubiquitin system that I would like to convey, mainly to young researchers, is the continued importance of biochemistry in modern biomedical research. In his book *For the Love of Enzymes*, Arthur Kornberg divided the history of biomedical research into four main periods. First were the "microbe hunters", the great microbiologists of the 19th century. They were followed by the "vitamin hunters", the discoverers of the vitamins. Next were the "enzyme hunters"—the biochemists, followed by the "gene hunters"—the molecular geneticists. However, the times of enzyme (or protein) hunting are far from being over. With the completion of the human genome project, all genes have been "hunted", but we know the functions of only about one-third of our genes. If we want to know what the roles of the rest of our genes in health and in disease are, we shall have to continue to use biochemistry, in combination with functional genetics, well into the future. Our story shows that the ubiquitin system

could not have been discovered without biochemical approaches. We would not have a clue to the ubiquitin-tagging mechanisms by genetics alone, or by the sequence of the genes in the ubiquitin system. On the other hand, once the basic biochemistry was known, molecular genetic approaches were essential for the discovery of the multitude of functions of the ubiquitin proteolytic pathway. So my advice to young investigators in biomedical sciences is: if you have a problem that cannot be solved by molecular genetics alone, do not be afraid to use biochemistry, do not hesitate to enter the cold room, and do not be wary of approaching the FPLC machine!

In experimental sciences, including biochemistry, discoveries are not made by a single person, but require the assistance of dedicated research teams and the help of friends, colleagues, and collaborators. In my laboratory at the Technion, Haifa, I was very fortunate to receive devoted help, at different times over a period of more than 30 years, from Dvora Ganoth, Hanna Heller, Esther Eytan, Sarah Elias, Clara Segal, and from my wife, Judith Hershko. Among my former graduate students, Aaron Ciechanover did tremendous work in the exciting times of the discovery of ubiquitin–protein ligation 25 years ago. Subsequently, many other graduate students (too many to list here) did very important work on the basic biochemistry of the ubiquitin system and more recently, on some roles of this system in cell-cycle control. Out of my several friends/collaborators, mentioned here, Irwin Rose had a very special role. My association with Ernie started with a sabbatical year in his laboratory in Fox Chase Cancer Center, Philadelphia, in 1977–1978 (see also the biography at the beginning of this Review). During this year, I continued to work on the initial fractionation of the reticulocyte system and the purification of ubiquitin, which we started in Haifa. In the following summer of 1979, Ernie invited me back to his laboratory, together with my graduate student Aaron Ciechanover and research assistant Hanna Heller. When we got there we already knew, from work done in the Haifa lab, that ubiquitin becomes bound to proteins in an ATP-dependent process. However, the discovery that a covalent amide bond is formed between ubiquitin and the substrate protein was made together with Ernie Rose in that summer in Philadelphia. A group picture, taken at the end of this memorable summer of 1979 at Fox Chase Center, included the people involved (Figure 13). The results of this summer's work are reported in ref. [16].*

Intracellular Protein Degradation: From a Vague Idea, through the Lysosome and the Ubiquitin–Proteasome System, and onto Human Diseases and Drug Targeting (Nobel Lecture)**

Aaron Ciechanover*

Between the 1950s and 1980s, scientists were focusing mostly on how the genetic code is transcribed to RNA and translated to proteins, but how proteins are degraded has remained a neglected research area. With the discovery of the lysosome by Christian de Duve it was assumed that cellular proteins are degraded within this organelle. Yet, several independent lines of experimental evidence strongly suggested that intracellular proteolysis is largely non-lysosomal, but the mechanisms involved remained obscure. The discovery of the ubiquitin–proteasome system resolved the enigma. We now recognize that degradation of intracellular proteins is involved in regulation of a broad array of cellular processes, such as the cell cycle and division, regulation of transcription factors, and assurance of the cellular quality control. Not surprisingly, aberrations in the system have been implicated in the pathogenesis of human disease, such as malignancies and neurodegenerative disorders, which led subsequently to an increasing effort to develop mechanism-based drugs.

1. Biographical Notes

The Formative Years—Childhood in the Newly Born State of Israel

I was born in Haifa, a port city in the northern part of Israel, in October 1947, one month before Israel was recognized by the United Nations as an independent state. It took several additional months to establish the necessary institutions and for the British to leave, and on May 15th 1948, David Ben-Gurion, the founding father of the modern Jewish state and its first Prime Minister made Israel a fact and declared its establishment as a democratic state and a home for every Jew in the world. The neighboring, but even more distant Arab countries, along with powerful Arab parties from within did not accept the UN resolution and deliberately decided to alter it by force. A bloody and costly war erupted. It lasted a year, and more than 1% of the population of the newly born and defenseless state sacrificed their lives on its defense. I assume that the first two years of my life (1947–1949) were extremely difficult for my parents, Bluma (née Lubashevsky) and Yitzhak, who immigrated from Poland with their families as adolescents in the mid-1920s. Why did their families leave Poland—their "homeland"—their homes, working places, property, relatives, and friends, and decide to make their new home in a place with a vague, if any, clear

future that was part of the British Empire? They were idealists who enthusiastically followed the call of the Zionist movement that was established at the turn of the century by Benjamin Ze'ev Herzel (the seer of the Jewish State) to settle the land and make it—after two thousand years in the Diaspora, since the destruction of the second temple in Jerusalem—a home for the Jews. Following the Jewish Congress in Basel (Switzerland) in 1896, Herzel declared: "*In Basel I founded the Jewish State*". At that time Israel was part of the Ottoman Empire and became in 1917 part of the British Empire. My parents came from religious families, and the move, I believe, also had religious roots: Jews, throughout their lives in the Diaspora, have not stopped dreaming of having their own country, a dream that was driven by a biblical decree and prophecy:

"*Thus saith the Lord GOD: Behold, I will take the children of Israel from among the nations, whither they are gone, and will gather them on every side, and bring them into their own land*" (Ezekiel 37:21); "*And they shall dwell in the land that I have given unto Jacob my servant, wherein your fathers dwelt; and they shall dwell therein, they, and their children, and their children's children, for ever*" (Ezekiel 37:25); "*And I will rejoice in Jerusalem, and joy in my people; and the voice of weeping shall be no more heard in her, nor the voice of crying*" (Isaiah 65:19); "*And they shall build houses, and inhabit them; and they shall plant vineyards, and eat the fruit of them*" (Isaiah 65:21).

The question of timing was an important one, as despite centuries of continuous persecution and discrimination in Europe, the initial idea to establish a Jewish State had been the dream of a few. Only small groups of Jews settled in Israel during the 18th, 19th, and the beginning of the 20th century. It was only towards the end of the 19th century, with the ideas of

Herzel and the moves that led to the Balfour declaration (the British Minister of Foreign Affairs who declared in 1917 the recognition of the need for a Jewish homeland) that an active Zionist movement and Institutions were established, resulting in the translation of the dream into reality. Yet, it took an enormous amount of courage and daring by these European Jews to materialize this dream and try to establish, with almost no resources or support, a homeland in a place they had dreamt of for two thousand years, but that was not theirs at the time. The process was clearly accelerated by the heavy clouds that then covered the skies of Europe and that ended with the Holocaust. Many members of my parents' families immigrated to Israel before the Holocaust, but those who remained in Poland perished at the hands of the murderous Germans and their loyal Polish collaborators. The conversion of this movement into a State at that particular time (1947–1948) was no doubt the direct historical result of the holocaust, and symbolized the rise of the Jewish Nation from ash.

My father was a clerk in a law firm (later, in parallel with my brother, he studied law and became a lawyer), and my mother was a housewife and English teacher. My brother, Joseph (Yossi), who is 14 years older then me, was already on his national military compulsory service when I was 4 years old, the age from which I remember myself. I grew up in Haifa and enjoyed the wonderful beaches and Mount Carmel that rolls into the Mediterranean Sea. From my early days at home I remember a strong encouragement to study. My father worked hard to make sure we obtained the best possible education, and at the same time he was a member in the "Haganah" (defense), one of the prestate military organizations that fought the British for an independent Jewish State. Working in a law firm in the Arab section of the city, he risked his life daily going to work during the prewar hostilities and then the war time. My brother Joseph told me that the family waited daily on the balcony to see him return home peacefully. At home he used every free minute to delve into classic literature, Jewish religious law (Mishnah and Talmud), and modern law books. An important part of the education at home involved Judaism and Zionism. On the Jewish side, we obtained a liberal modern orthodox education. We attended services in the synagogue every Saturday and during holidays, and celebrated all Jewish holidays. Needless to say that my mother kept a Kosher kitchen.

It was extremely important for my parents to educate us as a new breed of proud Israeli Jews in their own independent country. I inherited from my father his love of Jewish studies and cultural life. To this very day, along with several physicians and scientist colleagues, I take regular periodical lessons taught by a Rabbinical scholar on how the Jewish law views moral and ethical problems related to modern medicine and science. Jewish cantorial music reflecting the prayers of Jews along many centuries has become my favorite music, and I avidly search for it in flea markets, used records stores, and auctions all over. Different Judaica artifacts also decorate my study.

In parallel, my parents made sure we should also receive an excellent general education. My father spoke several

languages fluently, Hebrew, Polish, Arabic, French, English, German, and Yiddish, and wanted me to acquire his strong love for books: while our home was not a rich one, we had a huge library. My parents also loved classical music, so we had a great collection of 78 rpm, and later 33 rpm records. I remember that Bizet's Carmen occupied more than 20 RCA (His Master Voice) 78 rpm bakelite records.

The apparently peaceful life of our family in Israel (although under the British Crown) during the years of the Holocaust in Europe was overshadowed by the murder of family members and of many families of friends and relatives that did not escape Europe in time. For my parents, the establishment of the State of Israel as an independent and sovereign Jewish State was a direct historical result of the Holocaust in Europe and a clear statement of *"Never Massadah shall fall again*!" (Massadah was one of the last strongholds of Jews during the Roman Empire. It fell into Roman hands after all its defenders committed suicide.) They left us with the idea that the Jewish State will not only protect us as free people, but will allow us to develop our own unique culture in a more general national context rather than as minorities scattered in different countries in the Diaspora.

Falling in Love with Biology

From early days I remember my strong inclination towards biology, though it has taken different directions at different times. I remember collecting flowers on Mount Carmel and drying them in the heavy Babylonian Talmud of my brother. I will never forget his rage on discovering my love of nature hidden among the pages of the old Jewish tracts. Then came the turtles and the lizards, extracting chlorophyll from leaves with alcohol, and the first microscope my brother bought me from his trip to England when I was 11 years old. With this microscope I discovered cells (in the thin onion epithelium) and did my first experiment in osmosis, when I followed the alteration in the volume of the cells after immersing the epithelium in salt solutions of different strengths. With friends we tried to launch a self-propelled rocket. The flower collection kept growing, now in special dedicated albums, and with it, a small collection of skeletons of different animals: fish, frog, toad, snake, turtle, and even some human bones I received from an older friend who was a medical student.

After several years of amateurish flirting with biology, I decided to formalize my knowledge and love of biology, and to major in Biology in high-school. While my years in elementary (1953–1959) and junior-high (1959–1962) school were mostly uneventful and passed without any thoughts on my future, the last two years in "Hugim" (Circles) high-school in Haifa (1963–1965) were not. I had wonderful and inspiring teachers in biology (Naomi Nof), chemistry (Na'ama Greenspon), and physics and mathematics (Harry Amitay). Biology at that time was largely a descriptive discipline: while we studied the mechanism of conversion of glucose into H_2O and CO_2 and production of energy in yeast and mammals (and the opposite process of photosynthesis in plants), and became acquainted with simple graphic descriptions of mitotic and meiotic cell divisions, most of our studies were devoted to detailed descriptions of the flora and fauna in our region, to comparative zoology (I remember well the efforts invested in memorizing the twelve differences between the frog and the toad, or between the circulatory systems and skeletal structure of the cat and dog), and to basic descriptive human anatomy and physiology (for example, how the human skeleton enables posture to be maintained). Pathogenetic mechanisms of diseases had not been mentioned, and the structure of DNA and the genetic code had entered our textbooks only towards the end of our high-school studies, in 1964/65. On the other hand, chemistry and physics appeared to me, maybe naively, to be strong mechanistic disciplines built on solid mathematical foundations. As a result, I had a deep feeling that the future somehow resided in biology, in deciphering basic mechanisms, as so little was then known. Yet, the complexity of biological and pathological processes looked to me enormous, almost beyond our ability to grasp, and I was intimidated: while I was clearly attracted to the secrets of biology, I was afraid to get lost. Importantly, I had nobody around, close enough, to consult, to clarify my thoughts. While deliberating between the largely unknown of biology and what I naively thought were the already well-founded physics and chemistry, medicine emerged as a compromise.

While it suffered from an even higher level of complexity compared to biology, it enjoyed some other advantages, such as the fascinating ability to cure or at least to provide some temporary solution to diseases. For me, this choice offered also a practical solution as in these years I lost both of my parents: my mother died in 1958 and my father in 1964. Their death meant that I needed to become independent as soon as I could. After the death of my mother, I was left with my father who took wonderful care of me. When my father died several years later, my late aunt Miriam (Wishniak; my mother's sister), with the support of my brother, took me to her home in Haifa, enabling me to seamlessly complete my high-school studies, in the same class and along with my friends, without interruption. The other option was to move to Tel Aviv, to my brother's home, but this would have been much more complicated. Their help was a true miracle, as thinking of it retrospectively, being left alone, without parents, at the age of sixteen, the distance to youth delinquency was shorter than the one to the high-school class. Yet, with the help of these wonderful family members, I managed to continue.

How My Love of Biology Evolved To Become a Career

Towards graduation from high-school I had to make a decision: The regular track would have taken me, like most Israelis, to national compulsory service in the Israeli Defense Forces (IDF), a duty we were all eager to fulfill. In addition to the regular service, the army encourages certain high-school graduates to postpone their service and first obtain a university education, particularly in areas that are relevant

to the military, such as medicine and different disciplines in engineering and sciences. Lacking any economic support, I thought it would be better to acquire a practical profession as soon as I could. As I mentioned, it was also a compromise between the complexity and mysteries of biological mechanisms to what I thought were the already exhausted physics and chemistry. What also attracted me to medicine was my impression that diseases could be cured: as children, we may have been influenced by short, self-limiting diseases that affected us, like influenza and measles, and were not directly aware of the major killers that left physicians and scientists alike helpless (much like these days), such as malignancies, vascular diseases, and neurodegenerative disorders. I had not appreciated at the time how far more descriptive medicine is, much more than biology. Practically, and no less important (which helped me solve my dilemma), was the fact that biology was not an option in the military-supported service postponement program.

So, after a fierce competition I was accepted at the only medical school in Israel at that time, that of the Hebrew University and "Hadassah" in Jerusalem (1965). The first four years (1965–1969) were exciting. We studied basic and clinical sciences, and I began to seriously entertain the idea of broadening my knowledge base in biochemistry or pharmacology. Towards the end of the fourth year, once we started to see patients, I started to have serious doubts whether I had made the right choice and truly wanted to become a practicing physician. The imbalance between phenomenology and pathogenetic mechanisms on one hand, and the lack of mechanism-based treatment for most of the major killers on the other hand, made me seriously think that I was on the wrong trail. I felt restless and started to realize how little we knew, how descriptive is our understanding of disease mechanisms and pathology, and as a consequence how most treatments are symptomatic in nature rather then causative. The statement "with God's help" I heard so frequently from patients that were praying for a cure and health received a real meaning. I had a feeling clinical medicine was going to bore me, and decided to take one year off in order to "taste" true and "wet" basic research.

The Faculty of Medicine had a special, one-year program for the few who elected to broaden their knowledge in basic research, and I decided to major in biochemistry. I had to convince my brother that this was the right thing to do, as I needed his help to further postpone my military service by one year. This was not easy, as he too had a "dream"—to see me independent with a profession from which I could make my living, and which in the traditional Jewish spirit was nothing else but practical medicine. Following our parents' death, he felt he was responsible for my future and well-being, and wanted to see me independent as soon as he could. I nevertheless managed to convince him, and during that year (1969–1970), under the guidance of first-rate biochemists, Jacob Bar-Tana and Benjamin Shapira, I investigated mechanisms of CCl_4-induced fatty liver in a rat model, and discovered that it may be caused, at least partially, by an increased activity of phosphatidic acid phosphatase, a key enzyme involved in di- and triglyceride biosynthesis. Com-

pleting this research year (and obtaining an MSc degree), I knew I had found a new love—biochemistry. Jacob and Benjamin walked me through the exciting maze of biochemical pathways, and I was mystified. Yet, the consummation was still far away. Being loyal to the promise I made to my brother, and also to my commitment to the Israeli army, I completed the clinical years (1970–1972) and graduated Medical School.

To obtain my medical license, I still had to complete one additional year of rotating internship. At that time colleagues told me that a young talented biochemist, Dr. Avram Hershko, had just finished his postdoctoral training with Gordon Tomkins at the University of California in san Francisco (UCSF) and was recruited by the Dean and founder of the newly established Faculty of Medicine at the Technion in Haifa, the late Professor David Ehrlich, to establish a unit of Biochemistry. I wrote to Avram, with the intention to relocate to Haifa, to carry out my rotating internship there, and to use this year to carry out my MD thesis research project under his supervision. This was a small thesis I had to submit to the Medical School in partial fulfillment of the requirements for graduation. Typically for this thesis, most medical students evaluate statistically on-going treatments/procedures, but I decided to return to the laboratory and touch on yet another research project. He agreed to accept me as an MD student, and in October 1972 we started our more than three decades voyage.

Avram was still not certain about his own main research direction, and we discussed two possibilities for my MD thesis. One was obviously to further dissect the tyrosine aminotransferase (TAT) ATP-dependent proteolytic pathway. Avram started his own trip into the world of intracellular proteolysis with Gordon and discovered that the degradation of the gluconeogenetic enzymes in cells requires energy. This was a corroboration of an earlier finding of Simpson who demonstrated in the early 1950s that the degradation of the entire population of cellular proteins in liver slices requires energy, but the mechanism(s) of this thermodynamically paradoxical requirement had remained elusive.

The other possibility was to study the mechanisms involved in the cell's "pleiotropic response"—the immediate response of serum-starved, G0-synchronized cells to the addition of serum. During his postdoctoral studies with Gordon, Avram found that among the many stimulated processes are rapid uptake of nucleotides, amino acids, and phosphate. As during my studies on fatty liver I acquired experience working with lipids, and since Avram felt the elucidation of the TAT proteolytic mechanism may be a too difficult undertaking for a short MD thesis research project, we decided to add one additional layer to the study on the "pleiotropic response" and to analyze the effect of serum on the synthesis of phospholipids.

We assumed that following serum addition, cell membranes undergo major changes that will be reflected in phospholipid metabolism. Indeed, a few minutes after serum addition we were able to detect a dramatic increase in the turnover of the phosphoinositol moiety on the diglycerol skeleton. A review of the literature revealed a similar effect of

different target cells in response to a broad array of stimuli, including parasympathetic secretory cells responding to acetylcholine and thyroid gland cells to their cognate hormones, thyrotropin (TSH). The year (1972/73) I spent in the laboratory (it was not a real year but rather moonlighting, as a significant part of the time I was busy in the hospital rotating among the different clinical departments completing my duties as an intern towards graduation; I worked in the laboratory in my free evenings, nights, weekends, and holidays) finally convinced me to pursue a career in Biochemistry. But I still had three years of military service ahead of me (1973–1976).

Military Service and Professional Career—Have They Collided with One Another?

Following graduation, it was time to repay my national debt and serve in the IDF. I served for three years (1973–1976) and did it gladly. Serving in the army has always been regarded as an integral and important part of Israeli life and an entry card to its society, giving one the feeling of sharing—every one takes part in protecting this land and its inhabitants. In addition, the service itself was extremely interesting, technically, but also socially and historically. Technically, since I served in interesting units and socially, since the military service is a wonderful humane experience, the best melting pot one can go through, generating true friendships during hard times, friendships that are therefore deep, true, and lasting.

Historically, it spanned an interesting period. Initially I served in the navy, as a physician in the missile boats fleet. The year was 1973, immediately after the October Day of Atonement (Yom Kippur) war, and Israel faced a problem of protecting its southern gates, the Red Sea and the narrow Tiran (Sharm-a-Sheikh) strait that led to the port of Eilat. These were threatened by the Arab countries that neighbored the Red Sea, mostly Saudi Arabia and Egypt but also Yemen and Somalia, and Israel had to stretch its marine arm. To do so, it was necessary to transfer missile boats from the main naval bases in the Mediterranean to the Red Sea. At that time Israel did not have diplomatic relationship with Egypt, and the Suez Canal was closed by ships sunk by the Egyptians during the June 1967 Six Day War, so the decision was made to bring the boats from Haifa to Eilat, sailing through the Mediterranean Sea, and around the West and then East coasts of Africa. I was the physician on the "Reshef", one of the two boats (modern Israeli missile boats that were built in the Haifa naval shipyard) selected for the mission. One can imagine that for small missile boats, such a long (several weeks) voyage, a large part of it in the open oceans, is rather complicated, and for many reasons also risky. Beyond fueling and provision of supplies and spare parts to the crews and boats, one has to think of sailing in waterways surrounded by hostile countries, many miles away from home and a long flight distance for the Israeli Air Force. Another problem was obviously medical, how one treats emergencies, from possible gunshot wounds through "simple" daily problems like appen-

dicitis, in a small ship, far from any medical facility and with limited diagnostic and treatment capabilities. I was particularly concerned, as I was a young physician with almost no clinical experience. I assume this would have been a challenge for more experienced physicians as well. Luckily, the voyage was smooth.

The remaining part of my three years service was also interesting. I spent that time in the Research and Development unit of the Medical Corps, developing a broad array of sophisticated devices for the soldier in the battlefield. Because of the broad range of experiences, the military service has been my ever best school for real "life sciences". During all these years (1973–1976) I maintained tight connections with Avram and fulfilled my duties as an "external" department member: during vacations from the military and along with other members of the department, which grew meanwhile, I taught continuously the course in Clinical Biochemistry to third year medical students. I should mention in particular Michael (Mickey) Fry, with whom I have remained a good friend to the present day, and my good friend and colleague Erela Gorin, who died untimely in the early 1990s.

In 1975, during the military service, I married Menucha, a physician and a graduate of Tel Aviv University School of Medicine. Menucha was a resident in internal medicine in Tel Aviv Municipal Hospital, and we built our first home in this city. Marrying Menucha brought my wanderings to an end and I felt I had again a family and a home. During all the years since the death of my father (1963–1975) I did not have a really stable home, and I wandered between the homes of my brother and my aunt in Haifa. They were truly wonderful, but I needed a base, and Menucha, with her quiet approach and warm acceptance, along with our beautiful apartment, provided me with this so much needed shelter.

Discovery of the Ubiquitin System—Graduate Studies

Towards the end of the military service, I had to make what I assume has been the most important decision in my career: to start a residency in clinical medicine, in surgery, which was my favorite choice, or to enroll into graduate school and start a career in scientific research. It was clear to me that I was heading to graduate school. My disillusionment with clinical medicine that diseases can be cured based on the understanding of their pathogenetic mechanisms, along with a magical and enchanting attraction to biochemistry, made the decision easier. I received strong support and encouragement from my wife Menucha, who started to realize she was married to a graduate student with no clear future rather than to a physician with a bright career and broad financial horizons that she thought she had married.

So in November of 1976, after my discharge from the national service and a two months driving trip across the USA, I started my graduate studies with Avram Hershko. Since I had worked with him and known him for several years now, I thought he would be an excellent mentor. At that time his group focused mostly on studying intracellular proteolysis,

and I learnt from him that he had given up on trying to identify the mediator(s) and mechanism(s) involved in the serum-induced "pleiotropic response". The choice of Avram was to work on the degradation of abnormal hemoglobin in reticulocytes, a terminally differentiating red blood cell. The reason for the selection of the reticulocyte as a model system was that we were looking for a non-lysosomal (and energy-requiring) proteolytic system, as from many studies it had become clear that regulated proteolysis of intracellular proteins is non-lysosomal, and the reticulocyte no longer contains lysosomes which are removed during the final stages of its maturation before its release into the circulation. From he work of others, it was clear that the reticulocyte contained such a proteolytic system.

Interestingly, in the summer of 1978, during a Gordon Conference on Lysosomes, I met Dr. Alex Novikoff from Yeshiva University School of Medicine in New York. Alex, along with Dr. Christian de Duve, was one of the pioneers of the lysosome research field. When I told him we were working on the reticulocyte because this cell does not have lysosomes, he angrily dismissed this argument, telling me that he characterized, though morphologically, acid-phosphatase-positive organelles in reticulocytes. He even gave me the relevant paper he published on the subject, though it was not clear that these are proteolytically functional organelles.

Another reason for the choice of the reticulocyte as a model for studying intracellular proteolysis was that in its final stages of maturation in the bone marrow and prior to entering the peripheral circulation, a massive proteolytic burst destroys most of its machineries, making it clear that the cell is equipped with an efficient proteolytic system. Earlier studies by Rabinovitz and Fisher demonstrated that the reticulocyte degrades abnormal, amino acid analogue containing hemoglobin, yet the mechanisms had remained elusive. We assumed that it was probably the same mechanism that was also involved in the natural maturation process and also in the removal of "naturally occurring" mutant abnormal hemoglobins that are synthesized in different hemoglobinopathies, such as thalassemias and sickle-cell anemia. Thus, this important piece of information—the existence of a non-lysosomal proteolytic system—made the choice of the reticulocyte an obvious one.

It was still necessary to demonstrate that the process required energy, and indeed, following an initial characterization of energy-requiring degradation of abnormal hemoglobin in the intact cell (which was published in 1978 in the proceedings of a proteolysis meeting held in Buffalo, NY), we felt the time was ripe to break the cell open and isolate and characterize the non-lysosomal and ATP-dependent proteolytic enzyme(s). Shortly before, in 1977, Dr. Alfred Goldberg and his postdoctoral fellow Dr. Joseph Etlinger at Harvard Medical School characterized, for the first time, a cell-free proteolytic system from reticulocyte, which was exactly the point where we wanted to start our own march, so we basically adopted their system.

I will not describe here the detailed history of the discovery of the ubiquitin system, but rather highlight two important points along the five years of my exciting graduate studies (1976–1981) with Avram and Irwin A. (Ernie) Rose that led to the discovery of the system. The more detailed history can be found in several review articles written on the system at that time (see, for example, A. Hershko, A. Cienchanover, *Annu. Rev. Biochem.* **1982**, *51*, 335–364) and later, and in the accompanying Nobel Lecture.

The first point relates to the multiplicity of enzymatic components in the system: our first aim along the purification process of the ATP-dependent "protease" was to remove hemoglobin, the major protein in the crude extract. Towards that end, we resolved the extract on an anion-exchange resin, where we encountered the first exciting finding. The proteolytic activity could not be found neither in the non-adsorbed material, which we denoted fraction I, nor in the material eluted with a high salt concentration, denoted fraction II. Rather, we recovered the activity following reconstitution of the two fractions. We learnt two important lessons from this experiment which was published in 1978 in *Biochem. Biophys. Res Commun.* (in my opinion the first paper in the long historical trail of the ubiquitin proteolytic system) and which I regard as one of two or three key publications in the field. We learnt two lessons from this experiment: 1) The first lesson was that the protease we were after was not a "classical" single enzyme that degrades its substrate, but had at least two components. This was already a digression from the paradigm in the field at that time that proteolytic substrates, almost without exception, could be cleaved at least partially by single proteases with limited, yet defined specificities. Here we needed two components for proteolysis to occur. Now we know that the number of components of the ubiquitin system exceeds one thousand, but the first hint was already there; once one is left without a paradigm, all possibilities are open. 2) The second lesson was a methodological one. Each time we lost an activity during purification of any of the components we were characterizing, we returned to the chromatographic column fractions and tried to reconstitute it by complementation: "classical" biochemistry at its best was on our side.

Standing at a crossroads, we (luckily but thoughtfully) decided to start first with purification and characterization of the active component in fraction I. We decided so, because fraction I was the hemoglobin-containing fraction that did not adsorb onto the resin, and therefore we thought that it should not contain too many additional proteins. In the summer of 1977, ten months after I started my studies, Avram departed to a sabbatical with Ernie at the Fox Chase Cancer Center in Philadelphia, USA, and left me with the task of purifying the active component from fraction I. After many unsuccessful trials (along with another graduate student of Avram, Yaacov Hod), my colleague Mickey Fry, who was appointed as my substitute thesis advisor for this year (1977/78), came up with the "crazy" idea to heat fraction I and see if the active component was heat-stable, and indeed it was. He did so as all our attempts to resolve the activity from hemoglobin—despite the large difference in the molecular mass between the active protein (ca. 10 kDa) and hemoglobin (65 kDa)—failed. Following 5–10 min at 90°C, the hemoglobin in crude fraction I was "cooked" and precipitated like mud, and the activity remained soluble in the supernatant. It was hard to

believe it was a protein, but Mickey remembered several other heat-stable proteins. Immediately after, we showed directly that the activity in fraction I was also a protein: it was sensitive to trypsin and precipitable with ammonium sulfate. Further characterization revealed that the protein had a molecular mass of about 8500 Da, and we called it ATP-dependent proteolysis factor-1 (APF-1). All along the way I corresponded with Avram, sent him the data, and during his sabbatical we wrote the paper for *Biochemical and Biophysical Research Communications*.

The second key finding was also discovered in Haifa during the winter of 1978/79. We purified APF-1 to homogeneity and labeled it with radioactive iodine. When the radiolabeled protein was incubated in crude reticulocyte fraction II in the presence of ATP, we observed a dramatic increase in its molecular weight: it now migrated as a sharp peak in the void volume of the gel-filtration chromatographic column. For several months we tried to elucidate the mechanism that underlies this change, hypothesizing, for example, that APF-1 could be an activator of a protease that must generate a binary complex with the enzyme in order to stimulate it, but to no avail. An important breakthrough occurred during our 1979 summer stay of several months in the laboratory of Ernie. Through a series of extremely elegant, yet simple, experiments, in which we used the broad knowledge of Ernie in protein chemistry and enzymology, we found that APF-1 is covalently attached to the substrate through a bond that had all the characteristics of a peptide bond. Furthermore, we found that multiple moieties of APF-1 are attached to each substrate molecule, and that the reaction is reversible: APF-1 can dissociate from the substrate, though not by reversal of the conjugation reaction. Accordingly, we hypothesized that covalent attachment of multiple moieties of APF-1 to the target substrate is necessary to render it susceptible to degradation by a downstream protease that recognizes only tagged proteins, followed by the release of free and reusable APF-1.

The APF-1 cycle demonstrated unequivocally the existence of three, entirely novel activities: 1) APF-1-conjugating enzyme(s), 2) a protease that recognizes specifically the tagged substrates and degrades them, and 3) APF-1-recycling enzymes. All the enzymes involved were identified later by us (the three conjugating enzymes, E1, E2, and E3) or by others (the conjugates degrading protease known as the 26S proteasome complex, and the ubiquitin-recycling enzymes, the isopeptidases). The findings describing the covalent tagging of the target substrate by APF-1 as a degradation signal as well as its release, along with the first model of the newly discovered proteolytic system, were published in 1980 in two papers that appeared in the *Proceedings of the National Academy of Sciences*.

Another important development also occurred during our stay in Ernie's laboratory, and I am not sure whether it was shear luck or serendipity, probably both. We were not aware of any other precedent of a modification of a protein by another protein. The neighboring laboratories of Martin Nemer, Alfred Zweidler, and Leonard Cohen studied dynamics of variants of different histones during sea urchin development. They drew our attention to a protein called A24 (uH2A) which was discovered earlier by Ira Goldknopf and Harris Busch, and that was a covalent conjugate between two proteins: a small, approximately 8.5 kDa protein called ubiquitin and histone 2A (H2A). Goldknopf and Busch, and in parallel Margaret Dayhoff, identified the nature of the bond between the two protein moieties in the conjugate. They found that the ubiquitin–histone bond was an isopeptide/bifurcated bond between the C-terminal Gly^{76} residue in the ubiquitin moiety, and the ε-NH$_2$ group of Lys^{119} in the histone moiety of the conjugate. The role of this conjugate was not clear at the time, though its level was found to be dynamic and change during differentiation, when the histone moiety is subjected to ubiquitination and deubiquitination.

This information on the ubiquitin–histone adduct and the similarity we found between APF-1 and ubiquitin in general characteristics, molecular mass, and amino acid composition, led Keith Wilkinson and his colleagues Arthur (Art) Hass from the laboratory of Ernie, along with Michael Urban from Zweidler's laboratory, to carry out a series of direct experiments, which showed unequivocally that APF-1 is indeed ubiquitin. Our study on the characterization of APF-1 and its possible similarity to ubiquitin, and Wilkinson's study (along with Urban and Haas) on the identification of APF-1 as ubiquitin, led to the convergence of two fields, that of histone research and of proteolysis. More importantly, they suggested that the bond between ubiquitin and the target proteolytic substrate maybe identical to that between ubiquitin and histone, which we demonstrated later to be true. The elucidation of the nature and structure of the bond clearly paved the road to the later identification of the conjugating enzymes and their mode of action. The two studies on APF-1, ours and that of Wilkinson and co-workers, were published in tandem in the *Journal of Biological Chemistry*.

As for ubiquitin, the protein was identified in the 1970s by Gideon Goldstein (in the Memorial Sloan–Kettering Cancer Center in New York City) as a small, 76-residue thymic polypeptide hormone that stimulates T-cell differentiation by activation of adenylate cyclase. Additional studies by Gideon Goldstein had suggested that it was universally distributed in both prokaryotes and eukaryotes, thus giving rise to its name (coined by Gideon Goldstein). Later studies by Allan Goldstein showed that the thymopoietic activity was due to an endotoxin contamination in the protein preparation, and not to ubiquitin. By using functional assays, it was found in my laboratory (and I believe in others as well) that ubiquitin was limited to eukaryotes, and its apparent presence in bacteria was due to contamination of the bacterial extract with the yeast extract in which the bacteria were grown: growing the bacteria in a synthetic medium resulted in the "disappearance" of ubiquitin from the preparation. The later unraveling of the bacterial genome demonstrated unequivocally that the ubiquitin tagging system does not exist in prokaryotes, though there is some similarity between the proteasome and certain bacterial proteolytic complexes. Thus, in a relatively short period of time, ubiquitin was converted from a ubiquitous thymopoietic hormone to a eukaryotic proteolytic marker. While the term ubiquitin is not justified anymore, as it is

clearly not ubiquitous, we stopped using the term APF-1 and adopted the term ubiquitin as the modifying protein in the newly discovered proteolytic system. At times habits and tradition are stronger from the scientific validity and/or from logic in nomenclature. Accordingly, we adopted a general policy to use in our terminology the name that was first coined by the discoverer of any novel protein.

From that point on, the road was relatively short to the identification and characterization of the conjugation mechanism and the three enzymes involved in this process. En route to the unraveling of the conjugation mechanism, we followed partially the footsteps of Dr. Fritz Lipmann, the great biochemist from Rockefeller University (who was awarded the 1953 Nobel Prize in Physiology or Medicine for the discovery of coenzyme A). Lipmann continued to contribute to our understanding of basic biochemical processes. Among his many discoveries was the mechanism of non-ribosomal (and hence nongenetically encoded) peptide-bond formation that occurs during the biosynthesis of bacterial oligopeptides such as gramicidin S. We learnt that the principles of basic biochemical reactions, such as generation of high-energy intermediates involved in peptide-bond formation, were preserved along evolution regardless of whether the bond is encoded genetically or not, or whether it links two amino acids or two proteins. Initially, we identified the general mechanism of activation of ubiquitin in a crude extract. Later, using "covalent" affinity chromatography over immobilized ubiquitin and a stepwise elution (that was based on the general activation mechanism we deciphered earlier), we purified the three conjugating enzymes that act successively in a cascadelike mechanism, and catalyze this unique process: 1) the ubiquitin-activating enzyme E1, the first enzyme in the ubiquitin system cascade, 2) the ubiquitin carrier protein E2, to which the activated ubiquitin is transferred from E1, and 3) the ubiquitin protein ligase E3, the last and critical component in the three-step conjugation mechanism that specifically recognizes the target substrate and conjugates it with ubiquitin. The binding of E1 and E2 was mediated by the activation mechanism. The E3 was also adsorbed onto the resin, although by a mechanism distinct from that of E1 and E2.

Later studies by Avram in the late 1980s revealed that the E3 adsorbed by the column was E3α that recognizes substrates through their N-terminal residue. At this point, however, we were extremely lucky, when unknowingly we used as model substrates commercial proteins such as BSA, lysozyme, and RNase A that were all recognized by this ligase and through a similar targeting motif: their N-terminal residue. Had we used other substrates, such as globin, the model substrate we used in our initial experiments, the E3α adsorbed to the column would have escaped our attention, as E3 enzymes do not typically adsorb to ubiquitin. In parallel and independently, I also used this enzyme in the late 1980s in order to characterize a distinct subset of proteins recognized by this signal (see below). Last, and most importantly, using antibodies that we raised against ubiquitin with the help of Arthur Haas, we found that the ubiquitin system is involved in degradation of abnormal, short-lived proteins in hepatoma

cells, thus demonstrating that the system was not limited to the terminally differentiating reticulocyte, but was probably distributed more "universally" in nucleated mammalian cells, playing a role in maintaining the cell's quality control.

During my graduate studies at Avram's laboratory, I collaborated with Hannah Heller, an extremely talented and knowledgeable research associate (who also joined us for some of our summer stays in the laboratory of Ernie in Philadelphia) and with Yaacov Hod who was also a graduate student with Avram at that time. Other colleagues in the laboratory provided me with a lot of help during this period, including Dvorah Ganoth, Sarah Elias, and Esther Eythan who were research associates with Avram, and Clara Segal and Bruria Rosenberg, two dedicated technicians.

The Interaction with Irwin Rose

As noted, I spent an important part of my graduate studies in Ernie's laboratory. Avram spent a sabbatical in his laboratory in 1977/78, and I joined him for the first time for several months in the summer of 1978, after I completed the initial characterization of APF-1 in Haifa. I returned to Ernie's laboratory during the summers of 1979, 1980, and 1981. As noted, during our summer stay in 1979, we resolved the problem of the nature of the high-molecular-mass "compound" generated when APF-1 was incubated with fraction II in the presence of ATP. The change in the molecular mass of APF-1 was discovered several months earlier in Haifa, however, we were not able to unravel the nature of the "compound"; this had to await the knowledge and wisdom of Ernie. In a breakthrough discovery, we found that the target substrate is covalently modified by multiple moieties of APF-1, a modification that renders it susceptible to degradation. This was a novel type of posttranslational modification and clearly a new biological paradigm, that required—as I feel today in retrospect—a different type of knowledge and experimental approach. This would not have been possible without Ernie's advice that was based on his immense knowledge in enzymology and protein chemistry, accompanied by his unbiased way of original thinking and approach to problem resolving. This discovery, along with the discovery that APF-1 is ubiquitin in 1980, made Ernie, his fellows (in particular Keith Wilkinson and Arthur Haas), and laboratory crucial players in the historical trail of the discovery of the ubiquitin system. Interestingly, Ernie also studied proteolysis before Avram joined him first, but had never published in the field before.

Postgraduate Training at MIT and How I Continued My Studies on the Ubiquitin System Independently

The five years in graduate school had a significant impact on my future career, not only because I played an active part in such an important discovery, but maybe more importantly, because I learnt several basic and important principles of how to approach a scientific problem. From my mentors, first and

foremost Avram, but also Ernie, I learnt two important principles: first, to select an important biological problem (but in order to avoid fierce competition and to be original to ascertain it is not in the mainstream), and second, to make sure there are appropriate research tools to approach it experimentally.

From Avram I also learnt to become a book rather then a short stories writer: I learnt not to be opportunistic but rather to adhere to a project, to dig deeply into a problem, to resolve it mechanistically, to untangle complex mazes—peeling them like an onion, and not to be tempted to be dragged after fashions. I learnt to pay attention to small details, to carefully examine hints, as the important findings were not always obvious from the beginning. I learnt to be stubborn, to fight difficulties uphill, and most importantly to be critical: I believe I developed good senses that enable me to distinguish false from truth, and artifacts from meaningful findings.

Interestingly, I learnt all these principles not in frontal lessons or formal presentations, but as an apprentice, following my mentors own attitude and way of thinking. But I also learnt to question, to doubt, to ask, and to discuss, to follow my own gut feeling when it was necessary, not to always take advice and direction for granted, and to trust myself too. It did help in many occasions along the way, although at times I found myself swimming against the stream in my own school. Altogether these principles generated an important philosophy and shaped my approach to science, something I try to instill to my own students, as I strongly believe it is the only way one can make an impact and leave an imprint behind.

Toward graduation I had to think of the next step: postdoctoral training and planning of my future career as an independent scientist. I was in a dilemma. On the one hand I knew it was important to obtain training somewhere else, under different mentorship, in a different environment, being exposed to a different culture of science. On the other hand I knew for certain that the ubiquitin system was extremely important and that we were seeing only the tip of its iceberg. I therefore wanted to continue my studies in a related field, learning more on regulated proteolysis, but also to continue my own studies on ubiquitin.

I had several ideas in mind of where to go. The choice was quite narrow and also risky, as I did not have any idea of how much independence I could have as a postdoctoral fellow. Searching for a mentor, and with the advice of my colleague Mickey Fry, I looked for scientists whose work was related to regulated proteolysis. I wrote to Günter Blobel in the Rockefeller University, who worked at that time on translocation of proteins to the endothelium reticulum (ER), a process which involves cleavage of the leader peptide by signal peptidase, to Jeffrey Roberts in Cornell, who worked on *E. coli* RecA protein directed cleavage of phage λ repressor and its requirement for polynucleotide, and to Harvey Lodish at the MIT, who worked, among other subjects, on the processing of viral polyproteins. I am not sure Harvey was that impressed with the ubiquitin system at that time, but he was the only one to respond positively. Typical of his etiquette (as I learnt later), his response was prompt and direct, and he invited me for an interview, after which he accepted me.

Günter was kind enough to let me know he did not have space in his laboratory at that time, and Jeffrey never responded.

With two fellowships, one from the Leukemia Society of America and one from the Israel Cancer Research Fund (ICRF), I started a period of three wonderful years (1981–1984) in Harvey's laboratory in the Department of Biology at MIT. Harvey gave me complete freedom to choose my research subjects. What I had in mind was to take advantage of the exceptional strength of the laboratory and Harvey's unique expertise in cell biology, but in parallel, to continue my own studies on the ubiquitin system.

I realized that Harvey was no longer interested in viral protein processing, and along with Alan Schwartz who was a visiting scientist (from Harvard Medical School) in the laboratory, we started to characterize the transferrin receptor on a human hepatoma cell line with the aim of later studying the mechanism of transferrin and transferrin receptor mediated iron delivery to cells. This collaboration led us, along with another fellow in the laboratory, Alice Dautry-Varsat (from the Pasteur Institute) who joined us later, to the discovery of a fascinating mechanism of how iron is delivered into cells: in the neutral pH of the growth medium, the iron-loaded holotransferrin binds to its receptor with a high affinity and is endocytosed into the cell. At the low endosomal pH, the affinity between the iron and transferrin is weakened dramatically. As a result, the iron cation is released, but the apotransferrin, which has high affinity for the receptor at acidic pH, remains bound. Along with the receptor, the apotransferrin recycles to the cell surface. At the neutral pH of the growth medium, the apotransferrin loses its high affinity to the receptor and is released into the extracellular fluid where it can load additional iron ions and then rebind to its receptor with high affinity.

The transferrin/transferrin receptor pH-dependent and iron loading-dependent cycle has become a "classic" in the field of receptor-mediated endocytosis. Based on this, other phenomena related to receptor and ligand recycling to the cell surface or targeting to the lysosome could be explained, which are also due to the pH difference between the external environment and the interior of the endocytic pathway vesicles.

However, throughout this time I lived under the strong feeling that the ubiquitin system had barely started to emerge, with only the basic principles unraveled. I felt compelled to get back and work on it. So gradually I started to "crawl" and return to my "alma mater" research subject.

On one fascinating subject I worked on my own—continuing to explore a mysterious finding I discovered during my graduate training and which I did not pursue at the time: when we purified APF-1/ubiquitin in Haifa, we noticed a large discrepancy between its dry weight and the Lowry assay quantitative protein measurement. Avram hypothesized that the protein could be a ribonucleoprotein (RNP), and the remaining mass is that of the nucleic acid component. To test this hypothesis, we added DNase to the crude extract (ATP- and ubiquitin-containing) assay in which we monitored degradation of bovine serum albumin (BSA) that was used as one of our model substrates. The enzyme had no effect. We

then added RNase A, and to our surprise proteolysis was completely inhibited, even with an extremely small amount—a mere few nanograms—of the enzyme added: it looked as though the enzyme exerted its effect by catalysis—RNA degradation.

Avram suggested testing the RNase effect on lysozyme as well—our second model substrate. Here we got no effect, which was kind of a surprise, as proteolysis of the two substrates, BSA and lysozyme, behaved in an identical manner all along the way. ATP as well as all the different factors resolved from the crude extract were all required for the degradation of both proteins. Avram suspected that the RNase effect could be an artifact. Meanwhile, APF-1 was identified by Keith Wilkinson and his colleagues as ubiquitin, and the amino acid sequence/composition of ubiquitin disclosed the "secret" of the dry weight/protein measurement discrepancy—the molecule has a single tyrosine residue, thus eyplaining the low readings at 280 nm and in the Lowry assays. So we decided not to pursue this subject, and the selective inhibitory effect of RNase A on BSA degradation remained an unsolved mystery—for the time.

I had not stopped suspecting however that the findings must represent some true biological phenomenon, and used the opportunity of my independence at Harvey's laboratory to pull out the late 1970s data from my notebook and to start dissecting the RNase effect in a systematic manner. With some advice from Alexander (Alex) Varshavsky (MIT), and a lot of help from Joan Steitz (Yale), Harvey Lodish, and Uttam RajBhandary (MIT), I managed to make some progress. I discovered that the degradation of BSA was completely dependent on specific tRNAs (for Arg and His), and that the destruction of the tRNA led to inhibition of the reaction. The nature of the mechanism of action of the tRNAs and the problem of why the degradation of lysozyme was insensitive to RNase had remained a mystery at that time, which I resolved only when I retuned to Israel and established my own laboratory.

The other ubiquitin subject I was studying involved a collaboration with Alex Varshavsky and his then graduate student, Daniel (Dan) Finley. At that time Alex was studying the role of monoubiquitination of histones (see above for the histone H2A/ubiquitin adduct, also known as protein A24 or uH2A). He noted a series of publications on a temperature-sensitive cell-cycle-arrest mouse mutant cell ts85 that was generated and described by the group of M. Yamada. At the nonpermissive temperature, the cell lost the histone H2A/ubiquitin adduct. This loss could be due to one of two defects, either loss of ubiquitination, or activated deubiquitination. Alex asked me to collaborate with him and Dan to identify the mutation in this cell. We surmised that the defect in these cells was more likely due to loss rather then to gain of function, and set out to dissect the defect. The idea was that the same defect may also affect protein degradation, although it was clear that the single modification of the histone molecule by ubiquitin does not lead to its targeting to proteolysis.

Identification of the defect in the cells was not too difficult, as we used the isolation technique of the conjugation enzymes developed in Haifa, and demonstrated that the defect results from a temperature-sensitive ubiquitin-activating enzyme E1, the first enzyme in the ubiquitin system cascade. Importantly, inactivation of the enzyme led to inhibition of ubiquitin conjugation to the general population of cellular proteins, and was not confined to inhibition of conjugation of histone H2A. Consequently, degradation of short-lived proteins was also inhibited, demonstrating that the same enzyme that is involved in ubiquitin activation for histone modification is also involved in activation of ubiquitin for modification of substrates destined for degradation. Identification and characterization of the cell defect further corroborated our earlier general hypothesis that ubiquitination signals proteins for degradation, and that it also occurs in nucleated cells, a finding we had already demonstrated, albthough indirectly, in Haifa, using the anti-ubiquitin antibody. Since the ts85 cell was also a cell-cycle-arrest mutant, we hypothesized, but did not prove experimentally at the time, that the system might be involved in regulating the cell cycle, a hypothesis that later turned out to be correct.

The Return to Israel—Independent Research Career

After three years at MIT (1981–1984), it was time to seek an independent academic position. After many deliberations and despite attractive offers and a big temptation to stay in the US, I decided to return home, to Israel. With the help of Avram, I obtained an independent academic position in the Department of Biochemistry at the Faculty of Medicine of the Technion (where I graduated), and returned home towards the end of 1984, after a productive postdoctoral period. Importantly, I already had a research subject I wanted to pursue, the effect of RNase on ubiquitin-mediated proteolysis.

The years that followed the postdoctoral fellowship (1984–present) have been extremely rewarding. I was happy to return to Israel to my family and friends, to a place I felt I belong. I established my own independent research group and laboratory, obtained extramural competitive funding, and continued my research on the ubiquitin system. I have been lucky to have, through the years, a group of extremely talented graduate students and postdoctoral fellows.

In our first series of studies we elucidated the role of tRNA in the proteolytic process, a subject I discovered as a graduate student and continued to study independently at MIT. Along with one of my first graduate students, Sarah Ferber, we demonstrated that proteins with acidic N-termini, such as Asp or Glu, undergo arginylation at the N-terminus, converting the acidic, negatively charged residue at this site into a positively charged residue. The reaction is catalyzed by arginine tRNA-protein transferase, a known protein with a hitherto unknown function. The enzyme uses charged $tRNA^{Arg}$ as a source of activated Arg. Therefore, digestion of the cell extract RNA with RNase A inhibits this reaction. This finding explained the selectivity of the RNase effect to BSA and not to lysozyme: BSA has an Asp residue at the N-terminus, while lysozyme has lysine in this position. Interest-

ingly, the ligase involved is E3α, which we discovered during my graduate studies. The ligase recognizes only proteins with basic termini, but not with acidic N-termini. Thus, what appeared initially as an artifact turned out to be part of the first specific recognition signal in a target substrate.

Parallel to our work on the RNase effect, Avram and his graduate student Yuval Reiss characterized the E3α ligase and identified on it three distinct substrate binding sites for: 1) basic N-termini (the one involved in recognition of basic and Arg-modified acidic N-termini), 2) bulky-hydrophobic N-termini, and 3) "body" sites that reside downstream of the N-terminal residue. In parallel and by using a systematic genetic approach in the yeast *S. cerevisiae*, Alex Varshavsky and his colleagues formulated a general rule ("N-end rule") for recognition of all 20 different amino acid residues at the N-terminal site.

Research in the laboratory has also evolved in other directions. We have shown that N-α-acetylated proteins are also targeted by the ubiquitin system. This important finding demonstrated that the N-terminally modified proteins, a group that constitutes the vast majority of cellular proteins, must be targeted by signals that are distinct from the N-terminal residue and reside downstream to it: they do not have free N-termini and therefore cannot be recognized by the N-terminal amino acid residue. Along with the discovery of the "body" site in E3α, we felt that N-terminal recognition is of minor physiological significance, an exception rather then a rule, and the mode of recognition of the numerous substrates of the system must be broad and diverse: they are recognized by multiple and distinct targeting motifs.

At that point, towards the end of the 1980s, we felt it was time to move from studying model substrates to investigating the fate of specific native cellular substrates. We have shown that an important group of cell regulators—tumor suppressors (e.g. p53) and growth promoters (c-Myc)—are targeted by the ubiquitin cell-free system. We believed that this was true also for the targeting of these substrates in vivo, which later turned out to be correct. We continued and demonstrated that, unlike the thinking in the field until that time, that degradation of proteins in the lysosome proceeds independently from the ubiquitin system, the two proteolytic pathways are actually linked to one another, and ubiquitination is required for stress-induced lysosomal degradation of cellular proteins. This area later evolved in a dramatic manner, and engulfed involvement of the ubiquitin system in receptor-mediated endocytosis and autophagy. Other studies involved elucidation of some of the mechanisms involved in the two-step ubiquitin-mediated proteolytic activation of the transcriptional regulator NF-κB, demonstration of a role for heat-shock proteins in targeting certain protein substrates, and identification of a novel mode of ubiquitination at the N-terminal residue of the protein substrate. This modification is clearly different and distinct from recognition of the substrate by E3α at the N-terminal residue. In the latter case, the ligase binds to the N-terminal residue while ubiquitination occurs on an internal lysine. In N-terminal ubiquitination, modification occurs at the N-terminal residue, while the ligase binds, most probably, to an internal sequence in the protein target molecule. This subject has evolved in a surprising manner and changed another paradigm in the field that ubiquitination is limited to internal lysine(s) of the target substrate. We, and later others, have shown that the phenomenon is not limited to the one protein we identified initially (the muscle-specific transcriptional regulator MyoD), and identified a large group of proteins that undergo N-terminal ubiquitination. This group of proteins contain many that have internal lysine(s), but for some reason these residues cannot be targeted, and interestingly also a large group of proteins (such as p16^{INK4a} that plays an important role in cell-cycle regulation) that are devoid of any lysine residue. To be degraded by the ubiquitin system they must undergo N-terminal ubiquitination.

These years have not been simple, however. The Technion has traditionally been a school of engineering, and life sciences and biomedicine have been foreign to many of its senior faculty members and policy planners: we were treated in many ways like step-children, and thoughts of closing the school have been aired at times. This deeply rooted philosophy, which only now starts to change slowly, has severely hampered development in these fields and had left the body of researchers and infrastructure in these areas small and battling for survival. Through a network of wonderful colleagues all over the world (important among them is my friend Alan Schwartz from Harvard Medical School and then from Washington University in St. Louis) and fruitful collaborations, it was possible to establish an active research group and carry out what I believe was a good and original research program, even under less than optimal, and at times impossible conditions. This was important in balancing my desire to live in Israel, but at the same time to remain at the forefront of the ubiquitin research field that has grown in importance to become an extremely exciting, yet a highly competitive area.

Unpaid Debts

Last but not least, I owe a huge debt which I doubt I shall ever be able to repay to several people who helped me cross critical stormy waterways along my life. My aunt Miriam, who took me to her house after the death of my father and made her home a new home for me, thus enabling me to complete seamlessly my high-school studies without any interruption. My brother Yossi and my sister-in-law Atara, who opened their home for me during the fragile times of my high-school and medical studies, and made sure I would not collapse along the way, emotionally, but also economically. And last, my wonderful wife Menucha and my son Tzachi (Yitzhak, Isaac; named after my late father); they have flooded me with love, care, and deep understanding of my needs, and were always there for me, when I was flying high on the wings of my dreams, not always seeing them or listening to them or being with them, physically and emotionally. Without all these wonderful life partners, I could not have achieved anything.

I also owe special thanks to all my mentors, who each contributed in their own way to my upbringing as a scientist. I

have to thank Jacob Bar-Tana and Benjamin Shapira for taking me, hand in hand, through the complex maze of metabolic pathways, thus enabling me to fall in love with Biochemistry. Their enthusiasm and deep thinking convinced me, at a critical stage of my development, to pursue a career in biological sciences. I owe a big debt to my mentor, Avram Hershko, with whom I have come a long way in discovering the ubiquitin system, and from whom I learnt the very basic principles of how to approach a scientific problem. I owe special thanks to Ernie Rose for showing me that ordered thinking is not always necessary in science, and is even interfering at times, and that being erratic and disordered, absent minded at times, collecting sparks from all over the place, can yield wonderful ideas and results. Last, I owe a

huge debt to Harvey Lodish, who is not only a great cell biologist, but a wonderful spiritual mentor in a different way to how we tend to think of mentors. He gave me complete freedom to choose my own way, but did not let me fall. He always listened carefully and helped me to analyze data, and with his deep insight was able to find in the ocean of my numbers and graphic analyses new routes and pathways that I could have never seen or thought of. He used to gently comment on my approach when he felt I derailed, and helped redirecting me. Yet, he was never imposing: Harvey's active passive educational approach is truly unique. I owe many thanks to all my colleagues, in particular Alan Schwartz, Iasha Sznajder, and Kazuhiro Iwai, who helped me in many ways along this long voyage. I must also mention my laboratory

Table 1: Tabulated biography of Aaron Ciechanover.

Date and place of birth	October 1, 1947	Haifa, Israel
Education		
Elementary School	1953–1956	"Hashiloach" Elementary School, Haifa
High School	1959–1965	"Hugim" High School, Haifa
University (undergraduate studies)	1965–1972	"Hadassah" and the Hebrew University School of Medicine, Jerusalem (MSc, MD)
Clinical internship	1972–1973	"Rambam" Medical Center, Haifa
Military Service	1973–1976	Medical Corps, Israel Defense Forces (military physician)
University (graduate studies)	1976–1981	Faculty of Medicine, Technion, Haifa (DSc). Thesis advisor: Dr. Avram Hershko
Postdoctoral Training	1981–1984	Department of Biology and the Whitehead Institute, Massachusetts Institute of Technology, Cambridge, USA (with Dr. Harvey F. Lodish)
Faculty Position	1984–present	Faculty of Medicine, Technion, Haifa
Degrees		
MSc	1970	Medical Sciences. Faculty of Natural Sciences and the Department of Biochemistry, "Hadassah" and the Hebrew University School of Medicine, Jerusalem
MD	1974	"Hadassah" and the Hebrew University School of Medicine, Jerusalem
DSc	1981	Faculty of Medicine, Technion, Haifa
Academic Appointments		
1977–1979	Research Fellow	Department of Biochemistry, Faculty of Medicine, Technion, Haifa
1979–1981	Lecturer	
1984–1987	Senior Lecturer	
1987–1992	Associate Professor	
1992–	Full Professor	
2002–	Distinguished Research Professor	
Administrative Appointments		
1993–2000	Director	The Rappaport Family Institute for Research in the Medical Sciences, Technion, Haifa
Military Service		
1974–1977		Military Physician in the Israeli Navy and the Unit for Research and Development, Surgeon General Headquarters; discharged at the rank of Major
Visiting Appointments		
1978, 1979 1980 1981	Visiting Scientist	The Institute for Cancer Research, The Fox Chase Cancer Center, Philadelphia (with Dr. Irwin A. Rose)
1985–present	Visiting Professor	The Dana Farber Cancer Institute and Harvard Medical School, Boston; Washington University School of Medicine, St. Louis; University of Kyoto School of Medicine; Northwestern University School of Medicine, Chicago; STINT Fellow. Microbiology and Tumor Biology Center (MTC), The Karolinska Institute, Stockholm, Sweden; City University of Osaka School of Medicine, Osaka, Japan; Rockefeller University, New York

research associates, initially Sarah Elias and then Hedva Gonen and Beatrice Bercovich, who have become my eyes and hands since I established my own laboratory. Last but not least, my wonderful graduate students, fellows, and visiting scientists, with whom I discovered new and exciting paths in the rapidly evolving and exciting ubiquitin field.

2. Introduction

The concept of protein turnover is barely 60 years old. Beforehand, body proteins were viewed as essentially stable constituents that were subject to only minor "wear and tear". Dietary proteins were believed to function primarily as energy-providing fuel, which were independent from the structural and functional proteins of the body. The problem was hard to approach experimentally, as research tools were not available. An important research tool that was lacking at that time were stable isotopes. While radioactive isotopes were developed earlier by George de Hevesy (*Nobel Lectures in Chemistry 1942–1962*, World Scientific, **1999**, pp. 5–41), they were mostly unstable and could not be used to follow metabolic pathways.

The concept that body structural proteins are static and the dietary proteins are used only as a fuel was challenged by Rudolf Scheonheimer at Columbia University in New York city. Schoenheimer, like many other Jewish scientists (for example, Albert Einstein), escaped from Germany after the rise of the Nazis, and joined the Department of Biochemistry in Columbia University, founded by Hans T. Clarke.[1–3] There he met Harold Urey who was working in the Department of Chemistry and who discovered deuterium, the heavy isotope of hydrogen, a discovery that enabled him to prepare heavy water, D_2O. David Rittenberg, who had recently received his PhD in Urey's laboratory, joined Schoenheimer, and together they entertained the idea of "*employing a stable isotope as a label in organic compounds, destined for experiments in intermediary metabolism, which should be biochemically indistinguishable from their natural analog*".[1]

Urey later succeeded in enriching nitrogen with ^{15}N, which provided Schoenheimer and Rittenberg with a "tag" for amino acids and thus for their study on protein dynamics. They discovered that following administration of ^{15}N-labled tyrosine to rats, only about 50% was recovered in the urine, "*while most of the remainder is deposited in tissue proteins. An equivalent of protein nitrogen is excreted*".[4] They further discovered that from the half that was incorporated into body proteins "*only a fraction was attached to the original carbon chain, namely to tyrosine, while the bulk was distributed over other nitrogenous groups of the proteins*",[4] mostly as an NH_2 group in other amino acids. These experiments demonstrated unequivocally that the body structural proteins are in a dynamic state of synthesis and degradation, and that even individual amino acids are in a state of dynamic interconversion. Similar results were obtained using ^{15}N-labled leucine.[5]

This series of findings shattered the paradigm in the field at that time that: 1) ingested proteins are completely metabolized and the products are excreted, and 2) that body structural proteins are stable and static. Schoenheimer was invited to deliver the prestigious Edward K. Dunham lecture at Harvard University where he presented his revolutionary findings. After his untimely tragic death in 1941, his lecture notes were edited by Hans Clarke, David Rittenberg, and Sarah Ratner, and were published in a small book by Harvard University Press. The editors called the book *The Dynamic State of Body Constituents*,[6] adopting the title of Schoenheimer's presentation. In the book, the new hypothesis is clearly presented: "*The simile of the combustion engine pictured the steady state flow of fuel into a fixed system, and the conversion of this fuel into waste products. The new results imply that not only the fuel, but the structural materials are in a steady state of flux. The classical picture must thus be replaced by one which takes account of the dynamic state of body structure*". However, the idea that proteins are turning over was not accepted easily and was challenged as late as the mid-1950s. For example, Hogness and colleagues studied the kinetics of β-galactosidase in *E. coli* and summarized their findings:[7] "*To sum up: there seems to be no conclusive evidence that the protein molecules within the cells of mammalian tissues are in a dynamic state. Moreover, our experiments have shown that the proteins of growing E. coli are static. Therefore it seems necessary to conclude that the synthesis and maintenance of proteins within growing cells is not necessarily or inherently associated with a 'dynamic state'*". While the experimental study involved the bacterial β-galactosidase, the conclusions were broader, and included also the authors' hypothesis on mammalian proteins. The use of the term "dynamic state" was not incidental, as they challenged directly Schoenheimer's studies.

Now, after more then six decades of research in the field and with the discovery of the lysosome and later the complex ubiquitin–proteasome system with its numerous tributaries, it is clear that the area has been revolutionized. We now realize that intracellular proteins are turning over extensively, that this process is specific in most cases, and that the stability of many proteins is regulated individually and can vary under different conditions. From a scavenger, unregulated and nonspecific end process, it has become clear that proteolysis of cellular proteins is a highly complex, temporally controlled and tightly regulated process that plays major roles in a broad array of basic pathways. Among these processes are the cell cycle, development, differentiation, regulation of transcription, antigen presentation, signal transduction, receptor-mediated endocytosis, quality control, and modulation of diverse metabolic pathways. As a result, this development has changed the paradigm that regulation of cellular processes occurs mostly at the transcriptional and translational levels, and has placed regulated protein degradation in an equally important position. With the multitude of substrates targeted and processes involved, it is not surprising that aberrations in the pathway have been implicated in the pathogenesis of many diseases, among them certain malignancies, neuro-degeneration, and disorders of the immune and inflammatory system. As a result, the ubiquitin system has become a platform for drug targeting, and mechanism-based drugs are currently developed, one of them is already on the market.

3. The Lysosome and Intracellular Protein Degradation

In the mid-1950s, Christian de Duve discovered the lysosome (see, for example, Refs. [8,9] and Figure 1). The lysosome was first recognized biochemically in rat liver as a vacuolar structure that contains various hydrolytic enzymes which function optimally at an acidic pH. It is surrounded by a membrane that endows the contained enzymes with latency that is required to protect the cellular contents from their action (see below). The definition of the lysosome has been broadened over the years. This is because it has been recognized that the digestive process is dynamic and involves numerous stages of lysosomal maturation together with the digestion of both exogenous proteins (which are targeted to the lysosome through receptor-mediated endocytosis and pinocytosis) and exogenous particles (which are targeted through phagocytosis; the two processes are known as heterophagy), as well as digestion of endogenous proteins and cellular organelles (which are targeted by micro- and macro-autophagy; see Figure 2).

The lysosomal/vacuolar system as we currently recognize it is a discontinuous and heterogeneous digestive system that also includes structures that are devoid of hydrolases, for example, early endosomes which contain endocytosed receptor–ligand complexes and pinocytosed/phagocytosed extracellular contents. At the other extreme it includes the residual bodies—the end products of the completed digestive processes of heterophagy and autophagy. In between these extremes one can observe: primary/nascent lysosomes that have not yet been engaged in any proteolytic process; early
Figure 1. The lysosome: Ultrathin cryosection of a rat PC12 cell that had been loaded for 1 h with bovine serum albumin (BSA)·gold (5-nm particles) and immunolabeled for the lysosomal enzyme cathepsin B (10-nm particles) and the lysosomal membrane protein LAMP1 (15-nm particles). Lysosomes are recognized also by their typical dense content and multiple internal membranes. Scale bar, 100 nm. Figure 2. The four digestive processes mediated by the lysosome: 1) specific receptor-mediated endocytosis; 2) pinocytosis (nonspecific engulfment of cytosolic droplets containing extracellular fluid); 3) phagocytosis (of extracellular particles), and 4) autophagy (micro- and macro-autophagy of intracellular proteins and organelles). Printed from Ref. [83] with permission from Nature Publishing Group.

autophagic vacuoles that might contain intracellular organelles; intermediate/late endosomes and phagocytic vacuoles (heterophagic vacuoles) that contain extracellular contents/particles; and multivesicular bodies (MVBs) which are the transition vacuoles between endosomes/phagocytic vacuoles and the digestive lysosomes (Figure 2).

The discovery of the lysosome along with independent experiments that were carried out at the same time and that have further strengthened the notion that cellular proteins are indeed in a constant state of synthesis and degradation (see, for example, Ref. [10]), led scientists to feel, for the first time, that they had at hand an organelle that could potentially mediate degradation of intracellular proteins. The separation of the proteases from their substrates by a membrane provided an explanation for controlled degradation, and the only problem left to be explained was how the substrates are translocated into the lysosomal lumen, where they are degraded by the lysosomal proteases.

An important discovery in this respect was the unraveling of the basic mechanism of action of the lysosome, namely autophagy (reviewed in Ref. [11]). Under basal metabolic conditions, portions of the cytoplasm which contain the entire cohort of cellular proteins, are segregated within a membrane-bound compartment, and are then fused to a primary nascent lysosome and their contents digested. This process was denoted micro-autophagy. Under more extreme conditions (for example, starvation) mitochondria, endoplasmic reticulum membranes, glycogen bodies, and other cytoplasmic entities can also be engulfed by a process called macro-autophagy (see, for example, Ref. [12]). The different modes of action of the lysosome in digesting extra- and intracellular proteins are shown in Figure 2.

However, over a period of more than two decades (between the mid-1950s and the late-1970s) it became gradually more and more difficult to explain several aspects of intracellular protein degradation based on the known mechanisms of lysosomal activity. Accumulating lines of independent experimental evidence indicated that the degradation of at least certain classes of cellular proteins must be non-lysosomal. Yet, in the absence of any "alternative", researchers found different explanations, some more substantiated and others less, to defend the "lysosomal" hypothesis.

First was the gradually emerging notion, coming from different laboratories, that different proteins vary in their stability, and their half-life times ($t_{1/2}$) can span three orders of magnitude—from a few minutes to many days. Thus, the $t_{1/2}$ of ornithine decarboxylase (ODC) is about 10 min, while that of glucose-6-phosphate dehydrogenase (G6PD) is 15 h (for review articles, see, for example, Refs. [13,14]). Also, the rates of degradation of many proteins were shown to change with changing physiological conditions, such as availability of nutrients or hormones. It was conceptually difficult to reconcile the findings of distinct half-lives of different proteins with the mechanism of action of the lysosome, where the micro-autophagic vesicle contains the entire cohort of cellular (cytosolic) proteins that are therefore expected to degrade at the same rate. Likewise, if micro- and macro-autophagy had been the mechanisms that mediate intra-

cellular proteolysis, changing pathophysiological conditions, such as starvation or resupplementation of nutrients, would have been expected to affect the stability of all cellular proteins to the same extent. Clearly, this was not the case.

A second source of concern about the lysosome as the organelle in which intracellular proteins are degraded were the findings that specific and general inhibitors of lysosomal proteases have different effects on different populations of proteins, making it clear that distinct classes of proteins are targeted by different proteolytic machineries. Thus, the degradation of endocytosed/pinocytosed extracellular proteins was significantly inhibited, a partial effect was observed on the degradation of long-lived cellular proteins, and almost no effect could be detected on the degradation of short-lived and abnormal/mutated proteins.

Finally, the thermodynamically paradoxical observation that the degradation of cellular proteins requires metabolic energy, and more importantly, the emerging evidence that the proteolytic machinery uses the energy directly, were in contrast with the known mode of action of lysosomal proteases that under the appropriate acidic conditions, and similar to all known proteases, degrade proteins in an exergonic manner.

The assumption that the degradation of intracellular proteins is mediated by the lysosome was nevertheless logical. Proteolysis results from direct interaction between the target substrates and proteases, and therefore it was clear that active proteases cannot be free in the cytosol, which would have resulted in destruction of the cell. Thus, it was recognized that any suggested proteolytic machinery that mediates degradation of intracellular protein degradation must also be equipped with a mechanism that separates—physically or virtually—between the proteases and their substrates, and enables them to associate only when needed. The lysosomal membrane provided a physical fencing mechanism.

Of course, nobody could have predicted that a new mode of posttranslational modification—ubiquitination—could function as a proteolytic signal, and that untagged proteins would remain protected. Thus, while the structure of the lysosome could explain the separation necessary between the proteases and their substrates, and autophagy could explain the mechanism of entry of cytosolic proteins into the lysosomal lumen, major problems have remained unsolved. Important among them were: 1) the varying half-lives, 2) the energy requirement, and 3) the distinct response of different populations of proteins to lysosomal inhibitors.

Nevertheless, scientists tried to "defend" the lysosomal model. According to one model, it was proposed that different proteins have different sensitivities to lysosomal proteases, and their half lives in vivo correlate with their sensitivity to the action of lysosomal proteases in vitro.[15] To explain an extremely long half-life for a protein that is nevertheless sensitive to lysosomal proteases, or alterations in the stability of a single protein under various physiological states, it was suggested that although all cellular proteins are engulfed into the lysosome, only the short-lived proteins are degraded, whereas the long-lived proteins exit back into the cytosol: "*To account for differences in half-life among cell components or of a single component in various physiological*

states, it was necessary to include in the model the possibility of an exit of native components back to the extralysosomal compartment".[16]

According to a different model, selectivity is determined by the binding affinity of the different proteins for the lysosomal membrane which controls their entry rates into the lysosome, and subsequently their degradation rates.[17] For a selected group of proteins, such as the gluconeogenetic enzymes phosphoenolpyruvate carboxykinase (PEPCK), and fructose-1,6-biphosphatase, it was suggested, though not firmly substantiated, that their degradation in the yeast vacuole is regulated by glucose through a mechanism called "catabolite inactivation" that possibly involves their phosphorylation. However, this regulated mechanism for vacuolar degradation was limited only to a small and specific group of proteins (see, for example, Refs. [18],[19]).

More recent studies have shown that at least for stress-induced macro-autophagy, KFERQ, a general sequence of amino acids that in its general structure was identified in many proteins, directs, by binding to a specific "receptor" and in cooperation with cytosolic and lysosomal chaperones, the regulated entry of many cytosolic proteins into the lysosomal lumen. While further corroboration of this hypothesis is still required, it explains the mass entry of a large population of proteins that contain a homologous sequence, but not the targeting for degradation of a specific protein under defined conditions (reviewed in Refs. [20,21]). The energy requirement for protein degradation was described as indirect, and necessary, for example, for protein transport across the lysosomal membrane[22] and/or for the activity of the H^+ pump and the maintenance of the low acidic intralysosomal pH that is necessary for optimal activity of the lysosomal proteases.[23] We now know that both mechanisms require energy. In the absence of any alternative, and with lysosomal degradation as the most logical explanation for targeting all known classes of proteins at the time, Christian de Duve summarized his view on the subject in a review article published in the mid-1960s, saying: "*Just as extracellular digestion is successfully carried out by the concerted action of enzymes with limited individual capacities, so, we believe, is intracellular digestion*".[24] The problem of different sensitivities of distinct protein groups to lysosomal inhibitors has remained unsolved, and may have served as an important trigger in the future quest for a non-lysosomal proteolytic system.

Progress in identifying the elusive, non-lysosomal proteolytic system(s) was hampered by the lack of a cell-free preparation that could faithfully replicate the cellular proteolytic events, degrading proteins in a specific and energy-requiring mode. An important breakthrough was made by Rabinovitz and Fisher who found that rabbit reticulocytes degrade abnormal, amino acid analogue containing hemoglobin.[25] Their experiments modeled known disease states—the hemoglobinopathies. In these diseases abnormal mutated hemoglobin chains (such as sickle cell hemoglobin) or excess of unassembled normal hemoglobin chains (which are synthesized normally, but accumulate and found in excess in thalassemias, diseases in which the pairing chain is not synthesized at all or is mutated and rapidly degraded, and

consequently the hemoglobin complex is not assembled) are rapidly degraded in the reticulocyte.[26,27] Reticulocytes are terminally differentiating red blood cells that do not contain lysosomes. Therefore, it was postulated that the degradation of hemoglobin in these cells is mediated by a non-lysosomal machinery.

Etlinger and Goldberg[28] were the first to isolate and characterize a cell-free proteolytic preparation from reticulocytes. The crude extract selectively degraded abnormal haemoglobin, required ATP hydrolysis, and acted optimally at a neutral pH, which further strengthened the assumption that the proteolytic activity was of a non-lysosomal origin. A similar system was isolated and characterized later by our research group.[29] Additional studies by our group led subsequently to resolution, characterization, and purification of the major enzymatic components from these extracts, and to the discovery of the ubiquitin tagging system (see below).

4. The Lysosome Hypothesis Is Challenged

As mentioned above, the unraveled mechanism(s) of action of the lysosome could explain only partially, and at times not satisfactorily, several key emerging characteristics of intracellular protein degradation. Among them were the heterogeneous stability of individual proteins, the effect of nutrients and hormones on their degradation, and the dependence of intracellular proteolysis on metabolic energy. The differential effect of selective inhibitors on the degradation of different classes of cellular proteins could not be explained at all.

The evolvement of methods to monitor protein kinetics in cells, together with the development of specific and general lysosomal inhibitors, has resulted in the identification of different classes of cellular proteins, long- and short-lived, and the discovery of the differential effects of the inhibitors on these groups (see, for example, Refs. [30,31]). An elegant experiment in this respect was carried out by Brian Poole and his colleagues at the Rockefeller University. Poole was studying the effects on proteolysis of lysosomotropic agents—weak bases such as ammonium chloride and chloroquine—that accumulate in the lysosome and dissipate its low acidic pH. It was assumed that this mechanism also underlies the antimalarial activity of chloroquine and similar drugs, where they inhibit the activity of the parasite's lysosome, "paralyzing" its ability to digest the host's hemoglobin during the intraerythrocytic stage of its life cycle. Poole and his colleagues metabolically labeled endogenous proteins in living macrophages with ^{3}H-leucine and "fed" them with dead macrophages that had been previously labeled with ^{14}C-leucine. They assumed, apparently correctly, that the dead macrophages debris and proteins will be phagocytosed by the live macrophages and targeted to the lysosome for degradation. They monitored the effect of lysosomotropic agents on the degradation of these two protein populations. In particular, they studied the effect of the weak bases chloroquine and ammonium chloride (which enter the lysosome and neutralize the H^+ ions), and the acid ionophore X537A which dissipates the H^+ gradient across the lysosomal membrane.

They found that these drugs specifically inhibited the degradation of extracellular proteins, but not that of intracellular proteins.[32]

Poole summarized these elegant experiments and explicitly predicted the existence of a non-lysosomal proteolytic system that degrades intracellular proteins: "*Some of the macrophages labeled with tritium were permitted to endocytise the dead macrophages labeled with ¹⁴C. The cells were then washed and replaced in fresh medium. In this way we were able to measure in the same cells the digestion of macrophage proteins from two sources. The exogenous proteins will be broken down in the lysosomes, while the endogenous proteins will be broken down wherever it is that endogenous proteins are broken down during protein turnover*".[33]

The requirement for metabolic energy for the degradation of both prokaryotic[34] and eukaryotic[10,35] proteins was difficult to understand. Proteolysis is an exergonic process and the thermodynamically paradoxical energy requirement for intracellular proteolysis made researchers believe that energy cannot be consumed directly by proteases or the proteolytic process per se, and is used indirectly. As Simpson summarized his findings:[10] "*The data can also be interpreted by postulating that the release of amino acids from protein is itself directly dependent on energy supply. A somewhat similar hypothesis, based on studies on autolysis in tissue minces, has recently been advanced, but the supporting data are very difficult to interpret. However, the fact that protein hydrolysis as catalyzed by the familiar proteases and peptidases occurs exergonically, together with the consideration that autolysis in excised organs or tissue minces continues for weeks, long after phosphorylation or oxidation ceased, renders improbable the hypothesis of the direct energy dependence of the reactions leading to protein breakdown*". Being cautious, however, and probably unsure about this unequivocal conclusion, Simpson still left a narrow orifice opened for a proteolytic process that requires energy in a direct manner: "*However, the results do not exclude the existence of two (or more) mechanisms of protein breakdown, one hydrolytic, the other enrgy-requiring.*"

Since any proteolytic process must be at one point or another hydrolytic, the statement that makes a distinction between a hydrolytic process and an energy-requiring, yet nonhydrolytic one, is not clear. Judging the statement from a historical point of view and knowing the mechanism of action of the ubiquitin system, where energy is required also in the prehydrolytic step (ubiquitin conjugation), Simpson may have thought of a two-step mechanism, but did not give it a clear description: in retrospect, one can view ubiquitination as a nonhydrolytic, yet energy-requiring process. At the end of this clearly understandable and apparently difficult deliberation, he left us with a vague explanation linking protein degradation to protein synthesis, a process that was known at that time to require metabolic energy: "*The fact that a supply of energy seems to be necessary for both the incorporation and the release of amino acids from protein might well mean that the two processes are interrelated. Additional data suggestive of such a view are available from other types of experiments. Early investigations on nitrogen balance by Benedict, Folin, Gamble, Smith, and others point to the fact that the rate of protein catabolism varies with the dietary protein level. Since*

the protein level of the diet would be expected to exert a direct influence on synthesis rather than breakdown, the altered catabolic rate could well be caused by a change in the rate of synthesis."[10]

With the discovery of lysosomes in eukaryotic cells it could be argued that energy is required for the transport of substrates into the lysosome or for maintenance of the low intralysosomal pH, for example. The observation by Hershko and Tomkins that the activity of tyrosine aminotransferase (TAT) was stabilized following depletion of ATP[36] indicated that energy may be required at an early stage of the proteolytic process, most probably before proteolysis occurs. Yet, it did not provide a clue for the mechanism involved: energy could be used, for example, for specific modification of TAT, for example, phosphorylation, that would sensitize it to degradation by the lysosome or by a yet unknown proteolytic mechanism, or for a modification that activates its putative protease. It could also be used for a more general lysosomal mechanism, one that involves transport of TAT into the lysosome or maintenance of the low intralysosomal pH, as it is cleat that ATP depletion also inhibited completely lysosomal degradation. The energy inhibitors inhibited almost completely degradation of the entire population of cell proteins, confirming previous studies (see, for example, Ref. [10]) and suggesting a general role for energy in protein catabolism. An interesting finding was that energy inhibitors had an effect that was distinct from that of protein synthesis inhibitors, which affected only enhanced degradation (induced by steroid hormone depletion), but not basal degradation. This finding ruled out, at least partially, a tight linkage between protein synthesis and all classes of protein degradation.

In bacteria, which lack lysosomes, an argument involving energy requirement for lysosomal degradation could not have been proposed, but other indirect effects of ATP hydrolysis could have affected proteolysis in *E. coli*, such as phosphorylation of substrates and/or proteolytic enzymes, or maintenance of the "energized membrane state". According to this model, proteins could become susceptible to proteolysis by changing their conformation, for example, following association with the cell membrane that maintains a local, energy-dependent gradient of a certain ion. While such an effect was ruled out,[37] and since there was no evidence for a phosphorylation mechanism (although the proteolytic machinery in prokaryotes had not been identified at that time), it seemed that at least in bacteria, energy is required directly for the proteolytic process (which later turned out to be correct).

In any event, the requirement for metabolic energy for protein degradation in both prokaryotes and eukaryotes, a process that is exergonic thermodynamically, strongly indicated that in cells proteolysis is highly regulated, and that a similar principle/mechanism has been preserved in the evolution of the two kingdoms. From the possible direct requirement for ATP in the degradation of proteins in bacteria, it was not too unlikely to assume a similar direct mechanism involved in the degradation of cellular proteins in eukaryotes. Supporting this notion was the description of the cell-free proteolytic system in reticulocytes,[28,29] a cell that lacks lysosomes, which indicated that energy is probably required directly for the proteolytic process, although here

too, the underlying mechanisms had remained enigmatic at the time. Yet, the description of the cell-free system paved the road for detailed dissection of the underlying mechanisms involved.

5. The Ubiquitin–Proteasome System

The cell-free proteolytic system from reticulocytes[28,29] turned out to be an important and rich source for the purification and characterization of the enzymes that are involved in the ubiquitin–proteasome system. Initial fractionation of the crude reticulocyte cell extract on the anion-exchange resin diethylaminoethylcellulose (DEAE) yielded two fractions which were both required to reconstitute the energy-dependent proteolytic activity that was identified in the crude extract: The unadsorbed, flow-through material was denoted fraction I, and the adsorbed proteins which were eluted with a high concentration of salt was denoted fraction II (Table 2).[38]

Table 2: Resolution of the ATP-dependent proteolytic activity from crude reticulocyte extract into two essentially required complementing activities (adapted from Ref. [38] with permission from Elsevier).

Fraction	Degradation of [³H]globin [%]	
	−ATP	+ATP
lysate	1.5	10.0
fraction I	0.0	0.0
fraction II	1.5	2.7
fraction I + fraction II	1.6	10.6

This was an important observation and a lesson for the future dissection of the system. For one, it suggested that the system is not composed of a single "classical" protease that has evolved evolutionarily to acquire energy dependence (although such energy-dependent proteases such as the mammalian 26S proteasome and the prokaryotic *Lon* gene product, for example, were described later), but that it is made of at least two components. This finding of a two-component, energy-dependent protease left us with no paradigm to follow, and in attempts to explain the finding, we suggested, for example, that the two fractions could represent an inhibited protease and its activator.

Second, learning from this reconstitution experiment and the essential dependence of the two active components, we continued to reconstitute activity from resolved fractions whenever we encountered a loss of activity in further purification steps. This biochemical "complementation" approach resulted in the discovery of additional enzymes in the system, which are all required to be present in the reaction mixture in order to catalyze the multistep proteolysis of the target substrate. We chose first to purify the active component from fraction I. It was found to be a small, about 8.5 kDa heat-stable protein that was designated ATP-dependent proteolysis factor 1 (APF-1). APF-1 was later identified as ubiquitin (see below; I am using the term APF-1 to the point at which it was identified as ubiquitin, and then change terminology accordingly). In retrospect, the decision to start

the purification efforts with fraction I turned out to be important, as fraction I contained only one single protein, APF-1, that was necessary to stimulate proteolysis of the model substrates we used at the time, BSA and lysozyme, while fraction II turned out to contain many additional active factors. Later studies showed that fraction I contains other components necessary for the degradation of other substrates, but these were not necessary for the reconstitution of the system at that time. This enabled us not only to purify APF-1, but also to quickly decipher its mode of action. If we had started our purification efforts with fraction II, we would have encountered a significantly bumpier road. A critically important finding that paved the road for future developments in the field was that multiple moieties of APF-1 are covalently conjugated to the target substrate when incubated in the presence of fraction II, and the modification requires ATP (Figures 3 and 4).[39,40] It was also found that the modification is reversible, and APF-1 can be removed from the substrate or its degradation products.[40]

The discovery that APF-1 is covalently conjugated to protein substrates and stimulates their proteolysis in the presence of ATP and crude fraction II, led in 1980 to the proposal of a model, according to which protein-substrate modification by multiple moieties of APF-1 targets it for degradation by a downstream, at that time as yet unidentified, protease that cannot recognize the unmodified substrate; following degradation, reusable APF-1 is released.[40] Amino
Figure 3. APF-1/ubiquitin is shifted to high-molecular-mass compound(s) following incubation in an ATP-containing crude cell extract. ¹²⁵I-labeled APF-1/ubiquitin was incubated with reticulocyte crude fraction II in the absence (○) or presence (●) of ATP, and the reaction mixtures were resolved by gel-filtration chromatography. The radioactivity measured in each fraction is shown. As can be seen, following addition of ATP, APF-1/ubiquitin becomes associated with some component(s) (another enzyme of the system or its substrate(s)) in fraction II. Printed from Ref. [39] with permission from the National Academy of Sciences.
Figure 4. Multiple molecules of APF-1/ubiquitin are conjugated to the proteolytic substrate, probably signaling it for degradation. To analyze the data described in the experiment depicted in Figure 3 mechanistically and to test the hypothesis that APF-1 is conjugated to the target proteolytic substrate, ^{125}I-APF-1/ubiquitin was incubated along with crude fraction II in the absence (lane 1) or presence (lanes 2–5) of ATP and in the absence (lanes 1, 2) or presence (lanes 3–5) of increasing concentrations of unlabeled lysozyme. Reaction mixtures resolved in lanes 6 and 7 were incubated in the absence (lane 6) or presence (lane 7) of ATP, and included unlabeled APF-1/ubiquitin and ^{125}I-labeled lysozyme. C1–C6 denote specific APF-1/ubiquitin–lysozyme adducts in which the number of APF-1/ubiquitin moieties bound to the lysozyme moiety of the adduct increases, probably from 1 to 6. Reaction mixtures were resolved by SDS-polyacrylamide gel electrophoresis (SDS-PAGE) and visualized following exposure of the gel to an X-ray film (autoradiography). Printed from Ref. [40] with permission from the National Academy of Sciences.

acid analysis of APF-1, along with its known molecular mass and other general characteristics, raised the suspicion that APF-1 was ubiquitin,[41] a known protein of previously unknown function. Indeed, Wilkinson and colleagues confirmed unequivocally that APF-1 was indeed ubiquitin.[42]

Ubiquitin is a small, heat-stable, and highly evolutionarily conserved protein of 76 residues. It was first purified during the isolation of thymopoietin[43] and was subsequently found to be ubiquitously expressed in all kingdoms of living cells, including prokaryotes.[44] Interestingly, it was initially found to have lymphocyte-differentiating properties, a characteristic that was attributed to the stimulation of adenylate cyclase.[44,45] Accordingly, it was named UBIP for ubiquitous immunopoietic polypeptide.[44] However, later studies showed that ubiquitin is not involved in the immune response,[46] and that it was a contaminating endotoxin in the preparation that generated the adenylate cyclase and the T-cell-differentiating activities. Furthermore, the sequence of several eubacteria and archaebacteria genomes as well as biochemical analyses of cell extracts from these organisms (unpublished results) showed that ubiquitin is restricted only to eukaryotes. The finding of ubiquitin in bacteria[44] was probably due to contamination of the bacterial extract with yeast ubiquitin derived from the yeast extract in which the bacteria were grown. While, in retrospect, the name ubiquitin is a misnomer, as it is restricted to eukaryotes and is not ubiquitous as was previously thought, for historical reasons it has still maintained its name. Accordingly, and in order to avoid confusion, I suggest that the names of other novel enzymes and

components of the ubiquitin system, as well as of other systems, should remain as they were first coined by their discoverers.

An important development in the ubiquitin research field was the discovery that a single ubiquitin moiety can be covalently conjugated to histones, particularly to histones H2A and H2B. While the function of these adducts had remained elusive until recently, their structure was unraveled in the mid-1970s. The structure of the ubiquitin conjugate of H2A (uH2A; also designated protein A24) was deciphered by Goldknopf and Busch[47,48] and by Hunt and Dayhoff,[49] who found that the two proteins are linked through a forklike, branched isopeptide bond between the carboxy-terminal glycine of ubiquitin (Gly[76]) and the ε-NH$_2$ group of an internal lysine (Lys[119]) of the histone molecule. The isopeptide bond found in the histone–ubiquitin adduct was suggested to be identical to the bond that was found between ubiquitin and the target proteolytic substrate[50] and between the ubiquitin moieties in the polyubiquitin chain[51,52] that is synthesized on the substrate and that functions as a proteolysis recognition signal for the downstream 26S proteasome. In this particular polyubiquitin chain the linkage is between Gly[76] of one ubiquitin moiety and internal Lys[48] of the previously conjugated moiety. Only Lys[48]-based ubiquitin chains are recognized by the 26S proteasome and serve as proteolytic signals.

In recent years it has been shown that the first ubiquitin moiety can also be attached in a linear mode to the N-terminal residue of the proteolytic target substrate.[53] However, the subsequent ubiquitin moieties generate Lys[48]-based polyubiquitin chains on the first, linearly fused moiety. N-terminal ubiquitination is clearly required for targeting naturally occurring lysine-free proteins for degradation. Yet, several lysine-containing proteins have also been described that traverse this pathway, the muscle-specific transcription factor MyoD, for example. In these proteins the internal lysine residues are probably not accessible to the cognate ligases.

Other types of polyubiquitin chains have also been described that are not involved in targeting the conjugated substrates for proteolysis. Thus, a Lys[63]-based polyubiquitin chain has been described that is probably necessary for the activation of transcription factors (see Ref. [54]). Interestingly, the role of monoubiquitination of histones has also been identified recently, and this modification is also involved in regulation of transcription, probably by modulation of the structure of the nucleosomes (see, for example, Refs. [55,56]).

The identification of APF-1 as ubiquitin, and the discovery that a high-energy isopeptide bond, similar to the one that links ubiquitin to histone H2A, links it also to the target proteolytic substrate, resolved at that time the enigma of the energy requirement for intracellular proteolysis and paved the road to the untangling of the complex mechanism of isopeptide-bond formation. This process turned out to be similar to that of peptide-bond formation that is catalyzed by tRNA synthetase following amino acid activation during protein synthesis or during the nonribosomal synthesis of short peptides.[57] With the unravelled mechanism of ubiquitin activation and using immobilized ubiquitin as a "covalent" affinity bait, the three enzymes that are involved in the

cascade reaction of ubiquitin conjugation were purified by us. These enzymes are: 1) E1, the ubiquitin-activating enzyme, 2) E2, the ubiquitin carrier protein, and 3) E3, the ubiquitin protein ligase.[58,59] The discovery of an E3 which is a specific substrate-binding component indicated a possible solution to the problem of the varying stabilities of different proteins—they might be specifically recognized and targeted by different ligases.

Within a short period, the ubiquitin-tagging hypothesis received substantial support. For example, Chin and co-workers injected into HeLa cells labeled ubiquitin and hemoglobin, and denatured the injected hemoglobin by oxidizing it with phenylhydrazine. They found that ubiquitin conjugation to globin is markedly enhanced by denaturation of the hemoglobin, and the concentration of globin–ubiquitin conjugates was proportional to the rate of hemoglobin degradation.[60] Hershko and colleagues observed a similar correlation for abnormal, amino acid analogue containing short-lived proteins.[61] A previously isolated cell-cycle-arrest mutant that loses the ubiquitin–histone H2A adduct at the permissive temperature[62] was found to harbor a thermolabile E1.[63] Following heat inactivation, the cells failed to degrade normal short-lived proteins.[64] Although the cells did not provide direct evidence for substrate ubiquitination as a destruction signal, their characterization established the strongest direct linkage between ubiquitin conjugation and degradation.

At this point, the only missing link was the identification of the downstream protease that would specifically recognize ubiquitinated substrates. Tanaka and colleagues identified a second ATP-requiring step in the reticulocyte proteolytic system, which occurred after ubiquitin conjugation,[65] and Hershko and colleagues demonstrated that the energy is required for conjugate degradation.[66] An important advance in the field was a discovery by Hough and colleagues, who partially purified and characterized a high-molecular-mass alkaline protease that degraded, in an ATP-dependent mode, ubiquitin adducts of lysozyme, but not untagged lysozyme.[67] This protease which was later called the 26S proteasome (see below), provided all the necessary criteria for being the specific proteolytic arm of the ubiquitin system.

This finding was confirmed and the protease was further characterized by Waxman and colleagues who found that it is an unusually large, approximately 1.5 MDa enzyme, unlike any other known protease.[68] A further advance in the field was the discovery[69] that a smaller neutral multi-subunit 20S protease complex that was discovered together with the larger 26S complex is similar to a "multicatalytic proteinase complex" (MCP) that was found earlier in the bovine pituitary gland by Wilk and Orlowski.[70] This 20S protease is ATP-independent and has different catalytic activities: cleaving on the carboxy-terminal side of hydrophobic, basic, and acidic residues. Hough and colleagues raised the possibility—although they did not show it experimentally—that this 20S protease can be a part of the larger 26S protease that degrades ubiquitin adducts.[69] Later studies showed that, indeed, the 20S complex is the core catalytic particle of the larger 26S complex.[71,72] However, strong evidence that the active "mushroom"-shaped 26S protease was generated

through the assembly of two distinct subcomplexes—the catalytic 20S cylinder-like MCP and an additional 19S ball-shaped subcomplex (that was predicted to have a regulatory role)—was provided only in the early 1990s by Hoffman et al.[73] who mixed the two purified particles and generated the active 26S enzyme.

The proteasome is a large, 26S multicatalytic protease that degrades polyubiquitinated proteins to small peptides (Figures 5 and 6). It is composed of two subcomplexes: a 20S core

Figure 5. The ubiquitin–proteasome proteolytic system: Ubiquitin is activated by the ubiquitin-activating enzyme E1 (1), followed by its transfer to a ubiquitin-carrier protein (ubiquitin-conjugating enzyme, UBC) E2 (2). E2 transfers the activated ubiquitin moieties to the protein substrate that is bound specifically to a unique ubiquitin ligase E3. The transfer is either direct ((3) in the case of RING finger ligases) or via an additional thiol-ester intermediate on the ligase ((4, 4a) in the case of HECT domain ligases). Successive conjugation of ubiquitin moieties to one another generates a polyubiquitin chain that serves as the binding (5) and degradation signal for the downstream 26S proteasome. The substrate is degraded to short peptides (6), and free and reusable ubiquitin is released by deubiquitinating enzymes (DUBs; 7).

particle (CP) that carries the catalytic activity, and a regulatory 19S regulatory particle (RP). The 20S CP is a barrel-shaped structure composed of four stacked rings, two identical outer α rings and two identical inner β rings. The eukaryotic α and β rings are composed each of seven distinct subunits, giving the 20S complex the general structure $\alpha_{1-7}\beta_{1-7}\beta_{1-7}\alpha_{1-7}$. The catalytic sites are localized to some of the β subunits. Each extremity of the 20S barrel can be capped by a 19S RP each composed of 17 distinct subunits, 9 in a "base" subcomplex, and 8 in a "lid" subcomplex. One important function of the 19S RP is to recognize ubiquitinated proteins and other potential substrates of the proteasome. Several ubiquitin-binding subunits of the 19S RP have been identified, although their biological roles and mode of action have not been discerned. A second function of the 19S RP is to open an orifice in the α ring that will allow entry of the substrate into the proteolytic chamber. Also, since a folded protein would not be able to fit through the narrow proteasomal channel, it is assumed that the 19S particle unfolds substrates and inserts them into the 20S CP. Both the

dynamic state of proteins was followed by the discovery of the lysosome, that was believed between the mid-1950s and mid-1970s to be the organelle within which intracellular proteins are destroyed. Independent lines of experimental evidence gradually eroded the lysosomal hypothesis and resulted in a new idea that the bulk of intracellular proteins are degraded—under basal metabolic conditions—by a non-lysosomal machinery. This resulted in the discovery of the ubiquitin system in the late 1970s and early 1980s.

With the identification of the reactions and enzymes that are involved in the ubiquitin–proteasome cascade, a new era in the protein-degradation field began in the late 1980s and early 1990s. Studies that showed that the system is involved in the targeting of specific key regulatory proteins, such as light-regulated proteins in plants, and transcriptional factors, cell-cycle regulators, and tumor suppressors and promoters in mammalian cells, started to emerge (see, for example Refs. [74–78]). They were followed by numerous studies on the underlying mechanisms involved in the degradation of these specific proteins, each with its own unique mode of recognition and regulation. The unraveling of the human

channel opening function and the unfolding of the substrate require metabolic energy, and indeed, the 19S RP "base" contains six different ATPase subunits. Following degradation of the substrate, short peptides derived from the substrate are released, as well as reusable ubiquitin.

6. Concluding Remarks

The evolution of proteolysis as a centrally important regulatory mechanism is a remarkable example of the evolution of a novel biological concept and the accompanying battles to change paradigms. The five-decade journey between the early 1940s and early 1990s began with fierce discussions on whether cellular proteins are static, as had been thought for a long time, or are turning over. The discovery of the

Figure 7. Some of the different functions of modification by ubiquitin and ubiquitin-like proteins: a) Proteasomal-dependent degradation of cellular proteins (see Figures 5 and 6). b) Mono- or oligoubiquitination targets membrane proteins to degradation in the lysosome/vacuole. c) Monoubiquitination, or d) a single modification by a ubiquitin-like (UBL) protein, for example, SUMO, can target proteins to different subcellular destinations such as nuclear foci or the nuclear pore complex (NPC). Modification by UBLs can serve other nonproteolytic functions, such as protecting proteins from ubiquitination or activation of E3 complexes. e) Generation of a Lys[63]-based polyubiquitin chain can activate transcriptional regulators, directly or indirectly (through recruitment of other proteins, such as the shown protein Y, or activation of upstream components such as kinases). Ub = ubiquitin. Printed from Ref. [83] with permission from the Nature Publishing Group.

genome revealed the existence of hundreds of distinct E3s, attesting to the complexity and the high specificity and selectivity of the system.

Two important advances in the field were the discovery of the nonproteolytic functions of ubiquitin, among which are activation of transcription and routing of proteins to the vacuole, and the discovery of modification by ubiquitin-like proteins (UBLs) that are also involved in numerous nonproteolytic functions such as directing proteins to their subcellular destination, protecting proteins from ubiquitination, or controlling entire processes such as autophagy (see, for example, Ref. [79]). Some of the different roles of modifications by ubiquitin and UBLs are shown in Figure 7. All these studies have led to the emerging realization that this novel and general mode of covalent conjugation plays a key role in regulating a broad array of cellular processes—among them cell cycle and division, growth and differentiation, activation and silencing of transcription, apoptosis, the immune and inflammatory response, signal transduction, receptor-mediated endocytosis, various metabolic pathways, and cell-quality control—through proteolytic and nonproteolytic mechanisms. The discovery that ubiquitin modification plays a role in routing proteins to the lysosome/vacuole and that modification by specific and unique ubiquitin-like proteins and the conjugation mechanism controls autophagy, closed an exciting historical cycle, since it demonstrated that the two apparently distinct proteolytic systems communicate with one another.

With the many processes and substrates targeted by the ubiquitin pathway, it was not surprising to find that aberrations in the system underlie, directly or indirectly, the pathogenesis of many diseases. While inactivation of a major enzyme such as E1 is obviously lethal, mutations in enzymes or in recognition motifs in substrates that do not affect vital pathways, or that affect the involved process only partially, may result in a broad array of phenotypes. Likewise, acquired changes in the activity of the system can also evolve into certain pathologies. The pathological states associated with the ubiquitin system can be classified into two groups: 1) those that result from loss of function—mutation in a ubiquitin system enzyme or in the recognition motif in the target substrate that results in stabilization of certain proteins, and 2) those that result from gain of function—abnormal or accelerated degradation of the protein target.

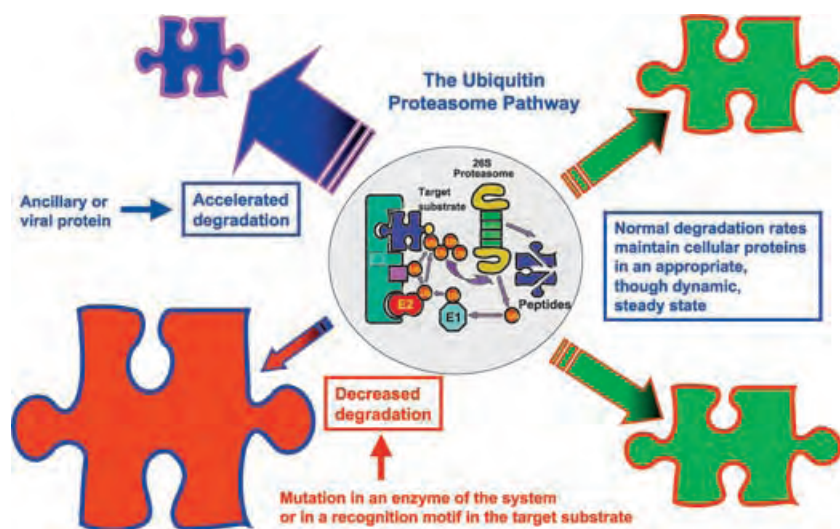
Aberrations in the ubiquitin system that result in disease states are shown in Figure 8. Studies that employ targeted inactivation of genes coding for specific ubiquitin system enzymes and substrates in animals can provide a more systematic view into the broad spectrum of pathologies that may result from aberrations in ubiquitin-mediated proteolysis. A better understanding of the processes and identification of the components involved in the degradation of key regulatory proteins will lead to the development of mechanism-based drugs that will target specifically only the involved proteins. While the first drug, a specific proteasome inhibitor


Figure 8. Aberrations in the ubiquitin–proteasome system and pathogenesis of human diseases: Normal degradation of cellular proteins maintains them at a steady-state level, although this level may change under various pathophysiological conditions (right side, top and bottom). When degradation is accelerated because of an increase in the level of an E3 (Skp2 in the case of p27, for example), or overexpression of an ancillary protein that generates a complex with the protein substrate and targets it for degradation (for example, the human papillomavirus E6 oncoprotein that associates with p53 and targets it for degradation by the E6-AP ligase, or the cytomegalovirus-encoded ER proteins US2 and US11 that target MHC class I molecules for endoplasmic reticulum-associated degradation, ERAD), the steady-state level of the protein decreases (top left). A mutation in a ubiquitin ligase (such as occurs in adenomatous polyposis coli, or EG-AP in Angelmans' syndrome), or in the substrate's recognition motif (such as occurs in β-catenin or in ENaC), will result in decreased degradation and accumulation of the target substrate (bottom left).

is already on the market,[80] it appears that one important hallmark of the new era we are entering now will be the discovery of novel drugs based on the targeting of specific processes such as inhibiting aberrant Mdm2- or E6-AP-mediated accelerated targeting of the tumor suppressor p53 which will lead to regeneration of its lost function.

Many reviews have been published on different aspects of the ubiquitin system. The purpose of this article was to bring to the reader several milestones on the historical pathway along which the ubiquitin system has evolved. For additional reading on the ubiquitin system the reader is referred to the many reviews written on the system, such as Refs. [81,82]. Some parts of this Review, including several figures, are based on another recently published review article (Ref. [83]).

Communications
A cubic Li_4H_4 species can be isolated in molecular form through the coordination of three $HAl\{N(SiMe_3)_2\}_2$ ligands. Steric factors prevent the coordination of a fourth ligand and result in the formation of an aggregate with nearly perfect C_3 symmetry. For more information see the Communication by M. Veith et al. on the following pages.

Lithium Hydride

Cubane-Like Li₄H₄ and Li₃H₃Li(OH): Stabilized in Molecular Adducts with Alanes**

Michael Veith,* Peter König, Andreas Rammo, and Volker Huch

Lithium hydride forms molecular adducts, especially with boranes, $R_x(H)_{3-x}B$, but also with alanes, $R_x(H)_{3-x}Al$, most of which can be described as boranate or aluminate anions with lithium as the cation. A frequently observed common structural element of these adducts is a four-membered Li_2H_2 ring that arises from dimerization of the simple lithium boranates and aluminates.[1–10] A particularly simple example from the area of lithium aluminates can be described briefly thus: $[(tBu)_3AlH]Li$ is a dimer and has a four-membered $\{Li_2H_2\}$ ring to which the aluminum atoms are bonded exocyclically through the hydridic hydrogen atom.[11] A different structural principle is the formation of Li-H-Al units where the metal atoms are each held together through hydrogen bonds and thus form a ring system.[12–15] In this way $[\{[(Me_3Si)_2N]AlH_3Li·2OEt_2\}_2]$ is formed from an eight-membered $\{Li_2Al_2H_4\}$ ring with the hexamethyldisilazyl groups as ligands on the aluminum atoms and the two Et_2O molecules linked to the lithium atoms.[16] The stabilization of larger LiH units in a molecule appears to be exceptionally difficult. To our knowledge such lithium hydride oligomers could only be confirmed structurally for one example: $[(tBuO)_{16}Li_{16}]Li_{17}H_{17}·3\,cyclohexane$.[17] This alkoxo-hydrido lithium compound is a complex agglomerate of LiOtBu and LiH.

Herein we report for the first time a Li_4H_4 cube that is coordinated through three bis(amino)alane units and as a result may be isolated in molecular form. We also describe the reaction of this molecule with an equivalent of water in which only one of the hydridic hydrogen atoms reacts. We have used the reaction of *tert*-butoxyalane[18] with hexamethyldisilazyl-lithium[19] for the in situ generation of lithium hydride (see also the synthesis of $[\{[(Me_3Si)_2N]AlH_3Li·2OEt_2\}_2]$ from hexamethyldisilazane and lithium alanate[16]). According to the reaction in Equation (1) a product mixture is formed in this reaction that consists of the lithium alanates **2** and **3** as

well as **1** which is the adduct of Li_4H_4 with three molecules of $[(Me_3Si)_2N]_2Al$-H .

We were able to separate all the components of this reaction mixture by fractional crystallization and to characterize them spectroscopically and by X-ray crystallography. In toluene solution **1–3** give simple ¹H, ¹³C, and ²⁹Si NMR spectra, which suggests weak associations or small degrees of oligomerization. The IR spectrum of **1** has a relatively broad absorption in the metal hydride region with a maximum at 1732 cm⁻¹ and an extensive shoulder at 1700 cm⁻¹, a situation

$$\text{[Structure]} + 4\,\text{LiN(SiMe}_3)_2 \xrightarrow{\text{toluene}} \mathbf{1} \tag{1}$$

$$+ 1/n\,[\{Li\{H(OtBu)_2Al[N(SiMe_3)_2]\}\}_n] + 1/n\,[\{Li\{H_2Al[N(SiMe_3)_2]_2\}\}_n]$$
$$\mathbf{2} \qquad\qquad \mathbf{3}$$

which is in agreement with the different hydride bridges found in the solid.

A ball and stick model of **1** derived from the X-ray structural analysis is reproduced in Figure 1.[20] The molecule has an approximate threefold axis that runs through atoms H7 and Li2. The molecule is most simply described as a Li_4H_4 cube at three edges of which Al–H units of $HAl\{N(SiMe_3)_2\}_2$ are inserted so that Li–H–Al–H loops are formed from the original Li–H edges. In spite of their weak Lewis basicity, a hexamethyldisilylazyl group of each the three aluminum atoms coordinates to one of the lithium atoms Li1, Li2, and Li3. This coordination is shown by the relatively short Li–N

Figure 1. Molecular structure of **1**. The methyl groups of the trimethylsilyl units (yellow Si) have been omitted for clarity. Selected (averaged) bond lengths [Å] and angles [°]: H7–Li(1,3,4) 2.03(2), H(1,2,3)–Li-(1,3,4) 1.89(2), H(4,5,6)–Li2 1.815(9), H(4,5,6)–Li(4,1,3) 2.26(2), Al-(1,2,3)–H(6,4,5) 1.64(1), Al(1,2,3)–H(1,2,3) 1.59(1), Al(1,2,3)–N(1,4,5) 1.846(5), Al(1,2,3)–N(2,3,6) 1.892(6), Li(1,3,4)···N(6,2,3) 2.191(8), Li-(1,3,4)···H(6,4,5) 2.77(2); Li1-H1-Al1 118.2(3), Li3-H2-Al2 116.6(3), Li4-H3-Al3 116.3(3), average angle about H7 100.6(3), about Li2 101.8(6), angle-sum about N1 359.5, N2 355.2, N3 355.7, N4 358.6, N5 359.0, N6 355.9.

distances (see Figure 1). Owing to the insertion of the Al–H units into the three edges of the Li_4H_4 cube the Li1–H6, Li3–H4, and Li4–H5 distances are greatly elongated, which is reinforced by the concomitant N coordination to these atoms (Figure 1). The different coordination behavior of the two hexamethyldisilylazyl groups on each Al atom is also evident from the angle-sum around the nitrogen atoms, almost trigonal planar environment are found for N1, N4 and N5, whereas N2, N3, and N6 are slightly pyramidalized. The lithium atoms Li1, Li3, and Li4 are approximately tetrahedrally coordinated by three hydride ligands and a nitrogen base, whereas Li2 is surrounded by a trigonal-pyramidal arrangement of hydrides. The hydrides can be divided into three categories: H1–H3 form angular bridges (mean value: 117°) between lithium and aluminum atoms, H4–H6 are coordinated by the metal atoms in an almost trigonal-planar arrangement, whereas H7 is surrounded only by lithium atoms (mean angle: 100.6(3)°) in a trigonal-pyramidal arrangement. Thus hydrogen atom H7 is the most accessible, at least in the kinetic sense (see below).

The other two main products of the reaction form coordination polymers in their crystal structures (Figure 2 and Figure 3). In the case of $[\{Li\{H(OtBu)_2Al[N(SiMe_3)_2]\}\}]_n$ (2) one-dimensional helical structures are formed from two crystallographically different units through almost linear Li–H–Al hydrogen bonds. They consist formally of aluminate units $\{H(OtBu)_2Al[N(SiMe_3)_2]\}$ that chelate the formal lithium cation through the oxygen atom of the alcohol residue (Figure 2).[20] The lithium atoms are coordinated by oxygen
Figure 2. Molecular structure of 2. Selected bond lengths [Å] and angles [°]: Al1–H1 1.61(1), Al2–H2 1.61(1), Li1′–H2 1.95(2), Li2–H1 1.86(2), Al1–N1 1.843(5), Al1–O1 1.769(4), Al1–O2 1.788(4), Li1–O1 1.910(7), Li1–O2 1.924(7), Al2–N2 1.848(5), Al2–O3 1.780(4), Al2–O4 1.771(4), Li2–O3 1.883(7), Li2–O4 1.890(7); O1-Li1-O2 82.2(1), O1-Al1-O2 90.27(8), Al1-H1-Li2 159.3(2), O3-Li2-O4 83.7(1), O3-Al2-O4 90.32(8), Al2-H2-Li1′ 164.7(2).

and hydrogen atoms in a distorted trigonal-planar arrangement, and the hexamethyldisilazyl substituents form simple terminal ligands to the aluminum atoms. An example of an isolated lithium alanate that is chemically very similar to 2 is $[Li(OEt_2)(\mu OCMetBu_2)_2Al(H)(OCMetBu_2)]$ in which polymerization is impeded by the bonding of the Et_2O base to the lithium atom.

The crystal structure of 3 is remarkable (Figure 3).[20] Two crystallographically independent strands of $[\{Li(H_2Al[N(SiMe_3)_2]_2)\}_n]$ run through the crystal as Al–H–Li–H–Al zigzag chains, which surprisingly (in spite of the weak Lewis basicity of the nitrogen atom in $\{N(SiMe_3)_2\}$) are reinforced by Al–N–
Figure 3. Molecular structure of 3. (only one of the two crystallographically independent but structurally very similar polymers is shown). Selected (averaged) bond lengths [Å] and angles [°]: Al1–H1 1.52(1), Al1–H2 1.79(1), Al1–N1 1.932(5), Al1–N2 1.846(5), Li1–H2 1.62(2), Li1–H1′ 1.81(2), Li1–N1 2.135(8), N1–Si(1,2) 1.752(9), N2–Si(3,4) 1.745(1); H2-Al1-N1, Al1-N1-Li1, N1-Li1-H2, Li1-H2-Al1 101.6(2), Li1-H1′-Al1′ 166.8(2).

Li bridges so that four-membered Al–N–Li–H rings are formed. An alternative description is that the lithium atom is coordinated by two hydrogen atoms and a nitrogen atom, this is in contrast to the isolated molecular diethyl ether adduct $[Li(OEt_2)_2(\mu H)_2Al\{N(SiMe_3)_2\}_2]$ in which the lithium atom is chelated by only two hydride hydrogen atoms.[16] Clearly the loss of base requires the lithium atoms to expand their coordination sphere from 2 to 3 with the silylazyl ligands.

If $Li_4H_4[HAl\{N(SiMe_3)_2\}_2]_3$ (1) is treated with a small amount of water only H7 of the seven hydride atoms (Figure 1) reacts, in the hydrolysis product $Li_4H_3(OH)[HAl\{N(SiMe_3)_2\}_2]_3$ (4; Figure 4 and the reaction in Equation (2)) it is substituted by an OH group.

$$Li_4H_4[HAl\{N(SiMe_3)_2\}_2]_3 \ (\mathbf{1}) + H_2O$$
$$\rightarrow H_2 + Li_4H_3(OH)[HAl\{N(SiMe_3)_2\}_2]_3 \ (\mathbf{4}) \qquad (2)$$
In many respects the structure of 4 resembles that of 1 since the whole basket-shaped $Li_4H_3[HAl\{N(SiMe_3)_2\}_2]_3$ part is essentially identical in both molecules (Figure 1 and Figure 4;[20] 1 and 4 crystallize in different crystal lattices and are therefore not isotopic). The Li–O1 bond in 4 is about 0.15 Å longer than the Li–H7 bond in 1, thus, the Li_4H_3-$[HAl\{N(SiMe_3)_2\}_2]_3$ basket part of 4 is somewhat extended (the nonbonding Li···Li distances in 4 are about 0.08 Å longer than in 1) and consequently the angles at the oxygen atom O1 are also more acute than at H7. As can be seen from the hydrolysis of 1, the three $HAl\{N(SiMe_3)_2\}_2$ loops not only stabilize the Li_4H_4 units coordinatively but also protect them in the kinetic sense. It is only at the unprotected, free position (H7 in 1) that substitution occurs (in careful hydrolysis).

Figure 4. Molecular structure of **4**. The methyl groups of the trimethyl-silyl units (yellow Si) have been omitted for clarity. Selected (averaged) bond lengths [Å] and angles [°]: O1–Li(1,2,3) 2.183(9), Al(1,2,3)–N-(2,4,6) 1.896(5), Al(1,2,3)–N(1,3,6) 1.841(5), Li4–H(1,4,5) 1.85(1), Li-(1,2,3)–H(2,6,3) 1.90(1), Al(1,2,3)–H(2,3,6) 1.57(1), Al(1,2,3)–H(1,4,5) 1.62(2); Li1-O1-Li2 94.5(1), Li2-O1-Li3 94.4(1), Li1-O1-Li3 94.6(1).

Experimental section

A stirred solution of $(H_2AlOtBu)_2$ (0.79 g, 3.84 mmol) in toluene (5.0 mL) at room temperature was slowly treated dropwise with a solution of $LiN(SiMe_3)_2$ (2.58 g; 13.4 mmol) in toluene (15.0 mL). After 18 h stirring the reaction mixture was heated for 7 h at about 95 °C. After cooling overnight in the oil bath the partly crystalline precipitate (amount: 0.6 g) is collected by filtration. Colorless crystals of **1** (0.05 g, 1.8%) and **2** (0.40 g, 15.3%) separate from the filtrate at room temperature. The crystals differ in their crystalline habit. After further concentration, further crystals separate, which after recrystallization from toluene yields 0.20 g (7.3%) of colorless crystals of **3**. If a solution of **1** is treated with wet toluene, crystals of **4** form after a few hours. Solvent in each case [D8]toluene: **1**: ^1H NMR (200.13 MHz): $\delta = 0.38$ ppm, ^{13}C NMR (50.3 MHz): $\delta = 5.96$ ppm, ^{29}Si NMR (39.7 MHz): $\delta = 0.01$ ppm; IR: (Al-H): $\tilde{\nu} = 1732, 1700$ cm^{-1}; **2**: ^1H NMR: $\delta = 0.45$ (SiC*H*), 1.31 ppm (CC*H*), ^{13}C NMR: $\delta = 6.04$ (Si*C*), 33.7 (*C*H), 68.9 ppm (*C*C), ^{29}Si NMR: $\delta = -2.96$ ppm; **3**: ^1H NMR: 0.37 ppm, ^{13}C NMR: $\delta = 5.90$ ppm, ^{29}Si NMR: $\delta = 0.25$ ppm. **4** was only characterized by X-ray diffraction.

Titanium-Catalyzed Intermolecular Hydroamination of Vinylarenes**

*Ludwig T. Kaspar, Benjamin Fingerhut, and Lutz Ackermann**

Most substituted amines are made today by multistep syntheses. Therefore, addition reactions of simple amines onto unsaturated carbon–carbon multiple bonds, hydroamination reactions,[1–6] are of considerable importance for industry and academia. Transformations of alkynes and allenes can be catalyzed by a variety of reagents.[7] However, protocols for intermolecular hydroamination reactions of more readily available olefins have thus far proven limited. Various lanthanide complexes catalyze hydroamination reactions of alkenes, but they lack compatibility with a number of important functional groups.[8,9] Significant research activity has focused on the use of late-transition-metal complexes for intermolecular hydroamination reactions of olefins, featuring iridium,[10–12] rhodium,[13–18] nickel,[19,20] palladium,[21–24] platinum,[25,26] and ruthenium.[27,28] The high cost of these complexes, their stabilizing ligands, or the additives constitute a limitation of these protocols. Recently, we reported a Group 4 metal catalyzed[29] intermolecular[30] hydroamination of norbornene.[31] Herein we present titanium-catalyzed[32] hydroamination reactions of vinylarenes as well as an application of this procedure to the synthesis of a tetrahydroisoquinoline.

Initial experiments showed that catalytic amounts of the Lewis acid TiCl4 converted styrene (**1a**) in the presence of four equivalents of 4-chloroaniline (**2a**) efficiently at 130°C (Table 1, entry 1). Control experiments indicated that a simple Brønsted acid mediated reaction is not operative (entries 3 and 4). These results are in agreement with observations made by Hartwig et al., who found that even the *intramolecular* addition of amines, not bearing an electron-withdrawing group, does not occur in the presence of concentrated sulfuric acid.[33,34]

Under the above reaction conditions, mixtures of hydroamination and *ortho*-hydroarylation products were obtained. While the reaction time for quantitative conversion could be reduced significantly with microwave irradiation, the amount

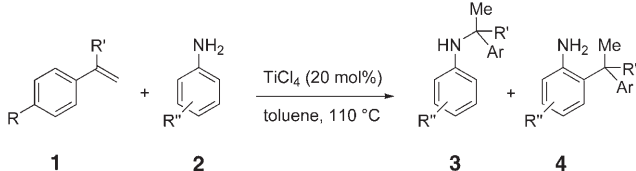
of hydroarylation product increased (entries 6, 9, and 10). As the *ortho*-alkylated product was also predominantly formed when stoichiometric amounts of the Lewis acid TiCl4 were employed (entry 7), we wondered if a rearrangement of the hydroamination product occurs. Accordingly, we synthesized secondary amine **3a** independently through a palladium-catalyzed amination reaction[35] and subjected it to the hydroamination reaction conditions [Eq. (1)]. Indeed, the secondary amine **3a** was quantitatively converted, while the primary amine **4a** remained unchanged under the reaction conditions [Eq. (2)].

(1)


Subsequently, we studied the scope of the catalytic intermolecular hydroamination of styrene derivatives (Table 2). A number of vinylarenes **1** and aniline derivatives **2** were efficiently converted with catalytic amounts of TiCl4, leading to the functionalized products in high yields. Electron-poor amines underwent more efficient reactions

[a] Reaction conditions: **1** (1 mmol), **2** (4 mmol), TiCl$_4$ (20 mol%), toluene (2 mL). [b] By GC analysis. [c] Yields of isolated product. [d] 130°C. [e] **1a** (4 mmol), **2c** (1 mmol). [f] With microwave irridiation. [g] 170°C. [h] TiCl$_4$ (1 mmol). [i] HfCl$_4$ (20 mol%).
(entries 1–6). A variety of functional groups was tolerated by the catalyst, such as CF$_3$ (entries 1–3), Cl (entry 2), CN (entry 4), F (entries 3 and 6), and Br substituents (entries 5 and 10). Additionally, α-methylstyrene (**1e**) was quantitatively converted into product **4k**, which contains a quaternary carbon center (entry 8). Interestingly, di-*ortho*-substituted aniline **2h** was not converted (entry 9).[31] In the reaction of aniline **2b** catalytic amounts of the Lewis acid HfCl$_4$ led to comparable results (entry 11).

Finally, we applied the titanium-catalyzed hydroamination reaction to a regioselective synthesis of a tetrahydroisoquinoline (Scheme 1).[36] The highly regio- and chemoselective titanium-catalyzed hydroamination[37,38] of enyne **5** and subsequent one-pot reduction gave aminoalkene **6** in good yield. Intramolecular hydroamination of the remaining

double bond yielded the desired tetrahydroisoquinoline **7** with excellent regioselectivity and a diastereoselectivity of 4:1.[39]

In summary, we have described a protocol for titanium-catalyzed hydroamination reactions of styrene derivatives. A subsequent rearrangement gives rise to *ortho*-alkylated products. The catalytic system was applied to the synthesis of a tetrahydroisoquinoline derivative.

Experimental Section

Representative procedure for titanium-catalyzed hydroamination: A sealed tube was equipped with a septum and purged with N$_2$. The tube was charged with dry toluene (2 mL), 3,5-bis(trifluoromethyl)aniline (**2b**; 917 mg, 4.00 mmol), and styrene (**1a**; 104 mg, 1.00 mmol). TiCl$_4$ (0.022 mL, 0.20 mmol, 20 mol%) was added, the tube was sealed, and the resulting mixture was stirred for 30 h at 110°C. CH$_2$Cl$_2$ (5 mL), Et$_2$O (60 mL), aq NH$_4$OH (1N, 15 mL), and brine (50 mL) were added to the cold suspension. The separated aqueous phase was washed with Et$_2$O (2×60 mL). The combined organic phases were dried over MgSO$_4$ and concentrated in vacuo. Purification by column chromatography (silica gel, *n*-pentane/Et$_2$O 100:1) yielded *N*-1-phenylethyl-3,5-bis(trifluoromethyl)aniline (**3d**) as a yellow oil (290 mg, 87%).

Origin of the High Activity of Second-Generation Grubbs Catalysts**

*Bernd F. Straub**

*Dedicated to Professor Rolf Huisgen
on the occasion of his 85th birthday*

Alkene metathesis has experienced a breathtaking success in the last decade. Organic synthetic applications were mainly facilitated by the development of highly active ruthenium carbene catalysts.[1] The increase in activity from the catalysts of the first generation **1**[2] to those of the second generation **2** further broadened their significance (Scheme 1).[3] However,
Scheme 1. Alkene metathesis with first-generation and second-generation Grubbs catalysts.

"there is so far no unique explanation for the enhanced reactivity of the 'second-generation' Grubbs-type ruthenium complexes".[4]

The influence of the ligands is reflected in Grubbs' conclusion: "Phosphines, which are larger and more electron donating, and likewise halogens, which are smaller and more electron withdrawing, lead to more active catalysts."[5] Since N-heterocyclic carbenes (NHC) behave as if they were extremely electron-donating phosphines, Grubbs' rule was

confirmed by the development of the second-generation catalysts. A first assumption concerning the origin of their high activity was based on the higher electronic *trans*-influence of NHC ligands compared to phosphines. An expected, more favored phosphine dissociation would result in higher concentrations of the active 14 valence-electron complexes. These complexes undergo [2+2] cycloaddition reactions with alkene substrates according to the Chauvin mechanism.[6] However, NMR spectroscopy studies by Sanford and Grubbs demonstrated exactly the opposite behavior for the ease of phosphine dissociation.[7] The least active first-generation iodide complex has the lowest barrier for phosphine dissociation, while the most active second-generation complex has the highest barrier (Scheme 2).

Scheme 2. Gibbs free activation energies for phosphine dissociation and the efficiency of alkene metathesis according to Grubbs et al.[7]

A more efficient partitioning between the coordination of the phosphine ligand and the alkene substrate by the 14 valence-electron ruthenium carbene complexes has been proposed to account for the high activity of second-generation Grubbs catalysts.[7,8] We encountered the challenging question concerning the origin of their outstanding catalytic activity in our recent quantum-chemical investigation on enyne metathesis.[9] The key to the understanding of metathesis activities is the existence of active and inactive conformations in the alkene–carbene intermediates (Scheme 3). Three conformers are inactive, and only one

INACTIVE   INACTIVE   INACTIVE

conformer is active for an immediate rearrangement into a ruthena(iv)cyclobutane.[10]

Based on this almost trivial consideration, two findings by Hansen and Hofmann are decisive for a deeper understanding of the electronic origin of catalyst activity:[11] 1) "The orientation of the carbene moiety allows for optimal back-bonding from the metal fragments [of both Grubbs complexes and Hofmann *cis*-diphosphine ruthenium complexes] to the carbene acceptor orbital". 2) The ruthenium–ligand unit (P-Ru-P, C-Ru-P, Cl-Ru-Cl, or Cl-Ru-P) "that interacts with the π-acceptor orbital of the methylene carbon is more strongly bent" than the unit which has an orthogonal orientation to the carbene π orbital.

The formally ideal angles at the ruthenium center can be derived from the classification of Grubbs carbene complexes as 16 valence-electron d^6-ML$_5$ species. As the Cl-Ru-Cl angle decreases from 180°, the nonbonding interaction between occupied chloride orbitals and an occupied ruthenium d orbital becomes increasingly antibonding (Figure 1, first
Figure 1. Stabilization of inactive and active carbene orientations: better backbonding by bending.

row). Intrafragment polarization (mixing of 5p and 4d orbitals) of the ruthenium fragment minimizes this antibonding orbital interaction and leads to increased backbonding to the empty p orbital of the carbene ligand. Overall, the bending of the chloride ligands results in a stronger ruthenium–carbene double bond and thus to a stabilization of the inactive carbene orientation. More electropositive iodide ligands are expected to further stabilize the inactive carbene conformation. An analogous line of argumentation can also be applied to the decrease of the NHC-Ru-alkene angle (Figure 1, second row). The alkene ligand is a worse σ donor than a chloride ligand, while the NHC ligand is a better σ donor and leads to a pronounced antibonding orbital interaction. With increasing antibonding interaction between

the NHC sp^2 orbital and a ruthenium d orbital, the back-bonding of the ruthenium fragment to the carbene acceptor orbital increases, and the active carbene conformation is stabilized.

This qualitative hypothesis can be tested by the quantum-chemical calculation of relative energies of catalytic intermediates, particularly of the four alkene–carbene conformers.[12] To our knowledge, the relative stabilities of the four alkene carbene conformations have not yet been investigated at the same level of theory. The catalytic cycle of alkene metathesis has already been thoroughly studied theoretically.[4,13] Thus, the predicted catalytic pathway in Scheme 4 comes as no surprise.

Even in the isomeric simplified Grubbs catalyst models **3a–c** and **4a–c**, the acceptor orbitals of the carbene fragments prefer a parallel orientation with the stronger σ-donor ligands ($2 I^-$ or $NHC + PMe_3 > 2 Cl^- > 2 PMe_3$). Intrinsic electronic barriers for the rotation of the methylene unit between model structures **3** and **4** are small.[14] Dissociation of PMe$_3$ from the models **4a–c** leads to the active carbene complexes **5a–c**. Then, alkene association yields the alkene–carbene complexes **6a–c**,[15] or their conformers **7a–c**, **8a–c**, and **9a–c**. [2+2] Cycloaddition via the transition states **10a–c** results in the ruthenacycles **11a–c**.[16] Interestingly, the low relative Gibbs free energy of the sterically simplified complex **5c** is in contrast to the high, experimentally observed dissociation barrier for PCy$_3$ from complex **2**. This result indicates that electronic factors are not responsible for the experimental anomaly. The overall Gibbs free activation energies in the transition state models **10a–c** fit nicely to the analogous experimental catalyst activities.

The computed Gibbs free energies of the alkene carbene ruthenium complexes show little preference for a particular alkene rotamer. The rotation of the alkene in the most stable conformers **6a–c** to give the rotamers **7a–c** is only slightly disfavored by 2.5 to 5.6 kJ mol^{-1}.[17] The orientation of the carbene fragment, however, strongly depends on the choice of the spectator ligands. The rotation of the carbene ligand into

its active orientation in **8a–c** is highly disfavored for the first-generation iodide model complex (**7a** versus **8a**, $\Delta G = 23.3$ kJ mol^{-1}), and it is also disfavored for the first-generation chloride complex (**7b** versus **8b**, $\Delta G = 21.0$ kJ mol^{-1}). In contrast, carbene rotation is essentially degenerate for the second-generation chloride complex (**7c** versus **8c**, $\Delta G = -1.6$ kJ mol^{-1}). We were unable to localize minimum structures **9a–c**, because either alkene–carbene structures **6a–c** or ruthenacycles **11a–c** were obtained after geometry optimization. The transition states **10a–c**, however, have the same alkene and carbene conformation as the hypothetical structures **9a–c**. Indeed, the transition states **10a–c** with their active carbene orientation have similar Gibbs free energies to the active carbene conformers **8a–c**.

Thus, the high reactivity of second-generation Grubbs catalysts mainly originates in the electronic stabilization of the active carbene conformation by the N-heterocyclic carbene ligands (Scheme 5). The computed total electronic energies for phosphine dissociation of the models **12a**, **12b**, and **14** to the model complexes **13a**, **13b**, and **15** correlate nicely with experimental Gibbs free activation energies for PCy$_3$ loss (Scheme 6 versus Scheme 2).[18] The differences in phosphine dissociation barriers for first- and second-generation complexes are caused almost exclusively by specific steric congestion. In this case the repulsive interaction of α- and β-hydrogen atoms of the cyclohexyl substituents with the halogen ligands is of primary importance.

In addition to the electronic benefit of using the strong σ-donor NHC ligands, their mesityl substituents also contribute to a favored active carbene orientation (Scheme 7). The association of ethene to complex **15** and the subsequent carbene rotation proceed without enthalpic barrier to the intermediate **16**, which is formally a minimum structure (NIMAG 0). The additional σ-donor ligand ethene as well as the steric repulsion between the hydrogen of an inactive carbene ligand and a mesityl substituent enforce an active carbene orientation. Finally, an essentially barrierless transformation leads to the cycloadduct **17**.

Scheme 7. Computed Gibbs free energies of non-simplified catalyst intermediates.

In summary, second-generation alkene–carbene complexes are characterized by their high efficiency in partitioning between unproductive alkene dissociation and successful [2+2] cycloaddition. The electronic and steric stabilization of the active conformation of the carbene moiety in second-generation Grubbs catalysts is responsible for their exceptional alkene metathesis activity.

[10] On the ^{1}H NMR spectroscopy time scale at room temperature, carbene rotation is rapid in a ruthenium complex. See T. Weskamp, F. J. Kohl, W. Hieringer, D. Gleich, W. A. Herrmann, *Angew. Chem.* **1999**, *111*, 2416; *Angew. Chem. Int. Ed.* **1999**, *38*, 2573. This feature indicates that the rotation barrier is below about 50 kJ mol^{-1}. The assumption of a "free" carbene rotation might have been a factor for considering the carbene rotation as irrelevant for the overall catalytic barrier.

The transition state connecting structures **3c** and **4c** has a relative Gibbs free energy of $G_{rel} = 11.8$ kJ mol^{-1}; see ref. [9].

[15] A derivative of model **6b** has been characterized crystallographically; see J. A. Tallarico, P. J. Bonitatebus, Jr., M. L. Snapper, *J. Am. Chem. Soc.* **1997**, *119*, 7157.

[16] Recently, a derivative of model **11c** has been characterized by NMR spectroscopy; see P. E. Romero, W. E. Piers, *J. Am. Chem. Soc.* **2005**, *127*, 5032.

[17] Owing to the low binding strength of the alkene ligand to ruthenium, alkene reorientation may proceed either by alkene dissociation and re-association or by intramolecular alkene ligand rotation. Since the active alkene conformation is more stable than the inactive conformation anyway, alkene rotation should be irrelevant in the catalytic cycle.

[18] Zero-point energy corrections to E_0 values would result in a decrease of the energy differences of about 5 kJ mol^{-1}.

Germanium Complexes

Ge₂ Trapped by Triple Bonds between Two Metal Centers: The Germylidyne Complexes *trans,trans*-[Cl(depe)₂M≡Ge−Ge≡M(depe)₂Cl] (M = Mo, W) and Bonding Analyses of the M≡Ge−Ge≡M Chain**

Alexander C. Filippou,* Gregor Schnakenburg, Athanassios I. Philippopoulos, and Nils Weidemann

Complexes, in which sp-hybridized carbon chains span two transition-metal centers, $[L_nMC_xM'L'_n]^{y+}$, (L_n, L'_n = ligand sphere; x, y = integer) have attracted particular attention in recent years.[1] These compounds form an important class of carbon-based molecular wires,[2] which are appealing for studies of the electronic communication between redox-active metal termini,[3] and are of potential practical importance in molecular electronics[4] and in nonlinear optics.[5] Moreover, these compounds can be viewed, at large carbon-chain lengths, as polymeric sp-hybridized carbon allotropes, revealing a conceptual relationship to the classical polymeric sp²- and sp³-hybridized carbon allotropes, graphite and diamond.[6] For $x = 2$, three classes of metal complexes have been reported to date (**Ia–Ic**, Scheme 1). The ethynediyl

$$\textbf{Ia} \qquad\qquad\quad \textbf{Ib} \qquad\qquad\quad \textbf{Ic}$$
Scheme 1. Valence bond structures of C₂ bridged complexes.

complexes **Ia** are by far the most prevalent.[1a,b,d,f,7] In contrast, analogous compounds of the heavier Group 14 elements Si–Pb are not known to date.[8] This situation is not surprising given the reluctance of these elements to form triple bonds.[9,10] A rich elimination and substitution chemistry of main-group elements was elaborated in recent years using the

heterolytic or homolytic cleavage of Cp*–element bonds (Cp* = C₅Me₅).[11] A successful implementation of this method in the synthesis of the first transition-metal complexes with triply bonded Ge₂ chains is presented herein.

For the synthesis, the dichloro complexes *trans*-[MCl₂(depe)₂] (depe = Et₂PCH₂CH₂PEt₂; M = Mo (**1-Mo-Cl**), M = W (**1-W-Cl**)) were employed. Complex **1-Mo-Cl** was obtained upon reduction of *mer*-[MoCl₃(thf)₃][12] with zinc in THF in the presence of 2.1 equivalents of depe, and **1-W-Cl** upon heating of *trans*-[WCl₂(PMe₃)₄][13] with 2.1 equivalents of depe in toluene at reflux. Both compounds were isolated as slightly air-sensitive, orange-yellow solids in 90% yield and decompose upon melting at 211 and 205°C, respectively.[14] Reduction of **1-M-Cl** with sodium powder in THF under N₂ atmosphere afforded selectively the dinitrogen complexes *trans*-[M(depe)₂(N₂)₂] (M = Mo (**2-Mo**), M = W (**2-W**)), which were isolated as air-sensitive, orange (**2-Mo**) and bright red (**2-W**) solids in 98 and 72% yields, respectively (Scheme 2).[14,15]
Scheme 2. Stepwise synthesis of the germylidyne complexes **4-M-X** and **5-M-Cl** starting from the dichlorides **1-M-Cl**.

Treatment of **2-Mo** with a stoichiometric amount of the germanium(ii) halides [{Ge(Cp*)X}ₙ] (X = Cl, n = 1 (**3-Cl**); X = Br, n = 2 (**3-Br**))[16] in toluene at reflux gave the brown-orange, air-sensitive molybdenum germylidyne complexes **4-Mo-Cl** and **4-Mo-Br** in 32% and 44% yields, respectively (Scheme 2).[14,17] Both compounds are very soluble in pentane and melt in sealed capillaries under vacuum at 152 and 155°C, respectively. Simultaneous thermal analysis (thermogravi-metry/differential thermal analysis/mass spectrometry (TG-DTA-MS) of **4-Mo-Cl** revealed that the germylidyne complex melts at the extrapolated onset temperature $T_{on}^{ex} = 144°C$ (peak temperature, $T_p = 149°C$) and then decomposes at 181°C releasing C₅Me₅H.[14,18] These results prompted us to study the thermolysis of **4-Mo-Cl** on a preparative scale. Upon heating the germylidyne complex **4-Mo-Cl** at 180–185°C under static vacuum, the brown-orange sample of **4-Mo-Cl** melted and then turned progressively to a red-brown mass. Analysis of the molten mass by ¹H and ³¹P{¹H} NMR

spectroscopy revealed a gradual conversion of **4-Mo-Cl** into the digermanium complex **5-Mo-Cl**, which after completion of the reaction and work-up was obtained as an air-sensitive, brown solid in 27% yield (Scheme 2).[14] During the thermolysis of **4-Mo-Cl**, a yellow volatile material deposited on the cold top part of the reaction tube and was identified by NMR spectroscopy to be a mixture of depe, Cp*H,[19] 1,2,3,4-tetramethylpentafulvene,[20] and some [GeCp*₂].[21] These results suggest that homolysis of the Ge–Cp* bond occurs upon thermal activation of **4-Mo-Cl** to generate [MoCl(Ge)-(depe)₂] and Cp* radicals. The [MoCl(Ge)(depe)₂] radicals dimerize to form **5-Mo-Cl**, whereas the Cp* radicals disproportionate under the reaction conditions to give Cp*H and 1,2,3,4-tetramethylpentafulvene.[22] Heating of an equimolar mixture of complex **2-W** and **3-Cl** in toluene at reflux afforded a 7.7:1 mixture of the tungsten germylidyne complexes **4-W-Cl** and **5-W-Cl** (Scheme 2). Thermolysis of this mixture at 190°C under static vacuum transformed **4-W-Cl** into the digermanium complex **5-W-Cl**, which was isolated as a very air-sensitive, green-brown solid in 30% overall yield. Complex **5-W-Cl** decomposes upon melting at 240°C.[14] The molecular structures of **4-Mo-Br** and **5-W-Cl** were determined by single-crystal X-ray diffraction (Figures 1 and 2). The

imposed center of symmetry at the midpoint of the Ge–Ge bond, an almost linear Ge₂ chain spanning the two *trans*-configured, octahedral tungsten centers (W-Ge-Ge# 175.13(3)°), and two W–Ge triple bonds (2.3087(5) Å) that are linked by a short Ge–Ge single bond (2.362(1) Å) (Figure 2). The W–Ge bonds of **5-W-Cl** compare well with

Selected bond lengths [Å] and bond angles [°]: Mo-Ge 2.2798(5), Ge-C1 2.046(3), Mo-Br 2.6899(5), Mo-P1 2.479(1), Mo-P2 2.498(1), Mo-P3 2.465(1), Mo-P4 2.4812(9), C1-C2 1.504(4), C2-C3 1.356(5), C3-C4 1.466(5), C4-C5 1.353(4), C1-C5 1.485(4); Mo-Ge-C1 177.46(8), Ge-Mo-Br 177.94(2), Ge-Mo-P1 95.38(2), Ge-Mo-P2 95.30(2), Ge-Mo-P3 96.86(2), Ge-Mo-P4 92.80(2), Ge-C1-C2 99.8(2), Ge-C1-C5 99.9(2), Ge-C1-C6 114.0(2).

trans-configured octahedral complex **4-Mo-Br** has a very short Mo–Ge triple bond (2.2798(5) Å) and an almost linear coordinated germanium atom (Mo-Ge-C$_{Cp*}$ 177.46(8)°) which has an η¹-bonded Cp* substituent as shown by the Ge–C1/C5 distances, the alternating (C–C)$_{ring}$ bond lengths, and the bond angles at the C1 atom (Figure 1).[23] The Mo–Ge bond of **4-Mo-Br** is even shorter than those of the dppe complexes *trans*-[X(dppe)₂Mo≡Ge-(η¹-Cp*)] (dppe = Ph₂PCH₂CH₂PPh₂, X = Cl, 2.3185(6) Å; X = Br, 2.3103(6) Å).[9c] This situation suggests that sterically less-demanding phosphine ligands of higher σ-basicity strengthen the metal–germanium triple bonds. Complex **5-W-Cl** features a crystallographically

those of the germylidyne complexes *trans*-[X(dppe)₂W≡Ge-(η¹-Cp*)] (X = H, Cl, Br, I, NCO, CN; W-Ge 2.293(1)–2.3184(6) Å).[9c,g] The Ge–Ge distance (2.362(1) Å) is the shortest known for a Ge–Ge single bond.[24,25] This distance can be rationalized with the increased s character of the σ hybrid orbitals forming the Ge–Ge bond and the π conjugation of the W≡Ge bonds (see below). Note the Ge–Ge bond length of **5-W-Cl** lies close to the range of lengths calculated for Ge₂ (2.36–2.46 Å).[26] The ¹H, ¹³C{¹H}, and ³¹P{¹H} NMR spectra corroborate the structures of complexes **4-M-X** and **5-M-Cl** (X = Cl, Br; M = Mo, W). Thus, the ¹H and ¹³C{¹H} NMR spectra display a double set of resonances for the diastereotopic ethyl groups and methylene protons of the depe ligands, as expected for diamagnetic complexes of the general formula *trans*-[M(depe)₂(L)(L')].[14] In addition, the NMR spectra of **4-M-X** reveal a fast haptotropic shift of the Cp* substituent. This shift gives rise to one singlet signal for the methyl protons in the ¹H NMR spectra, and two singlet resonances in the ¹³C{¹H} NMR spectra, one for the methyl carbon and one for the ring carbon nuclei of the Cp* group.[14] The ³¹P{¹H} NMR spectra display a singlet resonance confirming the *trans*-configuration of **4-M-X** and **5-M-Cl**. The ³¹P NMR signals of the Ge₂-bridged complexes (**5-Mo-Cl**, δ = 56.3 ppm; **5-W-Cl**, δ = 38.2 ppm) appear slightly upfield of those of the mononuclear complexes (**4-Mo-Cl**, δ = 57.2 ppm; **4-W-Cl**, δ = 39.2 ppm), and for the tungsten compounds are flanked by a pair of satellites arising from coupling with the ¹⁸³W nucleus (**4-W-Cl**, ¹J(W,P) = 259 Hz; **5-W-Cl**, ¹J(W,P) = 249 Hz).[14]

Density functional theoretical (DFT) calculations of the model complex *trans,trans*-[Cl(PH₃)₄WGe₂W(PH₃)₄Cl] (**5-PH₃-W-Cl**) were performed without symmetry restraints using the exchange correlation functionals B3LYP and BP86 and various basis sets.[14,27] Geometry optimization of the

model compound at the B3LYP/IIa level of theory led to six minimum structures on the ground-state singlet potential-energy surface, which can be classified into one pair of isomers featuring an end-on coordinated Ge_2 ligand (**A**), and two pairs of isomers displaying a side-on bonded Ge_2 ligand (**B**, **C**; Figure 3). Each pair consists further of an eclipsed (**e**)
Figure 3. Selected bond lengths [Å] and bond angles [°], symmetries, and relative energies [kJ mol^{-1}, ZPVE corrected] of the minimum structures of **5-PH$_3$-W-Cl** (B3LYP/IIa). Hydrogen atoms are omitted for clarity.

and a staggered conformer (**s**) differing in the orientation of the [WCl(PH$_3$)$_4$] fragments. The eclipsed isomer **A-e** of D_{4h} symmetry and the corresponding D_{4d} symmetric staggered isomer **A-s**, which feature a linear end-on bonded Ge_2 chain, are the most stable compounds and differ in energy by less than 1 kJ mol^{-1}. The isomers **B** displaying a planar W_2Ge_2 bicyclic ring lie at slightly higher energy than **A** (10–13 kJ mol^{-1}), whereas the species **C** with a W_2Ge_2 butterfly structure are considerably less stable than **A** (Figure 3). The calculated bond lengths and angles of the eclipsed isomer **A-e** compare well with the experimental values of **5-W-Cl** (Table 1).

Analysis of the electronic charge distribution of **A-e** using the natural bond orbital (NBO) partitioning scheme[28] gives an optimal Lewis structure with two W−Ge triple bonds connected by a Ge−Ge single bond. Both W−Ge triple bonds are composed of one σ component, which is polarized towards germanium (64.8%), and two degenerate π bonds, which result from the overlap of pure tungsten d orbitals and germanium p orbitals and are polarized towards tungsten (71.6%) (Table 2). The polarity of the W−Ge bonds is reflected in the partial charges of the W and Ge atoms (−1.25 and +0.30, respectively) and the Wiberg bond index of 1.71.[29] Further evidence for the considerable ionic character of the W−Ge triple bonds of **A-e** was provided by the energy-partitioning analysis of the interaction between the closed-shell fragments *trans*-[WCl(η^1-Ge$_2$)(PH$_3$)$_4$]$^+$ and [WCl(PH$_3$)$_4$]$^-$ using the energy decomposition analysis (EDA) method,[30] which revealed a considerable contribution of the electrostatic term ΔE_{elstat} (−622.6 kJ mol^{-1}) to the total attractive interactions ($\Delta E_{elstat} + \Delta E_{orb} = $ −1374.4 kJ mol^{-1}), leading to a 55% covalent character of the W−Ge triple bonds (Table 2). The EDA analysis also showed that the degenerate W−Ge π bonds make the largest contribution (78%) to the orbital interaction energy ΔE_{orb} indicating the same high π-bonding character of the W−Ge bonds in **A-e** as in *trans*-[Cl(CO)$_4$W≡GeH].[31] Taking into account the polarization of the W−Ge σ and π bonds, an extreme view of isomer **A-e** is that of a Ge_2^{2+} ion, which is embedded in an η^1:η^1 bonding mode between two d^6 [WCl-(PH$_3$)$_4$]$^-$ fragments by two σ ([Ge$_2$]$^{2+}$→[WCl(PH$_3$)$_4$]$^-$) and four π [WCl(PH$_3$)$_4$]$^-$→[Ge$_2$]$^{2+}$) donor–acceptor bonds. Ge_2^{2+} has a singlet ground state with a very weak and long Ge−Ge bond (3.099 Å) owing to Coulomb repulsion.[32] Metal complexation is accompanied by a considerable electron drift from the metal fragments to Ge_2^{2+}, which decreases the partial charges on the germanium atoms from +1 to +0.3, reduces thereby the Coulomb repulsion, and shortens the Ge−Ge bond by 0.694 Å (B3LYP/IIa, Table 1).

The π bonding and π* antibonding orbitals of the W-Ge-Ge-W chain form four doubly degenerate levels (HOMO−3, HOMO,

LUMO, and LUMO + 3; Figure 4) resulting from the in-phase or out-of-phase combination of the tungsten $d_{xz}(d_{yz})$ orbitals and the germanium $p_x(p_y)$ orbitals (the z axis of the Cartesian coordinate system and the C_4 symmetry axis of **A-e** are collinear).[33] Four electrons occupy the lowest energy e_{1u}
Figure 4. π and π* Kohn–Sham orbitals of the W-Ge-Ge-W chain in **A-e**. Only one of the doubly degenerate π and π* levels is depicted.

symmetric pair of molecular orbitals (HOMO−3), which are bonding with respect to the W−Ge and Ge−Ge linkages, and four electrons occupy the e_{1g} symmetric pair of orbitals (HOMO), which are bonding with respect to the W−Ge linkages but antibonding with respect to the Ge−Ge linkage (Figure 4).[33,34] This molecular orbital picture corresponds in valence bond terms to the digermanehexayl formula [$L_nW\equiv$Ge−Ge$\equiv WL_n$] and suggests some π conjugation of the W−Ge triple bonds.[35] This proposal is supported by the NBO and EDA analyses, which indicate the presence of a Ge−Ge σ bond with low π-bonding character (WBI (Ge−Ge) = 1.10; ΔE_π is 8.2% of ΔE_{orb}; Table 2), and the natural resonance theoretical (NRT) analysis of **A-e**,[36] which provides 21 different resonance structures with a resonance weight greater than 1% leading to a natural bond order of 2.76 for the W−Ge bonds and 1.06 for the Ge−Ge bond.[37]

Analysis of the wave function using the electron localization function (ELF)[38] at the B3LYP/IIa level of theory shows, that the density of localized electrons between tungsten and germanium has a toroidal shape typical for triple bonds.[9f,14,39] Volume integration of the electron density over the valence disynaptic basins connecting the W with the Ge nuclei and linking the two Ge nuclei, leads to a population of 5.7 electrons in the W−Ge bonding region and 2.6 electrons in the Ge−Ge bonding region, which supports the bonding picture of two conjugated W−Ge triple bonds in **A-e**.[40] This result is further confirmed by the quantification of conjugation in **A-e** using the anisotropy of the induced current density (AICD) of the Ge−Ge bond.[41] The AICD isosurface plot of **A-e** at an isosurface value of 0.015 displays strong delocalization over the atoms (Figure 5). The continuous boundary surface enclosing the conjugating Ge atoms breaks at an
Figure 5. Isosurface plots of the AICD in **A-e** at 0.015 (top) and the critical value of 0.041 (bottom), at which the topology of the AICD boundary surface changes.

isosurface value of 0.041 (Figure 5), which suggests that the extent of conjugation in **A-e** is lower that in benzene (0.08) or butadiene (0.069), but higher than in 1,3-butadiyne (0.013) at the same level of theory.[42] Conjugation in **A-e** might be caused by the small HOMO–LUMO gap of 2.7 eV which leads to an excitation energy of 2.67 eV ($\lambda = 464$ nm) for the allowed one-electron transition (TD-RIDFT/TZVPP).[43]

The Ge−Ge bond fragmentation energy of **A-e** ($\Delta E_{frag} = 221.0$ kJ mol^{-1}) is lower than that of Ge$_2$H$_6$ (288.5 kJ mol^{-1}) calculated at the same level of theory (B3LYP/IIa, Table 3).[44] Inclusion of relaxation and zero-point vibrational effects (ZPVE) leads to a theoretical value of 217.1 kJ mol^{-1} for the Ge−Ge bond dissociation energy of **A-e** ($D°_0$), which is also lower than that of Ge$_2$H$_6$ ($D°_0 = 270.4$ kJ mol^{-1}; Table 3),[44] the latter value comparing well with the experimental value ($D° = 276$ kJ mol^{-1}).[45] In comparison, the Ge−Ge bond length of **A-e** (2.405 Å) is shorter than that of Ge$_2$H$_6$ (2.439 Å, Table 3) leading to an opposite bond length/dissociation energy correlation to that usually observed. This result suggests that the radicals *trans*-[WCl(Ge)(PH$_3$)$_4$] formed upon Ge−Ge bond homolysis are stabilized by delocalization of the unpaired electron in the electronic ground state ($^2A_1$).[46] This electronic stabilization provides a rationale for the preferred formation of the radicals *trans*-[WCl(Ge)(depe)$_2$] during thermolysis of **4-W-Cl**. The energy (ZPVE corrected) required to cleave the W≡Ge bond of **A-e** into the fragments *trans*-[WCl(η^1-Ge$_2$)(PH$_3$)$_4$][47] and [WCl(PH$_3$)$_4$] in the respective $^2A_1$ and ^4A electronic ground states and minimum geometries, was calculated to be slightly lower (333.9 kJ mol^{-1}) than that of the germylidyne complex *trans*-[Cl(PH$_3$)$_4$W≡Ge-Me] (354.8 kJ mol^{-1}) (Table 3). The species *trans*-[WCl(η^1-Ge$_2$)(PH$_3$)$_4$] is a local minimum on the energy potential surface and relaxes to a C_{2v} symmetric species featuring a side-on bonded Ge$_2$ ligand.[47] The released relaxation energy of −52.2 kJ mol^{-1} reduces the W−Ge bond dissociation energy of **A-e** to 281.7 kJ mol^{-1} (Table 3).

Table 3: Fragmentation, bond dissociation, and Gibbs free dissociation energies [kJmol^{-1}] of the Ge—Ge and W—Ge bonds of **5-PH$_3$-W-Cl** (**A-e** isomer), Ge$_2$H$_6$, and *trans*-[Cl(PH$_3$)$_4$W≡Ge-Me] (B3 LYP/IIa).

Several experimental and theoretical studies have been carried out on the diatomic molecule Ge$_2$.[48] Ge$_2$ can be regarded as the lightest member in the family of germanium clusters Ge$_n$, which are of importance owing to their potential applications in nanoelectronics.[48] Encapsulation of this very reactive species in the complexes **5-M-Cl** provides a new example for the ability of stereoelectronically well-defined transition-metal fragments to stabilize high temperature molecules in unprecedented bonding patterns.

[32] Ge₂²⁺ is suggested to be metastable with respect to dissociation to Ge⁺ ions: W. A. Saunders, *Phys. Rev. B* **1989**, *40*, 1400.

[33] As in linear polyynes, the parity of the π-bonding orbitals of the W-Ge-Ge-W chain alternates with respect to the mirror plane bisecting the Ge–Ge bond of **A-e** (σ$_h$ plane of the molecule). The lowest energy orbital (HOMO−3) has zero nodes, the number of nodes increases by one on going from one orbital to the one next highest in energy, and the nodes are symmetrically located with respect to the σ$_h$ plane of **A-e**.

[34] HOMO−2 and HOMO−1 are molecular orbitals of δ symmetry resulting, respectively, from the in-phase and out-of-phase combination of the tungsten d$_{xy}$ orbitals (see Supporting Information).

[35] The coefficients of the germanium p$_x$(p$_y$) atomic orbitals are larger in the HOMO−3 than in the HOMO suggesting some Ge–Ge π overlap. Since the W–Ge π bonds are polarized towards the tungsten, the occupancies of the corresponding natural atomic orbitals at germanium are quite low (occ. p$_x$ and p$_y$ = 0.64 e⁻) depleting the π overlap of the germanium p$_x$(p$_y$) functions.

[36] E. D. Glendening, F. Weinhold, *J. Comput. Chem.* **1998**, *19*, 593.

[37] 13 of these resonances structures have W−Ge triple bonds and eight have W−Ge double bonds. The combined weight of resonance structures featuring W−Ge triple bonds is 76%.

[40] The high population of the W−Ge disynaptic basins justifies the denotation of the W−Ge bonds as triple bonds, for which six electrons would be needed. The disynaptic basin of the Ge−Ge bond has a population of 2.6 electrons, which suggests the Ge−Ge bond to be slightly more than a classical single bond, reflecting the effect of π conjugation.

Frenking, *Angew. Chem.* **2005**, *117*, 3683; *Angew. Chem. Int. Ed.* **2005**, *44*, 3617.

[43] This excitation gives the strongest absorption band in the calculated UV/Vis spectrum of **A-e** and may rationalize the green-brown color of complex **5-W-Cl** (see Supporting Information).

[44] The calculated Ge−Ge fragmentation energy of Ge_2H_6 compares well with that reported by H.-J. Himmel, H. Schnöckel, *Chem. Eur. J.* **2003**, *9*, 748. Our calculations show, however, that the GeH_3 radicals have a pyramidal C_{3v} symmetric minimum geometry (Ge−H 1.544 Å; H-Ge-H 110.8°) in the doublet ground state, which differs marginally from the geometry adopted by the GeH_3 fragments (Ge−H 1.540 Å; H-Ge-H 108.5°) in the D_{3d} symmetric minimum structure of Ge_2H_6. Our results lead to a very low relaxation energy of the two GeH_3 fragments (-2.3 kJ mol^{-1}) and differ from those of H.-J. Himmel and Schnöckel, according to which the GeH_3 radicals have a trigonal-planar minimum geometry.

[45] M. J. Almond, A. M. Doncaster, P. N. Noble, R. Walsh, *J. Am. Chem. Soc.* **1982**, *104*, 4717.

[46] Selected bond lengths [Å] and bond angles [°] of the radicals *trans*-[WCl(Ge)(PH$_3$)$_4$] in their C_{4v} symmetric minimum structure and doublet ground state: W-Ge 2.329, W-Cl 2.528, W-P 2.483; P-W-Cl 85.9, P-W-P$_{cis}$ 89.7. Additional evidence for the delocalization of the unpaired electron in *trans*-[WCl(Ge)(PH$_3$)$_4$] was provided by NBO and ELF analyses.

[47] Two minimum structures were found for the fragment *trans*-[WCl(Ge$_2$)(PH$_3$)$_4$] on the potential energy surface, a C_{4v} symmetric structure featuring an end-on bonded Ge$_2$ ligand, and a C_{2v} symmetric isomer featuring a side-on bonded Ge$_2$ ligand, which is 52.5 kJ mol^{-1} lower in energy than the end-on bonded species (see Supporting Information). Preference of the side-on coordination mode was also found in [W(CO)$_5$(Ge$_2$)]$^{2-}$ by calculations: C. Esterhuysen, G. Frenking, *Chem. Eur. J.* **2003**, *9*, 3518.

Biochemistry

Towards a Fully Synthetic Carbohydrate-Based Anticancer Vaccine: Synthesis and Immunological Evaluation of a Lipidated Glycopeptide Containing the Tumor-Associated Tn Antigen**

Therese Buskas, Sampat Ingale, and Geert-Jan Boons*

Dedicated to Professor Steven V. Ley
on the occasion of his 60th birthday

A common feature of oncogenic transformed cells is the overexpression of oligosaccharides, such as Globo-H, Lewis[Y], and Tn antigens.[1–4] Numerous studies have shown that this abnormal glycosylation can promote metastasis,[5] and hence its expression is strongly correlated with poor survival rates of cancer patients.

Several elegant studies have exploited the differential expression of tumor-associated carbohydrates for the development of cancer vaccines.[6,7] The inability of carbohydrates to activate helper T lymphocytes has complicated, however, their use as vaccines.[8] For most immunogens, including carbohydrates, the production of antibodies depends on the cooperative interaction of two types of lymphocytes, B cells and helper T cells.[9] Saccharides alone cannot activate helper T cells and therefore have a limited immunogenicity. The formation of low-affinity IgM antibodies and the absence of IgG antibodies manifest this limited immunogenicity.

To overcome the T cell independent properties of carbohydrates, past research has focused on the conjugation of saccharides to a foreign carrier protein (e.g. Keyhole Limpet Hemocyanin (KLH) or detoxified tetanus toxoid).[8,9] In this approach, the carrier protein enhances the presentation of the carbohydrate to the immune system and provides T epitopes (peptide fragments of 12–15 amino acids) that can activate helper T cells.

However, the conjugation of carbohydrates to a carrier protein poses several problems. In general, the conjugation chemistry is difficult to control, resulting in conjugates with ambiguities in composition and structure which may affect the reproducibility of an immune response.[10] Additionally, the foreign carrier protein can elicit a strong B cell response, which may lead to the suppression of an antibody response against the carbohydrate epitope. The latter is a greater

DISCOVER SOMETHING GREAT

problem when self-antigens are employed, such as tumor-associated carbohydrates. Also linkers for the conjugation of carbohydrates to proteins can be immunogenic, leading to epitope suppression.[11] Not surprisingly, several clinical trials with carbohydrate–protein conjugate cancer vaccines failed to induce sufficiently strong helper T cell responses in all patients.[7,12] Therefore, alternative strategies need to be developed for the presentation of tumor-associated carbohydrate epitopes that will result in a more efficient class switch to IgG antibodies.[13–18]

Herein, we report the synthesis and immunological evaluation of a structurally well-defined, fully synthetic anticancer vaccine candidate 9 that constitutes the minimal structural features required for a focused and effective T cell dependent immune response. The vaccine candidate is composed of the tumor-associated Tn antigen, the peptide T epitope YAFKYARHANVGRNAFELFL (YAF), and the lipopeptide S-[(R)-2,3-dipalmitoyloxy-propyl]-N-palmitoyl-(R)-cysteine (Pam$_3$Cys). The Tn antigen, which will serve as a B epitope, is overexpressed on the surface of human epithelial tumor cells of the breast, colon, and prostate.[3] This antigen is not present on normal cells, which thus renders it an excellent target for immunotherapy.[3,13,18] To overcome the T cell independent properties of the carbohydrate antigen, the YAF peptide was incorporated. This 20-amino acid peptide sequence is derived from an outer-membrane protein of *Neisseria meningitides* and has been identified as an MHC class II restricted site for human T cells.[19] It was envisaged that this helper T cell epitope would induce a T cell dependent immune response that results in the production of IgG antibodies against the Tn antigen. The combined B cell and helper T cell epitope lacks the ability to provide appropriate "danger signals"[20] for dendritic cell maturation. Therefore, the lipopeptide Pam$_3$Cys, which is derived from the immunologically active N-terminal sequence of the principal lipoprotein of *Escherichia coli*,[21] was incorporated. This lipopeptide has been recognized as a powerful immunoadjuvant,[22] and recent studies have shown that it exerts its activity through the interaction with Toll-like receptor 2 (TLR-2).[23] This interaction results in the production of pro-inflammatory cytokines and chemokines, which, in turn, stimulate antigen-presenting cells (APCs) and thus initiate development and activation of helper T cells.[24] The lipopeptide also facilitates the incorporation of the antigen into liposomes. Liposomes have attracted interest as vectors in vaccine design[25] owing to their low intrinsic immunogenicity, thus, avoiding undesirable carrier-induced immune responses.

The synthesis of target compound 9 requires a highly convergent synthetic strategy which employs chemical manipulations that are compatible with the presence of a carbohydrate, peptide, and lipid moieties. It was envisaged that 9 could be prepared from spacer-containing Tn antigen 7, polymer-bound peptide 1, and S-[2,3-bis(palmitoyloxy)-propyl]-N-Fmoc-Cys (Pam$_2$FmocCys, 2;[26] Fmoc = 9-fluorenylmethoxycarbonyl). The resin-bound peptide 1 was assembled by automated solid-phase peptide synthesis using Fmoc-protected amino acids in combination with the extremely acid-sensitive HMPB-MBHA (HMPB = 4-(4-hydroxy-methyl-3-methoxyphenoxy)butyryl; MBHA = p-

methylbenzhydrylamine) resin and 2-(1H-benzotriazol-1-yl)-oxy-1,1,3,3-tetramethyluronium hexafluorophosphate/1-hydroxybenzotriazole (HBTU/HOBt)[27] as activators (Scheme 1). The HMPB-MBHA resin was selected because it allows the cleavage of a compound from the resin without concomitant removal of side-chain protecting groups. This feature was important because side-chain functional groups of aspartic acid, glutamic acid, and lysine would otherwise interfere with the incorporation of the Tn antigen derivative 7. Next, the Pam$_2$FmocCys derivative (2) was coupled to the N-terminal amine of peptide 1 using PyBOP[28] and HOBt in the presence of DIPEA in a mixture of DMF and dichloromethane to give the resin-bound lipopeptide 3. The Fmoc group of 3 was removed under standard conditions, and the free amine of the resulting compound 4 was coupled with palmitic acid in the presence of PyBOP and HOBt to give the fully protected and resin-bound lipopeptide 5. The amine of the Pam$_2$Cys moiety was palmitoylated after coupling with 1 to avoid racemization of the cysteine moiety.[26] Cleavage of compound 5 from the resin was achieved with 2% TFA in dichloromethane followed by the immediate neutralization with 5% pyridine in methanol. After purification by LH-20 size-exclusion chromatography, the C-terminal carboxylic acid of lipopeptide 6 was coupled with the amine of Tn derivative 7, employing DIC/HOAt/DIPEA[29] as coupling reagents, to give, after purification by Sephadex LH-20 size-exclusion chromatography, fully protected lipidated glycopeptide 8 in 79% yield. MALDI-TOF mass spectrometry revealed signals at $m/z = 5239.6$ and $m/z = 5263.0$, which correspond to $[M+H]^+$ and $[M+Na]^+$ ions, respectively. Finally, the side-chain protecting groups of 8 were removed by treatment with 95% TFA in water using EDT as a scavenger. The alternative use of triisopropylsilane resulted in the formation of unidentified byproducts. The target compound 9 was purified by size-exclusion chromatography followed by reverse-phase HPLC using a Synchropak C4 column. Analysis of 9 by MALDI-TOF mass spectrometry revealed a signal at $m/z = 3760.3$ corresponding to $[M+Na]^+$.

Next, compound 9 was incorporated into phospholipid-based liposomes. Thus, after hydration of a lipid film that contained 9, cholesterol, phosphatidylcholine, and phosphatidylethanolamine, small unilamellar vesicles (SUVs) were prepared by extrusion through 100-nm Nuclepore polycarbonate membranes. Transmission electron microscopy (TEM) by negative stain confirmed that the liposomes were uniformly sized with an expected diameter of approximately 100 nm (Figure 1). The liposome preparations were analyzed for N-acetyl galactosamine (GalNAc) content by hydrolysis with TFA, followed by quantification with anion-exchange chromatography at high pH values. Concentrations of approximately 30 µg mL^{-1} of GalNAc were determined which corresponded to an incorporation of 9 of approximately 10%.

Groups of five female BALB/c mice were immunized subcutaneously with freshly prepared liposomes containing 0.6 µg carbohydrate at weekly intervals. To explore the adjuvant properties of the built-in lipopeptide Pam$_3$Cys, the antigen-containing liposomes were administered with or without the potent saponin immunoadjuvant QS-21 (Anti-

that the helper T epitope peptide of **9** had activated helper T lymphocytes. Furthermore, the observation that IgG antibodies were raised by mice which were only immunized with liposomes (group 1) indicated that the built-in adjuvant Pam$_3$Cys had triggered appropriate signals for the maturation of dendritic cells and their subsequent activation of helper T cells. However, the mice which received the liposomes in combination with QS-21 (group 2), elicited higher titres of anti-Tn antibodies. This stronger immune response may be due to a shift from a mixed Th1/Th2 to a Th1 response.[30]

The results presented herein provide, for the first time, a proof of principle for the use of lipidated glycopeptides as minimal subunit vaccines. Previous immunizations with a saccharide coupled to an immunoadjuvant such as Pam$_3$Cys resulted in no or very low titres of IgG antibodies[15,31,32] demonstrating that the incorporation of a peptide T epitope[16,17] is critical for a class switch to IgG antibodies.

It is to be expected that several improvements can be made to the tricomponent vaccine candidate presented here. For example, it has been found that a clustered presentation of the Tn antigen is a more appropriate mimetic of mucins, and hence antibodies raised against this structure recognize better Tn antigens expressed on cancer cells.[33–36] The Th epitope employed in this study is known to be a MHC class II restricted epitope for humans. Thus, a more efficient class switch to IgG antibodies may be expected when a murine Th epitope is employed. On the other hand, compound **9** is a more appropriate vaccine candidate for use in humans. A recent report indicated that Pam$_2$Cys is a more potent immunoadjuvant than Pam$_3$Cys.[37] It has also been suggested that the Pam$_2$Cys adjuvant has

genics Inc., Lexington, MA). Anti-Tn antibody titres were determined by coating microtitre plates with a BSA–Tn conjugate (BSA = bovine serum albumin) and detection was accomplished with anti-mouse IgM or IgG antibodies labeled with alkaline phosphatase. As can be seen in Table 1, the mice that were immunized with the liposome preparations elicited IgM and IgG antibodies against the Tn antigen (Table 1, entries 1 and 2). The presence of IgG antibodies indicated

Ion Transport

Synthesis, Anion-Binding Properties, and In Vitro Anticancer Activity of Prodigiosin Analogues**

Jonathan L. Sessler,* Leah R. Eller, Won-Seob Cho, Sergios Nicolaou, Apolonio Aguilar, Jeong Tae Lee, Vincent M. Lynch, and Darren J. Magda*

Prodigiosins, for example, **1** and **2**, are a family of naturally occurring tripyrrolic red pigments that were first isolated in
1: R^1 = H, R^2 = *n*-undecyl (prodigiosin 25-C)
2: R^1 = *n*-pentyl, R^2 = Me (prodigiosin)
3: R^1 = H, R^2 = Et

the 1930s from microorganisms including *Serratia* and *Streptomyces* and are characterized by a common pyrrolylpyrromethene skeleton.[1] These molecules, especially prodigiosin 25-C (**1**) but also synthetic analogues such as **3**,[2,3] have been studied extensively for their promising immunosuppressive[4] and anticancer activities.[5,6]

To date, two very different modes of action have been put forward to explain their anticancer activity. One suggestion, proposed by Manderville, Melvin, and co-workers,[7] and further supported by Fürstner and Grabowski,[8] is that prodigiosin mediates its anticancer effect through copper-mediated cleavage of double-stranded DNA. The second

mechanistic suggestion, proposed by Ohkuma, Wasserman, and co-workers in 1998,[9] is that the biological activity of prodigiosin derives from its ability to effect concurrent transmembrane transport ("symport") of H$^+$ and Cl$^-$ ions into cells.[9] Support for this mechanism came partly from the finding that the activity of prodigiosin as well as prodigiosin-based lysosomal acidification were dependent on the concentration of extracellular chloride ion and that chloride ion channels were not responsible for these effects.[9] However, to date, little in the way of direct chemical support for the mechanism has been provided.[10,11] Accordingly, we have undertaken a detailed study of the anion-binding and through-membrane transport properties of several prodigiosin analogues and corresponding dipyrromethene constituents. Herein, we report that it is the rate of transport, rather than the anion-binding ability, that correlates most closely with anticancer activity in vitro, as judged from cell proliferation assays involving A549 human lung and PC3 human prostate cancer cells.

To investigate the presumed anion binding and transport ability of prodigiosins, model compounds **3–7** were pre-

4   5

6   7
pared.[12] These systems contain either the basic prodigiosin skeleton or the key constituent dipyrromethene motif and were thus thought to provide a "basis set" sufficient to allow some limited structure–activity correlations to be made.

The first indication that the protonated forms of prodigiosins and dipyrromethenes can bind chloride ions came from X-ray crystal structure analyses of salts **4·HCl** and **7·HCl**.[12] As seen in Figures 1 and 2, 1:1 complexes are formed in the solid state as the result of oriented hydrogen-bonding interactions and, presumably, electrostatic effects. In the case of salt **4·HCl** the complex is essentially flat, whereas

Figure 1. Crystal structure of **4·HCl**. This complex is essentially planar.

Figure 2. Two views of the crystal structure of the complex formed between monoprotonated prodigiosin **7** and chloride ion.

some deviation from planarity is seen in **7**·HCl. In **4**·HCl, the NH⋯Cl distances (2.25 Å) are roughly equal, while in the case of **7**·HCl they are found to be longer for ring A than rings B and C (NH⋯Cl = 2.72, 2.28, and 1.97 Å for rings A, B, and C, respectively).

Evidence in support of chloride ion binding in solution came from isothermal titration calorimetry (ITC) studies carried out in acetonitrile at 303 K using tetrabutylammonium chloride (TBACl) as the source of chloride ions. Whereas the free-base forms of prodigiosins **6** and **7** as well as various neutral bipyrroles were found to display affinities for chloride ion that were too low to be determined by ITC methods in CH$_3$CN, the corresponding monoprotonated HI salts of these prodigiosin species were found to exhibit rather substantial apparent affinities for chloride ion (see Table 1). The same

Table 1: Apparent association constants (K_a) for binding of chloride ion to the monoprotonated (HI) salts of dipyrromethenes and prodigiosin analogues **3**–**7** in CH$_3$CN, as determined by ITC analysis at 30 °C using TBACl as the anion source. Errors are estimated to be 10%.

	3	**4**	**5**	**6**	**7**
ΔH [kcal mol^{-1}]	−4.2	−3.35	−2.27	−1.59	−2.03
$T\Delta S$ [kcal mol^{-1}]	3.8	4.88	5.33	5.35	4.93
ΔG [kcal mol^{-1}]	−8.0	−8.23	−7.60	−6.94	−6.96

proved true for the protonated dipyrromethene fragments **4** and **5**. As a rule, these latter compounds demonstrated slightly higher affinities for chloride ions than did the corresponding monoprotonated prodigiosins; a finding that reflects presumably the higher effective charge densities present in the smaller dipyrrolic species.

The efficiency of transport of chloride ions was determined by monitoring their efflux across a 200-nm POPC/POPS (POPC = 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phospho-choline; POPS = 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phospho-L-serine) liposome membrane as a function of time.[13] The

vesicles were loaded with a solution of NaCl (500 mM) and then diluted to produce a 1 mM suspension in a solution of NaNO$_3$ (500 mM). The integrity of the liposome membranes was established according to reported procedures.[14] The efflux of chloride ion was monitored as a function of time using an Accumet glass-bodied chloride-selective electrode in conjunction with a Jenco multimeter. The results of the transport studies are summarized in Figure 3. Note that
Figure 3. Time-dependent efflux of chloride ion from 200-nm vesicles loaded with a solution of NaCl (500 mM) and suspended in a solution of NaNO$_3$ (500 mM) and triethylsilane (5 mM), adjusted to pH 7.4. Prodigiosins are indicated by filled markers (**3** ●, **6** ■, **7** ◆); dipyrromethenes are indicated by open markers (**4** □, **5** ○).

tripyrrole **3**, the compound that bears the greatest structural similarity to the natural prodigiosins, demonstrated remarkably high transport efficiency. In fact, the rate of efflux of chloride ion was sufficiently rapid that studies were conducted using a 0.5 μM solution of the carrier. The remaining compounds were studied using 2 μM solutions. The order of transport efficiency, as inferred from initial rates, was found to be **3** ≫ **6** ≈ **4** > **5** ≫ **7**. Additionally, compounds **3**–**6** were all seen to prompt ≧ 60% release of chloride ions from the interior of the vesicles within 300 seconds.

To determine the mechanism of transport, the experiments were repeated with the pH of the external solution initially set at pH 5.5. The efflux of chloride ions was less efficient than when the external solutions were neutral or basic. This behavior is consistent with an H$^+$/Cl$^-$ ion mechanism of transport, as it is expected that the driving force for proton egress would be reduced with a lower external pH value.

Experiments were also carried out in which 8-hydroxypyrene trisulfonate (HPTS), a pH-sensitive fluorescent dye,[15] was included within the liposomes and the external solution was basified using NaOH. The excitation maxima (λ_{max}) for HPTS are 450 (at pH 7–8) and 405 nm (pH < 6). Excitation ratio experiments were performed in which the sample was excited at both 405 and 450 nm while the emission

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

intensity was monitored at 511 nm. Following addition of the carrier, an increase in the peak at 450 nm and a corresponding decrease in the peak at 405 nm were observed. Upon lysis of the vesicles and subsequent contact with external hydroxide ion, these spectral changes became even more pronounced. In contrast, in the absence of chloride ion (but in the presence of carrier) no effects were seen. Such findings are also consistent with an H^+/Cl^- ion symport mechanism.

Finally, transport experiments were performed in which the external nitrate ion was replaced by sulfate ion. No significant changes in the transport rates or overall efficiency were observed under these conditions, as would be expected for anion efflux conducted through a H^+/Cl^- ion symport mechanism. However, if transport were to occur through an anion-exchange (antiport) mechanism, the transport rates would be expected to change as a function of the lipophilicity of the external anion.

Anticancer activity in vitro was assessed using a cell proliferation assay with A549 human lung cancer and PC3 human prostate cell lines.[16] The order of activity in vitro in both cell lines was found to be similar, namely, **3** > **6** > **4** > **5** > **7** (A549; see Figure 4) and **3** > **6** > **4** > **5** ≈ **7** (PC3; see

Figure 4. Antiproliferative activity of prodigiosin analogues and dipyrromethenes in A549 human lung cancer cells. Exponential phase cells were treated with compounds **3–7** at the indicated concentrations for 24 h (**3** ▲, **4** ×, **5** ●, **6** ◆, **7** ■). The number of viable cells was determined after 3 days using a standard tetrazolium salt reduction assay. Data are presented as the fraction of untreated cells (see Supporting Information for details).

Supporting Information). Compounds **3**, **4**, **5**, and **6** all exhibited significant cytotoxic activity, with 100% of cancer cells killed at a concentration of 40 μM in both cell lines. As observed earlier in the transport studies, compound **3** proved to be more efficient than the other compounds examined, displaying a notably greater antiproliferative effect.

Among the prodigiosin analogues examined in this study, the rates of through-liposome transport and in vitro activity were found to correlate well. A general sequence of efficiency of **3** > **6** ≥ **4** > **5** ≥ **7** is seen in both cases. In contrast, the values of the effective association constant (K_a) in Table 1 do not correlate well with the observed activity in vitro. For instance, compound **4**·H^+, which displays the highest overall K_a value, is far less active in cell culture than prodigiosin **3**. Such reduced activity could reflect an anion affinity that is too high to afford an optimal rate of release of chloride ion. Likewise,

the low antiproliferative activity of **7** can be rationalized in terms of an anion affinity that is too low to make it a highly effective chloride ion carrier. The present findings thus provide support for a mechanism such as H^+/Cl^- ion symport that is dominated by kinetic rather than thermodynamic factors.

The present study does not address the issue of whether recruitment of copper and DNA modification plays a significant role in mediating the action of prodigiosin. However, the strong correlation between transport rates and anticancer activity in vitro, in conjunction with evidence for anion binding in the solid state and solution phase, lead us to suggest that the H^+/Cl^- ion symport mechanism proposed by Ohkuma, Wasserman, and co-workers[9] is chemically reasonable. If such a conclusion is correct, it leads to the suggestion that other chloride ion transport systems, including those that may have no direct structural resemblance to prodigiosins, may show interesting anticancer activity.

[10] In previous work, the HCl complexes of extended "vinylogous" prodigiosin analogues,[17] a cyclic prodigiosin derivative,[18] and a phenyl-substituted dipyrromethene derivative[3] were reported. While single-point binding of chloride ion is seen in the case of the latter system, the first two structures revealed binding modes that are analogous to those seen in the case of **4**·HCl and **7**·HCl, respectively.

[11] During the course of preparing this manuscript, we became aware of a parallel study of H^+/Cl^- ion symport using a different set of prodigiosin analogues, namely a set of wholly synthetic pyrrole amides. Synthesis of Imides, *N*-Acyl Vinylogous Carbamates and Ureas, and Nitriles by Oxidation of Amides and Amines with Dess–Martin Periodinane**

K. C. Nicolaou* and Casey J. N. Mathison

The synthetic utility and pervasiveness of hypervalent iodine(v) reagents have become increasingly evident in recent decades, as underscored by a multitude of protocols that highlight the oxidative capabilities of λ^5-iodanes and their

successful employment for the construction of diverse arrays of molecular targets.[1–3] As part of our explorations into the realm of hypervalent iodine(v) chemistry, we recently reported a number of useful applications involving both Dess–Martin Periodinane (DMP) and *o*-iodoxybenzoic acid (IBX). Included in these discoveries are the IBX-induced conversion of amines into imines[4] and the initiation of cascade reactions by DMP leading to a variety of imidoquinones and heterocycles from anilide precursors.[5,6] The intelligence gathered in the course of these investigations led us to hypothesize about additional modes of reactivity that could perhaps be unveiled through further explorations of the chemistry of such hypervalent iodine(v) reagents toward other classes of heteroatom-containing substrates. These speculations proved fruitful, and herein we report the direct oxidation of amides into imides and *N*-acyl vinylogous carbamates and ureas, the dehydrogenation of benzylic and related amines to aromatic nitriles by DMP, and applications thereof.

Imides are well represented in the literature, often appearing as productive components in a variety of reactions, ranging from condensations to alkylations and from acylations to cycloadditions.[7] This structural motif also appears in certain natural products such as fumaramidmycin,[8] coniothyriomycin,[9] and SB-253514.[10] Despite several procedures being available for their preparation, new methods for the synthesis of imides are nevertheless of considerable importance, especially when their direct access from readily available substrates could be secured under mild conditions.

The mechanistic rationale for the oxidation of amides to imides with DMP is shown in Scheme 1 A. Thus, it was anticipated that nucleophilic attack onto the iodine core of the reagent by the amide oxygen atom with concomitant expulsion of an acetate group may lead to intermediate **I**, whose spontaneous intramolecular rearrangement was anticipated to result in its collapse to Ac-IBA, AcOH, and *N*-acyl imine intermediate **3**. The latter, highly reactive, species **3** may then be transformed into imide **6**, either by addition of H_2O, with subsequent oxidation of the putative hemiaminal with DMP (Scheme 1 A, path A), or by the incorporation of Ac-IBX (**4**), to generate an intermediate of type **II** (Scheme 1 A, path B).

This hypothesis proved correct as secondary amides were smoothly oxidized to imides by heating with DMP in a mixture of fluorobenzene and DMSO at 80–85 °C. As seen by inspection of Table 1, an extensive range of functional groups is tolerated by this protocol, including aromatic halides, olefins, and acetates. Particularly significant are the results in Table 1, entries 3 and 5, which demonstrate the superiority of the present method over contemporary techniques employing RuO_4,[11] a reagent whose tolerance of the olefinic and ethereal sites of substrates **15** and **19**, respectively, would be questionable, at best.[12] Table 1, entries 7 and 8 are also noteworthy as they provide information regarding chemoselectivity preferences for the action of DMP on amide-containing substrates. Thus, carbamates are inert to these oxidation conditions (Table 1, entry 7), as are benzylic positions (Table 1, entry 8). The latter observation is expected as DMP is not, unlike IBX,[13] a willing single-electron-

A) DMP-mediated oxidation of amides to imides

B) DMP-mediated oxidation of β-amido esters and amides to their α,β-unsaturated counterparts

Scheme 1. Mechanistic rationale for the DMP-mediated oxidation of amides (A) and β-amido esters and amides (B). Ac-IBA = 1-acetoxy-1,2-benziodoxol-3(1H)-one; Ac-IBX = 1-acetoxy-1-oxide-1,2-benziodoxol-3(1H)-one.

Table 1: Synthesis of imides by oxidation of amides with DMP.[a]

Entry	Substrate	Product	t [h]	Yield [%][b]
1	**11**	**12**	1.0	98
2	**13**	**14**	0.5	86
3	**15**	**16**	3.0	61
4	**17**	**18**	0.5	98
5	**19**	**20**	5.0	96[c]
6	**21**	**22**	1.0	86
7	**23**	**24**	3.5	86[d]
8	**25**	**26**	2.0	98
9	**27**	**28**	1.0	92

[a] Reactions were conducted on a 0.2–0.5 mmol scale in PhF/DMSO (minimal amount of DMSO) at 85°C with DMP (2.0 equiv), unless otherwise noted. [b] Yield of isolated product with no chromatography necessary. [c] Based on 42% recovery of **19**. [d] DMP: 6.0 equiv. DMSO = dimethyl sulfoxide.

transfer reagent. The minimal amount of DMSO is recommended for this reaction as it was found that larger amounts of this solvent (needed to ensure dissolution of certain substrates) proved deleterious (see Table 1, entry 5).

The relevance and potential utility of this novel route to imides is underscored by a facile synthesis of the ethyl ester analogue **31** of the antibiotic fumaramidmycin (**32**), as depicted in Scheme 2. Thus, coupling of monoethyl fumarate with amine **29** and subsequent oxidation of the resulting amide (**30**) with DMP led to the targeted fumaramidmycin analogue **31** (Table 4). This endeavor was instructive, as it not only resulted in the specific synthesis of **31** in a most expeditious manner but also hinted at the wealth of additional natural or designed structures that could be easily accessed through the developed technology.

Encouraged by these results, we further postulated that secondary amides equipped with *N*-β-carbonyl structural motifs could furnish vinylogous carbamates and ureas under suitable conditions. This speculation, which rested on the mechanistic rationale shown in Scheme 1B, proved well founded as demonstrated in Table 2. Thus, the reaction conditions have been demonstrated to favor the *cis*-configured product, likely due to the stabilization provided by the

Scheme 2. Synthesis of the ethyl ester analogue of fumaramidmycin. Reagents and conditions: a) monoethyl fumarate (0.5 equiv), EDC (0.6 equiv), 4-DMAP (0.05 equiv), CH₂Cl₂, 25°C, 19 h, 73%; b) DMP (2.0 equiv), PhF/CH₂Cl₂/H₂O (40:20:1), 85°C, 14 h, 96% (36% conversion). EDC = 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride; 4-DMAP = 4-dimethylaminopyridine.

7		**45**		**46**	6:1	73

[a] Reactions were conducted on 0.1–0.3 mmol scale in PhF at 85 °C for 1 h with DMP (5.0 equiv). [b] Based on 45 % recovery of **35**. [c] Based on 41 % recovery of **39**. Bn = benzyl; Bz = benzoyl; THP = tetrahydropyranyl.

intramolecular hydrogen bond present within **9** and **10** (Scheme 1 B) which is reinforced by the use of a nonpolar solvent (fluorobenzene);[14] these conditions also tolerate the presence of phenolic acetates (Table 2, entry 3) and *N,N*-dibenzylamides (Table 2, entry 5). The latter example, in particular, along with that in Table 2, entry 6, underscores the oxidative potential of DMP, as it represents a direct dehydrogenation between two amide functionalities, a task very few reagents, if any, can smoothly achieve. Possible applications of this type of synthetic transformation include the construction of the *N*-acyl vinylogous urea and carbamic acid structural domains found in palytoxin,[15] enamidonin,[16] and CJ-15,801,[17] as specifically highlighted in Table 2, entry 7, in which tetrahydropyranyl derivative **45** was oxidized with DMP to compound **46**, which could, in principle, be converted into a palytoxin-like side chain following, among other steps, *cis–trans* isomerization of the alkene.[14]

To highlight the applicability of this reaction further, a formal total synthesis of the antibiotic CJ-15,801, along with the construction of its *cis* isomer, was also completed from commercially available starting materials (Scheme 3). Thus, allylation of β-alanine (**47**),[18] followed by subsequent reaction of the resulting amino ester **48** with D-(−)-pantolactone in refluxing toluene, afforded diol **49**. Acetonide formation within **49** led to **50**, whose oxidation with DMP gave a mixture

of the *N*-acyl vinylogous carbamates **51** (*cis* isomer) and **52** (*trans* isomer) in approximately 8:1 ratio in favor of the *cis* compound. While the arrival at **52** (Table 4) signals a formal total synthesis[19] of antibiotic CJ-15,801, the major isomer **51** was converted into *cis*-CJ-15,801 (**53**) by sequential cleavage of the acetonide (BiCl₃) and allyl ester ([Pd(PPh₃)₄])[20] protecting groups (Scheme 3).

As a result of the aforementioned successes, we sought to test the reactivity of DMP on additional nitrogen-containing substrates, namely benzylic primary amines. We were attracted by the prospect of directly accessing nitrile compounds, intermediates and products whose ubiquitous applications in synthesis are well appreciated and documented.[21] Our reasoning for this expectation is encapsulated in Scheme 4. Thus, it was hypothesized that aromatic amine substrates such as **55** could associate with DMP to form complexes such as **IV** with concomitant loss of AcOH, followed by an intramolecular benzylic hydrogen abstraction by an acetate group. This would then result in a net dehydrogenation to afford aldimines of type **56**. These fleeting intermediates would then be expected to be either hydrolyzed by H₂O to aldehydes (e.g. **57**) or oxidized a second time by DMP to furnish nitriles (e.g. **58**).

Indeed, we were pleased to discover that an assortment of benzylic and related primary amines undergo the projected
Scheme 3. Formal total synthesis of the antibiotic CJ-15,801 (**54**) and its *cis* isomer **53**. Reagents and conditions: a) see reference [18]; b) D-(−)-pantolactone (1.5 equiv), NaHCO$_3$ (5.0 equiv), PhMe, reflux, 20 h, 59% (23% of **48** was also observed by ^{1}H NMR prior to purification of crude mixture); c) 2-methoxypropene (10 equiv), *p*TsOH (0.1 equiv), acetone, 0°C, 1 h, 78%; d) DMP (5.0 equiv), PhF, 85°C, 2 h, 93% (based on 39% recovered **50**, *cis* and *trans* isomers isolated in ≈8:1 ratio, respectively); e) BiCl$_3$ (0.2 equiv), H$_2$O, MeCN, 25°C, 14 h, 98%; f) [Pd(PPh$_3$)$_4$] (0.2 equiv), dioxane/H$_2$O (4:1), 25°C, 14 h, 87%. Scheme 4. Mechanistic rationale for the oxidation of benzylic and related amines to aromatic nitriles with DMP.

transformation into nitriles upon reaction with DMP at 25°C in CH$_2$Cl$_2$. The generality and scope of this reaction is demonstrated in Table 3 with examples of substrates containing halide (Table 3, entries 3, 4, and 6), ether (entries 1 and 3), electron-donating (entry 1), and electron-withdrawing (entries 4 and 6) groups, as well as isoxazoles (entry 7) and

bifunctional systems (entry 5). Aside from demonstrating considerable tolerance, this DMP dehydrogenation protocol has proven capable of affording nitriles through the implementation of brief reaction times, without excessive amounts of aldehyde by-products, unlike previously reported procedures employing iodosobenzene[22] or IBX.[4b]

The described chemistry expands the repertoire of reactions carried out by DMP, a versatile oxidant with ever-increasing utility in chemical synthesis. Among the reported examples of new reactivity for this hypervalent iodine reagent are the one-step oxidation of secondary amides to imides and *N*-acyl vinylogous carbamates or ureas, and the direct oxidation of benzylic and related primary amines to their nitrile counterparts. The relevance of the present new synthetic technology to a rapid synthesis of analogues of fumaramidmycin and antibiotic CJ-15,801 demonstrates the mildness and applicability of some of these protocols to chemical synthesis, and bodes well for their future utilization in other situations.

Experimental Section

General procedure (amides): Generation of imides: In a sealed tube the amide (0.1–0.3 mmol) was dissolved in fluorobenzene (0.15 M) and several drops of wet DMSO were added (or enough to ensure dissolution of substrate). After addition of DMP (2.0 equiv), the mixture was heated behind a blast shield at 80–85°C until the starting material was consumed (monitored by TLC analysis). The resulting mixture was allowed to cool and was then quenched with saturated

aqueous Na$_2$S$_2$O$_3$ (2 mL) and stirred vigorously until the solution became clear. The mixture was poured into Et$_2$O (15 mL) and the ethereal phase was washed twice with 10% aq. Na$_2$S$_2$O$_3$/aq. NaHCO$_3$ (1:1 mixture, 15 mL) and brine (15 mL), and then dried (MgSO$_4$). Removal of the solvent in vacuo afforded the imide, often pure enough (by ^{1}NMR spectroscopic analysis) to forgo chromatography. Generation of *N*-acyl vinylogous carbamates and ureas: In a sealed tube the amide (0.1–0.3 mmol) was dissolved in fluorobenzene (0.1 M) and DMP (5.0 equiv) was added. The mixture was heated at 80–85 °C until full consumption of starting material was noted (monitored by TLC analysis). The reaction mixture was then quenched and purified in the same manner as for the preparation of imides described above.

General procedure (amines): The amine (0.1–0.4 mmol) was dissolved in a small amount of CH$_2$Cl$_2$ and added dropwise over a period of 5–10 min to a homogeneous mixture of DMP (2.0 equiv) in CH$_2$Cl$_2$ to form a 0.15 M solution with respect to the amine. The reaction mixture was stirred at 25 °C until the starting material was consumed (as observed by TLC analysis), at which time the reaction

was quenched with saturated aqueous Na$_2$S$_2$O$_3$ (2 mL) and the resulting mixture was stirred vigorously until it became clear. The mixture was then poured into Et$_2$O (15 mL) and the ethereal phase was washed twice with 10% aq. Na$_2$S$_2$O$_3$/aq. NaHCO$_3$ (1:1 mixture, 15 mL) and brine (15 mL) and then dried (MgSO$_4$). Removal of the solvent in vacuo afforded the nitrile, which was purified by silica-gel column chromatography.

Porous Materials

Selective Fabrication of Ordered Bimetallic Nanostructures with Hierarchical Porosity**

Lehui Lu, Richard Capek, Andreas Kornowski, Nikolai Gaponik, and Alexander Eychmüller*

There has recently been intensive effort to develop porous metallic materials because of their promising applications in catalysis, separation technology, sensors, and fuel cells. The success of these applications strongly relies on the availability of porous metallic materials with specific pore sizes and structures. In the quest to fabricate porous metallic materials with desired pore sizes and structures, attempts have been

made to use templates in a replication process.[1–6] For example, anodic alumina[1] and lyotropic liquid crystals[2] were used as templates to fabricate mesoporous (voids < 50 nm) metal films with cylindrical and parallel pores. It was also shown that techniques involving colloidal templates could be used to create ordered macroporous (voids > 50 nm) metal films.[3–6] The latter method is attractive because of its pore-size tuneability and the ordered structure it produces. A critical issue in using this method is how to controllably fill the interstitial space of the colloidal templates with a desired composition. In previous work,[3–6] the use of this method invariably led to a complete infiltration of the interstitial space with different materials, which, to some extent, limits the application of such a method to produce porous metal materials with novel structures.

Porous hollow metallic spheres often exhibit catalytic activities different from their solid counterparts and have the advantages of low density and the use of less material.[7,8] For example, Hyeon and co-workers[7] showed that hollow Pd spheres possess excellent catalytic activity in Suzuki reactions and can be recycled without loss of the catalytic activity. The extension of such a structure to bimetallic nanomaterials is of great importance since the properties of one metal are usually improved by the addition of another.[9,10] Nevertheless, we are not aware of publications on the generation of such materials with ordered structures that may lead to the formation of hierarchical porosity.

Herein we describe how two different kinds of ordered bimetallic nanostructures with hierarchical porosity, namely a macroporous nanostructure and a nanostructure consisting of hollow spheres, can selectively and conveniently be fabricated by a general template technique on silicon wafers and glass substrates.

The starting material for the template is a colloidal suspension of highly monodisperse silica spheres in ethanol. The silica spheres were prepared by the improved Stöber growing procedure,[11,12] and subsequently modified with 3-aminopropyltrimethoxysilane (APTMS). The closely packed colloidal template was assembled on silicon wafers or glass substrates that were placed vertically in a slowly evaporating dispersion of APTMS-modified silica spheres in ethanol, as described by Jiang et al.[13] The colloidal template was then immersed in an aqueous solution of gold nanoparticles having an average diameter of 3 nm. Since the cross-sectional area of the smallest channel inside the colloidal template is much larger than the gold nanoparticles, the nanoparticles can flow freely throughout the colloidal template. Different kinds of nanostructures can be prepared by varying the immersion times and concentrations of the gold solution (see below and the Experimental Section). Finally, the dried colloidal template with the gold nanoparticles was dipped into a plating solution for coating with platinum. During the plating process, the small gold nanoparticles can serve as seeds to accelerate the reduction of the $PtCl_6^{2-}$ ions by ascorbic acid. Removing the silica template with 4% HF solution gave black self-supporting flakes. Shrinkage of the pores was avoided since the silica template was removed at room temperature.

It is very important to generate high-quality templates for this template-directed method since the quality of any

material formed by this method depends sensitively on the ordering and the properties of the starting template. Figure 1 a shows a typical scanning electron microscopy (SEM) image of the top view of one of the silica colloidal templates. The SEM image reveals that the 267-nm silica spheres are
Figure 1. a) SEM image of a template consisting of 267-nm silica particles, and SEM images of typical ordered hollow nanostructures formed using b) 267-nm and c) 300-nm silica colloidal crystals as templates, respectively. The insets show the corresponding high-magnification images.

organized in a close-packed arrangement with long-range hexagonal order. These high-quality colloidal crystals can be used as templates for the fabrication of ordered structures constructed from hollow metallic spheres. The resulting materials exhibit a tunable hollow volume since the starting template can be formed from silica spheres with different sizes. Figure 1 b, c show typical SEM images (top views) of

hollow metallic nanostructured materials made by using 267-nm and 300-nm silica colloidal crystals as templates, respectively. It is evident from Figure 1 b, c that after removal of the template, the ordering feature—the original porous structure of the starting template—and the spherical shape of the silica spheres have clearly been retained. The hollow structure character of these materials is anticipated by inspection of the broken spheres seen in Figure 1 b, c. A closer look at Figure 1 b, c reveals another interesting feature, namely the existence of a hole with an average diameter of about 20 nm in almost every hollow sphere. These holes are arranged in order and the distances between neighboring holes are roughly equal to the center-to-center distances of the hollow metallic spheres. The detailed mechanism for the formation for this structural feature will be investigated further since it may open up a new route to the design of novel nanostructured materials. Higher magnification SEM images in Figure 1 b, c (insets) show that these hollow spheres consist of small nanoparticles (average diameter below 10 nm), which are interconnected to form relatively uniform porous hollow metallic nanoshells. The average nanoshell thickness of the hollow metal spheres in Figure 1 b and c is estimated to be about 20 nm and about 45 nm, respectively. The nanoparticle framework of the as-prepared materials provides yet another level of porosity which gives the structure a very high surface area: the size of the small pores and the overall surface area are determined by the size of the Au/Pt nanoparticles. Nanostructured materials with such controlled hierarchical porosity may be particularly suitable for catalytic applications.

Energy-dispersive X-ray analysis (EDX) is a technique that enables the elemental composition of a small selected area of the sample to be identified with a sensitivity of about 1% for elements heavier than beryllium. Figure 2 a shows an EDX analysis of the hollow nanostructures shown in Figure 1 b before (left) and after removal (right) of the SiO_2 template as an example. The EDX analysis shows strong Au and Pt peaks from the hollow nanostructures. The reasonably strong O peak present before removal stems from the SiO_2 template. The Si peak in both Figures originates most probably from the silicon wafer. The appearance of the remaining very weak O peak after the removal of the template can be attributed to the reduction reagents (citrate ions or ascorbic acid); this proposal is further supported by the presence of the C peaks (not shown). On the basis of the above EDX analysis it is reasonable to conclude that the silica template is completely removed and, thus, ordered hollow Au/Pt nanostructures are formed. Figure 2 b presents an X-ray diffraction (XRD) pattern of the sample shown in Figure 1 b. Broad diffraction peaks corresponding to metallic Au and Pt are observed which are indicative of the presence of nanosized Au/Pt particles (see the bulk reflexes, bottom of Figure 2 b).

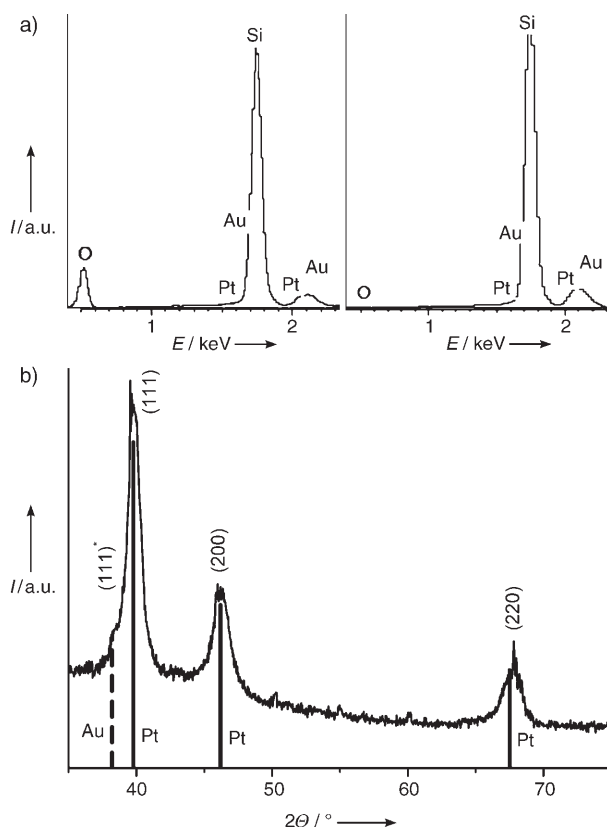
Ordered macroporous metallic nanostructures are another kind of important porous material. We found that the current method is also applicable to the formation of such structures if the experimental conditions are suitably controlled (see Experimental Section, Method B). Figure 3 shows a typical SEM image (top view) of the macroporous structure


Figure 2. a) EDX analysis of the ordered Au/Pt nanostructures shown in Figure 1b before (left) and after (right) HF treatment, and b) XRD pattern of the hollow nanostructure from Figure 1b.

formed by this method. It is evident that the resulting material exhibits relatively uniform porosity with hexagonal close packing, while the pores match the size of the starting silica, thus indicating that negligible shrinkage of the metallic structure occurs.[3a] The ordered regions can extend to several hundreds of micrometers. The small nanoparticles around the large pores in the original interstitial space can be clearly observed in the corresponding higher magnification images (Figure 3, inset). EDX and XRD analysis show that the as-prepared materials consist of nanosized metallic Pt and Au.
Figure 3. Typical SEM image of an ordered macroporous Au/Pt nano-structure. The inset shows a corresponding high-magnification image.

The success of the current method for selective fabrication of two different kinds of ordered bimetallic nanostructures with hierarchical porosity is rationalized as follows. According to previous reports,[3] in which the colloidal template was immersed in an aqueous solution of gold nanoparticles, small gold nanoparticles were deposited in the interstices of the colloidal template by an infiltration process to form a mesoporous structure around the silica spheres. Since the porosity allowed the solvent to flow freely through the structure, the pores can be completely filled with gold nanoparticles. However, the situation is different in the present study. Modification of the silica spheres with APTMS results in the APTMS molecules bonding to the surface of the silica spheres with their NH_2 groups directed outwards. Immersion of this modified colloidal template leads to an intense coverage of gold nanoparticles on the surface of the silica spheres through the interaction between the negatively charged gold nanoparticles and the positively charged NH_2 groups (see also ref. [14]). If the concentration of the gold nanoparticles is relatively low ([Au] = 0.06 mm) and the immersion time in the gold solution is comparatively short (8 h), the assembly of the gold nanoparticles on the surface of the silica spheres predominates. A small quantity of residual gold nanoparticles in the interstices of the colloidal template can be removed by rinsing with deionized water (and/or by deposition on the surface of the silica spheres during the drying process). This is followed by a 16-minute electroless deposition of Pt only on the surface of the silica spheres (Method A). As a result, the removal of the template leads to the formation of ordered porous Au/Pt nanostructures constructed from hollow spheres. In contrast, if the concentration of the gold nanoparticles is higher ([Au] = 0.3 mm) and the immersion time in the gold solution is long (16 h), besides the assembly of gold nanoparticles on the surface of the silica spheres, the relatively large amount of small gold nanoparticles in the interstices of the colloidal template in combination with those on the surface of the silica spheres associate into a larger, mesoporous structure. The following 16-minute Pt deposition leads to almost complete infiltration of the pores of the colloidal template, and macroporous Au/Pt nanostructures are obtained after removal of the template (Method B).

In a second set of experiments, monodisperse but non-ordered APTMS-modified silica spheres were used as templates and the same experimental procedures were performed. We found that only hollow porous Au/Pt nano-structures were obtained by both Methods A and B (Figure 4a). As evidenced in higher magnification images, the shell of the hollow spheres is built-up by stringlike, structured aggregates consisting of small Au/Pt nanoparticles which results in many pores with an average diameter of 32 nm. Such nanostructured materials can be particularly desirable for application in catalytic nanoreactors. This result further strengthens our above explanation: Since the templates are non-ordered and the silica spheres within the template are loosely arranged, the assembly of the gold nanoparticles and the following Pt deposition only occurred on the surface of the silica spheres. As a result, only hollow nanostructures can be formed under Methods A or B. Interestingly, porous
Figure 4. SEM images of a) hollow spheres prepared by Method B, and b) hollow hemispheres prepared by Method A with a concentration of gold of 0.06 mM, an immersion time in the gold solution of 10 h, and a Pt plating time of 12 min. Non-ordered APTMS-modified silica spheres on silicon wafers were used as templates.

hollow Au/Pt hemispheres can also be fabricated under appropriate experimental conditions (such as, for example, an increase in the Au concentration compared to Method A; Figure 4b), which may provide an alternative method for the synthesis of such materials.

In summary, ordered Au/Pt nanostructures with hierarchical porosity, such as macroporous nanostructures and nanostructures constructed from hollow spheres, can be selectively and conveniently prepared by a general template technique on silicon wafers and glass substrates. A possible explanation for the selective fabrication of the above-mentioned nanostructures is given. Furthermore, since protocols exist for the deposition of many other metals, such as Cu,[15] Pd,[16] and Ag,[17] this method could be successfully extended to other bimetallic systems including Au/Cu, Au/Pd, and Au/Ag (see Supporting Information). These ordered metallic nanostructures with hierarchical porosity could be useful in industrial applications including catalytic nanoreactors (see Supporting Information), sensors, porous electrodes, and fuel cells.

Experimental Section

3-nm gold nanoparticles:[18] A 1% solution of $HAuCl_4$ (1 mL) was added to water (90 mL) at room temperature. After stirring the mixture for 1 min, 1% sodium citrate solution (2 mL) was added. Freshly prepared 0.075% $NaBH_4$ (in 1% sodium citrate solution;

1 mL) was added 1 min later. The resulting solution was stirred for an additional 5 min and kept at about 4 °C until use.

Synthesis and modification of the silica spheres: Equal volumes of a solution containing absolute ethanol (50 mL) and 0.2 M tetraethyl orthosilicate (TEOS), and another containing absolute ethanol (50 mL), water (28 mL), and ammonia (28–30%; 4 mL) to give a total volume of about 100 mL were mixed rapidly. The reaction was allowed to continue for 6 h at room temperature. APTMS (100 μL) was then added and the mixed solution was stirred for an additional 12 h. The resultant APTMS-modified silica spheres were cleaned by consecutive centrifuging, decanting, and redispersing in ethanol by sonication (five times). Removal of aggregates and smaller spheres was performed by fractionation by removing the upper and the lower fractions (three times).

Assembly of the silica template and introduction of gold nanoparticles and deposition of platinum: The APTMS-modified silica spheres were assembled onto a silicon wafer that was placed vertically in a slowly evaporating dispersion of silica spheres in ethanol for 2 days. The dried colloidal template was then immersed in solutions of the gold nanoparticles at different concentrations for different times. The dried colloidal templates with the gold nanoparticles were dipped into a plating solution (50 mL) that contained 10% H_2PtCl_6 (1 mL) and 0.1 M ascorbic acid (3 mL) for different times (Method A: [Au] = 0.06 mM, immersion time in the gold solution = 8 h, Pt plating time = 16 min; Method B: [Au] = 0.3 mM, immersion time in gold solution = 16 h, Pt plating time = 16 min). All samples were placed into deionized water and were dried in air.

Removal of the colloidal template: All samples were dipped into 4% HF solution for 5 min. The metallic film could then be peeled off the silicon wafer. This procedure was repeated to completely remove the silica spheres.

Characterization: SEM images were obtained with a Leo 1550 supra instrument equipped with an EDX Si-detector (Oxford Instruments). All structures were characterized by XRD (Philips; X'pert MPD).

catalytic metal-mediated conversions of organonitriles into important organic compounds are currently being developed.[1,3] In contrast to other unsaturated molecules, such as alkynes, alkenes, CO, or RNC, nitriles insert less easily into metal–carbon bonds. Most of the known examples involve nitriles RCN and early-transition or actinide metal organocomplexes [M]−R′ to give azaalkenylidene complexes [M]−N=CRR′ upon insertion.[4,5] In a few cases, the azaalkenylidene ligand in [M]−N=C(R)CH$_2$R′ rearranges by a 1,3-H shift to the corresponding enamide [M]−NHC(R)=CHR′.[5] Some special cases involve low-valent transition-metal organocomplexes [M]−CH$_2$C(O)R′ that react at high temperature with a nitrile RCN and PPh$_3$ to give a κ^2-C,O-cyclometalated imino complex [M]−NHC(R)CHC(O)R′.[6] Another unusual case is the reaction between the extremely reactive Fe$_2$Mes$_4$ (Mes = 2,4,6-Me$_3$C$_6$H$_2$) and PhCN to give the dimer [{(PhCN)-(Mes)Fe}$_2$(µ-N=CPhMes)$_2$].[7] Herein, we report a new type of nitrile insertion that also represents the first example of the insertion of a nitrile into a C−M bond (in which M is a late-transition element).

[Pd{2-(OH)C$_6$H$_4$}I(tmeda)] (tmeda = N,N,N′,N′-tetramethylethylenediamine) reacts at room temperature with excess RCN and 1 equivalent of TlOTf (OTf = CF$_3$SO$_3$) to give [Pd{1-O-2-[C(R)=NH]C$_6$H$_4$-κ^2-O,N}(tmeda)]OTf [R = Me (**1**), C$_6$F$_5$ (**2**), CH$_2$=CH (**3**)] (Scheme 1). As many known

Reactivity of *ortho*-Palladated Phenol Derivatives with Unsaturated Molecules: Insertion of Nitriles into a Late-Transition-Metal–Carbon Bond**

José Vicente,* José Antonio Abad,
María-José López-Sáez, and Peter G. Jones

Nitriles have a very rich coordination chemistry because they are activated by some metals towards nucleophilic or electrophilic attack.[1,2] Based on this reactivity, stoichiometric and

Scheme 1. Reaction of [Pd{2-(OH)C$_6$H$_4$}I(tmeda)], excess nitrile, and TlOTf (1 equiv).

stable alkyl– and aryl–palladium complexes contain a *cis*-coordinated nitrile ligand,[8] we can assume that the *ortho*-hydroxy group plays a crucial role in the process and that after substitution of the iodo ligand by RCN (**A** in Scheme 2), the following step **B** is the protonation of the nitrogen atom of the nitrile. Unexpectedly, however, the usual nucleophilic attack at the nitrile carbon atom by the oxygen function[1,2] to give the addition product **C** does not occur. In our opinion, the resonance form **B′** contributes significantly to the electronic structure of the protonated intermediate because of the electron-withdrawing character of the positively charged metal center and the electron-releasing nature of the negatively charged oxygen substituent. Both favor the location of a partial negative charge on the *ipso* carbon atom of the aryl ligand. Therefore, our results can be explained through the nucleophilic attack at the nitrile carbon by the *ipso* carbon atom, probably via the four-membered metallacycle **D**. Consequently, this insertion process differs from those reported previously with other unsaturated molecules in the role played by the *ortho*-hydroxy group, first in the proto-

Scheme 2. Proposed mechanism for the reaction of [Pd{2-(OH)C₆H₄}I(tmeda)] with nitriles.

Figure 1. Thermal ellipsoid plot (50% probability) of **1**. Selected bond lengths [Å] and angles [°]: Pd–O1 1.9655(14), Pd–N1 1.9800(16), Pd–N2 2.0685(16), Pd–N3 2.0710(16), N1–C7 1.297(3), O1–C1 1.313(2); O1-Pd-N1 91.58(6), O1-Pd-N2 87.55(6), N1-Pd-N3 95.55(7), N2-Pd-N3 85.62(6), C7-N1-Pd 128.74(14), C1-O1-Pd 126.31(12), N1-C7-C2 123.24(17), N1-C7-C8 117.75(18), C2-C7-C8 118.95(17).

nation of the nitrile ligand and then in the generation of a partial negative charge on the *ipso* carbon atom of the aryl ligand.

Recently, the reaction of acrylonitrile with [PdMe-(NMe₂Ph)L₂]⁺, [{PdMe(L₂)}₂(μ-Cl)]⁺ (L₂ = various bidentate N-donor ligands),[9] and [Pd(O,N)Me(NCMe)] (O,N = Grubbs salicylaldiminato and related diazene ligands)[10] were reported to give α-cyanopropyl derivatives, that is, the insertion products of the olefinic part of the nitrile into the Pd−Me bond. In all cases, the first step was, as we propose in our case, the N-coordination of the nitrile but the difference from our result (complex **3**) proves to be the crucial role played by the hydroxy group in our reactions. We have reported that CO and olefins insert into the C−Pd bond of [Pd{2-(OH)C₆H₄}I(tmeda)] without intervention of the hydroxy group.[11]

The insertion of a nitrile group into an aryl–Pd bond has been postulated as a step in the mechanism of the synthesis of aryl ketones by the Pd-catalyzed reaction of arenes with nitriles at 75–100°C.[12] The proposed subsequent step is the protonation of the resulting imido complex to give an imine. Our results suggest that these two steps could occur in the reverse order.

Complexes similar to **1–3** were prepared by the reaction of 1) [Ru(L₂)₂(CO)₃] (L₂ = bpy (2,2′-bipyridyl), phen (1,10-phenanthroline)) with *p*-{CH₂N=C(Me)(2-OHC₆H₄)}₂C₆H₄,[13] 2) [Ru(PPh₃)₃Cl₂] with oximes of salicylaldehyde, 2-hydroxyacetophenone, or 2-hydroxynaphthylaldehyde,[14] and 3) aqueous ammonia, 2-hydroxo-4-methoxyacetophenone, and copper(II) salts.[15] Therefore, in the known complexes the main skeleton of the ligand is preformed in the organic reagent. Complexes **1–3** contain ligands of the same family as that present in Grubbs nickel catalysts.[16]

The crystal structures of the three complexes were solved by X-ray diffraction studies (Figures 1–3).[17] They show a distorted square-planar geometry at the palladium center, with normal bond lengths and angles. The chelate ring involving N1 and O1 is essentially planar in **1** but becomes less planar for **2** and **3** (mean deviations 0.03, 0.08, 0.11 Å).
Figure 2. Thermal ellipsoid plot (30% probability) of **2**. Selected bond lengths [Å] and angles [°]: Pd–N1 1.9769(13), Pd–O1 1.9804(12), Pd–N2 2.0636(15), Pd–N3 2.0698(14), O1–C1 1.308(2), N1–C7 1.288(2); N1-Pd-O1 90.91(5), N1-Pd-N2 94.21(6), O1-Pd-N3 89.00(5), N2-Pd-N3 85.88(6), C1-O1-Pd 125.59(10), C7-N1-Pd 127.26(11), N1-C7-C2 125.08(15), C2-C7-C11 119.29(14).

Cation/anion N−H···O(O₂)SCF₃ hydrogen bonds are observed.

In conclusion, we have reported the first examples of the insertion of nitriles into a late-transition-metal–carbon bond. The process involves the insertion of an alkyl (Me), aryl (C₆F₅), or vinyl nitrile into an aryl–palladium bond. The insertion is assisted by the protonation of the nitrile nitrogen atom by the *ortho*-hydroxy group present in the aryl ligand and thus represents a new type of insertion reaction.
Figure 3. Thermal ellipsoid plot (30% probability) of **3**. The anion has been omitted. Selected bond lengths [Å] and angles [°]: Pd–O1 1.966(2), Pd–N1 1.983(2), Pd–N3 2.054(2), Pd–N2 2.060(2), O1–C1 1.319(3), N1–C7 1.287(4), C8–C9 1.310(4); O1-Pd-N1 90.11(11), N1-Pd-N3 95.10(11), O1-Pd-N2 88.65(9), N3-Pd-N2 86.12(10), C1-O1-Pd 123.44(18), C7-N1-Pd 128.7(2), N1-C7-C2 121.4(3), N1-C7-C8 116.8(3), C2-C7-C8 121.8(3).

Preliminary results allow us to state that the process also occurs with other alkyl and aryl nitriles.

Experimental Section

General procedure: The nitrile (1.15 mmol) and TlOTf (81 mg, 0.23 mmol) was added to a solution of [Pd{2-(OH)C$_6$H$_4$}I(tmeda)][11] (100 mg, 0.23 mmol) in CH$_2$Cl$_2$ (15 mL). The resulting mixture was stirred for 4 h at room temperature, the suspension was filtered over celite, the yellow solution was concentrated (3 mL), and Et$_2$O (10 mL) was added, which resulted in the precipitation of a solid. The precipitate was filtered, washed with Et$_2$O (3 × 5 mL), and dried to give the corresponding complex as a yellow solid.

Synthesis of Stable Aragonite Superstructures by a Biomimetic Crystallization Pathway**

Nadine Nassif,* Nicole Gehrke, Nicola Pinna, Natasha Shirshova, Klaus Tauer, Markus Antonietti, and Helmut Cölfen*

Many organisms make use of calcium carbonate as a construction material, and for this purpose are able to selectively control the formation of the different polymorphs of this material. This is not the case for technical processes. Calcite is thermodynamically more stable at ambient pressure and temperature[1] than the other anhydrous $CaCO_3$ polymorphs (vaterite and aragonite), and thus is most easily obtained with long reaction times. There are some technical procedures which generate vaterite (usually the first polymorph formed as a result of the Ostwald rule of stages) by performing the precipitation along the kinetic pathway and yielding the kinetic metastable vaterite product or by trapping and stabilizing the very early crystals[2] with appropriate stabilizers. However, the mechanically very interesting aragonite (usually a high-pressure modification) is virtually inaccessible by chemical means, except by adding extreme amounts of Mg^{2+} ions to the mother liquor.[3,4] It should be recalled that nacre, with its extraordinary mechanical performance, is based on pure aragonite platelets[5] and shows clear long-time stability even in the presence of water. In contrast, aragonite usually starts to transform to calcite within a day or faster depending on the pH value and temperature.[6,7] Thus, one of the main challenges in the crystallization of calcium carbonate remains the synthesis of pure aragonite of uniform size and morphology under ambient conditions.

It has previously been described that aragonite is formed in a biomimetic pathway in the presence of several extracted

macromolecules from different shells in the presence[8] or absence[9] of an organic matrix, under compressed mono-layers[10, 11] or at the liquid–liquid interface in a radial Hele–Shaw cell.[12] More recently, aragonite was obtained as a metastable intermediate at the air–water interface by the use of a basic polymer.[13] Other reported ways to obtain aragonite include, for example, the transformation of amorphous calcium carbonate nanoparticles in reverse surfactant microemulsions,[14] by heat-induced precipitation onto self-assembled monolayers of anthracene-terminated thiol chains,[15] or by high-power ultrasonic irradiation at certain sound amplitudes.[16]

Herein we report the simple synthesis of homogeneous aragonite crystals with structural complexity by applying the standard vapor diffusion method to particles of a hydrophilic block copolymer.[17] These particles are composed of a triblock copolymer, poly(diethylaminoethyl methacrylate)-*b*-poly(*N*-isopropylacrylamide)-*b*-poly(methacrylic acid) (PDEAEMA-*b*-PNIPAM-*b*-PMAA), in which the poly-(methacrylic acid) core is cross-linked by 1,3-diisopropylene-benzene.[18, 19] The current process, contrary to previously reported syntheses, does not rely on an excess of inorganic metal ions nor the presence of a whole assembly of macro-molecules or surfactants; only cheap and commonly accessible chemicals are required for the polymer preparation as well as a small amount of polymer template particles under bio-inspired crystallization conditions, that is, water at ambient pressure and temperature. Furthermore, the experiment is particularly easy to set up.

The beneficial and useful application of block copolymers with more than one hydrophilic block in crystallization has been known for several years.[20, 21] So-called "double hydro-philic block copolymers" are currently used to mimic the processes occurring in natural biological materials. They consist of two hydrophilic blocks: one is a polyelectrolyte, and thus strongly interacts with crystal surfaces, and the other one is a non-ionic block, which provides the water solubility without interacting with the crystal.

The current system is such that it contains both an outer positive and an inner negative polymer block, the poly(di-ethylaminoethyl methacrylate) and poly(methacrylic acid) PDEAEMA and PMAA blocks, respectively, which can interact with both ions and different crystal moieties and faces. In this way, its role is expected to act as an ion sponge and to nucleate and stabilize nanocrystals which will constitute the building units of a crystalline superstructure. The PNIPAM part is expected to mediate sufficient steric stability to the particles throughout all steps of the process at room temperature where PNIPAM is hydrophilic. PDEAEMA-PNIPAM-*b*-PtBMA/MAA (cross-linked) also exhibits some hydrophilic microgel properties, which are provided mostly by the third block (PMAA). The hydrodynamic diameter of the microgel particles dispersed in water is about 1 μm, but after drying, TEM images show an average particle size of about 200 nm with a narrow size distribution between 170 and 220 nm.[19] Thus, the size of these spherical microgels can vary by swelling according to the medium (dried or in water) in which they are placed.

Precipitation experiments were performed using the so-called vapor diffusion method, with calcium carbonate synthesized by the diffusion of carbon dioxide vapor (obtained from the thermal decomposition of ammonium carbonate) into a calcium chloride solution (0.01 M) mixed with very small amounts of PDEAEMA-PNIPAM-*b*-PtMA/MAA (10^{-4} mg mL^{-1}, 0.1 ppm). It is emphasized that the relative ratio of these compounds is so high that the polymer practically does not contribute by weight to the final crystals (ratio CaCO$_3$/block copolymer $\leq 10^4$:1), that is, it is essentially its influence on nucleation which is relevant.

Scanning electron microscopy (SEM) studies of a sample collected after 12 days from the bottom of the reaction flasks shows "sheaf bundle" crystals[10–12] as the predominant morphology, slightly contaminated with a few calcite rhom-bohedra from the free growth of CaCO$_3$ (Figure 1a). A higher
Figure 1. Lower (a) and higher (b) magnification SEM images showing a rather narrow distribution of "sheaf bundle" crystals at the bottom of the precipitation flask.

magnification (Figure 1b) reveals the high uniformity of this superstructure morphology and the quite narrow size distri-bution with a diameter of about 60 μm. It will be shown below that all the superstructures have been heterogeneously nucleated at interfaces. We therefore assume that the calcite contamination arises from the co-occurrence of free calcite nucleation in homogeneous solution, which cannot be com-pletely suppressed by the very low concentrations of polymer modifier employed (0.1 ppm).

The identification of the phase of the synthesized $CaCO_3$ was carried out by X-ray powder diffraction (XRD) analysis. The XRD pattern of the sample displays the following diffraction peaks (2θ [°]): 26.12, 27.10, 32.74, 33.06, 36.12, 37.29, 37.89, 38.48, 39.42, 41.27, 43.01, 45.96, 48.44, 50.25, 52.44, and 52.92, which can be correlated to the (hkl) indices (111), (021), (121), (012), (200), (031), (112), (130), (211), (220), (221), (202), (132), (113), (321), respectively, of pure aragonite. For the sample collected from the bottom of the flask, peaks of rhombohedral calcite are also observed (diffraction peaks 2θ [°] (hkl): 29.27 (104), 39.42 (202), 47.36 (018)). These results are in agreement with the SEM observations. The identification of the phase of these crystals was also confirmed by Fourier transform infrared (FTIR) spectroscopy, which showed characteristic vibrational bands at 699, 711, 852, and 1082 cm^{-1}. The characteristic vibrational band corresponding to the asymmetric C–O stretch is 1469 cm^{-1} for aragonite and 1422 cm^{-1} for calcite. However, the broadness in this wavenumber region means that it is not possible to assign the band at 1445 cm^{-1}.

Nucleation at interfaces is also proven by analyzing finer details of the "sheaf bundles". Analysis of the trunk attachment on the glass surface (Figure 2a) and the fine structure of fallen-off crystal trunks (Figure 2b) leads us to suggest that nucleation of these crystals indeed occurs from the two-

dimensional structure already present at the flat end of the trunk. The central hole in the trunk even has the correct size (of about 1 µm) to formerly have hosted one of the microgel particles of the polymer, that is, one polymer particle promotes the heterogeneous nucleation of one crystal superstructure. This view is supported by attachment of the externally positively charged particles (outer PDEAEMA layer) to the negatively charged glass surface at the starting pH value of 5.8 for crystallization, as shown by the adsorption of positive dyes or positively charged latexes onto the glass slide (see also the Supporting Information for the adsorption of the triblock copolymer particle).

Other experiments were performed to understand how such stable aragonite crystallization can occur under ambient conditions. Figure 3 presents TEM measurements performed

Figure 2. SEM images showing the trunk attachment to the glass wall (a) and the root (b) of a fallen-off "sheaf bundle" crystal.
Figure 3. TEM overview images of two building blocks (a, c) and their respective electron diffractions (b, d). HRTEM image of parts of different building blocks (e, f) and their respective power spectra (g, h). The arrows indicate the [001] direction.

on the primary building blocks seen clearly in Figure 2b. These subunits are quite homogeneous and have a rodlike shape with lengths ranging from 500 nm to a few micrometers (Figure 3a and 3c). Their diffraction patterns are in some cases typical of mesocrystals such as the particle presented in Figure 3a (Figure 3b; in this case the crystal is oriented along the [110] direction) or typical of a single crystal such as the one presented in Figure 3d which is characteristic of the [010] zone axis. In both cases the long axis of the crystal is [001].

High-resolution TEM (HRTEM) was used to study the crystallinity and the surface of the particles (Figure 3e and f). The particles show a well-defined crystalline core as demonstrated by their power spectra (PS, Figure 3g and 3h), which are characteristic of single crystals viewed along the [110] and [010] directions, respectively. Surprisingly, they also show a clearly developed amorphous layer of around 5-nm thickness on their surface. This layer can not be formed by organic compounds such as the 1-μm polymer template used to induce the nucleation, and in fact this thin layer starts to crystallize slowly under the intense electron beam of the microscope. This observation suggests that this layer is composed of amorphous calcium carbonate (ACC), as was found recently on the aragonite platelets of nacre.[22] Thus, the above observations show the possibility to retrosynthesize the amorphous-layer-coated aragonite platelets in nacre by using the current synthetic polymers and crystallization conditions. The exact reason for the stabilization of the aragonite polymorph by a protective ACC layer is as yet unknown and the subject of ongoing work. Nevertheless, this amorphous "coating" could protect the aragonite against recrystallization when in contact for longer times with water.

Finally, experiments were also performed with higher polymer concentrations (10^{-3} to $1 \mathrm{~mg\,mL^{-1}}$), while keeping the $CaCl_2$ concentration (0.01M) constant. The increase leads first to a higher heterogeneity of the crystals until the specific crystal shape disappears. Only the mineralization of the microgel particles towards amorphous composite structures could be observed at the highest polymer concentrations (Figure 4), because of the lower available mineral concentration for each polymer particle.
Figure 4. SEM images at lower and higher (inset) magnification of the mineralized polymer microgels ($1 \mathrm{~mg\,mL^{-1}}$).

tration for each polymer particle. Dynamic light scattering (DLS) investigations confirmed the interactions between the core of the particle, which is mainly composed of acidic groups (PMAA), and the calcium ions of the solution. Indeed, DLS studies have shown that an increase in the ionic strength of the solution leads to a decrease in the average particle diameter of the stabilizing microgel particles (the average diameter of the triblock particles is ca. 1000 nm in water[19] whereas it decreases to ca. 800 nm in 0.01M $CaCl_2$ solution).

The increase in the pH value in the experimentally important range from the starting value of 5.8 to the end value of 9.5 slightly increases the size of the particles to 1200 nm as a consequence of PMAA charge repulsion in the core.

Presumably the higher polymer concentrations model the very early stages of the formation of the "sheaf bundles". The amphoteric microgels are strong enough to bind all counterions and amorphous intermediates up to a critical concentration. When the binding concentration is exhausted (which is the case for concentration/weight ratios of $CaCl_2$/polymer greater than 1:1), this highly concentrated salt phase can specifically nucleate the aragonite phase, presumably as a result of the stabilization effects specific for the precursor-loaded polymer. The hydrogen exchange between the amine and the acid blocks could be expected to contribute to this effect. Indeed, such an interaction has been observed in the diblock copolymer poly(diethylaminoethyl methacrylate)-*b*-poly(methacrylic acid) and led to insolubility in water even at high pH values.[23] However, in the case of the triblock microgel particles here, their solubility and their size in water (ca. 1000 nm) prove that the interaction between the outer poly(diethylaminoethyl methacrylate) block and the inner poly(methacrylic acid) block is only of minor importance. Apparently, both the reduced mobility of the poly(methacrylic acid) acid groups, because of cross-linking, and a shielding action of the poly(*N*-isopropylacrylamide) middle block efficiently prevent this interaction. On the basis of Figure 4 it can be suggested that the amphoteric polymer microgel increases the salt concentration in its interior/proximity as a consequence of some zwitterionic moieties (this proposal is supported by the decrease in the particle size upon the addition of salt, as evident from DLS studies), whereas the excess of the outer PDEAEMA block nucleates a ring of radially aligned primary aragonite nanocrystals (see Supporting Information). Other molecules containing tertiary amine functions also induced aragonite formation.[24] This observation is in line with a recent finding that many molluscan shell proteins found in nacre could be less acidic than previously thought.[25] However, the controlled crystallization experiment with the PDEAEMA homopolymer additive indicated the beginning of the formation of elongated aragonite particles as well as the typical calcite rhombohedra found in the experiment with polymer concentrations greater than $1 \mathrm{~mg\,mL^{-1}}$. At lower concentrations, the morphology of the formed calcite was still modified and resulted in roughly spherical particle superstructures up to polymer concentrations of $0.01 \mathrm{~mg\,mL^{-1}}$, when the default calcite rhombohedra are almost exclusively obtained. This observation indicates that a high local polycation concentration should be present for the aragonite nucleation (see Supporting Information). Regardless, this ring of nanocrystals, once nucleated, propagates by growth to a distance of about 20 μm from the glass wall until the single components lose vectorial alignment and fold up to the head of the aragonite superstructure.

The lower the polymer concentration, the fewer the nucleation sites, so that the most developed and diversified structures are indeed formed at the extremely low concentration of $0.1 \mathrm{~mg\,L^{-1}}$ (0.1 ppm), a reactant concentration well

Communications

below usual values chosen to modify a physicochemical process. The fact that the aragonite superstructures nucleate on the glass walls indicates that the amphoteric microgels with a cationic outer layer indeed interact with the negatively charged glass wall. This interaction was confirmed by SEM investigations (see Supporting Information). Indeed, the triblock particles were still found to be attached to the glass surface after immersion of the glass slide in the 0.01M CaCl$_2$ solution and extensive washing.

In conclusion, it has been shown that it is possible to generate aragonite crystals by the gas-diffusion technique under ambient pressure and temperature. As the employed amphoteric polymer microgels only act as a highly selective nucleation and polymorph control agent, and are already active at the lowest concentrations (0.1 mg L^{-1}, 0.1 ppm), the resulting aragonite particles are practically free from organic contaminants and can potentially be used as they are.

Furthermore, all the structures are found to adopt a structurally well-defined, highly reproducible, "sheaf bundle" morphology. This shows that propagation of a structurally confined nucleation on the micrometer scale (a ring of radially aligned aragonite nanocrystals) can lead to control of crystals with high structural complexity, even without the action of geometric confinements, templates, and outer force fields. The formed superstructures are stable against recrystallization for at least two weeks even in contact with water, thus indicating the stability of the formed aragonite in this special morphology, which is in contrast to literature reports on aragonite stability in water.[6,7] This stability could arise from the observed outer ACC layer (Figure 3) preventing the aragonite–water contact. The unexpected stability of the ACC layer in water is the subject of ongoing investigations. However, this ACC layer does not seem to perfectly protect the aragonite crystals as deduced from the observation that a single microgel particle is able to nucleate a whole trunk of apparently unconnected aragonite crystals (Figure 2). As calcite is observed as the default solution-nucleated product (Figure 1a) and there is no additional polymer available beside the microgel templates, the exclusive formation of aragonite in the complex superstructures (Figure 2) could not be explained unless a crystallographic bridge is present between the individual particles. Such a bridge extending throughout the ACC layer could then act as a nucleation site for the formation of another aragonite particle by mesoscopic transformation of ACC precursors.[26] This result means that the whole particle superstructure is crystallographically connected, thus giving a possible explanation for the finding in biomineralization that very minute amounts of additive can influence a much larger amount of inorganic crystals. The present synthetic block copolymer microgels are indeed able to selectively nucleate aragonite at 0.1 ppm at ambient conditions in water. In summary, our study reveals three important and novel points: an easy biomimetic set-up to obtain aragonite with only a negligible concentration of polymer, the presence of an ACC layer never observed before around each single crystal block of the bundle, and the probable influence of the tertiary amine in this example as opposed to acidic molecules which are normally discussed as effective crystallization additives.

Experimental Section

CaCO$_3$ synthesis: Calcium carbonate polycrystals were grown by diffusion of carbon dioxide into calcium chloride solutions according to the gas diffusion method by thermal decomposition of ammonium carbonate. Experiments were performed at room temperature ($22 \pm 1\,°C$). Two flasks containing 0.01M calcium chloride solutions (20 mL) mixed with different concentrations of DHBC particles (10^{-4}, 10^{-3}, 10^{-2}, 0.1, and 1 mg mL^{-1}) and fresh ammonium carbonate (2 g) were placed into a closed chamber (1000 cm^3). The aqueous solutions of CaCl$_2$ were prepared in doubly distilled water and bubbled with N$_2$ overnight before use. The decomposition of ammonium carbonate produced ammonia and carbon dioxide diffusing through 5 needle-holes pierced into the parafilm cover of the flasks. The initial solution was slightly acidic (pH 5.8) but the pH value rose to 9.5 because of the dissolved NH$_3$. After completion of mineral deposition (12 days), the sample was removed from solution, rinsed with filtered water and ethanol, then air-dried.

Polymer synthesis: After preparation by aqueous heterophase polymerization, cleaning by ultrafiltration, and isolating by freeze drying, the solid could easily be dispersed into water.[19]

Crystal characterizations: The crystals were washed with distilled water then ethanol and dried in air for further characterization. Powder X-ray diffraction (XRD) patterns were recorded on a PDS 120 diffractometer (Nonius GmbH, Solingen) with Cu$_{K\alpha}$ radiation. The SEM measurements were performed on a LEO 1550–GEMINI with gold-coated samples. FT-IR spectra were recorded either on a Nicolet Impact 400 or a BioRad FTS6000 spectrometer. For TEM studies one or more drops of the solution of the nanoparticles dispersed in ethanol were deposited on an amorphous carbon film. A Phillips CM200 FEG microscope, 200 kV, equipped with a field emission gun was used. The coefficient of spherical aberration was $C_s = 1.35$ nm. The average particle diameter was determined by dynamic light scattering methods with a NICOMP particle sizer (model 370, NICOMP particle sizing systems, Santa Barbara, California, USA) as well as with a commercial goniometer with a digital correlator (both ALV, Langen, Germany) and a helium–neon laser (Polytec, Waldbronn, Germany) with wavelength $\lambda = 633$ nm. The data evaluation of the correlation functions was based on the computer program CONTIN (Provencher, 1982), which performs an inverse Laplace transformation.

Polymer Films

Reversible Conversion of Conducting Polymer Films from Superhydrophobic to Superhydrophilic**

*Lianbin Xu, Wilfred Chen, Ashok Mulchandani, and Yushan Yan**

Controlling the wettability of a solid surface is important for myriad applications, ranging from self-cleaning surfaces to microfluidics to biomedicine.[1–3] Recently, a variety of smart surfaces with reversibly switchable wettability have been developed. The reversible switching is realized through the adjustment of electrical potential,[4–6] temperature,[7,8] and light illumination,[9–13] adsorption of biopolymer,[14] and treatment of selective solvents.[15,16] Among these approaches, the

switch of the electrical potential receives special attention because it is simple and conveniently controlled by electricity. Moreover, the switching is readily individually addressable when an array of small surfaces is involved. Lahann et al.[4] constructed a reversibly switching surface by depositing a low-density carboxylate-terminated self-assembled monolayer on a gold surface. Electrical potential was used to trigger the conformational transition of the monolayer, resulting in switching of the surface wettability. However, the change in surface wettability is small (20 to 30° water contact angle), which is likely to limit its practical applications. It is reported that ZnO films[11,12] and poly(*N*-isopropylacrylamide)-modified patterned surfaces[7] can undergo reversible wettability switching between two extremes, superhydrophobicity (water contact angle > 150°) and superhydrophilicity (water contact angle < 5°) through the use of ultraviolet light and a temperature change, respectively. The photoswitching requires several days to achieve the hydrophilic-to-hydrophobic conversion, and both the photoswitching and thermal switching are difficult to implement to individually address an array of small surfaces. Herein we report a simple electrochemical process to fabricate superhydrophobic conducting polypyrrole (PPy) films and demonstrate that their properties can be switched conveniently from superhydrophobic to superhydrophilic by changing the electrical potential.

Conducting polymers (also called conjugated polymers or synthetic metals) such as polypyrrole (PPy) have been studied in great detail because their unique optical, electrical, and mechanical properties offer many new possibilities for device fabrication.[17,18] Interest has recently developed in their surface properties such as wettability because of potential applications in corrosion protection,[19] conductive textiles,[20] and antistatic coatings,[21] and in the immobilization of biopolymers[22] and growth control of living cells.[23] Usually the conducting polymers contain a positively charged conjugated backbone and negatively charged counterions (dopants). The wettability of conducting polymers depends greatly on the types of dopants used.[22] For example, a PPy film containing a perfluorinated dopant exhibited hydrophobicity (water contact angle > 90°), while ClO_4^--doped PPy was hydrophilic.[21] Furthermore, the doping level can be controlled by changing the electrical potential, resulting in reversibly switchable surface wettability.[23,24] Scheme 1
Scheme 1. $A^- =$ anion.

shows the reversible switching process between the doped (oxidized) state and dedoped (neutral) state of PPy. To achieve a large variation in wettability (water contact angle difference ≥ 80°) between the doped and neutral states of conjugated polymers, researchers have focused on fabricating hydrophilic conducting polythiophene and then converting it into hydrophobic neutral polythiophene.[25,26] This study

describes the first synthesis of superhydrophobic conducting polymers and the reversible control of the wettability of conducting polymer films between superhydrophobicity and superhydrophilicity.

Superhydrophobic PPy films were synthesized on a conducting surface such as Au-coated glass by electrochemical polymerization. The electroplating solution contained 0.1M pyrrole, 0.05M tetraethylammonium perfluorooctanesulfonate (TEAPFOS, $Et_4N^+CF_3(CF_2)_7SO_3^-$), and 2.0×10^{-4}M $FeCl_3$ in acetonitrile. The electropolymerization was carried out galvanostatically. Figure 1a is a typical top view obtained
Figure 1. SEM images of PPy films. a) Top view of a large area of the porous film. The pore size ranges from 10–50 μm. b) Top view of a single pore and the surrounding PPy particle assemblies. c) Structure of the pore wall of the porous PPy. The small pores are on the order of 1–4 μm; the diameters of the PPy particles range from 0.5–1 μm. d) Top view of the compact PPy film.

by scanning electron microscopy (SEM) of the as-deposited perfluorooctanesulfonate (PFOS)-doped PPy film. The image reveals an extended porous structure of the PPy film. The pore size ranges from 10 to 50 μm. A magnified image of a single pore shows that the pore wall is also highly porous (Figure 1b). Figure 1c reveals the structure of the pore wall. The smaller pores (compared with the pores in Figure 1a) are on the order of 1–4 μm. The particle assemblies surrounding the smaller pores are composed of submicron PPy particles with diameters of 0.5–1 μm. As will be discussed later, this porous structure with roughness on both coarse and fine scales is most effective in achieving superhydrophobicity and superhydrophilicity.

The tiny amount of Fe in the plating solution plays a key role in the formation of this highly porous structure. When no Fe was in the solution, a compact structure (Figure 1d) was obtained. Fe^{3+} and Fe^{2+} salts have been used as catalysts for the chemical polymerization of conducting polymers such as PPy and polyaniline (PAni), while oxygen, ozone, or H_2O_2 were used as the oxidizing reagent.[27–29] In our system, the formation of the porous PPy film may be attributed to the coexistence of electropolymerization and chemical polymerization processes. Without Fe in the plating solution, the PPy was produced by only electropolymerization and had a compact structure. When Fe^{3+} was included in the solution,

besides the electropolymerization, Fe^{3+}-catalyzed bulk chemical polymerization may also occur (Scheme 2). For the Fe^{3+}-catalyzed polymerization, the tiny amount of Fe^{3+} first oxidizes the pyrrole monomer to give PPy and the Fe^{3+} ions are reduced to Fe^{2+} ions. Then the Fe^{2+} ions are oxidized into

$$Fe^{2+} - e^- \longrightarrow Fe^{3+}$$

Electrochemical oxidation
Scheme 2.

Fe^{3+} by the positive potential and used again to chemically synthesize PPy. Thus, Fe^{3+} acts as a catalyst in the synthesis of PPy. The need to regenerate Fe^{3+} by the electrode is believed to confine the chemical polymerization to the vicinity of the electrode surface, leading to closely coupled electropolymerization and chemical polymerization. And this combined polymerization process promotes the growth of porous and rough PPy film.

Other types of iron salts, such as $FeCl_2$, $Fe(ClO_4)_3$, $Fe(ClO_4)_2$, and $FeSO_4$, can also be used to produce similar PPy structures. To control the rate of chemical polymerization and the import of excess amounts of codopants such as Cl^-, ClO_4^-, and SO_4^{2-}, the concentration of the iron salts is usually kept very low ($< 10^{-3}$M).

As-prepared highly porous PPy films have interesting surface properties. As can be seen from the SEM images (Figure 1a–c), the porous PPy films exhibit both coarse-scale and fine-scale roughness (so-called double-roughness structure), which is a favorable structure for mimicking the lotus-leaf effect for repelling water.[30] When low-surface-energy perfluorooctanesulfonate (PFOS) was used as a dopant in the polymerization, the PPy films showed superhydrophobicity with a static water contact angle as high as $152 \pm 2°$ (Figure 2a left), while the water contact angle of the compact smooth PPy film was about $105 \pm 2°$ (Figure 2b left). It is well-known that surface roughness amplifies hydrophobicity.[31–33] The common way to obtain superhydrophobicity is to modify a rough surface with low-surface-energy materials such as perfluorinated materials, or to produce a rough structure on a hydrophobic surface. The advancing (θ_A) and receding (θ_R) contact angles of the superhydrophobic surface were measured to be $155 \pm 2°$ and $147 \pm 2°$, respectively. The low contact angle hysteresis ($\sim 8°$) of water on the PPy surface confirms the lotus effect which results from the double-roughness structure of the porous PPy films. Our method offers a simple, one-step process to fabricate conducting
Figure 2. Electrical-potential-induced wettability conversion between PFOS-doped (oxidized) PPy films and dedoped (neutral) PPy films. Under negative potential (−0.6 V vs. Ag/AgCl), the oxidized PPy films were reduced to neutral PPy films, and under positive potential (1.0 V vs. Ag/AgCl), the neutral PPy films were again oxidized to oxidized PPy films. The conversion is reversible. a) The profile of a water drop on a highly porous PPy film. Oxidized PPy film shows superhydrophobicity with a water contact angle of $152 \pm 2°$ (left); neutral PPy film shows superhydrophilicity with a water contact angle of $\approx 0°$ (right). b) The profile of a water drop on a compact PPy film. Oxidized PPy film is hydrophobic with a water contact angle of $105 \pm 2°$ (left); neutral PPy film is hydrophilic with a water contact angle of $48 \pm 2°$ (right).

polymers with superhydrophobicity. The superhydrophobic PPy films can be deposited on common conducting substrates such as metals and indium tin oxide (ITO)-coated glasses. Our experiments revealed that the superhydrophobic PPy films adhered well to the Au-coated glass surface, and they can be easily peeled off for convenient transfer to other substrates.

Conducting polymers like PPy can be reduced and oxidized reversibly by controlling the electrochemical potential. It is expected that the oxidized (doped) PPy and neutral (dedoped) PPy show different wettability. Neutral PPy, which contains pyrrole moieties, is usually slightly hydrophilic. Surface roughness enhances both the hydrophilicity of hydrophilic surfaces and the hydrophobicity of hydrophobic ones. When we held the PFOS-doped PPy in a 0.05 M solution of TEAPFOS in acetonitrile at a negative potential (−0.6 V vs. Ag/AgCl reference electrode) for 20 minutes, the superhydrophobic PPy film was converted to neutral PPy film, which exhibits a water contact angle of about 0°, indicating that a superhydrophilic PPy surface was achieved (Figure 2a). The superhydrophilicity results from the imbibition of water into the texture of neutral PPy films with high roughness and a hydrophilic nature (see Supporting Information). Under similar switching conditions, the compact PPy film changed to a neutral one having a contact angle of $48 \pm 2°$ (Figure 2b). When we held the superhydrophilic (neutral PPy) film in a 0.05 M solution of TEAPFOS in acetonitrile at a positive potential (1.0 V vs. Ag/AgCl reference electrode) for 20 minutes, the superhydrophobic (oxidized PPy) surface was regenerated. Through controlling the electrochemical potential, PPy films were changed between the oxidized state and neutral state repeatedly, resulting in a reversibly switchable superhydrophobic and superhydrophilic surface (Figure 3).

The neutral and oxidized PPy films are different not only in their surface properties but also in their chemical composition, electronic structure, color, conductivity, and volume. Energy dispersive X-ray (EDX) spectra reveal that little PFOS dopant exists in the neutral PPy films but significant amounts are found in the oxidized ones. Neutral PPy films are
Figure 3. Reversible superhydrophobic-to-superhydrophilic conversion of the porous PPy films through applying alternative negative potential (−0.6 V vs. Ag/AgCl) and positive potential (1.0 V vs. Ag/AgCl). $\theta =$ contact angle.

brown, while the PFOS-doped PPy films are black. The major UV/Vis absorption band of the PPy film is blue-shifted from 460 nm (2.7 eV in energy) for the PFOS-doped PPy film to 395 nm (3.1 eV in energy) for the neutral one. The conductivities of the PFOS-doped PPy film and the neutral film are around $50 \, \text{S cm}^{-1}$ and $0.02 \, \text{S cm}^{-1}$, respectively. (A trace amount of the PFOS dopant still exists in the neutral film.) The volume (the pores and submicron PPy particles) of the PPy film retracted after the oxidized PPy was reduced to neutral PPy.

In summary, we have demonstrated a simple facile electropolymerization of superhydrophobic PPy films and the reversible switching of the PPy films between superhydrophobicity and superhydrophilicity. The PPy films exhibit an extended porous structure. These highly porous conducting polymers may have unique surface properties. Though we used pyrrole monomer and PFOS dopant in our synthesis, it is expected that our method can be extended to prepare other types of conducting polymers such as polythiophene, polyaniline, and poly(N-methyl pyrrole), and polypyrrole with other types of dopants. The reversible superhydrophobic-to-superhydrophilic switching of the PPy films is achieved by simply adjusting the electrical potential. These smart films may find numerous applications, for example, in drug delivery, biochips, microfluidics (e.g., switches and pumps), and biosensors. In addition to the wettability switching, the volume, conductivity, and color of the PPy films also undergo reversible conversion, making it possible to construct multifunctional conducting polymer devices combining special mechanical, electrical, optical, and interfacial properties.

Experimental Section

Synthesis of superhydrophobic polypyrrole films: The electrochemical cell, which consisted of a glass tube 3 cm in diameter that terminated in a 1.6-cm^2 "O" ring seal, was placed on top of the conducting substrate (such as Au-coated glass slides, steel foils, and ITO-coated glass slides) and held in place with a clamp. The electroplating solution, which contained 0.1 M pyrrole, 0.05 M tetraethylammonium perfluorooctanesulfonate (TEAPFOS), and 2.0×10^{-4} M FeCl$_3$ in acetonitrile, was then added to the cell, and conducting polypyrrole (PPy) was plated at a constant current of $\approx 0.25 \, \text{mA cm}^{-2}$

Communications

in an argon atmosphere using a Solartron 1287 A potentiostat/galvanostat. Pt wire and Ag/AgCl electrode (sat. KCl) were used as the counter electrode and reference electrode, respectively. The time for the polymerization was usually 1 h. After polymerization, the PPy films were washed in acetonitrile and then dried under a flow of argon.

Switching experiments: The device for the switching experiments was the same as that used for the synthesis of the PPy films. The solution for switching contained 0.05 M TEAPFOS in acetonitrile. By holding the PFOS-doped (oxidized) PPy films in the solution at a negative potential (−0.6 V vs. Ag/AgCl reference electrode) for 20 min, the oxidized PPy was converted to neutral PPy. Neutral PPy films were then washed in acetonitrile and dried under a flow of argon. By holding the neutral PPy films in the solution at a positive potential (1.0 V vs. Ag/AgCl reference electrode) for 20 min, the neutral PPy was converted to oxidized (PFOS-doped) PPy. Oxidized PPy films were then washed in acetonitrile and dried under a flow of argon. The switching experiments can be conducted repeatedly on the same sample.

Characterization: SEM images and EDX spectra were obtained on an XL30 FEG scanning electron microscope. Contact angle measurements were performed using a VCA Optima contact angle instrument at ambient temperature (AST Products, Inc.). The water droplets used for measurements had a volume of 3.0 μL. Dynamic advancing (θ_A) and receding (θ_R) contact angles were recorded as water was added to and withdrawn from the water droplet, respectively. The conductivity of the samples in the plane direction was determined by a standard four-probe method. UV/Vis absorption spectra of PPy films were recorded on Varian Cary 50 UV/Vis spectrophotometers (190–1000 nm).

Nanolithography

Nanoarrays of Single Virus Particles**

*Rafael A. Vega, Daniel Maspoch, Khalid Salaita, and Chad A. Mirkin**

Microarray technology has led to significant advances in many areas of medical and biological research,[1] opening up avenues for the combinatorial screening and identification of single-nucleotide polymorphisms (SNPs),[2] high-sensitivity expression profiling of proteins,[3,4] and high-throughput analysis of protein function.[5] With the advent of high-resolution direct-write lithographic methods such as dip-pen nanolithography (DPN),[6] it is possible to conceive of methods for miniaturizing such structures to the nanometer-length scale.[7–9] Such massive miniaturization provides the clear potential advantages of larger, denser libraries for screening complex chemical and biological systems. However, miniaturization on this size scale also provides the potential to site-isolate nano- and microscale biological entities (proteins, viruses, and cells) at the single-particle level. Once this can be done routinely for many different systems, new opportunities will be available to the biochemical and biomedical research communities to study such entities individually rather than collectively. Herein, we describe a novel strategy that uses DPN in combination with coordination chemistry to precisely immobilize and position many individual virus particles in the context of large arrays. Tobacco mosaic virus (TMV) was chosen as the test case scenario because of its anisotropic tubular structure (length ≈ 300 nm, diameter $= 18$ nm), size, stability, and well-characterized carboxylate-rich surface.[10] It serves as an excellent model system to evaluate how DPN can be used to control the positioning and orientation of nanoscale virus particles within an extended array.

Prior to this study, advances were made in immobilizing virus particles on templates created by DPN and μ-contact printing.[11,12] Thus far, there has been no demonstration of the ability to chemically control the position of the immobilized virus structures at the single-particle level. This is partially the result of limited resolution, the size of the particles interrogated, and the chemistry used to immobilize them. Indeed, previous efforts focused on the genetic modification of a virus particle to present unnatural surface binding functionality to

the patterned interface.[11,12] This strategy has allowed researchers to prepare arrays of collections of virus particles at individual feature sites, but not to site-isolate individual particles. The approach used herein relies on the ability of metal ions (Zn^{2+}) to bridge a surface patterned with features made of 16-thiohexadecanoic acid (MHA) and the TMV with its carboxylate-rich surface.

Virus nanoarrays were fabricated by initially generating chemical templates of MHA on a gold thin film by using DPN (Scheme 1). The regions surrounding these features were
Scheme 1. Selective immobilization of single virus particles on DPN-generated MHA nanotemplates treated with $Zn(NO_3)_2 \cdot 6H_2O$.

passivated with a monolayer of 11-thioundecyl-penta(ethylene glycol) (PEG-SH) by immersing the substrate in an alkanethiol solution (5 mM in ethanol) for 30 min followed by copious rinsing with ethanol. The passivation layer minimizes nonspecific binding of the virus particles to the unpatterned areas. The carboxylic acid groups of MHA were coordinated to Zn^{2+} ions (represented as spheres) by exposing the substrate to a solution of $Zn(NO_3)_2 \cdot 6H_2O$ (5 mM in ethanol) for one hour followed by rinsing with ethanol to remove any unbound metal ions from the surface. The metallated substrate was then exposed to TMV (100 μg mL^{-1}, American Type Culture Collections) in phosphate-buffered saline (PBS, 10 mM with NaCl (0.15 M), pH 7) for 24 h at room temperature in an air-tight humidity chamber. Excess virus particles were removed by washing the substrates with highly purified (NANOpure) water. The cleaned substrates were then dried under a stream of N_2. All virus arrays were characterized by tapping mode AFM (TMAFM), and the chemical identity of the surface-immobilized virus particles was confirmed by treatment with a highly specific antiserum (American Type Culture Collections) against TMV, which upon binding increases the height of each virus particle (see below).

A series of DPN-patterned linear nanostructures of MHA with varied dimensions (length × width: 600 × 200 nm^2, 500 × 180 nm^2, 400 × 50 nm^2, and 350 × 110 nm^2) were systematically studied to determine the optimal feature size for single virus particle attachment. Under the conditions studied, MHA templates with feature dimensions of 350 × 110 nm^2 spaced one micrometer apart were ideal for individual particle assembly. The tendency of each virus to occupy the largest number of coordination sites results in near-perfect alignment

of all the virus particles along the long axis of each rectangular template (Figure 1 a,b). The average height of each feature on the template is 16 ± 1 nm. Furthermore, each virus particle on the lines is 45 ± 2 nm wide and 320 ± 40 nm long (measured at the base, disregarding tip convolution), parameters consistent

Figure 1. AFM tapping mode (silicon cantilever, spring constant ≈ 40 N m^{-1}) images and height profiles of TMV nanoarrays: a) 3D topographical images of pairs of virus particles within larger arrays: a parallel array (left), a perpendicular array (middle), and dot arrays (right); b) topography images and height profiles of a perpendicular array of single virus particles (40×40 µm^2); c) topography image and height profiles of a TMV nanoarray (20×20 µm^2) formed on an array of MHA dot features ($\varnothing = 350$ nm) pretreated with Zn(NO$_3$)$_2$·6 H$_2$O. All images were collected at a scan rate of 0.5 Hz.

with the presence of only one TMV particle on each MHA feature.[13] The dimensions of the features within the array are critical for virus particle site-isolation. For example, rectangular templates greater than 500 nm long or 200 nm wide yield multiple yet oriented viruses at each site, thus preventing the formation of a single virus particle array (see Supporting Information). Features significantly smaller (less than 300×100 nm^2) do not result in uniform assembly of the virus particles; numerous sites remain unoccupied.

The chemical templates can also be used to control the assembly of the flexible virus into unnatural conformations such as circles and other curved architectures. For example, dot templates 350 nm in diameter can capture multiple virus particles, many of which adhere to the rim of the dot and adopt a curved shape (Figure 1 c). Curved TMV structures have been made previously, but through mechanical manipulation of the virus.[14] This approach to virus bending is different from the templated chemical approach described herein.

To demonstrate that the virus orientation is not the result of external variables such as washing, drying with N$_2$, or capillary effects, the independent organization of each virus

particle was tested by immobilization along two different directions within one array. Indeed, the use of an MHA template consisting of 350×110 nm^2 features perpendicular to each other produced an array of site-isolated single TMV virus particles perpendicular to each other (Figure 1 b).

Polarization modulation infrared reflection absorption spectroscopy (PM-IRRAS) was used to characterize bulk gold thin-film substrates modified with TMV by using the same coordination chemistry approach used to generate the TMV arrays (Figure 2 a). The MHA monolayer exhibits two main bands in the high-frequency CH$_2$ stretch region at 2856 and 2930 cm^{-1} and two in the C=O stretch region at 1741 and 1718 cm^{-1}, which are attributed to the presence of free and hydrogen-bonded carboxylic groups,[15] respectively. After the substrate was immersed in an ethanolic solution of Zn(NO$_3$)$_2$·6 H$_2$O (5 mM) for 1 h, the coordination of MHA carboxylic groups to Zn^{2+} metal ions was confirmed by Λ_{CO} band shifts to lower energy ($\tilde{v} =$ 1602/1556 and 1453 cm^{-1}). The C=O stretch region changes again after exposing the MHA–Zn^{2+} surface to the TMV solution. Three main bands are detected in this spectral region that can be identified as the amide I band centered at 1661 cm^{-1} (which is characteristic of proteins in TMV[16]), the amide II and asymmetric COO$^-$ bands centered at 1546 cm^{-1}, and a symmetric COO$^-$ band at 1458 cm^{-1}. Also, the presence of CH$_3$ features,

Figure 2. a) PM-IRRAS spectra of a monolayer of MHA on Au (bottom spectrum), after treatment with Zn(NO$_3$)$_2$·6 H$_2$O (middle spectrum), and subsequent incubation with TMV (top spectrum). b) Topography image and height profile of an MHA array treated with the antiserum against TMV. The antibodies are electrostatically attached to the MHA features. Topography images and height profiles of a pair of parallel single virus particles c) before and d) after treatment with a PBS solution containing the antiserum against TMV. All AFM images were taken at a scan rate of 0.5 Hz in tapping mode.

attributed to proteins with methyl groups, is confirmed by the emergence of a new band at 2967 cm^{-1} after incubation with TMV.

The coordination chemistry of Zn^{2+} is essential for the virus particle assembly process. The results of control experiments support this conclusion, as TMV does not assemble on MHA coated or patterned substrates (dot diameter = 1 μm), even after exposure of the template to the virus in a PBS solution for 48 h.

To provide further evidence for the chemical identity of the tubular virus structures imaged by AFM, the single virus arrays were treated with a PBS solution containing an antiserum against TMV (200 μg mL^{-1}, pH 7) at 37 °C for 30 minutes. The substrates were rinsed with PBS and then dried under a stream of N$_2$. A comparison of the AFM images of the substrate before and after incubation with antibody shows a height increase of approximately 9 nm (Figure 2c,d). This increase is consistent with the height of the antibody (Figure 2b) and therefore, the presence of TMV particles on the arrays.[17] Note that the expected height increase upon antibody binding was independently modeled and measured by using direct adsorption of the antibody onto an MHA array (Figure 2b). This approach has been used to study protein binding events in the context of other protein immobilization experiments.[8]

In conclusion, we report a versatile coordination-chemistry-based approach for the immobilization of TMV virus particles on surfaces and show that through the use of DPN and small features, it is possible to isolate and control the orientation of these virus particles. Many virus particles have metal-binding groups for Zn^{2+} and other ions in their protein coats.[18] Therefore, it is likely that this approach can be generalized for manipulating many virus structure classes at the single-particle level. Such capabilities will expand the scope of application for virus structures in fields ranging from biology to molecular electronics,[19] in which such control opens new opportunities for research that cannot be addressed with microarrays or bulk systems.

Experimental Section

All DPN patterning was done with a CP AFM (ThermoMicroscopes) interfaced with commercialized lithographic software (DPNwrite, NanoInk Inc., Chicago, IL) and conventional Si$_3$N$_4$ cantilevers (ThermoMicroscopes-sharpened Microcantilever A, force constant = 0.05 N m^{-1}). Tapping mode images were taken with a Nanoscope IIIa and MultiMode microscope (Digital Instruments). Unless noted otherwise, all DPN patterning experiments were conducted at 35% relative humidity and 24 °C with a tip–substrate contact force of 0.5 nN. DPN was used to pattern MHA on gold substrate (50 nm Au and 10 nm Cr on a silicon wafer, Silicon Sense, Inc.). PM-IRRAS spectra of 2048 scans at a resolution of 4 cm^{-1} were obtained with a Thermo Nicolet Nexus 870 with tabletop optics module (TOM) (courtesy of the Keck II Center at Northwestern University). The PM-IRRAS differential reflectance (%$\Delta R/R$) values were converted into absorbance units for comparison with conventional IRRAS data.

Communications

Preparation of Heterobimetallic Oxide–Hydroxide–Hydrogensulfides [LAl(OH)(μ-O)MCp₂(SH)] (M = Ti, Zr)**

*Vojtech Jancik and Herbert W. Roesky**

Dedicated to Professor Thomas B. Rauchfuss

Recently we reported the preparation of heterobimetallic sulfides that contained aluminum atoms [LAl(μ-S)₂MCp₂] (M = Ti, **1**; M = Zr, **2**; L = HC[C(Me)N(2,6-iPr₂C₆H₃)]₂; Cp = C₅H₅).[1] The X-ray crystal structural analysis of the titanium compound **1** confirmed the presence of a highly strained {Al(μ-S)₂Ti} four-membered ring (S-Al-S 102.5(1), Al-S-Ti 84.7(1) and 83.6(1), S-Ti-S 89.3(1)°). The ring strain and the short Al···Ti separation (3.118 Å) prompted us to examine the reactivity of **1** and **2** with water in expectation of a nucleophilic attack that would lead to the opening of the ring and to the isolation of compounds containing the {LAl(EH)(μ-E)M(EH)Cp₂} framework (E = O or S depending on the degree of hydrolysis). Such species could serve as unique precursors for the preparation of trimetallic systems comparable with the alumoxane [(μ-O)[LAl(μ-O)]₂AlMe], which is prepared from [(μ-O)[LAl(OH)]₂] and AlMe₂H.[2] Although a few dinuclear systems that contain the {M′(EH)-(μ-E)M(EH)} arrangement have been described (M′ = Al,[2] Fe,[3a] Ge,[3b,c] In,[3d] Re,[3e] Ru,[3f] Sn,[3g] V,[3h] Zr[3i]) none has been structurally characterized that contains two different metal atoms stabilized by organic ligands.

The addition of two equivalents of water to a solution of **1** or **2** in THF at room temperature led, after overnight stirring, to the precipitation of a crystalline material. H₂S was identified as a by-product. The solid product was filtered off, dried in vacuo, and isolated as pale brown (Ti) or pale yellow (Zr) microcrystals. The ¹H NMR spectroscopic, EI mass spectrometric, and X-ray crystal structural analysis of these products confirmed that the ring-opening reaction had occurred, but revealed the presence of two derivatives in the samples. The major component (about 85 %) was identified as [LAl(OH)(μ-O)MCp₂(SH)] (M = Ti, **3**; M = Zr, **4**) whereas the minor component (about 15 %) was the intermediate of the hydrolysis, [LAl(SH)(μ-O)MCp₂(SH)]. One of the first steps of the hydrolytic ring opening is the formation of an unobserved intermediate [LAl(OH)(μ-S)MCp₂(SH)], which subsequently rearranges into [LAl(SH)(μ-O)MCp₂(SH)].

The driving force for this intramolecular rearrangement is the high oxophilicity of the metal centers and the higher stability of the {Al-O-Ti} frame compared to {Al-S-Ti}.[4] Compound [LAl(SH)(μ-O)MCp₂(SH)] reacts with a second equivalent of water with elimination of H₂S to form **3** or **4** (Scheme 1).
Scheme 1. Preparation of compounds **3** and **4**.

After elucidating the course of the hydrolysis, we focused on the optimization of the hydrolysis conditions. The presence of the intermediates in the final product can be explained by the low solubility of the bridged species in THF and their crystallization from the mother liquor before the reaction was complete. Thus, the use of THF/CH₂Cl₂ (1:1) in the reaction mixture led to the formation of pure **3** or **4**. It is surprising that in these reactions, the Al–S bond is more reactive than the M–S bond. [LAl(SH)₂] reacts smoothly with two equivalents of water to give [LAl(OH)₂] with elimination of H₂S,[5] but the reaction is relatively slow and needs at least 20 minutes to reach completion at room temperature. It was reported that even traces of moisture in systems that contain Ti–S or Zr–S bonds lead to fast hydrolysis of these bonds.[6] As reported earlier, the alumoxane [{LAl(OH)}₂O][2] is stable, whereas [LAl(OH)₂] decomposes even under an inert atmosphere.[7] It seems that the presence of at least one bridging oxygen atom is necessary for the stabilization of the species containing the {AlO₂} unit.

The isomorphous compounds **3** and **4** crystallize in the monoclinic space group $P2_1/n$, with one molecule in the asymmetric unit (Figure 1).[8] We were not able to crystallize pure **4**, thus data for **4** contaminated with about 15 % of the intermediate [LAl(SH)(μ-O)Zr(SH)Cp₂] were used. The OH moiety on the Al atom and the SH groups on the Ti (**3**) and Zr (**4**) atoms adopt a *cis* conformation and are involved in an intramolecular hydrogen bond O–H···S (**3** 2.66 Å; **4** 2.80 Å). The Al–O(H) (**3** 1.726 Å; **4** 1.720 Å) and Al–O(M) (**3** 1.717 Å; **4** 1.713 Å) bond lengths are similar to those in [LAl(OH)₂] (1.711 and 1.695 Å),[9] [{LAl(OH)}₂O] (1.694–1.741 Å),[2] and in the trimeric alumoxane [(μ-O)[LAl(μ-O)]₂(MeAl)] (1.726–1.708 Å),[2] but considerably shorter than those in the μ-OH derivatives (1.787–1.928 Å).[10] The O-Al-O angles (**3** 114.0°; **4** 114.7°) are similar to those of
Figure 1. XP plots at the 50% probability level of **3** (a) and **4** (b; the presence of the reaction intermediate that contains an SH group on the aluminum atom, the proton of which could not be localized, is obvious). Hydrogen atoms except those of the SH and OH groups and the H(3A) protons are omitted for clarity. Selected bond lengths [Å] and angles [°]: **3**: Al(1)-N(1) 1.897(2), Al(1)-N(2) 1.901(2), Al(1)-O(1) 1.726(2), Al(1)-O(2) 1.719(2), O(1)-H(1) 0.85(2), Ti(1)-O(2) 1.820(2), Ti(1)-S(1) 2.482(1), S(1)-H(2) 1.25(3), Ti(1)-X_{Cp1} 2.107(3), Ti(1)-X_{Cp2} 2.098(3); N(1)-Al(1)-N(2) 95.7(1), O(1)-Al(1)-O(2) 114.0(1), Al(1)-O(1)-H(1) 119(3), Al(1)-O(2)-Ti(1) 148.9(1), O(2)-Ti(1)-S(1) 97.3(1), Ti(1)-S(1)-H(2) 100(2), X_{Cp1}-Ti(1)-X_{Cp2} 128.6(2). **4**: Al(1)-N(1) 1.895(2), Al(1)-N(2) 1.898(2), Al(1)-O(1) 1.720(6), Al(1)-S(2) 2.08(1), Al(1)-O(2) 1.713(2), O(1)-H(1) 0.85(2), Zr(1)-O(1) 1.939(2), Zr(1)-S(1) 2.573(1), S(1)-H(2) 1.19(3), Zr(1)-X_{Cp1} 2.237(3), Zr(1)-X_{Cp2} 2.240(3); N(1)-Al(1)-N(2) 96.1(1), O(1)-Al(1)-O(2) 114.7(1), O(2)-Al(1)-S(2) 112.2(4), Al(1)-O(1)-H(1) 122(3), Zr(1)-S(1)-H(1) 100(2), Al(1)-O(2)-Zr(1) 147.2(1), O(2)-Zr(1)-S(1) 98.7(1), X_{Cp1}-Zr(1)-X_{Cp2} 128.0(2).

[LAl(OH)$_2$], [{LAl(OH)}$_2$O], and [(μ-O)[LAl(μ-O)]$_2$-(MeAl)] (108.3–115.3°);[2,9] the Al-O-M angles are 148.9° for **3** and 147.2° for **4**. The Ti–O (1.820 Å) and Ti–S (2.482 Å) bond lengths and the O-Ti-S angle (97.3°) are similar to those reported for other [Cp$_2$TiOS] fragments: Ti–O 1.845–1.872 Å; Ti–S 2.314–2.467 Å; O-Ti-S 87.7–97.9°.[11] Furthermore, in the zirconium derivative the Zr–O (1.939 Å) and Zr–S (2.573 Å) bond lengths and the O-Zr-S angle (98.7 Å) are similar to those reported previously for species that contain the {Cp$_2$ZrOS} moiety: Zr–S 2.459–2.554 Å; Zr–O 1.941–2.199 Å; O-Zr-S 92.6–103.3°.[6b, 12]

In summary, the heterobimetallic sulfides [LAl(μ-S)$_2$-MCp$_2$] are ideal precursors for the preparation of the heterobimetallic oxide–hydroxide–hydrogensulfides **3** and **4** by hydrolysis. The presence of two free reactive functionalities in a *cis* arrangement makes them potential starting materials for the heterotrimetallic oxide–sulfides. Such reactions are the subject of our ongoing research.

Experimental Section

All manipulations were performed under a dry and oxygen-free atmosphere (N$_2$ or Ar) by using Schlenk-line and glovebox techniques.

3: H$_2$O (26 μL, 1.46 mmol) was added quickly to a solution of **1** (0.50 g, 0.73 mmol) in THF/CH$_2$Cl$_2$ (45 mL, 1:1) at room temperature. The suspension was stirred for 10 h and filtered. All the volatile species were removed under vacuum to leave a brown solid residue, which was treated twice with cold toluene (5 mL). After filtration and drying in vacuo, **3** was obtained as a light brown powder. Yield 0.31 g (60%); m.p.: 227°C (decomp); ^{1}H NMR (500.13 MHz, CDCl$_3$, 25°C, TMS): δ = 1.07 (s, 1H, OH), 1.10 (d, $^3J_{H\text{-}H}$ = 6.9 Hz, 6H, CH(CH$_3$)$_2$),

1.20 (d, $^3J_{H\text{-}H}$ = 6.7 Hz, 6H, CH(CH$_3$)$_2$), 1.37 (d, $^3J_{H\text{-}H}$ = 6.9 Hz, 6H, CH(CH$_3$)$_2$), 1.44 (d, $^3J_{H\text{-}H}$ = 6.7 Hz, 6H, CH(CH$_3$)$_2$), 1.77 (s, 6H, CH$_3$), 2.08 (s, 1H, SH), 3.03 (sept, $^3J_{H\text{-}H}$ = 6.9 Hz, 2H, CH(CH$_3$)$_2$), 3.49 (sept, $^3J_{H\text{-}H}$ = 6.7 Hz, 2H, CH(CH$_3$)$_2$), 5.20 (s, 1H, γ-CH), 5.36 (s, 10H, Cp–H), 7.04–7.20 ppm (m, 6H, *m*-, *p*-Ar–H); ^{13}C NMR (125.77 MHz, CDCl$_3$, 25°C, TMS): δ = 23.6, 24.2, 24.4, 24.7 (CH(CH$_3$)$_2$), 26.1, 27.5 (CH(CH$_3$)$_2$), 28.7 (CH$_3$), 97.5 (γ-CH), 113.9 (C of Cp) 124.0, 125.2, 127.3, 140.9, 142.9, 145.6 (*i*-, *o*-, *m*-, *p*-C of Ar), 170.6 ppm (C=N); IR (KBr pellet): $\tilde{v}$ = 3551 br (OH), 2574 vw (SH) cm^{-1}; EI MS (70 eV): *m/z* (%): 623 (10, [*M*−Cp]$^+$), 605 (50, [*M*−Cp−H$_2$O]$^+$); elemental analysis calcd for C$_{39}$H$_{53}$AlN$_2$O$_2$STi (688.78 gmol^{-1}): C 68.0, H 7.8, N 4.1; found: C 67.5, H 8.0, N 4.2%.

4: The synthesis of **4** was similar to that of **3**. Compound **4** was obtained from the reaction of H$_2$O (25 μL, 1.37 mmol) with **2** (0.50 g, 0.69 mmol) as a pale yellow powder. Yield 0.31 g (62%); m.p.: 235°C (decomp); ^{1}H NMR (500.13 MHz, CDCl$_3$, 25°C, TMS): δ = 0.36 (s, 1H, OH), 1.11 (d, $^3J_{H\text{-}H}$ = 6.8 Hz, 6H, CH(CH$_3$)$_2$), 1.21 (d, $^3J_{H\text{-}H}$ = 6.8 Hz, 6H, CH(CH$_3$)$_2$), 1.38 (d, $^3J_{H\text{-}H}$ = 6.8 Hz, 6H, CH(CH$_3$)$_2$), 1.39 (d, $^3J_{H\text{-}H}$ = 6.8 Hz, 6H, CH(CH$_3$)$_2$), 1.65 (s, 1H, SH), 1.77 (s, 6H, CH$_3$), 3.04 (sept, $^3J_{H\text{-}H}$ = 6.8 Hz, 2H, CH(CH$_3$)$_2$), 3.50 (sept, $^3J_{H\text{-}H}$ = 6.8 Hz, 2H, CH(CH$_3$)$_2$), 5.20 (s, 1H, γ-CH), 5.46 (s, 10H, Cp-H), 7.04–7.20 ppm (m, 6H, *m*-, *p*- Ar-H); ^{13}C NMR (125.77 MHz, CDCl$_3$, 25°C, TMS): δ = 23.5, 24.4, 24.5, 24.6 (CH(CH$_3$)$_2$), 27.5, 28.6 (CH(CH$_3$)$_2$), 28.7 (CH$_3$), 97.4 (γ-CH), 111.8 (C of Cp), 124.0, 125.1, 127.3, 140.6, 143.2, 145.5 (*i*-, *o*-, *m*-, *p*- C of Ar), 170.6 ppm (C=N); IR (KBr pellet): $\tilde{v}$ = 3560 br (OH), 2562 vw (SH) cm^{-1}; EI-MS (70 eV): *m/z* (%): 665 (5, [*M*−Cp]$^+$), 647 (50, [*M*−Cp−H$_2$O]$^+$); elemental analysis calcd for C$_{39}$H$_{53}$AlN$_2$O$_2$SZr (732.12 g·mol^{-1}): C 64.0, H 7.3, N 3.8; found: C 63.5, H 7.4, N 3.9%.

[4] One can argue that the unobserved intermediate could be [LAl(SH)(μ-S)MCp$_2$(OH)], rather than [LAl(OH)(μ-S)MCp$_2$(SH)]. However, the higher stability of the Ti–SH bond towards hydrolysis, the shielding of the Ti center by two Cp rings, and the easy replacement of the Al–SH group by an Al–OH moiety in the next reaction step support our conclusion.

[8] a) Crystal data for **3**: C$_{39}$H$_{53}$AlN$_2$O$_2$STi (688.77), monoclinic, space group $P2_1/n$, $a = 10.903(2)$, $b = 20.543(4)$, $c = 16.222(3)$ Å, $\beta = 99.02(3)°$, $V = 3589(1)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.275$ Mg m^{-3}, F-(000) = 1472, $\lambda = 1.54178$ Å, $T = 100(2)$ K, $\mu(Cu_{K\alpha}) = 3.075$ mm^{-1}. Of the 22938 measured reflections, 5087 were independent ($R_{int} = 0.0495$). The final refinements converged at $R1 = 0.0397$ for $I > 2\sigma(I)$, $wR2 = 0.1125$ for all data. The final difference Fourier synthesis gave a min/max residual electron density of $-0.260/+0.477$ e Å^{-3}; b) crystal data for **4**: C$_{39}$H$_{53}$Al-N$_2$O$_{1.87}$S$_{1.13}$Zr (734.14), monoclinic, space group $P2_1/n$, $a = 11.064(2)$, $b = 20.627(3)$, $c = 16.242(3)$ Å, $\beta = 97.76(3)°$, $V = 3673(1)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.328$ Mg m^{-3}, $F(000) = 1548$, $\lambda = 1.54178$ Å, $T = 100(2)$ K, $\mu(Cu_{K\alpha}) = 3.548$ mm^{-1}. Of the 15708 measured reflections, 5150 were independent ($R_{int} = 0.0351$). The final refinements converged at $R1 = 0.0291$ for $I > 2\sigma(I)$, $wR2 = 0.0764$ for all data. The final difference Fourier synthesis gave a min/max residual electron density of $-0.447/+0.399$ e Å^{-3}; c) data for the structures were collected on a Bruker three-circle diffractometer equipped with a SMART 6000 CCD detector. Intensity measurements were performed on a rapidly cooled crystal $(0.40 \times 0.30 \times 0.30$ mm$^3)$ in the range $7.00 \leq 2\theta \leq 117.92°$ (**3**) and in the range $6.96 \leq 2\theta \leq 117.94°$ (**4**; $0.10 \times 0.05 \times 0.05$ mm^3). The structures were solved by direct methods (SHELXS-97)[13] and refined against all data by full-matrix least-squares on F^2.[14] All the C—H hydrogen atoms except H(3A) were included in geometrically idealized positions and refined with the riding model. Localization of the H(3A) hydrogen from the electron-density map in both structures proved to be more accurate than its fixing in the idealized position and led to a lowering of the $R1$ and $wR2$ values. The hydrogen atoms of the OH and SH moieties in **3** and **4** were localized from the difference electron-density map and refined isotropically with U_{ij} tied to the parent atom. The Al—SH proton belonging to the [LAl(SH)(μ-O)ZrCp$_2$(SH)] in the crystal of **4** could not be localized due to its low content (about 15%). CCDC-270756 (**3**) and CCDC-270757 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Alkali-Metal-Mediated Zincation of Ferrocene: Synthesis, Structure, and Reactivity of a Lithium Tmp/Zincate Reagent**

Helen R. L. Barley, William Clegg, Sophie H. Dale, Eva Hevia,* Gordon W. Honeyman, Alan R. Kennedy, and Robert E. Mulvey*

Lithium dialkyl tetramethylpiperidino zincates of the general formula "[LiR$_2$Zn(tmp)]" (tmp = 2,2,6,6-tetramethylpiperidine) represent an important subfamily of organozincate reagent. Established only in 1999 through the pioneering work on "[LitBu$_2$Zn(tmp)]" by Kondo et al.,[1] "tmp zincates" have found application as highly chemo- and/or regioselective bases for the metalation of alkyl benzoates and related aza aromatic compounds, bromopyridines, and various halobenzenes.[2,3] Recent reports[4] have highlighted the poverty of structural information available on lithium zincates in general. Tmp zincates are no exception in this regard, with a ^{13}C NMR spectroscopic study of "[LitBu$_2$Zn(tmp)]" in solution[1] providing the only morsel of structural evidence

gathered hitherto. Elucidation of the structures of zincate reagents and the intermediates formed in deprotonative zincation processes would enhance our understanding of zincate chemistry; not least in the case of tmp zincates, which because of their heteroleptic formulation can act as alkyl, amido, or dual alkyl/amido bases. Previously, we reported a series of mixed alkali-metal/magnesium amides, a number of which are tmp magnesiates.[5] This magnesium-based research uncovered several remarkable mixed-metal-induced synergic effects, which most notably lead to "inverse-crown" ring compounds.[6] The likelihood that mixed alkali-metal/zinc amides would exhibit similar synergic behavior provided a further incentive to extend our studies to the tmp zincates. Thus, we introduce herein the lithium tmp/zincate reagent [(tmeda)Li(μ-nBu)(μ-tmp)Zn(nBu)] (**1**; tmeda = N,N,N',N'-tetramethylethylenediamine) and break new ground with a report of its structure and the structure of two zincated intermediates generated when **1** is used to selectively (mono)deprotonate ferrocene (Fc) in the first example of direct zincation of a metallocene.

It is surprising that prior to this investigation nBu_2Zn had not been subjected to a transformation to prepare a tmp zincate system given that both the parent organozinc reagent[7] and its homoleptic zincate derivative "[LinBu_3Zn]"[8] have reasonably well developed chemistries. In the event, the transformation proved straightforward by applying the same method of addition as that used previously to prepare "[LitBu_2Zn(tmp)]";[1] however, the bulk solvent was changed from polar THF to nonpolar hexane and then the reaction was completed with the introduction of a stoichiometric amount of the donor solvent, TMEDA, in a deliberate attempt to afford a crystalline zincate [Eq. (1)].[9]

$$Li(tmp) + nBu_2Zn + TMEDA \xrightarrow{hexane} [LinBu_2Zn(tmp)(tmeda)] \quad (1)$$
The new zincate **1** was produced as colorless crystals (65% yield of the isolated product). NMR (^1H, ^7Li, and ^{13}C) spectroscopic characterization of these crystals in a solution of deuterated benzene established the co-complexed nature of **1**, as revealed most diagnostically in the chemical shift of the $M-CH_2$ resonance of the M-nBu linkage. This signal appears at $\delta = 0.24$ ppm in **1** relative to $\delta = 0.27$, -0.23, and -0.83 ppm in nBu_2Zn, "[LinBu_3Zn]", and nBuLi, respectively, thus suggesting that the nBu group in the new mixed-metal co-complex retains much of its original "zinc character".

This last point was confirmed when the complete molecular structure of **1** was revealed through an X-ray crystallographic study (Figure 1).[10] Both nBu ligands remain attached to the Zn center, one at a modestly shorter distance than the other (namely, C(5)–Zn: 2.011(2) Å; compare with C(1)–Zn: 2.041(2) Å). The nBu attachment is terminal for the shorter bond; however, the other nBu ligand bridges to the Li center, which explains the slight bond elongation. The Li–C(1) connection is relatively long (2.551(5) Å) relative to corresponding bonds in, for example, [{(LinBu)_4(tmeda)}_∞] (2.131(8)–2.326(8) Å)[11] but markedly shorter than the Li···C separation (2.736 Å) in the hexamethyldisilazido zincate [Li{μ-N(SiMe_3)_2}Zn(CH_2SiMe_3)_2(tmta)] (tmta = trimethylenediamine-N,N,N',N'-tetraacetic acid),[12] which is
Figure 1. Molecular structure of **1**. The hydrogen atoms are omitted for clarity. Only one component is shown for each disordered group. Displacement ellipsoids are shown at the 30% probability level.

considered to have an open rather than a closed cyclic arrangement, such as the {LiNZnC} unit. This weak, but significant, attraction of the Li center to the C(1) center results in a slight pyramidalization of the {LiNNN} coordination sphere (sum of the N-Li-N bond angles: 350.98°) that is made up of μ-tmp and bidentate tmeda ligands. In contrast, the {Zn-N(1)-C(1)-C(5)} coordination is nearly perfectly planar (sum of the bond angles around Zn: 359.98°). Completing the four-membered {LiNZnC} ring, the tmp nitrogen bridge, unlike its nBu carbon bridge counterpart, is much more symmetrical (span lengths: 2.047(4) and 2.0612(18) Å to the Li and Zn centers, respectively).

We explored the reactivity of **1** toward ferrocene under a range of conditions to probe its deprotonative metalation ability in solution. This investigation revealed a complicated sequence of stoichiometry- and time-dependent reactions (Scheme 1). The first detectable (and isolable) metalated product was the lithium-free neutral bis(ferrocenyl) zinc complex [(Fc)_2Zn(tmeda)] (**2**). This orange solid, which precipitated from the reaction mixture within minutes, was characterized by NMR spectroscopy and X-ray crystallography (see below). Its formation is both surprising and significant, as it establishes for the first time that intermediate metalo products from the deprotonative metalation of a substrate by a lithium zincate (prior to any electrophilic workup) are not necessarily zincates themselves (in contrast to what appears to be the case with "[LitBu_2Zn(tmp)]" and related reagents)[1–3] but could possibly be, depending on the conditions, distinct Li and Zn compounds. No lithium-containing products could be isolated from solution at this stage, though investigation of the filtrate following removal of **2** suggested the presence of [Li_2nBu_2Zn(tmp)_2(tmeda)], which exists as an oil when prepared independently from a Li(tmp)/nBu_2Zn/tmeda (2:1:1) mixture. When the reaction is repeated over a longer time (24 h), a small amount of tris(ferrocenyl) zincate separated from the solvent. This product was characterized as the THF adduct [Li(thf)_4][(Fc)_3Zn] (**3**) and is formed in addition to **2**. On repeating the reaction with two equivalents of ferrocene, precipitation of **2** still occurred but the yield of **3** was significantly increased. In support of the
Scheme 1. Reaction of **1** (formed in situ) with ferrocene in hexane to yield both neutral zinc and anionic zincate products.

Figure 2. Molecular structure of **2**. The hydrogen atoms, except those belonging to the ferrocene rings, are omitted for clarity. Displacement ellipsoids are shown at the 30% probability level.

Figure 3. Molecular structure of one anion of **3**. Displacement ellipsoids are shown at the 10% probability level. Only one component of the disorder is shown.

reaction pathway shown in Scheme 1, it was found that pure "[Li$_2$$nBu_2$Zn(tmp)$_2$(tmeda)]" also metalates ferrocene to yield **3**. The first step in the pathway remains an open question as no intermediate could be detected/isolated at this juncture, though logically it is likely to be the hypothetical "[LinBu(Fc)Zn(tmp)]", which must undergo a fast disproportionation reaction to the neutral zinc and the zincate species [(Fc)$_2$Zn(tmeda)] and "[Li$_2$$nBu_2$Zn(tmp)$_2$(tmeda)]", respectively.

Two polymorphs of **2** crystallize from hexane/toluene and hexane/THF solutions to form monoclinic and orthorhombic systems, respectively. Because of the general similarity of these systems, only the former is discussed herein. A simple mononuclear arrangement is revealed,[13] with Zn at the center of a distorted (2 × C; 2 × N) tetrahedron, which is made up of two monodeprotonated ferrocene units and one bidentate tmeda ligand (Figure 2). The Zn center, on a twofold rotation axis, is almost coplanar (0.064 Å deviation) with each of the C$_5$H$_4$ rings to which it is bonded. This structure bears some similarity to [Zn{2-(CH$_2$NMe$_2$)$_2$C$_5$H$_3$FeC$_5$H$_5$}$_2$],[14] though the ligating nitrogen atoms belong to N,N-dimethylaminomethyl side arms on the ferrocenyl framework. However, there is a major synthetic distinction, as the latter compound is not prepared through direct zincation but by a common metathetical approach from ZnCl$_2$ and the analogous ferrocenyllithium. Three crystallographically independent ion pairs that have essentially the same structure make up the asymmetric unit of **3**, together with three uncoordinated THF molecules.[15] The anion is unprecedented, with the Zn center in a distorted trigonal planar (3 × C) arrangement comprising three monodeprotonated ferrocenyl ligands (Figure 3). The countercation, pseudotetrahedral [Li(thf)$_4$]$^+$ ion, is known. The crystal structure shows extensive disorder, thus requiring the use of
synchrotron radiation for data collection and a combination of constraints and restraints in the refinement.

Control reactions have established that the monometallic reagents Li(tmp) and nBu$_2$Zn are both inert towards ferrocene, even in the presence of TMEDA. Therefore the success of the solution of **1** formed in situ in the production of **2** and **3** can be attributed to a mixed-metal synergic effect or, more specifically, to alkali-metal-mediated zincation. Future work will be directed towards pinpointing the active base species in solution that produce such an alkali-metal-mediated zincation of organic substrates.[16,17]

Experimental Section

All reactions were carried out in a protective argon atmosphere.

1: Bu$_2$Zn (5 mL, 1 M solution in hexane, 5 mmol) was added to a suspension of Li(tmp) in hexane (prepared in situ by reaction of BuLi (3.1 mL, 1.6 M solution in hexane, 5 mmol) with TMP(H) (0.85 mL, 5 mmol)). The reaction mixture was stirred for 30 min, thus affording a pale yellow solution. At this stage, TMEDA (0.75 mL, 5 mmol) was introduced. After the solution was stirred for 15 min, it was

concentrated by removal of some solvent in vacuo. Placed in the refrigerator at 0°C, the resulting pale yellow solution deposited a crop of colorless crystals (1.42 g, 64%). ¹H NMR (400 MHz, 25°C, C_6D_6): $\delta = 2.08$ (m, 4H; CH_2 Bu), 1.84 (m, 14H; CH_3 tmeda and H_γ tmp), 1.79 (s 4H; CH_2 tmeda), 1.69 (m, 4H; CH_2 Bu), 1.51 (m, 4H; H_β tmp), 1.21 (m, 18H; 12H of CH_3 tmp and 6H of CH_3 Bu), 0.28 ppm (m, 4H; Zn−CH_2 Bu); ¹³C{¹H} NMR (100.63 MHz, 25°C, C_6D_6): $\delta = 57.70$ (CH_2 tmeda), 53.47(C_α tmp), 47.30 (CH_3 tmeda), 39.04 (C_β tmp), 36.24, 34.28 (CH_3 tmp), 33.53 (CH_2 Bu), 31.44 (CH_2 Bu), 20.41 (C_γ tmp), 16.42 (Zn−CH_2 Bu), 15.15 ppm (CH_3 Bu); ⁷Li NMR (155.50 MHz, 25°C, C_6D_6, reference LiCl in D_2O at 0.00 ppm): $\delta = 0.561$ ppm.

2: Bu_2Zn (1 mL, 1M solution in hexane, 1 mmol) was added to a solution of Li(tmp) in hexane (prepared in situ by reaction of BuLi (0.62 mL, 1.6M solution in hexane, 1 mmol) with TMP(H) (0.17 mL, 1 mmol)), and TMEDA (0.15 mL, 1 mmol) was introduced, thus affording a pale yellow solution. Ferrocene was added (0.18 g, 1 mmol), and the reaction mixture was stirred for 12 h. An orange solid started to precipitate after 0.5 h. THF (2 mL) was added to this suspension to afford an orange solution that was placed in the freezer at −20°C. A crop of orange crystals was obtained after 24 h (0.20 g, 35%; note: maximum yield possible is only 50%). ¹H NMR (400 MHz, 25°C, C_6D_6): $\delta = 4.55$ (m, 4H; CH_β C_5H_4 Fc), 4.30 (s, 10H; C_5H_5 Fc), 4.17 (m, 4H; CH_γ C_5H_4 Fc), 1.97 (s, 12H; CH_3 tmeda), 1.60 ppm (s, 4H; CH_2 tmeda); ¹³C{¹H} NMR (100.63 MHz, 25°C, C_6D_6): $\delta = 79.39$ (Zn−C_α Fc), 77.94 (C_β Fc), 70.60 (C_γ Fc), 68.04 (C_5H_5 Fc), 57.45 (CH_2 tmeda), 48.10 ppm (CH_3 tmeda).

3: A solution of **1** in hexane was prepared in situ as described above for **2** by reaction of Bu_2Zn (1 mmol), Li(tmp) (1 mmol), and TMEDA (1 mmol). Two equivalents of ferrocene (0.37 g, 2 mmol) were then introduced, and the reaction mixture was stirred for 24 h, thus producing an orange solid. THF (2 mL) was added to the reaction mixture to afford an orange solution. Placed in the refrigerator at 0°C, this solution deposited a crop of orange crystals (0.34 g, 34%). ¹H NMR (400 MHz, 25°C, C_6D_6): $\delta = 4.57$ (m, 6H; CH_β C_5H_4 Fc), 4.49 (m, broad, 21H; 6H of CH_γ C_5H_4 and 15H of C_5H_5 Fc), 3.41 (m, 16H; CH_2O thf), 1.36 ppm (m, 16H; CH_2 thf); ¹³C{¹H} NMR (100.63 MHz, 25°C, C_6D_6): $\delta = 86.70$ (Zn−C_α Fc), 79.38 (C_β Fc), 70.33 (C_γ Fc), 68.37 (CH_2O thf), 67.67 (C_5H_5 Fc), 26.11 ppm (CH_2 thf); ⁷Li NMR (155.50 MHz, 25°C, C_6D_6, reference LiCl in D_2O at 0.00 ppm): $\delta = -1.05$ ppm.

Intramolecular Rotation through Proton Transfer: [Fe(η^5-C$_5$H$_4$CO$_2^-$)$_2$] versus [(η^5-C$_5$H$_4$CO$_2^-$)Fe(η^5-C$_5$H$_4$CO$_2$H)]**

*Xue-Bin Wang, Bing Dai, Hin-Koon Woo, and Lai-Sheng Wang**

Intramolecular rotation is important in molecular dynamics; it is a fundamental molecular property and can be used to understand the concept of molecular motors. Inspired by elegant biological and macroscopic analogues,[1–3] the fabrication of molecular machines has been very actively pursued recently,[4] resulting in a variety of molecular devices, such as rotors,[5–8] shuttles,[9–11] and ratchets.[12] The central theme of molecular devices is to control molecular motions and bindings upon external stimuli. The smallest molecular machine can downscale to a single molecule, and such a single molecular rotor has been observed.[13] Herein, we report the observation of intramolecular rotations of a single ferrocene derivative through proton transfer.

Ferrocene is a prototypical sandwich complex with an iron atom symmetrically situated between two C$_5$H$_5$ (cyclopentadienyl, Cp) rings and has been the subject of many experimental and theoretical studies since its discovery.[14–19] It has many applications in both fundamental research and materials science. In the solid phase the two Cp rings are in a staggered confirmation (D_{5d}),[14] whereas in the gas phase they are eclipsed (D_{5h}).[20] The rotational barrier of the two rings along the C_5 axis is very small in the gas phase ($E \approx 1.1$ kcal mol^{-1}).[20] Therefore, ferrocene would be an ideal candidate

for a molecular rotor if the rotational freedom can be controlled. Proton transfer, that is, acid–base chemical reaction, is one of the most commonly used external stimuli along with photoinduced processes and electrochemical reactions in realizing molecular devices.[4,21] Proton transfer is also ubiquitous and plays a vital role in biological motors.[22] It changes the charge state of a molecule to result in alternation of electrostatic interactions. Such effects may influence molecular binding, particularly in the gas phase or hydrophobic environments. Here, we study the energetics and conformations of two ferrocene derivatives, the doubly charged [Fe(η^5-C$_5$H$_4$CO$_2^-$)$_2$] ([FeCp$'_2$], **1**) and the singly charged [(η^5-C$_5$H$_4$CO$_2^-$)Fe(η^5-C$_5$H$_4$CO$_2$H)] (**2**; see Scheme 1), and demonstrate that they can be viewed to form a model molecular rotor system controlled by proton transfer.
Scheme 1. Structures of the ferrocene derivatives **1**–**3**.

Complexes **1** and **2** were produced using electrospray ionization, and their geometric and electronic structures were probed by photoelectron spectroscopy (PES) and theoretical calculations. The experiments were carried out on a newly developed low-temperature PES apparatus coupled with an electrospray source.[23] We detected abundant **1** and **2** by electrospray of a 1 mM solution of 1,1′-ferrocenedicarboxylic acid in a water/methanol mixed solvent system. The 193-nm (6.424 eV) PES spectrum of **1** (Figure 1a) reveals two broad spectral bands, which likely contain many overlapping detachment transitions. No transitions were observed beyond binding energies of 3 eV owing to the cut-off by the repulsive coulomb barrier, unique to photodetachment of multiply charged anions.[24–26] We also measured the photoelectron spectrum of **1** at 266 nm (4.661 eV) with slightly better resolution. Molecular orbital analysis based on the optimized structure (see below) indicates that the lower-binding-energy features (0.2–1 eV) are due to detachments from primarily lone-pair electrons of the carboxylate groups, whereas the higher-binding-energy features (1.5–2.5 eV) are due to detachments from the ferrocene framework, which contains closely spaced molecular orbitals from both the Fe 3d orbitals and the Cp′ rings. The surprising observation is the extremely low electron-binding energy for **1**. We measured an adiabatic detachment energy (ADE) of 0.25 ± 0.05 eV for **1** (Figure 1a). This low electron-binding energy is a result of the strong intramolecular coulomb repulsion due to the two negative charges in **1**. To assess the influence of the coulomb repulsion, we performed a control experiment on a monocarboxylated ferrocene anion, [(η^5-C$_5$H$_5$)Fe(η^5-C$_5$H$_4$CO$_2^-$)] (**3**, Scheme 1), as shown in Figure 1c. Three spectral bands were observed, all with very high electron-binding energies, in

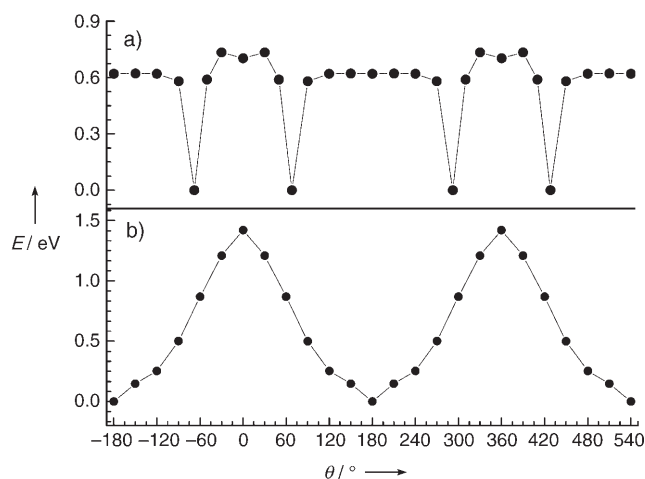
precisely staggered. Instead, there is a 68° angle between them to optimize the intramolecular hydrogen-bond formation. The *trans* conformation of **2** lies 0.62 eV higher in energy relative to the *cis* form (also see Figure 3a). The calculated


Figure 3. Calculated energies as a function of rotational angle defined by the two carboxylate groups for a) **2** and b) **1**. The two minima located at 68° and −68° for **2** are identical. At these angles, the intramolecular hydrogen bond is optimized. Deviation from these angles disrupts the hydrogen bond to result in a non-hydrogen-bonded form of **2**. The sharp minima in (a) reflect the narrow angles for the hydrogen bonding, outside which the rotational potential is relatively flat. The potential for **1** is primarily coulombic and is simpler: the minimum at 180° corresponds to the *trans* structure, whereas the maxima at 0° and 360° correspond to the *cis* form.

contrast to **1**. The ADE of **3** was measured to be 3.31 ± 0.03 eV, which is almost identical to that of acetate and other long-chain aliphatic carboxylate groups.[27] Thus, the extremely low ADE of **1** is purely due to the intramolecular coulomb repulsion, which can be approximately estimated as the difference in ADE between **3** and **1**; a very large value of approximately 3 eV is obtained.

Figure 1b displays the 193-nm spectrum of **2**, which reveals spectral patterns that are similar to those for **1** but at much higher binding energies. We expected that **2** would have binding energies similar to **3** because the first electron detachment in both systems should be from the CO_2^- group. However, the ADE of **2** was measured to be 3.80 ± 0.03 eV, about 0.5 eV higher than that of **3**. This observation suggests that the CO_2^- group in **2** is stabilized relative to that in **3**. The only mechanism for this stabilization is through an intramolecular hydrogen-bonding interaction between the CO_2^- group and the COOH group on the second Cp′ ligand. This is possible if the two Cp′ ligands in **2** would adopt a staggered conformation, that is, if the two Cp′ ligands would be rotated 180° relative to each other, as shown in Scheme 1.

To obtain more definitive information about the structures and energetics, we performed theoretical calculations on the three species.[28] The optimized structure of **1** indeed shows C_{2h} symmetry (Figure 2), in which the two CO_2^- groups are opposite each other in a *trans* conformation. For **2**, an intramolecular hydrogen bond is observed between the -COOH and -COO$^-$ groups, as expected, that lock the two Cp′ ligands in a *cis* conformation. The two Cp′ ligands are not

ADEs for **1**, **2**, and **3** are compared with the experimental values in Table 1. Although the theoretical values are consistently lower than the experimental values by approximately 0.2 eV, they reproduce the experimental trend very well. In particular, a significantly smaller ADE is predicted for the *trans* confirmation of **2**. In fact, the predicted ADE for the *trans* form of **2** is in remarkable agreement with the ADE of **3**, and confirms unequivocally that the hydrogen-bonded *cis* form is more stable and is the structure that was observed experimentally.

Therefore, we see that the different electrostatic interactions lock **1** and **2** in two different conformations. The

Communications

intramolecular coulomb repulsion dictates that the two negative charges in **1** lie as far apart as possible, locking it in the *trans* conformation, whereas intramolecular hydrogen bonding locks **2** in the *cis* conformation. Deviation from the optimal angle of 68° disrupts the hydrogen bond and results in non-hydrogen-bonded forms of **2**. The rotational barriers for **1** and **2** are 1.4 and 0.6 eV, respectively (see Figure 3), in the gas phase, which are much higher than thermal energies at ambient temperatures. As shown in the Figure 2, structures **1** and **2** are controlled by a proton-transfer process. Protonation of **1** induces a 112° rotation that leads to **2**, while deprotonation of **2** results in **1** by also involving a 112° intramolecular rotation.

[23] The experiments were carried out on a new homebuilt instrument, which couples electrospray ionization with a magnetic-bottle time-of-flight photoelectron spectrometer and the capability of controlling ion temperatures. The electrospray source and the magnetic-bottle photoelectron spectrometer are similar to that described previously (L. S. Wang, C. F. Ding, X. B. Wang, S. E. Barlow, *Rev. Sci. Instrum.* **1999**, *70*, 1957). Briefly, the anions of interest were produced from a solution of the corresponding acids under slightly basic conditions in a mixed solvent system of methanol/water (3:1 v/v). After their desolvation from the electrospray source, anions were guided by a RF-only (RF = radiofrequency) octopole device and transported through a quadrupole mass filter (operated at RF-only mode), before they entered a 3D Paul trap. The trap was attached to a cryostat, which consists of a closed-cycle helium refrigerator and a feedback heater. Temperatures of the trap can be controlled from 18–400 K. Ions were trapped for a period of 20–100 ms and collisionally cooled by using a 10^{-4} Torr He background gas containing about 10% H_2. The cold anions were then unloaded from the trap and were analyzed using a time-of-flight mass spectrometer. The ions of interest were selected and decelerated before they were intercepted with a laser beam in the interaction zone: 266 nm from a Nd:YAG laser and 193 nm from an ArF excimer laser. The lasers were operated at 20 Hz repetition rate, with the ion beam off at alternate laser shots for background subtraction. The photodetached electrons were collected with nearly 100% efficiency by a magnetic bottle and analyzed in a 5-m long electron-flight tube. The electron-energy resolution of the apparatus is $\Delta E/E \approx 2\%$, that is, 20 meV for 1 eV electrons. Photoelectron time-of-flight spectra were collected and then converted to kinetic-energy spectra, calibrated by the known spectra of ClO_2^- and I^-. The electron-binding-energy spectra presented were obtained by subtracting the kinetic-energy spectra from the detachment photon energies.

A Dendron Based on Natural Amino Acids: Synthesis and Behavior as an Organogelator and Lyotropic Liquid Crystal**

Yan Ji, Yu-Fei Luo, Xin-Ru Jia, Er-Qiang Chen,
Yun Huang, Chun Ye, Bing-Bing Wang, Qi-Feng Zhou,
and Yen Wei**

Biomolecules are prone to self-assemble in vivo and in vitro.[1] For example, collagen proteins can self-organize initially into triple helices and then into ordered fibers, gels, and liquid-crystalline (LC) phases through noncovalent forces.[2a,b] Elucidation of the underlying mechanisms is important but tremendously challenging. An alternative is to decipher nature's bewildering tricks with the help of synthetic systems made from natural starting materials.[2] In this context, the natural amino acid based dendrons or dendrimers (NAADs) are of great significance because of their similarity to proteins in composition and topology,[3] as well as their architectural difference from currently prevalent linear model peptides. In addition, potentially chiral and biocompatible NAADs provide exciting possibilities in the creation of new materials for nano- and biotechnology.[4]

However, little attention has been paid to the self-assembly of NAADs,[5] and especially to their gelation and LC properties. Only polylysine dendrimers have been studied as gelators by Smith et al.[6] and gelation is mentioned for dendrimers built from glutamates by Ranganathan et al.[3c,7] Research on NAADs as liquid crystals is even scarcer. Moreover, to the best of our knowledge, there is no report on amino acid based dendrimers that function as gelators and form liquid crystals. We have been interested in the synthesis and self-assembly of dendrimers for many years.[8] Herein, we

present the synthesis of a dendron composed of two natural amino acids, glycine and aspartic acid, and its self-assembly which leads not only to organogels but also to lyotropic liquid crystals. Recently, a type of amphiphilic dendritic dipeptide was described by Percec et al.[9] as self-assembling in helical pores. In contrast to their design of an aromatic dendron and a peptide core, our NAADs have peptidic dendrons with a benzyl periphery.

The poly(Gly-Asp) dendrons were convergently synthesized as depicted in Scheme 1. It is well-known that glycine appears at every third position in the predominant sequences of collagen,[2] and aspartic acid is similar to the building unit of a well-investigated linear model peptide, poly(benzyl L-glutamate) (PBLG), which behaves as a gelator and liquid crystal.[10] The dendrons, which resemble the repetitive patterns always found in the sequences of natural fibrous proteins,[2d] were branched iteratively with Gly-Asp dipeptides, instead of with one amino acid as in other NAADs,[11] and without any help from a nonnatural amino acid linkage.

Standard DCC coupling of Boc-glycine and benzyl-protected aspartic acid, which was readily prepared by the benzyl esterification of aspartic acid, gave the branching unit in 60% yield. This is the first generation (**G1**) of the dendron. The second (**G2**) and third generations (**G3**) were synthesized convergently in 35 and 17% yields, respectively, by repeating a two-reaction cycle, that is, by removing the Boc group of the lower-generation dendron with TFA, and then coupling the resultant *N*-deprotected intermediate to the *C*-deprotected **G1** (Boc-**G1**-COOH), prepared by hydrogenative debenzylation of the dipeptide. Currently, one of the major obstacles that hindered the research and applications of NAADs is the tedious process for the purification of the dendritic products.[10] Notably, **G3** is relatively easy to obtain by simple precipitation in water and MeOH consecutively (see Supporting Information). [1]H, ^{13}C, two-dimensional, and DEPT NMR techniques, MALDI-TOF mass spectrometry, and elemental analyses were used to verify the structure and purity of the **G3** dendron (see Supporting Information).

We found that **G3** could act as an efficient low-molecular-mass organogelator (LMOG). LMOGs[12c] are a family of low-molecular-mass organic molecules ($M_w \leq 3000$) that can gel organic solvents at very low concentrations through non-covalent forces. LMOGs have attracted considerable renewed interest in recent years, not only because of their interesting roles in materials science and supramolecular chemistry but also because gelation remains poorly understood. Most organogels are achieved through the ordered arrangement of gelators during the cooling of the mixture of LMOGs and organic solvents after heating to form a homogeneous solution.[12] However, a solvent–solvent gel preparation procedure distinguishes **G3** from other LMOGs, including the previously reported dendritic ones.[13] In a typical example, **G3** (0.04 g) was first dissolved in CHCl₃/CH₃OH (9:1 v/v; 6 mL) by sonication. Then, with the addition of ethyl acetate (4 mL), the solution immediately became viscous and gelled within 5 seconds. Meanwhile, a 10-mL gel as dilute as 0.2 wt% (0.98 mM, one **G3** molecule entraps about 9000 solvent molecules) in a 1-cm-diameter test tube could be turned upside down without downward flow of the gel. A thin

Scheme 1. Convergent synthesis of the first three generations of poly(Gly-Asp) dendrons **G**n (n = 1–3). Reagents and conditions: a) p-toluenesulfonic acid, benzene, benzyl alcohol, reflux; b) CH$_3$OH, KOH; c) Boc-glycine, DCC, −10°C; d) TFA, CH$_2$Cl$_2$; e) Pd-C, H$_2$, ethanol; and f) DCC, Boc-**G1**-COOH, N-methyl-morpholine, NHS, −10°C. Boc = tert-butoxycarbonyl, DCC = dicyclohexylcarbodiimide, TFA = trifluoroacetic acid, NHS = N-hydroxysuccinimide.

atomic force microscopy (AFM) image recorded in the tapping mode (Figure 1c) revealed that the smaller fibers were about 30–70 nm in width, many micrometers in length, but less than 20 nm in height. Considering the convolution effect arising from the finite size of the AFM tips, the real width of the fibers should be even less.

The gel preparation details have a great effect on gelation. If ethyl acetate was added before **G3** was totally dissolved in CH$_3$OH/CHCl$_3$, an opaque suspension was formed instead of a gel. TEM shows a rather different morphology of the aggregates in such a suspension (Figure 1b). In addition to the above case, **G3** dissolved in and gelled a mixture of CH$_3$OH and THF in several hours. However, the resultant gels were less stable than the CH$_3$Cl/CH$_3$OH/ethyl acetate gels at the same concentrations. Neither **G1** nor **G2** formed a gel in the above-mentioned mixed solvents under similar experimental conditions. CH$_3$OH, CHCl$_3$, CH$_2$Cl$_2$, THF, acetone, ethyl acetate, diethyl ether, ethanol, petroleum ether, hexane, cyclohexane, dioxane, acetonitrile, N,N-dimethylformamide, dimethyl sulfoxide, styrene, water, and benzyl alcohol were tested for the preparation of **G3** gels by the conventional heating and cooling method. Except for benzyl alcohol, none of the single solvents could be gelled by **G3**.

layer of liquid exuded as time went by, but the main part kept its gel state for more than half a year. The transmission electron microscopy (TEM) image of the **G3** gel showed that the **G3** dendrons self-assembled into a ramified network of intertwined fibers. The width of the fibers ranged from several dozen to more than a hundred nanometers (Figure 1a). The

Noncovalent forces, mainly hydrogen-bonding and aromatic-stacking interactions, were proposed to be the driving force for the self-assembly of **G3** dendron. The role of hydrogen bonding in gelation is supported by the fact that the gels changed into clear solutions after the addition of LiCl, which is known to interact strongly with amides and break hydrogen bonds (see Supporting Information). The FT-IR spectrum of the dry gel also revealed characteristic stretching vibrations as a result of hydrogen-bonding interactions in the N−H (3309 cm^{-1}) and C=O (amide I: 1660 cm^{-1}) moieties. However, further proof is needed to verify the presence of hydrogen bonds in the gel state. Other weak interactions may also play an important role in the self-assembly. Fluorescence spectroscopy[14] with pyrene as a probe was employed to examine the effect of benzyl rings. The intensity ratio I_1/I_3 of pyrene emissions is an established index for the polarity of the environment. This ratio decreased as the concentration of **G3** was increased in THF/CH$_3$OH (9:1; see Supporting Information), which suggests that nonpolar domains were formed as a consequence of the aromatic stacking of peripheral benzyl rings.

What is the relationship between the structure of a native gel and the organization of gelators in the solid state? This is an important question that has puzzled researchers for many years. To address this question in the case of **G3**, as well as to

Figure 1. Morphology of **G3**: a) TEM image of a **G3**/CH$_3$Cl/CH$_3$OH/ethyl acetate gel; b) TEM image of a **G3**/CH$_3$Cl/CH$_3$OH/ethyl acetate suspension; c) AFM image of the **G3**/CH$_3$Cl/CH$_3$OH/ethyl acetate gel ([**G3**] = 0.02 wt%).

obtain some hints on its packing pattern in native gels, X-ray diffraction (XRD) was carried out on the native gel, xerogel, and dendrite. No reflection could be detected in the CH₃OH/CHCl₃/ethyl acetate gel, presumably as a consequence of strong scattering from the electron-rich $CHCl_3$ solvent. The one-dimensional (1D) XRD pattern of the xerogel is shown in Figure 2. The large scattering halo with a maximum in 2θ at
Figure 2. 1D XRD pattern of the **G3**/CH₃OH/CHCl₃/ethyl acetate xerogel. The inset shows reflections around $2\theta = 7.86°$.

around 20° (corresponding to a d spacing of ≈ 0.45 nm) indicates that the major portion of **G3** in the xerogel was amorphous. However, the existence of a series of sharp diffractions reveals that the **G3** of the xerogel could partially crystallize. Efforts were made to grow single crystals, but failed. However, **G3** dendrites up to centimeter dimensions were obtained in DMF through evaporation at room temperature for a month. Figure 3 shows a two-dimensional (2D)
Figure 3. 2D WAXD pattern (left) and its schematic drawing (right) for one fiber-like branch in a **G3** dendrite.

wide-angle XRD (WAXD) pattern obtained from one fiber-like branch of a dendrite, which was collected in the transmission mode with the X-ray incident beam perpendicular to the long axis of the fiber. The sample was rotated through 360° around the long axis during exposure. It was difficult to deduce the precise crystal structure of **G3** because of the scarcity of diffraction lines. However, by assuming that the crystallographic c axis is parallel to the fiber long

axis, and that the diffraction lines that correspond to a d spacing of 1.162, 0.581, 0.522, and 0.451 nm are the (100), (200), (141), and (006) planes, respectively (Figure 2), we might tentatively propose an orthorhombic lattice with $a = 1.162$, $b = 2.395$, and $c = 2.706$ nm. As shown in the right-hand side of Figure 3, all the diffraction lines observed can be indexed. The calculated d spacings fitted the measured ones quite well (see Supporting Information). Meanwhile, we noted that the (100) diffraction with a d spacing of 1.162 nm in the dendrite could also be identified in the xerogel (see the inset of Figure 2). Although the intensity is relatively weaker, it indicates that the crystal in the xerogel could have the same structure as the dendrite. However, the coexistence of three peaks with very close d spacings proves that the **G3** crystals are in fact polymorphic. Still assuming an orthorhombic lattice, we found that the strongest diffraction with a d spacing of 1.126 nm and following peaks in the higher 2θ region in Figure 2 could be indexed with $a = 1.126$, $b = 2.331$, and $c = 2.582$ nm, values that deviate only slightly from those proposed for the dendrite. Reexamination of the dendrite testified that polymorphism also occurred. Occasionally, two sets of diffractions could be detected (see Supporting Information) in one fiber. This polymorphism may arise from the rich intra- and intermolecular hydrogen-bonding interactions, which lead to a **G3** molecular packing trapped in different local Gibbs energy minima during crystallization by solvent evaporation.

The gel became a turbid solution and would not regel after it was destroyed by mechanical agitation. Therefore, the morph responsible for gelation is probably not of the most thermodynamically stable phase. Recently, it was proposed[15] that one prerequisite of gel formation is the 1D alignment of gelator molecules. If so, the morph in the gel state should be different from that in the 3D orthorhombic crystals. A structure change, such as crystallization, is quite possible during the formation of a xerogel from a gel by the evaporation of solvents.

G3 can self-organize into lyotropic LC phases in benzyl alcohol. When the concentration of **G3** exceeds a certain limit (about 6 wt%), spherulites and oily streaks (Figure 4a) appeared, as viewed by polarizing optical microscopy (POM). With an increase of the concentration, more spherulites formed and eventually the whole field of view became dominated by a polygonal texture (Figure 4b). The textures can be deformed with pressure and are self-healing. No evidence of microcrystallites was observed. The lyotropic LC
Figure 4. Representative microphotographic textures of **G3** in benzyl alcohol under crossed polarizers. a) Spherulites and oily streaks in 14-wt% samples at room temperature (RT); b) polygonal texture (or focal–conic-like texture) in 30-wt% samples at RT; c) filament texture of 40-wt% samples heated at 10 K min⁻¹ and held for 5 min at 100°C.

behavior of the **G3**/benzyl alcohol phase at several representative concentrations was also examined by differential scanning calorimetry (DSC; see Supporting Information). A single endothermal peak was observed on heating 8-, 14-, and 20-wt% samples. The peak temperature increased monotonously from 60°C for 8-wt% samples to 80°C for 20-wt% samples, which was in accordance with the trend of transition of birefringence from anisotropic to isotropic observed by POM.

In the cases of 25-, 30-, 40-, and 50-wt% samples, the DSC heating traces showed a broad endothermic process with two peaks, which indicates two possible transitions. For example, the 40-wt% sample exhibited a lower peak at 88°C and a higher peak at 95°C before it completely entered the isotropic state after 105°C. A new POM texture different to that in Figure 4b developed above the lower transition temperature (Figure 4c). This was also the case for the other samples in the range of 25–50 wt%. The combination of the POM and DSC results suggests that the **G3**/benzyl alcohol mixture may have one lyotropic LC phase below the isotropic temperature at a concentration of 5–20 wt%. As the concentration ranged from 25 to 50 wt%, the samples may have one low- and one high-temperature LC phase prior to the LC-to-isotropic transition.

In contrast to most other LC dendrimers,[16] **G3** is lyotropic and intrinsically mesogenic with relatively flexible chains. It may serve as a good testing bench for the study of the structure–mesophase relationship. The lyotropic LC phase structure of the **G3**/benzyl alcohol mixture at low temperature (below the isotropic temperature for 5- to 20-wt% samples and below the lower transition temperature for 25- to 50-wt% samples) was identified by XRD. In the low 2θ region (Figure 5), a series of scatterings up to the fourth order could be observed for all the concentrations investigated, and the corresponding scattering vector ratios exactly followed 1:2:3:4 which clearly indicated a lamellar structure. This finding agrees well with the spherulites, oily streaks, and polygonal textures observed with POM, which were believed to be the characteristic features of the lyotropic lamellar phase.[17]

Despite varying the concentration, the long period of the lamellae was measured as 4.59 nm. This result indicated that,

at low temperature, the samples shared the same lyotropic LC phase where the lamellae coexisted with the solvent. We expected that the lamellae should be a bilayer structure. According to our preliminary computer modeling of the **G3** molecule, the distance from the focal point to the periphery was estimated to be about 2.8 nm if the **G3** molecules were fully extended. Hence, each lamella might consist of two layers of **G3** molecules that are partially interdigitated. In the inner part of the lamellae, the **G3** molecules might associate with their neighbors through hydrogen bonds, while the benzyl rings of the **G3** molecules are packed on the lamellar top and bottom surfaces. More systematic structural and thermodynamic transition property analyses, as well as more morphological studies, are necessary to finally identify the textures and the corresponding phases.

In summary, we have successfully synthesized a novel dipeptide-branched poly(Gly-Asp) dendron (**G3**) capable of self-organizing into organogels and lyotropic LC phases. With a solvent–solvent gel preparation process, the **G3** dendrons self-assembled into a network of intertwined fibers. Both hydrogen-bonding and aromatic-stacking interactions might be responsible for the aggregation. The ordered structure in the xerogel has a close relationship with the orthorhombic packing of **G3** in dendritic crystals. **G3** exhibits lyotropic LC behavior in benzyl alcohol, and a low-temperature lamellar phase with a long period of 4.59 nm can be identified. Fibrous proteins are ubiquitous in nature. Silk fibroin, amyloid, and collagens are but a few remarkable examples.[18] The systems described herein may give us more chance to understand the basic principles governing their supramolecular organization from a new angle different to that offered by linear model peptides. Further investigation is in progress to gain deeper insight into the mechanisms of gelation and mesophase formation, and to unravel the precise molecular-packing patterns of **G3** in the gels, crystals, and liquid crystals. In addition, the applications of such nanostructured materials could be explored as potentially biocompatible systems for drug delivery, molecular recognition, and other diagnostic or therapeutic functions.

Communications

Tautomers of One-Electron-Oxidized Guanosine**

Chryssostomos Chatgilialoglu,* Clara Caminal, Maurizio Guerra, and Quinto G. Mulazzani

8-Bromoguanine derivatives, such as **1a** and **1b**, capture electrons (e_{aq}^-) with quantitative formation of the corresponding debrominated nucleosides[1,2] and, therefore, they are efficient detectors of excess electron-transfer processes.[3] Indeed, in two recent papers 8-bromo-2′-deoxyguanosine (**1b**) was incorporated in a variety of single- and double-

1a: R = ribose
1b: R = 2′-deoxyribose
1c: R = methyl
stranded oligonucleotides and G-quadruplexes, and the reaction with e_{aq}^- indicated that excess electron transfer is effective.[2,4]

The reaction of e_{aq}^- with **1a** was previously studied by pulse-radiolysis techniques in some detail.[1] These experiments revealed the formation of two short-lived intermediates at pH ≈ 7. Figure 1 shows the absorption spectrum of the first observable species (solid line) obtained 2 μs after the pulse. This species of uncertain structure decays by first-order kinetics ($k = 5.0 \times 10^4 \text{ s}^{-1}$) to produce the one-electron-oxidized guanosine (dashed line).[1] In the present work we studied the kinetics in the temperature range of 5.8–50.3 °C and obtained the following Arrhenius parameters: $\log(A/\text{s}^{-1}) = 8.7 \pm 0.4$ and $E_a = 23.0 \pm 2.5 \text{ kJ mol}^{-1}$ (errors correspond to one standard deviation).

What is the structure of the first observable species, which has a characteristic absorbance around 600 nm? We found previously that time-dependent (TD) DFT calculations at the B3LYP/6-31G* level[5,6] provide reliable optical transitions for nucleoside radicals.[7,8] In neutral solution, the initial electron adduct of **1** should be rapidly protonated.[9] Therefore, TD-B3LYP/6-31G* calculations were carried out on 8-

Figure 1. Absorption spectra obtained from the pulse radiolysis of Ar-purged solutions containing 1 mM **1a** at pH ≈ 7 with 0.25 M *t*BuOH, recorded 2 μs (solid line) and 45 μs (dashed line) after the pulse (adapted from ref. [1]). The lines show the calculated vertical optical transitions for radical **2** (dashed lines, λ(*f*): 290 (0.128), 350 (0.054), 470 nm (0.014)) and its tautomer **3** (solid lines, λ(*f*): 290 (0.138), 350 (0.042), 610 nm (0.051)).

bromo-9-methylguanine (**1c**) radical anion, protonated at N7 (as suggested previously[1]) and at any other possible sites; no optical transition was predicted to exist above 500 nm. Interestingly, protonation at C8 produces loss of Br⁻, and it could be hypothesized that the first observable species in pulse radiolysis had already lost Br⁻. Consequently, we computed the optical spectra (transition wavelengths λ and oscillator strengths *f*) of the deprotonated 9-methylguanine radical cation (i.e., oxidized 9-methylguanine **2**) and its tautomers bearing an iminic substituent at C2. The computed data for the radical **2** are reported in Figure 1 and are in good accord with values assigned with certainty to the oxidized guanosine.[10] More interestingly, calculations showed that a band is computed at wavelengths longer than 500 nm only for the tautomer **3**. The computed optical transitions are also reported in Figure 1 and are in good agreement with the experimental spectrum recorded 2 μs after the pulse; these data correspond to the transient of uncertain structure.

On the basis of these findings, we propose a revised mechanism for the reaction of e_{aq}^- with **1** (Scheme 1). The

Scheme 1. Proposed mechanism for the reaction of e_{aq}^- with 8-bromo-guanosine (**1a**). The initial adduct **4** is rapidly protonated to give the first observable species **5**. The tautomer **6** is assigned to the second transient species observed in the pulse-radiolysis studies (see Figure 1).

initial electron adduct **4** is rapidly protonated at the C8 position to release Br^- and the first observable transient species **5**,[11] which should have a pK_a value similar to that of oxidized guanosine ($pK_a = 3.9$).[10] The subsequent tautomerization **5**→**6** occurs with a $\log(A/s^{-1}) = 8.7$, which suggests a complex transition state, and an activation energy of 23.0 kJ mol^{-1}. Another point supporting a complex transition state is also the previously reported kinetic isotope effect $k(H_2O)/k(D_2O) = 8.0$.[1]

The reaction barrier (E_a) for the direct tautomerization **3**→**2** is computed to be 183.7 kJ mol^{-1} at the B3LYP/6-31G* level. Such a large value is in evident contrast with the activation energy measured for the tautomerization **5**→**6**. In analogy with the keto–enol tautomerization in guanine[12] and 8-oxo-7,8-dihydroguanine,[13] the water-assisted proton transfer is computed to occur with a much lower reaction barrier (the calculated transition-state structure is given in Figure 2). Indeed, the reaction barrier is computed to be as small as 18.8 kJ mol^{-1}, in good accord with experiment.[14]

Figure 2. Structure of the transition state for the water-assisted tautomerization **3**→**2** computed at the B3LYP/6-31G* level. Distances are in Å.

To gain insight into the different tautomeric forms, the 8-bromo derivatives **7** and **10** (Scheme 2) were prepared, since the analogous tautomerization **5**→**6** could not occur as a result of alkylation at NH and NH_2 moieties. γ-Radiolysis of **7** and **10** in aqueous solutions at pH ≈ 7 was followed by product studies, which showed the quantitative formation of debrominated derivatives **9** and **12**, respectively.[15] Rate constants of 1.1×10^{10} and 8.0×10^9 M^{-1}s^{-1} were determined at pH ≈ 7 for the reactions of e_{aq}^- with **7** and **10**, respectively, by measuring the rate of the optical density decrease of e_{aq}^- as a function of the concentration of the added nucleoside.[18] Figures 3 and 4 show the optical absorption spectra obtained from these reactions. The ε values were calculated using $G = 0.27$ μmol J^{-1}, since HO· species are scavenged by the added tBuOH, and the H· atoms follow another path and therefore do not contribute to the reaction.[16] The decay of these transients follows second-
Figure 3. Absorption spectrum (■) obtained from the pulse radiolysis of Ar-purged solutions containing 0.5 mM **7** at pH ≈ 7 and 0.25 M tBuOH, recorded 10 μs after the pulse. Absorption spectrum (○) is taken from reference [10] and refers to the reaction of $Br_2^{·-}$ with **9**. The lines show the calculated vertical optical transitions for radical **8** (R = Me) ($\lambda(f)$: 290 (0.063), 360 (0.036), 650 nm (0.040)).
Figure 4. Absorption spectrum (■) obtained from the pulse radiolysis of Ar-purged solutions containing 0.5 mM **10** at pH ≈ 7 and 0.25 M tBuOH, recorded 2 μs after the pulse. Absorption spectrum (○) obtained from the pulse radiolysis of Ar-purged solutions containing 0.1 mM **12** and 10 mM $K_2S_2O_8$ at pH ≈ 7 with 0.1 M tBuOH, recorded 6 μs after the pulse. The lines show the calculated vertical optical transitions for radical **11** (R = Me) ($\lambda(f)$: 290 (0.149), 390 (0.070), 480 (0.029), 1030 nm (0.027)).

Scheme 2. Reactions of e_{aq}^- with 8-bromoguanosine derivatives **7** and **10**, of $Br_2^{·-}$ with **9**, and of $SO_4^{·-}$ with **12**. The radicals **8** and **11** are assigned to the transient species observed in the pulse-radiolysis studies (see Figures 3 and 4, respectively).

order kinetics and their disappearance does not lead to other transients. Furthermore, these spectra are identical to those obtained after the oxidation of **9** by $Br_2^{·-}$[10] and of **12** by $SO_4^{·-}$ at pH ≈ 7 (Figures 3 and 4).

Therefore, the spectra in Figures 3 and 4 are assigned to radicals **8** and **11**, respectively, which can be obtained either from the reduction of 8-bromoguanine derivatives or from the oxidation of the debrominated compounds as illustrated in Scheme 2. TD-B3LYP/6-31G* calculations carried out on the corresponding 9-methyl derivatives of radicals **8** and **11** fit very well with our assignment. Indeed, the computed optical spectra for the radical **8** and for the radical **11**[19] are in good agreement with the spectra shown in Figures 3 and 4, respectively. Interestingly, both the spectrum of radical **8** and that of radical **5** have a band at 610–620 nm, which is consistent with an iminic substitution at the C2 position. Obviously, radical **5** can tautomerize to **6**, whereas radical **8** is blocked in one form.

Communications

In conclusion, our work here demonstrates the first directly observed differences of the two tautomeric forms of oxidized guanosine. The energetically most stable form **6** is the one that is obtained directly by oxidation of guanosine. The less stable form **5** is obtained from the protonation of the 8-bromoguanosine electron adduct, and its tautomerization to **6** has an activation energy of 23.0 kJ mol^{-1}.

Ionic Liquids

Transition-State Effects of Ionic Liquids in Substitution Reactions of Pt[II] Complexes**

Christian F. Weber, Ralph Puchta,
Nico J. R. van Eikema Hommes, Peter Wasserscheid,
and Rudi van Eldik*

Ligand-substitution reactions of square-planar complexes of d[8] metal ions such as Pt[II] and Pd[II] play a fundamental role in many chemical processes, for instance, in the treatment of tumors and in homogeneous catalysis.[1,2] Detailed mechanistic studies have demonstrated that such complexes usually undergo associative ligand-substitution reactions as a result of the 16-valence-electron structure of the square-planar complex.[3] The transition state has either a semi-five-coordinate character in the case of an associative interchange (I$_a$) mechanism, or forms a short-lived, five-coordinate intermediate in the case of a limiting associative (A) mechanism. Exceptions are found in cases in which two neighboring spectator ligands form metal–carbon bonds with the metal center and induce a dissociative mechanism.[4]

In terms of the biological or catalytic application of such metal complexes, the fundamental understanding of the ligand-substitution mechanisms enables a systematic tuning of the lability of the metal center, that is, the efficiency of the chemical process. A distinction between the three mechanisms can usually be made on the basis of activation parameters derived from the temperature and pressure dependence of the reaction, that is, ΔH^+, ΔS^+, and ΔV^+.[3,5,6] In recent work performed in our laboratories, the lability of Pt[II] complexes could be systematically tuned through the

introduction of σ-donor and π-acceptor spectator chelates.[7,8] Rate and activation parameters clearly supported the associative nature of the underlying substitution mechanism.

In recent years, ionic liquids have become a popular research area that is expected to grow as a result of their potential industrial application.[9] Not only are such liquids interesting in terms of applications in separation techniques but also they may be used to improve the solubility of weakly soluble gases and enhance the catalytic activity of metal complexes.[10] The first industrial process based on the application of ionic liquids has been launched.[11]

Mechanistic studies on chemical reactions in ionic liquids have only been performed to a limited degree. Skrzypczak and Neta determined the rate constants for the reaction of 1,2-dimethylimidazole with benzyl bromide (Menschutkin reaction) in a series of ionic liquids and organic solvents. The rate constants in the ionic liquids are comparable with those for polar aprotic solvents, but much larger than those for weakly polar organic solvents and alcohols.[12] Chiappe and Pieraccini determined rate constants and activation parameters (ΔH^+ and ΔS^+) for the reactions of Br_3^- and ICl_2^- ions with some alkenes and alkynes in a series of ionic liquids and in 1,2-dichloroethane.[13] McLean and co-workers[14] studied the effect of ionic liquids on bimolecular rate constants for the displacement of solvent from $[(C_6H_6)Cr(CO)_2(solv)]$. Inhibition of the catalytic activity of a Ru[II] catalyst in ionic liquids was recently reported by Daguenet and Dyson for a reaction system in which chloride dissociation is a crucial step.[15] More recently, work in our laboratory demonstrated that this inhibition could be related to the selected anionic component of the employed ionic liquids, since other anions in our hands clearly lead to a faster chloride dissociation step from a Pt[II] complex in the catalytic process studied.[16] Following the submission of this work, Shaughnessy and co-workers reported kinetic data for oxidative-addition and ligand-substitution reactions in ionic liquids.[17,18]

A fundamental question, however, does remain: Do ionic liquids really behave as "normal" solvents, or are there unknown aspects that could affect the substitution behavior of square-planar Pt[II] complexes? We report herein a detailed kinetic study of the substitution reactions of the $[Pt^{II}(apa)Cl]^+$ complex **1** (apa = 2,6-bis(aminomethyl)pyridine; Scheme 1) with thiourea and iodide as nucleophiles, in water, methanol, and the ionic liquid 1-butyl-3-methylimidazolium bis(trifluor-

Scheme 1. Chemical formula and DFT structure of complex **1**; distances in pm.
omethylsulfonyl)amide ([BMIM]BTA) as solvents. This ionic liquid has a melting point of $-4\,°C$[19] and a polarity close to that of ethanol.[9d] We studied the reaction as a function of the concentration of the entering ligand, the temperature, and the pressure to determine all the rate and activation parameters

[BMIM]BTA
$(\Delta H^+, \Delta S^+,$ and $\Delta V^+)$. This is, as far as we know, the first time that a systematic pressure-dependence study was undertaken for a chemical reaction in an ionic liquid. The reported rate and activation parameters show a rather "normal" behavior for the employed ionic liquid and demonstrate some unique properties of the ionic liquid as medium for the investigated substitution reactions.

The solvent dependence of the ligand-substitution reactions of **1** with thiourea (TU) and iodide (Scheme 2) were
Scheme 2. The investigated substitution reaction for thiourea (Nu⁰) and iodide ion (Nu⁻).

studied by dissolving the isolated complex **1**-Cl in the selected solvents followed by rapid mixing with a stock solution of the nucleophile. Typical examples of the observed spectral changes and kinetic traces are shown in Figure 1. The overall spectral changes were found to be rather similar for the studied solvents, with the exception of [BMIM]BTA due to the absorption of this liquid in the wavelength range $\lambda < 350\,nm$ (see Figure 1c). All kinetic traces (Figure 1b,d) showed excellent fits to a single-exponential function, in line with pseudo-first-order behavior. The calculated pseudo-first-order rate constants, k_{obs}, were plotted against the concentration of the entering nucleophiles, TU and iodide, and are linear with a zero intercept under all conditions (see typical examples given in the Supporting Information). The rate constant k_{obs} can be expressed as a function of the concentration of the entering ligand, namely, $k_{obs} = k_2[Nu]$, in which k_2 is the second-order rate constant.

We also studied the effect of the water content of the ionic liquid on the second-order rate constant for the reaction of **1** with TU in [BMIM]BTA. The following k_2 values were obtained at 25°C (water content in ppm in brackets): 0.260 (23), 0.245 (100), and 0.259 $M^{-1}s^{-1}$ (200). It follows that the water content has no significant effect on the rate constant in the investigated concentration range.

The activation parameters were determined from the effect of temperature and pressure on k_2. Spectral changes observed for the reaction in [BMIM]BTA at 100 MPa (see Supporting Information) are in excellent agreement with those observed at ambient pressure. The thermal activation parameters, ΔH^+ and ΔS^+, were obtained from Eyring plots (see example in the Supporting Information), whereas ΔV^+ was calculated from the gradient $(-\Delta V^+/RT)$ of the plot of $\ln k$ versus pressure (see Supporting Information). Table 1 summarizes the values of the dielectric constants (ε), E_T^N, k_2, ΔH^+, ΔS^+, and ΔV^+ for the studied reactions in the three selected solvents. It should be noted that the reactions in the ionic liquid showed the same behavior as that found for other more conventional solvents as a function of the experimental variables.

The reaction of **1** with TU, a strong nucleophile, is considerably faster than the reaction with iodide in the same solvent. The k_2 values show that the substitution reactions depend significantly on the polarity of the solvent, namely, $k_2(H_2O) \gg k_2(MeOH) \approx k_2(\text{ionic liquid})$. A likely reason is an increase in the dipole moment during the course of the reaction due to partial lengthening of the Pt–Cl bond in the five-coordinate trigonal-bipyramidal transition state. In general, a decrease in solvent polarity results in a decrease in the rate of a reaction that involves an increase in dipole moment in going from the reactant to the transition state.[22] The trend in the values of k_2 clearly indicates that the ionic liquid behaves like methanol and that no drastic acceleration or deceleration of the substitution of chloride, as reported for other Pt^{II} complexes in this and closely related ionic liquids, can be observed.[15,16]
Figure 1. UV/Vis spectra (a,c) and typical kinetic traces at 320 nm (b,d) recorded for the reaction of **1** with iodide in methanol (a,b) and [BMIM]BTA (c,d). The experimental kinetic traces can be perfectly fitted with a single-exponential function. Experimental conditions: a) [Pt^{II}]=9.5×10^{-5} M, LiCl (0.002 M), [I⁻]=0.015 M, ionic strength=0.2 M (LiClO$_4$), pH 2 (0.01 M trifluoromethanesulfonic acid), T=25°C, optical path length=10 mm. b) [Pt^{II}]=9.5×10^{-5} M, LiCl (0.002 M), [I⁻]=0.0090 M, ionic strength=0.2 M (LiClO$_4$), pH 2 (0.01 M trifluoromethanesulfonic acid), T=25°C. c,d) [Pt^{II}]=3.3×10^{-4} M, [I⁻]=0.0392 M, T=25°C, optical path length=5 mm.

Table 1: Summary of second-order rate constants and activation parameters[a] for the displacement of chloride by iodide and thiourea in **1** in different solvents.

	Solvent	ε(298 K), $E_\mathrm{T}^{\mathrm{N[b]}}$	$10^3 k_2$ at 25°C [$\mathrm{M}^{-1}\mathrm{s}^{-1}$]	$\Delta H^{\pm}$ [kJ mol^{-1}]	$\Delta S^{\pm}$ [J K^{-1} mol^{-1}]	$\Delta V^{\pm}$ [cm^3 mol^{-1}]

[a] Activation parameters were calculated from the temperature and pressure dependence of the second-order rate constant in the usual way. No corrections were made for changes in solvent density[20] or viscosity[21] as a function of temperature and pressure. [b] Dielectric constant (ε) of the solvent and its polarity ($E_\mathrm{T}^{\mathrm{N}}$).

The activation parameters summarized in Table 1 show some interesting trends. Throughout the series of reactions studied, the negative activation entropy and volume data clearly support the operation of a compact transition state in terms of an associative mechanism.[3] For the reaction between complex **1** and TU, significantly more negative activation entropies and volumes are found for water and [BMIM]BTA as the solvent irrespective of their significant difference in polarity. This finding suggests that reorganization in the transition state is not controlled by solvent electrostriction. The less negative activation entropies and volumes for the reaction in methanol once again illustrate that solvent electrostriction does not contribute significantly to the transition state, otherwise the opposite effect would occur. In this case, TU is a neutral entering nucleophile and the mentioned activation parameters mainly correspond to intrinsic entropy and volume changes.

In the case of iodide as the entering nucleophile, the values of the activation entropy are almost the same for the different solvents, whereas the activation volumes are significantly more negative in the case of methanol and [BMIM]BTA as solvents. This result suggests that charge neutralization in the five-coordinate transition state leads to a decrease in electrostriction—that is, a less negative activation volume—in the more polar solvents (water and methanol). This trend, however, does not show up in the values of the activation entropy, which is probably related to the usually larger error limits of this parameter. Nevertheless, the trend in the activation volumes for the different solvents is quite convincing.

The activation volumes for the reactions with TU and iodide in [BMIM]BTA are indeed very similar, which suggests that volume changes in this ionic liquid do not respond to changes in the overall charge of the transition state. We suggest that this lack of response is due to strong hydrogen bonding and possibly also van der Waals forces in ionic liquids, which result in specific solvent structures that consist of well aligned cation–anion aggregates. The formation of such aggregates in ionic liquids has recently been investigated by using microcalorimetry.[23] The stability of such aggregates will show a resistance towards solvent structural changes (electrostriction/solvation) as a result of charge neutralization or charge creation. The value of about −14 cm^3 mol^{-1} for $\Delta V^{\pm}$ is close to that expected for an associative ligand-substitution

mechanism and represents the intrinsic volume collapse associated with the formation of a five-coordinate transition state.[5,6]

To gain further insight into the details of the ligand-substitution mechanism, in particular, the question of associative interchange (I_a) versus associative (A), we calculated the pathways for the reactions of **1** with chloride (chloride exchange), iodide, and thiourea by using B3LYP hybrid density functional theory[24] and the LANL2D-Z ECP basis set augmented with polarization functions.[25,26] We have employed this theoretical level in previous work.[16,27]

The first step in the reaction is the formation of a precursor complex between the platinum complex **1** and the incoming ligand. As **1** bears a positive charge, interaction energies in the gas phase are dominated by electrostatics and exaggerated interaction energies are calculated, particularly for the complexes with the anionic nucleophiles chloride and iodide. Nevertheless, the structures of the precursor complexes for all incoming ligands indicate rather weak bonding. The main contact consists of a hydrogen bond to one of the amine hydrogen atoms (202, 249, and 221 pm for Cl$^-$, I$^-$, and S, respectively). On the other hand, the platinum–halide distances, 386 (chloride) and 437 pm (iodide), and the platinum–sulfur separation (for the reaction with thiourea), 458 pm, are very long. The other bonds around platinum differ only to a minor extent from those in **1**.

Hydrogen bonds to an amine hydrogen atom are well known in the solid state,[28] but may be unrealistic in the gas phase. Therefore, we also studied the reactions for the dimethylamino derivative, [Pt{2,6-bis(dimethylamino-methyl)pyridine}Cl]$^+$ ([Pt^{II}(mapa)Cl]$^+$, **2**). As expected, the platinum–ligand bonds are shorter in the absence of the hydrogen bonds, but only modestly: Pt−Cl 346, Pt−I 409, Pt−S 378 pm.

All reactions proceed through a single transition-state structure. Despite extensive searches along the reaction coordinate, no stationary points other than the precursor and product complexes could be located. Thus, the reactions clearly proceed by an interchange-type mechanism. The calculated activation barriers range from 64 to 89 kJ mol^{-1} and show that the nucleophile has a remarkably small influence (Table 2). Due to the presence of the hydrogen bond in the precursor complex, the barriers for the reactions of **1** are somewhat higher than for the reactions of **2**. The influence of *N*-methylation on the coordination sphere around the platinum center appears to be negligible.

The transition-state structures are compact, with relatively short bonds to the ligands that are being exchanged (Figure 2). This compactness is best seen in the reaction of **1** with Cl$^-$: the Pt−Cl bonds of the transition state are 259 pm, only 26 pm longer than the Pt−Cl bond in **1** itself and 23 pm longer than the Pt−Cl bond in the precursor complex. The situation in the other transition-state structures is very similar.

[a] E_{cpx}: complexation energy released on the formation of the precursor complex; E_{react}: reaction energy for the formation of the product complex; E_{act}: activation energy for the formation of the transition state relative to the precursor complex.
Figure 2. Calculated transition-state structures for the reaction of **1** with Cl⁻, I⁻, and thiourea. Distances are given in pm.

Hence, the reactions are best characterized as proceeding by an associative interchange, I_a, mechanism. In addition, in the reactions with thiourea, a hydrogen bond between chloride and one of the thiourea hydrogen atoms is preserved throughout the reaction.

The reactions of **1** with I⁻ and TU are both calculated to be mildly endothermic (+3 and +13 kJ mol⁻¹, respectively) in the gas phase. This is due to the lack of stabilizing solvation of the leaving chloride ion. For the reaction of **1** with iodide, inclusion of the influence of the bulk solvent through the isodensity polarizable continuum model (IPCM) gives a reaction energy of −7 kJ mol⁻¹.[29]

In conclusion, the studied substitution reaction was selected as a test system to investigate the behavior of ionic liquids as reaction medium for ligand-substitution reactions in comparison to conventional solvents. The observed spectral changes, kinetic traces, rate, and activation parameters clearly demonstrate the "normal" behavior and innocence of the selected ionic liquid in ligand-substitution reactions of Pt^{II} complexes. The kinetic data can be treated according to the transition-state theory as for any other solvent. No deviations

whatsoever were observed. For the first time it has been possible to determine the activation volume for a ligand-substitution reaction on a metal complex in an ionic liquid. An analysis of the thermal and pressure activation parameters indicates that the ionic liquid exhibits rather unique properties in terms of electrostriction/solvation of transition states that involve different degrees of polarity as reflected by similar activation parameters in conventional solvents. The apparent insensitivity of the ionic liquid towards changes in polarity on going to the transition state can be ascribed to its tendency to form well-structured cation–anion aggregates. As a result of the apparent absence of solvent reorganization due to changes in electrostriction in this medium, the observed activation volume can be directly correlated with intrinsic volume changes that result from changes in bond lengths and bond angles on going to the transition state. This factor can, in principle, considerably simplify the accurate assignment of intimate mechanisms in cases in which changes in the polarity of the transition state cause large solvent effects in terms of electrostriction/solvation in conventional solvents and complicate the mechanistic assignment on the basis of activation parameters, especially activation entropy and volume data. This unique property of ionic liquids may come in very handy to resolve mechanistic discrepancies in conventional solvents.

Experimental Section

All chemicals used were of analytical reagent grade and of the highest purity commercially available. K₂[PtCl₄] was obtained from Strem Chemical Co.; [BMIM]Cl and lithium bis(trifluoromethylsulfonyl)-amide were obtained from Solvent Innovation. Ultrapure water was used for the spectroscopic and kinetic measurements. The solvatochromic Reichardt's dye, (2,6-diphenyl-4-(2,4,6-triphenylpyridinium-1-yl)phenolate hydrate, was obtained from Aldrich.

The complex **1**-Cl·H₂O, was synthesized following a reported procedure.[7] The ligand, 2,6-bis(aminomethyl)pyridine, was prepared according to a method used to synthesize 6-(aminomethyl)-2,2′-bipyridine[30] by using 2,6-bis(bromomethyl)pyridine[31] as the starting material. The corresponding platinum complex was prepared as described previously and was obtained in the same quality (see Supporting Information).[7]

The ionic liquid [BMIM]BTA was synthesized by using a reported procedure.[32,33] A solution of [BMIM]Cl (705 g, 4.04 mol) in H₂O (200 mL) was added to a solution of Li(bis(trifluoromethylsulfonyl)amide) (1.054 kg, 3.67 mol) in H₂O (200 mL; 1.1:1 molar ratio). The reaction media was mixed whereupon two phases formed: the bottom, slightly yellow phase was [BMIM]BTA; the

top phase was aqueous LiCl. The reaction mixture was stirred overnight at room temperature and the top phase was decanted off. CH_2Cl_2 (200 mL) was then added and the mixture was washed three times with H_2O (500 mL). The addition of CH_2Cl_2 led to an improved separation of the phases. After removal of CH_2Cl_2 and addition of activated carbon, the mixture was stirred for over 48 h at room temperature. Filtration of the mixture through a normal frit followed by Millipore filtration (pore size 0.22 μm) afforded a colorless liquid, which was washed with water once more, dried at 50–60 °C under vacuum for 48 h and filtered through a Millipore filter (pore size 0.22 μm). The product, [BMIM]BTA, was a clear colorless liquid; its NMR data are in close agreement with those reported for an acetone solution (see Supporting Information).[33] The water content of [BMIM]BTA was determined by a Karl–Fischer titration by using a Metrohm 756 KF coulometer and found to be 23 ppm.

Instrumentation and measurements: [BMIM]BTA was dried and degassed before use. Its polarity was determined by using the solvatochromic Reichardt's dye (see the Supporting Information). The dimensionless normalized E_T^N values of the solvent were calculated according to reference [34].

Carlo Erba Elemental Analysers 1106 and 1108, and Bruker Avance DPX 300 and DRX 400 NMR spectrometers were used for chemical analysis and compound characterization, respectively. The UV/Vis spectra for the study of slow reactions were recorded on a Varian Cary 1G spectrophotometer equipped with a cell holder and thermostat. For the kinetic measurements on fast reactions an Applied Photophysics SX 18MV stopped-flow instrument was used. The wavelengths used are listed in the Supporting Information. Kinetic experiments at elevated pressure (1 to 130 MPa) were performed in a laboratory-made high-pressure stopped-flow instrument[35] or a Shimadzu UV-2101-PC spectrophotometer equipped with a high-pressure cell designed for the study of slow reactions.[36] The temperature of the instruments was controlled within an accuracy of ± 0.1 K. TU and I⁻ (as LiI) were used as entering nucleophiles. Their high nucleophilicity prevents the back reaction. The starting complex was dissolved in water and methanol that contained LiCl (0.002 M) to avoid its solvolysis. Trifluoromethanesulfonic acid (0.01 M) was added to avoid formation of hydroxo or alcoholate ions, which could compete in the chloride displacement. In the case of iodide as nucleophile and methanol and water as solvent, the ionic strength was kept at 0.2 M (LiClO₄). The reactions were studied under pseudo-first-order conditions by using at least a tenfold excess of the nucleophiles. All listed rate constants represent an average value of at least five kinetic runs for each experimental condition.

Calculations: Structures were fully optimized at B3LYP/LANL2DZp[24–26] and characterized by calculation of vibrational frequencies. Relative energies include corrections for zero-point vibrational energy differences. Solvent effects were probed with IPCM single-point energy calculations by using the default parameters, that is, water as solvent.[29] The Gaussian program was used.[37]

Supporting Information available: Yields, elemental analyses, and ¹H NMR data for synthesized compounds; plots showing the concentration, temperature, and pressure dependence of the observed rate constants for the reactions between complex **1** and thiourea or iodide.

Polycyclic Molecules from Linear Precursors: Stereoselective Synthesis of Clavolonine and Related Complex Structures**

David A. Evans and Jonathan R. Scheerer*

At the time of this publication, over 100 lycopodium alkaloids have been isolated.[1] The 16-carbon-atom-containing lycopodium alkaloid family features a variety of polycyclic ring sizes, stereochemistry, and oxidation patterns. The classic tetracyclic skeleton of the lycopodane family has a rich history in organic chemistry and has been a proving ground for new approaches to the synthesis of polycyclic alkaloid targets.[2] Despite the number of research groups that have contributed to the synthesis of this family of alkaloids, all have proceeded in a linear fashion from cyclic starting materials.

The structure of lycopodine provides an instructive model to explore a strategy centered on 1) a convergent synthesis of a linear precursor that contains the complete carbon backbone and 2) the incorporation of a reaction cascade sequence to construct the remaining carbon–carbon bonds. In this study, we pursued the synthesis of clavolonine (**2**), which was

lycopodane (**1**) lycopodine clavolonine (**2**)
first isolated in Jamaica in 1960[3] from the club moss *Lycopodium clavatum* and was synthesized as a racemate by Wenkert and Broka.[4a]

The disconnections required to transform the lycopodium skeleton **3** into its derived acyclic precursor may be accomplished with three principal constructions: 1) a Mannich reaction, 2) a Michael addition, and 3) a C–N alkylation (Figure 1). If the C–N alkylation is the last skeletal disconnection, then these reactions are implemented in a macrocyclic manifold (path A). Alternatively, if the C–N alkylation is the first skeletal disconnection, the same reactions are implemented in a linear environment (path B). Herein, we report the evaluation of both distinct approaches to the synthesis of the lycopodium skeleton.

Figure 1. Synthesis plan: macrocyclic path A and linear path B.

line **4** as a single diastereomer.[6] This aldol adduct was successively reduced to the diol and trapped as the derived benzylidine acetal. Subsequent reductive cleavage revealed the primary alcohol (DibalH, CH$_2$Cl$_2$, −35°C) which was transformed into nitrile **5** via the intermediate tosylate.[7] Following ozonolysis of the styrene moiety, the aldehyde derived from **5** was condensed with β-ketophosphonate **7** to afford α,β-unsaturated ketone **8** in 90% yield.[8] After protection of the enone in **8**, the nitrile and protected hydroxyl termini were modified to the macrocyclization requisite precursor **9**.[9] Macrocyclization was accomplished by activation of the primary alcohol as its iodide derivative, which was immediately subjected to ketoester alkylation conditions (Cs$_2$CO$_3$, THF, 37°C, 0.007 M).[10] In this manner, macrocycle **10** was reproducibly obtained in good yield. Oxidation of the allylic alcohol afforded the desired enone **11a**, which was crystallized as a single diastereomer (m.p.: 127°C) and analyzed by X-ray diffraction.

The deprotected macrocyclic amine **11b** may react with either the C13 or the C5 carbonyl groups. We predicted that deprotection of the amine would result in condensation at the C13 ketone to provide the vinylogous urethane **12** (Scheme 2).[11] In the event, carbamate cleavage of amine **11a** afforded none of the desired enaminone **12**; rather, exclusive formation of **13** (attack at C5) was observed (97% yield). Exposure of **13** to protic or Lewis acids promoted a stereoselective transannular Michael addition of the ketoester to the α,β-unsaturated iminium ion **14**. The derived tricyclic enamine **15** was unstable

First, let us consider path A. Macrocycles often adopt well-defined conformations that exhibit a pronounced influence on the stereochemical course of reactions.[5] The investigation of this route required the synthesis of the 16-membered macrocycle **11a** (Scheme 1). The synthesis began by the boron-mediated aldol addition of (R)-3-propionyl-4-benzyloxazolidinone to cinnamaldehyde to provide crystal-

and underwent a spontaneous intramolecular Mannich cyclization to the tetracyclic ketoester **17** upon attempted purification by chromatography on silica gel or alumina. In practice, enamine **13** was transformed directly into **17** (81% yield) upon heating in ethanol with piperidinium acetate. The structural assignment of this compound was verified by X-ray diffraction analysis of derivative **18** (m.p.: 194°C). For the purpose of complete characterization, enamine **15** was selectively reduced to amine **19** and analyzed by X-ray diffraction as its hydrochloride salt (m.p.: 225°C). An examination of the solid-state conformation of macrocycle **11a** provides no clear rationale for the observed N–C5 condensation of amine **11b**. The protected amine is positioned at the same distance from both the ketones at C5 and C13 (5.38 and 5.41 Å, respectively). As a result of the undesired chemoselectivity of the transannular amine condensation,[12] we turned our attention to an alternative sequence of events.

Macrocycle **11a** underwent a selective transannular Michael reaction upon exposure to base (Cs$_2$CO$_3$, EtOH, −78°C) to

provide **21** as a mixture of diastereomers (94:6) in 83% yield (Scheme 2, m.p.: 136°C). The stereochemical outcome of this cyclization was established by X-ray crystallography. Both newly formed stereocenters are those desired for construction of the lycopodium core. The crystal structure of the Michael product **21** depicts a cyclohexane-ring conformer that minimizes nonbonding interactions. If we assume that the transition state resembles the solid-state conformer, then the transannular addition of the dipole minimized *E,E*-enolate **20** into a pseudo-axially disposed enone rationalizes the outcome and minimizes developing *syn*-pentane interactions. Removal of the carbamate protecting group in **21** results in condensation at C5 to yield the previously described tricyclic enamine **15**. It was apparent that protection of the ketone at C5, which is positioned in close proximity to the carbamate nitrogen center (4.7 Å by X-ray crystallography), would be necessary to divert the condensation to the carbonyl group at C13. A variety of protections at C5 were investigated, however, no reaction between the free amine and C13 ketone could be observed. In conclusion, it appears that the C13 condensation pathway to provide intermediate **22** is disfavored for both entropic and steric reasons. To effect reaction between the amine and C13, we reasoned that disconnection of the N−C1 bond would be necessary (Figure 1, path B).

With respect to path B, the linear precursors **26** and **27** were selected as targets and assembled in a manner analogous to the preparation of **8** (see above, Scheme 1). This synthesis employed a similar Horner–Wadsworth–Emmons coupling to afford **23**. After reduction of the ketone and protection of the alcohol as its silyl ether, the nitrile terminus was converted into aldehyde **24** (DibalH, CH$_2$Cl$_2$, −50°C). An aldol–

oxidation sequence provided flexibility in the synthesis of both substituted and unsubstituted β-ketoesters **26** and **27** (Scheme 3)
Scheme 3. Reagents and conditions: a) L-selectride, −78°C; b) TESCl, imid., DMF, 73%; c) DibalH, CH$_2$Cl$_2$, −50°C, 83%; d) LDA, **25**; PPTS, EtOH; DMP, NaHCO$_3$, 87% (3 steps); e) LDA, tBuOAc; PPTS, EtOH; DMP, NaHCO$_3$, 84% (3 steps).

A survey of conditions to effect a selective intramolecular Michael reaction was undertaken (Scheme 4). The unstable β-ketoester precursor **27** was immediately subjected to cyclization conditions (Cs$_2$CO$_3$, EtOH, −78°C) to provide **28** as a mixture (> 10:1) of diastereomers (Scheme 4, equation (1)).[13] The additional three carbon atoms and amino terminus were appended through an acrylonitrile Michael addition (Bu$_4$NOH·30H$_2$O, MeCN, 0°C, 71%) to provide **29** as a single diastereomer.

In general, Michael additions with the substituted β-ketoester **26** were less selective than with its unsubstituted counterpart **27** (Scheme 4, equation (2)). Products **30a** and

30d contain the requisite stereochemistry at C7 for elaboration to the lycopodium skeleton. Generation of chelate-organized *Z,Z*-enolate complexes (NaH or LiOMe/LiClO$_4$) afforded predominately diastereomer **30c**.[14] Conditions that favor extended or dipole-minimized *E,E*-ketoester enolates (Me$_3$NBnOMe or Cs$_2$CO$_3$) afforded a turnover in selectivity, providing a modest bias for the desired diastereomeric Michael reaction product **30a**.[15,14c–f] Both Me$_3$NBnOMe or Cs$_2$CO$_3$ reaction conditions were equally convenient to execute and high yielding (55–60% **30a**, 22–24% **30b**). Product **30d** was not detected under any conditions.[16]

With the configuration at C7 established through a selective Michael reaction, the next objective toward the lycopodium skeleton was the Mannich addition between the

C4 enol and C13-derived imminium ion. This objective was realized on both Michael adducts **30a** and **29** which were independently carried forward to the common tetracyclic dihydropyran **32** (Scheme 5). Carbamate deprotection (TFA, CH$_2$Cl$_2$) of **30a** initiated condensation, leading to intermediate imine **31**. On exposure to methanolic HCl,[17] a series of reactions ensued, including decarboxylation, formation of a dihydropyran, and Mannich cyclization to provide **32** in 71% yield. To effect a similar sequence from **29**, it was necessary to reduce the nitrile (Raney Ni, H$_2$) to give imine **33**. The adjacent quaternary center sufficiently retards reduction of the imine moiety to prevent over-reduction.[18] Methanolic HCl converted imine **33** into the aforementioned dihydropyran **32**. Inspection of intermediates **31** and **34** indicates an epimeric configuration at C12. Owing to the stereoelectronic imperatives of the Mannich reaction, the latter will not undergo cyclization without prior decarboxylation and formal inversion.[19]

Treatment of dihydropyran **32** with HBr/HOAc cleaved both the benzyl ether and the dihydropyran functions to provide intermediate ammonium bromide salt **35**. On exposure to methanolic base, intramolecular *N*-alkylation and saponification of the acetate was realized, leading to clavolonine (**2**) in 95% yield. The structure of clavolonine (**2**) was verified by single-crystal X-ray crystallography (m.p.: 227°C).[20]

In conclusion, the synthesis of clavolonine (**2**) has been an exercise in the conversion of functionalized linear carbon chains into polycyclic architectures. The end products include

[11] If carbinolamine dehydration is rate-limiting, formation of the stabilized vinylogous urethane **12** is predicted to occur favorably. If carbinolamine formation is rate-determining, condensation at the more electrophilic (C13) ketone should be observed. These predictions are reinforcing for C13 condensation. Saturated ketones are more electrophilic than unsaturated ketones. This can be observed spectroscopically (e.g. IR shift approximately $\Delta \tilde{\nu} = 40\ cm^{-1}$) and experimentally, for example, by competitive reductive amination. A saturated carbonyl group is preferentially reduced in the presence of $NaB(OAc)_3H$, as noted in the following reference: A. F. Abdel-Magid, K. G. Carson, B. D. Harris, C. A. Maryanoff, R. D. Shah, *J. Org. Chem.* **1996**, *61*, 3849. Macrocycle **11a** demonstrates no enol content by ^{1}H NMR or IR spectroscopy. For this reason, the ketone at C13 should be regarded as a saturated ketone.

[12] Macrocycle **11a** was decarboxylated under Krapcho conditions. This material also exclusively favors condensation at C5.

[13] Ketoester **28** exists as a mixture of keto and enol tautomers. For this reason, an accurate diastereomeric ratio of the preceding Michael addition could not be determined. A small amount of **28** was decarboxylated under Krapcho conditions. The derived ketone was isomerically pure (d.r. ≥ 10:1), and the stereochemistry at C7 was proven by 2D ^{1}H NMR spectral analysis (NOESY).

Asymmetric Catalysis

Highly Enantio- and Regioselective Quinone Diels–Alder Reactions Catalyzed by a Tridentate [(Schiff Base)Cr^III] Complex**

*Elizabeth R. Jarvo, Brian M. Lawrence, and Eric N. Jacobsen**

The octocoral *Pseudopterogorgia elisabethae* produces a variety of terpenoids, such as colombiasin A, elisapterosin B, and elisabethin A, that display diverse structural frameworks and bioactivities.[1] These secondary metabolites are possibly

Colombiasin A   Elisapterosin B

Elisabethin A   1
derived from a relatively simple common biosynthetic precursor; indeed, compounds such as **1**, which could undergo transformation to the more complex polycyclic natural products by divergent cyclization pathways, have been isolated from the same organism.[2] We became interested in developing efficient quinone Diels–Alder (qDA) catalysts for the preparation of intermediates related to **1** [e.g. **2**, Eq. (1)] as part of a unified biomimetic strategy for the syntheses of this family of natural products. Herein, we report a new method for highly enantioselective qDA reactions of quinones with a variety of dienes catalyzed by a new, monomeric [(Schiff base)Cr^III] complex.[3] In the following paper in this issue, we describe concise asymmetric catalytic syntheses of

(1)
(−)-colombiasin A and (−)-elisapterosin B employing this methodology in the pivotal step.[4]

The reaction of quinones with dienes was the first class of cycloaddition pathways to be recognized by Diels and Alder,[5] and it has enjoyed widespread use in organic synthesis ever since.[6] However, until recently, effective catalysts for enantioselective qDA reactions have remained elusive. In seminal studies by Mikami and co-workers, Ti–binolate complexes were found to be effective for a limited range of substrates.[7,8] Subsequently, Evans and co-workers reported bis(oxazoline)–lanthanide complexes as asymmetric catalysts for reactions of methyl-substituted dienes with ester-substituted quinones capable of two-point binding.[9] Corey and co-workers described the use of cationic oxazaborilidines as enantioselective qDA catalysts that promote cycloaddition through single-point binding, with unsymmetrical quinones undergoing reaction by activation of the most Lewis basic carbonyl group.[10] Despite these important advances, identification of new and highly active qDA catalysts with broad substrate scope remains an important goal, particularly for accessing the diversity of cycloadducts of interest in the synthesis of biologically active compounds.

Our own catalyst development studies focused initially on the reaction of quinone **3** and diene **4**, a model relevant to the colombiasin A effort and designed to gauge both catalyst enantioselectivity and regioselectivity (Scheme 1). As the
Scheme 1. Quinone Diels–Alder (qDA) reaction followed by in situ derivatization of the cycloadduct. TES = triethylsilyl; DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene; DMAP = 4-dimethylaminopyridine.

qDA cycloadduct obtained is not stable to air or silica gel at room temperature, further functionalization of the cycloadduct was performed to facilitate isolation and analysis. In situ air oxidation to the quinone **5**, or tautomerization and

trapping with acetic anhydride to **6**, provided stable materials that could be handled easily using standard laboratory techniques.[11,12]

Recognizing the demonstrated ability of chiral [(Schiff base)Cr^{III}] catalysts to activate simple carbonyl compounds to cycloaddition through one-point binding mechanisms,[3,13] we explored their possible application to the qDA reaction. Preliminary studies with the broadly useful dimeric catalyst **8**[14] led to an intriguing and unexpected observation: catalysts prepared by different extractive workup procedures led to dramatically different results in the model reaction (Table 1).

8
Table 1: Effect of catalyst preparation conditions on the asymmetric qDA reaction of quinone **3** with diene **4**.[a]

Entry	Catalyst preparation		Quinone Diels–Alder			
	Extractive workup	Predominant species	Reaction time	Yield [%][b]	ee [%]	Regioselectivity[c]
1	H$_2$O	**8**	26 h	82	39	3.3:1
2	1 N HCl	**8** (+**9**)	35 min	70	96	12:1
3	3 N HCl	**9**	10 min	86	96	12:1

[a] Reactions were carried out with 5 mol% catalyst and 1.5 equiv diene **4** in the presence of crushed 5 Å molecular sieves in toluene (0.2 M). [b] Yield of isolated product after oxidation to quinone **5** and purification by silica gel chromatography. [c] Determined by HPLC analysis with commercial chiral stationary phases. See Supporting Information for full details.

We had found previously that synthesis of **8** accompanied by aqueous workup under either neutral or acidic (1 N HCl) conditions afforded catalysts that performed similarly in hetero-Diels–Alder (HDA) reactions, with the preferred method of catalyst preparation involving extraction with neutral H$_2$O.[15] Catalyst prepared in this manner is dimeric in the solid state[3b] and in solution.[16] However, the qDA reaction catalyzed by dimer **8** was sluggish and afforded products with low enantio- and regioselectivity, whereas catalyst prepared by acidic workup procedures afforded markedly improved results (Table 1, entry 2, 96% *ee*, 12:1 regioselectivity). This suggested that another chromium–ligand complex was being generated as a minor component under the acidic workup conditions, and that this impurity

could be the active species in the quinone DA reaction. The conditions for catalyst preparation were therefore varied systematically to optimize the rate and enantioselectivity in the qDA reaction. Catalyst prepared by using 3 N HCl for the extractive workup proved most effective, affording product **5** with 96% *ee* and 12:1 regioselectivity after a reaction time of only 10 min. The major regioisomer was found to be that which would arise from Lewis acid coordination to the less Lewis basic carbonyl group, as would be required for our syntheses of colombiasin A and related natural products.[17]

Catalyst prepared by using the 3 N HCl workup protocol was recrystallized to afford single crystals suitable for X-ray analysis. In the solid state, complex **9** has a monomeric, pseudooctahedral structure with two water molecules and a chloride ligand in the coordination sphere of the metal (Figure 1).[18] This crystalline material was introduced in the
Figure 1. Preparation of catalysts **8** and **9**, and the X-ray crystal structure of **9**. Ellipsoids are drawn at the 30% probability level.

qDA reaction between **3** and **4**, and it exhibited nearly identical selectivity to the bulk catalyst (95% *ee* versus 96% *ee*, 12:1 regioselectivity). Thus, Cr^{III} complexes derived from the same tridentate Schiff base ligand **7** are generated in different aggregation states depending only on the workup conditions (Figure 1), with the dimeric complex **8** being optimal for HDA reactions, and the monomeric complex **9** optimal for qDA reactions.[19] While the aggregation state of the active catalyst derived from **9** has not yet been elucidated, it is clear that it is distinct from the dimeric catalyst derived from **8**.[20]

The scope of catalyst **9** in qDA reactions is illustrated by the examples in Tables 2 and 3. A variety of cycloadducts were prepared with greater than 90% *ee* in reactions carried out at 0°C.[21] Despite the fact that quinone **3** undergoes reaction by apparent activation of the less basic carbonyl group adjacent to the methoxy group, bidentate chelation to the catalyst by the quinone is not required. Thus, naphthoquinone (**10**) and 2,3-dimethylquinone both underwent reaction with diene **4** to yield products in 94% *ee* (Table 2, entries 2 and 3). The same sense of stereoinduction was observed in reactions with **3** as in reactions with quinones incapable of two-point binding.[22]

Table 2: Enantio- and regioselective qDA reactions of a variety of quinones with diene **4**.[a]

Entry	Quinone	Temperature [°C]	Reaction time	Yield [%][b]	ee [%], regioselectivity[c]
1	**3** (MeO, Me quinone)	0	10 min	83 (q)	96, 12:1
2	**10** (naphthoquinone)	0	10 min	85 (q)	94
3[d]	Me, Me quinone	0	30 min	75 (q)	94
4	benzoquinone	−40	3 h	80 (hd)	86

[a] Unless noted otherwise, reactions were carried out using 5 mol% catalyst **9** with 1.1 equiv diene **4** in the presence of crushed 5 Å molecular sieves in toluene (0.2 M). [b] Yields of isolated quinone (q) or hydroquinone diacetate (hd, see Scheme 1), after purification by silica gel chromatography. [c] Determined by HPLC. [d] Reaction carried out at higher concentration (0.8 M in quinone). See Supporting Information for full details.

The reactions of a variety of dienes with napthoquinone (**10**) and methoxy-substituted quinone **3** were also examined (Table 3). Electronic activation of the diene by silyloxy or alkoxy substituents is not required, as dienes such as 1,3-pentadiene and 2-methyl-1,3-pentadiene were found to

undergo reaction with acceptable rates to afford highly enantioenriched qDA products (Table 3, entries 1–3). Sterically demanding substituents at both the 1- and 3-positions of the diene are well tolerated: *i*Pr-substituted dienes **11** and **12** (Table 3, entries 6 and 8) required prolonged reaction times, but afforded products with high levels of enantioselectivity (90 and 96% *ee*, respectively). Reaction of diene **11** with quinone **3**, a model system for our synthetic efforts [see Eq. (1)], provided the required isomer with high regioselectivity (9:1).

In conclusion, a seemingly minor change in the conditions used for workup in the catalyst synthesis resulted in the identification of a new, monomeric [(Schiff base)Cr^III] complex with broad scope in the asymmetric qDA reaction. The utility of this catalyst in natural product synthesis is illustrated in the following communication, where we report the total syntheses of (−)-colombiasin A and (−)-elisapterosin B.[4] Further studies related to the scope and mechanism of catalyst **9** are underway.

[15] D. E. Chavez, E. N. Jacobsen, *Org. Synth.*, in press.

[16] Kinetic and mechanistic studies of HDA reactions promoted by **8** indicate a dimeric catalyst structure both in the ground state and in the rate-determining transition state. R. T. Ruck, E. N. Jacobsen, unpublished results.

[17] See Supporting Information for details. Cationic oxazaborolidine catalysts afford products with opposite regioselectivity (see ref. [10]).

[18] Details of the crystal structure analysis are provided as Supporting Information. CCDC-262884 (**9**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

[19] For example, the inverse electron demand hetero-Diels–Alder reaction employed in the first step of the colombiasin synthesis (see preparation of **6** in Scheme 3 in reference [4]) proceeded with 78% *ee* with monomeric catalyst **9** and 93% *ee* with dimeric catalyst **8**.

[20] If a monomeric catalyst structure analogous to that of **9** is assumed in the *ee*-determining step with one of the water molecules replaced by the quinone substrate, then the intriguing question arises about which of the two stereochemically inequivalent binding sites is engaged. Qualitatively, it would appear that binding to the inner, concave face of the catalyst would be most consistent with the high enantioselectivities observed in the qDA.

[21] Reactions carried out at −40°C generally afforded higher enantioselectivity, albeit with slower rates; these conditions were employed for those substrates that were generated in < 90% *ee* at 0°C. For example, the reaction of benzoquinone with diene **4** afforded cycloadduct in 79% *ee* at 0°C, and 86% *ee* at −40°C (Table 2, entry 4).

Efficient Total Syntheses of (−)-Colombiasin A and (−)-Elisapterosin B: Application of the Cr-Catalyzed Asymmetric Quinone Diels–Alder Reaction**

*Alessandro A. Boezio, Elizabeth R. Jarvo, Brian M. Lawrence, and Eric N. Jacobsen**

The gorgonian corals are notable as sources of many diverse pharmacological agents,[1] and substantial effort has been directed toward isolation of natural products from these organisms. One species from this family, the soft coral *Pseudopterogorgia elisabethae*, has provided compounds with antiinflamatory, analgesic, cytotoxic, antiviral, antibacterial, antituberculosis and antimalarial activity.[2] Members of the pseudopterosin family of diterpene glycosides (Scheme 1) were isolated from this organism and have subsequently been found to be potent antiinflamatory and analgesic agents.[3] This class of natural products, which contains more than 15 variants, has been shown to be derived from a common biosynthetic precursor, erogorgiaene.[4] More recently, other secondary metabolites that appear to originate from a related biosynthetic pathway have been recovered from extracts of this species.[5] These compounds, such as colombiasin A, elisapterosin B, and elisabethin A, have attracted considerable interest from the synthetic community, due in significant part to the challenge presented by their interesting molecular architectures.[6–8] It has been proposed that these natural products could be derived from a common intermediate such as **1** by different cyclization pathways.[9]

Scheme 1. Representative secondary metabolites isolated from *Pseudopterogorgia elisabethae.*

Such diversity-oriented synthesis practiced on a biosynthetic level would allow the organism to generate an array of compounds for chemical defence, and is supported by the observation of **1** in extracts from *P. elisabethae.*[10]

We were intrigued by the versatility of putative biosynthetic intermediate **1**, and became interested in developing a synthetic route to (−)-colombiasin A that would proceed through a similar advanced intermediate, such as alcohol **2** (Scheme 2). We envisioned preparation of **2** by a diastereo-
Scheme 2. Retrosynthetic analysis applied to colombiasin.

and regioselective quinone Diels–Alder (qDA) reaction. This strategy would require a method to adjust the stereochemistry at C6 (colombiane numbering) in a subsequent step. Indeed, while several elegant syntheses of colombiasin A have been reported, control over all stereochemical elements of the molecule has proven to be a most significant challenge.[6] To insure high selectivity in the qDA reaction, we undertook an effort to develop new catalysts for this reaction as an integral part of our synthetic plan. The details of those studies are presented in the preceding communication in this issue.[11] To address the stereochemistry at C6, we chose to employ silyl enol ether **5** as the diene component, with the thought that the ketone **3** could undergo epimerization to afford the desired diastereomer. The silyl enol ether would also serve to differentiate the diene termini, and thus allow high regioselectivity in the qDA reaction.

Our synthesis of diene **5** began with an inverse electron demand hetero-Diels–Alder (HDA) reaction catalyzed by dimeric chromium complex **8**, a reaction that was developed in our group for the preparation of optically pure dihydropyrans.[12, 13] Reaction of ethyl vinyl ether with *trans*-crotonaldehyde afforded cycloadduct **6** in good yield (81%) and high enantioselectivity (93% *ee*) on multigram scale, thereby introducing the requisite stereochemistry of the methyl-bearing stereocenter at C7 (Scheme 3). Palladium-catalyzed
Scheme 3. Synthesis of diene **5**. a) (1*S*,2*R*)-**8** (5 mol%), MS 4 Å, 20 h; b) 1. *t*BuLi, THF, −78 to 0°C, 0.5 h; 2. ZnCl₂, THF, 0°C to RT, 0.5 h; 3. [Pd-(PPh₃)₄] (2.5 mol%), 1-bromopropene (2 equiv, *cis/trans* 1:1), THF, 2 h; 4. HCl (aq.) (0.5 M), 1 h; c) 1. BrCH₃PPh₃, KHMDS, PhMe, 0°C, 1 h; 2. **7**, −78 to 0°C, 82%; d) 1. KHMDS, THF, −78°C, 0.5 h; 2. TESCl, −78°C, 0.5 h, 90% (90% isomerically pure). HMDS = bis(trimethylsilyl)amide, TES = triethylsilyl.

Negishi coupling with 1-bromopropene (1:1 *E/Z* mixture) was performed after lithiation of **6** with *t*BuLi and transmetalation with ZnCl₂.[14] The isomerically pure cross-coupled product was hydrolyzed directly to afford ketoaldehyde **7** in 81% yield. Selective olefination of the aldehyde in the presence of the enone was achieved by a standard Wittig olefination. The enone was then treated with KHMDS and the resultant enolate was quenched with TESCl to provide diene **5**.[15]

With diene **5** in hand, catalysis of the key qDA reaction was investigated (Table 1). Reactions of simpler model dienes

suggested that monomeric chromium complex **12** might be a suitable catalyst (see previous paper for a detailed discussion).[11,16] The inherent substrate-induced diastereoselectivity, as measured by catalysis with achiral catalyst **11**, was low (1.8:1 d.r., 3:1 regioselectivity; Table 1, entry 1), though the

diastereomer required for the synthesis was obtained as the major product.[17] Gratifyingly, chiral catalyst **12** was found to exert high levels of stereocontrol over the reaction. In the matched case, catalyst (1*R*,2*S*)-**12** provided the desired product in high diastereoselectivity (17:1) and regioselectivity (10:1; Table 1, entry 2). The mismatched catalyst, (1*S*,2*R*)-**12**, though less selective overall, induced a reversal in diastereoselectivity (1:6.5 d.r., 4.6:1 regioselectivity; Table 1, entry 3).

Having demonstrated the highly stereoselective qDA reaction, we next investigated the crucial epimerization of the C6 stereocenter (Figure 1). The qDA reaction of **4** and **5** afforded silyl enol ether **13**, along with an olefin isomer **13′**, in 86% yield.[18] These isomers were not separated as both led to the desired ketone upon hydrolysis. Treatment with a 1:1 mixture of concentrated HCl and methanol effected deprotection of the silyl enol ether, tautomerization of the enedione to the hydroquinone, and epimerization to the desired diastereomer (> 10:1 d.r. as measured by ¹H NMR spectroscopy).[19] The relative stereochemistry of ketone **14** was confirmed

by X-ray crystallography (Figure 1).[20] A highly diastereoselective reduction followed by in situ aerobic oxidation furnished quinone alcohol **15** in 75% yield (over two steps from **13** + **13′**).[21]

We planned to install the tertiary allylic alcohol by a cross-metathesis reaction catalyzed by the Grubbs second-generation ruthenium catalyst **18** (Scheme 4).[22] Preliminary studies suggested that the free secondary alcohol of **15** could interfere with the subsequent dehydration reaction to the requisite diene, so we chose to block this group first. As deoxygenation at C5 would ultimately be required, xanthate was chosen as a functional protecting group.[23,24] The cross-metathesis reaction of quinone **16** with 2-methyl-3-buten-2-ol catalyzed by **18** (10 mol%) proceeded smoothly at room temperature (87% yield).[25] Warming a solution of tertiary alcohol **2** in benzene to reflux in the presence of MgSO₄ resulted in a tandem dehydration-intramolecular qDA reaction to assemble the tetracyclic colombiane framework (77% yield). The ¹H and ¹³C NMR spectra of xanthate **17** matched those reported by Nicolaou and co-workers for this intermediate in their synthesis of colombiasin A.[6a] Completion of the synthesis proceeded in a straightforward fashion. Deoxygenation and demethylation were performed by using modifications of the literature conditions,[6a,c] affording the natural product, (−)-colombiasin A in 67% yield for the two-step sequence. Spectral data (NMR, HRMS, IR) of synthetic material and natural (−)-colombiasin A were in complete accord.[26]

During the course of investigations into alternate deprotection conditions for methyl colombiasin A, we discovered that treatment of (−)-colombiasin A with superstoichiometric quantities of BF₃·Et₂O resulted in smooth conversion to (−)-elisapterosin B (Scheme 5). This reaction may proceed by a fragmentation reaction, affording an allylic cation that undergoes subsequent cyclization, or by a retro [4+2] cycloaddition followed by a [5+2] cycloaddition. While the mechanism of this reaction has yet to be determined, it is stereoselective and

high-yielding (94%), and underlines the close structural relationship between these natural products.

The enantioselective synthesis of (−)-colombiasin A was accomplished in 12 steps and 11.5% overall yield from ethyl vinyl ether and *trans*-crotonaldehyde. A stereoselective qDA reaction catalyzed by a [(Schiff base)Cr^III] complex developed expressly for this purpose allowed control of diastereo- and regioselectivity in one of the key steps of the sequence. Other key steps included highly selective installation of the C6 stereocenter under thermodynamic control, and a tandem dehydration-qDA reaction to assemble the tetracyclic framework of the molecule. The use of protecting groups was minimized by careful synthetic design. (−)-Elisapterosin B was prepared by a remarkably facile Lewis acid-mediated rearrangement of colombiasin A. Current studies focus on

biomimetic syntheses of other natural products isolated from *Pseudopterogorgia elisabethae* by way of intermediates such as tertiary alcohol **2**.

A Template-Based Electrochemical Method for the Synthesis of Multisegmented Metallic Nanotubes**

Woo Lee,* Roland Scholz, Kornelius Nielsch, and Ulrich Gösele

Tubular nanostructures have stimulated extensive research efforts in recent years because of their technological importance in advanced electronic or magnetic devices[1] and prospective applications in catalysis,[2] sensors,[3] and biological separation and transport.[4] To date, various methods[5] including reductive sulfidization,[6] thermal decomposition of precursors,[7] atomic layer deposition (ALD),[8] hydrothermal pyrolysis,[9] galvanic replacement reactions,[10] and surfactant- or template-based growth[11] have been developed for the fabrication of such tubular nanostructures. Among them, template-based synthesis using anodic aluminum oxide (AAO) or track-etched polymer membranes has attracted much attention, because it provides several distinct advantages over other approaches. It offers a convenient way for producing structurally uniform nanostructures periodically aligned in template matrices. A wide range of materials including metals, semiconductors, and polymers have been prepared in the form of nanotubes.[12] However, few examples have been reported on the fabrication of metal nanotubes despite their technological importance. The development of a generalized method for the fabrication of aligned metal-nanotube arrays remains a challenge. Precise control of the nanotube growth process and formation of well-aligned arrays will greatly assist investigations of their physical properties and their potential use in nanoscale fluidics, chemical and biological separations, sensors, and catalysts.

Herein, we report a novel approach for the preparation of metallic nanotubes based on the preferential electrodeposition of a metal along the pore walls of an AAO membrane in the presence of metallic nanoparticles on the wall surfaces (Figure 1). Several reports on the immobilization of metallic nanoparticles on the pore walls of AAO have been published previously. Schmid and co-workers showed that Au nanoparticles can be self-assembled on AAO channels modified with organosilane molecules, which function as molecular anchors binding the nanoparticles.[13] More recently, Rubin-

Ag^I/Ag^0 pair (0.80 V versus SHE). Therefore, the surface-bound $Sn_{surface}^{II}$ cations would be spontaneously oxidized into Sn^{IV}, thus producing discrete metallic Ag nanoparticles on the surface of the Sn^{II}-treated AAO membrane upon immersion in an aqueous solution of $AgNO_3$ [Eq. (1)].

$$2\,Ag_{aq}^I + Sn_{surface}^{II} \rightarrow 2\,Ag_{surface}^0 + Sn_{surface}^{IV} \qquad (1)$$

This process results in homogeneous deposition of metal nanoparticles over the entire surface (pore walls and faces) of AAO membranes (Figure 2a). The size and the number of
Figure 2. a) Cross-sectional SEM image of the Ag-nanoparticle-immobilized anodic aluminum oxide (AAO) membrane. b) Cross-sectional SEM image of the Au nanotube–AAO composite showing Au nanotubes embedded in the alumina matrix. c) and d) SEM images of Au nanotubes after removal of alumina matrix with NaOH (1.0 m); part d) illustrates the open-end tips of Au nanotubes at the levels of different length. e) Representative TEM image of Au nanotubes showing their tubular structure.

stein and co-workers demonstrated the preparation of Au nanoparticle nanotubes (NPNTs) by introducing a colloid solution of Au nanoparticles into the pores of an organo-silane-modified AAO, followed by spontaneous coalescence of the surface-bound Au nanoparticles.[14] In an alternative approach, Johansson et al. deposited Pd nanoparticles on the pore walls of AAO by using a sequential electroless deposition technique, in which a palladium complex ($[Pd(NH_3)_4]^{2+}$) was thermally reduced to metallic Pd.[15] In the present study, metallic nanoparticles (for example, Ag) were immobilized on the pore walls of an AAO membrane by the spontaneous reduction of Ag^I by Sn^{II}, which is a modification of the previously established sensitization–preactivation process of AAO[16] or polymer membranes[17] prior to the electroless deposition of metals. To induce the selective reduction of metal cations on the surfaces of oxide membranes, Sn^{II} was first deposited on the pore walls by immersing the membranes in an aqueous solution of $SnCl_2$. After a drying step, the resulting membranes were soaked in an aqueous solution of $AgNO_3$. These two steps constitute one deposition cycle and were repeated several times (typically six cycles). The standard reduction potential of Sn^{IV}/Sn^{II} (0.151 V versus standard hydrogen electrode, SHE) is lower than that of the

metal nanoparticles depend on the number of deposition cycles. The average particle size determined by TEM analyses was 11 ± 4 nm (Supporting Information). Unlike the Au NPNTs reported by Rubinstein and co-workers[14] which showed good electrical conductivity with a specific resistivity of 6 Ω cm, our Ag-nanoparticle-modified AAO membranes exhibited a typical insulating behavior even after 10 deposition cycles. This finding indicates that the Ag nanoparticles immobilized on the surfaces of AAO membranes are isolated from each other without the formation of a continuous conduction path for current transport. Electrodeposition of Au at current densities ranging from 2.2 to 2.5 mA cm^{-2} resulted in the formation of Au nanotubes embedded in the alumina matrix (Figure 2b). Subsequent removal of the oxide matrix with NaOH (1.0 m) led to the release of Au nanotubes with surfaces decorated with Ag nanoparticles (Figure 2c,d). The presence of Ag nanoparticles on the surface of the metal nanotubes is inevitable, and results in mixed-metal nanotubes. TEM investigations of Au nanotubes revealed that the average outer diameter of the nanotubes is 330 nm (Figure 2e). Further evidence for the tubular nanostructure was

Communications

obtained directly from water permeation experiments through the gold nanotube arrays embedded in the alumina matrix: a drop of water placed on one side of the membrane was transported to the other side.

In the process described herein, the growth of metal nanotubes starts at the base-metal electrode at the bottom of the pores (that is, a bottom-up deposition of metal) as a result of the nonconducting nature of the nanochannels. It is believed that Ag nanoparticles immobilized on the oxide nanochannel surfaces play a key role in the growth of the metallic nanotubes, and enable preferential electrodeposition of metal along the nanochannel surfaces. Nanotube formation in this electrodeposition process can be understood in terms of the relative rates of deposition and the diffusion of metal ions. It is believed that the deposition process takes place at the tube tips, and therefore the deposition interfaces and the diffusion layers of metal ions move dynamically with the growth process of the tubes (Figure 1). Once a small conducting path is created by electrodeposition between the tube tip and an isolated Ag nanoparticle, the deposition interface will move toward the recently created area, and a majority of the metal ions will be deposited on the newly connected nanoparticle until another isolated particle is electrically connected. This electrodeposition effect establishes a depletion layer of metal ions, and thus the ion concentration below the tube tips should be very low, and the metal deposition on the inner tube wall should be negligible. Our assumptions were proven by electrodeposition experiments with different deposition rates. The electrodeposition carried out at a low current density (< 0.4 mA cm^{-2}), at which the focusing effect at the tube tip could be neglected as a result of the slow deposition rate, produced only arrays of solid metal nanorods. In contrast, the electrodeposition performed at a high current density (> 3.0 mA cm^{-2}) resulted in mechanically unstable metal nanotubes with highly porous wall surfaces (Supporting Information).

For cases in which the whole surface of the membrane is electrically conductive, electrodeposition of metal should occur evenly over the entire membrane surface at the same time. In other words, radial growth of metal nanotubes occurs inside the nanochannels, gradually decreasing the channel diameter. The underpotential deposition (UPD) technique is required[18] for the fabrication of pore walls of uniform thickness over the whole length of the membranes. The deposition rate must be sufficiently lower than that of the axial mass transfer of metal cations to guarantee a homogeneous ion concentration over the whole pore length.

By taking advantage of the preferential deposition of metal along the wall surfaces of oxide nanochannels, we were able to prepare multisegmented metallic nanotubes with a bimetallic stacking configuration along the nanotube axes. Figure 3 shows representative SEM images of multisegmented metallic nanotubes with a stacking configuration of Au-Ni-Au-Ni-Au, before (Figure 3a) and after (Figure 3b,c) removal of the alumina matrix with a solution of NaOH (1.0 M). The average outer diameter of the nanotubes was estimated to be 300 nm. Ni segments about 800 nm long with a dark image contrast can be clearly observed between adjacent Au nanotube sections (Figure 3c; see also the color-

Figure 3. SEM images of multisegmented metal nanotubes with a stacking configuration of Au-Ni-Au-Ni-Au along the nanotube axis. a) Cross-sectional SEM image of as-prepared metal nanotube–AAO composite, which shows metal nanotubes embedded in an alumina matrix. The signals from Au and Ni are shown in yellow and purple, respectively. b) and c) SEM images of multisegmented metal nanotubes after removal of alumina matrix with NaOH (1.0 M); part c) clearly shows the stacking configuration of multisegmented metal nanotubes in which the segments with bright and dark image contrasts correspond to Au and Ni, respectively.

enhanced view of Au–Ni segments in Figure 3a). This contrast in the SEM images results from differences in the intensity of backscattered electrons from the two metals. In this nanofabrication process, various metallic segments (Ag, Au, Pt, Pd, Fe, Co, Ni, etc.) can be incorporated into the nanotube structure, thus enabling the fabrication of barcode-type nanotubes.[19] The length of each metal segment can be tuned by controlling the amount of total integrated charges involved in the electrochemical reaction. Such a unique capacity for tailoring the nanotube structure could provide an opportunity for engineering the physical properties of nanotube materials.

Arrays of continuous Ni nanotubes and of multisegmented nanotubes (Au-Ni-Au-Ni-Au stacking configuration, Figure 3) were examined by a superconducting quantum interference device (SQUID) magnetometer at 298 K for comparison of their magnetic properties. The corresponding hysteresis loops are presented in Figure 4. With the magnetic field applied along the nanotube axis ($\parallel$), both samples showed coercivities $H_{c\parallel}$ in the range of 85 to 90 A m^{-1} and relatively low remanence values (4 and 17%). As the saturation field $H_{s\parallel} \gg H_{c\parallel}$, both samples exhibited reversible magnetic behavior. The nanowire diameter was at least one order of magnitude larger than the magnetic exchange length for nickel $\lambda_{Ni} \approx 13$ nm, and we therefore assume that the Ni nanotubes switched by a curling-like switching mode.[20] The

presence of Ag nanoparticles on the wall surfaces. We have demonstrated for the first time the preparation of multi-segmented metallic nanotubes with a bimetallic stacking configuration along the nanotube axes. This nanofabrication method can be readily extended to a wide range of metallic or semiconducting materials. Furthermore, the unique capacity for tailoring the nanotube structure, along with the function-alization of the inner wall surface of metal nanotubes with various molecules (for example, proteins and DNA), are expected to be particularly useful in the field of catalysis, advanced microfluidics, biological and magnetic sensors, and molecule separation.

Experimental Section

Membrane preparation: Self-ordered nanoporous Al_2O_3 membranes were prepared by the two-step anodization[21] of surface-finished aluminum. In brief, Al sheets (typical diameter 4 cm) were anodized under a regulated cell voltage of 195 V with H_3PO_4 as electrolyte. The first anodization was started under relatively mild electrochemical conditions with H_3PO_4 (0.5 wt.%, 0.6°C) to prevent the Al from breakdown in the early stages of anodization. After 3 h, the concentration of the H_3PO_4 was increased to 1.0 wt.% by directly injecting 85 wt.% H_3PO_4 into the electrochemical cell, and the temperature of the electrolyte was adjusted to 1.4°C. The anodization proceeded for 15 h under these conditions. Afterward, the porous oxide layer was completely removed by immersion in an acid mixture (1.8 wt.% chromic acid and 6 wt.% H_3PO_4) at 43°C for 12 h to obtain a textured surface on the Al sheet. The second anodization was conducted in H_3PO_4 (1.0 wt.%, 1.4°C) for 16 h. Subsequently, free-standing alumina membranes were obtained by a stepwise voltage reduction technique. The membranes had nominal pore diameters of 300 nm and contained 4.6×10^8 pores per cm^2 of membrane surface area.

Immobilization of metal nanoparticles: The immobilization of metal nanoparticles on the surfaces (pore walls and faces) of an AAO membrane was carried out as follows. First, Sn^{II} was deposited on the surfaces by immersing an AAO membrane in an aqueous mixture of $SnCl_2$ (0.02 M) and HCl (0.01 M) for 2 min. The membrane was thoroughly rinsed in distilled water several times, subsequently in acetone, and finally dried at 70°C for 1 min. Second, the resulting membrane was dipped into an aqueous solution of $AgNO_3$ (0.02 M) for 2 min to deposit Ag nanoparticles on the pore walls of the AAO, followed by the same drying process used in the first step. These two steps constituted one cycle for metal nanoparticle deposition on the surfaces of a membrane. Typically, six deposition cycles were employed.

Electrodeposition: A thin Au layer was deposited by sputtering on the pore-mouth surface of a nanoparticle-modified AAO membrane to make the surface electrically conductive. This Au layer served as a working electrode in the subsequent electrodeposition of the desired metal. A commercially available plating solution (Auruna 5000) was used for Au nanotubes. Nickel was deposited from a solution of $NiCl_2 \cdot 6H_2O$ (8.41×10^{-2} M), $Ni(H_2NSO_3)_2 \cdot 4H_2O$ (1.59 M), H_3BO_3 (0.33 M), and sodium acetate buffer (pH 3.4). The typical current density was about 2.4 mA cm^{-2}. The total membrane area in contact with the electrolyte was 2.7 cm^2; the total pore area (actual deposition area) was estimated to be 33% of this area.

multisegmented nanotube arrays could be completely mag-netized at lower saturation fields ($H_{s\parallel} \approx 750$ A m^{-1}) than the array of continuous Ni nanotubes ($H_{s\parallel} \approx 2300$ A m^{-1}). The positions of the Ni segments along the pore axis showed large variations (Figure 3a). Although the tube diameter, spacing, and wall thickness for both samples were similar, we assume that the array of multisegmented nanotubes exhibited lower dipolar interactions. The average distance between the neighboring Ni segments was larger than the intertube distance of the continuous nanotube array. In the perpendic-ular field direction ($\perp$), both samples were completely magnetized around $H_{s\perp} \approx 2000$ A m^{-1} and show highly similar hysteresis loops with a reversible magnetic behavior ($H_{s\perp} \gg H_{c\perp}$). In comparison of the hysteresis loops for both magnet-ization directions the array of continuous nanotubes showed a nearly isotropic magnetic behavior, whereas the multiseg-mented sample exhibited a preferential magnetic orientation along the direction of the magnetic nanotubes as a conse-quence of the low dipolar interactions and the magnetic anisotropy resulting from the nanotube shape.

In summary, we have developed a simple electrochemical method for the preparation of metal nanotubes. The process is based on the preferential electrodeposition of a metal along the pore walls of an anodic alumina membrane in the

highly luminescent, and, more importantly, ultrasensitive in both in vitro and in vivo bioassays. To find fluorophores that can meet these requirements, various semiconductor quantum dots (QDs) with tunable size-dependent emission, high quantum yields of photoluminescence (PL), broad excitation spectra, and narrow emission bandwidths have been developed and successfully applied in biological analyses.[1–5] However, they also have intrinsic limitations. On the one hand, their inherent toxicity and chemical instability limits their application in biological detection and medical diagnosis.[6] On the other hand, although these QDs work well under laboratory conditions, an increase in their background signal may be noted in the presence of interfering biomolecules (such as green-fluorescent proteins) and other fluorescent organic molecules that are usually present in biological and environmental samples and which can also be excited by UV radiation. The sensitivity of detection would hence be lowered. To improve the sensitivity, fluorescence resonant energy transfer (FRET) has been introduced into QD-based bioanalysis of molecular structure and protein–protein, protein–nucleic acid, and other interactions.[7,8] Owing to the specificity and the intrinsic sensitivity of FRET to small changes in donor–acceptor distances,[9] these FRET-QD systems have been demonstrated to show higher sensitivity. However, the inherent limitations of the fluorescence of QDs, including high background noise, potential toxicity, and instability, as mentioned above, cannot be eliminated by incorporating FRET technology and still restrict their application in the analysis of biological samples.

Hence, to find a more appropriate luminescent label remains a challenging task and is crucial to the development of modern gene technology and medical sciences. Upconversion (UC) nanophosphors, which are excited in the infrared region instead of the UV region to give emission in the visible domain, may be such an alternative. These UC nanophosphors show a high chemical stability, high quantum yields, and low toxicity, and their optical properties can be tuned by variation of lanthanide dopants and the host matrix.[10] In particular, the fluorescence from biological samples (background) upon excitation with IR radiation is extremely low as the interfering biomolecules in question absorb in the UV (not the IR) region. All these favorable properties have indicated the great potential of UC nanoparticles in the analysis of biological and environmental samples, and especially for fluorescence imaging in vivo.[11] Furthermore, if FRET technology can be coupled with bioassays based on UC nanoparticles, a further enhancement in the selectivity and sensitivity of detection can be expected. However, to the best of our knowledge, no such system has yet been reported. Herein, we demonstrate a novel biosensor for the detection of trace amounts of avidin which is based on FRET between bioconjugated UC nanoparticles and gold nanoparticles.

The UC nanoparticles we chose are $Na(Y_{1.5}Na_{0.5})F_6:Yb^{3+},Er^{3+}$. As can be seen in the spectrum shown in Figure 1a, the nanoparticles show three emission bands at $\lambda = 525$, 540, and 655 nm, which correspond to energy-transfer processes from the excited states $^2H_{11/2}$, $^4S_{3/2}$, and $^4F_{9/2}$, respectively, to the ground state $^4I_{15/2}$.[12] However, the peak at 540 nm is the main peak, while the other peaks are very
Figure 1. a) Upconversion luminescence spectrum of hexagonal-phase upconversion nanoparticles in solution upon excitation with a 980-nm laser; b) green luminescence observed from sample. c) UV/Vis absorption spectrum of 7-nm gold nanoparticles in aqueous solution.

weak in comparison, which makes it an excellent single-emission biological label. As typical organic fluorescent dyes display broad emission spectra with a long tail, an "impurity" in the form of the emission from the nanoparticles can introduce spectral cross-talk between different detection channels which thus makes them unsuitable for biological applications and creates difficulties in the quantification of the relative amounts of different probes. An ideal probe for multicolor experiments should emit at spectrally resolvable energies with a narrow, symmetric emission spectrum, and the complete set of probes should be excitable at a single wavelength.[2] Here, the monodispersed nanoparticles emit strong and pure green fluorescence with a symmetric and narrow emission spectrum upon excitation at a single wavelength (980-nm laser), which makes them more suitable as a probe for multicolor biological detection. The strong green UC luminescence from suspensions of the nanoparticles in water upon excitation with a 980-nm laser is easily visible to the naked eye.

It is also well-known that gold nanoparticles have good absorption properties in the UV region.[13] The 7-nm gold nanoparticles used in our experiments show a strong absorption at $\lambda \approx 520$ nm, which matches well with the UC emission of $Na(Y_{1.5}Na_{0.5})F_6:Yb^{3+},Er^{3+}$. According to the theory of FRET, when the absorption of the energy acceptor is close to the emission of the phosphor and when the donor and the acceptor are close enough, the emission of the energy donor (upconversion phosphor nanoparticles) will be quenched by the energy acceptor (gold nanoparticles). Thus it is intrinsically possible to couple the UC $Na(Y_{1.5}Na_{0.5})F_6:Yb^{3+},Er^{3+}$ nanoparticles (energy donors) with 7-nm gold nanoparticles (energy acceptors) to give a FRET biosensor.

To test the UC phosphor-based FRET biosensor, first, we functionalized the UC nanoparticles by the layer-by-layer (LbL) method[14] to introduce an NH_2 group that can be attached to biotin. The LbL approach is based on the electrostatic attraction between the oppositely charged species deposited, and its major advantage is that it permits the preparation of coated colloids of different shapes and sizes, with uniform layers of diverse composition as well as controllable thickness.[14] To enable the application of the green upconversion phosphors as fluorescent biological probes, the 50-nm upconversion hexagonal-phase nanoparticles were

functionalized by the LbL method (Figure 2; see also Supporting Information). Zeta potential experiments indicated that the UC nanoparticles were negatively charged under weakly basic conditions (Figure 3a), so the fabrication of the polyelectrolyte was performed at pH 8.5. The fabrica-
Figure 2. Schematic illustration of the functionalization of the upconversion nanoparticles. PAH = poly(allylamine hydrochloride); PSS = poly(styrene sulfonate), EDC = 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide; NHS = N-hydroxysuccinimide.
Figure 3. Zeta potentials a) of the upconversion-luminescent nanoparticles at different pH values and b) of negatively charged (under weakly basic conditions) phosphor nanoparticles as a function of the number of layers of the polyelectrolyte: 1) naked phosphor nanoparticle; 2) phosphor/PAH; 3) phosphor/PAH/PSS; 4) phosphor/PAH/PSS/PAH.

tion process slightly affected the luminescence of the phosphors. The functionalized upconversion-luminescent nanoparticles were then conjugated with biotin according to a reported procedure[15] (see Supporting Information). The phosphor/PAH/PSS/PAH nanocomposites were characterized by analysis of the zeta potential (Figure 3b) and FTIR spectroscopy (Figure 4). The zeta potential of the nanocomposites alternated from negative to positive values with the alternating absorption of the polyelectrolyte, which indicated that PAH and PSS were absorbed alternately onto the surface of the phosphor nanoparticles. Figure 4 presents a series of peaks corresponding to the stretching vibrations of organic functional groups in the polyelectrolyte absorbed onto the phosphor nanoparticles. Strong bands at $\tilde{\nu} = 3433$ cm^{-1} indicate the N–H stretch for the amine group in PAH. The weak bands at $\tilde{\nu} = 1647$ and 1414 cm^{-1} result from the vibrations of the C–C skeleton of the benzene rings in PSS. The band at $\tilde{\nu} = 739$ cm^{-1} results from the bending
Figure 4. IR spectrum of the as-prepared phosphor/PAH/PSS/PAH nanocomposite.

vibration of the N–H bond in the primary amine in PAH which further indicates the existence of amine groups on the surface of the functionalized phosphor nanoparticles. Thus, the data from zeta potential and FTIR experiments indicated that the fabrication of phosphor/PAH/PSS/PAH nanocomposites was successful. Similarly, we prepared biotin-conjugated gold nanoparticles (Au-biotin; see Supporting Information). Thus, on the basis of Au-biotin nanoparticles and biotinylated UC phosphor nanoparticles, the FRET system was developed as shown in Figure 5.

To demonstrate the practicality of the UC nanoparticle-based FRET method, the probe was applied to the detection of trace amounts of avidin. Different concentrations of avidin were added to the mixture of the biotin-phosphor nanoparticles (80 nM) and Au-biotin nanoparticles (144 nM), and PL spectra were measured as a function of the concentration of avidin. When avidin was added, Au-biotin nanoparticles were conjugated to the surface of the UC phosphor-biotin nanoparticles through the sensitive and selective interaction between avidin and biotin. As shown in Figure 6a, the luminescence was gradually quenched with increasing amounts of avidin added to the system. Figure 6b shows the linear relationship between the relative intensity of PL (F_0/F) of the system and the concentration of avidin, wherein F_0 and F represent the intensity of luminescence in the absence and presence of different amounts of avidin, respectively. The
Figure 5. Scheme of the FRET system, with phosphor-biotin nanoparticles as energy donors and Au-biotin nanoparticles as energy acceptors, in the analysis of avidin. ET = energy transfer.
Figure 6. FRET-based assay of avidin: a) PL spectra of the FRET system at different concentrations of avidin as indicated (nM); b) linear relationship between the relative intensity of PL (F_0/F) and the concentration of avidin in the system.

intensity of upconversion luminescence varied linearly with the concentration of avidin in the solution from 0.5 nM to 370 nM. The results indicated that a FRET system based on upconversion-luminescent nanoparticles was reasonable and feasible.

To further test the FRET system based on the upconversion-luminescent nanoparticles, we also prepared $Na(Y_{1.5}Na_{0.5})F_6:Yb^{3+},Tm^{3+}$ nanoparticles using solvothermal technology. The as-prepared upconversion-luminescent $Na(Y_{1.5}Na_{0.5})F_6:Yb^{3+},Tm^{3+}$ nanoparticles emit violet fluorescence with single excitation at $\lambda = 980$ nm. These nanoparticles were also bioconjugated with biotin and applied to a FRET study using Au-biotin nanoparticles to quench the violet emission (see Supporting Information). The results showed that the FRET system based upon the single-emission upconversion nanoparticles was very efficient and versatile. Applications of the FRET system in fluorescence immunoassays, DNA detection, and fluorescence imaging are in progress.

In conclusion, hexagonal-phase $Na(Y_{1.5}Na_{0.5})F_6:Yb^{3+},Er^{3+}$ and $Na(Y_{1.5}Na_{0.5})F_6:Yb^{3+},Tm^{3+}$ nanoparticles with good crystallinity, strong single-emission upconversion fluorescence, good monodispersibility, and controllable size have been successfully prepared. The synthetic methodology also can be used to prepare other single-emission upconversion-luminescent nanoparticles. A FRET system with upconversion-luminescent nanoparticles as energy donors and gold nanoparticles as energy acceptors has been developed and applied to detect trace amounts of avidin. The results indicated that such a FRET system is sensitive and simple for use in biological analyses. Further studies may pave the way to wider applications of these upconversion phosphors in ultrasensitive multicolor detection of nucleic acids and proteins, fluorescence immunoassays, and fluorescence imaging performed in vitro and in vivo.

Experimental Section

Bioconjugation of nanoparticles: Biotin (0.1 mmol) was added to morpholine ethanesulfonic acid (MES) buffer solution (pH 6.0, 2.5 mL) containing functionalized luminescent nanoparticles

(20 mg; ≈ 50 nm), and the mixture was ultrasonicated for 10 min. Then, EDC (0.1 mmol) and NHS (0.2 mmol) were added, and the mixture was mixed slowly with a vortex stirrer for 3 h. Excess biotin, EDC, and NHS were removed by three repeated separation/wash/redispersion centrifugation cycles. The biotin-conjugated phosphors were dispersed in water (10 mL) and stored at 4°C.

Determination of avidin: Different concentrations of avidin were added to the mixture of the biotin-phosphor nanoparticles (concentration fixed at 80 nM) and biotin-Au nanoparticles (concentration fixed at 144 nM), and the mixtures were mixed thoroughly. After stirring the mixtures with a vortex stirrer at room temperature for 30 min and ultrasonication for a further 5 min, PL spectra were measured of the samples.

Organocatalytic Diastereo- and Enantioselective Annulation Reactions—Construction of Optically Active 1,2-Dihydroisoquinoline and 1,2-Dihydrophthalazine Derivatives**

*Kim Frisch, Aitor Landa, Steen Saaby, and Karl Anker Jørgensen**

The isoquinoline skeleton is found in a large number of naturally occurring and synthetic biologically active heterocyclic compounds.[1] In particular, interesting characteristics of 1,2-dihydroisoquinolines and the closely related 1,2,3,4-tetrahydroisoquinolines have been reported. Such characteristics include the ability to act as delivery systems that transport drugs through the otherwise highly impermeable blood-brain barrier.[2] These substances also exhibit sedative,[3] antidepressant,[4] antitumor, and antimicrobial activity.[1d,5] Many of these compounds, natural or synthetic in origin, are chiral and owe their chirality to a stereogenic carbon atom located adjacent to the nitrogen atom (carbon 11 b in Scheme 1).[1,6] Herin, we present the construction of optically active 1,2-dihydroisoquinoline and -phthalazine derivatives based on the general structure shown in Scheme 1.

Scheme 1. Structural skeleton of the optically active synthesized compounds ($R = CH_2OH$, CHO; $Z = CH$, N).

Synthetic methodologies for the formation of chiral isoquinoline derivatives either involve the use of chiral building blocks or rely on diastereoselective reactions with a stoichiometric amount of chiral sources.[6,7a–d] To our knowledge, only few approaches are based on asymmetric catalysis.[7e–g,8] Herein we present a novel approach based on organocatalysis employing chiral C_2-symmetric secondary amines for the diastereo- and enantioselective annulation reaction of 2-(5-oxopentyl)isoquinolinium and -phthalazinium derivatives.

Asymmetric amine catalysis has received much attention in recent years, and a large number of reactions catalyzed by chiral secondary amines have been reported.[9,10] As 1,2-dihydroisoquinolines may be prepared by nucleophilic addition to isoquinolinium salts[7,11] we envisioned that aldehydes

and/or ketones would be able to add to appropriate isoquinolinium salts under organocatalysis. Potentially, such a reaction would lead to the formation of optically active 1,2-dihydroisoquinoline derivatives that contain two adjacent stereocenters together with a carbonyl group suitable for further chemical transformations.

Initially, isoquinolines activated by ethyl chloroformate, were treated with, for example, 3-methylbutyraldehyde in the presence of different organocatalysts. However, all reactions studied proceeded with very low yield and stereoselectivity.

We next turned our attention to the intramolecular variant of the reaction.[12] Scheme 2 outlines our proposal for the catalytic intramolecular annulation reaction cycle. The
Scheme 2. Mechanistic proposal for the organocatalytic asymmetric annulation reaction.

first is the reaction of the chiral amine **1** with the aldehyde of the 2-(5-oxopentyl)isoquinolinium derivative **2** which results in the formation of the corresponding enamine **3** and H_2O. Attack of the nucleophilic enamine carbon atom at the electrophilic carbon atom of the isoquinolinium moiety then results in ring closure and formation of iminium ion **4**. Finally, **4** is hydrolyzed to give the 1,2-dihydroisoquinoline derivative **5** and HX, which is scavenged by an external base to regenerate the organocatalyst.

The synthetic route for model substrate 2-(5-oxopentyl)-isoquinolinium iodide (**2a**) (Scheme 2, $Z = CH$) used in the screening process is outlined in the Supporting Information. Table 1 presents the results for the screening of different chiral amines **1a–g** as catalysts for the annulation reaction of **2a**. It should be stressed that in all cases the reactions proceeded with good to high conversions without formation of by-products. However, the product **5a** was unstable and was protected to facilitate its isolation and full analysis.[13] Protection of the enamine moiety of **5a** in situ using $(CF_3CO)_2O$ gave the isolable compound **6a**, which was subsequently reduced with $NaBH_4$ to produce the fully analyzable alcohol **7a**.

(−)-(S)-Proline (**1a**) proved to be an effective catalyst for the annulation reaction of 2-(5-oxopentyl)isoquinolinium

Table 1: Screening of chiral amines **1a–g** as catalysts for the annulation reaction of 2-(5-oxopentyl)isoquinolinium iodide (**2a**)[a].

Entry	Catalyst	t [min]	Conversion [%][b]	d.r. (*trans:cis*)[c]	ee [%][d]
1[e]	**1a**	20	95	2:1	rac
2	**1b**	5	88	2:1	rac
3	**1c**	90	40	2:1	7
4	**1d**	10	92	2:1	11
5	**1e**	180	40	3:1	rac
6	**1f**	90	47	8:1	8
7	**1g**	190	94	8:1	84

[a] All reactions were performed on a 0.20-mmol scale. [b] The conversion of **2a** into **5a** was estimated by ^{1}H NMR spectroscopy. [c] Determined by ^{1}H NMR spectroscopy. The *trans/cis* ratio refers to the relationship between 1-H and 11b-H. [d] The *ee* value of the major diastereomer of compound **7a** was determined by chiral HPLC. [e] The reaction was performed at room temperature.

iodide **2a** with almost full conversion into the desired product **5a** after 20 min at room temperature (Table 1, entry 1). However, the diastereoselectivity of the reaction was low, and the two diastereomers were formed as racemates. For the catalysts **1b–e**, the annulation reaction also proceeded with low diastereo- and enantioselectivity (Table 1, entries 2–5). Improved diastereoselectivities were observed for the catalysts (2S,5S)-2,5-diphenylpyrrolidine (**1f**) and (2S,5S)-2,5-dibenzylpyrrolidine (**1g**). However, whereas **1f** gave very low enantioselectivity, catalyst **1g** produced the major diastereomer with 84% *ee* (Table 1, entries 6 and 7). A number of solvents were also screened for the annulation reaction of **2a** catalyzed by **1g**. In all cases high conversions (>75%) were observed; however, the stereoselectivity of the annulation reaction performed in CH$_2$Cl$_2$ was superior.[14]

Table 2 summarizes the results obtained from the screening of external bases in the annulation reaction of **2a**. In the absence of an external base, the reaction did not proceed (Table 2, entry 2). Furthermore, a 1:1 ratio of the amount of added base and the amount of formed product resulted (Table 2, entry 3 vs. 1). A possible explanation for these observations is protonation of the catalyst which renders it unreactive. Also, compound **5a** could revert back to **2a** owing to the presence of HI. The essential external base also promotes a racemic background reaction in the absence of the chiral amine catalyst (Table 2, entry 4), and dropwise addition of Et$_3$N over the course of 4 h resulted in a significant improvement only in the diastereoselectivity (Table 2, entry 5 vs. 1). Application of a stronger base, such as DBU, resulted in

Table 2: Screening of external bases for the organocatalytic annulation reaction of **2a** catalyzed by **1g**.[a]

Entry	External base (equiv)	t [h]	Conv. [%][b]	d.r.[c]	ee [%][d]

9	*N*-methylmorpholine (1.0)	96	37	8:1	44
10	2,6-di-*tert*-butylpyridine (1.0)	96	0	–	–

[a] All reactions were performed at −20°C in the presence of **1g** (10 mol%) in CH$_2$Cl$_2$ on a 0.20 mmol scale. [b] The conversion of **2a** into **5a** was estimated by ^{1}H NMR spectroscopy. [c] Determined by ^{1}H NMR spectroscopy of **7a** (the *trans/cis* ratio refers to the relationship between 1-H and 11b-H). [d] The *ee* value of the major diastereomer of compound **7a** was determined by chiral HPLC. [e] Reaction performed without a catalyst. [f] Slow addition of the external base. [g] Overnight reaction.

a conversion and diastereomeric ratio similar to those obtained with Et$_3$N. However, the reaction was almost racemic, therefore indicating that the background reaction caused by the achiral base superseded the chiral-amine-catalyzed reaction (Table 2, entry 6). The use of bases of similar strength to that of Et$_3$N, such as diisopropylethylamine (DIPEA) and quinuclidine, resulted in a higher diastereo-

Communications

meric ratio, whereas the conversion and enantioselectivity were either unaltered or lower (Table 2, entries 7, 8 vs. 1). A decrease in the strength of the added base had a significant effect on the conversion of the reaction. The use of *N*-methylmorpholine resulted in a slow reaction and the production of compound **5a** with low conversion and low enantiomeric excess, whereas 2,6-di-*tert*-butylpyridine gave no conversion at all (Table 2, entries 9 and 10, respectively). In conclusion, 1 equivalent of Et$_3$N as an external base proved to be optimal for the annulation reaction.

Table 3 summarizes the results of the annulation reaction of **2a** catalyzed by C_2-symmetric disubtituted pyrrolidines **1g**–

Table 3: Catalyst modifications and screening of catalyst loading and reaction temperature for the annulation reaction of 2-(5-oxopentyl)-isoquinolinium iodide **2a**[a].

Entry	Cat.	t [h]	T [°C]	Loading [mol %]	Conv. [%][b]	d.r.[c]	ee [%][d]

3	**1g**	3	−20	10	94	8:1	84
4	**1g**	3	−20	20	94	8:1	87
5	**1g**	o.n.[e]	−40	10	94	15:1	92
6	**1h**	6	−20	10	90	7:1	36
7	**1i**	o.n.[e]	−40	10	96	15:1	88

[a] All reactions were performed in the presence of Et$_3$N (1 equiv) in CH$_2$Cl$_2$. Entry 1 was performed on a 0.40-mmol scale, entries 2–7 on a 0.20-mmol scale. [b] The conversion of **2a** into **5a** was estimated by ^{1}H NMR spectroscopy. [c] Determined by ^{1}H NMR spectroscopy of **7a** (the *trans/cis* ratio refers to the relationship between 1-H and 11 b-H). [d] The *ee* value of the major diastereomer of compound **7a** was determined by chiral HPLC. [e] Overnight reaction.

i under various reaction conditions. The conversion and diastereoselectivity of the annulation reaction were found to be independent of the catalyst loading (Table 3, entries 1–4). However, a significant drop in the enantiomeric excess (indicating considerable involvement of the racemic background reaction caused by the external base) was observed with low catalyst loadings. An increase in the catalyst loading from 10 to 20 mol % did not significantly improve the stereoselectivity (Table 3, entries 1–4). A decrease in the reaction temperature from −20 to −40°C maintained a high conversion of the reaction, but resulted in a significant increase in both the diastereo- and enantioselectivity to 15:1 and 92% *ee*, respectively (Table 3, entry 5 vs. 3).

The dependence of the structural and electronic properties of **1g** on the stereoselectivity of the reaction was also investigated. Replacement of the phenyl groups of **1g** by bulky non-aromatic groups, such as cyclohexyl groups (catalyst **1h**), did not change the diastereoselectivity of the reaction. However, catalyst **1h** was slightly less active than catalyst **1g**, and the enantioselectivity decreased significantly (Table 3, entry 6 vs. 3). The effect of the electron density of the aromatic substituents was tested by applying a catalyst with electron-donating substituents such as (2*S*,5*S*)-2,5-bis(4-methoxybenzyl)pyrrolidine (**1i**). The results in Table 3, entry 7 show that no significant changes in the outcome of the reaction were observed when **1i** was applied as catalyst.

With the optimized conditions for the catalytic diastereo- and enantioselective annulation reaction at hand, the scope and limitation of the system was investigated (Table 4). In general, the annulation reactions proceeded with good to high conversions (70–100%), high diastereoselectivity (d.r. ≥ 15:1) and excellent enantioselectivity (85–96% *ee*). Products with functional groups suitable for further manipulations were obtained (Table 4, entries 2 and 4), and the scope of the annulation reaction could be extended beyond isoquinolinium salts to substrates based on the phenanthridine and phthalazine skeleton (Table 4, entries 5 and 6). Limitations of the reaction were observed for substrates based on the electron-rich isoquinolines 5,7-dimethoxyisoquinoline (Table 4, entry 7) and 6,7-dimethoxyisoquinoline (the latter gave < 10% conversion after several days).

The reported yields are for two (Table 4, entries 3, 5, and 6) or three (Table 4, entries 1, 2, 4, and 7) reaction steps that were performed to obtain compounds that could be isolated and fully analyzed.[15] Additionally, although the final products **7a–g** were obtained in low yields, the conversions of **2a–g** into **5a–g** in the catalytic enantioselective annulation step were high. With the exception of substrate **2g** (Table 4, entry 7), the catalytic annulation reaction proceeded without the formation of by-products.

Compound **7b** was obtained as a white solid, which after a single recrystallization from CH$_2$Cl$_2$ and hexane gave crystals suitable for X-ray crystallographic analysis.[16] The analysis revealed that the absolute configurations of the newly formed stereocenters at C1 and C11b could both be described as *S* (Figure 1).
Figure 1. X-ray crystal structure of compound **7b**.

A proposal for the transition state involved in the stereoselective step of the annulation reaction is presented in Figure 2. In this transition state a favorable interaction between the isoquinolinium moiety and a phenyl ring of the catalyst—a cation–π interaction[17]—was anticipated. The phenyl ring, positioned parallel to and above the cationic isoquinolinium moiety with a face-to-face interaction,[17a–c] allows the *Re* face of the enamine double bond to approach the *Si* face of the iminium double bond without significant steric hindrance. With this approach, the annulation reaction results in the product with 1*S* and 11b*S* configurations at the formed stereocenters in accordance with the experimental observation.

Table 4: Scope and limitation of the organocatalytic annulation reaction catalyzed by **1g**.[a]

Entry	Substrate	Product	Conv. [%][b]	Yield [%][c]	d.r.[d]	ee [%][e]
1	**2a**	**7a**	94	41	15:1	92
2	**2b**	**7b**	70	40	24:1	92
3	**2c**	**7c**	70	18	16:1	85

Communications

In conclusion, we have developed the first organocatalytic diastereo- and enantioselective annulation reaction of 2-(5-oxopentyl)isoquinolinium derivatives. The reactions generally proceed with good to high conversions (70–100%), high diastereoselectivities (d.r. ≥ 15:1), and good to excellent enantioselectivities (85–96% *ee*). The scope of the annulation reaction is demonstrated in the synthesis of a series of optically active 1,2-dihydroisoquinoline and -phthalazine derivatives. The stereochemical outcome of the organocatalytic asymmetric annulation reaction is explained on the basis of a favourable cation–π interaction between the isoquinolinium moiety and one of the phenyl rings of the catalyst.

Metal–Organic Frameworks

Crystal Engineering: Toward Intersecting Channels from a Neutral Network with a bcu-Type Topology**

Tzuoo-Tsair Luo, Hui-Lien Tsai, Shang-Li Yang, Yen-Hsiang Liu, R. Dayal Yadav, Chan-Cheng Su, Chuen-Her Ueng, Lee-Gin Lin, and Kuang-Lieh Lu*

A great deal of interest has developed in the synthesis of metal–organic coordination polymers as they offer opportunities for preparing materials with controllable functionalities.[1] Although remarkable progress has been made in this new field of chemistry and materials science, largely due to efficient design strategies,[2,3] it is still difficult to prepare metal–organic frameworks with predictable topologies, even structures composed of simple inorganic salts.[4] The mimicking of topologies of natural minerals has rapidly become one of the most challenging issues in the design of metal–organic frameworks.[3c] Many 3D structures with mineral topologies such as NbO, quartz, pyrite, rutile, sodalite, CdSO$_4$, and halite[5] have been reported recently from attempts to obtain geometric characteristics with designable functionalities. From the reported characterization of the net topologies,[6]

all of these networks are based on the use of three-, four-, or six-connected building blocks.[5] Connectivities of five, seven, or eight are extremely rare as a result of limitations in the symmetry or steric hindrance associated with connected nodes.[7,8] Although the body-centered cubic (bcu) net[8a–c] and the fluorite (flu) net[8d] are commonly seen in textbooks, such topologies with eight connecting nodes in a cubic geometry have only appeared in a few examples. To fulfill their geometric limitations, an eight-coordinated metal center or an eight-connecting polynuclear metal cluster block would be required; neither is easily achieved.[8] The former has been obtained with eight-coordinated lanthanide ions or $[M(CN)_8]^{4-}$ to form the bcu-type net,[8a,b] and the latter by using an eight-connecting cluster containing a tetracadmium carboxylate moiety and a four-connecting ligand to form the flu-type net. However, the bcu-type topology with only an eight-connecting polynuclear metal cluster unit has not yet been realized.

As part of our ongoing efforts in the design and synthesis of functional crystalline materials,[3e] we report herein the rare, porous bcu-type framework of {[Cu$_3$Cl$_2$(4-ptz)$_4$(H$_2$O)$_2$]·3DMF·5H$_2$O}$_n$ (**1**), assembled from 5-(4-pyridyl)-tetrazolate (4-ptz) as a bridging ligand and an eight-connecting tricopper cluster (Cu$_3$Cl$_2^{4+}$ = Cu$_3$ cluster) as a building block. To the best of our knowledge, this is the first bcu-type structure with an eight-connecting polynuclear metal cluster unit, and represents one of the highest connected topologies known for coordination polymers. The appropriate choice of an organic ligand with specific functional groups and geometry is also a major factor in achieving this target. The reasons for using the 4-ptz ligand are twofold: first, the tetrazole group is a widely known alternative to a carboxylate moiety, and second, the five-membered heterocyclic tetrazole group, which contains four N donors and a pyridine group, could serve both as a potential active coordination site and a hydrogen-bond acceptor, thus permitting the polymeric framework to be expanded through hydrogen-bonding interactions. Interestingly, until now, such coordination polymers based on tetrazole derivatives[9,10] have not been extensively studied, in contrast to metal carboxylates.[1e] Inspired by the work of Sharpless and co-workers,[11] the preparation of 5-substituted 1*H*-tetrazoles is now a safe and convenient route. Nevertheless, the generation of tetrazole-based coordination polymers would be a new and potentially useful research theme, which is currently in its infancy.

Compound **1** was synthesized by the reaction of copper(II) chloride and 5-(4-pyridyl)tetrazole (4-H-ptz) in DMF at ambient temperature in high yield by a single-step self-organization process (Scheme 1). The asymmetric unit consists of two Cu^{II} centers, one bridging chloride ion, one 4-ptz ligand, one coordinated water molecule, and other disordered guest molecules (Figure 1a). An analysis of the local symmetry of the two nonequivalent Cu centers reveals that the Cu1 center resides on a special symmetry site (SOF = 0.25) containing three mutually perpendicular twofold axes of rotation, and the Cu2 center resides on the other special symmetry site (SOF = 0.5) containing a twofold axis of rotation. Cu1 is bound to four tetrazole nitrogen atoms and two bridging chlorine atoms, and Cu2 is bound to two

Scheme 1. Synthesis of **1** by a one-step organization; DMF = N,N-dimethylformamide.

Figure 1. a) Local coordination environment of Cu^{II} in **1** (atoms are represented as 30% thermal ellipsoids); hydrogen atoms and disordered molecules have been omitted for clarity. b) Simplified view of an eight-connected Cu$_3$-cluster subunit. c) Perspective view of the network of **1** simplified according from part (b). d) The body-centered cubic lattice net (bcu net).

The bcu-type topology of **1** is as follows: the motif of the Cu$_3$ cluster connected to eight 4-ptz linkers is represented by a box connected with eight bars (Figure 1b). The positions of the eight connecting nodes correspond to the four pyridyl nitrogen atoms and the centers of the 2,3-nitrogen atoms of the tetrazole group, which results in an eight-connected net with the Schläfli symbol $\{4^{24}6^4\}$ that resembles the topology of a bcu net (Figure 1c, d). To fulfill a bcu-type topology, our design strategies were focused on the selection of clusters with eight connectivities as secondary building units (SBUs)[12] as they provide a suitable geometry that permits the target structures to be constructed. The assembly of the eight-connected Cu$_3$ clusters and the tetrazolate ligand successfully forms the first example of a neutral body-centered-type metal–organic framework. Owing to limitations in geometry, the angle of the unit cell diagonals is distorted from 90° to 75.8° and the symmetry of the crystal system is lowered from cubic to orthorhombic (see Supporting Information).

As a result of the geometry of the bcu-type net, the combination of channels running parallel and perpendicular to each other gives rise to large pockets of extra-framework space. Considering the octahedron-shaped chamber (Figure 2a) in the framework, the diagonal distances of the chamber are 15.507(0) Å (Cu1−Cu1) and 19.917(3) Å (Cu1−Cu1). Such a

tetrazole nitrogen atoms, two pyridyl nitrogen atoms, one bridging chlorine atom, and one coordinated water molecule. The two nonequivalent Cu atoms adopt a distorted octahedral (Cu1)Cl$_2$N$_4$ and (Cu2)ClN$_4$O coordination geometry, respectively. The tetrazole ligands adopt a bridging mode with a coordinating pyridyl group and a μ_2,η^2-tetrazolato bridge. The copper–copper separation, bridged by the chloride and tetrazole moiety of the 4-ptz ligands, is 3.545(1) Å. Each 4-ptz ligand coordinates through the 1,2-nitrogen atoms of the tetrazole group and the pyridyl nitrogen atom. Each Cu2 atom is weakly coordinated by a water molecule (Cu−O = 2.890(3) Å) resulting from a strong Jahn–Teller effect. Except for the coordinated water molecules, all donor atoms form reasonably strong bonds with the copper atoms. All of the Cu−N distances are in the range between 2.015(3) and 2.024(3) Å.

From further analysis of the structure of **1**, five unique features are apparent: 1) a three-dimensional neutral network with a bcu-type topology; 2) eight-connected Cu$_3$-cluster-building subunits; 3) large octahedron-shaped chambers; 4) potential functionalization sites on the copper atoms; 5) nanoscale open windows and a 3D intersecting channel system with an extra-framework volume of 57%.

Figure 2. Views of the octahedron-shaped chamber: a) A few large van der Waals spheres with diameters of about 5.78–7.14 Å inside. b) Weakly coordinated water molecules on Cu$_3$ clusters act as removable shutters.

chamber, with an inner void space, can accommodate at least two van der Waals spheres with maximum diameters of up to 7.14 Å without coming into contact with the framework. The calculated density (in the absence of guests) of compound **1** is 0.99 g cm^{-3}. Analysis with the PLATON[13] software tool

indicates that the extra-framework volume per unit cell is approximately 57%. The use of the "CAVITY" routine in PLATON indicates that the six largest voids are located at (0.3, 0, 0.625) and other symmetric sites with diameters of 7.14 Å, four other middle voids at (0, 0.5, 0) with diameters of 5.84 Å, and so on, with fourteen other cavities with diameters in the range of 5.78–5.04 Å (van der Waals surfaces considered). Furthermore, the overall shape of the void does not allow the packing of spheres larger than 7.14 Å, although several spheres with different diameters can be accommodated by the same large elongated void. The void is actually a large ellipsoid with a total volume of 1775 Å³. These large free spaces within the framework cause the structure to be highly porous. In addition, four weakly coordinated water molecules serve to gate the chamber (Figure 2b). The O1−O1 distance is 4.63(1) Å, and the naked Cu2−Cu2 distance is 10.338(1) Å. Therefore, the chamber is a potential candidate for a microreactor with metal-containing active sites. These sites in crystalline porous materials have functionalities that could permit molecular recognition, catalysis, or gas storage.[3f]

An inspection of Figure 3 reveals that the overall array contains a 3D intersecting channel system and nanoscale open windows, with an approximate diameter of up to 10 Å. Notably, the 3D intersecting channels, which frequently occur in zeolites, are constructed by the interconnection of 1D channels from different directions. Coordination polymers with 3D intersecting channels are often unstable upon loss of solvent as a result of framework instability associated with high porosity.[1d]

Compound **1** is non-interpenetrating, despite the large pores and channels within its framework, mainly because the bcu-type net is not self-dual.[5a] The unique eight-connected Cu₃-cluster SBUs cause compound **1** to contain nbo-type intersecting channels, which is the dual net of body centered cubic (Figure 4). Thus, compound **1** is a perfect candidate for a highly porous network.

A thermogravimetric analysis of **1** shows that guest molecules are eliminated from the network (calcd. 71%; found 74%) when the temperature is increased from room temperature to about 220°C, after which decomposition of the framework occurs. Powder X-ray diffraction spectra recorded after heating samples of **1** at 220°C show some indication of stability upon the removal of guest molecules. However, the broadening and decrease of intensity of the
Figure 4. a) Dual relationship of the bcu net (blue) and the nbo net (yellow). b) The nbo-type intersecting channels (yellow) in the bcu-type framework of **1**.

peaks implies that the material appears to lose crystallinity gradually, thus producing an amorphous phase upon heating.

The magnetic exchange coupling between the copper centers for compound **1** was analyzed based on the Curie–Weiss expression and a trinuclear magnetic model. The negative values of the Weiss constant and the magnetic exchange coupling constant indicate the antiferromagnetic characteristics of the copper centers. At temperatures below 20 K, the Cu^{II} ions are weakly antiferromagnetically coupled, with $J = -2.84$ cm^{-1} (based on the Hamiltonian $\mathcal{H} = -2J [(S_{Cu1}S_{Cu2}) + (S_{Cu1}S_{Cu2A})]$ and using the expression for the molar magnetic susceptibility $S = 1/2$ of a linear trinuclear system). The observed antiferromagnetic interaction is resolved into contributions arising from each Cu–ligand–Cu linkage. The propagation of the antiferromagnetic exchange interaction in the linear Cu₃ unit is expected to depend predominantly on 4-ptz bridges. It may be processed through the $d_{x^2-y^2}$ orbitals on the Cu^{II} ions that interact with the σ orbitals of the nitrogen atoms of the tetrazolate ligands, which are all situated in the equatorial plane and contain Cu–N–N–Cu torsion angles of −3.41°. Crystal engineering of the substituent on the 4-pyridyl moiety could increase the Cu–N–N–Cu torsion angles in the tricopper center and thereby change the exchange coupling from antiferromagnetic to ferromagnetic.[14]

In conclusion, compound **1** is the first porous, neutral, bcu-type structure that contains an eight-connected polynuclear cluster unit and a tetrazole-based ligand. The synthesis of bcu-type frameworks with expanded analogous ligands offers the
Figure 3. Superimposed space-filling representation of **1** showing channel openings along the *a*, *b*, and *c* axes. Hydrogen atoms have been omitted for clarity (red = Cu, blue = N, green = Cl, yellow = O).

Communications

potential for pore-size expansion in their nbo-type intersecting channel systems. The preparation of a rare framework from 4-ptz and Cu_3 clusters confirms the potential for synthesizing new structures of functional materials using tetrazole derivatives as ligands. Further research is currently in progress.

Experimental Section

1: A solution of $CuCl_2 \cdot 2H_2O$ (0.10 mmol) and 4-H-ptz (0.13 mmol) in DMF (8 mL) was stirred for 15 min. It was then allowed to stand at room temperature for several days, whereupon deep-blue, rhombus-like crystals were formed in 61% yield (based on 4-H-ptz). The solid product was washed with deionized water and ethanol, and dried in air. Elemental analysis (%) calcd for $C_{33}H_{51}Cl_2Cu_3N_{23}O_{10}$: C 33.27, H 4.31, N 27.04; found: C 33.59, H 4.51, N 25.66. The formula $[Cu_3Cl_2(4\text{-ptz})_4(H_2O)_2] \cdot 3DMF \cdot 5H_2O$ was assigned by elemental microanalysis, thermogravimetric analysis, and single-crystal X-ray diffraction studies.[15]

[15] A suitable single crystal of **1** with dimensions $0.12 \times 0.10 \times 0.08$ mm^3 was mounted on the tip of a glass fiber and placed onto the goniometer head for indexing and intensity data collection using a Bruker Smart CCD diffractometer (Mo$_{K\alpha}$ = 0.71073 Å). The raw frame data for **1** were integrated into SHELX-format reflection files and corrected for Lorentz and polarization effects with the Denzo program. An empirical absorption correction was applied by using the Multiscan method. The structure of **1** was solved by direct methods and refined against F^2 by the full-matrix least-squares technique, using the WINGX, PLATON, and SHELX software packages. Except for the guest molecules, non-hydrogen atoms were refined with anisotropic displacement parameters, and the hydrogen atoms of aromatic rings were calculated and refined as riding modes. The water and DMF guest molecules that show positional disorder could not be fixed in the structure model. During the final stages of refinement, several Q peaks were found, which probably correspond to highly disordered solvent molecules and were fixed as oxygen atoms and refined with isotropic displacement parameters. The hydrogen atoms associated with the coordinated water molecules and disordered guest molecules could not be located from difference Fourier maps, and no attempt was made to place them. However, they are included in the empirical formula. Further details of experimental and magnetic studies are given in the Supporting Information. Crystal data for **1**: $C_{33}H_{51}Cl_2Cu_3N_{23}O_{10}$ {[Cu$_3$Cl$_2$(4-ptz)$_4$(H$_2$O)$_2$]·(3 DMF·5 H$_2$O)}, $M_r = 1191.45$, orthorhombic, *Pnmn*, $a = 12.3305(2)$, $b = 15.5069(3)$, $c = 15.6412(3)$ Å, $V = 2990.72(9)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.366$ g cm^{-3}, $\mu = 1.180$ mm^{-1}, λ-(Mo$_{K\alpha}$) = 0.71073 Å, $F(000) = 1780$, $T = 293(2)$ K, A total of 19 921 reflections were collected in the range $\theta = 4.12$–27.49°, of which 3538 were unique ($R_{int} = 0.0512$). Final R indices: $R_1 = 0.0399$, $wR_2 = 0.1716$ for 2818 reflections [$I > 2\sigma(I)$]; $R_1 = 0.0725$, $wR_2 = 0.1830$ for 3538 independent reflections (all data) and 147 parameters, GOF = 1.060. These data can be obtained free of charge from the Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

Cluster Compounds

Metal Ions Play Different Roles in the Third-Order Nonlinear Optical Properties of d10 Metal–Organic Clusters**

Hongwei Hou,* Yongli Wei, Yinglin Song, Liwei Mi, Mingsheng Tang, Linke Li, and Yaoting Fan

Research into nonlinear optical (NLO) materials has become increasingly intensive because of their potential applications in optical fibers, data storage, optical computing, image processing, optical switching, and optical limiting.[1] Thus, the design and synthesis of new materials with large NLO capability represents an active field in modern chemistry, physics, and materials science.[2] Metal clusters are reported to be excellent candidates for NLO materials[3] since they involve $d\pi$–$p\pi$ delocalized systems and $d\pi$–$d\pi$ conjugated systems.[4] These compounds have a large variety of structures and diverse electronic properties that can be tuned by virtue of the coordinated metal;[5] thus the opportunity exists to tune the NLO properties of metal complexes. Metal clusters can also extend the π-conjugated length, which is one of the many methods used to increase molecular NLO susceptibility $\chi^{(3)}$ values. Moreover, the NLO properties of metal clusters can be enhanced by the introduction of metal→ligand and ligand→metal charge-transfer states.[6] Although many methods can be used to promote the NLO properties of metal clusters, the origination of the NLO properties is the delocalization of the π-electron cloud.[7] This delocalization in metal clusters is mainly brought about by metal ions constructing the skeleton and organic ligands fixing the skeleton, thus both the metal ions and the organic ligands should be important for the nonlinear optical properties of the clusters. To the best of our knowledge, however, all studies confirm that heavy-metal ions play very important roles on the third-order NLO properties of metal clusters because their incorporation introduces more sublevels into the energy hierarchy, which permits more allowed electronic transitions to take place and hence a larger NLO effect to be produced.[8]

However, we believe that both metal ions and ligands affect the NLO properties from their contribution to the delocalization of the π-electron cloud. If metal ions make a greater contribution than ligands, then the effect of the metal ions on the NLO properties will be greater; however, ligands can also make an important contribution to the NLO properties.

How do we investigate the contribution of metal ions and ligands to the delocalization of the π-electron cloud? The frontier molecular orbital corresponds to the delocalization of the π-electron cloud, so we can understand the contribution of metal ions and ligands to the delocalization of the π-electron cloud by calculating their component of the frontier molecular orbital. We can then deduce whether the metal ions or ligands play more important roles in the NLO properties. This approach has been utilized herein. We prepared 2,6-dicarboxamido-2-pyridylpyridine (H_2dcapp), the unique crownlike cluster $[Ag_{10}(dcapp)_4]\cdot 2(OH)\cdot 12H_2O$ (**1**), as well as clusters $[Zn_4O(dcapp)_3]\cdot 6H_2O$ (**2**) and $[Hg_2(dcapp)_2]$ (**3**), and studied their third-order NLO properties. We determined by quantum chemical calculations the contribution the metal ions and organic ligands make to the NLO properties and found them to be consistent with the experimental results. In addition, we found that the population of the triplet excited state for nanosecond laser radiation is responsible for the third-order nonlinear properties of these compounds.

The reaction of $AgNO_3$ with 0.5 equivalents of H_2dcapp in a mixture of THF, DMF (*N,N*-dimethylformamide), and H_2O leads to the formation of the light-yellow decanuclear cluster $[Ag_{10}(dcapp)_4]\cdot 2(OH)\cdot 12H_2O$ (Figure 1).[9] The main unit is a decanuclear silver aggregate $[Ag_{10}(dcapp)_4]^{2+}$, which has a crownlike architecture. The ten silver atoms are arranged in two irregular tetrahedrons (Ag1-Ag1A-Ag2-Ag2A and Ag1B-Ag1C-Ag2B-Ag2C) and a distorted octahedron (Ag2-Ag2A-Ag2B-Ag2C-Ag3-Ag3A). The two tetrahedrons and the octahedron are connected by the two edges Ag2-Ag2A and Ag2B-Ag2C. The edge lengths of the tetrahedra are in the range 2.8329(16)–3.0259(9) Å, and in the octahedron the closest Ag···Ag contacts are found and range from 2.6521(9) to 2.9345(11) Å. The Ag2···Ag3 distance (2.6521(9) Å) is much shorter than that in elemental silver (2.88 Å). The distances of 2.8329(16)–3.0259(9) Å are comparable to 2.88 Å and twice the van der Waals radius for silver atoms (3.44 Å). We could calculate Wiberg bond orders[10] by quantum chemical calculation and found that the Ag2−Ag3 bond order is 0.1354, thus indicating a strong metal–metal bond between the Ag2 and Ag3 atoms, while other Ag−Ag bond orders are in the range from 0.0847 to 0.0371, thus suggesting the existence of further metal–metal bonds. In addition, Wiberg bond orders of Ag−N range from 0.2329 to 0.3453 and the C−C bond orders are about 1.4.

There are three crystallographically distinct silver ions in the decanuclear silver cluster $[Ag_{10}(dcapp)_4]^{2+}$. Ag1 ions are located on both sides of the crown and are coordinated to three nitrogen atoms and three Ag ions; Ag3 ions coordinate with two N atoms and further bond to four Ag2 ions; and Ag2 ions are surrounded by two N atoms and six Ag ions. Each ligand surrounds the silver ions in a helical conformation and functions as a pentadentate building block, in which
Figure 1. a) Crystal structure of the decanuclear cluster $[Ag_{10}(dcapp)_4]$ $\cdot 2(OH)\cdot 12H_2O$ (**1**). Ag atoms are shown as green, yellow, and pink spheres; O red, N blue, C gray, H white. b) Arrangement of the 10 silver atoms.

N1, N3, N4, and N5 are monocoordinated to a silver center, while N2 acts as a μ_2 donor.

The colorless tetranuclear cluster **2** was prepared from H_2dcapp and $Zn(OAc)_2\cdot 6H_2O$.[9] The arrangement of the zinc ions and the bridging modes of the dcapp^{2-} ligands are shown in Figure 2. The cluster consists of three dcapp^{2-} and four zinc ions and a central oxygen atom. Five N atoms of each ligand coordinate to three Zn ions. The four Zn−$O_{central}$ bond lengths are almost equivalent, and the Zn-$O_{central}$-Zn bond angle (av) is 109.4°. The Zn_4O^{6+} core is an almost perfect tetrahedron, with Zn···Zn separations ranging from 3.117 to 3.240 Å, which is consistent with tetrazinc carbamato complexes having a Zn_4O^{6+} core.[11] Wiberg bond orders of Zn−Zn are about 0.01, thus showing the presence of a weak Zn−Zn metal bond. The corresponding Wiberg bond orders of Zn−O and Zn−N are about 0.38 and 0.26, respectively. The Zn_4O^{6+} cluster ion plays an important role in metal organic frameworks (MOFs), which are novel microporous materials that show potential applications in catalysis, gas storage, and molecular recognition.[12]

The reaction of H_2dcapp with $Hg(OAc)_2\cdot 2H_2O$ leads to colorless block crystals $[Hg_2(dcapp)_2]$ (**3**, Figure 3).[9] The Hg(1)···Hg(2) distance is 3.157 Å, which is comparable to twice the van der Waals radius of Hg atoms (3.10 Å). The Wiberg bond order of Hg(1)−Hg(2) is 0.0106, thus indicating

Figure 4. The linear absorption spectra of H$_2$dcapp, **1**, **2**, and **3**, at 6.2×10^{-4}, 2.0×10^{-5}, 3.7×10^{-5}, and 4.8×10^{-5} M, respectively, in DMF.

wavelength of the laser light (532 nm) is within the non-resonant absorption region.

The NLO absorption components were evaluated by a Z-scan experiment using an open-aperture configuration. Figure 5 depicts the NLO absorptive properties of **1** and
Figure 5. NLO absorptive properties of a 4.1×10^{-4} M solution of [Ag$_{10}$-(dcapp)$_4$]·2 (OH)·12 H$_2$O (**1**) in DMF. The black squares are the experimental data, and the solid curve is the theoretical fit.[15]

a weak interaction between the two Hg ions. The corresponding Wiberg bond orders of Hg−N are about 0.52. There are few reports of polynuclear Hg complexes,[13] apart from organomercury compounds.[14] The two dcapp^{2-} ligands wrap helically around the two Hg centers, with the length of the double helix being 3.157 Å.

The third-order NLO properties of **1**–**3** and H$_2$dcapp were investigated with laser pulses of wavelength 532 nm and duration 8 ns by a Z-scan experiment in DMF solution. The results show that cluster **1** exhibits both very strong NLO absorptive and refractive effects, while H$_2$dcapp as well as clusters **2** and **3** show weaker NLO absorption and strong NLO refractive behavior. The linear absorption spectra of H$_2$dcapp and **1**–**3** in DMF are shown in Figure 4. The absorption of the ground state is low in the visible and near-infrared wavelength region (> 380 nm); the maxima of the absorption bands for the ground state are 286 nm for H$_2$dcapp, 282 nm for **1**, 311 nm for **2**, and 296 nm for **3**. The

clearly illustrates that the absorption increases as the intensity of the incident light rises, with light transmittance (*T*) being a function of the Z position of the samples. A reasonably good fit between the experimental data and the theoretical curves was obtained. This result suggests that the experimentally detected NLO effects have an effective third-order characteristic. It is clear that the theoretical curves qualitatively reproduce the general pattern of the observed experimental data.[16] The nonlinear absorptive index a_2 is calculated to be 1.4×10^{-9} mW^{-1} for a 4.1×10^{-4} M solution in DMF.

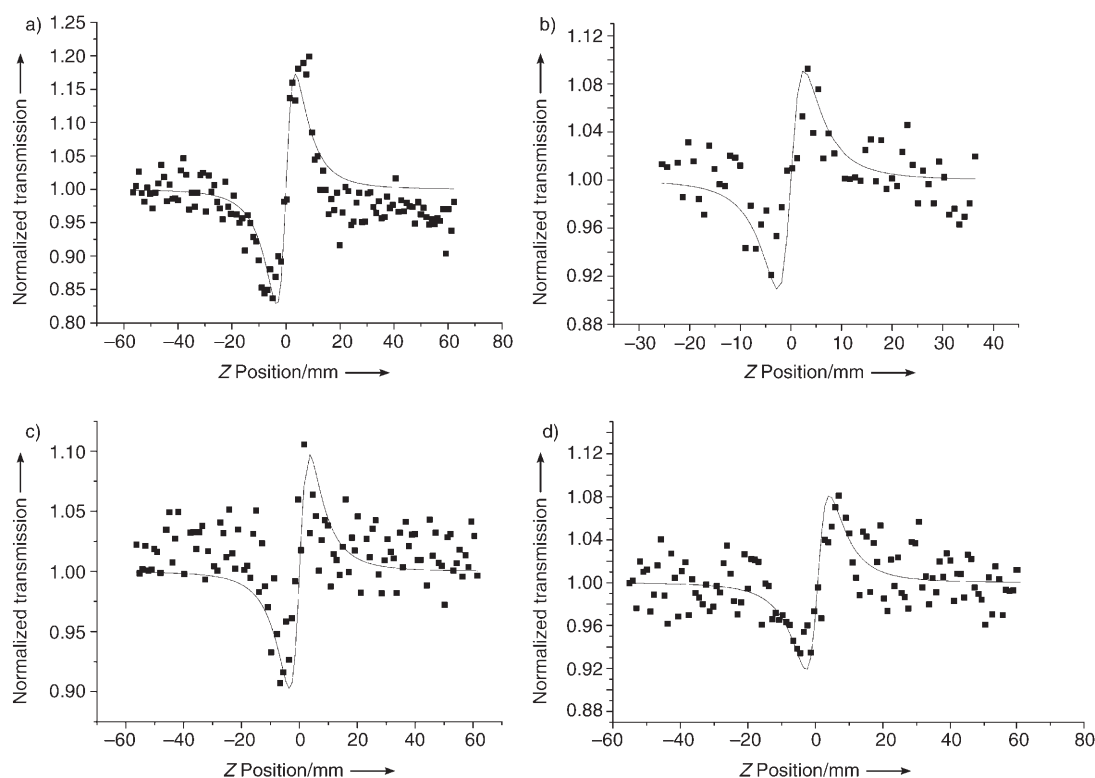
The nonlinear refractive components were assessed by dividing the normalized Z-scan data obtained under a closed-aperture configuration by the normalized Z-scan data obtained under the open-aperture configuration. Figure 6 depicts the nonlinear refractive effects of **1**–**3** and H$_2$dcapp. The valleys and peaks occur at equal distances from the focus. These results are consistent with the notion that the observed optical nonlinearity has an effective third-order dependence


Figure 6. NLO refractive properties: a) $[Ag_{10}(dcapp)_4] \cdot 2\,(OH) \cdot 12\,H_2O$ (4.1×10^{-4} M) in DMF; b) $[Zn_4O(dcapp)_3] \cdot 6\,H_2O$ (7.5×10^{-4} M) in DMF; c) $[Hg_2(dcapp)_2]$ (9.7×10^{-4} M) in DMF; d) H_2dcapp (3.1×10^{-3} M) in DMF. The black squares are the experimental data, and the solid curves are the theoretical fit.

on the incident electromagnetic field.[16] A reasonably good fit between the experimental data (black squares) and the theoretical curves (solid curves) was obtained.[15] The effective third-order refractive index n_2 of **1–3** and H_2dcapp are calculated to be 2.2×10^{-11}, 1.2×10^{-11}, 1.3×10^{-11}, and 1.1×10^{-11} esu, respectively.

It is very interesting that the NLO properties of **1** are completely different from those of **2**, **3**, and H_2dcapp. Cluster **1** shows strong NLO absorption and refractive effects, but **2**, **3**, and H_2dcapp only show NLO refractive behavior and give the same refractive index n_2 value. It can be seen from the results that the Ag ions play very important roles in the NLO behavior of **1**, while the influence of the Zn and Hg ions to the optical nonlinearity of **2** and **3** is very small, with the $dcapp^{2-}$ ligands dominating the optical nonlinearity. The reason for this difference cannot be explained by the heavy-atom effect: the strength of the NLO properties can be altered by the π-back-donation capacity of the metal ions to the ligands, and the increased π-back-donation capacity of the metal ions to the ligands may enhance the extension of the electronic π system and improve the NLO properties.[8]

It was reported that the NLO properties of π-conjugated complexes originate from the delocalization of the π-electron cloud.[7] Since the delocalization corresponds to the frontier molecular orbital, we can determine the contribution of the Ag^+, Zn^{2+}, Hg^{2+}, and $dcapp^{2-}$ ions to the NLO properties of clusters **1–3** by molecular orbital theory. We have calculated the frontier molecular orbitals of cluster skeletons $[Ag_{10}(dcapp)_4]^{2+}$, $[Zn_4O(dcapp)_3]$, and $[Hg_2(dcapp)_2]$ by density

functional theory (DFT) and Hartree–Fock (HF) calculations using the LanL2MB basis set.[17] It can be seen from Figure 7 that the frontier molecular orbitals of $[Ag_{10}(dcapp)_4]^{2+}$, namely HOMO−1, HOMO, LUMO, and LUMO+1, are Ag^+- and $dcapp^{2-}$-based orbitals (DFT/B3LYP 11.08, 5.01, 37.06, 80.84%, respectively, and HF 6.13, 6.94, 63.96, 83.28%, respectively, for Ag^+_{10}): HOMO−1 and HOMO are primarily $dcapp^{2-}$-based orbitals, while LUMO+1 is primarily an Ag^+-based orbital. The frontier molecular orbitals in $[Zn_4O-(dcapp)_3]$ (Figure 8) are primarily $dcapp^{2-}$-based orbitals (DFT/B3LYP 0.92, 0.94, 1.80, 2.03%, respectively, and HF 1.48, 1.24, 2.01, 2.22%, respectively, for Zn^{2+}_4), and the four orbitals have barely any Zn^{2+} character. In addition, the frontier molecular orbitals in $[Hg_2(dcapp)_2]$ (Figure 9) are also primarily $dcapp^{2-}$-based orbitals (DFT/B3LYP 1.48, 1.58, 1.58, 1.61%, respectively, and HF 1.88, 1.79, 1.32, 7.50%, respectively, for Hg^{2+}_2). It is usually found that the electron in the highest occupied molecular orbital (HOMO) or the next highest occupied molecular orbital (HOMO−1) is excited to the lowest unoccupied molecular orbital (LUMO) or the next lowest unoccupied molecular orbital (LUMO+1) to give the first excited singlet state S_1 or the first excited triplet state T_1. In general, the photochemical and photophysical properties of compounds are governed by the first excited singlet state S_1 and the first excited triplet state T_1, thus the most important frontier orbital is LUMO or LUMO+1. Both the Ag^+ and $dcapp^{2-}$ ions contribute to the LUMO and LUMO+1 of $[Ag_{10}(dcapp)_4]^{2+}$, while the LUMO and LUMO+1 of $[Zn_4O-(dcapp)_3]$ and $[Hg_2(dcapp)_2]$ primarily have $dcapp^{2-}$ charac-
Figure 7. The frontier molecular orbital of [Ag₁₀-(dcapp)₄]²⁺: a) HOMO−1, b) HOMO, c) LUMO, d) LUMO+1. Ag light blue, N dark blue, O red, C gray, H white.

ter. Therefore, we can deduce that the NLO properties of cluster **1** are controlled by the Ag⁺ and dcapp²⁻ ions while in clusters **2** and **3** the Zn²⁺ and Hg²⁺ ions have no influence on the NLO properties, which are dominated by the dcapp²⁻ ligands. This finding is consistent with the experimental results: **2**, **3**, and H₂dcapp show the same NLO refractive behavior (self-focusing effect) and also have the same refractive index n_2 value, while **1** not only shows a strong NLO refractive effect (self-focusing) but also displays strong NLO absorptive properties. It should be pointed out that both the excited-state population (and absorption) and the two-photon absorption can be responsible for the measured NLO effect.[16] In addition, it can be seen from Figure 7 that there are large dπ–dπ conjugated systems in the LUMO and LUMO+1 of [Ag₁₀(dcapp)₄]²⁺ which can enhance the molecular NLO properties.

The strong nonlinear absorption makes cluster **1** an interesting case for an optical limiting (OL) study. An ideal OL material should be able to respond quickly to the incident light and become increasingly opaque as the incident light increases in intensity. Cluster **1** displays such an OL ability, but **2**, **3**, and H₂dcapp do not; they give weaker OL effects. The optical limiting effect of **1** is depicted in Figure 10. The linear transmittance is 70%. The light energy transmitted starts to deviate from Beer's law as the intensity of the input light reaches 0.03 J cm⁻², and the material becomes increasingly less transparent as the intensity rises. The optical limiting threshold, which is defined as the incident intensity at which the actual transmittance falls to 50% of the corresponding linear transmittance, is 0.15 J cm⁻², with a saturation intensity transmitted of 0.23 J cm⁻². Lower limiting thresholds and saturation levels provide a greater safety margin for device protection. It is interesting to compare cluster **1** with other well-known optical limiting materials for nanosecond pulsed radiation of 532 nm wave-

length. The optical limiting threshold of **1** (0.15 J cm^{-2}) is lower than that observed in C$_{60}$ and the octanuclear Ag cluster [Ag$_8$(2,4,6-iPr$_3$C$_6$H$_2$Se)$_8$].[18] The lower limiting threshold makes cluster **1** a very promising candidate for broadband OL applications.

It should be pointed out that our measurement of the transmitted pulse energy was conducted with a full collection of the transmitted pulse, and no aperture was used. Therefore, the observed OL originates from an NLO absorptive process.[16] Most nanosecond OL performances, such as that of C$_{60}$, can be interpreted by the five-level (three singlet states and two triplet states) model, and a triplet–triplet transition has been identified as the main mechanism responsible for nanosecond OL effects.[19] Ji et al. developed a five-level model for metal clusters: one ground state, one excited singlet state, one ionized state, one first excited triplet state, and one higher excited triplet state. The initial absorption promotes molecules from the ground to the excited singlet state, the ionized state, and to the first excited triplet state, and then further absorption excites the molecules in the first excited triplet state to the higher excited triplet state. If the absorption cross-section of the triplet state is greater than that of the ground state, then the absorption becomes stronger as the incident intensity increases, which results in an OL effect.[16]

To further study the third-order optical nonlinearity performance of **1–3**, and H$_2$dcapp we investigated their NLO properties with laser pulses of wavelength 532 nm and duration 30 ps by the closed-aperture Z-scan experiment in DMF solution (Figure 11). We find from the data that the closed-aperture Z-scan experimental curves of **1–3** and H$_2$dcapp in DMF solution are the same as that of the DMF solvent for laser radiation of picosecond duration. Moreover, the experimental curve (+) of H$_2$dcapp at a higher concen-
Figure 11. The NLO properties of clusters **1**, **2**, **3**, and H$_2$dcapp (3.4×10^{-4}, 2.3×10^{-4}, 3.4×10^{-4}, and 2.0×10^{-3} M (or 9.3×10^{-3} M), respectively) in DMF solution, as well as DMF itself, with laser pulses of wavelength 532 nm and duration 30 ps by the closed-aperture Z-scan experiment.

tration (9.3×10^{-3} M) in DMF solution is the same as that ($\triangle$) of H$_2$dcapp at lower concentration (2.0×10^{-3} M). Hence, we believe that there exists no third-order optical nonlinearity for **1–3** and H$_2$dcapp with laser radiation of picosecond duration. This result also shows that the population of the singlet excited state cannot contribute to the third-order optical nonlinearity performance of **1–3** and H$_2$dcapp with laser radiation of nanosecond duration. The third-order nonlinearity performance results from the population of the triplet excited state in nanosecond laser radiation. For comparison, the closed-aperture Z-scan experiment of a solution of C$_{60}$ in toluene was also investigated with laser pulses of wavelength 532 nm and 30 ps duration (C$_{60}$ gives strong NLO properties; see Supporting Information). This result illustrates that the NLO performance of C$_{60}$ is brought about by the population of the singlet excited state and triplet excited state in laser radiation of nanosecond duration, and it is different from those of **1–3** and H$_2$dcapp.

Experimental Section

H$_2$dcapp: 2,6-Pyridyldicarboxylic acid (1.67 g, 10 mmol) was dissolved in SOCl$_2$ (20 mL). The resulting 2,6-pyridinedicarboxylic acid chloride was dissolved in anhydrous pyridine (10 mL), and a solution of 2-aminopyridine (1.90 g, 20 mmol) in pyridine was added dropwise with stirring in an ice bath. Yield: 4.21 g (70%). IR (KBr): $\tilde{v}$ = 1698, 1579, 1545, 1442, 1322, 999, 780 cm^{-1}. Elemental analysis (%) calcd for C$_{17}$H$_{13}$N$_5$O$_2$: C 63.95, H 4.08, N 21.94; found: C 63.14, H 4.51, N 21.81; ^{1}H NMR (400 MHz, DMSO, 25°C, TMS): δ = 7.25 (quin, 2H; C$_6$H$_4$), 7.93 (hept, 2H; C$_6$H$_4$), 8.31 (hept, 3H; C$_6$H$_3$), 8.41 (d, 2H; C$_6$H$_4$), 8.50 ppm (d, 2H; C$_6$H$_4$); ESI-MS: m/z: 319.9 [H$_2$dcapp+H]$^+$.

1: The cluster was prepared by reaction of AgNO$_3$ (0.0169 g, 0.1 mmol) with H$_2$dcapp (0.0161 g, 0.05 mmol) in a mixture of THF (1 mL), water (1 mL), and DMF (4 mL). The reaction mixture crystallized at room temperature on slow evaporation of the solvent to give the desired decanuclear silver cluster as a light-yellow crystalline solid. Yield: 63%. IR (KBr): $\tilde{v}$ = 1702, 1572, 1532, 1439, 1419, 1384, 1319, 1148, 774 cm^{-1}. Elemental analysis (%) calcd for C$_{34}$H$_{35}$Ag$_5$N$_{10}$O$_{11}$: C 32.15, H 2.75, N 11.03; found: C 33.01, H 2.12, N 11.03.

2: A solution of H$_2$dcapp (0.0161 g, 0.05 mmol) in DMF (5 mL) was added to a solution of Zn(OAc)$_2$·2H$_2$O (0.1 mmol, 0.0219 g) in methanol (5 mL). The mixture solution was left to stand in the air at room temperature for a week, which resulted in colorless crystals suitable for X-ray diffraction analysis. Yield: 46%. IR (KBr): $\tilde{v}$ = 1616, 1578, 1556, 1477, 1434, 1381, 1312, 1160, 779 cm^{-1}. Elemental analysis (%) calcd for C$_{51}$H$_{45}$N$_{15}$O$_{13}$Zn$_4$: C 45.76, H 3.36, N 15.70; found: C 44.98, H 3.21, N 15.38.

3: Complex **3** was prepared in an analogous manner to that used to prepare **2**, except that Hg(OAc)$_2$×2H$_2$O was used instead of Zn(OAc)$_2$×2H$_2$O. Yield: 40%. IR (KBr): $\tilde{v}$ = 1630, 1581, 1460, 1433, 1385, 1355, 779 cm^{-1}. Elemental analysis (%) calcd for C$_{34}$H$_{22}$Hg$_2$N$_{10}$O$_4$: C 39.47, H 2.13, N 13.54; found: C 38.95, H 2.00, N 13.27.

Communications

DNA Tube Structures Controlled by a Four-Way-Branched DNA Connector**

Masayuki Endo, Nadrian C. Seeman, and Tetsuro Majima**

The programmed self-assembly of molecular building blocks into desired structures is one of the most fascinating challenges in the field of supramolecular chemistry, and the basic methodology is also applicable for the creation of nanoscale materials.[1–3] Double-stranded DNA is a promising candidate for achieving the desired structural formation and arrangement, because of the reliable molecular assembly based on the base-pairing system and well-defined periodic structure of the double helix DNA. Structurally controlled crossover DNA motifs, called "DNA tiles", have been used as building blocks for creating one- and multi-dimensional nanostructures.[4–7] Recently, by utilizing these crossover DNA molecules, extended structures such as tube structures have been created.[8–10] Further extension of the design of desired DNA structures could be achieved by employing various chemically modified oligonucleotides.

Here we report a novel method for preparation of structurally controlled DNA tubes by using a DNA tile system[4–7] with the assistance of a four-way-branched DNA connector. Branched DNA can assemble multiple double helices by duplex formation.[11] In this study, we designed and synthesized a DNA–porphyrin connector, Porph-(Tc)$_4$ **1**, in which 10-mer DNA strands are connected to four spacers of a tetraphenylporphyrin derivative (Figure 1a). We also employed the DNA tile system which can assemble two planar DNA tiles (tile A and tile B) into two-dimensional (2D) array structures by using the geometry of 2.5 helical turns between two DNA tiles (Figure 1b and the upper part of

Figure 1. The DNA–porphyrin connector and the DNA tiles system employed in the experiment. a) Structure of the DNA–porphyrin conjugate, Porph-(Tc)$_4$ **1**. b) The sequences of DNA tile A (green) and DNA tile B^T (blue), which has an extra single strand (orange sequence). The orange dot on tile B represents the extra single strand. c) Two-dimensional DNA array prepared from the tiles A and B^T (top) and the three-dimensional DNA tube structure formed in the presence of Porph-(Tc)$_4$ **1** (bottom).

Figure 1c).[4–7] The center strand of tile B^T has an extra 12-mer single strand (T = tag strand) that has 10 bases as a recognition sequence for hybridization with a complementary DNA strand (Tc = complementary to the tag strand) and two additional thymidines as a linker. We planned to assemble the four B^T tiles by using the DNA–porphyrin connector, which captures and brings multiple B^T tiles together by hybridizing with the extra tag strands of the B^T tiles. The four neighboring tiles constrained by the DNA–porphyrin connector could then induce tube formation during assembly with the A tiles. The length between the center of the porphyrin and the 5′-end of the DNA strand in the DNA–porphyrin connector is 7–8 nm (Figure 1a), which could allow the alignment of the four short axes of the B^T tiles side by side (total 16 nm) for A–B^T array formation.

DNA–porphyrin conjugate **1** was synthesized by coupling the tetramaleimide-linked tetraphenylporphyrin with a 3′-

thiol-modified 10-mer DNA strand (Tc) that is complementary to the tag strand of the tile B^T (see Supporting Information). Ten DNA strands and Porph-(Tc)$_4$ **1** were mixed together and annealed from 95°C to room temperature for 36 h in a buffer containing 2-[4-(2-hydroxyethyl)-1-piperazinyl]ethanesulfonic acid (HEPES; pH 7.5), ethylenediaminetetraacetate (EDTA), and Mg^{2+}.[12]

After complex formation, we observed the DNA nanoscale structures by using atomic force microscopy (AFM) in solution.[12] In the case of annealing with tiles A and B^T only, 2D DNA arrays were obtained which were similar to those previously described with the A–B array system (Figure 2a).[6,7] By contrast, with addition of 1/4th of an equivalent of Porph-(Tc)$_4$ **1** connector and annealing with tiles A and B^T, the large 2D structures were not observed and fiber-like structures appeared (Figure 2b), the lengths of which reaching over 20 μm. When 1/16th of an equivalent of **1** was annealed with tiles A and B^T, we obtained a mixture of fibers and the usual 2D arrays (see Supporting Information). Thus, the formation of fiber structures depended on the stoichiometry between the tiles and Porph-(Tc)$_4$ **1**.

To characterize the detailed nanoscale structures, we analyzed the surface of the DNA fibers. A cross-section analysis of the long axis of the DNA fiber structure reveals
Figure 2. AFM images of the DNA structures. a) Annealing with tiles A and B^T. Image size: 8×8 μm^2. b) Annealing with tiles A and B^T in the presence of Porph-(Tc)$_4$ **1**. Image size: 8×8 μm^2. Inset: Expanded image of the DNA structure prepared from tiles A and B^T with **1**. Image size: 500×500 nm^2. c) Cross-section analysis of the long axis of the DNA structure shown in the inset of (b). Orange arrows represent peaks of the periodical stripes. d) Cross-section analysis of the short axis of the DNA structure shown in the inset of (b).

that periodic stripes are observed on the surface of the fiber (Figure 2 c). The distance between two stripes was 29–34 nm, which corresponds to the total length of the long axis of the A and B tiles (32 nm; Figure 1 c). Therefore, these stripes originated from the extra strand of tile B^T. In the case of the initial A–B^T 2D array without the addition of the connector **1**, stripes were not clearly observed, because the extra single strand (tag strand T) attached to the B^T tile was flexible (see Supporting Information). In contrast, the A–B* 2D array, which has hairpins on the 2D tile that work as topological markers, showed clear stripes, because the stable hairpins are oriented out of the plane of the 2D array as described previously (see Supporting Information).[6,7] These suggest that the strong stripe formation on the DNA fiber is induced by duplex formation between the tag strand of the tile B^T and its complementary strand (Tc) of the connector **1**. The individual DNA fibers showed uniform width (approximately 55 nm) and height (5.2–5.6 nm; Figure 2 d). The height of the stripes was 0.3–0.8 nm. The analysis indicates that the height of the DNA fiber structures is larger than the two layers of the double helices. According to the cross-section analysis of the DNA fiber (Figure 2 b, inset), the center of the top surface is slightly squashed by 0.2–0.3 nm as compared to both edges (Figure 2 d).[13] From these observations, the DNA structures observed here exhibited the features of DNA tube structures, similar to those described in previous reports.[8,12,13] We conclude that the DNA structures obtained here are tube structures. In the present study, the locations of the DNA–porphyrin connectors in the DNA tube structures remain unclear. Casual inspection of the AFM images gives the impression that the DNA–porphyrin connectors are on the outside of the tube structures. However, from thickness measurements, we cannot exclude the possibility that they are on the inside, the circumstance that is most likely to lead to tube formation.

We also obtained DNA structures with a height lower than the tubes, and these two structures were located on the same DNA fibers (Figure 3 a). We noted that in the detailed images of these lower-height structures (Figure 3 b), each stripe on the DNA surface has two or three blocks of dotlike structures, which were characterized by a cross-section analysis of the stripes (red arrows in Figure 3 d). Cross-section analysis for the long axis revealed that the stripes were separated by 29–34 nm (Figure 3 c), which corresponds to the total length of the long axis of the A–B^T tiles as described previously. The height of the surface of the lower-height structures was 2.7 nm (Figure 3 d). The height of the stripes was 0.3–1.0 nm, which is comparable to the stripes of the tube structures shown in Figure 2. A high-resolution AFM image of the DNA surface in the lower-height structures in a different area is shown in Figure 3 e. Each stripe is separated and the individual A tiles can be observed to be the same as those of the A–B* arrays. In this lower-height section, the visible part of the array contains seven A tiles and a similar number of less well resolved B^T tiles as repeating units.

To examine the difference between the tube and lower-height structures, we analyzed the boundaries of these structures on the same fiber (Figure 3 a), and two interesting features were observed: 1) The stripes in the tube and lower-
Figure 3. AFM images of the DNA structures. a) Mixed area of normal and lower-height DNA structures. Image size: 1×1 μm^2. b) Expanded image of the lower-height section. Image size: 300×300 nm^2. c) and d) Cross-section analysis of the lower-height area in Figure 3 b for the long (c) and short (d) axes. Orange arrows in (c) represent peaks of the periodical stripes and red ones in (d) represent dotlike structures on the stripe of the lower-height area. e) High-resolution AFM image of the DNA nanostructure of the lower-height area. Image size: 200×200 nm^2.

height areas are successive without any gap. 2) The height of the lower-height DNA structures is clearly changed to almost half the height of the tube ones, and the width of the short axis of the lower-height structures (ca. 65 nm) is always larger than that of the tubes (ca. 55 nm) on the successive DNA structures. From these observations, we conclude that the lower-height areas on the DNA fibers are incomplete tubes with the height of single-layer duplexes, as described previously.[8,13]

We estimated the complex-formation process by using the UV absorption change at 260 nm versus temperature. The duplex formation of Porph-(Tc)$_4$ **1** with its complementary strand occurs at 46°C, which is slightly higher than the initial temperature of the A–B array formation (40–45°C). This indicates that the complex formation between **1** and four B^T tiles precedes assembly of the A–B tiles, and then the constrained B^T tiles with **1** and the A tiles form some constrained array leading to the tube formation.

We have demonstrated a novel method for the preparation of DNA tubes, by using the A–B tile system and the four-way-branched DNA connector which converts DNA arrays into DNA tube structures. The DNA–porphyrin connector clearly restricted the extension to the short axis of the tile, while the long axis did not change as compared to that of the usual A–B tile system. We expect that the DNA tubes

prepared by using this method can be employed as nanoscale scaffolds for the preparation of structurally defined materials and devices.[13,14]

Peptides

Mechanism of the Initial Conformational Transition of a Photomodulable Peptide**

Tadeusz Andruniów, Simona Fantacci,*
Filippo De Angelis, Nicolas Ferré, and
Massimo Olivucci*

The ability to control the specific conformation of peptides or proteins is highly desirable in the design of bioactive materials,[1] optical data storage devices,[2] or for triggering the folding/unfolding of oligopeptide chains.[3,4] Conformational changes in macromolecules can be achieved by incorporating a photoresponsive "monomer" into the molecule backbone;[5] such a monomer is capable of converting light energy into a permanent change in geometry. This approach is also seen in biological receptors[6–9] where the photoisomerization of organic chromophores is used to switch between different conformations. One of the most prominent examples of such switches is the protonated Schiff base (PSB) of retinal found in rhodopsin proteins. This chromophore undergoes a *cis*→all-*trans* photoisomerization that triggers a conformational change of the native protein scaffold.[10,11]

We recently concluded that synthetic PSBs may provide suitable frameworks for the design of molecular switches or motors.[12] We demonstrated that 5-methyl-4-(5′-methyl-

cyclopent-2′-enylidene)-3,4-dihydro-2*H*-pyrrolinium, **1** in Scheme 1, a PSB featuring a "locked" backbone, satisfies the criteria for an efficient switch.

Previous studies on the octapeptide (**OP**) H₂N-Ala1-Cys2-Ala3-Thr4-Cys5-Asp6-Gly7-Phe8-COOH, derived
Scheme 1. Subsystems of *cis*-**1-OP** treated by quantum mechanics (QM) and molecular mechanics (MM). Box (dotted lines) encloses **1**. Angles α, β, α′, and β′ are discussed in the text.

from the thioredoxin reductase active site, revealed that this chain can be conveniently used to prepare a bicyclic peptide incorporating the azobenzene (Ab) photoisomerizable unit and a disulfide bridge.[7–9] In such a system light irradiation may be used to permanently switch the conformation of the peptide.

Herein, our target is to investigate the photoisomerization mechanism of an analogue system, **1-OP** in Scheme 1, where Ab is replaced with the computationally tractable[13] PSB unit **1**. While in previous studies,[3] which focused on longer timescales, the photochemical step was treated empirically, herein we show that the photoisomerization of *cis*-**1-OP** can be characterized by the novel quantum mechanics/molecular mechanics (QM/MM)[14,15] strategy recently applied to rhodopsin[16] and featuring a CASPT2//CASSCF QM level (see Experimental Section). To determine the intrinsic factors driving the transmission of the photoinduced strain to the peptide backbone we focus on gas-phase **1-OP**. The results indicate that while the switch starts to change immediately after excited state (S₁) population, the change of the peptide moiety occurs only after decay to the ground state (S₀). The resolution of the structure of the conical intersection funnel (CI) driving the S₁→S₀ decay, allows the effect of the S₀ energy surface on the initial S₀ dynamics of **1-OP** to be explored. This effect is simulated at the QM level by running a 3 ps ground state Car–Parrinello[17] molecular dynamics (CPMD) trajectory.

Photoexcitation of *cis*-**1-OP** initiates the relaxation along the S₁ energy surface (Figure 1), ultimately leading to a CI located approximately 30 kcal mol⁻¹ lower in energy. The deformation driving the reactant out of the Franck–Condon (FC) region corresponds to a skeletal single-bond contraction and double-bond expansion (the reactive C4−C1′ double bond is lengthened to 1.48 Å) coupled with an approximate 3° increase of the C5-C4-C1′-C2′ torsion angle. Further evolution along the same coordinate, leads to a transition structure (TS$_{ex}$) located about 4 kcal mol⁻¹ higher than *cis*-**1-OP**. Analysis of the TS$_{ex}$ structure indicates that the corresponding
Figure 1. Energy profiles along the paths describing the S₁ and S₀ relaxation. The structures (geometrical parameters in [Å] and [°]) document the progression of the molecular structure of **1** and related link regions. The agreement between different computational methods is also shown (for computational details see Experimental Section and Supporting Information). ○ S₁ CASPT2//CASSCF/6-31G*/Amber, ● S₀ CASPT2//CASSCF/6-31G*/Amber, ■ PBE/6-31G*; ▲ CP plane-wave PBE.

barrier is due to the steric repulsion between the hydrogen at C3 and methyl group at C5′. The steric repulsion is decreased by further twisting about the C4−C1′ bond that drives the system along a barrierless region of the S₁ path. Along this region the stretching deformation of **1** decreases, the C4−C1′ bond length stabilizes at 1.46 Å, and the twisting about this bond becomes dominant. The CI structure, located at the bottom of the S₁ surface, features a central double bond twisted by 89°.

Inspection of superimposed peptide backbones of the *cis*-**1-OP** and CI structures (Figure 2) reveals that, despite the difference in twist of unit **1** of approximately 75° in these two structures, the peptide conformations are still remarkably similar with a root-mean-square (rms) deviation of less than 0.6 Å. Both conformations exhibit a right-handed helical shape at Ala3 and an inverse γ turn centered on Asp6.

To provide mechanistic insight into the ground-state decay we have calculated the S₀ path departing from CI and leading to the photoproduct (*trans*-**1-OP**; Figure 1). The S₀ energy profile displays an approximately 0.9 kcal mol⁻¹ barrier at 102° twisting, suggesting the presence of a restrain force, attributed to initial peptide deformation. Further progression along the isomerization coordinate induces a limited change in energy up to 114° followed by a slope leading to the *trans*-**1-OP** energy minimum (characterized by a *trans* configuration of the switch).

Even though the superimposed peptide backbones of *cis*-**1-OP**, CI, and photoproduct structures share a common overall fold, *trans*-**1-OP** displays a more extended (stretched) conformation. Rms deviation between the CI and *trans*-**1-OP** peptide is about 1.5 Å. Analysis of the standard dihedral angles φ and ψ along the backbone reveals that the helical character of Ala3 in the product is less pronounced than in the
Figure 2. Top: superposition of the *cis*-**1-OP** (red), CI (blue), and *trans*-**1-OP** (magenta) structures. Bottom: hydrogen-bond patterns of CI and *trans*-**1-OP**. The hydrogen bonds a–e are discussed in the text.

reactant. However, *cis*- and *trans*-**1-OP** differ mainly in the orientation of the inner cycle formed by the disulfide bridge between Cys2 and Cys5. In fact, the limited twisting of the Cys2-S-S-Cys5 dihedral angle by about 25° is accompanied by the reorientation of residues Asp6, Gly7, and Phe8 of the C-terminal part of the peptide backbone.

The response of the peptide secondary structure to the isomerization of **1** is described in terms of the changes in the hydrogen–bond pattern (a–e, see Figure 2). The results suggest that on S_1 there is no change in the number or location of the hydrogen bonds (three hydrogen bonds, indicated as a, b, and c in Figure 2, could be detected). However, upon departure from the CI structure and relaxation on the S_0 energy surface, two new hydrogen bonds d and e that run between the Thr4 carbonyl group and the N7-H group of the link region and between the N^+-H group of **1** and the Ala3 carbonyl group are formed. Similarly, the hydrogen bonds a and b between the Asp6 hydroxy and Phe8 carbonyl groups and between the N7-H of the link group and the Ala3 carbonyl, respectively, are broken. The only hydrogen bond that remains intact during both the S_0 and S_1 relaxations is c between the N-H group of Gly7 and the carbonyl group of Cys5. The treatment of the hydrogen bonds between atoms treated by QM and MM methods, has been validated by comparing the QM/MM and the full PBE-functional optimized structures of *cis*- and *trans*-**1-OP**. It is shown that by the QM/MM methods the hydrogen bonds a, b, and d are less than 0.04 Å longer at the PBE level. A larger difference is found for the bent hydrogen bond e that is 0.14 Å longer when computed at the PBE level.

The link regions between the switch **1** and the octapeptide are made up of the -CH$_2$-NH- and -CH$_2$-CO- groups

connected to carbon atoms C5 and C2′, respectively (see Scheme 1). Accordingly, the evolution of these links is characterized in terms of the values of the angles α (C4-C5-C6-N7) and β (C5-C6-N7-C8), and α′ (C1′-C2′-C6′-C7′) and β′ (C2′-C6′-C7′-N8′). It is apparent from Figure 1 that α and β undergo a limited overall change (+40° and −18°) with respect to α′ and β′ (+133° and −145°). Since, these changes provide information on the way the photoinduced torsional strain is transmitted from the switch to the octapeptide, we conclude that the strain is transmitted asymmetrically by the two link regions. This behavior is easily related to the fact that α and β are made stiffer by the involvement of the N7-H, C8=O, and N^+-H groups in the hydrogen-bond network. Notice that the change of α′ and β′ along the S_1 path is very limited. Thus, similar to the octapeptide chain, the link region changes mainly during S_0 relaxation.

Information on the effect of the S_0 path on the early S_0 relaxation dynamics including the relative timescales of the leading molecular modes, are obtained through the analysis of a 3 ps CPMD trajectory. As shown in Figure 1, both CPMD (CP plane-wave PBE) and Gaussion 98 PBE/6-31G* yield energy profiles qualitatively close to the QM/MM one. The largest discrepancies are found in the initial part of the path where the density functional theory (DFT) curves show an inflection. The consistency of DFT//CASSCF and CASPT2//CASSCF S_0 energy profiles for PSBs has been previously evaluated.[18] The relaxation process of the chromophore is monitored by the time evolution of the torsional deformation and length of the C4−C1′ bond. The relaxation of the peptide is monitored by studying four hydrogen-bond lengths. Finally, the evolution of the link region between the switch and the peptide is studied by monitoring the α′ and β′ angles.

As shown in Figure 3 the relaxation of the switch is characterized by coherent changes in torsional deformation
Figure 3. Time evolution of the C5-C4-C1′-C2′ dihedral angle [°] and C4-C1′ bond length [Å]. The arrows indicate the *trans*-**1-OP** values.

and bond lengths. In fact, both quantities approach the S_0 equilibrium values in less than 0.5 ps. No back oscillation towards the S_1 values is observed. On the other hand, the change in the peptide secondary structure reported in Figure 4 is consistent with a slower process (> 3 ps). In fact, although breaking of hydrogen bond a seems to occur on the picosecond timescale, a large oscillation is observed which continues up to 3 ps. An oscillatory behavior is also observed for the switching in the hydrogen bonds b and d. After 1 ps b is broken while d is formed. However, after 2 ps these hydrogen bonds are pushed back to their original positions, while at 2.5 ps a new inversion takes place. Remarkably, after 3.0 ps a,
Figure 4. Evolution of the hydrogen bonds a, b, d, and e defined in Figure 2. The arrows indicate the *trans*-**1-OP** values.

b, and d seem to have reached the final values of the S_0 *trans*-**1-OP** energy minimum. The behavior of hydrogen bond e is different. Although initial relaxation promotes formation of this (looser and bent) hydrogen bond just after 0.6 ps, the bond breaks and remains substantially broken up to the end of the simulation. This bond will require a longer time to reach the predicted equilibrium value. A behavior that can be associated to the bent geometry of e that features a N−H···O angle of 132°.

The dynamics of the link region is displayed in Figure 5. There is a high correlation between angles α′ and β′ all along
Figure 5. Time evolution of the link-region torsional angles α′ and β′. The arrows indicate the *trans*-**1-OP** values.

the simulation. They move according to a hula-twist motion (a clockwise and counterclockwise twist about two adjacent bonds) of the -CH$_2$- unit of the link. This movement provides a way to efficiently bend the linkage without introducing angular strain. The *trans*-**1-OP** product values are reached in less than 1 ps.

In conclusion, we describe the mechanism of photo-induced strain transmission in a naked macrocyclic cation. (Of course, owing to its effect on the hydrogen-bond stability and formation, a protic solvent may substantially change the mechanism and timescale of the relaxation. Solvent and counterion effects on **1-OP** are currently under investigation). While the photoinduced conformational transition from *cis*-**1-OP** to *trans*-**1-OP** involves a total rms deviation of 2.0 Å, only a fraction of this change occurs during the S_1 evolution, which mainly features stretching relaxation and an approximately

90° twisting of the switch unit **1**. The documented S_1 relaxation path indicates an ultrafast $S_1 \rightarrow S_0$ decay dynamic at room temperature. In fact, 1) there is only a small barrier restraining the S_1 evolution and 2) a S_1/S_0 conical intersection provides a fully efficient $S_1 \rightarrow S_0$ decay channel. These conclusions are consistent with the behavior observed for experimentally accessible Ab-peptide analogues[3,9] where decay to S_0 occurs in under 1 ps. Our reaction path and trajectory analysis indicate that the peptide relaxation occurs entirely on S_0 on a much longer timescale. Indeed, while the relaxation of the switch is substantially completed within 0.5 ps, the hydrogen bonds b, d, and e oscillate even after 2 ps with e still broken after 3 ps. On the other hand, the asymmetric relaxation of the link regions is found to occur on an intermediate time scale (< 1 ps) indicating a sequential (switch→link→peptide) mechanism for the transmission of the strain generated by the switch. Loosely, these results are consistent with ultrafast IR spectroscopy measurements on an Ab-peptide analogue indicating that the photoinduced peptide stretching dynamics (that is associated with the redistribution of the strain) is completed in a time window between 6 and 20 ps.[9] Finally, notice that within the first half-oscillation in Figure 4, the backbone changes described by the trajectory and S_0 relaxation path of Figure 1 (i.e. the static minimum energy path) are similar. Indeed, a transient geometry close to *trans*-**1-OP** is generated and lost after 0.7 ps indicating that the path accelerates the system directly towards the product structure.

Experimental Section

Computational Details: Our QM/MM implementation is based on a hydrogen link-atom scheme with the frontier placed at the CO−C$_\alpha$H and NH−C$_\alpha$H bonds of Ala1 and Phe8, respectively (see Scheme 1). The ab initio QM calculations are based on a CASSCF/6-31G* level. The active space comprises the full π system of **1** (six electrons in six π orbitals). For the MM part we use the Amber force field[19] with standard or re-parameterized van der Waals potentials. CASSCF/6-31G*/Amber geometry optimizations are carried out with the GAUSSIAN98[20] (G98) and TINKER[21] programs. To account for dynamic electron correlation effects, re-evaluation of the energy of the optimized structures was carried out at the multiconfigurational second-order perturbation theory level using the CASPT2 implementation of MOLCAS-5[22] and a two-root state-averaged CASSCF zeroth-order wavefuntion (CASPT2//CASSCF/6-31G*/Amber level). The initial relaxation direction (IRD) method[23] was used to locate the steepest-descent direction to be followed when computing the S_1 (starting at *cis*-**1-OP**) and S_0 (starting at CI) branches of the reaction path of Figure 1. To simulate the S_0 relaxation dynamics a single CPMD trajectory starting at CI with zero initial velocities (the sensitivity of the trajectory to a random distribution of velocities at CI has been tested. α′ and β′ are found to be the most sensitive variables) was calculated at the full QM level, using the PBE exchange-correlation functional[24] with a plane-wave basis set and ultrasoft pseudopotentials.[25,26] Additional single-point CPMD and G98 PBE/6-31G* calculations were performed on the QM/MM S_0 branch to check the consistency of DFT and QM/MM results. See Supporting Information for further computational details.

Cover Picture

Shun-ichi Ishiuchi, Makoto Sakai, Yuji Tsuchida, Akihiro Takeda, Yasutake Kawashima, Masaaki Fujii,* Otto Dopfer,* and Klaus Müller-Dethlefs*

The intermolecular binding motif of the argon atom in a phenol···Ar dimer has been monitored on the picosecond timescale by time-resolved UV–UV(pump)–IR(probe) ionization depletion spectroscopy. The cover picture shows the dynamic process, which involves a shift of the initially π-bound Ar atom to a hydrophilic, hydrogen-bound site. For more details, see the Communication by M. Fujii, K. Müller-Dethlefs, and co-workers on page 6149 ff.
Odor Perception

Humans can distinguish more than 10000 odors. But how are these odors perceived and processed in the brain? R. Axel and L. Buck describe their research on page 6111 ff. and page 6128 ff., respectively, work for which they received the 2004 Nobel Prize for Medicine or Physiology.
Coordination Chains

In their Communication on page 6142 ff., T. Classen, S. Fabris, K. Kern, and co-workers describe the templating effect of the Cu(110) surface on trimesitylic acid that results in the formation of one-dimensional metal–organic coordination chains.
Metal Nanoparticles

Porous coordination polymers such as MOF-5 readily accept MOCVD precursors, and the stored compounds are easily reduced to give the corresponding metal nanoparticles, as described by R. Fischer et al. in their Communication on page 6237 ff.

Meeting Reviews

Books

Reviews

A sense of occasion: Around 20 years after the start of their pioneering studies on the function of the nose and brain in odor perception, R. Axel and L. Buck have received the 2004 Nobel Prize for Medicine or Physiology. The picture shows schematically the coding of different odors in the olfactory epithelium (OE) and olfactory bulb (OB).
Communications

Line them up: Metal–organic chains (see scanning tunneling microscopy image) have been created in situ by self-organized growth at a metal surface under ultrahigh vacuum. These 1D arrangements of metal centers (Fe, Cu), regularly spaced by organic linkers such as trimesitylic acid, open new possibilities for the study of low-dimensional magnetism.
Support for the direct route: That cyclobutenes are not necessary intermediates in the skeletal rearrangement of enynes is supported by DFT calculations and kinetic studies. Cyclobutenes may arise from the corresponding *syn*-cyclopropylgold(I) carbenes (see scheme).

That's quite a switch! The ionization-induced switch in the preferred intermolecular binding motif of the phenol···Ar interaction from π bonding to hydrogen bonding (see picture) has been monitored in real time by time-resolved picosecond UV-UV-IR pump-probe spectroscopy. The timescale for this prototypical intermolecular hydrophobic→hydrophilic (π→H) isomerization process (10 ps) has been measured for the first time.

The liquid–solid transition: Automatic assignment of solid-state NMR data as well as fast and accurate calculation of the structure of immobilized proteins at atomic resolution can be achieved by using the program SOLARIA (a modification of the ARIA protocol). The picture shows the lowest energy structures of the α-spectrin SH3 domain calculated by SOLARIA (blue) overlaid with the X-ray crystal structure (red).
Caught in a barrel: AFM studies indicate that the host–guest complexes formed between β-barrel pores and polymer blockers are pseudorotaxanes. The non-statistical location of the contracted supramolecular barrels on the polymers indicates that the sticky polymer templates insert quickly into the β barrels (see schematic representation) and then undergo slow motion through the barrels.

D-glucal is the starting point for the efficient synthesis of the F–J fragment of the gambieric acids (see scheme). The H-ring diol was subjected to double two-directional alkynyl ether formation, carbocupration ring-closing metathesis, and hydroboration. The tricyclic G–I diol was then converted into the F–J fragment by a sequence that involves another double two-directional ring-closing metathesis reaction.
Cyclic pseudopeptidic thiosulfinates reveal a new type of reaction that may be important in biological systems. It involves hydrolytic cleavage of the S(O)—S bond on **1** followed by metalation to form a dissymmetrical Co^{III} complex with a mixed diamidato-N, thiolato-S, sulfinato-S donor set in **2** that is related to the nitrile hydratase active site.
Highly efficient: Tetraarylphosphonium halides, Ar$_4$P$^+$X$^-$, as arylating reagents efficiently deliver an aryl group in Pd-catalyzed reactions with olefins, organoboron compounds, and terminal alkynes (see scheme).

The benzhydryl group is the key: Efficient alkylation of 3-substituted aziridine-2-carboxylates is only possible with *N*-benzhydryl-protected aziridines and occurs with complete retention of the configuration at the 2-position. Sequential catalytic asymmetric aziridination and aziridine alkylation reactions have been applied to the synthesis of BIRT-377 (see structure).
BIRT-377

Contents

Amphiphilic phosphine ligands (see structures; Cy = cyclohexyl) were prepared and utilized in palladium-catalyzed Suzuki–Miyaura and Sonogashira coupling reactions in water or water/organic biphasic solvents, providing excellent yields of functionalized biaryls and aryl alkynes, respectively.
for Suzuki–Miyaura couplings

for Sonogashira couplings
eupomatilone-3

Only six steps were needed for the total synthesis of eupomatilone-3 in 48 % overall yield thanks to the development of a dynamic kinetic resolution that allowed the reductive conversion of a racemic α,β-unsaturated butenolide in high yield and high enantiomeric and diastereomeric excess. This copper-catalyzed dynamic kinetic resolution was then applied to several γ-aryl-containing α,β-unsaturated butenolides.
Let's twist again: A cation–π interaction between Trp and Arg is designed at the interface between two α helices of a coiled-coil structure and stabilizes the structure more than Glu and Lys ion-pair interactions. Two or three Trp–Arg sets form an extended array of interactions (see picture) and increase the melting temperature of the peptide.

RSO_2 + $PhSO_2SPh$ + CO →[V-40 / heptane, 100 °C] R(C=O)SPh + SO_2Ph + SO_2
Remove contents from tin ... Thiol esters have been successfully synthesized through tin-free radical carbonylation (see scheme; V-40 = initiator). This approach can be further extended to sequential radical reactions involving cyclization, carbonylation, and trapping of acyl radicals by phenyl benzenethiosulfonate.
A fine pair: Excellent levels of regio-, *endo/ exo*-, diastereo-, and/or enantioselectivity are attained in the Cu-catalyzed cycloaddition of nitrones with α′-hydroxy enones (see scheme). The resulting adducts can be further elaborated to the corresponding isoxazolidines bearing aldehyde, ketone, and carboxylic acid functions.
The direct generation of boryl enamine **2** by radical addition to the chiral α,β-unsaturated oxime ether **1** (X = (1R)-camphorsultam, Bn = benzyl) followed by reaction with aldehydes gave rise to a tandem carbon–carbon bond-forming method, yielding lactones **3**. The result is a novel asymmetric synthesis of γ-butyrolactones and γ-amino acids by way of both a radical and an ionic process.
A new and effective use of hypervalent iodine(III) reagents as catalysts involves the transformation of iodoarenes **1** into hypervalent iodine(III) species **2** with *meta*-chloroperbenzoic acid (*m*CPBA) as the appropriate cooxidant. With observed turnover numbers greater than 70, this procedure paves the way for broader application of these useful oxidants in organic synthesis.
Methylation or phosphenium insertion reactions with cyclopolyphosphines (PtBu)₃ or (PCy)₄ (Cy = cyclohexyl) are presented as stereospecific and high-yielding preparative approaches to cyclopolyphosphinophosphonium cations. The cations [(PtBu)₃Me]⁺, [(PCy)₄Me]⁺, and [(PtBu)₃PMe₂]⁺ (see picture; P orange, C gray) are prepared as trifluoromethanesulfonate salts and represent key frameworks in fundamental *catena*-phosphorus chemistry.

Contents

A reflection on neptunium absorption: The absorption spectrum of Np^V around 980 nm originates from a 5f→5f electric-dipole transition, which is allowed if the Np^V ion lies in a coordination environment that lacks a center of inversion, such as in $[NpO_2(H_2O)_5]^+$. However, the transition is completely forbidden by Laporte's rule in the highly symmetrical Np^V diamide complex $[NpO_2(L)_2]^+$ (see structure; Np green, O red, N blue, C gray).
High-valent imido complexes are obtained by reaction of the manganese-(III) corrole [Mn(tpfc)] with aryl azides by a novel reaction mechanism in which singlet nitrene undergoes intersystem crossing to the triplet state, which is trapped by the metal corrole, in competition with dimerization to the azo compound (see scheme).
Energy transfer at the interface of two dissimilar conjugated polymer chains (see picture; DMOS = 2-dimethyloctylsilyl-*p*-phenylenevinylene; MEH = 2-methoxy-5-(2'-ethylhexyloxy)-*p*-phenylenevinylene) has been studied using single-molecule spectroscopy. Morphological features control energy-transfer processes between the blocks and lead to strongly heterogeneous efficiencies of energy transfer.
Torn genes: DNA tetramers containing the 2-deoxyribonolactone (dL) lesion have been isolated by HPLC from d(CGCG) and d(pCGCG) films irradiated with X-rays. Upon treatment with spermine as a catalyst, the dL-containing tetramers decompose to 5-methylene-2-furanone (5-MF; see scheme), a characteristic product of dL decomposition. Hence, 5-MP can be used to quantify dL lesions in DNA.
Very low loading and short reaction times are characteristic features of the quantitative reduction of different ketones using 2-propanol and terdentate [RuX(CNN)-(dppb)] (X=H, Cl (see structure); dppb=Ph$_2$P(CH$_2$)$_4$PPh$_2$) complexes prepared from 6-(4'-methylphenyl)-2-pyridylmethylamine. The reduction apparently takes place by reversible insertion of the substrate into the Ru–H bond, thus leading to a Ru^{II} alkoxide.

$R = Me:$ pamamycin-621A
$R = Et :$ pamamycin-635B
Sultones swing again: The first total syntheses of the title antibiotics (see scheme) were achieved by application of sultone methodology. Since the final lactonizations with formation of the ester linkage between C1′ and the oxygen substituent on C8 proceeded with complete epimerization at C2′, the more readily available C2′ epimeric smaller fragments could be used for streamlining the synthetic sequence.

The phosphane unit is deprotonated in the reaction of dialkylzinc with $H_2PSitBu_3$ and (thf)$_2$Ba[N(SiMe$_3$)$_2$]$_2$ to give the title compound (molecular structure shown), which has a coordinatively unsaturated barium center. In the absence of excess THF, the zinc-bound alkyl groups are activated by formation of Ba-C_{Et}-Zn three-center bonds.
Precursors and particles captured in a net: Porous coordination polymers such as MOF-5 are efficient gas storage devices and are also able to absorb metal organic chemical vapor deposition (MOCVD) precursors (see picture, red: [(η^5-C$_5$H$_5$)Pd(η^3-C$_3$H$_5$)]). These incorporated compounds are easily reduced to give the corresponding metal nanoparticles. Applications in heterogeneous catalysis, for instance, methanol synthesis or hydrogenation, are described.
Plenty of phosphorus: The first Cu^I oligophosphanido complex [Cu$_4$(P$_4$Ph$_4$)$_2$-(PCyp$_3$)$_3$] (**1**; Cyp $=$ $cyclo$-C$_5$H$_9$), synthesized from [CuCl(PCyp$_3$)$_2$] and [Na$_2$(thf)$_4$-(P$_4$Ph$_4$)], displays a remarkable cage structure in the solid state. The central Cu$_4$P$_8$ core of **1** (with appendant phosphane P atoms) is shown in the picture.
Corrigendum

New results have revealed that some values given in this original contribution are incorrect. The determined cloud point of polymer **5** does not lie over 95 °C as originally reported, but is actually 17 °C. The previously observed high optical transparency of a dispersion of polymer **5** was a result of the very small particle size that resulted from ultrasonic treatment. In light of this new result, the data for cyclodextrin-free polymer **5** presented in Table 1 and Figures 1, 2, and 3 are incorrect. In Table 1, the LCST value of polymer **5** of > 95 °C should be replaced by 17 °C, while the monomer ratio (n/m) for polymers **5** and **6** should now read as 20:1 instead of 1:20. In Figures 1 and 3, the plotted data for polymer **5** in the absence of cyclodextrin should be replaced by a function which shows a turbidity point at 17 °C. In Figure 2, the LCST value of > 95 °C should be corrected to 17 °C. In the text, all passages that refer to the cloud point of cyclodextrin-free polymer **5** are incorrect. However, all the other presented data as well as the conclusion remain valid.

Influence of Cyclodextrin Molecules on the Synthesis and the Thermoresponsive Solution Behavior of *N*-Isopropyl-acrylamide Copolymers with Adamantyl Groups in the Side Chains

ADHOC 2005 in Cologne: The Latest in Dioxygen Activation and Homogeneous Catalytic Oxidation**

Christian Limberg*

The selective functionalization of hydrocarbons is one of the most important challenges of chemistry and is of great interest for the purposes of basic research and technology. Homogeneous, heterogeneous, and enzymatic processes are being pursued worldwide as potential solutions to this problem. The mechanisms of oxidation reactions remain among the most puzzling issues in chemistry. To gain better insight, model systems with well-defined active sites are being developed, while with the aid of kinetic measurements, sophisticated isotope-labeling experiments, molecular probes, and especially computational chemistry, structure–activity relationships can be discussed and current proposed mechanisms can be either supported or rejected. Naturally, there is an intense interest in new oxidation reactions and catalysts as well as in novel applications of oxidation chemistry. All of this was the subject of the 9th International Symposium of Activation of Dioxygen and Homogeneous Catalytic Oxidation (ADHOC) in Cologne, Germany, which was organized for over 200 participants from

industry and academia by Albrecht Berkessel (University of Cologne) and Henrique Teles (BASF, Germany).

The opening lecture was given by R. Diercks (BASF, Germany) in which he introduced industrially relevant oxidation processes for the production of base chemicals, explained some problems therein, and addressed the importance of catalyst and reactor design. It was clearly pointed out that the use of HNO_3 as an oxidizing agent is frowned upon, as the nitrogen oxide byproducts are frequently cited in the literature as environmental hazards. However, the coupling of industrial oxidations to other processes (NO_x recovery, N_2O decomposition) can effectively turn HNO_3 into a "green" reagent. Remaining N_2O can also be an attractive source of oxygen, as outlined in the talk given by G. I. Panov (Boreskov Institute, Novosibirsk, Russia). With this reagent it is possible to oxidize benzene to phenol and its derivatives, as well as various olefins to carbonyl compounds, and to carry out the chemical modification of polymers such as polybutadiene.

New perspectives in the use of singlet oxygen were also highlighted. It has been known for some time that Na_2MoO_4 at appropriate pH values can catalyze the disproportion of H_2O_2 to give $^1O_2$. J.-M. Aubry (ENSCL, Lille, France) reported that $[Mo(O_2)_3O]^{2-}$ represents the catalytically active species. He introduced a method with which the $^1O_2$ produced can be used for "dark" oxygenations of hydrocarbons. A problem with this is the short lifetime of $^1O_2$ in aqueous medium, which opposes the oxidation of hydrophobic compounds. It is possible, however, to carry out peroxidations as a continuous process by using specially designed multiphase microemulsions. P. Alsters (DSM, The Netherlands) discussed the applications of this procedure

and simultaneously presented a way to solve the problem of parallel concurrent activation of H_2O_2 for epoxidations (Scheme 1): the use of pure inorganic compounds in heterogeneous phases. Elsewhere, A. Griesbeck (University of Cologne, Germany) described how $^1O_2$, with the aid of tetraarylporphyrin-loaded polystyrene, can be used for ene reactions, [4+2] cycloadditions, and can make ordinary organocatalytic reactions "chiral".

Many contributions this year also focused on natural approaches toward oxygen activation. These include direct investigations of metalloenzymes and studies concerning for the use of biocatalysts, as well as the development of biomimetic and bioinspired systems. J. D. Lipscomb (University of Minnesota, USA) was able to show that in soluble methane monooxygenase, the formation of a complex between the regulatory protein MMOB and the active component MMOH creates a very narrow pore, through which only methane has access to the active site (Scheme 2). This was proposed as one reason for this enzyme's high substrate selectivity for methane. This understanding should facilitate mutagenesis experiments designed to expand the oxidation capacity of this enzyme. Furthermore, this represents the first time that the dioxygenase mechanism could be followed spectroscopically through systematic substrate variation.

Such non-heme-containing enzymes were also the basis for the talk given by L. Que, Jr. (University of Minnesota, USA). He reported molecular models that catalyze the H_2O_2-mediated oxidation of olefins through a nonradical mechanism. The results of isotope-labeling experiments with these systems have led him to conclude that the active species bears an $O=Fe^V-OH$ unit (Scheme 3).

Scheme 2.

Scheme 4.

A dioxygenase reaction intermediate inspired T. D. P. Stack (Stanford University, USA) to employ single-core Fe and Mn complexes to catalyze the epoxidation of terminal olefins with peracids. A group of Mn complexes has proven itself especially active and selective, and its heterogenization by binding to silica gel adds to its list of advantages. W. Kroutil (University of Graz, Austria) was able to show that a dehydrogenase from *Rhodococcus ruber*, which is stable in organic solvents, can carry out highly stereoselective alcohol oxidations. It differentiates between not only *R* and *S* stereocenters, but also primary and secondary alcohols (intramolecular as well).

Many newly developed systems use Pd catalysts in combination with O_2. The prime example for such systems, namely the Wacker process, occasionally served as a source of ideas. S. S. Stahl (University of Wisconsin, Madison, USA) discussed an aza-Wacker process, which gives rise to enamines, and M. S. Sigman (University of Utah, USA) reported the dialkoxylation of olefins. Alcohol oxidations can also be carried out in aqueous media with water-soluble catalysts, as described by I. W. C. E. Arends (TU Delft, The Netherlands). D. De Vos (University of Leuven, Belgium) introduced a new procedure for the alkenylation of aromatic compounds, the mechanism of which was also studied in detail. Furthermore, he discussed the application of immobilized tungstate catalysts with haloperoxidase activity: these effect the oxidation of bromide to bromonium ions, which in turn, can be reactive under nonacidic conditions with olefins and aromatic compounds. M. S. Sanford (University of Michigan, USA) dealt with ligand-directed oxidations of C—H bonds, and in the process of investigations with the oxidizing agent PhI-$(OAc)_2$ she successfully isolated and characterized a Pd^{IV} intermediate. The relevance of the +4 oxidation state in Pd-catalyzed reactions has been the subject of controversy for some time, and here could be some initial evidence that such compounds actually do exist (Scheme 4).

The "slow-burners" of oxidation catalysis are the polyoxometallates (POMs), for instance, as ligands for other transition-metal oxo units, which then become active as the oxidant. M. Bonchio (University of Padova, Italy) reported the synthesis of POM–Ru and POM–Fe complexes, which catalyze reactions with O_2 upon microwave irradiation. POMs can also exhibit interest-ing chemistry in combination with noble metals. Not long ago, M=O compounds of late transition metals were unknown, as their d electrons occupy the π* orbitals of the M=O bond. The latter, however, are clearly stabilized by POM ligands; their use, as described by C. L. Hill (Emory University, Atlanta, USA), had recently allowed the isolation and characterization of the first Pd=O complex, and now he reported $K_9Na_4[(O=Pd^{IV}-OH)WO(OH_2)L_2]$ (L = $[PW_9O_{34}]^{9-}$). Furthermore, there is evidence for the first O=Au complexes, which can be produced by oxidation in air (Scheme 5).
Scheme 5. Blue circle right: K^+

The talk given by R. Neumann (Weizmann Institute, Israel) made it clear just how broad the range of POM–transition-metal-catalyzed oxidation reactions really is. Interestingly, with substrate-immobilized dipyrimidyl-platinum–POM hybrid compounds, even the catalytic oxidation of methane with O_2 in water was achieved, whereby methanol and acetaldehyde are formed, the mechanism of the surprising formation of $CH_3C(O)H$ is currently investigated. Altogether, there is still great interest in the oxidation of methane, the simplest natural yet most resistant source of C_1 hydrocarbons. After a mechanistic discussion of proton-coupled electron transfer, J. M. Mayer (Uni-
Scheme 3. Tf = trifluoromethylsulfonyl.

Meeting Reviews

versity of Washington, Seattle, USA) first introduced results of his investigation of the reaction of OsO_4 with H_2 and subsequently described initial results of the extension of this work toward methane as a substrate. R. A. Periana (USC, Los Angeles, USA) reported the use of CH_4 to generate acetic acid in the metal-catalyzed oxidation with O_2 as well as the first efforts toward the establishment of a catalytic cycle for the O_2-oxidation of hydrocarbons starting from Ir alkoxides.

A further important area of oxidation chemistry (especially within the detergent industry) is bleaching catalysis, to which an entire section of lectures was devoted. There is great interest in the development of active metal catalysts, and the most prominent representative of these is $[(Me_3tacn)Mn(\mu-O)_3Mn(Me_3tacn)]^{2+}$ (tacn = 1,3,7-triaza-cyclononane). The talk given by J. R. Lindsay-Smith (University of York, UK) dealt with mechanistic investigations of this system, and R. Hage (Unilever, UK) introduced the general development of metal-mediated bleaching. The lecture given by G. Reinhardt (Clariant, Germany) made it clear that there is not, and never will be a panacea for the bleaching industry. Additional talks on this subject were given by G. Miracle (P&G, USA) and J. J. Dannacher (University of Basel, Switzerland).

Efficient systems for the oxidation of prochiral thioethers to enantiomerically pure sulfoxides were introduced by R. F. W. Jackson (University of Sheffield, UK) und C. Bolm (RWTH Aachen, Germany). Through systematic variation of the ligand, metal, and additives, enantiomeric excesses of up to 99.5% could be reached, making the procedure suitable for the synthesis of biologically active compounds. Y. Shi (CSU, Fort Collins, USA) reported equally impressive *ee* values and yields in his investigation of organocatalyzed epoxidations. His research group succeeded in finding chiral ketone catalysts, which are converted in situ by an external oxidant into dioxiranes, which in turn, effect an enantioselective oxygen transfer to olefin substrates. M. Beller (Leibniz Institute for Organic Catalysis (IFOK), Rostock, Germany) presented a novel chiral pyridine bisimidazoline ligand system, in which Ru complexes in conjunction with pyridine dicarboxylic acid give the highest reported *ee* values for a transition-metal-mediated epoxidation with H_2O_2. The talk by I. Hermans (University of Leuven, Belgium) gave rise to controversial discussions, as it dealt with autoxidation of hydrocarbons. The validity of the conventionally accepted mechanistic model of alcohol and ketone formation, was put into question based on current experimental and theoretical data; a new proposal was presented in which cyclohexylperoxyl radicals, for example, do not abstract hydrogen atoms from cyclohexane, but instead from cyclohexylhydroperoxide ($\rightarrow$ketone).

There were many other interesting talks regarding mechanistic and preparative aspects of oxidation catalysts the discussion of which would significantly expand the scope of this report [A. Llobet (University of Barcelona, Spain), Y. Naruta (Kyushu University, Fukuoka, Japan), T. Geller (Bayer CropScience, Germany), J. P. Roth (Johns Hopkins University, Baltimore, USA), W. R. Thiel (University of Kaiserslautern, Germany), T. Funabiki (Doshisha University, Japan), C. Punta (University of Milan, Italy), I. Weinstock (City College New York, USA), Z. Gross (Technion, Haifa, Israel), C. Limberg (HU Berlin, Germany)]. The closing talk was given by R. A. Sheldon (TU Delft, The Netherlands), in which he discussed the imposing range of oxidation reactions that can be catalyzed by nitroxyl radicals.

Overall, the conference demonstrated that through the intense efforts of the past few years in the area of oxidation chemistry, many breakthroughs were made which, of course, have given rise to new questions and challenges. Among these, for example, the application of atmospheric oxygen for the selective oxidation of hydrocarbons remains an important goal. The mechanistic understanding was broadened, refined, and even renewed, and many novel systems can be developed from this. That oxidation chemistry—regardless of whether fundamental or technical questions are examined—is, as always, a very lively and rapidly developing research area was demonstrated impressively at ADHOC 2005. The pronounced emphasis on application was underscored by the fact that this year's meeting was, for the first time, organized jointly by both the industrial and academic spheres, and through the strong participation and generous support of industry (especially BASF).

Biography

New York City is my world. I was born in Brooklyn, the first child of immigrant parents whose education was disrupted by the Nazi invasion of Poland. Although not themselves learned, my parents shared a deep respect for learning. I grew up in a home rich in warmth, but empty of books, art, and music. My early life and education were centered on the streets of Brooklyn. Stickball—baseball with a pink ball and broom handle—and schoolyard basketball were my culture. In stickball, a ball hit the distance to one manhole cover was a single, and four manhole covers, a home run, a "Nobel Prize". My father was a tailor. My mother, although quick and incisive, did not direct her mind to intellectual pursuits and I had not even the remotest thought of a career in academia. I was happy on the courts. In those days, we worked at a relatively young age. At eleven, I was a messenger, delivering false teeth to dentists. At twelve, I was laying carpets, and at thirteen, I was serving corned beef and pastrami in a local delicatessen. Vladimir, the Russian chef, was the first to expose me to Shakespeare, which he recited as we sliced cabbage heads for coleslaw.

My local high-school had the best basketball team in Brooklyn, but the Principal of my grade school had a vision different from my own and insisted that I attend Stuyvesant High-School, far away in Manhattan. Stuyvesant High advertised itself as a school for intellectually gifted boys but had the worst basketball team in the city. I was unhappy about the prospect of attending, for it seemed antithetical to my self-image. Shortly after I entered, however, my world changed. I

E-mail: ra27@columbia.edu

embraced the culture and aesthetics of Manhattan. The world of art, books, and music opened before me and I devoured it. In school, I heard bits of an opera for the first time. I remember it distinctly, the Letter Duet from Mozart's *Marriage of Figaro*. The next night I attended *Tannhauser* at the Metropolitan Opera and thus began a love affair, bordering on an obsession, that has had no end. Twice a week, I stood in line for standing room tickets at the Metropolitan Opera where I was exposed to a cult of similarly obsessed but far more knowledgeable afficionados who taught me the intricate nuances of this rich genre. The great Italian tenor, Franco Corelli, would serve us coffee as we waited, and the diva, Joan Sutherland, would invite us backstage.

Richard Axel

On other days, I would read in a most beautifully appointed place, the Reading Room of the Central New York Public Library on 42nd Street. One passes the pair of sculpted lions, ascends a flight of stairs into a huge high-ceilinged room of impressive silence where I read incessantly without direction but with a new-found fascination that made up for years of illiteracy. I met a coterie of library dwellers, men and women of New York, who spent all of their days in the Reading Room. I did not know who they were or how they came to be there, but they had an insight and understanding of literature that amazed and still perplexes me, and they were my teachers. This was New York for me, a city of the culturally obsessed that opened up before me and framed my new world.

To support a seemingly extravagant life for a young high-school student, I worked. I used my skills as a waiter in a delicatessen in Brooklyn, to wait tables in the cafes and nightspots of Greenwich Village. In the sixties, the Village was the home of the beat generation that, through music and poetry and ultimately protest, translated discord into meaningful changes in both America and the world. Stuyvesant High School was on the fringe of Greenwich Village and some of its teachers were artists, writers, and performers who fueled the politically fired student body, many the sons of Marxist immigrants. With this array of artistic faculty, Stuyvesant nourished my new and voracious appetite.

But old worlds die hard. I continued to play basketball in high-school and this led to a most memorable and humbling experience. I came onto the court as the starting center, and the center on the opposing team from Power Memorial High School lumbered out on the court, a lanky 7 foot 2 inch sixteen year old. When I was first passed the ball, he put his hands in front of my face, looked at me and asked, "What are you going to do, Einstein?" I did rather little. He scored 54 points and I scored two. He was the young Lew Alcindor, later known as Karim Abdul Jabar, who went on to be among the greatest basketball legends, and I became a neurobiologist.

My decision to remain in New York and attend Columbia College revealed the provincial but endearing quality of my family. When I chose to accept a gracious scholarship offered by Columbia, my father was disappointed. It was a well known fact that the brightest children of Brooklyn immigrants attended City College. My freshman year at Columbia, I lived with abandon. The opera, the arts, the freedom, the protest left little time for study. In the first semester, I met a student from Tennessee, Kevin Brownlee, who remains a dear friend and is now a Professor of Medieval French at the University of Pennsylvania. Brownlee urged me to redirect this intensity to learning. The world of the arts will remain, but my time at Columbia University was limited. Once again, a new world opened before me. With Kevin as my guide, I became a dedicated, even obsessed, student. My life was spent in a small room lined with volumes of Keats' poetry at the Columbia Library and I immersed myself in my studies. The study of literature at Columbia in the sixties was exciting in the presence of the poet, Kenneth Koch, the critics, Lionel Trilling, Moses Hadas, and Jacques Barzun. It was largely chance, however, that led me to biology.

To support myself in college, I obtained a job washing glassware in the laboratory of Bernard Weinstein, a Professor of Medicine at Columbia University. Bernie was working on the universality of the genetic code. The early sixties was a time shortly after the elucidation of the structure of DNA and the realization that DNA is the repository of all information and from which all information flows. The genetic code had just been deciphered and the central dogma was complete. I was fascinated by the new molecular biology with its enormous explanatory power. I was a terrible glassware washer because I was far more interested in experiments than dirty flasks. I was fired and was rehired as a Research Assistant and Bernie spent endless hours patiently teaching this scientifically naïve, but intensely interested young student. I was torn between literature and science. Dubious about my literary ambitions and fascinated by molecular biology, I decided to attend graduate school in genetics.

My plans were thwarted by an unfortunate war and to assure deferment from the military, I found myself a misplaced medical student at Johns Hopkins University School of Medicine. I entered medical school by default. I was a terrible medical student, pained by constant exposure to

the suffering of the ill and thwarted in my desire to do experiments. My clinical incompetence was immediately recognized by the faculty and deans. I could rarely, if ever, hear a heart murmur, never saw the retina, my glasses fell into an abdominal incision and finally, I sewed a surgeon's finger to a patient upon suturing an incision. It was during this period of incompetence and disinterest that I met another extremely close friend, Frederick Kass, now a Professor of Psychiatry at Columbia University. Fred was an unusual medical student, a Texan with a degree in art history from Harvard, who remains a kindred spirit.

It was a difficult time, but I was both nurtured and protected by Howard Dintzis, Victor McCusick, and Julie Krevins, three professors at Johns Hopkins who somehow saw and respected my conflict. Without them, there is little question that I would not have been tolerated but they urged the deans to come up with a solution. I was allowed to graduate medical school early with an MD if I promised never to practice medicine on live patients. I returned to Columbia as an intern in Pathology where I kept this promise by performing autopsies. After a year in Pathology, I was asked by Don King, the Chairman of Pathology, never to practice on dead patients.

Finally, I was afforded the opportunity to pursue molecular biology in earnest. I joined the laboratory of Sol Spiegelman in the Department of Gentics at Columbia University. Spiegelman was a short, incisive, witty man with a tongue as sharp as his mind. Spiegelman was the first to synthesize infectious RNA in vitro and this led to a series of extremely interesting and clever experiments revealing Darwinian selection at the level of molecules in a test tube. Sol recognized the importance of the early RNA world in the evolution of life and had recently turned his laboratory to a study of RNA tumor viruses. An immediate bond formed between us, and Sol taught me how to think about science, to identify important problems, and how to effect their solution.

Although I felt a growing confidence in my abilities in molecular biology, I was naïve in other areas of biology, notably biophysics. Importantly, I had a sense early in my career that my interest in biology was eclectic and that I would need a concomitantly broad background to embrace the different areas of biology without trepidation. I left to begin a second postdoctoral fellowship at the National Institutes of Health, working with Gary Felsenfeld on DNA and chromatin structure. Since I entered medical school to avoid the draft, I had a military obligation that was fulfilled by my years at the NIH and was endearingly termed a "yellow beret." Gary was great, but the NIH was alien, a government reservation with a fixed workday. As a night person, I found it strange and at some level difficult since I arrived at noon after all the parking spaces were occupied, left at midnight and accumulated an increasing number of parking tickets. In the midst of a molecular hybridization reaction, I was arrested by two FBI agents (the NIH is a federal reservation) for 100 summonses for parking violations.

As a fellow in Felsenfeld's lab studying how chromatin serves to regulate gene expression, I formed close friendships that continue to the present. On the beach at Cold Spring Harbor, I sat with Tom Maniatis and Harold Weintraub and talked about chromosome replication and gene expression and within a few hours a bond formed, a respect for one another and for one another's thinking, that has lasted for thirty years. Hal, unfortunately, died ten years ago of a brain tumor, but his warmth, his creativity persist.

Sol Spiegelman invited me to return to Columbia as an Assistant Professor in 1974 at the Institute of Cancer Research. I was ecstatic to occupy a lab and office adjacent to his. Sol had many visitors in those years, and when he felt bored in a meeting he would excuse himself and hide in my office where we talked science until his visitors finally gave up and left. I was studying the structure of genes in chromatin and had the good fortune of participating in a revolution made possible by recombinant DNA technology. I spent a great deal of time with Tom Maniatis, who pioneered many of the techniques in recombinant DNA. Tom left Harvard for Caltech, because he was restricted from performing recombinant DNA experiments in Cambridge, Massachusetts. We learned how to cut and paste DNA, to isolate genes, and to analyze their anatomy down to the last detail. We recognized that to understand gene control and gene function, however, required a functional assay. Within months of establishing my own laboratory in 1974, Michael Wigler, my first graduate student along with Sol Silverstein, a Professor at Columbia, developed novel procedures that allowed DNA-mediated transformation of mammalian cells. Michael, even at this very early stage in his career, was conceptually and technically masterful and within a few years he devised procedures that permitted the introduction of virtually any gene into any cell in culture. He developed a system that not only allowed for the isolation of genes, but also for detailed analysis of how they worked. We now had a facile assay to study the sequences regulating gene expression as well as gene function.

Michael went off to the Cold Spring Harbor Laboratories and, simultaneous with Bob Weinberg at MIT, identified the mutant ras gene as the gene responsible for malignant transformation in many cancer cells. My laboratory went off in many directions, first identifying the regulatory sequences responsible for control of specific gene expression. At the same time, a research fellow, Dan Littman, now a Professor at NYU, joined the lab and was interested in two molecules that characterize the major classes of T cells. Dan, along with a student, Paul Maddon, succeeded in exploiting the gene transfer to isolate these two molecules. As often in science, serendipity heightened the interest in these molecules: we demonstrated that one of these receptors, CD4, was the high-affinity receptor for HIV, allowing attachment and infection of immune cells.

This early work on recombinant DNA was a period of enormous excitement, for it led to a revolution in both thinking and technology in biology. It provided a new tool for the study of fundamental problems and spurred a new and valuable industry: biotechnology. We, who were involved at its inception, were perhaps a bit haughty, aggressive, and proud, and were accused by many of playing "God." As evidence, the press noted that "I baptized my first child, Adam."

Recombinant DNA aroused a good deal of passion and hostility. The notion of tinkering with life was thought to endanger life and this cry became one of the major indictments of modern biology. These experiments raised endless debate because the idea that genes can be taken out of one organism and introduced into the chromosome of another is by itself upsetting. The very notion of the performance of recombinant DNA was linked with the mysterious and supernatural. This conjured up myths that elicited intense anxiety. Recombinant DNA, it was feared, would permit biologists to alter individual species as well as the evolution of species. This controversy emphasized the fact that advances in science may indeed bring harm as well as benefit. In the case of recombinant DNA, as Francois Jacob said, "Apocalypse was predicted but nothing happened." In fact, with recombinant DNA, only good things happened. At a practical level, the ability to construct bacteria-replicating eucaryotic genes has allowed for the production of an increasingly large number of clinically important proteins. At a conceptual level, gene cloning has permitted a detailed look at the molecular anatomy of individual genes, and from a precise analysis of these genes we have deduced the informational potential of the gene and the way in which it dictates the properties of an organism.

At a personal level, the emergence of a new discipline, biotechnology, introduced me to a world outside of academia. This important excursion showed me that brilliance is not limited to universities. I met and remain very close to two dynamic leaders of technology development, Fred Adler and Joe Pagano. Despite disparate histories, we remain very close and they continue to fascinate me with lives quite different from that of a university professor.

In 1982, I began to think about the potential impact of the new molecular biology and recombinant DNA technology on problems in neuroscience. Molecular biology was invented to solve fundamental problems in genetics at a molecular level. With the demystification of the brain, with the realization that the mind emerges from the brain and that the cells of the brain often use the very same principles of organization and function as a humble bacterium or a liver cell, perhaps molecular biology and genetics could now interface with neuroscience to approach the tenuous relationship between genes and behavior, cognition, memory, emotion, and perception. This thinking was the result of a faculty meeting at which Eric Kandel and I overcame our boredom with administration by talking science. Eric was characteristically exuberant about his recent data that revealed a correlation between a simple form of memory in the marine snail *Aplysia* and cellular memory at the level of a specific synapse. Molecular biologists had encountered cellular memory before in the self-perpetuating control of gene expression. This led to the realization that this was the moment to begin to apply the techniques of molecular biology to brain function and I would attempt to recruit Eric Kandel as my teacher.

A courageous new postdoctoral fellow in my laboratory, Richard Scheller, now Director of Research for Genentech, was excited about embarking on an initial effort in molecular neurobiology in a laboratory with absolutely no expertise in neuroscience. Together with Richard and Eric, we set out to isolate the genes responsible for the generation of stereotyped patterns of innate behaviors. All organisms exhibit innate behaviors that are shaped by evolution and inherited by successive generations that are largely unmodified by experience or learning. It seemed reasonable to assume that this innate behavior was dictated by genes that might be accessible to molecular cloning. It was an exciting and amusing time, with myself unfamiliar with action potentials and Kandel uncomfortable with central dogma. Richard Scheller exploited the techniques of recombinant DNA to identify a family of genes encoding a set of related neuropeptides whose coordinated release was likely to govern the fixed action pattern of behaviors associated with egg laying. A single gene, the ELH gene, specifies a polyprotein that is cut into small biologically active peptides such that individual components of the behavioral array may be mediated by peptides encoded by one gene.

Watching the story unfold, observing the interface of molecular biology and neuroscience, provided great pleasure. More importantly, this collaboration formed the basis of a continuing relationship with Eric Kandel, with his incisive mind, inimitable laugh, and boundless energy. In 1986 neuroscience for me was made even richer when Tom Jessell came along. Tom joined the faculty at Columbia and was to occupy a lab adjacent to my own. Not surprisingly, the lab was not ready and I had the great pleasure of hosting Tom in my own laboratory, and this forged a long-lasting scientific and personal relationship. Jessell, the understated British scientist with a wry wit and piercing mind, joined a fellow in my laboratory, David Julius, now at the University of California at San Francisco, and together they devised a clever assay for the isolation of genes encoding the neurotransmitter receptors. These experiments, which might have been the last performed by the hands of Jessell, led to the isolation of genes encoding the seven transmembrane domain serotonin receptor 5HT1C, and more generally provided an expression system that permitted the identification of functional genes that encode receptors in the absence of any information on the nature of the protein sequence. With Kandel one floor above, and Jessell next door, there was no departure from neuroscience. I was surrounded and I did not want to escape. I was beginning to feel that neuroscience was indeed an appropriate occupation for a molecular biologist. To quote Woody Allen, a fellow New Yorker, "The brain is my second favorite organ."

In the late 1980s I became fascinated in the problem of perception: how the brain represents the external world. I was struck by observations from animal behavior that what an organism detects in its environment is only part of what is around it and that part can differ in different organisms. The brain functions then not by recording an exact image of the world, but by creating its own selective picture. Biological reality will therefore reflect the particular representation of the external world that a brain is able to build, and a brain builds with genes. If genes are indeed the arbiters of what we perceive from the outside world, then it follows that an understanding of the function of these genes could provide

insight into how the external world is represented in the brain. Together with Linda Buck, a creative research fellow in the lab, we began to consider how the chemosensory world is represented in the brain. The problem of olfaction was a perfect intellectual target for a molecular biologist. How we recognize the vast diversity of odorous molecules posed a fascinating problem. We assumed that the solution would involve a large family of genes and Linda Buck devised a creative approach that indeed identified the genes encoding the receptors that recognize the vast array of odorants in the environment. Linda came to me with the experimental data late one night, exuberant, and I fell uncharacteristically silent. There were 1000 odorant receptor genes in the rat genome, the largest family of genes in the chromosome, and this provided the solution to the problem of the diversity of odor recognition. More importantly, the identification of these 1000 genes and their expression revealed an early and unanticipated logic of olfaction. Indeed, the subsequent use of these genes to manipulate the genome of mice has afforded a view of how the olfactory world could be represented in the brain and how genes shape our perception of the sensory environment. From that late night moment to the present, it has been a joy to watch this story unfold.

It is this work for which Linda Buck and I share the profound honor and good fortune of having been awarded the Nobel Prize in Physiology or Medicine. But there are, deeper, more human joys, two sons, Adam and Jonathan, my sister, Linda, a very close coterie of friends, and a new love. Watching, contributing to the growth of my children is not only moving but humbling and puts my intense life in science in perspective. Often this intensity, bordering on obsession, distracted me from fathering and this is a regret. But my sons have emerged from a frenetic teenage into very human college students, extremely unlikely to pursue a career in science. My sister remains a close and dedicated member of an increasingly small family. A new love, Cori Bargmann, a behavioral geneticist now at Rockefeller University, has entered my world. Her intensity for science hides a knowledge and passion for books, music, and art. I have learned much from her, but most importantly Cori has shown me how to combine intellectual intensity with humanity and warmth.

Finally, the Nobel Prize was awarded to me not as a man, but for my work, a work of science that derives from the efforts of many brilliant students as well as from the incisive teachings of devoted colleagues. I take equal pride in the science that has been accomplished in the laboratory as in the scientists that have trained with me and are now independently contributing to our understanding of biology. I therefore feel that I can only accept the Nobel Prize in trust, as a representative of a culture of science in my laboratory and at Columbia University. I am deeply grateful for this culture.

1. Introduction

The image in the painting *La Bonne Aventure* is not a nose (Figure 1). It is a portrayal by the surrealist René Magritte of his own brain's representation of the external world. It is a

Figure 1. The painting *La Bonne Aventure* (Fortune Telling), by René Magritte (1937) portrays a monumental nose. I have added the inscription "Ceci n'est pas un nez" ("This is not a nose") in Magritte's script to emphasize the tension between image and reality, a conflict inherent in much of his art as well as in the science of perception.

vignette that reveals a tension between image and reality, a tension that is a persistent source of creativity in art, brought to its culmination by the surrealists. The problem of how the brain represents the external world is not only a central theme in art but is at the very core of philosophy, psychology, and neuroscience. We are interested in how the chemosensory world is represented in the brain.

All organisms have evolved a mechanism to recognize sensory information in the environment and transmit this information to the brain where it then must be processed to create an internal representation of the external world. There are many ways for organisms to probe the external world: some smell it, others listen to it, many see it. Each species therefore lives in its own unique sensory world of which other species may be partially or totally unaware. A whole series of specific devices alien to human perception have evolved: biosonar in bats, infrared detectors in snakes, electrosensitive organs in fish, and a sensitivity to magnetic fields in birds. What an organism detects in its environment is only part of what is around it and that part differs in different organisms. The brain functions, then, not by recording an exact image of the world, but by creating its own selective picture—a picture largely determined by what is important for the survival and reproduction of the species.

Sensory impressions, therefore, are apprehended through the lens of the particular perceiving brain, and the brain must therefore be endowed with an a priori potential to recognize the sensory world.[1] Our perceptions are not direct recordings of the world around us, rather they are constructed internally

according to innate rules. Colors, tones, tastes, and smells are active constructs created by our brains out of sensory experience. They do not exist as such outside of sensory experience.[2] Biological reality, I argue, therefore reflects the particular representation of the external world that a brain is able to build, and a brain builds with genes.

If our genes are indeed the arbiters of what we perceive from the outside world, then it follows that an understanding of the function of these genes could provide insight into how the external world is represented in our brain. But what can molecular biology really tell us about so elusive a brain function as perception? Molecular biology was invented to solve fundamental problems in genetics at a molecular level. With the demystification of the brain, with the realization that the mind emerges from the brain, and that the cells of the brain often use the very same principles of organization and function as a humble bacterium or a liver cell, molecular biology and genetics could now interface with neuroscience to approach the previously tenuous relationship between genes and behavior, cognition, memory, emotion, and perception.

Why would a molecular neuroscientist interested in perception choose to focus on the elusive sense of smell? In humans, smell is often viewed as an aesthetic sense, as a sense capable of eliciting enduring thoughts and memories. Smell, however, is the primal sense. It is the sense that affords most organisms the ability to detect food, predators, and mates. Smell is the central sensory modality by which most organisms communicate with their environment. Second, humans are capable of recognizing hundreds of thousands of different odors. For molecular neuroscientists studying the brain, the mechanism by which an organism can interact with the vast universe of molecular structures defined as odors provides a fascinating problem in molecular recognition and perceptual discrimination. Finally, the problem of perception necessarily involves an understanding of how sensory input is ultimately translated into meaningful neural output: thoughts and behavior. In olfaction, the sensory input is extremely well defined and consists of chemicals of precise molecular structure. The character of the input in olfaction is far simpler than that of a visual image, for example, which consists of contours, texture, color, movement, and form of confounding complexity. Representation of an olfactory image is simpler and reduces to the problem of how precisely defined chemical structures are transformed in brain space.

As molecular neurobiologists, Linda Buck and I approached olfactory sensory perception by dividing it into two problems: First, what mechanisms have evolved to allow for the recognition of the vast array of molecular structures we define as odorants? Clearly, there must be receptors in the sensory neurons of the nose capable of associating with odor molecules. Do we have a relatively small number of "promiscuous" receptors, each capable of interacting with a large number of odorous molecules? Alternatively, olfactory recognition may involve a very large number of "chaste" receptors each capable of interacting with a limited set of odor molecules. The second problem is conceptually more difficult: how does the olfactory sensory system discriminate among the vast array of odorous molecules that are recognized by the nose? Put simply, how does the brain know what

the nose is smelling? This question will ultimately require knowledge of how the different odors are represented and encoded in the brain.

2. A Large Family of Odorant Receptor Genes

We approached the problem of odor recognition directly by isolating the genes encoding the odorant receptors.[3] The experimental design we employed to isolate these genes was based on three assumptions: 1) the odorant receptors were likely to belong to the superfamily of receptors, the G-protein coupled receptors (GPCRs), that transduce intracellular signals by coupling to GTP-binding proteins.[4–7] 2) The large repertoire of structurally distinct, odorous molecules suggests that the odorant receptors themselves must exhibit significant diversity and are therefore likely to be encoded by a multigene family. 3) The expression of the odorant receptors should be restricted to the olfactory epithelium. Experimentally, we used the polymerase chain reaction (PCR) to amplify members of the GPCR gene superfamily expressed in olfactory sensory neurons. We then investigated whether any of the PCR products were indeed members of a large multigene family. We observed that restriction-enzyme cleavage of a single PCR band generated a set of DNA fragments whose molecular weight summed to a value significantly greater than that of the original PCR product.[3] In this manner, we identified a multigene family that encodes a large number of GPCRs whose expression is restricted to the olfactory sensory neurons. The receptors were subsequently shown to interact with odors, translating the energy of odor binding into alterations in membrane potential.[8–11]

The completed sequence of both the murine and human genome ultimately identified 1300 odorant receptors in the mouse[12,13] and 500 in humans.[14–16] If mice possess 20 000 genes, then as much as 5% of the genome (one in 20 genes) encodes the odorant receptors. A large family of odorant receptors is observed not only in vertebrates, but in the far simpler sensory systems of invertebrates. A somewhat smaller but highly diverse family of about 80 odorant receptor genes has been identified in the *Drosophila* genome.[17–19, 50, 67] The invertebrate, *C. elegans*, with only 302 neurons and 16 olfactory sensory neurons expresses about 1000 odorant receptor genes.[20, 21] These experiments provide a solution to the first question: we recognize the vast array of molecular structures defined as odorants by maintaining in our genome a large number of genes encoding odorant receptors.

The observation that over 1000 receptors are required to accommodate the detection of odors suggests a conceptual distinction between olfaction and other sensory systems. Color vision in humans, for example, allows the discrimination of several hundred hues with only three different photoreceptors.[22, 23] These photoreceptors each have distinct but overlapping absorption spectra. Discrimination of color is thought to result from comparative processing of the information from these three classes of photoreceptors. Whereas three photoreceptors can absorb light across the entire visible spectrum, our data suggest that a small number of odorant receptors cannot recognize the full spectrum of distinct

molecular structures perceived by the mammalian nose. Rather, olfactory perception requires a large number of receptors, each capable of recognizing a small number of odorous ligands.

The large number of odorant receptor genes when compared with receptor numbers in other sensory systems perhaps reflects the fact that in vision and hearing the character of the sensory stimulus is continuously variable. Color is distinguished by quantitative differences in a single parameter, the wavelength of light. Similarly, one important parameter of hearing, the frequency of sound, is continuously variable. The diversity of chemical structures of odors do not exhibit continuous variation of a single parameter and therefore cannot be accommodated by a small number of receptors. Rather, the full spectrum of distinct molecular structures perceived by the olfactory system requires a large number of receptors, each capable of interacting with a small number of specific odorous ligands.

3. A Topographic Map in the Olfactory Bulb

We next turned to the question of olfactory discrimination: how does the brain know what the nose is smelling? The identification of a large family of receptor genes allowed us to pose this question in molecular terms. We could now ask how the brain knows which of the numerous receptors have been activated by a given odor. The elucidation of a mechanism by which the brain distinguishes the different combinations of receptors activated by different odors would provide a logic of odor discrimination. This problem was further simplified by the demonstration that an individual sensory neuron expresses only one of the 1000 receptor genes.[10,24] This observation emerged from single-neuron cDNA cloning experiments, and allowed us to translate the problem of how the brain determines which receptor has been activated to a far simpler problem: how does the brain know which neuron has been activated by a given odor? As in other sensory systems, an invariant spatial pattern of olfactory sensory projections could provide a topographic map of receptor activation that defines the quality of a sensory stimulus.

In other sensory systems, spatially segregated afferent input from peripheral sensory neurons generates a topographic map that defines the location of a sensory stimulus within the environment as well as the quality of the stimulus itself. Olfactory sensory processing does not extract spatial features of the odorant stimulus. Relieved of the requirement to map the position of an olfactory stimulus in space, we asked whether the olfactory system might employ spatial segregation of sensory input to encode a quality of an odorant. Robert Vassar in my lab and Kerry Ressler in Linda Buck's lab therefore analyzed the spatial patterns of receptor expression in the olfactory epithelium by in situ hybridization and observed that cells expressing a given receptor are restricted to one of four broad but circumscribed zones.[25,26] The overriding feature of this organization, however, is that within a zone, neurons expressing a given receptor are not topographically segregated, rather they appear randomly dispersed. When they performed in situ hybridization experiments to the bulb, the first relay station for olfactory sensory neurons in the brain, they observed that topographic order was restored.[27,28] Neurons expressing a given receptor, although randomly distributed in the epithelium, project to spatially invariant glomeruli in the olfactory bulb, thus generating a topographic map.

Peter Mombaerts, then a research fellow in the lab, developed a genetic approach to visualize axons from olfactory sensory neurons, thereby expressing a given odorant receptor as they project to the brain.[29] We modified receptor genes by targeted mutagenesis in the germ line of mice. These genetically altered receptor genes now encoded a bicistronic mRNA that allows the translation of receptor along with tau-lacZ, a fusion of the microtubule-associated protein tau with β-galactosidase. In these mice, olfactory neurons that transcribe a given receptor also express tau-lacZ in their axons, permitting the direct visualization of the pattern of projections in the brain (Figure 2).

We observe that neurons expressing a receptor project to only two topographically fixed loci, or glomeruli, in the bulb, thus creating mirror-image maps in each bulb. Neurons expressing different receptors project to different glomeruli. The position of the individual glomeruli is topographically defined and is similar for all individuals in a species (Figure 3). Individual odors could activate a subset of receptors that would generate specific topographic patterns of activity within the olfactory bulb such that the quality of an olfactory stimulus could be encoded by spatial patterns of glomerular activity.

The identification of an anatomic olfactory sensory map poses four questions. The first addresses the singularity of receptor gene choice. What mechanism assures that a sensory neuron expresses only a single receptor and then projects with precision to one of 1000 topographically fixed glomerular loci? Second, does the anatomic map translate into a functional map such that different odors elicit different patterns of activity? Third, can we relate specific spatial patterns of glomerular activity to specific behaviors? Finally how is the map read? How does the brain look down upon a spatial pattern of activity and associate this pattern with a particular odor?

4. Receptor Choice and the Topographic Map

The topographic map in the olfactory system differs in character from the orderly representation inherent in the retinotopic, tonotopic, or somatotopic sensory maps. In these sensory systems, the peripheral receptor sheet is represented in the central nervous system (CNS), such that neighboring relations in the periphery are preserved in the CNS (for reviews, see Refs. [30,31]). In this manner, peripheral receptor cells may acquire a distinct identity that is determined by their spatial position in the receptor sheet. Spatial patterning in the periphery can therefore endow individual neurons with positional information that directs their orderly representation in the brain.

The olfactory system, however, does not exhibit an orderly representation of receptor cells in the periphery.
Figure 2. Convergence of axons from neurons expressing a given receptor. Odorant receptor loci were modified by homologous recombination in ES cells to generate strains of mice in which cells expressing a given receptor also express a fusion of the microtubule-associated protein tau with β-galactosidase. These photographs reveal neurons expressing either the M12 (left) or P2 (right) receptors along with their axons as they course through the cribriform plate to a single locus in the olfactory bulb. Neurons expressing different receptors converge on different glomeruli. The genetic modifications that assure the coordinate expression of receptor and tau-lacZ are shown beneath the photographs.
Figure 3. A Topographic map of olfactory sensory axons in the bulb. The picture reveals neurons expressing two modified P2 alleles: P2-IRES-tau-lacZ (red) or P2-IRES-GFP (green). These neurons send axons that co-converge on the same glomerulus in the olfactory bulb. Neurons expressing other receptors converge on different glomerular loci that are shown schematically. All nuclei are stained blue with TOTO-3. The relative positions of the different glomeruli are maintained in different mice, thus revealing an invariant topographic map in the olfactory bulb.

Neurons expressing a given receptor are randomly dispersed within a given zone and order is restored in the bulb where neurons expressing a given receptor converge on discrete loci to create a topographic map. Olfactory neurons differ from one another not by virtue of their position in a receptor sheet, but rather by the nature of the receptor they express. The tight linkage between the choice of an odorant receptor and the site of axon convergence suggests a model in which the odorant receptor is expressed on dendrites, where it recognizes odorants in the periphery, and also on axons, where it governs target selection in the bulb. In this manner, an olfactory neuron would be afforded a distinct identity that dictates the nature of the odorant to which it responds as well as the glomerular target to which its axon projects. If the odorant receptor also serves as a guidance molecule, this leads to two experimental predictions. First, the receptor should be expressed on axons as well as on dendrites, and second, genetic modifications in the receptor sequence might alter the topographic map.

The first prediction was tested by Gilad Barnea, who generated specific antibodies against two odorant receptors and examined the sites of receptor expression on sensory neurons.[32] Antibodies were raised against extracellular and cytoplasmic epitopes of the mouse odorant receptors MOR28 and MOR11-4. In the sensory epithelium, we observe intense staining in the dendritic knobs, the site of odor binding. In the olfactory bulb, antibody stains axon termini whose arbors are restricted to two glomeruli (Figure 4). Antibody-staining of the bulb from mice bearing the MOR28-IRES-tau-lacZ allele reveals that the glomeruli stained by antibodies to MOR28 also receives the tau-lacZ fibers. Thus, the receptor is expressed on both dendrites and the axons of sensory neurons.

In a second series of experiments performed by my student, Fan Wang, we provided genetic evidence suggesting that the receptor on axons is indeed a guidance molecule. We modified our gene-targeting approach to ask whether substitutions of the P2 receptor coding sequence alter the projections of neurons that express this modified allele.[33] We replaced the coding region of the P2 gene with the coding regions of several other receptors, and examined the consequences on the formation of the topographic map. Substitution of the P2 coding region with that of the P3 gene, a linked receptor gene homologous to P2 and expressed in the same epithelial zone, results in the projection of axons to a glomerulus distinct from P2 that resides immediately adjacent to the wild-type P3 glomerulus. Other substitutions that replace the P2 coding sequences with receptor sequences expressed either in different zones or from different chromo-somal loci also result in the convergence of fibers to glomeruli distinct from P2. These observations, along with recent experiments involving more extensive genetic modifications[34,35] provide support for the suggestion that the olfactory receptor plays an instructive role in axon targeting as one component of the guidance process.

How may the odorant receptors participate in the guidance process? In one model, the odorant receptor is expressed on the axon termini along with other guidance receptors where it recognizes positional cues elaborated by the bulb. Each of the 1000 distinct types of sensory neuron will therefore bear a unique combination of guidance receptors that define a code dictating the selection of a unique glomerular target. Such a model does not necessarily imply that there are 1000 distinct cues, each spatially localized within the bulb. Rather, a small number of graded cues may cause the differential activation of the different odorant receptors on axon termini. In this manner, the different affinities of individual receptors for one or a small number of cues, and perhaps different levels of receptor, might govern target selection. Such a model is formally equivalent to models of retinotopy in which a gradient of guidance receptors on retinal axons is matched by a positional gradient of guidance cues in the tectum (for a review see Ref. [31]).

5. The Singular and Stable Choice of Receptor

If the odorant receptor defines the functional identity of a sensory neuron and also determines the site of projection in
Figure 4. The odorant receptor gene is expressed on both dendrites and axons of olfactory sensory neurons. The mouse sensory epithelium (top picture) or olfactory bulb (bottom picture) was stained with antibody to either an extracellular (middle) or cytoplasmic (left) epitope of the MOR28 receptor. These experiments reveal the expression of odorant receptor in the cell body and dendrites in the epithelium as well as on axon termini within a defined glomerulus in the bulb. Antibody staining in the olfactory bulb coincides with the site of convergence of MOR28 axons. Adapted with permission from Ref. [32].

the brain, then the expression of a single receptor gene in a neuron is an essential feature in models of olfactory perception. This immediately poses the question as to what mechanism has evolved to assure the expression of a single receptor gene from the family of 1000 genes in the chromosome. One model for the control of olfactory receptor expression invokes the existence of 1000 different sensory neurons, each expressing a unique combination of regulatory factors that governs the choice of a different olfactory receptor gene. This deterministic model predicts that all olfactory receptor genes will contain different *cis*-regulatory sequences that are recognized by unique sets of transcription factors. An alternative, stochastic model of receptor gene selection suggests that all odorant receptor genes within a zone contain the same *cis*-regulatory information and are controlled by the same set of transcription factors. In this model, a special mechanism must exist to assure that only one receptor gene is chosen. Moreover, once a specific receptor is chosen for expression, this transcriptional choice must be stable for the life of the cell, because receptor switching after stable synapse formation would seriously perturb odor discrimination.

A series of transgene experiments performed by Ben Shykind in my own laboratory, as well as by other researchers, provide evidence for a mechanism of receptor choice that is stochastic.[36,37] We have generated mice in which the endogenous P2 allele has been replaced with the P2-IRES-tau-lacZ allele. We have also introduced a randomly integrated P2-IRES-GFP transgene into the chromosome of this strain. In a deterministic model, we predict that a unique combination of transcription factors would activate both the endogenous and

transgenic P2 alleles such that cells that express lacZ from the endogenous P2-IRES-tau-lacZ allele should also express GFP from the P2 transgene. Examination of the sensory epithelium in these mice, however, reveals a singularity of P2 expression. Cells that express the endogenous P2 allele never express the transgene. In a conceptually similar experiment, we generated transgenic mice that harbor an integrated array of multiple P2 transgenes that include P2-IRES-tau-lacZ and P2-IRES-GFP linked at the same chromosomal locus. In these strains, we also observe a singularity of transgene expression. Neurons that express the P2-IRES-tau-lacZ transgene do not express the linked P2-IRES-GFP gene. Taken together, these experiments provide support for a model in which receptor choice is not deterministic, rather it is stochastic.

Once a single receptor gene is chosen for expression, this transcriptional choice must be stable for the life of the cell because receptor switching after stable synapse formation would seriously perturb odor discrimination. In recent experiments, Ben Shykind in my lab along with the research groups of Randall Reed and Hitoshi Sakano devised genetic strategies that permit the analysis of the stability of receptor choice.[38–40] We have employed a lineage tracer to map the fate of sensory neurons that express either an intact or a nonfunctional deletion of the MOR28 gene. Mature neurons that express an intact MOR28 receptor, but have not yet formed stable synapses in the brain, can switch receptor expression, albeit at low frequency. Thus, we observe that switching is an inherent property of wild-type receptor gene choice. Neurons that choose to express a mutant MOR28 receptor subsequently extinguish its expression and switch at
Figure 5. A feedback model assuring the stable expression of a functional receptor. A) The transcriptional machinery (blue sphere) expresses only one of 1000 odorant receptor genes (in this case, R2). R2 encodes a functional receptor that elicits a feedback signal that leads to the stabilization of receptor choice (purple sphere). B) If the transcriptional machinery chooses the nonfunctional receptor R1, which is not competent to mediate feedback stabilization, switching occurs. The transcriptional machine is then free to select a second receptor for expression that will ultimately mediate feedback stabilization. This model provides a mechanism to assure that a neuron expresses a functional odorant receptor.

high frequencies to express alternate receptors such that a given neuron stably transcribes only a single receptor gene. These observations suggest a mechanism of olfactory receptor gene choice in which a cell selects only one receptor allele but can switch at low frequency. Expression of a functional receptor would then elicit a signal that suppresses switching and stabilizes odorant receptor expression. Neurons that initially express a mutant receptor fail to receive this signal and switch genes until a functional receptor is chosen (Figure 5).

The mouse genome contains 340 olfactory receptor pseudogenes, whereas the human genome contains 550 pseudogenes, several of which continue to be transcribed.[12,16] Expression of a pseudogene would result in the generation of sensory neurons incapable of odor recognition. A mechanism that allows switching provides a solution to the pseudogene problem such that if pseudogenes are chosen, another transcriptional opportunity is provided, thus assuring that each neuron expresses a functional receptor. This model of serial monogamy assures that neurons will express a single receptor throughout their life. This feedback model in which expression of a functional odorant receptor suppresses switching to other olfactory receptor genes is reminiscent of one mechanism of allelic exclusion in T and B lymphocytes.

6. Cloning a Mouse from an Olfactory Sensory Neuron

What mechanism assures that a single receptor gene is chosen stochastically in a sensory neuron? One model invokes DNA recombination of odorant receptor genes at a single active expression site in the chromosome. DNA recombination provides *Saccharomyces cerevisiae*,[41] trypanosomes,[42] and lymphocytes[43] with a mechanism to stochastically express one member of a set of genes that mediate cellular interactions with the environment. One attractive feature shared by gene rearrangements in trypanosomes and lymphocytes is that gene choice is a random event, a feature of receptor gene selection in olfactory sensory neurons. However, efforts to demonstrate a recombination event involving receptor genes have been seriously hampered by the inability to obtain populations of neurons or clonal cell lines that express the same receptor. Kristin Baldwin in my laboratory, in a collaboration with Rudy Jaenisch, Kevin Eggan, and Andy Chess at MIT, addressed this problem by generating ES cell lines and cloned mice derived from the nuclei of olfactory sensory neurons expressing the P2 receptor (Figure 6).[44] The generation of cloned mice from cells of the nose derives from an initial insight of Woody Allen in his 1978 futuristic comedy, *Sleeper*. In this film, efforts are made to resurrect a totalitarian leader by cloning from his only surviving body part, his nose. Twenty-five years later, science successfully imitated art with the generation of mice cloned from a single sensory neuron from the nose.

We would predict that if DNA recombination accompanies receptor gene choice, then the olfactory epithelium from cloned mice derived from a sensory neuron expressing the P2 gene should be clonal with respect to receptor expression,
Figure 6. Cloning a mouse from olfactory sensory neurons expressing the P2 odorant receptor. A) A genetic strategy to label P2-expressing sensory neurons with GFP as well as to mark olfactory sensory neurons by virtue of a unique deletion in DNA. B) The olfactory epithelium of a mouse with the genetic modifications described in (A). A single nucleus expressing the P2 odorant receptor gene was picked and introduced into an enucleated oocyte. The epithelium was stained with antibody to Cre recombinase (red) to mark sensory neurons and GFP (green) to identify P2-expressing cells. C) A green neuron expressing P2-IRES-GFP was picked from dissociated olfactory epithelium of donor animals. D) The olfactory epithelium from a mouse cloned from a nucleus expressing the P2 receptor gene shows the normal distribution of P2-expressing cells. Axons from these neurons converge on a single glomerulus in the olfactory bulb (E). All nuclei are stained with TOTO-3 blue. The observation that mice cloned from a nucleus expressing the P2 receptor gene do not preferentially express this gene in the sensory epithelium suggests that DNA recombination events do not accompany receptor gene choice. Adapted with permission from Ref. [44].

such that all cells transcribe the rearranged P2 allele. Analysis of the sequence and organization of the DNA surrounding the P2 allele expressed in cloned mice revealed no evidence for either gene conversion or local transposition at the P2 locus. In addition, the pattern of receptor gene expression in the sensory epithelium of cloned mice was normal. Multiple odorant receptor genes are expressed without preference for the P2 allele transcribed in the donor nucleus (Figure 6). These data, along with similar experiments by Peter Mombaerts,[45] demonstrate that the mechanism responsible for the choice of a single odorant receptor gene does not involve irreversible changes in DNA. In a broader context, the generation of fertile cloned mice that are anatomically and behaviorally indistinguishable from wild-type indicates that the genome of a postmitotic, terminally differentiated olfactory neuron can re-enter the cell cycle and be reprogrammed

to a state of totipotency after nuclear transfer. The stochastic choice of a single olfactory receptor gene is therefore not accomplished by DNA recombination but rather by a rate-limiting transcriptional process, perhaps involving a single transcriptional machine capable of stably accommodating only one olfactory receptor gene.

7. Olfaction in the Fly: A Functional Map in the Antennal Lobe

The identification of an anatomic map in the olfactory bulb immediately poses the question as to whether this map provides a meaningful representation of odor quality that is translated into appropriate behavioral output. Recently, we have become interested in how the olfactory world is represented in the brain of the fruit fly. *Drosophila* provides an attractive system to understand the logic of olfactory perception. Fruit flies exhibit complex behaviors controlled by an olfactory system that is anatomically and genetically simpler than that of vertebrates. Genetic analysis of olfaction in *Drosophila* may therefore provide a facile system to understand the mechanistic link between behavior and the perception of odors. The recognition of odors in *Drosophila* is accomplished by sensory hairs distributed over the surface of the third antennal segment and the maxillary palp. Olfactory neurons within sensory hairs send projections to one of the multiple glomeruli within the antennal lobe of the brain.[46,47] Leslie Vosshall and Allan Wong showed that most sensory neurons express only one of about 80 odorant receptor genes. Neurons expressing the same receptor project with precision to one or rarely two spatially invariant glomeruli in the antennal lobe, the anatomic equivalent of the olfactory bulb of mammals (Figure 7).[48–50]
Figure 7. An olfactory sensory map in the fly antennal lobe. Neurons expressing the odorant receptor gene OR47b, also express the trans-gene synaptobrevin GFP, thus revealing convergence on a single spatially invariant glomerulus that is bilaterally symmetric in the antennal lobe.

The anatomic organization in *Drosophila* is therefore remarkably similar to that of the olfactory system of mammals, suggesting that the mechanism of odor discrimination has been shared despite the 600 million years of evolution separating insects from mammals. This conservation may reflect the maintenance of an efficient solution to

the complex problem of recognition and discrimination of a vast repertoire of odors in the environment. In both flies and mice, the convergence of like axons into discrete glomerular structures provides a map of receptor activation in the first relay station for olfactory information in the brain, such that the quality of an odorant may be reflected by spatial patterns of activity, first in the antennal lobe or olfactory bulb and ultimately in higher olfactory centers.

An understanding of the logic of odor perception requires functional analysis to identify odor-evoked patterns of activity in neural assemblies and ultimately the relevance of these patterns to odor discrimination. We have performed two-photon calcium imaging to examine the relationship between the anatomic map and the functional map in the antennal lobe.[51] Jing Wang and Allan Wong in my lab developed an isolated *Drosophila* brain preparation that is amenable to two-photon imaging and is responsive to odor stimulation for up to five hours. We expressed the calcium-sensitive fluorescent protein G-CaMP in primary olfactory sensory neurons and projection neurons. G-CaMP consists of a circularly permuted EGFP flanked at the N-terminus by the calcium-binding site of calmodulin and at the C-terminus by the M13 fragment of myosin light chain kinase.[52] In the presence of calcium, calmodulin interacts with the M13 fragment and elicits a conformation change in EGFP. The resulting elevations in fluorescent intensity reflect changes in the intracellular calcium concentration, a presumed mirror of electrical activity. Moreover, the ability to express G-CaMP in genetically defined populations of neurons allowed us to determine with certainty the locus of neural activity. Odor-evoked changes in fluorescence intensity within the antennal lobe are monitored by a laser-scanning two-photon microscope.[53]

This imaging technique has allowed us to measure the responsivity of 23 glomeruli to 16 different odors.[51] A number of interesting features of the glomerular response to odors are revealed by these experiments. First, different odors elicit different patterns of glomerular activation and these patterns are conserved among different animals (Figure 8). At odor concentrations likely to be encountered in nature, the map is sparse and glomeruli are narrowly tuned.

Second, the patterns of activity are insular, such that neighboring glomeruli do not necessarily respond together to a given odor. Each glomerulus visualized anatomically appears to be a functional unit. Third, the patterns of glomerular activity are qualitatively similar upon imaging either sensory or projection neurons. These observations suggest the faithful transmission of sensory input to higher brain centers. Fourth, we have coupled genetic experiments with imaging to demonstrate that the odor-evoked profile for a given glomerulus directly reflects the responsivity of an individual odorant receptor. This finding is consistent with previous molecular and anatomic studies that reveal that neurons that express only a single receptor in like axons converge on a single glomerulus. Thus these studies, along with other imaging approaches in insects,[54,55] demonstrate that the anatomic map is indeed functional and suggests that each odor elicits a sparse pattern of glomerular activation that may confer a signature for different odors in the brain.
Figure 8. Different odors elicit different patterns of glomerular activation that are conserved among different organisms. Two different flies (top and bottom panels) bearing the GH146-Gal4 and UAS-G-CaMP transgenes were exposed to three odors. Glomerular responses reveal different patterns of activity for the different odors that are conserved in different animals. The pre-stimulation images (left) shows the glomerlar structure and the images on the right show the specific glomeruli schematically.

Imaging experiments in vertebrates similarly reveal a functional representation of the anatomic map.[56–58]

8. Spatial Representations and Innate Behavior

All animals exhibit innate behaviors in response to specific sensory stimuli that are likely to result from the activation of developmentally programmed circuits. Allan Wong and Jing Wang in my lab, in collaboration with Greg Suh, David Anderson, and Seymour Benzer at Caltech, asked whether we can relate patterns of glomerular activity elicited by an odor to a specific behavior.[59] Some time ago Benzer observed that *Drosophila* exhibits robust avoidance to odors released by stressed flies. Gas chromatography and mass spectrometry identified one component of this "*Drosophila* stress odorant (DSO)" as CO_2. Exposure of flies to CO_2 alone also elicits an avoidance behavior at levels of CO_2 as low as 0.1% (Figure 9).

We therefore performed imaging experiments with the calcium-sensitive fluorescent indicator G-CaMP and two-photon microscopy to ask whether we could discern a pattern of glomerular activity in response to DSO and CO_2. We first examined flies in which the G-CaMP indicator is driven in all neurons by the pan-neural activator Elav-Gal4. DSO activates only two glomeruli, DM2 and the V glomerulus, whereas CO_2 activates only the V glomerulus. Activation of the V glomerulus was detected at CO_2 levels as low as 0.05% and this glomerulus was not activated by any of 26 other odorants tested (Figure 9).

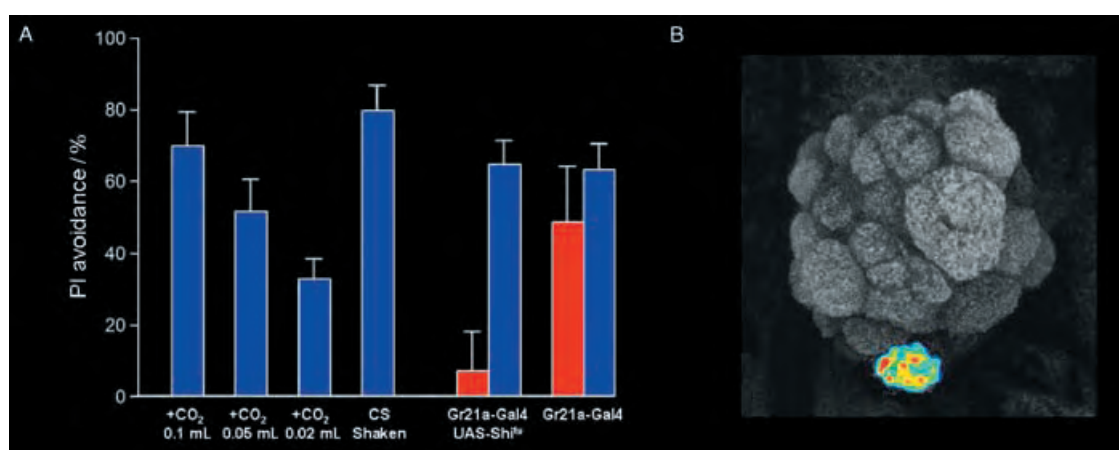
We demonstrated that axonal projections to the V glomerulus originate from sensory neurons expressing the receptor GR21A.[50] We therefore performed calcium imaging with flies in which the UAS G-CaMP reporter was driven by a GR21A promoter Gal4 activator. CO_2, as well as DSO, activated GR21A sensory termini in the V glomeruli. We next asked whether the GR21A sensory neurons are necessary for the avoidance response to CO_2. Inhibition of synaptic trans-


Figure 9. CO_2 activates a single glomerulus and elicits avoidance behavior. A) Avoidance of air from stressed flies (CS) as well as of increasing concentrations of CO_2. Inhibition of synaptic transmission in GR21A neurons that project to the V glomerulus using shi[ts] blocks CO_2 avoidance. Red and blue bars indicate avoidance behavior at the nonpermissive (28°C) and permissive (21°C) temperatures, respectively. B) Two-photon imaging in a strain harboring GR21A-Gal4 and UAS G-cAMP reveals robust activation of the V glomerulus.

mission in the GR21A sensory neurons that innervate the V glomerulus, using the temperature-sensitive *shibire* gene shi[ts],[60] blocks the avoidance response to CO_2 (Figure 9). Inhibition of synaptic release in the vast majority of other olfactory sensory neurons or in projection neurons other than those that innervate the V glomerulus had no effect on this behavior.

The identification of a population of olfactory sensory neurons innervating a single glomerulus that mediates robust avoidance to a naturally occurring odorant provides insight in the neural circuitry that underlies this innate behavior. These observations suggest that a dedicated circuit that involves a single population of olfactory sensory neurons mediates detection of CO_2 in *Drosophila*. The simplicity of this initial olfactory processing offers the possibility of tracing the circuits that translate odor detection into an avoidance response.

9. How is the Map Read?

Our experiments indicate that different odors elicit different patterns of glomerular activity within the antennal lobe and moreover that defined patterns of activity can be associated with specific behaviors. We can look at the pattern of activity in the fly antennal lobe with a two-photon microscope and discern, with a reasonable degree of accuracy, what odorant the fly has encountered in nature. Thus, we can determine with our eyes (and our brain) what odors the fly has encountered, but how does the fly brain read the sensory map?

A topographic map in which different odors elicit different patterns of activity in the antennal lobe suggests that these spatial patterns reflect a code defining odor quality. However, the mere existence of a map, whether anatomic or functional, does not prove that spatial information is the underlying parameter of an odor code. It has been suggested, for example, that the quality of an odor is reflected in temporal dynamics of a distributed ensemble of projection neurons.[61, 62] In this model, a given odor might activate a small number of glomeruli and a large ensemble of projection neurons such that different odors elicit different temporal patterns of activity in the same projection neuron. This temporal hypothesis in its simplest form postulates that the brain exploits circuit dynamics to create spatiotemporal patterns of neuronal activation to achieve a larger coding space. Whatever the code, patterns of activity in the antennal lobe must be translated by higher sensory centers to allow the discrimination of complex olfactory information. If odor quality is encoded by spatial patterns, we might expect that a representation of the glomerular map is retained in the protocerebrum.

We have begun to address the question of how the map in the antennal lobe is represented in higher olfactory centers by examining the pattern of projections of the neurons that connect the glomeruli to the protocerebrum. Allan Wong and Jing Wang randomly labeled individual projection neurons to visualize their processes that connect defined glomeruli with their targets in the mushroom body and protocerebrum. We

have used an enhancer trap line in which Gal4 is expressed in a subpopulation of projection neurons along with the "FLP-out" technique to label single projection neurons with a CD8 GFP reporter.[63] A similar experimental approach has been used to determine the lineage relationship of individual projection neurons and to examine their pattern of axonal projections.[64, 65] We observe that most projection neurons send dendrites to a single glomerulus. Projection neurons that receive input from a given glomerulus extend axons that form a spatially invariant pattern in the protocerebrum (Figure 10).
Figure 10. Projection neurons that innervate to the same glomerulus have similar axonal projection patterns. Individual projection neurons that connect to the VA1Lm glomeruli are visualized in the protocerebrum in different flies. These images reveal a striking constancy in the projection pattern among projection neurons that project to a given glomerulus. These observations reveal an invariant topographic map in the protocerebrum that differs in character from the map in the antennal lobe (prinetd with permission from Ref. [63]).

Projection neurons from different glomeruli exhibit patterns of axonal projections that are distinct, but often interdigitated (Figure 11). Our data reveal a striking invariance in the spatial patterns of axon arbors of projection neurons that
Figure 11. Axonal projections from single projection neurons can be visualized as they branch in the mushroom body and ultimately arborize in the protocerebrum. Projections neurons that connect to different glomeruli exhibit different patterns of axonal projections. The axon arbors in the protocerebrum are dispersed unlike the insular segregated arbors in the glomerulus, affording the possibility for integration in higher olfactory centers (printed with permission from Ref. [63]).

innervate a given glomerulus, a precision of connectivity that assures the specificity of information transfer.

The precision of projections of projection neurons reveals a spatial representation of glomerular activity in higher brain centers, but the character of the map differs from that observed in the antennal lobe. Axon arbors in the protocerebrum are diffuse and extensive, often extending over the entire dimension of the brain hemisphere (Figures 10, 11). This is in sharp contrast to the tight convergence of primary sensory axons, whose arbors are restricted to a small 5–10 μm spherical glomerulus. As a consequence, the projections from different glomeruli, although spatially distinct, often interdigitate. Thus, the point-to-point segregation observed in the antennal lobe is degraded in the second order projections to the protocerebrum. This affords an opportunity for the convergence of inputs from multiple different glomeruli essential for higher order processing. Third-order neurons in the protocerebrum might synapse on projection neurons from multiple distinct glomeruli, a necessary step in decoding spatial patterns to allow the discrimination of odor and behavioral responses.

10. Concluding Remarks

These data suggest a model in which the convergence of information from deconstructed patterns in the antennal lobe are reconstructed by "cardinal cell assemblies" that sit higher up in a hierarchical perceptual system in the protocerebrum. Olfactory processing will initially require that the structural elements of an odor activate a unique set of receptors that in turn result in the activation of a unique set of glomeruli. The odorous stimuli must then be reconstructed in higher sensory centers that determine which of the numerous glomeruli have been activated. The identification of a spatially invariant sensory map in the protocerebrum that is dispersive affords an opportunity for integration of multiple glomerular inputs by higher odor neurons.

The elucidation of an olfactory map in both the olfactory bulb or antennal lobe and in higher olfactory centers leaves us with a different order of problems. Though we may look at these odor-evoked images with our brains and recognize a spatial pattern as unique and can readily associate the pattern with a particular stimulus, the brain does not have eyes. How does the brain perceive the olfactory image? How is the map read? How are spatially defined bits of electrical information in the brain decoded to allow the perception of an olfactory image? We are left with an old problem, the problem of the ghost in the machine.

Finally, how do we explain the individuality of olfactory perception? The innately configured representation of the sensory world, the olfactory sensory maps that I have described, must be plastic. Our genes create only a substrate upon which experience can shape how we perceive the external world. Surely the smell of a madeleine does not elicit in all of us that "vast structure of recollection" it evoked for Marcel Proust. For Proust, smell is the evocative sense, the sense that brings forth memory and associations with a richness not elicited by other sensory stimuli. Nowhere is this more apparent than in the eloquent words recalling the madeleine incident from "*Remembrance of Things Past*".[66]

"*… But when from a long distant past nothing subsists, after the people are dead, after the things are broken and scattered, still alone, more fragile but with more vitality, more unsubstantial, more persistent, more faithful, the smell and taste of things remain, poised a long time, like souls ready to remind us, waiting and hoping for their moment, amid the ruins of all the rest; and bear unfaltering in the tiny and impalpable drop of their essence, the vast structure of recollection.*"

Biography

SEATTLE

I was born in 1947 in Seattle, Washington, a city surrounded by mountains, forests, and the sea. My mother was the daughter of Swedish immigrants who had come to the US in the late nineteenth century while my father's family had Irish roots on one side and ancestors extending back to the American Revolution on the other. I was the second of three children, all girls. My mother was a homemaker who was exceptionally kind and witty and loved word puzzles. My father was an electrical engineer who, at home, spent much of his time inventing things and building them in our basement. It may be that my parents' interest in puzzles and inventions planted the seeds for my future affinity for science, but I never imagined as a child that I would someday be a scientist.

During my childhood, I did the things that girls often do, such as playing with dolls. I was also curious and easily bored though, so I frequently embarked on what were to me new adventures. Aside from school and music lessons, my life was relatively unstructured and I was given considerable independence. I learned to appreciate music and beauty from my mother and my father taught me how to use power tools and build things. I spent a lot of time with my maternal grandmother, who told me magical stories about her childhood in Sweden and, to my delight, taught me how to sew clothes for my dolls. I was fortunate to have wonderfully supportive parents who told me that I had the ability to do anything I wanted with my life. They taught me to think independently and to be critical of my own ideas, and they urged me to do something worthwhile with my life, in my mother's words, to "not settle for something mediocre". I realize now that I internalized those lessons and that they have influenced my work as a scientist.

I received my undergraduate education at the University of Washington, which was only a few miles from our home. I had always wanted to have a career in which I would help others, so I initially decided to major in psychology, thinking that I would become a psychotherapist. Over time, my interests expanded and I entertained a variety of different career possibilities. However, none seemed ideal and I was reluctant to embark on something that might prove to be inappropriate. Over the next several years, I intermittently traveled, lived on a nearby island, and took more classes in Seattle. I finally found my direction when I took a course in immunology, which I found fascinating. I would be a biologist.

DALLAS

In 1975, I began graduate school in the Microbiology Department at the UT Southwestern Medical Center in Dallas. The department had recently undergone an expansion in the area of immunology, making it a major center in this still young area and a stimulating place to learn. I had done a small amount of research at the University of Washington, first in psychology with Walter Makous and then in immunology with Ursula Storb, but it was in Texas that I truly learned to be a scientist. I had a wonderful thesis advisor, Ellen Vitetta, who demanded excellence and precision in research, habits that I believe are important to learn as a student. For my thesis, I compared the functional properties of subsets of B lymphocytes that differed in the class of cell-surface immunoglobulin that they used as antigen receptors. In this work and much of my subsequent work, I thought in terms of molecules and the molecular mechanisms underlying biological systems, and sought to gain insight into those mechanisms in my experiments.

NEW YORK

In 1980, I moved to Columbia University in New York City to do postdoctoral work in immunology with Benvenuto Pernis. As a graduate student, I had become fascinated with the unexplained requirement for major histocompatibility complex (MHC) proteins in immune responses, a mystery that was later solved. I decided to explore this puzzle, focusing on class II MHC proteins found on the surface of B lymphocytes. I found that, contrary to expectation, the MHC proteins rapidly accumulated inside these cells when they were activated. My further experiments indicated that they were being internalized from the cell surface and were probably being recycled to it. It was known that antigens are endocytosed with antigen receptors and then degraded. One possibility raised by the internalization and apparent recycling of MHC molecules was that, following internalization, they might be targeted to a specialized microenvironment where they could interact with degraded antigen. The MHC–antigen complexes might then be exported to the cell surface for co-recognition by T-helper cells.

By this time, it had become clear to me that to study molecular mechanisms underlying biological systems, which is what interested me, I needed to learn the recently developed techniques of molecular biology. To this end, I moved to the laboratory of Richard Axel, at Columbia University. Richard had begun to work in the area of neuroscience several years earlier through collaboration with Eric Kandel, who was also at Columbia. Their collaboration had focused on molecular studies on the nervous system of Aplysia, a sea snail. This was the model organism that Eric had used in many of his studies of learning and memory, for which he received a Nobel Prize in 2000. Perhaps not surprisingly, I was interested in searching for genes encoding neuronal cell surface receptors. However, at that time, Richard wanted to continue studying Aplysia, so I agreed to a project in which I would try to develop a

technique for cloning genes expressed in one Aplysia neuron, but not another. After spending a short time learning molecular techniques from Jim Roberts, a student in the lab, I started my Aplysia project. Eric Kandel's group showed me how to isolate giant Aplysia neurons that had been assigned names and could be identified by their locations and, within a relatively short time, I began to uncover genes that were differentially expressed among Aplysia neurons.

While studying a neuropeptide gene expressed in neuron number R15, I discovered that the gene was also expressed in some other neurons, but that its primary transcript was alternatively spliced in different neurons to give different polyproteins. The two polyproteins could generate two different combinations of peptides in different neurons, thus suggesting a way to produce physiological or behavioral programs with partially overlapping components. While working on the neuropeptide gene, I encountered numerous technical challenges that increased my knowledge of molecular biology and honed my abilities. During this period, I learned a lot of molecular biology from Richard and other members of his lab. I also got to know Eric Kandel, who has continued to be a wonderful source of inspiration and encouragement for me over the years.

From my first introduction to neuroscience, I had been fascinated by the brain's cellular and connectional diversity. In parallel with my Aplysia experiments, I sporadically tried to find a way to scan the genome for genes that had undergone gene rearrangement or gene conversion in neurons, thinking that genes that showed this characteristic might be involved in the generation of neuronal diversity. One method that I devised showed promise in Drosophila, but was not sensitive enough for the much larger genome of a mammal, which is what interested me. Nonetheless, these efforts were a great source of creative enjoyment for me as I proceeded with the more mundane task of searching for minute alternative exons in the Aplysia genome.

I was grateful that Richard was tolerant of my high-risk endeavors. He was an unusual mentor in that he gave people in his lab extensive independence in charting their own course once they had established themselves. During this time, I had many colleagues at Columbia with whom I enjoyed long discussions about science. Among these were George Gaitanaris, who has remained a close friend over the years, as well as Tom Jessell and Jane Dodd, neuroscientists from whom I learned a great deal about neural development.

As I was nearing the end of my Aplysia project, I read a paper that changed my life. It was a 1985 publication from Sol Snyder's group that discussed potential mechanisms underlying odor detection. This was the first time I had ever thought about olfaction and I was fascinated. How could humans and other mammals detect 10 000 or more odorous chemicals, and how could nearly identical chemicals generate different odor perceptions? In my mind, this was a monumental puzzle and an unparalleled diversity problem. It was obvious to me that the first step to solving the puzzle was to determine how odorants are initially detected in the nose. This meant finding odorant receptors, a class of molecules that had been proposed to exist, but had not been found. I decided that

this is what I had to do as soon as my neuropeptide work was completed.

In 1988, I embarked on a search for odorant receptors, staying on in Richard's lab for this purpose. In a recent commentary in the journal *Cell*, I described what was known about odor detection at that time and the approaches that I tried in the quest to find the elusive odorant receptors. In short, it was known that odorants depolarize, and thereby activate, olfactory sensory neurons in the nose. Although there were varied proposals as to what kind of molecules might interact with odorants, there was compelling evidence that olfactory transduction involved G-protein-induced increases in cAMP. After trying several different approaches, I identified the odorant receptor family by designing experiments based on three assumptions: First, since odorants vary in structure and can be discriminated, there would be a family of varied, but related odorant receptors, which would be encoded by a multigene family. Second, odorant receptors would be at least distantly related to the relatively small set of G-protein-coupled receptors whose sequences were known at that time. Finally, odorant receptors would be selectively expressed in the olfactory epithelium, where olfactory sensory neurons are located. It took some time to devise and develop the methods I used in my search, but in the end they succeeded. Looking at the first sequences of odorant receptors obtained from rats, I was moved by nature's marvelous invention. This work showed that the rat has a multigene family that codes for in excess of one hundred different odorant receptors, all related, but each one unique. The unprecedented size and diversity of this family explained the ability of mammals to detect a vast array of diverse chemicals as having distinct odors. In 1991, Richard Axel and I published the identification of odorant receptors.

BOSTON

In 1991, I departed for Boston to be an assistant professor in the Neurobiology Department at Harvard Medical School. There, I was immersed in an environment in which I could broaden my understanding of the nervous system. I received excellent support from my chairman, Gerry Fischbach, as I set up my lab. I also acquired many excellent colleagues, including David Hubel, whose pioneering studies of the visual system with Torsten Wiesel (for which they received a Nobel Prize in 1981) had always been an inspiration to me. In 1994, I became an Investigator of the Howard Hughes Medical Institute, which has generously supported our work for the past 11 years. Over the next decade, I remained at Harvard, gradually rising through the ranks to become associate and then full professor. In 1994, I met Roger Brent, a marvelous intellect and fellow scientist who has been my partner and an important part of my life ever since.

The discovery of odorant receptors had explained how the olfactory system detects odorants. My next goal was to learn how signals from those receptors are organized in the brain to generate diverse odor perceptions. I was joined in this endeavor by a series of excellent students and postdoctoral

(Photo: Roland Morgan)

fellows. The discoveries on the organization of the olfactory system that were cited by the Nobel Foundation were made over a period of ten years, during which I was a faculty member at Harvard.

The first question we asked was how odorant receptors are organized in the olfactory epithelium of the nose. This work was begun by Kerry Ressler, an MD/PhD student who came to the laboratory for a few months just as the equipment and supplies I had ordered began to arrive in January 1992. I had decided to switch from the rat to the mouse as a model organism because of the advantage of using isogenic inbred strains for dissecting a multigene family, and the possibility of generating transgenic mice. After cloning and sequencing a series of mouse odorant receptor genes, Kerry did our first in situ hybridization experiments to examine patterns of receptor gene expression. By June, Kerry had returned as a full-time student and Susan Sullivan had joined the lab as a postdoctoral fellow. At this point, we began to precisely analyze gene-expression patterns and to compare them in different individuals. Prior to the present era of digital photographs that can be stored and analyzed on a computer, this was painstaking work that involved displaying photographic slides on a desktop viewer and recording, on transparencies, the locations of individual labeled cells in different animals. Our studies showed that each receptor gene is expressed in about 1/1000 olfactory sensory neurons, that the olfactory epithelium has several spatial zones that express non-overlapping sets of odorant receptor genes, and that neurons with the same odorant receptor are randomly scattered throughout one zone. This indicated that signals derived from different odorant receptors are segregated in different sensory neurons and in the information they transmit to the brain. It further indicated that, in the olfactory epithelium, neurons that detect the same odorant are dispersed and those that detect different odorants are interspersed. Thus, there is a broad organization of sensory information into several zonal sets in the epithelium, but, overall, information is encoded in a highly distributed manner. We published these findings in 1993. Similar

observations in rats by Richard Axel and his colleagues were also reported that year.

Having determined how inputs from different odorant receptors are organized in the nose, we asked how they are arranged at the next structure in the olfactory pathway, the olfactory bulb. In the bulb, the axons of olfactory sensory neurons synapse in about 2000 spherical structures, called glomeruli. Kerry began to use retroviral vectors to investigate how the axons of neurons expressing specific receptors are organized in the bulb, but then we inadvertently found another way to address the question. While using in situ hybridization to identify a number of receptor genes expressed in each epithelial zone for chromosomal mapping studies, Susan found that, in one tissue section, a receptor probe labeled a single spot in the bulb, which proved to be a glomerulus. Using probes that recognized single receptor genes rather than subfamilies of related receptor genes, we found that each probe labeled odorant receptor mRNAs in sensory axons that were confined to one or a few glomeruli at only two sites, one on either side of the bulb. Different probes labeled different glomeruli and those glomeruli had virtually identical locations in different individuals. I still remember a meeting with Kerry and Susan in my office in which I asked Kerry how many sections separated different labeled glomeruli in different bulbs. All of us were stunned by his answer, because it provided the first hint that the bulb might have a stereotyped map of receptor inputs and we could not imagine how this could be generated given the organization of receptor gene expression in the epithelium. This mystery still has not been solved. These studies indicated that while thousands of neurons expressing the same receptor are highly dispersed in the epithelium, their axons all converge in a few specific olfactory bulb glomeruli. The result is a stereotyped map of receptor inputs in which signals derived from different receptors are segregated in different glomeruli and in the bulb projection neurons whose dendrites innervate those glomeruli. Remarkably, Bob Vassar in Richard Axel's lab had concurrently found that different receptor probes labeled different glomeruli in the rat bulb. Our two groups published these findings in 1994.

Several years later, we began to investigate how the receptor family and the patterning of receptor inputs encode the identities of different odorants. By using single-cell RT-PCR (reverse transcriptase–polymerase chain reaction), Bettina Malnic, a fellow in the lab, had been comparing gene expression in single olfactory sensory neurons. Her work demonstrated that each neuron expresses only a single receptor gene, something that we had previously suspected, but that needed to be verified. Bettina was initially focused on the identification of genes that might be involved in receptor gene choice or axon targeting in the bulb, but we decided to change course when Takaaki Sato visited our lab and told us about his calcium imaging studies of odor responses in the olfactory epithelium. This was the beginning of a highly successful collaboration in which Takaaki used calcium imaging to define the odor response profiles of individual neurons and Bettina then used RT-PCR to identify the receptor expressed by each responsive neuron. These studies

demonstrated that the receptor family is used in a combinatorial manner. Different neurons are recognized, and thereby encoded, by different combinations of receptors, but each receptor is used as one component of the combinatorial receptor codes for many different odorants. These studies also provided explanations for several intriguing features of human odor perception, including how a slight change in the structure of an odorant can dramatically change its perceived odor quality.

As soon as we had determined how receptor inputs are organized in the olfactory bulb, we began to explore how they are arranged at the next structure in the olfactory pathway, the olfactory cortex. Lisa Horowitz, an MD/PhD student in the lab, initially investigated connections between the bulb and cortex using classical anatomical techniques. By depositing different tracers in the dorsal and ventral bulb, she determined that these areas project axons to the same regions of the cortex. In agreement with previous findings, this indicated that there could not be a point-to-point patterning of connections between the bulb and cortex. We decided to abandon traditional approaches and to instead ask whether we could chart neural pathways genetically by expressing a gene encoding a transneuronal tracer in olfactory sensory neurons. Lisa found that this was indeed possible. When she made transgenic mice that expressed barley lectin in all olfactory sensory neurons, the lectin crossed two synapses, labeling second-order neurons in the bulb, and then third-order neurons in the cortex. This work, which we published in 1999, opened the way to investigating a wide array of questions concerning neural circuits, including those that carry olfactory information.

We then went on to use the genetic tracer to examine how inputs from individual types of receptors are organized in the olfactory cortex. To do this we used gene targeting to generate mice that coexpressed barley lectin with a single receptor gene. Lisa, together with a fellow in the lab, Jean-Pierre Montmayeur, prepared the DNA constructs for gene targeting. Zhihua Zou, another fellow, then generated and analyzed mice that coexpressed the tracer with different receptor genes. The approach worked, but was difficult, with Zhihua investing almost a year in perfecting the conditions needed to detect minute amounts of the tracer in cortical neurons. These studies revealed that the olfactory cortex has a stereotyped map of receptor inputs, but one that is radically different from that in the bulb. The segregation of receptor inputs in different glomeruli and neurons in the bulb gives way in the cortex to a complex array of receptor inputs in which signals from different receptors partially overlap and single cortical neurons appear to receive signals from combinations of different receptors. This offers a means by which the individual components of an odorant's receptor code could be integrated at the level of single neurons. This could serve as an initial step in the reconstruction of an odor image from its deconstructed features, which are conveyed by the receptor elements of the receptor code. We published our findings on the cortex in 2001.

During the ten-year period at Harvard in which we did the work described above, my laboratory also investigated a

number of other questions. These included studies of the chromosomal organization of receptor genes and the evolution of the receptor gene family by Susan Sullivan, studies of the development of receptor gene expression patterns by Susan and Staffan Bohm, and bioinformatic studies by Bettina Malnic and Paul Godfrey that defined and compared the receptor gene repertoires of humans and mice. We also conducted a series of studies on the detection of pheromones in the vomeronasal organ, including studies by Emily Liman and Anna Berghard that revealed differences between transduction molecules involved in odor versus pheromone detection, the discovery of zonal patterns of transduction molecules likely to be involved in pheromone detection by Anna, analyses of vomeronasal responses to pheromones and odorants by Mehran Sam, and the discovery, by Hiroaki Matsunami, of a family of candidate pheromone receptors. During the latter part of this period, Hiroaki Matsunami, Jean-Pierre Montmayeur, and Stephen Liberles also began to explore the mechanisms underlying taste detection, in the process discovering candidate receptors for both bitter and sweet tastes, both of which were also found by other groups at about the same time.

SEATTLE

In 2002, I returned to Seattle to be a Member of the Division of Basic Sciences at the Fred Hutchinson Cancer Research Center and Affiliate Professor of Physiology and Biophysics at the University of Washington. I had always intended to someday return to the West Coast and had already stayed longer in Boston than I had anticipated. When Mark Groudine, then Director of the Basic Sciences Division at Fred Hutchinson, offered me a faculty position there, I gladly accepted. The Hutchinson Center had a reputation for cutting-edge science as well as a high level of collegiality, both of which were important to me. In addition, by moving to Seattle, I would be closer to my partner, Roger, who lived in Berkeley, and to my family and friends in Seattle.

In Seattle, we are continuing to explore the mechanisms underlying odor perception as well as the means by which pheromones elicit instinctive behaviors. We have also become interested in the neural circuits that underlie innate behaviors and basic drives, such as fear, appetite, and reproduction. We are currently developing molecular techniques to uncover those circuits and to define their composite neurons and the genes they express. In a different vein, we have developed a high-throughput approach in which we are using chemical libraries to identify genes that control aging and lifespan, our chief interest being whether there might be a central mechanism that determines lifespan and regulates the aging of cells throughout the body.

LOOKING BACK

Since Richard Axel and I published the discovery of odorant receptors in 1991, it has been immensely satisfying for me to see many laboratories using these receptors in a large-scale effort to dissect the mechanisms that underlie the sense of smell and the developmental processes that shape the organization of the olfactory system. Molecular approaches to studying olfaction have extended to other vertebrates as well as to invertebrate species, with Cori Bargmann's group discovering a large variety of chemosensory receptors in the nematode worm *C. elegans*, and several groups, including Richard Axel's, identifying families of odorant and taste receptors in the fruit fly *D. melanogaster*.

Looking back over my life, I am struck by the good fortune I have had to be a scientist. Very few in this world have the opportunity to do everyday what they love to do, as I have. I have had wonderful mentors, colleagues, and students with whom to explore what fascinates me, and have enjoyed both challenges and discoveries. I am grateful for all of these things and look forward to learning what nature will next reveal to us.

As a woman in science, I sincerely hope that my receiving a Nobel Prize will send a message to young women everywhere that the doors are open to them and that they should follow their dreams.

1. Introduction

The subject of my lecture is the sense of smell, one of the five senses through which we perceive the world. Through the sense of smell, humans and other mammals can perceive a vast number and variety of chemicals in the external world. It is estimated that humans can sense as many as 10000 to 100000 chemicals as having a distinct odor. All of these "odorants" are small, volatile molecules. However, they have diverse structures and somehow those different structures are perceived as having different odors (Figure 1).

The sense of smell is mediated by the olfactory system, a system that is characterized by exquisite sensitivity and discriminatory power. Even a slight change in the structure of an odorant can change its perceived odor. For example, the close relative of a chemical that is perceived as pear can have the scent of an apple. In addition to odorants, the olfactory system detects pheromones, chemicals that are released from animals and act on members of the same species, stimulating hormonal changes or instinctive behaviors, such as mating or aggression. The olfactory system also detects predator odors, which can elicit innate fear responses.

Over the past 16 years, our work has focused on two questions: First, how do mammals detect so many different environmental chemicals? And second, how does the brain translate those chemicals into diverse odor perceptions and behaviors?
Figure 1. Humans and other mammals perceive a vast number of chemicals as having distinct odors.

Odorants are initially detected by olfactory sensory neurons, which are located in the olfactory epithelium lining the nasal cavity (Figure 2). These neurons transmit signals to
Figure 2. The olfactory pathway. Odorants are detected by olfactory sensory neurons in the olfactory epithelium. Signals generated in those neurons are relayed through the olfactory bulb to the olfactory cortex and then sent to other brain areas.

the olfactory bulb of the brain, which then relays those signals to the olfactory cortex. From there, olfactory information is sent to a number of other brain areas. These include higher cortical areas thought to be involved in odor discrimination as well as deep limbic areas of the brain, which are thought to mediate the emotional and physiological effects of odors. In contrast to odorants, pheromones are detected primarily in the vomeronasal organ (VNO), a separate olfactory structure in the nasal septum. From VNO neurons, signals are relayed through the accessory bulb to the medial amygdala and then the hypothalamus, areas implicated in hormonal and behavioral responses to pheromones.

The olfactory epithelium contains millions of olfactory sensory neurons. It also contains supporting cells and a basal layer of stem cells. Olfactory sensory neurons are short-lived cells that are continuously replaced from the stem-cell layer. At the surface of the epithelium, each neuron extends cilia into the nasal lumen, allowing it to come in contact with

odorants dissolved in the nasal mucus. Each neuron communicates with the brain through a single axon that it extends to the olfactory bulb.

2. Odorant Receptors

In our initial experiments, Richard Axel and I asked how it is that these neurons detect odorants. Beginning in 1965 with the work of Robert Gesteland,[1] numerous electrophysiological studies had shown that different olfactory sensory neurons are depolarized, or activated, by different odorants. John Amoore proposed that these neurons had odorant receptor proteins that varied in their affinity for different odorants.[2,3] In the mid 1980s, hints started to emerge about signal transduction in the cilia of the olfactory neurons. Doron Lancet, Sol Snyder, and their colleagues showed that odorants induce GTP-dependent increases in adenylyl cyclase activity in the cilia, thus suggesting the involvement of intracellular G proteins,[4,5] and Randy Reed identified $G_\alpha$olf, a G protein that could mediate this response and was highly expressed in olfactory sensory neurons.[6]

In 1988, Richard Axel and I embarked on a search for odorant receptors. The strategy we devised was based on three assumptions. First, odorant receptors would be selectively expressed in the olfactory epithelium. Second, since odorants vary in structure, there would be a family of varied, but related receptors, and those receptors would be encoded by a multigene family. Third, odorant receptors would be related to other types of receptors that interact with intracellular G proteins. By 1989, molecular cloning had revealed the structures of about 20 of these G-protein-coupled receptors (GPCRs). All of these receptors had seven potential transmembrane domains and they shared a few amino acid sequence motifs.

On the basis of these assumptions we set out to search for a family of GPCRs expressed in the rat olfactory epithelium.[7] To do this, we first used the polymerase chain reaction (PCR) to look for receptors expressed in the olfactory epithelium that were related to known GPCRs. We designed 11 degenerate oligonucleotide primers that matched amino acid sequences in transmembrane domains 2 and 7 of known GPCRs. We then used these primers in all 30 pairwise combinations to amplify related sequences in cDNA prepared from rat olfactory epithelium RNA. From the 30 PCR reactions, we obtained 64 different PCR products in the appropriate size range. Each of these appeared as a distinct band by agarose gel electrophoresis.

We then asked whether any of the 64 PCR products contained multiple members of a multigene family. To do this we cut the DNA in each PCR product with a restriction enzyme. Most of the bands were cut into a small number of fragments that added up to the original in size. However, one band, no. 13, was cut into a large number of fragments, thus suggesting that it might contain multiple members of a multigene family. When we cloned and sequenced five of the DNAs in this band, we found what we had been looking for: all five encoded novel proteins with the hallmarks of GPCRs. Moreover, all five were related, but each one was unique.

By using these DNAs as probes, we isolated a series of related cDNAs from an olfactory epithelium cDNA library. We initially examined the proteins encoded by ten of the cDNAs. All ten proteins had the seven potential transmembrane domains characteristic of GPCRs. In addition, they had several amino acid sequence motifs seen in other GPCRs. However, the ten receptors all shared sequence motifs not seen in any other GPCRs, thus indicating that they were members of a novel receptor family.

Figure 3 shows a model of one of these receptors in the membrane with individual amino acids represented as balls. Red balls indicate amino acids that were especially variable
Figure 3. Topology of an odorant receptor in the membrane. Individual amino acid residues are indicated by balls. Red balls indicate residues that were hypervariable among ten odorant receptors. Adapted from Ref. [7].

(ORs) expressed by olfactory sensory neurons in the nose.[7] Subsequent studies showed that homologous families of odorant receptors are present in vertebrate species ranging from fish to humans.[8] In 1991, after publishing our work on odorant receptors,[7] I left Richard Axel's lab to join the faculty of Harvard Medical School.

A decade later, the sequencing of human and mouse genomes made it possible to determine the number of OR genes in these species. This was done by Lancet and Zozulya for human[9, 10] and by Firestein and Trask for mouse,[11, 12] and in my lab it was done for both species by Bettina Malnic and Paul Godfrey.[13, 14] These studies indicate that humans have about 350 different ORs and mice have about 1000. This result indicates that roughly 1–5 % of the genes in the genome are devoted to the detection of odorants. Odorant receptor genes are highly distributed across the genome. In our studies of the human genome, we found OR genes on 21 different chromosomes and at 51 different chromosomal loci, where they are found singly or in clusters (Figure 4).[14]

In the mid 1990s, two additional families of receptors were found in the olfactory system. These receptors, called V1Rs and V2Rs, are unrelated to ORs in protein sequence, but both types have the characteristic seven-transmembrane domain structure of GPCRs. V1R and V2R genes are selectively expressed in the VNO, thus suggesting that they might be pheromone receptors. Both receptor families have more than 100 members. The V1R family was identified in 1995 by Dulac and Axel,[15a] and the V2R family was identified in 1997 by Hiroaki Matsunami in my lab and also by the laboratories of Catherine Dulac and Nicholas Ryba.[15b, 16, 17]

among the ten receptors. Importantly, though related, the ten olfactory receptors varied extensively in amino acid sequence. This hypervariability was consistent with an ability of the receptors to interact with odorants of different structures.

Consistent with the selective expression of these receptors in the olfactory epithelium, a mixed olfactory receptor DNA probe hybridized to RNA from the olfactory epithelium, but not other tissues. Moreover, enriching for olfactory sensory neurons also enriched for receptor RNAs, thus suggesting that the receptors were expressed predominantly or exclusively by olfactory sensory neurons.

On Southern blots of genomic DNA, single receptor probes hybridized to multiple bands, and a mixed receptor probe hybridized to a large number of bands. This further indicated that the receptors we had found were encoded by a large multigene family. Genomic library screens indicated that the multigene family contained in excess of 100 members. In later studies, we obtained evidence for about 1000 different olfactory receptor genes in mice.

On the basis of these results, we concluded that the receptor family we had identified coded for odorant receptors

Figure 4. The chromosomal distribution of human odorant receptor genes. Intact receptor genes are shown in red and pseudogenes in green. Adapted from Ref. [14].

3. Organization of Odorant Receptors in the Olfactory Epithelium

The discovery of odorant receptors explained how the olfactory system detects a vast array of chemicals in the external world. It also did something else that was important: it provided a set of molecular tools to explore how the nervous system translates chemical structures into odor

perceptions. This is what we set out to do in my lab at Harvard.

In the mouse, we found evidence for as many as 1000 different OR genes. We first asked how information from different ORs is organized in the olfactory epithelium.[18] In these experiments, Kerry Ressler, a graduate student in the lab, and Susan Sullivan, a postdoctoral fellow, hybridized labeled OR gene probes to sections through the mouse nose (Figure 5). These studies showed that the olfactory epithelium
Figure 5. Expression patterns of odorant receptor genes in the mouse olfactory epithelium. Tissue sections through the mouse nose were hybridized to four different receptor gene probes. Adapted from Refs. [18, 30].

has distinct spatial zones that express non-overlapping sets of OR genes (Figure 6). Each OR gene is expressed in about 1/1000 neurons and those neurons are randomly scattered within one zone. Similar findings were made in Richard Axel's lab in rats.[19] The OR expression zones form stripes that extend along the anterior–posterior axis of the nasal cavity.

These findings told us two important things. First, input from one type of OR is highly distributed in the epithelium. Therefore, neurons with receptors for one odorant (for example, a strawberry odorant) must be interspersed with neurons that have receptors for another odorant (such as a
Figure 6. The organization of odorant receptor inputs in the olfactory epithelium and olfactory bulb. Sensory neurons expressing the same receptor are scattered within one epithelial zone, but their axons converge in specific glomeruli in the olfactory bulb. Adapted from Refs. [18, 22, 30].

lemon one). Second, each neuron may express only one OR gene. We later confirmed this by examining gene expression in single neurons.[20] Thus, in the nose, inputs from different ORs are segregated in different neurons, and the information that each neuron transmits to the brain is derived from a single receptor type.

4. Combinatorial Receptor Codes for Odors

In later studies, we asked how the OR family encodes the identities of different odorants. To explore this question, we searched for ORs that recognize specific odorants.[20] This work was done by Bettina Malnic in my lab in collaboration with Takaaki Sato and Junzo Hirono at the Life Electronics Research Center in Japan. We first exposed single mouse olfactory sensory neurons to a series of odorants, using calcium imaging to visualize their responses. We then isolated each responsive neuron and used reverse transcriptase–PCR (RT-PCR) to determine the OR gene it expressed. In every case, we identified only one expressed OR per neuron, thus confirming that each neuron expresses a single OR gene.

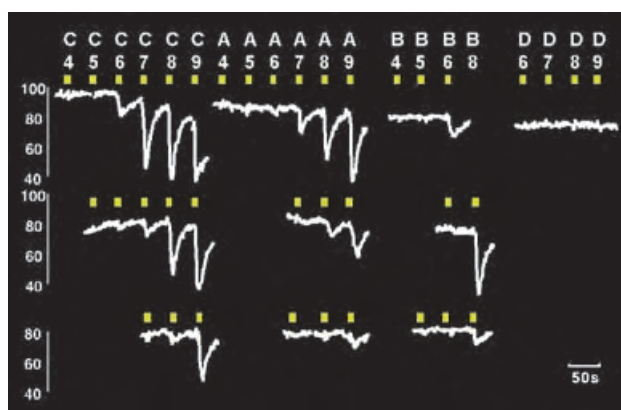
For test odorants, we used four different classes of linear aliphatic odorants with different functional groups and carbon chains ranging in length from four to nine carbon atoms. Each neuron was imaged as it was exposed sequentially to different odorants (Figure 7). If a response was seen, the neuron was retested with a lower concentration of the same odorant.


Figure 7. Responses of a single olfactory sensory neuron to different odorants. Fluorescence emission was monitored during sequential exposure of a neuron containing an indicator dye (Fura-2) to a series of odorants (C4–D9). Responses to lower odorant concentrations are shown below. Adapted from Ref. [20].

Figure 8 shows the response profiles of 14 neurons and therefore the recognition properties of the ORs expressed in those neurons. These data make three important points. First, each OR can recognize multiple odorants, something previously shown by Stuart Firestein for one rat OR.[21] Second, each odorant can be detected by multiple different ORs. Finally, and most importantly, different odorants are recognized by different combinations of ORs.
Figure 8. Odorant receptors are used combinatorially to detect odorants and encode their identities. The recognition profiles of individual odorant receptors to a series of odorants were determined by calcium imaging and single-cell RT-PCR. The sizes of circles reflect response intensity. Adapted from Ref. [20].

These results indicated that ORs are used combinatorially to encode odor identities.[20] Different odorants are detected and thereby encoded by different combinations of ORs. However, each OR serves as one component of the codes for many odorants. Different odorants have different "receptor codes". Given the number of possible combinations of 1000

Figure 9. Closely related odorants with different perceived odors are detected by different combinations of receptors. Adapted from Ref. [20].

different ORs, this combinatorial coding scheme could allow for the discrimination of an almost unlimited number of odorants. Even if each odorant were detected by only three ORs, this scheme could potentially generate almost one billion different odor codes.

These studies also provided insight into several puzzling features of human odor perception.[20] Changing the structure of an odorant even slightly can alter its perceived odor. Sometimes the change in odor can be dramatic. The aliphatic acids and alcohols that we used in our studies are excellent examples of this phenomenon (Figure 9). All of the acids have unpleasant odors, such as rancid, sour, or sweaty. In contrast, all of the alcohols have pleasant odors, such as herbal, woody, or orange. In our studies, pairs of acids and alcohols that differed by a single functional group invariably had different receptor codes (Figure 9).

Our studies showed that a change in the concentration of an odorant can also change its receptor code. At higher concentrations, additional ORs were invariably recruited into the odor response. This may explain why changing the concentration of an odorant can alter its perceived odor.

5. A Stereotyped Map of Odorant Receptor Inputs in the Olfactory Bulb

These studies indicated that, in the nose, different odorants are detected by different combinations of ORs, and that the different combinations of ORs ultimately generate different odor perceptions. How is this accomplished? How does the brain translate an odorant's combinatorial receptor code into a perception?

Each olfactory sensory neuron in the olfactory epithelium sends a single axon to the olfactory bulb of the brain. Here the sensory axon enters a spherical structure called a glomerulus, where it synapses with the dendrites of bulb neurons. The mouse olfactory bulb has about 2000 glomeruli, each of which receives input from several thousand olfactory sensory neurons. Each sensory neuron synapses in only one glomerulus. Similarly, each mitral cell in the bulb receives input from a single glomerulus. Mitral cells are relay neurons that transmit signals to the olfactory cortex.

In the bulb, we found something very different from what we had seen in the nose.[22] Here, single receptor probes labeled receptor mRNA in sensory axons in only a few glomeruli, and those glomeruli were located at only two spots, one on either side of the bulb (Figure 10 A). We found that different receptor probes labeled different glomeruli, and surprisingly, those glomeruli had nearly identical locations in different individuals (Figure 10 B). These findings were made

by Kerry Ressler and Susan Sullivan in my lab. In independent experiments in rats, Vassar and Axel obtained similar results, although individual receptor probes generally labeled a larger number of glomeruli at more locations in the bulb in their studies.[23]

Our studies in mice indicated that the axons of thousands of sensory neurons with the same OR converge in only 2–4 glomeruli, each of which is likely to be dedicated to one OR (Figure 10).[22] They further indicated that sensory informa-
Figure 10. The olfactory bulb has a stereotyped map of OR inputs. A) A single OR gene probe hybridized to sensory axons in only one or two glomeruli on either side of the olfactory bulb. B) Different OR probes (A16, M50, M71) hybridized to different glomeruli and those glomeruli had similar locations in six different bulbs.

tion that is broadly organized into four zonal sets in the nose is transformed in the bulb into a stereotyped sensory map (Figure 6). In this map, inputs from different ORs are targeted to different glomeruli and the bulb neurons associated with those glomeruli. Remarkably, this map is virtually identical in different individuals.

The olfactory epithelium and bulb have one important thing in common, however: At both sites, inputs from different ORs are segregated. Each sensory neuron in the epithelium, and each glomerulus and relay neuron in the bulb, appears to be dedicated to only one type of OR.

The structure of the bulb map is likely to be important in at least two respects. First, it is likely to maximize sensitivity to low concentrations of odorants. Signals from 5000 or so neurons with the same OR converge on 2–4 glomeruli and about 50 mitral cells, thus allowing a high degree of signal integration. Second, the bulb map is likely to be important for the stimulation of odor memories. Sensory neurons in the epithelium are short lived and are continuously replaced. However, the bulb map remains constant over time. Thus, the neural code for an odor remains intact, assuring that odorants can elicit distant memories.

6. Odor Coding in the Olfactory Epithelium and Bulb

Given our finding that each odorant is recognized by a combination of ORs,[20] these results imply that the code for an odor in the nose is a dispersed ensemble of neurons, each expressing one OR component of the odorant's receptor code (Figure 11). In the bulb, the code is a specific combination of
Figure 11. Odor coding in the olfactory epithelium and olfactory bulb. In this schematic representation, inputs from different ORs that recognize an odorant are indicated by different colors. In the olfactory epithelium (OE), the code for an odorant is a dispersed ensemble of neurons, each expressing one component of the odorant's receptor code. In the olfactory bulb (OB), it is a specific combination of glomeruli whose spatial arrangement is similar among individuals. Partially overlapping combinations of OR inputs generate distinct odor perceptions.

glomeruli that receive inputs from those ORs and have a similar spatial arrangement in different individuals. This arrangement is consistent with many studies of odor-induced activity in the epithelium and bulb, beginning in the 1950s with the studies of Lord Adrian, who discovered that different mitral cells in the rabbit bulb respond to different sets of odorants.[24–26]

7. Stereotypy, Divergence, and Convergence in Olfactory Cortex

What happens to this information at higher levels of the nervous system to ultimately generate diverse odor perceptions?

Mitral cell relay neurons in the bulb extend axons to the olfactory cortex, a large area that stretches along the ventral–lateral part of the brain. The olfactory cortex is composed of a number of distinct anatomical areas, at least some of which are likely to have different functions. The largest area is the piriform cortex, which itself has morphologically distinct anterior and posterior halves.

In the 1980s, Lewis Haberly and others showed that a tracer placed in one small region of this cortex would back-label mitral cells in many parts of the bulb.[27] This clearly

indicated that the organization of sensory information in the olfactory bulb could not be recapitulated in the cortex, but how olfactory information is organized in the olfactory cortex was a mystery.

We were initially interested in three questions regarding the olfactory cortex. First, do different areas of the olfactory cortex, which may have different functions, receive signals derived from different subsets of ORs or, alternatively, does each area receive input from the entire OR repertoire? Second, is input from one OR scattered in the cortex (as in the nose), is it targeted to unique, stereotyped sites (as in the bulb) or is it organized in some other way? Finally, given that each odorant is recognized by multiple ORs, are inputs from different ORs combined in individual cortical neurons, or are they segregated in different neurons as in the nose and bulb?

To determine how OR inputs are organized in the cortex, we first asked whether it would be possible to trace neural circuits genetically. In those studies, Lisa Horowitz, a graduate student in the lab, made transgenic mice that expressed a plant protein, barley lectin, in all olfactory sensory neurons in the nose. In those mice, the expression of barley lectin (BL) was controlled by the promoter of the OMP gene, a gene that is selectively expressed by olfactory sensory neurons.

Using BL-specific antibodies, we detected BL in olfactory sensory neurons in the olfactory epithelium, glomeruli, and relay neurons in the bulb, and also in neurons in the olfactory cortex.[28] This indicated that BL produced by olfactory sensory neurons in the nose could travel across two synapses to label connected neurons first in the olfactory bulb and then in the olfactory cortex.

Having developed a genetic method for charting neural circuits, we were able to move to the next step. That was to ask how inputs from individual ORs are organized in the cortex. Our goal was to coexpress BL with only one of the 1000 different OR genes. To do this, Lisa Horowitz and Jean-Pierre Montmayeur in our lab altered individual OR genes by inserting, 3′ to their coding regions, an internal ribosome entry site (IRES) sequence followed by a BL coding sequence. Using gene targeting in embryonic stem cells, Zhihua Zou, a postdoctoral fellow in the lab, then made "knockin" mice that contained an altered allele of either the M5 or M50 OR gene.[29] In these knockin mice, BL was produced only in neurons that expressed the M5 or M50 OR.

In the olfactory cortex, the axons of bulb neurons branch and form synapses in layer Ia with the dendrites of pyramidal neurons located in layers II and III. In PompBL mice, which express BL in all olfactory sensory neurons,[28] we saw labeled neurons in layers II and III throughout the olfactory cortex (Figure 12). In the M5 and M50 knockin mice, we also detected labeled cortical neurons, but they were located in distinct clusters (Figure 12).[29] Moreover, the clusters appeared to have similar locations in different individuals.

In each knockin strain, we detected 2–3 clusters of labeled neurons in the anterior piriform cortex (Figure 12). Most of
Figure 12. Inputs from one OR are targeted to two to three clusters of neurons in the anterior piriform cortex. Coronal sections through the anterior piriform cortex of mice in which barley lectin was expressed in all olfactory sensory neurons (PompBL) or only in neurons expressing the M5 (M5iBL) or M50 (M50iBL) odorant receptor. Asterisks indicate the outer limits of the piriform cortex (Pir). The distance from an anterior–posterior landmark is shown in mm. Adapted from Ref. [29].

these clusters were bilaterally symmetrical in the left and right brain. We also found clusters of labeled neurons in several other areas of the olfactory cortex. In each cluster, the highest density of labeled neurons was in the center, but even in the center, only about half of the resident pyramidal neurons were labeled with the BL tracer.

Detailed analysis of the clusters in the anterior piriform cortex revealed that they had similar locations and similar dimensions in different individuals and, in most cases, they were bilaterally symmetrical.[29] The clusters had different locations in the two knockin strains, but one of the M5 clusters appeared to partially overlap with one of the M50 clusters.

These results showed that the olfactory cortex has a stereotyped map of OR inputs (Figure 13). In this map, signals derived from one type of OR are targeted to several loose clusters of cortical neurons. The clusters of neurons that receive input from a particular OR are found at specific locations, which are virtually identical among individuals.

These studies clearly indicated that input from one OR diverges to multiple areas of the olfactory cortex. This
Figure 13. The olfactory cortex has a stereotyped map of OR inputs. Organization of inputs from the M5 (yellow) and M50 (pink) odorant receptors in the olfactory epithelium, bulb, and cortex. Black lines and abbreviations indicate different areas of the olfactory cortex. divergence of OR inputs may allow a parallel processing of OR signals in which signals from the same ORs are combined or modulated in different ways prior to transmission to other brain regions that have different functions.

We found that in the anterior piriform cortex, the clusters of neurons that receive input from one OR occupy about five percent of the total area along the anterior–posterior and dorsal–ventral axes.[29] In PompBL mice, which express BL in all olfactory sensory neurons, there were about 180 000 BL-labeled neurons in the anterior piriform cortex. If each cortical neuron received input from only one of 1000 different ORs, one might expect to see about 180 labeled neurons in this area in each knockin mouse. However, we detected about 4000–6000 BL-labeled neurons in the anterior piriform cortex in each knockin strain.[29]

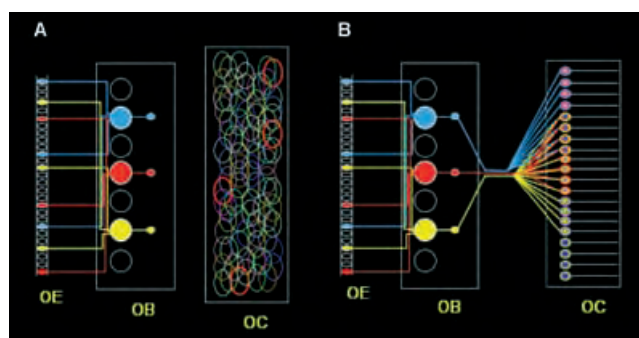
These results indicated that the map of OR inputs in the olfactory cortex is markedly different from that in the olfactory bulb. First, while inputs from different ORs are spatially segregated in different glomeruli in the bulb, they are likely to overlap extensively in the cortex (Figure 14 A).


Figure 14. Schematic diagrams showing the organization of odorant receptor inputs in the olfactory epithelium (OE), olfactory bulb (OB), and olfactory cortex (OC). Inputs from different ORs are segregated in different neurons and glomeruli in the OE and OB. In contrast, it appears that different receptor inputs overlap extensively in the OC (A) and that single cortical neurons receive signals from a combination of receptors (B).

Second, while signals from different ORs are segregated in different neurons in both the nose and bulb, each cortical neuron is likely to receive signals derived from multiple different ORs (Figure 14 B). Since each odorant is recognized by a combination of ORs, this may permit an initial integration of multiple components of an odorant's receptor code that is critical to the generation of diverse odor perceptions.

These findings raise the possibility that neurons in the olfactory cortex function as coincidence detectors that are activated only by correlated combinatorial inputs from different ORs. For example, in a simple model, signals from different ORs that recognize vanillin would be targeted to partially overlapping locations in the cortex, but the only neurons activated by vanillin would be those that receive coincident signals derived from more than one of the vanillin ORs.

In sensory systems, environmental stimuli are deconstructed and then reconstructed in the brain to create perceptions. The organization of receptor inputs seen in the olfactory cortex may serve as an initial step in the reconstruction of an odor image from its deconstructed features.

Communications
Highly anisotropic metal surfaces can drive the formation of metal–organic coordination chains, as shown by scanning tunneling microscopy analysis and density functional calculations. For details about the templated coordination of Cu and Fe atoms with trimesitylic acid on a Cu(110) surface, see the Communication by T. Classen, S. Fabris, K. Kern, and co-workers on the following pages.

Coordination Chains

Templated Growth of Metal–Organic Coordination Chains at Surfaces**

Thomas Classen,* Guido Fratesi, Giovanni Costantini, Stefano Fabris,* Frank Louis Stadler, Cheolkyu Kim, Stefano de Gironcoli, Stefano Baroni, and Klaus Kern*

Metal–organic coordination networks (MOCNs) formed by coordination bonding between metallic centers and organic ligands can be efficiently engineered to exhibit specific magnetic, electronic, or catalytic properties.[1–6] Instead of depositing prefabricated MOCNs onto surfaces, it has been recently shown that two-dimensional (2D) MOCNs can be directly grown at metal surfaces under ultrahigh vacuum (UHV), thus creating highly regular 2D networks of metal atoms.[7–12] These grids have been pointed out to be potentially relevant for devices that involve sensing, switching, and information storage.[13,14] We show here that this approach offers the additional advantage to predefine the geometry of the MOCN by using the substrate as a template to direct the formation of novel 1D metal–organic coordination chains (MOCCs).

The templating role of substrates is well known in the field of surface epitaxial growth.[15–19] Among the highly anisotropic substrates, the Cu(110) surface is one of the most commonly used (Figure 1a and b). To demonstrate its strong 1D templating effect on organic molecules, a ligand with a triangular symmetry was selected, namely 1,3,5-benzenetricarboxylic acid (trimesic acid, TMA; Figure 1c). The three-

fold rotation symmetry of TMA supports the formation of hexagonal 2D and 3D architectures,[20–22] therefore strongly disfavoring the linear geometry. On the isotropic Cu(100) surface, TMA forms 0D carboxylate complexes and 2D networks.[9,10]
The deposition of TMA on Cu(110) under UHV at 300 K results in the formation of 1D chains along the $\langle 1\bar{1}0 \rangle$ direction, as observed by scanning tunneling microscopy (STM). This deposition temperature is high enough to provide mobile Cu adatoms through evaporation from kinks and steps onto the terraces.[23] Analysis of similar systems by X-ray photoelectron spectroscopy[24,25] showed that these adatoms catalyze the deprotonation of molecular carboxylate groups. The adatoms are furthermore necessary for the formation of copper carboxylate complexes.[23,24,26] Deposition at lower temperatures, 210 K and 250 K, resulted in disordered structures with a tip-to-tip bonding motif. This signature, which is never observed above 300 K, is characteristic for intermolecular dimeric hydrogen bonds of carboxylate groups,[20–22,24] thus indicating that the carboxylate groups are protonated at temperatures below 300 K. Upon annealing to 300 K, these structures yield to the same 1D chains described above. The chains formed at 300 K typically show irregular kinks and poor long-range order. These inhomogeneities are removed by post-annealing to 380–410 K to yield straight and highly periodic chains, referred to as MOCC-I hereafter (Figure 2). At low coverage, chains predominantly attach to step edges, whereas upon increasing the coverage chain nucleation takes place also on terraces.

Figure 1. a) High-resolution STM image in 3D representation and b) structural model of the Cu(110) surface. c) Trimesic acid (TMA).
Figure 2. Representative STM images of [-Cu-TMA-Cu-]$_n$ chains (MOCC-I) on Cu(110) for TMA coverages of a) 0.36 and b) 0.13 monolayers (ML), respectively. Comparison of c) the high-resolution STM image of MOCC-I, d) the atomistic MOCC-I model, and e) the corresponding simulated STM image.

These findings allow the substrate templating effect to be rationalized as follows: Upon deprotonation, the molecule–molecule interaction (favoring hexagonal geometries) is overcome by the molecule–substrate interaction, which effectively controls the 1D character of these MOCCs.

The chains consist of triangles alternating with round protrusions (Figure 2b and c). The apparent height of the two units is significantly different, 140 ± 30 pm and 75 ± 20 pm, respectively, when scanning at -1 V and 1 nA. Following previous analysis,[9,10,20–22] the triangles are identified as flat-lying TMA molecules. The round protrusions can be attrib-

uted to Cu adatoms,[7,9,10] coordinated by two of the carboxylate groups of the TMA molecule. The third functional group of TMA is pointing out of the chain with no preferential up or down orientation (Figure 2b).

The periodicity of MOCC-I along ⟨1$\bar{1}$0⟩ is five Cu lattice spacings (12.70 ± 0.15 Å). High-resolution STM images indicate that the distance between the Cu protrusions and the oxygen atom of the molecular carboxylate groups is approximately 2.8 Å, a rather large value when compared to the typical Cu−O bond length of 1.9–2.2 Å.[27] The simplest [-TMA-Cu-]$_n$ chain model for the adsorption geometry of MOCC-I seems therefore to be outruled by these observations.

Indeed, the lowest energy structure of MOCC-I as predicted by density functional theory (DFT) calculations is a [-Cu-TMA-Cu-]$_n$ chain in which a dimer of Cu metal adatoms forms unidentate Cu–carboxylate bonds with adjacent TMA molecules (Figure 2d). The dimer binds to the surface by 6.3 eV with respect to isolated Cu atoms, and each adatom is fivefold coordinated to the substrate. This structure has the correct 5× periodicity. Its simulated STM image (Figure 2e) closely agrees with that found experimentally, with the Cu–Cu dimer imaged as a single spot centered between the adatoms. The resulting Cu–O distance is 2.02 Å, which lies in the range of typical Cu−O bond lengths. Also the calculated apparent heights, 170 pm for the TMA unit and 90 pm for the Cu adatom unit, are in good agreement with those determined experimentally.

The theoretical analysis provides an unprecedented level of insight into the adsorption geometry of surface MOCNs. The phenyl ring of TMA and the Cu adatoms are located on the short-bridge and hollow sites, respectively (Figure 2d). The molecule stands 1.14 Å above the outermost Cu layer, with the carboxylate groups bending towards the surface by as much as 0.69 Å. With respect to a neutral Cu atom, surface complexation of Cu weakly reduces the metal center occupations of both the s and d electronic states by approximately 0.2 electrons.

[-Cu-TMA-Cu-]$_n$ chains are the intrinsic nanostructures on Cu(110), but functional MOCCs also require different elements than Cu as metallic centers. Extrinsic [-TMA-Fe-]$_n$ chains (MOCC-II) were created by holding the Cu(110) crystal at 230 K—thus preventing the formation of Cu–TMA complexes—and by depositing first TMA and then Fe at coverages higher than 0.04 ML. The sample was then annealed to 390 K for one minute. The number of chains increased with the amount of deposited Fe and saturation was reached for a coverage of around 0.08 ML of Fe. Further deposition of Fe results in the nucleation of Fe islands.

The 4× in-chain periodicity of these chains (Figure 3) leaves space for just one Fe metal center between TMA molecules. The TMA–TMA distances are therefore shorter when linked by Fe than when linked by Cu, similar to that reported for 2D MOCNs on the Cu(001) surface.[9,10] According to DFT calculations the geometry of the adsorbed TMA molecule is weakly dependent on the metal center, with the phenyl ring lying 0.09 Å higher in the case of Fe. The metal–carboxylate bond is still unidentate and the Fe–O distance is 1.95 Å, thus 0.07 Å shorter than the Cu–O distance in
Figure 3. [-TMA-Fe-]$_n$ chains (MOCC-II): a) Overview image of the coordination chains formed upon deposition of 0.04 ML Fe and 0.40 ML TMA. Comparison of b) the high-resolution STM image, c) the atomistic MOCC-II model, and d) the corresponding simulated STM image.

MOCC-I. Single metal centers lead to very weak features in the simulated STM image (Figure 3d), in agreement with experiment (Figure 3b). With respect to a neutral Fe atom, surface complexation of Fe strongly reduces the occupations of the Fe s states by 1.3 electrons while it increases that of the d states by 0.5 electrons.

Insight into the potentially interesting magnetic properties of Fe-complexed MOCC-II can be gained by projecting the electron density on the atomic Fe d orbitals (Figure 4b).
Figure 4. a) Total density of electronic states (DOS, in [eV] with respect to the Fermi energy E_F) of the [-TMA-Fe-]$_n$ chain (MOCC-II). Projected DOS (PDOS) on the atomic d states of b) the Fe center in MOCC-II and c) an Fe atom isolated on the Cu(110) surface.

The projected density of electronic states (DOS) displays a large splitting between the majority spin-up and minority spin-down electronic d states. The former are completely filled and well hybridized with the substrate Cu d states, extending from −5 to −1 eV in the total DOS of the [-TMA-Fe-]$_n$ chain (Figure 4a). The latter spin-down states are only partially filled and extend in the energy region dominated by the substrate s states. As a consequence, the Fe atoms are strongly magnetized with a spin polarization of 3.3 μ_B per Fe atom. The polarization of a Fe adatom isolated on the Cu(110) surface is very similar, 3.2 μ_B, and the corresponding projected DOS is shown in Figure 4c. The comparison shows that the coordination with the carboxylate group does not affect the electron localization at the Fe adatoms and thus

does not produce any relevant quenching of the spin magnetic moment. This is a necessary (although not sufficient) condition for the emergence of intriguing magnetic properties induced by the low dimensionality, such as a giant magnetic anisotropy.[28,29] Because of their high thermal stability, MOCNs similar to those presented here could thus be convenient model systems to explore the occurrence of low-dimensional magnetism.

In conclusion, metal–organic coordination chains were created in situ by self-organized growth at a metal surface under UHV. The 1D anisotropy of the substrate was effectively transferred to the resulting metal–organic coordination chains. This strategy was shown to work for intrinsic as well as for extrinsic metal–carboxylate systems. The precise atomic configuration of the structures was revealed by a combined use of STM and DFT. Spin-polarized DFT suggests that Fe centers within the 1D chains have magnetic properties similar to those of isolated Fe adatoms. This renders such regular and unidirectional arrangement of magnetic centers attractive candidates for the investigation of low-dimensional magnetism in thermally stable structures.

Experimental Section

Methods: The sample was prepared in a standard UHV preparation chamber with a base pressure of less than 2×10^{-10} mbar. The Cu(110) single crystal was cleaned by cycles of Ar^+ sputtering (900 eV) and annealing to 830–850 K. Commercially available TMA (Fluka Chemie AG, purity > 97%) was evaporated from a ceramic crucible at 460 K for sample temperatures between 130 K and 300 K. The sample was then transferred under UHV conditions to a STM chamber (base pressure of 6×10^{-11} mbar) that comprised a commercial variable-temperature STM apparatus. Measurements were carried out at 300 K and 130 K with typical tunneling conditions of −1 V and 1 nA (filled-state imaging).

The computer simulations were based on DFT, in the generalized gradient approximation of Perdew–Burke–Ernzerhof.[30] The calculations were performed in the pseudopotential plane-wave framework (plane-wave cutoff of 326.4 eV) using ultrasoft pseudopotentials[31] as implemented in the PWscf simulation package.[32] A three-layer slab provided a simplified model of the Cu(110) surface. The atomic positions were determined by relaxing the upper layer and keeping the distance between the others fixed at the bulk value. Metal adatoms and deprotonated TMA molecules were positioned on the upper surface of the slab and were structurally relaxed according to the Hellmann–Feynman forces. STM images were simulated by means of the Tersoff–Hamann method,[33] that is, by a spatially resolved DOS integrated in energy from a bias potential (−1.0 eV) to the Fermi energy.

Communications

Divergent Mechanisms for the Skeletal Rearrangement and [2+2] Cycloaddition of Enynes Catalyzed by Gold**

*Cristina Nieto-Oberhuber, Salomé López,
M. Paz Muñoz, Diego J. Cárdenas, Elena Buñuel,
Cristina Nevado, and Antonio M. Echavarren**

Transition-metal-catalyzed reactions of 1,6-enynes proceed via two general pathways (Scheme 1).[1,2] If the metal coordinates selectively to the alkyne **1**, cyclopropyl–metal
Scheme 1.

carbenes **2** are initially formed, which can react with alcohols or water to give products of alkoxy- or hydroxycyclization,[1,2] whereas in the absence of nucleophiles, skeletal rearrangement forms dienes **3** (*single cleavage*) and/or **4** (*double cleavage*).[1,3] Alternatively, coordination of MX_n to the alkyne and the alkene (as in **5**) is followed by oxidative cyclometalation to form **6**, which usually evolves by β-hydrogen elimination to give Alder–ene-type products.[2] Formation of products **3** could also occur by conrotatory ring-opening of cyclobutenes **7**,[4,5] which are formed either from **2** or by reductive elimination of **6**.

A pathway for the formation of **3** via ring-opening of **7** is favored by most authors.[4,6] However, the formation of dienes **4** requires a different mechanistic rationalization. An earlier mechanistic proposal by Oi et al.[3] suggested a direct pathway for the skeletal rearrangement via intermediates of type **2**. Herein we report experimental and theoretical results that shed new light into this complex mechanistic issue. In particular, this work strongly suggests that cyclobutenes **7** are not necessary intermediates in the skeletal rearrangement of enynes.

Alder–ene-type products have not been observed in Au^I-catalyzed reactions, which is consistent with the selective coordination of cationic $[Au(L)]^+$ complexes to the alkyne.[2c,7,8] In the presence of catalysts formed from **8a–c** and $AgSbF_6$,[7b] or new cationic complexes **9a,b**, enyne **10**
undergoes a *single cleavage rearrangement* to form **11** quantitatively at a temperature as low as −63 °C (Scheme 2). On the other hand, enyne **12** undergoes a

	$\Delta G^{\ddagger}_{298}$	$\Delta H^{\ddagger}$	$\Delta S^{\ddagger}$
9a	21.7 ± 1.1	3.7 ± 0.3	−60.6 ± 1.2
9b	21.2 ± 2.1	6.2 ± 0.5	−50.3 ± 2.0
Scheme 2. $Z = C(CO_2Me)_2$. $\Delta G^{\ddagger}_{298}$ and $\Delta H^{\ddagger}$ in kcal mol^{-1}; $\Delta S^{\ddagger}$ in cal K^{-1} mol^{-1}.

double cleavage rearrangement with $[Au(PPh_3)]SbF_6$ to give exclusively **13**.[3,9] These are the skeletal rearrangements occurring at the lowest temperatures. Reaction of enyne **10** with catalyst **9a** (−63 to −26 °C) or **9b** (−43 to −28 °C) was monitored by ^{1}H NMR spectroscopy in CD$_2$Cl$_2$. Under these conditions, smooth and quantitative formation of diene **11** was observed without the build up of any intermediate. The rearrangement is pseudo-first order in **10**, which allowed us to determine the thermodynamic parameters shown in Scheme 2.

The large and negative activation entropies suggest that an associative ligand substitution[10] (diene **11** by incoming enyne **10**) is the rate-determining step of the process. These results establish a very low activation energy (E_a) for the

hypothetical conrotatory ring-opening of a cyclobutene of type **7**, which therefore should be a fast process at temperatures as low as −63 °C. This is not consistent with the ring-opening of bicycle **14** and its 6,7-dimethyl derivatives,[11] for which activation energies of 29.0–32.7 kcal mol⁻¹ and low entropies of activation (1.4–2.2 cal K⁻¹ mol⁻¹) have been determined. DFT calculations predict an E_a of 25.6 kcal mol⁻¹ for the conrotatory ring-opening of bicyclo[3.2.0]hept-5-ene (**15**) to 1-vinyl-1-cyclopentene ($\Delta G_{298K} = -22.5$ kcal mol⁻¹).

It is important to note that **15** has a lower olefin strain (OS = 16.7 kcal mol⁻¹) than **14** (OS = 20.5 kcal mol⁻¹), which is stable up to 118 °C.[12] Additional evidence against the ring-opening of a cyclobutene in the low temperature skeletal rearrangement of **10** is provided by the isolation of bicycle **16** as a stable compound.[13]

DFT calculations[14] support pathways for the skeletal rearrangement that do not involve the intermediacy of cyclobutenes **7**. Thus, complex **17a** evolves via **TS₁** to form cation **18**, which could furnish dienes **3** by elimination of [Au(L)]⁺ (Scheme 3). Alternatively, a 1,2-shift gives gold

Scheme 3. L = PH₃. ΔG at 298 K (energies in kcal mol⁻¹).

carbene **19a** via **TS₂** in an almost flat potential surface. Dienes **4** would result from **19a** by β-hydrogen elimination and demetalation. In the case of **20**, which is the intermediate in a reaction of an enyne of type **12**, a double-cleavage rearrangement was found to give **19b** directly, in agreement with the experimental results. This remarkable process involves a 1,2-

shift of a metal carbene with concomitant cleavage of the distal C−C bond of the cyclopropane and formation of a double bond.

No direct pathway for the formation of a cyclobutene from **17a** was found. In contrast, *syn*-**17′a** forms **22a** via **TS₅**, although the *anti* to *syn* isomerization from **17a** to **17′a** requires a rather high activation energy (Scheme 4).[14] This

Scheme 4. L = PH₃. ΔG at 298 K (energies in kcal mol⁻¹) and selected bond lengths [Å] for **17a**, **17′a**, and **TS₄**.

high activation energy of 24.7 kcal mol⁻¹ can be attributed to the loss of conjugation between the gold carbene and the cyclopropane, as shown by the significant shortening of the cyclopropane and C=Au bonds and the lengthening of the C−C bond connecting the cyclopropane and the gold carbene in **TS₄**. This isomerization process is rather unlikely under the reaction conditions, as the initially formed *anti*-**17a** would undergo a more facile rearrangement via **18** ($\Delta G^{\neq} = 9.1$ kcal mol⁻¹, Scheme 3). However, an alternative pathway has been found for a more direct formation of complexes **17′a,b** by a *syn*-type attack of the alkene, via **TS₅**, to the (alkyne)gold moiety of **21a,b** (Scheme 4).

Although the *anti* attack of the alkene is more favorable,[7a] the *syn* attack could compete if substitution at the alkene and/or the alkyne disfavors the skeletal rearrangement. In particular, this should be more favorable for the formation of bicyclo[3.2.0]oct-6-enes from 1,7-enynes, in accordance with the calculations (**17′b→22b**, Scheme 4) and experiments.[4] Significantly, cationic gold complexes catalyze the [2+2] cycloaddition of 1,7-enynes. Thus, enynes **23** and **24**

Communications

react with complexes [Au(L)]$^+$ at room temperature to give **25** and **26**,[4b,d] respectively (Scheme 5).

Tricycles **25** and **26** do not undergo ring-opening at 120–150°C to form 1,3-dienes.[15] To study the possible effect of transition metals in the ring-opening of the cyclobutene,[16] **25**
Scheme 5. Reactions of **23** and **24**: a) **9b** (2 mol%), CH$_2$Cl$_2$, room temp., 14 h (80%); b) **8c** (2 mol%), AgSbF$_6$ (2 mol%), CH$_2$Cl$_2$, room temp., 45 min (67%); c) PtCl$_2$ (5 mol%), MeCN, 120°C, 20 h (67%).

was heated in MeCN at 120°C in the presence of 5 mol% PtCl$_2$ (Scheme 5). Interestingly, under these conditions, Pt^{II},[1,3,4d,f,g] which is a known catalyst for the skeletal rearrangement, does not promote the ring-opening of the cyclobutene but rather promotes isomerization to form the less-strained tricycle **27**.[17]

In summary, calculations on the Au^I-catalyzed skeletal rearrangement of enynes support the earlier proposals suggested by Oi et al.[3] and others,[1,4] although Scheme 3 provides a more rigorous and concise mechanistic picture. An alternative pathway has been found for the formation of cyclobutenes via *syn*-cyclopropyl–metal carbenes, formed by a *syn* electrophilic addition of the metal and the alkene to the alkyne. Kinetic experiments indicate that if a conrotatory ring-opening of a cyclobutene intervenes in the skeletal rearrangement, its E_a value would be unreasonably low.

Molecular Dynamics

Real-Time Observation of Ionization-Induced Hydrophobic→Hydrophilic Switching**

Shun-ichi Ishiuchi, Makoto Sakai, Yuji Tsuchida, Akihiro Takeda, Yasutake Kawashima, Masaaki Fujii,* Otto Dopfer,* and Klaus Müller-Dethlefs*

Noncovalent interactions are responsible for fundamental properties of complex molecular systems that occur in our macroscopic world.[1] In particular, the structure, dynamics, and function of supramolecular systems such as DNA are entirely governed by noncovalent interactions.[2,3] Most of our understanding of noncovalent forces has come from quantum chemical calculations.[1,2] For example, a sophisticated ab initio treatment of intermolecular interactions in DNA base pairs has elucidated the competition between specific hydrogen-bonding and aromatic π-stacking interactions.[2] For the total stabilization energy of DNA, the stacking contribution was estimated to be about two-thirds of that of the hydrogen-bond contributions, substantially higher than it was previously thought.[2] This competition between hydrogen bonding and π stacking[4] can also be viewed as competition between hydrophilic and hydrophobic binding sites. Experimental work in the area of intermolecular forces is challenging and employs specific model systems to provide the detailed answers required to understand complex noncovalent interactions at the molecular level. Molecular clusters are one such model system,[5] and their spectroscopic characterization in molecular beams provides currently the most direct and most

detailed experimental access to the intermolecular interaction potential[1,6] and excited-state dynamics.[7] In particular, clusters of acidic aromatic molecules with rare-gas atoms, such as phenol···Ar, constitute the simplest model systems to study the competition between hydrophobic and hydrophilic binding motifs, as they exhibit both dispersion interactions (binding to the π ring) and hydrogen bonding to the acidic functional group, which are essential forces for chemical and biological recognition.[2,3] As an example of such a chemical recognition process at the molecular level, we report here the first direct observation of a hydrophobic→hydrophilic site-switching process induced by ionization. This switching is initiated in the phenol···Ar_2 trimer by resonant photoionization. When the cation is prepared by photoionization, it is produced in the π-bound geometry of the neutral precursor, with argon binding to the hydrophobic ring site. On the timescale of a few picoseconds, one of the Ar atoms switches from the hydrophobic ring site to the hydrophilic OH site and creates a hydrogen bond. The dynamics of this isomerization process is monitored in real time by a change in the OH stretch vibrational wavenumber using time-resolved picosecond UV/IR pump-probe ionization depletion spectroscopy.

The competition between π bonding and hydrogen bonding in the phenol···Ar dimer cluster has been studied in the neutral ground electronic state (S_0), the electronically excited state (S_1), and the cation ground state (D_0).[4,8] In the neutral S_0 state, only the π-bound isomer is observed because dispersion forces between Ar and the aromatic π-electron system dominate the attraction. In contrast, in the ionic D_0 state the hydrogen-bound isomer is more stable, as the additional induction forces between Ar and the acidic OH group that arise from the excess charge override dispersion. Hence, Ar binds preferentially to the hydrophobic site in the neutral cluster and to the hydrophilic site in the cationic cluster. Figure 1 shows the two binding sites for the argon atom and the relevant potential energy diagrams along with the available energetic data.[4,8]

How does the system switch between the hydrophobic and hydrophilic sites? When the cation is prepared by photoionization, it is produced in the geometry of the neutral precursor (Franck–Condon principle), that is, argon binds to the hydrophobic site. Energetically, this π-bound cation is a metastable local minimum and could, in principle, switch by itself to the hydrogen-bound global minimum. However, the substantial energetic barrier between both minima[4] prevents this isomerization for the phenol···Ar dimer. In contrast, in the phenol···Ar_2 trimer the energetics change in a subtle way that enables us to present the first direct evidence for ionization-induced hydrophobic→hydrophilic site switching. The spectroscopic method employed is a sophisticated extension of the IR hole-burning technique[9] using three tuneable picosecond lasers. The excitation/ionization/depletion scheme is shown in Figure 2. Two UV lasers provide resonant ionization of phenol···Ar_2 via the S_1 state.[8] The first UV photon (UV1) excites the phenol···Ar_2 complex from the neutral S_0 state to its excited S_1 state. The second UV photon (UV2) ionizes phenol···Ar_2 from the excited S_1 state, thus producing the phenol···Ar_2 cation in its electronic ground

Figure 1. Hydrophobic ring site (π bonding) and hydrophilic OH site (hydrogen bonding) in the phenol⋯Ar cluster, along with potential diagrams[4, 8] for the neutral S_0 ground state, the S_1 excited state, and the D_0 cation ground state.
Figure 2. Excitation scheme for time-resolved picosecond UV-UV-(pump)-IR(probe) ionization depletion spectroscopy of phenol⋯Ar$_2$.

state, D_0. Two different colors for the UV photons are required to prevent the dissociation of the cluster cation upon ionization. The energy of the second photon results in an excess energy of less than 300 cm^{-1}, which is sufficiently small to prevent direct dissociation of the doubly π-bonded phenol⋯Ar$_2$ trimer cation. After an adjustable delay, the IR laser is fired to probe if one of the Ar atoms of the cation produced by the two UV lasers has moved from the ring to the OH group. To this end, the IR laser is tuned from 3400 to 3600 cm^{-1} through the range of the OH stretch wavenumber, $\tilde{v}_{OH}$, to distinguish between the free OH ($\tilde{v}_{OH} = 3537$ cm^{-1}) and the hydrogen-bonded OH⋯Ar vibration ($\tilde{v}_{OH} = 3467$ cm^{-1}).[4] The v_{OH} wavenumber is substantially reduced by hydrogen bonding of argon to the OH group, whereas π-bound ligands have virtually no effect.[4] When the IR laser is resonant to the OH stretch vibration, the trimer is vibrationally excited and subsequently dissociated. Thus, the wavenumber of the OH stretch vibration, that is, the spectroscopic signature of the binding site of the Ar atom, is detected in the experiment by the depletion of the signal of the parent ion.

Figure 3 shows the results of the UV-UV(pump)-IR-(probe) experiment for pump-probe delay times between 1 and 50 ps. Because ionization occurs in the geometry of the neutral cluster, in which the OH bond is free (both Ar atoms are π-bound), the cation is initially produced in the same
Figure 3. Time-resolved IR spectra of phenol⋯Ar$_2$ at various pump-probe delay times as indicated beside each spectrum. The vertical axis shows the signal for the phenol⋯Ar$_2$ ion, while the horizontal axis presents the wavenumber of the IR laser. When the IR laser is resonant to the OH stretch vibration, the ion signal is depleted because of vibrational predissociation of the parent cluster. Least-squares fits to the experimental data are included to guide the eyes.

geometry (Franck–Condon principle). This "free OH" structure is indeed detected immediately after ionization for IR probe delay times of up to 3 ps, for which only the free OH band is observed at $\tilde{v} = 3537$ cm^{-1}. With increasing probe delay, from around 7 ps onwards, an additional peak is observed at $\tilde{v} = 3467$ cm^{-1}. This peak corresponds to hydrogen-bonded OH⋯Ar and it grows with delay time, whereas the free OH band disappears. For delay times of 10, 20, and 50 ps, only the "bound OH" structure is seen. This result can only be explained by switching of one Ar atom from the π-bonding hydrophobic to the hydrogen-bonding hydrophilic site, which has been initiated by the ionization and is completed after around 10 ps. Such a timescale for the π-to-hydrogen-bonding isomerization is consistent with a (nearly) barrierless intermolecular isomerization process.

This first observation in real time of the dynamics of a molecular hydrophobic→hydrophilic switch represents a fundamental example of molecular recognition dynamics. The direct observation of this intermolecular reorganization process has been possible because the change in the charge state of the aromatic molecule phenol from 0 to +1 induces the switch in the preferred aromatic solvent recognition motif

from π bonding to hydrogen bonding.[10] Thus, these experiments represent a milestone in the characterization of dynamical processes of noncovalent interactions and solute–solvent binding-site specificity. The experimental approach will be used to investigate the dynamics of other molecular recognition mechanisms, such as the ionization-triggered π-to-hydrogen-bonding switch in the fundamental benzene–water interaction.[10,11]

Experimental Section

Phenol···Ar$_2$ complexes were produced in a supersonic molecular beam expansion of phenol seeded in Ar carrier gas. The UV1 and UV2 lasers were tuned to 36 280 and 32 260 cm^{-1} to prepare phenol···Ar$_2$ cations through resonant ionization via the S$_1$ origin with an excess energy of ca. 300 cm^{-1} above the ionization threshold. After an adjustable delay time, the phenol···Ar$_2$ cations interacted with a tuneable IR laser. Resonant vibrational excitation induces cleavage of one of the intermolecular bonds, leading to a depletion of the phenol···Ar$_2$ ion current. Ions were extracted in a time-of-flight (TOF) mass spectrometer and monitored as a function of the IR laser wavenumber to obtain the IR depletion spectrum. Further details of the experimental setup and the three-color picosecond laser system are provided in the Supporting Information.

SOLARIA: A Protocol for Automated Cross-Peak Assignment and Structure Calculation for Solid-State Magic-Angle Spinning NMR Spectroscopy

Michele Fossi, Federica Castellani, Michael Nilges, Hartmut Oschkinat,* and Barth-Jan van Rossum*

Recently, it has been shown that structures of proteins can be determined by magic-angle-spinning (MAS) solid-state NMR spectroscopy.[1,2] Central to most structure-determination procedures is the collection of a set of distance restraints that is sufficiently large to achieve convergence in the calculations. In our previous solid-state NMR spectroscopic structure investigation on a microcrystalline preparation of the α-spectrin SH3 domain these distance restraints were obtained by manual assignment of cross-peaks from 2D and 3D proton-driven spin diffusion (PDSD) correlation experiments.[1,3] Extensively ^{13}C-labeled preparations obtained by protein expression on a medium containing either [1,3-^{13}C]glycerol or [2-^{13}C]glycerol as the carbon source were used for all the experiments. In such preparations, only a few amino acid types have ^{13}C labels in adjacent positions, which led to a substantial suppression of dipolar attenuation effects[4,5] and enabled a straightforward detection of long-range ^{13}C-^{13}C correlations (Figure 1). The spectra used in these studies displayed a high level of resonance overlap, which resulted in many assignment options per signal and led to the exclusion of a large fraction of ambiguous cross-peaks that could not be assigned manually. Automation of the cross-peak assignment would be beneficial to avoid this problem and to speed-up the structure-determination process.

In liquid-state NMR spectroscopy, software packages such as ARIA,[6–10] CANDID,[11] DYANA,[12] KNOWNOE,[13] NOAH,[14,15] and AUTOSTRUCTURE[16,17] have provided a way to handle ambiguous cross-peaks to derive distance restraints in an automated fashion. In ARIA, ambiguous NOE interactions are handled by treating them as "ambiguous distance restraints" (ADR).[18,19] The calculated structures are then refined in an iterative manner, each time using the structures of the latest round of calculations to find new assignments as the input for the next round.

We developed SOLARIA,[‡] a MAS NMR-dedicated version of ARIA for solid-state NMR spectroscopic studies.

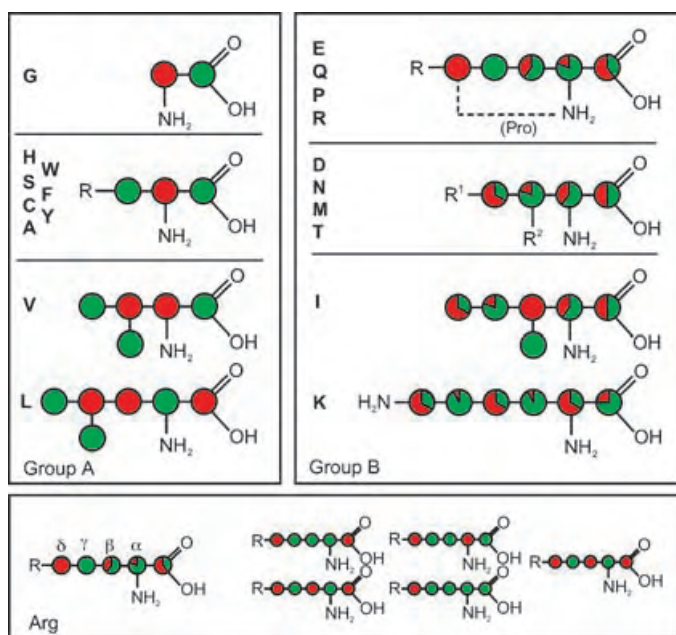

Figure 1. Labeling patterns for the different amino acids in the α-spectrin SH3 domain preparations used in these studies. Schematic representation of the effective ^{13}C enrichment for the different residues, as obtained by protein expression in *E. coli* BL21 (DE3). The green color corresponds to the degree of ^{13}C labeling obtained by growth of the bacteria on [1,3-^{13}C]-glycerol; the opposite labeling pattern, obtained by growth on [2-^{13}C]gly-cerol, is represented in red. There are two groups of amino acids (A and B). In group A, the various carbon sites are either approximately 100% or 0% labeled, in group B the residues show fractional labeling. This fractional labeling is the result of the production of isotopomers of residues with different labeling patterns, as illustrated for arginine at the bottom. These percentages were estimated from extensive solution NMR studies using 2D and 3D heteronuclear NMR techniques.

The two programs share the same overall architecture consisting of nine iterations of cross-peak assignment and structure calculations. However, there are also significant differences. First, SOLARIA can handle peak lists containing not only ^{1}H-^{1}H, but also typical solid-state ^{13}C-^{13}C, ^{15}N-^{15}N, and ^{13}C-^{15}N correlations. Second, in contrast to solution NMR spectroscopy, it is very difficult to find a satisfying relationship between experimental volumes and distances in solid-state NMR spectroscopy. Peak volumes do not depend exclusively on the distance; they are strongly affected by mobility, which interferes with dipolar couplings. This situation can significantly alter the dipolar polarization transfer efficiency and often makes it difficult to achieve a uniform excitation of all the relevant spins. The proton environment may also influence the efficiency of mixing. Further complications may arise through offset-dependent transfer processes, interference with heteronuclear decoupling schemes, and sample heterogeneity. Finally, even with the reduced label-

ing, dipolar attenuation effects are not fully suppressed and the transfer efficiency between two spins can still be largely affected by coupling to other nearby spin systems. For these reasons, the program does not use volumes to set the boundaries for distance restraints, as done in ARIA. Therefore, all distance constraints are represented by the same lower boundary and the same generous upper boundary, and input peak lists do not require the presence of cross-peak volumes or intensities. Third, the labeling pattern in samples made by using 2- or 1,3-labeled glycerol is exploited by SOLARIA for better convergence of the automated assignment process. This is achieved by removal of all assignment options which are not allowed according to the labeling pattern. In principle, other labeling patterns can be easily implemented, for example, for proteins obtained from growth media containing selectively ^{13}C-labeled succinic acid as a precursor.[20]

We tested SOLARIA on lists with the coordinates of manually picked peaks from PDSD-type spectra of the α-spectrin SH3 domain. Intermolecular cross-peaks were identified previously on an experimental basis[1] and removed from the lists. To face the computational difficulties inherent to the use of highly ambiguous solid-state peak lists (the average number of assignment candidates per signal was approximately 6 for the two 3D spectra, and 16 and 19 for the 2-CC and 1,3-CC 2D spectra, respectively) and very loose boundaries (all constraints are restrained between 2.5 and 6.5 Å, independent of the peak volume), we decided to enhance the convergence capability of the software by substantially increasing the number of cooling steps.[21] We raised the number from 9000, which is the commonly used value, to 100 000. Under these conditions and using standard ARIA1.2 input values for all other parameters SOLARIA produced convergent results. The 11 lowest-energy structures (blue) overlaid with the X-ray structure (red) as reference are shown in Figure 2. Despite the use of extremely generous boundaries for the distance restraints, well-defined (0.73-Å ensemble backbone rmsd) and accurate (1.3-Å backbone rmsd to the X-ray reference) structures could be obtained.
Figure 2. Stereoview of the 11 lowest-energy solid-state NMR structures of the α-spectrin SH3 domain calculated by SOLARIA (blue). For comparison, the X-ray reference structure is included (PDB entry: 1SHG; red) and overlaid with the family of solid-state structures by fitting the backbone atoms to the average solid-state structure. The calculations were performed on peak lists where intermolecular cross-peaks were manually removed.

These structures were calculated in approximately 12 h, which is in striking contrast to the several months required in our previous work for the manual assignment of the same spectra.[1] More importantly, SOLARIA allowed the assignment of approximately 20% more cross-peaks than in the previous manual assignment procedure (Figure 3). All

Figure 3. Visualization of the assignments. A strip of a two-dimensional PDSD spectrum recorded using [1,3-^{13}C]glycerol-grown α-spectrin SH3 domain sample is shown.[1] In (a), the cross-peaks that could be assigned manually using 2D and 3D data are indicated. In (b), cross-peaks assigned and used for the structure calculations by SOLARIA using the same dataset are indicated.

manual assignments obtained from the evaluation of 2D and 3D spectra are indicated in Figure 3a, displayed in a region of a 2D experiment, and all automatically assigned peaks are indicated in Figure 3b.

In summary, the program SOLARIA produced, in a few hours, accurate structures (1.3 Å rmsd to the X-ray reference) using unassigned peak lists from 2D and 3D MAS-NMR spectra of the α-spectrin SH3 domain, where intermolecular cross-peaks were discarded prior to the calculation. These structures exemplify a first successful attempt to introduce automation to structure determination of solid proteins by MAS NMR spectroscopy. The automation of the cross-peak assignment resulted in a dramatic speed-up of the whole procedure and, most importantly, provided a way to handle ambiguous cross-peaks in MAS NMR spectra. Hence, we expect that this work will open new possibilities for the use of MAS NMR to determine the structures of larger systems, such as membrane proteins, where the number of cross-peaks may become unmanageably large for manual assignment methods. For these reasons, we believe that SOLARIA

represents an important step forward for the rapidly developing MAS NMR technique.

Experimental Section

Sample preparation and solid-state MAS NMR spectroscopy: The main characteristics of the SH3 domain and the spectra used in this work are summarized in Table 1. The sample preparation is described

Table 1: Spectra used in the calculation.[a]

Spectrum	Dimensionality	Labeling	Number of peaks
1,3-CC	2D	1,3-glycerol	566
2-CC	2D	2-glycerol	461
1,3-NCOCX	3D	1,3-glycerol	477
2-NCACX	3D	2-glycerol	377

[a] Peaks were picked manually. The numbers in parenthesis refer to the total number of peak list entries after the manual removal of intermolecular cross-peaks. No manual assignment was included in the lists.

in detail elsewhere.[22] Peak lists for the structure calculations were generated from solid-state 2D ^{13}C-^{13}C and 3D ^{15}N-^{13}C-^{13}C correlation spectra.[1,3]

Structure calculations: The software SOLARIA was used to perform the automatic assignment of manually picked cross-peaks and to generate structures. The calculations were performed on a SGI Origin 2100 cluster at the FMP, Berlin. The chemical shift tolerances were set to 0.4 ppm for carbon and 0.5 ppm for nitrogen dimentions. The number of calculated structures was 20 for the first eight iterations and 100 for the final one. The results of the calculations were evaluated by computing a pairwise backbone rmsd (precision) and a backbone rmsd (accuracy) to the X-ray reference-structure[23] (PDB entry: 1SHG) of the 15 lowest-energy structures.

Communications

rod β barrels. Their practical usefulness as detectors of chemical reactions has been demonstrated,[1,2] and applications toward multicomponent sensing in complex matrixes are in progress.[3] Structural studies naturally have low priority in research focusing on the creation and application of advanced function.[4] Nevertheless, structural studies on molecular recognition by synthetic multifunctional pores under conditions relevant for function indicated that pore blockage occurs by the physical insertion of the guest into the transmembrane host.[4] These findings implied the formation of inclusion complexes with small guests and of pseudorotaxanes[5–11] with macromolecular guests. Herein, we report on atomic force microscopy (AFM) studies in which single polyacetylene-blocked rigid-rod β-barrel pores were imaged as giant, supramacromolecular pseudorotaxanes.

AFM imaging of molecular recognition by synthetic multifunctional pores became a realistic prospect only because of steady progress made in terms of both pores and blockers. The availability of a fine-tuned set of pores covering the complete spectrum of thermodynamic and kinetic stabilities,[12] for example, promised a rapid identification of the optimal characteristics for the self-assembly of barrels on mica during drying from a buffer solution. As in the formation of synthetic multifunctional pores,[12] the unstable but inert, namely, "self-repairing", rigid-rod β-barrel **1** with internal KH dyads and external LLL triads (Figures 1 and 2a) gave the best AFM images rather than stable/inert barrels with internal RH dyads or stable/labile barrels with internal HH dyads.[13] Consistent with previous AFM results,[13] the obtained objects had an average height of approximately 3.6 nm that matched the height of the barrels standing on the mica surface. The heterogeneous height distribution of 2.3–4.1 nm was suggestive of the additional presence of barrels lying sideways on the surface. In this case, barrel widths of up to about 4 nm were conceivable for the "square-type" conformation **1^S** that was presumed to be observed in single-channel measurements.[12] However, a "diamond-type" conformation **1^D** could exhibit a barrel width down to about 2 nm. The flattened appearance of vesicles, for example, in tapping-mode AFM images[14] suggests that it was conceivable that external pressure by the AFM tip could compress the square **1^S** conformation into the local energy minimum of the diamond **1^D** conformation. Possible stabilization of diamond-like conformations **1^D** by interactions with the mica surface could neither be excluded nor confirmed.

Previously, anionic polyacetylene blockers such as **2** have served as probes to study molecular recognition by synthetic multifunctional pores in lipid bilayer membranes by circular dichroism (CD) spectroscopy.[15] It now transpires that problems of imaging extended linear polymers on mica with classical blockers such as α-helical or random-coil polyglutamate could also be solved by using the more shape-persistent polyacetylene blockers. Poly(ethyl(4-ethynylphenyl)phosphonate)s **2**[16] were detected as wormlike objects with an average height of 0.66 nm and a local maximal height of 1.1–1.5 nm (Figure 2b). Both values were independent of the molecular-weight distribution, whereas the average length found of course increased from low- to high-molecular-weight polymers.

Molecular Recognition

AFM Snapshots of Synthetic Multifunctional Pores with Polyacetylene Blockers: Pseudorotaxanes and Template Effects**

Jiro Kumaki, Eiji Yashima, Guillaume Bollot, Jiri Mareda, Svetlana Litvinchuk, and Stefan Matile**

Synthetic multifunctional pores are constructed from abiotic scaffolds and not only mediate molecular translocation across the membranes of lipid bilayers but also act as hosts or as catalysts.[1,2] Synthetic multifunctional pores became accessible with the discovery of synthetic access to artificial, rigid-

Figure 1. Notional structures and geometry-minimized models of pore **1** in a vertical ($\perp$) and horizontal position relative to a mica surface in open, "square-like" (**1ᔆ**) and closed, "diamond-like" conformations (**1ᴰ**) with pseudorotaxane **3ᴰᴿ**, and indication (red) of the expected **S**→**D** contraction by external pressure from the AFM tip and internal templation by blocker **2**.
β Sheets are given as solid (backbone) and dotted lines (hydrogen bonds, **1ᔆ**, **1ᴰ**, **3ᴰᴿ**) or as arrows (N→C, **1⊥**). External amino acid residues are shown in white circles, internal ones in dark circles (single-letter abbreviations).

These characteristics suggested that molecular recognition by synthetic multifunctional pores could be studied by AFM using barrel **1** and polymer **2**. The ability of polymer **2** to block pore **1** in lipid bilayers was confirmed by using methods described previously. The dose/response curve revealed an effective inhibitory concentration (IC$_{50}$) of 40 nM for a low-molecular-weight polymer **2**. This excellent molecular recognition was confirmed in AFM images of mixtures of pore **1** and blocker **2**. The ratio of bound to free barrels in the above example was 8:1 (Figure 2c); at higher polymer concentrations all the barrels were bound. On average, every second barrel was located at the end of the polymers (Figure 2c, e). Although the probability of observing pseudorotaxane motifs with barrels located more than half of the average polymer length from one terminus should decrease rapidly, the value was still far above the low number of end-on complexes expected for statistical ion pairing along the polymer template (Figure 2e). Under the studied conditions, excluding, for example, the experimentally inaccessible excess barrels, only a few examples with more than one barrel per polymer were found (see, for example, Figure 3, panels d1–d3 and c2).

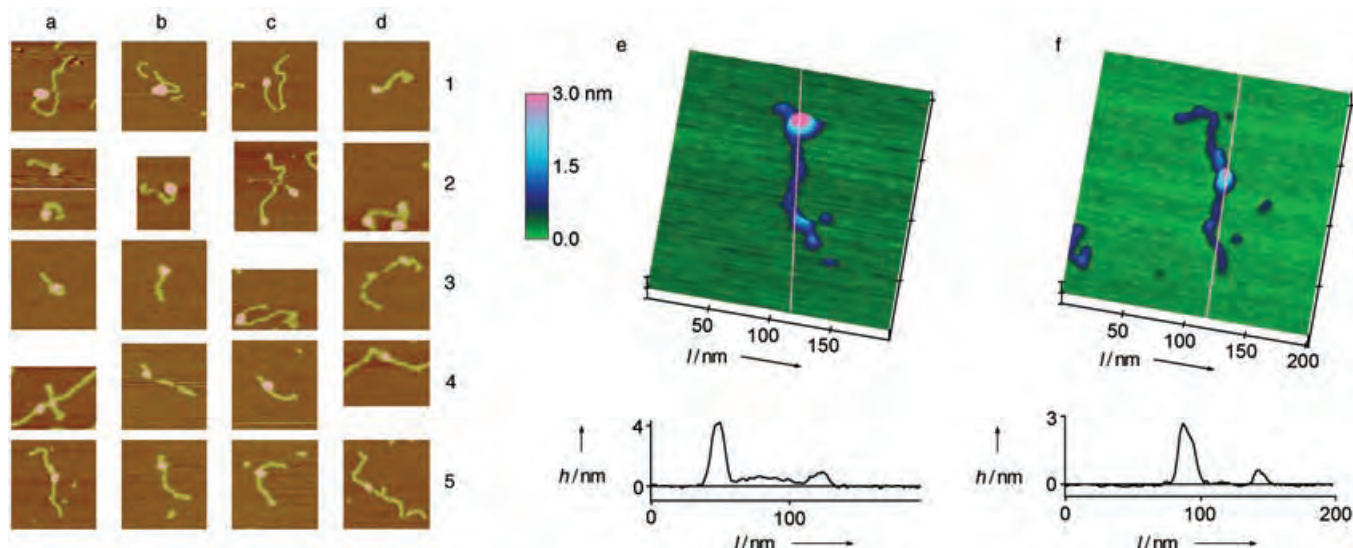
End-on preference over rotaxane motifs suggested that molecular recognition occurs within the hollow supramolecule and that it is strong enough to hinder the continuing motion of the sticky polymer through the barrel. Consistent with earlier results on blockage and catalysis[12] by synthetic multifunctional pores in bilayer membranes,[4] this result
Figure 2. AFM images of a) barrel **1**, b) polymer **2**, and c) **1** and **2** together with object heights indicated in nm. d) Collection of possible structures as a function of their object height. Detected motifs are shown in a solid box, possibly detected in a dotted box, and undetected without a frame. For **1**, **3**, $\perp$, **S** (square-like), **D** (diamond-like), and **R** (pseudorotaxane), see Figure 1; **E**: "end-on" complexes, **L**: "lateral" complexes, **C**: crossovers. e) 2D Histogram with the relative abundance *A* as a function of object height *h* and distance *l* from the nearest polymer terminus ($n=20$); red: eccentric barrel position, see Figure 3e.


Figure 3. Gallery of rotaxane and "end-on" motifs (a–d, arbitrary scales) with magnification and height profile for eccentric (e) and centered rotaxanes (f).

demonstrated that molecular recognition by synthetic multifunctional pores occurs by threading of the polymer guest through the barrel host to form supramolecular pseudorotaxane complexes 3^R. This key finding explained the absence of polyrotaxanes under the studied conditions (namely, more than two barrels per polymer; Figure 3, panels d1–d3 and c2).[5–11] Moreover, it excluded the existence of nonspecific interactions with monomeric rods and at the external barrel surface (that is, lateral complexes 3^{DL}, $3^{\perp L}$, and 3^{SL} as well as crossover motifs 3^{DC}, 3^{SC}, and $3^{\perp C}$, Figure 2d).

On average, barrels at the end of the polymer were clearly higher than barrels in the middle (Figure 2c, e). The height distribution of end-on objects 3^E implied that different conformers are likely to exist in different orientations relative to the mica surface (for example, vertical in $3^{\perp E}$, horizontal in 3^{DE}, and perhaps the square-type 3^{SE}, Figure 2d). The accumulation of pseudorotaxane motifs with low object height in the middle of the polymer (Figure 2e) excluded the existence of crossover motifs (3^{DC}, 3^{SC}, $3^{\perp C}$) as well as pseudorotaxanes with vertical ($3^{\perp R}$) and horizontal barrels in a square-type conformation (3^{SR}, Figure 2d). Pseudorotaxane 3^{DR} remained as the only meaningful suprastructure of the frequently found rotaxane-type objects with low height (Figure 2d).

The formation of pseudorotaxane 3^{DR} suggested that template effects[5–11] may contribute to molecular recognition by synthetic multifunctional pores. Namely, as a polymer guest **2** enters into an open pore 1^S, the square-type barrel 1^S may flip into the energetically higher local minimum of the diamond-type barrel 1^D to firmly bite into the internal thread. This experimental evidence for guest templation could, however, not be considered as unambiguous because contributions from the external pressure of the AFM tip to the low barrel width in most rotaxane motifs could not be excluded. However, optimizations of the average geometries obtained during the last 50 ps of a short molecular dynamics simulation revealed the separate local minima of the square- and diamond-shaped conformers of β barrels and of rotaxanes. The conformational change of the square- to diamond-shaped barrel was associated with a pronounced shrinkage of the rod–rod barrel width from 3.5 nm for 1^S to 1.8 nm in the optimized structure of 1^D. In the computed structure of the diamond-shaped rotaxane 3^{DR} (Figure 4), the rod–rod width
Figure 4. Fully optimized cutaway structures of diamond-shaped pseudorotaxane 3^{DR} in axial view (top, **2**: 20-mer, backbone in red) and in side view (bottom: **2**: 40-mer, Connolly surface in red). β Sheets are highlighted as arrows (green), p-octaphenyl groups as ball-and-stick models (silver); 100% phosphonate deprotonation, 100% K and 0% H protonation.

was also reduced to 2.2 nm. This finding corroborated the proposal of guest templation and was in agreement with the nonstatistical height distribution in the AFM images (Figure 2e). Similar guest templation has been observed in previous molecular dynamics simulations with α-helical blockers.[4]

The few rotaxane motifs observed with object heights exceeding the range of 2–3 nm expected for diamond-type pseudorotaxanes **3**^{DR} could not be interpreted convincingly (Figure 2e). The eccentric position of the barrel with respect to the polymer was consistent with lateral complexes **3**$^{\perp L}$ or **3**^{SL} (Figures 2d, 3e). The existence of nonspecific surface-to-surface association was, however, incompatible with the observed nonstatistical location of the barrel on the polymer. These infrequent rotaxane motifs with eccentric and high barrels may, therefore, be considered either as diamond-type pseudorotaxanes **3**^{DR} with imperfect barrel positioning or as an "accidental" detection of unfavored lateral complexes **3**$^{\perp L}$/**3**^{SL} at the single-molecule level without relevance to the average of the ensemble. The interpretation and significance of this exception—but not of the more important and unambiguous end-on preference and low-height pseudorotaxanes—deserve further reservation considering the low number of complexes observed as well as unexplored alternative conditions.

In summary, AFM snapshots of molecular recognition by synthetic multifunctional pores provide experimental evidence that the host–guest complexes formed between rigidrod β-barrel pore and polymer blockers are pseudorotaxanes. The nonstatistical location of the barrel on the polymer indicates that entry of the polymer into the pore is favored over the motion of the polymer through the sticky pore. Although the clearly different conditions call for cautious interpretation,[4] it can be considered as structural support for the possibility of blocker efflux through blocked, "blocker-selective" pores, a concept central to the understanding of synthetic multifunctional pores that has been verified previously at the functional level.[17] Predicted[4] and supported in silico, the nonstatistical object height distribution can be considered, with similar caution, as the so far elusive structural evidence for guest templation during molecular recognition by synthetic multifunctional pores.

Rapid Two-Directional Synthesis of the F–J Fragment of the Gambieric Acids by Iterative Double Ring-Closing Metathesis**

J. Stephen Clark,* Marc C. Kimber, Jerod Robertson, Christopher S. P. McErlean, and Claire Wilson

The gambieric acids A–D are potent antifungal agents, first isolated by Yasumoto and co-workers from a culture of the marine dinoflagellate *Gambierdiscus toxicus* (GII1 strain) collected near the Gambier Islands in French Polynesia (Scheme 1).[1] The structures of these complex fused poly-ether natural products and the relative stereochemistry of the

Scheme 1. The structures of the gambieric acids A–D.

trans-fused ring system (rings B–J) were determined by using NMR spectroscopic analysis in conjunction with mass-spectrometric analysis.[1b] Absolute stereochemical assignments were later established by NMR spectroscopic analysis of compounds obtained by derivatization as the Mosher ester followed by oxidative cleavage of the side chain attached to the J ring, and by functionalization of the carboxylic acid functionality by using a chiral anisotropic reagent.[1c]

The gambieric acids are potent and selective antifungal agents—they display significant activity against filamentous fungi but are inactive against yeasts—that exhibit up to 2000-fold higher activity against some fungi than amphotericin B in certain assays.[2] The gambieric acids are also cytotoxic, but they do not possess the significant neurotoxicity associated with most other large marine fused-polyether natural products, such as the brevetoxins, ciguatoxins, yessotoxins, and maitotoxins.[2] Interestingly, although the gambieric acids do not function as potent neurotoxins, gambieric acid A does inhibit binding of the brevetoxin B derivative PbTx-3 to site 5 of voltage-gated sodium channels of excitable membranes.[3]

The obvious synthetic challenges presented by the gambieric acids, coupled with their potent antifungal activity, make them alluring targets for total synthesis. Recently, elegant total syntheses of the related marine polyether natural products brevetoxin A,[4] brevetoxin B,[5] ciguatoxin CTX-3,[6] gambierol,[7] and gymnocin[8] have been reported. In contrast, there is a paucity of published work that concerns the synthesis of the polycyclic ether framework of the gambieric acids or even small subunits of these natural products.[9]

We recently initiated a program to synthesize the gambieric acids based on the ring-closing metathesis (RCM) methodology that we had developed to address the general problem of fused-polyether construction[10] and have recently described a concise synthesis of the A ring fragment of the gambieric acids by using copper-carbenoid chemistry.[11] To construct the full ten-ring polyether system of the gambieric acids, we intend to pursue a highly convergent synthetic strategy in which the target will be constructed by the union of a tetracyclic A–D fragment and a pentacyclic F–J fragment followed by final closure of the E ring. Retrosynthetic disconnection of the F–J fragment **I** by removal of the side chain (R[1]) and functional group interconversion suggests the enol ether **II** as an advanced precursor (Scheme 2). Scission of the F and J rings then leads to the tricyclic intermediate **III**, and removal of the acyclic ether substituents leads to the diol
Scheme 2. Retrosynthetic analysis of the F–J fragment of the gambieric acids.

IV. Removal of the methyl group and retrosynthetic dehydration then reveals the bis(enol ether) **V**, and scission of the G and I rings leads to the monocyclic intermediate **VI**, which corresponds to the H ring. The tetrahydropyran unit can then be straightforwardly disconnected through the diol **VII** to reveal D-glucal as the chiral-pool starting material.

The use of a two-directional double-RCM reaction twice in the synthetic sequence to construct the tetrahydropyran G and I rings simultaneously and then the nine-membered F ring and the six-membered F ring and the six-membered J ring simultaneously is intrinsic to the retrosynthetic analysis shown in Scheme 2. In the forward direction, this approach would involve double RCM of a bis(enol ether) **VI** and then hydroboration of the tricyclic product **V** to give the diol **VIII** after oxidative work-up (Scheme 3).[10a,e,12] The diol **VIII** would then be converted into the triene enol ether **III**; a second double two-directional RCM reaction would then deliver the pentacyclic F–J fragment to which the requisite side chain could be attached.

The anticipated strategy involves two-directional synthesis by iterative double simultaneous (as opposed to sequential) ring closure. Although there have been some early examples of two-directional synthesis, the potential of simultaneous two-directional homologation has only been fully appreciated within last decade.[13] Some of the most elegant examples of this approach have been reported by Schreiber and co-workers in connection with their syntheses of the polyol-containing natural products mycotycins and hizikimycin.[14] The implementation of a synthetic strategy that involves simultaneous two-directional homologation is attractive because such a reflexive approach can, in principle, improve the efficiency of both linear and convergent syntheses.[15] However, unless the target molecule is entirely symmetrical, it must be possible to perform reactions simulta-

neously at both ends of the molecule while being able to differentiate the termini at various stages along the synthetic route.

We have recently demonstrated that it is possible to construct tricyclic polyether fragments that possess a variety of ring sizes in good-to-excellent yield by performing simultaneous double ring construction by using RCM.[16] Substrates bearing enol ethers, allylic ethers, and alkynyl ethers or mixtures of these functional groups were employed as substrates for the double-RCM reactions. The objective of the investigation described herein was to demonstrate that the F–J fragment of the gambieric acids could be assembled by a two-directional approach, in which simultaneous double-RCM reactions are used twice, and that many of the other reactions used to assemble the pentacyclic unit could be performed in a simultaneous or sequential two-directional fashion.

The two-directional synthesis of the F–J fragment of the gambieric acids commenced with deacetylation of the commercially available triacetate **1** (Scheme 4). Conversion of the resulting D-glucal into ether **2** was accomplished by protection of the primary and proximal secondary hydroxy groups with a di-$tert$-butylsilylene group and benzylation of the remaining hydroxy group.[16,17] The enol ether **2** was then subjected to highly diastereoselective oxidation with dimethyldioxirane[18] and the resulting anomeric epoxide underwent ring opening with allylmagnesium chloride to give the alcohol **3** in good yield.[19] Swern oxidation followed by treatment of the resulting ketone with methyllithium at low temperature afforded the tertiary alcohol **4** in good yield and with a reasonable level of diastereocontrol (d.r. = 6:1). Subsequent removal of the di-$tert$-butylsilylene protecting group afforded the corresponding triol **5** in high yield, and sequential treatment of this triol with trifluoromethanesulfonic anhydride and triethylsilyl trifluoromethanesulfonate in the presence of 2,6-lutidine in a one-pot procedure gave the primary triflate with concomitant protection of the secondary hydroxy group. Introduction of the alkene side chain was then accomplished in a single operation by displacement of the

triflate group with the higher-order cyanocuprate, generated from vinyllithium (formed in situ by transmetalation from tri-n-butylvinylstannane) and copper(I) cyanide at low temperature,[20] and the diol **6** was obtained in good yield thereafter by desilylation of the secondary hydroxy site. The alkenyl side chain was also constructed by displacement of the triflate with lithium trimethylsilylacetylide followed by treatment of the alkyne product with fluoride and partial hydrogenation using the Lindlar catalyst in the presence of quinoline. The overall yield of the diol **6** obtained by using the less-direct route was similar to that obtained by using the higher-order cyanocuprate to displace the triflate directly. Diol **6** was then converted into the bis(alkynyl ether) **7** by using the one-pot alkynylation procedure developed by Greene and co-workers.[21] The alkynylation reaction was the first two-directional reaction in our synthetic sequence, and it is noteworthy that both alkynyl ethers were generated simultaneously in excellent yield and that the highly hindered tertiary alcohol underwent reaction cleanly.

The bis(enol ether) required for the first double-RCM reaction was prepared from the bis(alkynyl ether) **7** by using sequential carbocupration reactions (Scheme 5).[22] The first side chain was introduced by a completely regioselective addition of a homocuprate reagent at the less sterically encumbered alkynyl ether. An acetal-containing side chain was then installed by reaction of the remaining hindered alkynyl ether with an excess of the cyanocuprate generated from equimolar amounts of the Grignard reagent 1,3-dioxolan-2-ylethylmagnesium bromide and copper(I) cya-

nide.[23] The yields for both carbocupration reactions were
excellent and the exceptionally high level of regiocontrol
obtained during the first carbocupration reaction of the
sequence is remarkable.

The bis(enol ether) **8** was subjected to double RCM by
treatment with ruthenium catalyst **14**,[24] and the tricyclic
product **9** was obtained in excellent yield from this two-
directional ring-closure reaction (Scheme 5).[16] Double
hydroboration of the metathesis product **9** was accomplished
by using an excess of thexylborane, and mild oxidation of the
intermediate organoborane with sodium perborate delivered
the required diol in 62% yield.[25] Treatment of the diol with
para-toluenesulfonic acid in methanol yielded the tetracyclic
acetal **10** in excellent yield and resulted in differentiation of
the two secondary hydroxy groups. The free secondary
alcohol was then protected as its *tert*-butyldimethylsilyl
ether and the *para*-methoxybenzyl ether side chain was
cleaved with CAN. The resulting alcohol **11** was a crystalline
solid, and both the structure and relative stereochemistry of
this tetracyclic intermediate were confirmed by X-ray crys-
tallographic analysis.[26]

The alkene required for the second double-RCM reaction
was installed by dehydration of the side chain (Scheme 5).
Thus, the primary alcohol **11** was treated with *ortho*-nitro-

phenyl selenocyanate and tri-*n*-butylphosphine followed by
oxidation of the intermediate selenide with buffered hydro-
gen peroxide and thermal elimination of selenoxide in situ.[27]
Removal of the silicon protecting group afforded the alcohol
12, and subsequent oxidation and stereoselective addition of
methylmagnesium iodide to the intermediate ketone deliv-
ered the tertiary alcohol **13** in a highly diastereoselective
manner.

Acetal **13** was then elaborated to give the F–J ring
fragment of the gambieric acids by using the sequence shown
in Scheme 6. Acetal **13** was converted into the corresponding

cyclic hemiacetal by treatment with aqueous acid, and
subsequent reduction with sodium borohydride gave diol **15**.
Dehydration of the side chain was effected by formation of
selenide, oxidation, and elimination of selenoxide (cf. **11**→**12**,
Scheme 5), but protection of the secondary alcohol was not
required in this case. Selective monoalkylation of the
secondary hydroxy group of diene **16** was accomplished by
sequential treatment with sodium hydride and 5-bromo-1-
pentene in the presence of tetra-*n*-butylammonium iodide.
The remaining hydroxy group of triene **17** was then converted
into the requisite vinyl ether by sequential alkynyl ether
formation and Lindlar reduction,[16] thus giving the second
double-RCM precursor **18** in reasonable yield. The final
crucial double-RCM reaction to give the required nine- and
six-membered cyclic ethers was then effected by treatment of
the tricyclic compound **18** with the ruthenium complex **14**.[24]
The pentacyclic array **19**, which corresponds to the F–J ring
fragment of the gambieric acids, was obtained from the
reaction in 60% yield. Analysis of partially cyclized material
isolated from the reaction suggested that ring closure of the
enol ether proceeds at a much faster rate than formation of
the nine-membered ring.

In summary, we have demonstrated that the F–J fragment of the gambieric acids can be assembled by a rapid and efficient two-directional approach in which simultaneous double-RCM reactions are employed in an iterative manner. The formation of alkynyl ethers and carbocupration have also been performed in a two-directional manner, and it should be noted that by reordering some of the steps in the synthetic sequence, other reactions (e.g., the formation of selenide, oxidation, and elimination of selenoxide) could also be performed simultaneously, thus leading to an even more efficient route. The synthesis of the F–J fragment with the appropriate functionalities for the attachment of the A–D fragment is currently in progress, and results of these synthetic studies will be reported in due course.

Direct Synthesis of a Thiolato-S and Sulfinato-S Co^{III} Complex Related to the Active Site of Nitrile Hydratase: A Pathway to the Post-Translational Oxidation of the Protein**

*Emilie Bourles, Rodolphe Alves de Sousa,
Erwan Galardon, Michel Giorgi, and Isabelle Artaud**

A group of sulfur-oxidized species found in biological systems includes sulfenic, sulfinic, and sulfonic acids derived from cysteine.[1,2] Currently "sulfur-oxidized" proteins are known to carry only one type of modification at a time, except for nitrile hydratase (NHase), which is the only system known to contain thiolate, sulfenate, and sulfinate groups in close proximity through coordination to a metal center.[3] Despite

intense studies,[4] the origin of the post-translational modification of NHase remains unclear. The prevalent hypothesis for cysteine sulfur oxidation involves a two-step reaction in which iron or cobalt is bound by the protein ligands within the consensus sequence Cys-X-Y-Cys-Ser-Cys. This results in the formation of an $[Fe(N_2S_3)]^{2-}$ or a $[Co(N_2S_3)]^{2-}$ species which is followed by oxidation of the two bound thiolate groups in the equatorial plane *trans* to two deprotonated amides to give sulfinate and sulfenate. The design of all models synthesized to mimic the NHase active site follows this hypothesis.[5] The result is that only a few iron[6] or cobalt[7,8] complexes show dissymmetrically oxidized thiolate groups, and most of these contain two sulfinate groups irrespective of whether the oxidant used is O_2,[5,9–11b] H_2O_2,[5,11c,d] or dimethyl dioxirane.[11a] This prompted us to find another route to prepare a dissymmetrically oxidized complex. Herein, we describe a new and simple strategy toward mixed thiolate/sulfinate complexes which involves the metalation of a thiosulfinate following cleavage of the S–S bond with HO⁻. By using a cyclic pseudopeptidic thiosulfinate, we prepared and structurally characterized a six-coordinate Co^{III} bisamidato/thiolato/sulfinato complex with two axial isonitrile ligands. This enables us to propose an alternate pathway for the post-translational modification of the cysteine residues in NHase, thus extending the implication of disulfide *S*-oxides, a second emerging group of sulfur-oxidized species, in biological systems.[2]

The cyclic disulfide *S*-monoxide **3** shown in Scheme 1 was synthesized in two steps from dithiol **1**, which was previously used to prepare both dithiolato $[CoN_2S_2](Et_4N)$ and disul-
Scheme 1. Synthesis and Co metalation of a cyclic thiosulfinate. DMD = 2,2-dimethyl dioxirane, DMF = *N,N*-dimethyl formamide.

finato $[CoN_2(SO_2)_2(tBuNC)_2](Et_4N)$ complexes.[11a] Oxidative cyclization of dithiol **1** with iodine in the presence of triethylamine[12] afforded the cyclic disulfide **2**. Oxidation of **2** with 1 equivalent of 2,2-dimethyl dioxirane (DMD) in acetone at −20 °C afforded the thiosulfinate **3** selectively and in high yield.

Thiosulfinates are very sensitive to nucleophiles, which cleave the S(O)–S bond, and nucleophilic attack can occur at the sulfenyl or sulfinyl sulfur atom.[13] However, alkaline

hydrolysis of thiosulfinate has been described as quite selective for sulfinyl sulfur to afford a thiolate and a sulfinate as the predominant products [Eq. (1), route (a)].[13a] We used

$$R-\overset{\overset{\displaystyle O}{\|}}{S}-S-R \ + \ 2\,OH^- \ \underset{(b)}{\overset{(a)}{\diagup\!\!\diagdown}} \ \begin{array}{l} RSO_2^- \ + \ RS^- \ + \ H_2O \\[4pt] 2\,RSO^- \ + \ H_2O \end{array} \qquad (1)$$

a combination of alkaline hydrolysis of compound **3** and metalation with a Co[III] salt, Na$_3$[Co(NO$_2$)$_6$], to trap the open species. Incorporation of a Co[II] salt followed by a single-electron oxidation with 2,3-dichloro-5,6-dicyano-1,4-benzo-quinone is also possible, but the final purification of the complex is very tedious. This is why the use of the new hexanitritocobalt(III) sodium salt is much more convenient. Typically, the addition of 2 equivalents of Et$_4$NOH to a solution of **3** in DMF at $-40\,°$C is followed by 1 equivalent of the Co[III] salt. At this stage, the amide nitrogen atoms are likely coordinated in their imine tautomer form. After the addition of *tert*-butylisocyanide in excess, two other base equivalents are required to deprotonate the amides. The final complex is stable as a six-coordinate species with two isonitrile groups as axial ligands as previously observed for the disulfinate complex.[11a]

Complex **4** (Scheme 1) was thoroughly characterized. All the spectroscopic data are in agreement with a dissymmetrical thiolate/sulfinate structure, [CoN$_2$S(SO$_2$)(*t*BuNC)$_2$](Et$_4$N), with an S-bonded sulfinate, as in Co-NHase.[3b] There is no evidence for a disulfenate species resulting from the cleavage of the S(O)–S bond by HO$^-$ group attack at the sulfenyl sulfur atom [Eq. (1), route (b)]. The IR spectrum of **4** (Supporting Information) exhibits the two SO$_2$ stretching frequencies expected for an S-bound sulfinate at 1185 ($\tilde{\nu}_{as}$(SO$_2$)) and 1047 cm^{-1} ($\tilde{\nu}_s$(SO$_2$)). There is no strong absorption around 950 cm^{-1} that could be attributed to the stretching frequency of a disulfenate species.[11c] ESI MS (negative ion) analysis of **4** shows a molecular peak at $m/z = 426.9$, which corresponds to the mass of the anion of **4** with loss of the two isonitrile axial ligands. Further MS–MS analysis of this peak gives a daughter peak at $m/z = 363.1$ resulting from the loss of SO$_2$. As with all six-coordinate Co[III] complexes in this series, **4** is diamagnetic. In contrast to the previously characterized [CoN$_2$(SO$_2$)$_2$(*t*BuNC)$_2$](Et$_4$N) species, which is completely symmetrical and exhibits only one resonance in its ^{1}H NMR spectrum for the methyl groups and another for the CH$_2$ protons,[11a] both the methyl and the CH$_2$ protons of **4** are split and each appears at two different chemical shifts. The cyclic voltammogram of **4** in CH$_3$CN with NBu$_4$BF$_4$ as supporting electrolyte exhibits an oxidation step at $+510$ mV versus standard calomel electrode (SCE). This oxidation wave is located between that observed for [CoN$_2$-(SO$_2$)$_2$(*t*BuNC)$_2$](Et$_4$N) ($E_{pa} = +640$ mV (vs. SCE)) and [CoN$_2$S(*t*BuNC)$_2$](Et$_4$N) ($E_{pa} = +390$ mV (vs. SCE)).[11a] The anodic shift is about 125 mV for each addition of two oxygen atoms. The same trend has been observed upon sequential thiolate oxygenation of Ni complexes.[14]

The dissymmetry of the coordination sphere is further supported by the crystal structure of the anion of **4** (Figure 1)
Figure 1. Thermal ellipsoid plot (50% probability level) of the anion of **4**. The hydrogen atoms, countercation, and solvent molecules have been omitted for clarity. Only one anionic enantiomer is shown. Selected bond lengths [Å]: Co2–C43 1.872(4), Co2–C48 1.870(4), Co2–N5 1.980(3), Co2–N6 1.997(3), Co2–S3 2.2205(11), Co2–S4 2.2505(12), S3–O8 1.463(4), S3–O9 1.467(4), N7–C43 1.143(5), N8–C48 1.142(5). Selected bond angles [°]: C48-Co2-C43 177.31(18), C48-Co-N5 89.84(15), C48-Co2-N6 87.55(15), C43-Co2-N6 92.60(15), C43-Co2-N5 92.84(15), N5-Co2-N6 81.90(13), N5-Co2-S3 95.53(10), N5-Co2-S4 178.63(10), N6-Co2-S4 96.87(10), O8-S3-O9 113.9(2).

and by comparison with the disulfinate complex.[11a] The Co[III] center exhibits an octahedral geometry as does the disulfinate complex, but with one thiolate group and one S-bonded sulfinate group *trans* to the two carboxamido nitrogen atoms in the equatorial plane. The Co–S distances show significant variation (2.221–2.259 Å), which underscores the inequivalence of the two sulfur sites; these distances are almost equal in the disulfinate complex owing to the equivalence of the sulfur atoms. Whereas ^{1}H NMR analysis reveals a plane of symmetry in solution, the aromatic ring and the lateral chains relating N5 to S3 and N6 to S4 are on either side of the N$_2$S$_2$ plane, and the molecule is asymmetrical in the solid state. This can be related to the fact that the complex crystallizes with two enantiomers in the asymmetric unit (Experimental Section). The crystal structure of **4** also reveals the presence of hydrogen bonds between the co-crystallized water molecules and the oxygen atoms of the amides and one sulfinate, as previously observed in the crystal structure of the disulfinate complex.

Our results show that cyclic pseudopeptidic thiosulfinates can be efficiently trapped by a metallic cation under basic conditions. The alkaline cleavage occurs upon reaction of HO$^-$ at the sulfinyl sulfur atom to give the selective formation of the thiolate/sulfinate complex. As in other six-coordinate Co[III] complexes,[9,11] the sulfinate has a strong preference for a

sulfur-to-cobalt binding mode. Clearly, this is the only route to selectively prepare such a complex, as H_2O_2 oxidation of the dithiolate $[CoN_2S_2(tBuNC)_2](Et_4N)$ affords a mixture of sulfur-oxygenated species, whereas DMD oxidation gives the S-bonded disulfinate complex.[11a] Such a reaction could be biologically relevant and could probably be extended to alkaline hydrolysis and metalation of cyclic pseudopeptidic thiosulfonates. Disulfide S-dioxides are much more sensitive to nucleophiles such as oxy anions than are disulfide S-monoxides; their alkaline hydrolysis has been described as selective for the sulfenyl sulfur atom [Eq. (2), route (a)].[13]

$$R-\overset{O}{\underset{O}{\overset{\|}{S}}}-S-R \ + \ 2\,OH^- \underset{(b)}{\overset{(a)}{\diagup}} \begin{array}{l} RSO_2^- + RSO^- + H_2O \\ \\ RSO_3^- + RS^- + H_2O \end{array} \qquad (2)$$
The higher selectivity of thiosulfonates towards hydrolysis relative to thiosulfinates results from the fact that the sulfenyl sulfur is much more readily accessed than is the sulfonyl sulfur, and from the fact that a sulfinate is a better leaving group than a thiolate.[13]

X-ray analysis of both Fe- and Co-NHases,[3] as well as enzymatic inhibition studies[4c] support the presence of a sulfenate group in the metal environment of NHase. Moreover, a Co complex with two S-bonded sulfenates has been shown recently to promote nitrile hydration.[11d] With the aim of isolating a mixed sulfinate/sulfenate complex, the reactivity of **4** toward oxidants was studied. The products were identified by ^1H NMR spectroscopy. Oxidation of **4**, even at low temperature and with less than 1 equivalent of H_2O_2 or DMD, provides the previously isolated S-bonded disulfinato species, either alone or as a mixture with the starting product.[11a]

On the basis of our results with a thiosulfinate, we can propose an alternate pathway for the specific thiolate oxidation of NHases into sulfinate and sulfenate species (Scheme 2). This sequence involves a post-translational modification of the protein prior to metal insertion as follows: the two cysteine residues of the consensus sequence that are

Scheme 2. Alternate pathway to the post-translational oxidation of nitrile hydratase.

separated by a serine residue are initially oxidized to a disulfide, then to a disulfide S-dioxide. This is followed by alkaline hydrolysis and then by iron or cobalt insertion. A selective HO^- attack at the sulfenyl sulfur should directly afford the mixed sulfenate/sulfinate in the mean plane of the active site. Indeed, there is now clear evidence that disulfide S-oxides have important biological implications.[2] Their production is either mediated by reactive oxygen, nitrogen species generated under oxidative stress conditions,[2] or catalyzed by monooxygenases[15a] or dioxygenases.[15b] These disulfide oxides, mainly studied as their glutathione derivatives, lead to (gluta)thionylation of proteins or metallothionein by reaction of the free or zinc-bound cysteinate group at the sulfenyl sulfur atom of the disulfide S-oxide.[16] We suggest that these disulfide oxides might also result from a post-translational oxidation of proteins, with NHase possibly being the first example. Finally, we have shown that the reactivity of disulfide S-oxides is not limited to reaction with thiolates in proteins, but that they can also react with metallic cations after hydrolytic cleavage of the S–S bond. A more complete study of such reactions of thiosulfinates and thiosulfonates is in progress.

Experimental Section

All procedures were carried out under argon with standard Schlenk techniques. Solvents were dried following standard procedures and stored under argon.

3: Elemental analysis (%) calcd for $C_{16}H_{22}N_2O_3S_2 \cdot 0.33\,H_2O$ (360.49): C 53.31, H 6.34, N 7.77; found: C 53.50, H 6.21, N 7.48. ^1H NMR (250 MHz, CDCl$_3$): $\delta = 1.52$ (s, 3H), 1.63 (s, 3H), 1.67 (s, 3H), 1.79 (s, 3H), 2.66–2.74 (m, 2H), 2.92–2.99 (m, 2H), 7.23 (m, 2H), 7.41 (m, 2H), 8.02 (s, 1H), 8.33 ppm (s, 1H). IR (neat): $\tilde{v} = 3253$ (N–H), 1665 (C=O), 1069 cm^{-1} (S=O).

4: The sodium hexanitrocobaltate(III) salt is not soluble in DMF, but a solution was prepared as follows: DMF (3 mL) and trimethylorthoformate (10 mL) as a dehydrating agent were added to an aqueous solution (1.5 mL) of Na$_3$[Co(NO$_2$)$_6$] (114 mg, 0.282 mmol). After stirring for 30 min, excess orthoformate as well as CH$_3$OH and HCOOCH$_3$ (products derived from the reaction of HC(OMe)$_3$ with H$_2$O) were removed under controlled vacuum to prevent the complete evaporation of DMF. Then, Et$_4$NOH (1.4M in MeOH, 405 μL, 2 equiv) and the Co^{III} solution were added to a solution (2 mL) of **3** (100 mg, 0.282 mmol) in DMF at −40°C. After stirring for a few minutes, a large excess of tBuNC (1 mL in 1 mL DMF) and 2 further equivalents of Et$_4$NOH (405 μL) were added to the mixture. The solution was then allowed to warm to room temperature. After evaporating to dryness in vacuo, the residue was dissolved in CH$_3$CN (1 mL) and a powder containing **4**, NaNO$_2$, and Et$_4$NNO$_2$ was isolated upon precipitation with Et$_2$O. This powder was dissolved in acetone (2 mL) and nitrite salts were removed through careful precipitation by dropwise addition of Et$_2$O. After centrifugation, the supernatant was slowly poured into Et$_2$O while stirring to afford **4** as a brown powder. Yield: 130 mg (60%). Crystals suitable for X-ray crystallographic analysis were grown by diffusion of Et$_2$O into a CH$_3$CN solution of **4**. Elemental analysis (%) calcd for $C_{34}H_{58}CoN_5O_4S_2 \cdot 3\,H_2O$ (777.96): C 52.49, H 8.29, N 9.00; found: C 52.77, H 8.17, N 9.29. ^1H NMR (250 MHz, CD$_3$CN): $\delta = 1.01$ (m, 12H, CH$_3$), 1.15 (s, 6H, CH$_3$), 1.3 (s, 18H, tBuNC), 1.39 (s, 6H, CH$_3$), 2.55 (s, 2H, CH$_2$), 2.69 (s, 2H, CH$_2$), 2.95 (m, 8H, CH$_2$, Et$_4$N), 6.54 (m, 2H$_{ar}$), 7.94 ppm (m, 2H$_{ar}$). IR (neat): $\tilde{v} = 2200$ (C≡N), 1538 (C=O), 1185 and 1047 ($\tilde{v}_s$ and $\tilde{v}_{as}$ SO$_2$), 1173, 1002 cm^{-1} (Et$_4$N$^+$). Cyclic voltammetry (vs. SCE, nBu$_4$NBF$_4$ (0.1M), 20 mV s^{-1}, CH$_3$CN): $E_{pc} = -1860$ mV, $E_{pa} = +510$ mV. FAB MS (positive ion): m/z (%) = 853.39 (100) {[CoN$_2$S-
$(SO_2)(tBuNC)_2](Et_4N)_2\}^+$; ESI MS (negative ion): m/z (%) = 426.9 (40) $[CoN_2S(SO_2)]^-$, 363.1 (100) $[M-SO_2]^-$.

Crystal data for complex **4**: $(C_{26}H_{38}CoS_2O_4N_4)_2(C_8H_{20}N_2)_2(C_2H_3N)_2(H_2O)_3$, $M_w = 1583.96$, pale-yellow crystal ($0.6 \times 0.4 \times 0.15$ mm³), triclinic, space group $P\bar{1}$, $a = 11.727(4)$, $b = 20.031(9)$, $c = 20.614(9)$ Å, $\alpha = 116.804(2)°$, $\beta = 90.384(3)°$, $\gamma = 95.913(3)°$, $V = 4291.3(3)$ Å³, $Z = 2$, $\rho = 1.226$ g cm⁻³, $\mu(Mo K_\alpha) = 5.43$ cm⁻¹, $T = 223$ K, $\theta = 1.18–28.62°$. 47 639 reflections measured at on a Bruker–Nonius Kappa CCD diffractometer, 20 515 unique reflections, 946 parameters refined on F^2 (20 515 reflections) using SHELXL-97 to final indices $R[F^2 > 4\sigma(F^{2)}] = 0.099$, $wR = 0.149$ [$w = 1/[\sigma^2(F_o^2) + (0.0001P)^2 + 12.4629P]$ in which $P = (F_o^2 + 2F_c^2)/3$]. Compound **4** crystallized as two independent anionic monomers in the asymmetric unit, with two Et₄N cations, two molecules of acetonitrile, and three water molecules. The anionic moiety was found to be a disordered mixture of two isomers corresponding to the two possible sulfur oxidation sites that afford sulfinates. The refinement was therefore carried out by considering two positions for the sulfinate group on each monomer: the occupancy factors for both the oxygen atoms of the sulfinate group were fixed to 0.8 and 0.2 on the two sites for the first monomer and to 0.2 and 0.8 on the two sites for the second monomer. Most of the H atoms, including one hydrogen of one water molecule, were found experimentally. The remaining H atoms (excluding those on the water molecules) were introduced in theoretical positions. They were all included in the calculations but not refined. The final residual Fourier positive and negative peaks were equal to 0.91 and -0.804 e Å⁻³, respectively. CCDC-262627 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Tetraarylphosphonium Halides as Arylating Reagents in Pd-Catalyzed Heck and Cross-Coupling Reactions**

Lee Kyoung Hwang, Youngim Na, Junseong Lee, Youngkyu Do, and Sukbok Chang*

Transition-metal-catalyzed olefination and cross-coupling reactions have become one of the most powerful tools in organic synthesis.[1] While aryl, alkenyl, alkynyl, and, more recently, alkyl halides are typically employed as coupling reagents, a variety of different types of pseudohalide species have been also investigated as useful electrophiles. Among these, representative recent examples are carboxylic acids,[2] acid anhydrides,[3] aryl esters,[4] sulfonates,[5] phosphonic acids,[6] sulfonium ions,[7] and ammonium salts.[8] Although metal-mediated C–P bond cleavage of organophosphorus species was previously investigated,[9] the use of such compounds in cross-coupling reactions has been relatively underdeveloped. Yamamoto and co-workers suggested that quaternary phosphonium iodide ($Ph_4P^+I^-$) oxidatively adds to Pd^0 complexes through P-aryl bond cleavage and they showed briefly that one phenyl group was transferred to react with activated olefins, although in low yields (32–36%).[10] Reetz et al. reported that the efficiency of the Heck reaction with normally unreactive aryl halides was significantly improved by the presence of phosphonium halides.[11] Additionally, several research groups described mechanistic details for the observed aryl–aryl interchange process between phosphinyl- and Pd-bound aryl groups in cross-coupling reactions that relied on the composition of the products[12] and theoretical considerations.[13] Herein, we describe our recent studies on the utility of tetraarylphosphonium halides as arylating reagents in Heck and cross-coupling reactions, as well as providing spectroscopic details on the activation process.[14]

At the outset of our studies, we attempted to optimize the reaction conditions for the Pd-catalyzed olefination reaction using tetraarylphosphonium ions. When tetraphenylphosphonium chloride (**1**) was treated with *n*-butyl acrylate (3.0 equiv) in the presence of $Pd(OAc)_2$ (10 mol%) and sodium acetate (3.0 equiv), *n*-butyl *trans*-cinnamate was isolated in 85% yield [Eq. (1)], which thus clearly suggested that the C–P bond of **1**

is activated catalytically in agreement with the previous report.[10] We envisioned that the employment of electrospray ionization mass spectrometry (ESI-MS) could lead us to trace the activation process because it allows facile detection of highly unstable and/or sensitive metal-containing intermediates.[15]

$$Ph_4P^+ Cl^- + \overset{}{\diagup}CO_2Bu \xrightarrow[\substack{DMF,\ O_2 \\ 130\ ^\circ C,\ 12\ h}]{\substack{Pd(OAc)_2 \\ (10\ mol\%) \\ NaOAc}} Ph\diagdown\diagup CO_2Bu \qquad (1)$$

(**1**)   (85%)

When **1** was treated with 0.5 equivalents of $[Pd_2(dba)_3]$ (dba = *trans,trans*-dibenzylideneacetone) at 100°C, a set of ion peaks were detected in the ESI-mass spectra which were attributed to transient metal species resulting from the activation of the P–phenyl bond of **1** (Figure 1). It was observed that a dba ligand in the complex was gradually displaced by acetonitrile to give a series of peaks for $[(PPh_3)_2PhPd(CH_3CN)_m]$ ($m = 1$–3) at the expense of phosphonium ion (Figure 1, all m/z values are reported on the basis of the ^{106}Pd isotope).[16] When $Pd(OAc)_2$ was employed instead of $[Pd_2(dba)_3]$, the activation process occurred more slowly and the corresponding peaks started to appear only after a few hours under the same conditions. The fact that a complex of Pd^0 is more active than a Pd^{II} species for the activation is in a good agreement with the generally accepted assumption that Pd^{II} precursors are reduced initially into Pd^0 complexes, which are catalytically active in most cross-coupling reactions.[17]

Pd-mediated cleavage of the P–C bond of tetraarylphosphonium ions was further supported by the isolation and characterization of an oxidatively inserted palladium species. When $Ph_4P^+Cl^-$ (**1**) was treated with 0.5 equivalents of $[Pd_2(dba)_3]$ in the presence of PPh_3, a transparent solid **2** was isolated (54%) that revealed a square-planar geometry with two triphenylphosphine groups positioned *trans* to each other (Figure 2). The bond lengths and angles of **2** are within comparable range of those previously reported, although the same palladium species was prepared starting from a different precursor by a ligand-exchange method.[18] When the isolated Pd complex **2** was treated with *n*-butyl acrylate,[19] reaction occurred readily in the presence of sodium acetate at temperatures over 80°C to afford butyl cinnamate in 55%.[20] This result led us to postulate that phosphonium species play a dual role, as a source of the arylating group and as a stabilizing ligand on palladium complexes, upon release of phosphine from the phosphonium ions.

During the course of optimization of the conditions for olefination with phosphonium halides, it was found that higher yields (ca. 20%) were obtained when the reaction was carried out under atmospheric oxygen relative to those performed under N_2.[21] It is thought that oxygen oxidizes liberated triphenylphosphine into its oxide, thus driving the reaction to completion more readily. Indeed, a side product of triphenylphosphine oxide was seen to be generated (>80%) during the olefination reaction under an O_2 atmosphere

[Eq. (1)]. Whereas sodium acetate turned out to be most effective of the various bases examined, it was interesting to observe that olefination proceeds even in the absence of an external base, albeit with moderate yields (53% from the reaction of Equation (1) under such conditions).[22] Additionally, the efficiency of the reaction was dependent on the nature of the counteranions of the phosphonium salts [Eq. (2)]. Whereas reactions with phosphonium species that bear chloride ions gave the highest yield, other halide salts such as bromide and iodide resulted in reduced yields. However, upon addition of LiCl (2.0 equiv) in a reaction with Ph$_4$P$^+$Br$^-$, the efficiency was recovered to the same level as with Ph$_4$P$^+$Cl$^-$.

Under the optimized conditions, the olefination of **1** was examined with a range of alkenes (Table 1).[23] Whereas reactions with acrylic esters, amides, vinyl sulfone, and vinyl phosphonate proceeded efficiently to afford the corresponding olefinated products exclusively in the *E* form, olefination with acrylonitrile produced cinnamonitrile with modest

effects on efficiency, several functional groups were tolerated under the reaction conditions. As demonstrated in entry 9, a boronic ester derived from catechol was also employed as an efficient coupling partner with **1**. Although the exact reason is not clear at present, the effect of oxygen observed in the Heck olefination was not observed in case of Suzuki and Sonogashira reactions (see below).[25]

In the Sonogashira-type reaction, tetraarylphosphonium halides were also readily employed as efficient arylating reagents with a wide range of alkynes (Table 3). In a similar

manner as observed in Heck and Suzuki reactions, the alkynylation was not significantly affected by aryl substituents. Note that coupling of **1** with 1-phenyl-2-(trimethylsilyl)-acetylene, an internal alkyne, was also carried out efficiently (98% yield) when 1,3-bis(2,4,6-trimethylphenyl)imidazolium chloride was employed as an additive (10 mol%).

When differently substituted tetraarylphosphonium halides[26] were used in olefinations, a selective aryl transfer was

not observed [Eq. (3)]. Independent of the electronic nature of the aryl substituents, a mixture of unsubstituted (major) and substituted cinnamates (minor) were produced with a ratio of 3–4:1. The rather statistical aryl transfer in the Heck olefination was also observed in Suzuki and Sonogashira reactions. These results can be presumably attributed to fast aryl–aryl interchange processes between phosphinyl- and Pd-bound aryl groups that are generated upon cleavage of the C—aryl bond of the heterogeneously substituted phosphonium species.

$$Ph_3P^+\!-\!Ar \ I^- + \ \diagup\!\!\diagdown CO_2Bu \longrightarrow Ar'\diagdown\!\!\diagup CO_2Bu \quad (3)$$

Ar = 4-MeO-C_6H_4 (66%) Ph / Ar = 3.6:1

4-Ac-C_6H_4 (64%)   3.9:1
In summary, conditions have been optimized for the Pd-catalyzed reactions of tetraarylphosphonium halides with olefins, organoborons, and alkynes that demonstrate the utility of the phosphonium species as facile arylating reagents. Characterization of reaction intermediates by ESI mass spectrometry and X-ray crystallography add important knowledge to the Pd-mediated activation pathway of the C—P bond of phosphonium precursors.

[18] A. Mentes, R. D. W. Kemmitt, J. Fawcett, D. R. Russeli, *Polyhedron* **1999**, *18*, 1141.

[19] It was reported that some [ArPdCl(PPh$_3$)$_2$] complexes react with olefins in the presence of Et$_3$N as base; see: a) H. A. Dieck, R. F. Heck, *J. Am. Chem. Soc.* **1974**, *96*, 1133; b) C.-M. Andersson, A. Hallberg, G. D. Daves, *J. Org. Chem.* **1987**, *52*, 3529.

[20] Amatore et al. established that acetate ions substitute the iodide ion from [PhPdI(PPh$_3$)$_2$] to afford [PhPd(OAc)(PPh$_3$)$_2$], which is determined to be an essential intermediate in the Heck reaction; see: C. Amatore, E. Carré, A. Jutand, M. A. M'Barki, G. Meyer, *Organometallics* **1995**, *14*, 5605.

[21] Although the intermediate [Pd^0(PPh$_3$)$_2$] species that is generated at the end of the catalytic cycle is known to be very sensitive to oxygen,[1] the present results suggest that its oxidative addition with the phosphonium salts might be faster than its reaction with oxygen. We thank one reviewer for indicating this.

[22] One reviewer suggested that triphenylphosphine, which is liberated during the reaction, may serve as a base, although the same role by chloride ion cannot be ruled out at present.

[23] Although the reported yields were obtained from reactions with Pd(OAc)$_2$ catalyst (10 mol%), use of [Pd$_2$(dba)$_3$] (5 mol%) resulted in almost comparable results.

[24] When tetra-*p*-tolylphosphonium chloride was employed, *n*-butyl *trans*-3-(4-methylphenyl)acrylate was obtained in 99% yield.

[25] Suzuki and Sonogashira reactions under oxygen atmosphere afforded significantly lower yields relative to those obtained under N$_2$; see the Supporting Information for details.

Highly Diastereoselective Alkylation of Aziridine-2-carboxylate Esters: Enantioselective Synthesis of LFA-1 Antagonist BIRT-377**

*Aniruddha P. Patwardhan, V. Reddy Pulgam, Yu Zhang, and William D. Wulff**

Aziridines are important synthons in organic chemistry as they provide convenient entry to optically pure amines, α-amino acids, amino alcohols, diamines, and a variety of other amino compounds that are useful both in industrial and academic endeavors. In the past, most optically pure aziridines were derived from acyclic members of the chiral pool, however, methods are emerging for the direct synthesis of optically pure aziridines through catalytic asymmetric reactions.[1] We have developed a process for the catalytic asymmetric synthesis of aziridines from the reaction of benzhydryl imines with diazo compounds mediated by a chiral boron Lewis acid prepared from the VAPOL and VANOL ligands.[2–4] This asymmetric aziridination (AZ) proved general for a range imines including those prepared from a variety of aryl aldehydes and also from primary, secondary, and tertiary aliphatic aldehydes (90–99% *ee*). Much lower enantioselectivities were observed with *N*-benzyl imines.[2d]

α-Amino acids which are tetrasubstituted at the α-carbon are very popular tools that are used to control conformation in peptides, and hence their biological and pharmaceutical properties. A large number of methods have been developed for the synthesis of tetrasubstituted α-amino acids, and this subject has been reviewed.[5] Interestingly, aziridines have rarely been used for the synthesis of tetrasubstituted α-amino acids and this may be partly due to the fact that the alkylation of aziridine-2-carboxylates is virtually an unknown reaction. Typically, attempts to alkylate aziridine-2-carboxylate esters leads to either ring opening or to self-condensation.[6,7] The only known examples involve the use of either thioesters of aziridine-2-carboxylates[6] or the use of a nitrogen substituent on the aziridine that can chelate a metal enolate.[7]

A direct application of the AZ reaction to the synthesis of tetrasubstituted α-amino acids could be envisioned through the asymmetric aziridination of imine **1** with diazo compound

4 followed by the reductive opening of the aziridine ring (route a, Scheme 1). However, we found that substituted diazoesters of the type **4** ($R^2 \neq H$) are sluggish substrates in the AZ reaction. Thus route B, which involves the less readily available and sterically hindered diazo compound **4**, is not viable. Herein, we report the development of an alternative method (route A, Scheme 1) that utilizes commercially available ethyl diazoacetate and a subsequent stereoselective alkylation of an aziridine-2-carboxylate. This strategy has led to the first examples of alkylations of aziridine-2-carboxylate esters with noncchelating N substituents. The synthetic utility of the sequential AZ reaction and aziridine alkylation is illustrated in the asymmetric catalytic synthesis of the leukointegrin LFA-1 antagonist BIRT-377.[8]

Aside from thioesters,[6] the only known examples of aziridine-2-carboxylate alkylations employ a 2-methoxy-1-phenylethyl substituent on nitrogen to stabilize the metal enolate intermediate.[7] Thus it was not clear if the desired alkylation of **3** to **5** would be feasible. Indeed, initial attempts to alkylate the aziridine **3a** with methyl iodide met with failure. Both the lithium and potassium amides of hexamethyldisilazane failed to deprotonate aziridine **3a**. Methylation was successful with lithium diisopropy-

lamide (LDA). The optimal conditions involved the treatment of **3a** with 2.0 equivalents of LDA at −78°C followed by addition of 3 equivalents of methyl iodide, and then allowing the reaction mixture to warm to room temperature to give **5a** in 82% yield (1.1 equiv of LDA gave a 48% yield of **5a**). We screened the reactions in Table 1 with a mixture of DME (1,2-dimethoxyethane) and diethyl ether (5:1) as solvent,[7] but have subsequently found that comparable yields of **5a** can be achieved with either DME (79%) or THF (85%). Interestingly, the use of diethyl ether led to a complicated reaction mixture with the formation of only a trace amount of the product. The aziridine **5a** was formed as a single diastereomer, as determined by ¹H NMR spectroscopy (>99% d.r.). The assignment of the stereochemistry of **5a** was made on the basis of NOE experiments and by an X-ray diffraction analysis of a single crystal of **5a**.

The scope of the alkylation reaction was investigated with a number of different aziridines and electrophiles (Table 1). In all cases a single C2 epimer was observed and, on the basis of the structure of **5a**, was assigned as that formed from retention at the 2-position. Attempts to epimerize the enolate of **3a** failed. Deprotonation of **3a** at −78°C and then warming to 0°C for 2 h before quenching with water at −78°C led to 98% recovery of **3a** with complete retention of stereochemistry. Primary alkyl iodides gave moderate yields, while aldehydes gave high yields but with no selectivity at the alcohol sterogenic center. The only electrophile that gave a mixture of isomers at the aziridine was tributyltin chloride, and in this case the minor product was assigned as the *O*-alkylated product.

The alkylations of aziridine-2-carboxylates with a benzhydryl group on the nitrogen have never been reported, nor have the alkylations of aziridine-2-carboxylates with a

Table 1: Alkylation of **3**.[a]
Entry	R	Substrate	EX	Product	Yield [%]
1	Ph	**3a**	H₂O	**3a**	98

substituent in the 3-position. Thus, we decided to investigate the alkylations of aziridines **9** and **11** in an effort to see which has the greater influence (Scheme 2). The results indicate that the benzhydryl group has the most significant impact. Whereas the cyclohexyl-substituted aziridine **3e** is methylated cleanly in 70% yield with methyl iodide (Table 1, entry 14), the benzyl analogue **9** gives a complicated reaction mixture under the same conditions and none of the expected alkylated aziridines could be detected or isolated from the crude reaction mixture (all starting material was consumed). The only product that was isolated and identified from this reaction mixture was the pyrrole **10**, whose origin is unclear but whose structure was confirmed by X-ray diffraction analysis. It is also clear that the presence of a substituent at the 3-position of the aziridine is important. Aziridine **11** which has no substituent in the 3-position gives only a 15% yield of the alkylated aziridine **12** while all of the aziridines in Table 1 can be alkylated with methyl iodide in 64–82% yield under the same conditions. The major product in the methylation of **11** is the Claisen condensation product **13**, which is the only product that has been seen from the attempted alkylation of ethyl esters of aziridine-2-carboxylates.[7]

Interestingly, the optical purity of the methylated aziridine **12** (81% *ee*) is less than the starting aziridine **11** (94% *ee*). The loss of optical activity (47% *ee*) is greater for the protonation of the enolate of **11** which occurs with retention of configuration. This result suggests that the loss of optical activity is dependent on the electrophile. The enolate of **11** was allowed to age for only 2 minutes before methyl iodide was added, and the optical purity of **12** was found to be

73% *ee*. Thus, there does not seem to be a time dependence on the loss of optical activity. The normal aging time of the enolate is 30 minutes, and in this case its optical purity is not lower but in fact slightly higher (81% *ee*). Increasing the time of addition of **11** to LDA leads to only a slight increase in the proportion of the alkylated product **12** to the Claisen product **13**. Seebach and co-workers previously observed that the enolates of aziridine thioesters can also be alkylated with retention and that the enolate must either exist as the *C*-metalloenolate **14a** or the *O*-metalloenolate **14b**, which is substantially pyramidal at the enolate carbon (Scheme 3).[6b] We interpret the above results as involving a configurationally stable enolate (drawn as the *C*-enolate **15a** but could also be the pyramidal *O*-enolate **15b**) that does not epimerize with time but rather reacts with either retention or inversion, the proportion of which is electrophile dependent. This would be consistent with the observation that all of the *cis*-3-substituted aziridines shown in Table 1 give exclusively alkylated products with retention of configuration. The R group in enolate **16a** would be expected to disfavor alkylation with inversion by approach of the electrophile from the rear side.
Scheme 3. Alkylation of aziridine thioesters. E = electrophile.

The utility of the alkylation of aziridine-2-carboxylates in the synthesis of tetrasubstituted α-amino acids is demonstrated in the synthesis of BIRT-377 (Scheme 4). BIRT-377 has been developed as an agent for the treatment of inflammatory and immune disorders.[8] The asymmetric synthesis was achieved through the aziridine **3d**, which was prepared by the AZ reaction with 1 mol% catalyst in 87% yield and with 94% *ee* with greater than 50:1 selectivity for the *cis* isomer. A single recrystallization gave material with over 99% *ee* (72% recovery, first crop). The methylation of **3d** followed from the above procedure to give **5k** in 86% yield as a single diastereomer. Reductive ring opening was performed with borane–trimethylamine complex in the presence of trifluoroacetic acid (TFA) to give the amino ester **19** in 87% yield (BH₃·Me₃N with TFA gave a 6:1 mixture of **19** and **22**).[9] Ring opening by hydrogenolysis under a variety of conditions including Pd-C/HCO₂H occurred with simultaneous bromide reduction. Surprisingly, the
Scheme 4. Reagents and conditions: a) Ph$_2$CHNH$_2$ (1.0 equiv), CH$_2$Cl$_2$, MgSO$_4$, room temperature, 24 h; b) ethyl diazoacetate (1.1 equiv), (S)-VAPOL-B catalyst (1 mol%; see footnote 3), CCl$_4$, room temperature, 20 h; c) LDA (2 equiv), DME/Et$_2$O (5:1), −78°C, 0.5 h; MeI (3 equiv), −78 to RT; d) BH$_3$·Me$_3$N (12 equiv), TFA (9 equiv), CH$_2$Cl$_2$, 0° to RT, 36 h; e) Et$_3$SiH (3 equiv), TFA, reflux, 5 h; f) 3,5-dichloro-phenyl isocyanate (1.1 equiv), DMSO, Na$_2$CO$_3$, 120°C, 1.5 h; g) NaHMDS (1.2 equiv), DMF, room temperature; MeI (1.2 equiv), 2 h. DMSO = dimethyl sulfoxide; HMDS = hexamethyldisilazide; DMF = N,N-dimethylformamide.

reductive ring opening of **5k** with triethylsilane and TFA gave mainly the amino alcohol **22**, which results from ring opening with trifluoroacetate. Cleavage of the benzhydryl group in **19** with triethylsilane in the presence of trifluoroacetic acid gave the amine **20** in 95% yield. The conversion of amine **20** into BIRT-377 (**21**) follows methods employed in previous syntheses.[8d]

The fact that benzhydryl-protected aziridine-2-carboxylates can be readily alkylated at the 2-position greatly enhances the synthetic utility of the asymmetric aziridination (AZ) reaction, as illustrated by the synthesis of BIRT-377. Additional studies with other electrophiles and applications in other syntheses will be reported in due course.

C–C Coupling Reactions

General Catalysts for the Suzuki–Miyaura and Sonogashira Coupling Reactions of Aryl Chlorides and for the Coupling of Challenging Substrate Combinations in Water**

*Kevin W. Anderson and Stephen L. Buchwald**

Metal-catalyzed cross-coupling methodology to form carbon–carbon bonds has inarguably advanced organic synthesis.[1] The Suzuki–Miyaura coupling is one of the preeminent methods for formation of carbon–carbon bonds and has been used in numerous synthetic ventures.[2] We recently reported a new catalyst system that manifested high activity paired with extremely broad scope.[3] There remained, however, a need to develop reaction conditions for the coupling of water-soluble aryl chlorides and for the combination of difficult coupling partners in aqueous conditions. Additionally, substrates containing hydrophilic functional groups, which are insoluble in organic solvents and are present in many pharmaceutically interesting compounds, may be transformed, obviating the need for additional protection/deprotection steps. Furthermore, reactions conducted in water are attractive as water is nontoxic, nonflammable, and inexpensive, and is easily separated from organic products.[4]

Very few examples have been reported concerning palladium-catalyzed cross-coupling reactions of hydrophilic aryl chlorides with aryl boronic acids using purely aqueous reaction conditions.[5–9] Several sulfonated phosphine derivatives have been prepared and used in cross-coupling reactions conducted in water or water/organic biphasic solvent systems.[10,11] Shaughnessy and coworkers reported that use of sterically demanding, water-soluble, alkylphosphine salts in the Suzuki–Miyaura, Sonogashira, and Heck coupling reactions of unactivated aryl bromides provided products derived from carbon–carbon bond formation in excellent yields.[12] Limitations to this methodology include a lengthy synthesis and poor thermal and air stability of the ligand. Furthermore, only a single example of a substituted aryl chloride was described. The activated aryl chloride 4-chlorobenzonitrile was combined with phenylboronic acid in a reaction that

required 4 mol% of the palladium catalyst. Very recently, a Pd/glucosamine-based dicyclohexylarylphoshine catalyst was reported that displayed modest activity in Suzuki–Miyaura couplings of activated aryl chlorides when conducted in a mixture of water, toluene, and ethanol.[13] This system, as reported, was not general and the ligand was not readily available.

We felt that the electron-rich lower aromatic ring on **1** would be readily amenable to the incorporation of a water-solubilizing sulfonate group. In fact, treatment of **1** with concentrated H_2SO_4 at 40°C for 24 h gave **2** with exclusive monosulfonation at the 3′-position in 99% yield after treatment with NaOH and workup [Eq. (1)]. With **2**, excellent yields were obtained in Suzuki–Miyaura couplings of highly functionalized aryl chlorides or heterocyclic chlorides/bromides (containing carboxy, amino, hydroxy, sulfonamide, or sulfonate groups) and aryl or alkyl boronic acids in aqueous media.

$$\text{(1)}$$
Using a catalyst system based on **2**, we investigated the coupling of hydrophobic and hydrophilic substrates (Table 1). The coupling of electronically neutral 1-chloro-3,4-dimethylbenzene and phenylboronic acid at room temperature using water as the solvent provided the corresponding biaryl product in 99% yield (Table 1, entry 1). A temperature of 100°C was necessary for successful coupling of 3-chlorobenzamide and hindered 2,6-dimethylphenylboronic acid resulting in 99% yield of the biaryl amide (Table 1, entry 2). Using microwave irradiation (150°C), the same coupling product was obtained in 94% yield in 10 minutes.[14,15] This result indicates that the catalyst system based on **2** exhibits high thermal stability. We found that coupling of 3-chlorobenzoic acid with phenylboronic acid proceeds at room temperature using 0.5% Pd and at 100°C using 0.1% Pd to provide the coupled product in 97% yield in both cases (Table 1, entry 3). Similar catalytic activity was observed in the coupling of 3-chlorobenzoic acid and 2-methylphenylboronic acid using 0.5% Pd at room temperature and 0.1% Pd at 100°C to give the desired product in yields of 95% and 96%, respectively (Table 1, entry 4). Using microwave irradiation (150°C) and 0.1% Pd, the same coupling product was obtained in 98% yield in 10 minutes. The combination of 5-chloro-2-hydroxybenzoic acid and 2-methylphenylboronic acid, while slower, provided an excellent yield of the biaryl product using 2% Pd (room temperature) or 0.1% Pd (100°C; Table 1, entry 5).

The Suzuki–Miyaura coupling of hydrophobic aryl bromides in aqueous media has been reported to occur with an assortment of catalysts including those that operate without a supporting ligand. Successful application to moderately hindered substrate combinations, however, has not been

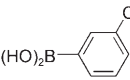
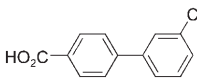
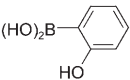
[a] Reaction conditions: 1.0 equiv aryl chloride, 1.2 equiv boronic acid, 3.0 equiv K₂CO₃, degassed water (1.5 mL mmol⁻¹), cat. Pd(OAc)₂, ligand **2**, L/Pd = 2:1. [b] Yield of isolated product (average of two runs). [c] Conducted using microwave irradiation with cooling. [d] 4.0 equiv K₂CO₃ was used.

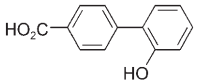
disclosed or possible.[11,12,15] To ascertain whether our Pd-(OAc)₂/**2** catalyst system could address this limitation, we examined two reasonably hindered substrate combinations using water as the solvent at room temperature: the reactions of 2-bromomesitylene with 2-methylphenylboronic acid and 2-bromotoluene with 2,6-dimethylphenylboronic acid to form biaryl products that contain three substituents *ortho* to the aryl–aryl connection (Table 1, entries 6, 7).[16] To our knowledge, this represents the first successful coupling of a hindered substrate combination conducted using a water or water/organic biphasic solvent at room temperature.

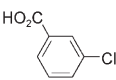
To determine the scope of this process, we examined the reaction of chlorobenzoic acids with 3-carboxyphenylboronic acid, 2-hydroxyphenylboronic acid, 2-aminophenylboronic acid, 2-acetylphenylboronic acid, and 2-formylphenylboronic acid. These coupling processes all proceeded in excellent yields using 1% catalyst (Table 2, entries 1–3). Using microwave irradiation (150 °C), 4-chlorobenzoic acid and 3-carboxyphenylboronic acid were coupled in 10 minutes with 1% Pd to provide the product in 95% yield (Table 2, entry 1), again demonstrating catalyst stability at higher temperatures.

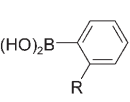
We next turned our attention to Suzuki–Miyaura couplings of functionalized hydrophilic aryl chlorides and substituted arylboronic acids. Chlorobenzoic acids containing hydroxy (Table 2, entry 4) and amino (Table 2, entry 5) groups on the aromatic ring were effectively coupled with substituted arylboronic acids (4-cyanophenylboronic acid and 3-aminophenylboronic acid, respectively) to generate the biaryl products in high yields (92% and 99%, respectively). 4-Chlorobenzenesulfonic acid successfully coupled with methylboronic acid to give the sulfonic acid derivative in 96% yield, (Table 2, entry 6). To the best of our knowledge, this is the first reported Suzuki–Miyaura coupling of an aryl halide bearing an unprotected sulfonic acid.[17]


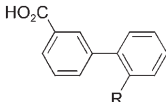


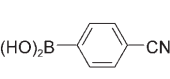


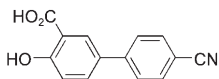


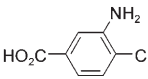


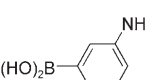


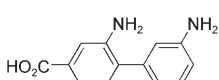


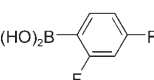


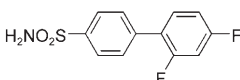






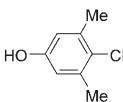


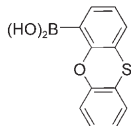


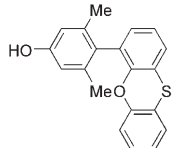


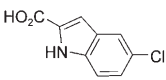
Applications of heterocyclic compounds in cross-coupling processes remain a challenge. To the best of our knowledge, very few examples of aqueous-phase Suzuki couplings of water-soluble heterocyclic halides have been published.[18] We have examined the use of **2** as a supporting ligand in the Suzuki–Miyaura coupling with a variety of challenging hydrophilic heterocyclic halides (Table 3). As is shown, the method worked well for a number of different carboxy-group-containing heterocyclic chlorides and bromides, including indole (with a free N−H bond), pyridine, and thiophene derivatives (Table 3, entries 2, 3, 5). Even 2-amino-5-chloropyridine, which can potentially chelate to metal centers such as Pd^II, was successfully coupled with 3-pyridylboronic acid in 93% yield (Table 3, entry 4).[19]

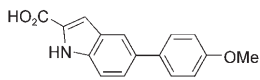
The Suzuki–Miyaura coupling of 3-chlorobenzoic acid and phenylboronic acid employing **1** provided efficient conversion and yield of the desired product using a water/organic biphasic solvent system at 100 °C (Table 4, entries 3, 4). However, at room temperature this reaction was sluggish (Table 4, entry 5). A dramatic increase in activity was observed when using the amphiphilic ligand **2** in water at room temperature, which provided the biaryl product in 97 % yield (Table 4, entry 7). Although a catalyst system using **1** in a similar biphasic solvent system may work in many instances, this has not yet been explored.

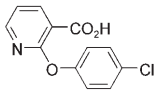
Recently, we disclosed that a catalyst system based on [PdCl$_2$(CH$_3$CN)$_2$]/**3** provided excellent reactivity in the copper-free Sonogashira coupling of aryl chlorides or tosylates and terminal alkynes.[20] This catalyst system was successful in coupling aryl alkynes only when the alkyne was added slowly over the course of the reaction. This is presumably due to competing oligomerization of the alkyne at higher concentrations in the presence of the catalyst. We felt that incorporation of a water-solubilizing sulfonate group on **3** would provide an amphiphilic Sonogashira catalyst which might address the limitations that were previously reported and allow for the coupling of hydrophilic substrate combinations.[21] We found that treatment of **3** with fuming sulfuric acid (H$_2$SO$_4$/20 % SO$_3$) at room temperature for 24 h provided **4**, with selective monosulfonation at the 4′-position, in 93 % yield after treatment with NaOH and workup [Eq. (2)].[22]


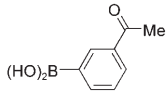


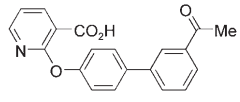


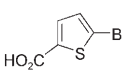


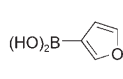


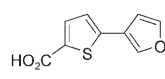












For the first time, by using a catalyst system based on [PdCl$_2$(CH$_3$CN)$_2$]/**4** and a water/acetonitrile biphasic solvent system, propiolic acid was successfully coupled with 3-bromoanisole and 3-bromobenzoic acid to provide aryl alkynoic acids in yields of 70 % and 69 %, respectively (Table 5, entries 1, 2). This result represents a significant advancement in Sonogashira coupling reactions, as electron-deficient propiolate esters have been problematic coupling partners due to their increased reactivity towards nucleophilic attack and their propensity to polymerize in the presence of Pd catalysts.[23] Good yields were obtained for the coupling of hydrophilic aryl chlorides bearing carboxy groups (Table 5, entries 3, 5) and an alkyne derived from an aliphatic carboxylic acid (Table 5, entry 4). Interestingly, by using **4** and a water/acetonitrile solvent system, the coupling of aryl chlorides and aryl alkynes

proceeds and obviates the need to employ slow addition of the aryl alkyne (Table 5, entries 6–8). This result may be attributed to the lower effective concentration of the alkyne in proximity to the catalyst, which resides at the water/organic interface.

We have demonstrated that use of sulfonated ligands **2** and **4** provides highly active catalyst systems for Suzuki–Miyaura and Sonogashira cross-coupling reactions, with unprecedented scope, reactivity, and stability for aqueous-phase processes. Further work to apply sulfonated biaryl-phosphines in other transition-metal-catalyzed processes is underway in our laboratories.

Stereoselective Butenolide Reduction

Dynamic Kinetic Resolution of α,β-Unsaturated Lactones through Asymmetric Copper-Catalyzed Conjugate Reduction: Application to the Total Synthesis of Eupomatilone-3**

Matthew P. Rainka, Jacqueline E. Milne, and Stephen L. Buchwald

Eupomatilones 1–7 are a family of lignans[1] isolated from the Australian shrub *Eupomatia bennettii*, found in the tropical and subtropical forests of New South Wales and Queensland.[2] All seven members of this family contain a highly oxygenated biaryl motif, as well as a *cis* orientation of the substituents at C4 and C5 of the butyrolactone ring. Of all the members of the eupomatilone family, there have only been three for which a total synthesis has been reported: eupomatilone-6, eupomatilone-4, and 3-*epi*-eupomatilone-6.[3] Despite this work, the total synthesis of enantiomerically enriched members of the eupomatilone family has remained an unsolved problem. Herein, we report the first asymmetric

E-mail: sbuchwal@mit.edu

total synthesis of one member of the family, eupomatilone-3. The success of the synthesis was based on a highly efficient Suzuki–Miyaura cross-coupling,[4] along with a dynamic kinetic resolution[5] of an unsaturated lactone.

Our interest in the synthesis of eupomatilone-3 emanated from the compound's interesting structural features, in particular the biaryl motif, along with the *cis* orientation of the substituents at C4 and C5 of the lactone portion of the molecule. Our retrosynthetic analysis of eupomatilone-3 is shown in Scheme 1. On the basis of our recent work in the area of palladium-catalyzed cross-coupling reactions,[6] it was believed we could assemble the highly oxygenated biaryl portion of the molecule **III** by utilizing either a Negishi or Suzuki–Miyaura coupling. Furthermore, we envisioned generating the desired lactone stereochemistry in **I** through either a diastereoselective or an enantioselective copper-catalyzed conjugate reduction reaction.[7]

The synthesis was begun by investigating the cross-coupling of known aryl bromide **1**[8] with organometallic reagents derived from bromo-3,4,5-trimethoxybenzene. By employing reaction conditions found to be optimal with palladium catalysts derived from the bulky phosphanylbiaryl ligands RuPhos **L1** (Negishi)[6b] or SPhos **L2** (Suzuki–Miyaura)[6a,c] allowed for efficient production of biaryl **2** (Scheme 2). The Negishi coupling produced **2** in 93 % yield at a catalyst loading of 1 mol % palladium. With the corresponding Suzuki–Miyaura reaction, it was found that **2** could be obtained in 93 % yield even when the catalyst
loading was lowered to 0.005 mol % palladium (0.00025 mol % [Pd$_2$(dba)$_3$]; dba = dibenzylideneacetone).

With a means to rapidly construct the biaryl portion of eupomatilone-3, investigation began into the preparation of the butenolide **6**. When examining this motif, we turned to Knochel's method for the synthesis of butenolides by the reaction of stabilized vinyl Grignard reagents with aldehydes.[9] To apply this method to this synthesis, the methyl ester **2** first needed to be transformed to the corresponding aryl aldehyde **4**. Conversion of **2** into the benzyl alcohol **3** was accomplished by borane reduction in THF. Intermediate **3** was oxidized with MnO$_2$ to give the desired benzaldehyde derivative **4** in essentially quantitative yield. Treatment of this

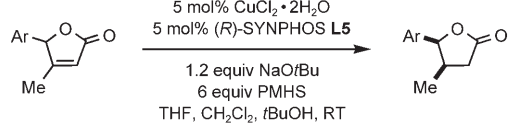
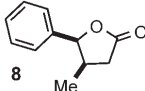
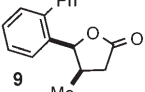
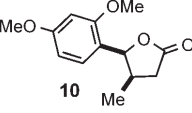
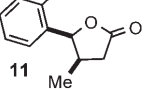
aldehyde with the vinyl Grignard reagent **5** (formed in situ from the corresponding vinyl iodide[10]) according to Knochel's procedure provided the desired unsaturated lactone in 76% yield.

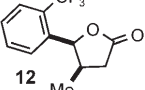
The next hurdle in the synthesis was the conversion of butenolide **6** into *cis*-4,5-disubstituted lactone **7**. The installation of this stereochemistry was explored by using an asymmetric conjugate reduction reaction.[11,12] We have previously demonstrated the asymmetric reduction of unsaturated lactones using a chiral copper–hydride catalyst.[12b] Furthermore, we have succeeded in carrying out both kinetic as well as dynamic kinetic resolutions of 3,5-disubstituted cyclopentenones by employing similar catalysts.[12d] Despite unsatisfactory results when reducing 3,4-disubstituted cyclopentenones,[12d] we decided to attempt the kinetic resolution of **6** under our standard conjugate reduction conditions[12] at −30°C in a 1:1 mixture of THF/CH$_2$Cl$_2$ (dichloromethane was necessary due to the poor solubility of the lactone in THF). After 50% conversion of **6**, the desired *cis* compound **7** was isolated in 46% yield and with 87% *ee*. Interestingly, the process was completely diastereoselective: none of the *trans* isomer was ever detected.












With this promising result, we sought to extend the method to the dynamic kinetic resolution of unsaturated lactones. We felt that performing the reaction in the presence of excess base (NaO*t*Bu) should allow for racemization of the starting material such that complete conversion may be effected. Unfortunately, no racemization occurred when 1.2 equivalents of NaO*t*Bu was used at −30°C, even after prolonged reaction times. When the same experiment, however, was conducted at room temperature, complete conversion of the starting material into the desired product was observed. As in the case of the simple kinetic resolution, the product was obtained as a single diastereomer and with 83% *ee*. This represents the first copper-catalyzed dynamic kinetic resolution of an unsaturated lactone.

In an attempt to improve the enantioselectivity of the reaction, other chiral bisphosphine ligands were used. It was found that replacing *p*-tol-BINAP **L3** with MeO-BIPHEP **L4** while still performing the reaction at room temperature provided the desired compound, again as a single diastereomer, but now with 93% *ee* (when the kinetic resolution was carried out at −30°C with **L4**, the product was obtained with 95% *ee*). With the *cis* lactone prepared, all that remained to complete the synthesis was to install the final methyl group in the α position on the lactone ring. This was accomplished by enolization of lactone **7** with NaHMDS followed by alkylation with iodomethane to give synthetic eupomatilone-3 in 85% yield; its spectra were in agreement with those published for material obtained from the natural source.[2,13]

On the basis of the success of the dynamic kinetic resolution reaction described above, we briefly examined the scope of this process by using other γ-aryl-containing unsaturated lactones. Initial results employing **L4** as the supporting ligand provided poor enantioselectivity for substrates other than the natural product, however the diastereoselectivity remained high. A brief survey of the efficiency of ligands for this process was undertaken and it was observed that the commercially available SYNPHOS ligand **L5** pro-

vided the highest enantioselectivities (except in the case of the natural product, in which **L4** gave the best result).[14] The scope of the reaction was examined and the results are shown in Table 1. Aside from **8**, all products were formed with enantioselectivities ranging from 77 to 87%. Thus, no clear

dependence on steric or electronic factors could be ascertained.

Unfortunately, use of the same reaction conditions for the dynamic kinetic resolution of lactones that contain simple alkyl substituents in the γ position failed to give more than 50% conversion of the starting material. This is presumably due to poor racemization of the starting lactone. Additionally, the reaction provided both the *cis* and *trans* isomers of the product, and the enantiomeric enrichment of the *cis* product was found to be low (<25% *ee*).

In conclusion, the total synthesis of eupomatilone-3 was achieved in six steps and in 48% overall yield. The key to the success of the synthesis was the development of a dynamic kinetic resolution that allowed the α,β-unsaturated butenolide **6** to be reduced in high yield and with both high enantiomeric and diastereomeric excess. This is the first example of a copper-catalyzed dynamic kinetic resolution of an unsaturated lactone. The method was then applied to several γ-aryl containing α,β-unsaturated butenolides. While a number of catalysts based on chiral bisphosphines were found to successfully promote this transformation, optimal

High Thermal Stability Imparted by a Designed Tandem Arg–Trp Stretch in an α-Helical Coiled Coil**

*Yuuki Sakurai, Toshihisa Mizuno, Hidekazu Hiroaki, Keigo Gohda, Jun-ichi Oku, and Toshiki Tanaka**

Studies on de novo designed proteins involve the construction of unique tertiary structures and the creation of novel functions. Protein structures are mainly formed by various interactions, such as ion-pair, hydrogen-bonding, and hydrophobic interactions. Recently, the cation–π interaction was noted as one of the effective interactions judging from various protein structures in the PDB (protein data bank) databases,[1] and it is thought to contribute to protein structure stabilization and protein–ligand interactions.[2–4] The cation–π interaction is formed between aromatic rings and cationic groups.[1b,5] In proteins, Trp, Tyr, Phe, and His are aromatic residues, while Lys and Arg are cationic residues, and the interaction between Trp and Arg is considered to be the best combination.[1c,6] The cation–π interaction is favored several-

fold over the formation of a salt bridge in water, in terms of the desolvation energy penalty of the ionic residues. A cation–π interaction stabilizes proteins by 2–3 kcal mol⁻¹ more than an ion-pair interaction, which is estimated to contribute 1–3 kcal mol⁻¹.[7] Thus, the cation–π interaction provides strong and specific interactions, and therefore it should be considered in protein design.

Designed cation–π interactions have been assessed using the solvent-exposed sites of the short α helices, turn structure, and coiled-coil structure.[8] These data suggested that the contributions of the cation–π interactions to the stability depend on the species and the positions of aromatic and cationic amino acids. However, the effects of the cation–π interactions on the structural stability are quantitatively lower than the values obtained from calculations, probably as a result of the flexibility of the amino acid side chains on the freely exposed sites of the α helix.

The location of the cation–π interaction is neither completely solvent-exposed nor deeply buried within the protein.[6] It is often found between a solvent-exposed site and a completely buried site. We designed a cation–π interaction to reside at the interface between two α helices of a coiled-coil structure. The coiled coil consists of several α helices wrapped around each other, and it represents a heptad repeat sequence designated by *abcdefg* from each position.[9] The *e* and *g'* positions exist between the hydrophobic–hydrophilic interfaces and are close to each other between two adjacent α helices. Glu and Lys at these positions are close and form an ion pair, which contributes to the stabilization and configuration of the coiled-coil structure. Therefore, the *e* and *g'* positions of the coiled coil might be suitable places to design a cation–π interaction. We designed a cation–π interaction at the *e* and *g'* positions and compared the ion-pair interaction between Glu and Lys at the same positions. Our results support the existence of the cation–π interaction.

A de novo designed peptide (IZ), [YGG(IEKKIEA)₄] (*defgabc*), forms a parallel triple-stranded α-helical coiled-coil structure.[10] The IZ peptide has a melting temperature (T_m) of more than 95 °C, which makes it difficult to compare the thermal stabilities of coiled-coil structures. Therefore, the amino acid at the *a* position of the second heptad was substituted with Gln to adjust the stability and to increase the uniqueness of the structure.[11] We also mutated the amino acid residues on the IZ derivatives, where Lys at the *g* position and Glu at the *e* position were reversed. The prepared peptides are listed in Table 1. There are three possible sites

for interactions using the *e* and *g'* positions after homotrimerization. Trp and Arg were placed in the middle of the peptide. The rest of the *e* and *g'* positions contained Glu and Lys, respectively, for the ion-pair interactions. A series of cation–π interactions was designed, and the peptides containing Trp and Arg were named WR1, WR2, and WR3, depending on the number of Trp–Arg sets. The *e* position of one peptide and the *g'* position of the other peptide were alternated between the two α helices, and therefore Trp and Arg were designed to generate an extended array of cation–π interactions, formed by two and three Trp–Arg sets for WR2 and WR3, respectively. WRRW has two Trp–Arg sets; however, because of the repulsive positive charge from Arg, the two Trp–Arg interactions should work separately.

Molecular modeling of WR3 was performed by using molecular mechanics calculations to obtain the preferable spatial position of Trp and Arg residues in the α-helical coiled-coil structures.[12] The energy-minimized WR3 model suggested that the designed three Trp–Arg sets were placed close enough together for cation–π interactions (Figure 1).
Figure 1. Energy-minimized model of WR3, which was constructed on the basis of a leucine-zipper coiled-coil structure (PDB ID: 1GCM) as template, followed by energy minimization with the OPLS-AA force field and GB/SA solvation model. Trp and Arg residues are illustrated by space-filling molecular graphics.

Circular dichroism (CD) spectroscopy was performed to characterize the secondary structures of the designed peptides (Figure 2). All of the peptides exhibited the spectra of typical α-helical structures, with the characteristic minima at 208 and 222 nm. To analyze the stoichiometry of the peptide aggregates, they were subjected to gel filtration on Sephadex G-50. The peptides eluted at the same position as the standard triple-stranded coiled-coil peptide with a similar amino acid length. These results indicate that the peptides assembled into the trimer with a coiled-coil structure.

The thermal stabilities of the peptides were analyzed by monitoring $[\theta]_{222}$ as a function of temper-

Figure 2. CD spectrum of WR3. EK, WR1, WR2, and WRRW exhibited the same CD spectra as WR3. The measurement was performed in sodium phosphate (20 mM, pH 7.0) containing NaCl (0.1 M) at 20°C. The peptide concentration was 20 μM.
Figure 3. Thermal denaturation curves for EK, WR1, WR2, WR3, and WRRW. The curves were recorded in sodium phosphate (20 mM, pH 7.0) containing NaCl (0.1 M), with a peptide concentration of 20 μM.

ature (Figure 3). EK exhibited a T_m of 52°C. When one Glu–Lys set was changed to Trp–Arg, the T_m was increased to 58°C (WR1), which is 6 K higher than that of EK, in spite of the removal of one of the ion pairs. This finding implies the presence of an interaction between Trp and Arg which is stronger than that of the ion pair. The effect on the thermal stability was more remarkable when a couple of Trp–Arg sets were placed at the *e* and *g* positions. WR2 exhibited a T_m of 75°C, which is 23 K higher than that of EK. On the other hand, WRRW had a T_m of 65°C, which is 13 K higher than that of EK. This 13-K increase is almost twice the ΔT_m between EK and WR1, which indicates that the two sets of Trp–Arg in WRRW do not interact cooperatively but separately, and that the orientation of WR (N→C or C→N) does not affect the stability of the coiled-coil structure. WR2 has an even higher T_m value, which is 10 K more than that of WRRW. Furthermore, when three Trp–Arg sets were used, the α-helical conformation was significantly more stable, leading to a T_m value greater than 95°C for WR3. These results suggest that when Trp and Arg are aligned contigu-

ously between two α helices, they interact cooperatively. It is apparent that the alternating alignment of aromatic and cationic side chains multiplies their effects on the thermal stability.

The fluorescence maximum of Trp is 327–332 nm under hydrophobic conditions and 354 nm in solvent-exposed sites.[13] We placed Trp at the *g* position, at the edge of the hydrophobic and hydrophilic environments. Trp might participate in the hydrophobic interaction, rather than the interaction with Arg, because the aromatic residues tend to be buried in the proteins. Therefore, we measured the fluorescence spectrum of the Trp residue. All of the peptides exhibited fluorescence maxima at 347–351 nm, with their intensities depending on the number of Trp residues. This finding indicates that the Trp residues exist at the solvent-exposed sites, and do not contribute to the hydrophobic interactions. The Trp residues in both WR2 and WRRW reside at solvent-exposed sites; however, WR2 is thermally more stable than WRRW. This result also supports the conclusion that the contiguous alignment of Trp and Arg augments the structural stability.

To obtain further physicochemical information concerning the Trp–Arg interaction, we prepared three more derivative peptides, AA, WA, and AR (see Table 1). These peptides formed triple-stranded coiled-coil structures. We carried out Gdn·HCl (guanidine hydrochloride) denaturation experiments to calculate the stabilization energy ΔG. The ΔG values obtained for AA, WA, and AR were similar at −14.6, −14.8, and −14.7 kcal mol⁻¹, respectively. Thus, the side chain of Trp or Arg alone does not contribute to the structural stability. The fact that the stabilization energies of EK and WR1 were −15.3 and −15.8 kcal mol⁻¹, respectively, indicates that an interhelical interaction between Glu and Lys, or Trp and Arg, was formed, and that one Trp–Arg interaction is stronger than one Glu-Lys ion-pair interaction by 0.17 kcal mol⁻¹. WR2 is even more stable, with a ΔG value of −16.7 kcal mol⁻¹, which shows that the stabilization energy of one Trp–Arg interaction is more than 0.23 kcal mol⁻¹ higher than that of one Glu–Lys ion pair. Thus, one continuous Trp–Arg interaction stabilizes the structure even more, by 0.06 kcal mol⁻¹.

In conclusion, we have designed a cation–π interaction at the interface between two α helices. Physicochemical experiments suggested the existence of an interaction between Trp and Arg, and showed that its contribution to stabilizing the protein structure is greater than that of an ion pair. In particular, the tandem repeats of Trp and Arg alignment, which imply a network of cation–π interactions, substantially stabilize the structure. The extended cation–π interaction is observed in natural proteins, such as the human growth hormone receptor extracellular domain.[1a, 14] Although the role of the interaction was not revealed by the amino acid mutation, it may function to increase the protein stability. Our design strategy using the Trp–Arg interaction should contribute to increase protein stability and specificity.

Synthetic Methods

Tin-Free Radical Carbonylation: Thiol Ester Synthesis Using Alkyl Allyl Sulfone Precursors, Phenyl Benzenethiosulfonate, and CO**

Sangmo Kim, Sunggak Kim,* Noboru Otsuka, and Ilhyong Ryu*

Free-radical carbonylation is synthetically very useful in preparing various carbonyl compounds.[1] Synthetic methods based on free-radical carbonylation utilize mainly highly toxic organotin reagents as mediators.[2] In our efforts to address the problems associated with toxic organotin reagents, we reported that the use of alkyl allyl sulfone precursors is one of the most useful and reliable methods for the generation of alkyl radicals under tin-free conditions and are very effective in radical carbon–carbon bond-formation reactions.[3,4] In our continued efforts to achieve tin-free radical carbon–carbon bond formations,[5] we have recently focused on tin-free radical carbonylations that use alkyl allyl sulfone precursors to prepare thiol esters [Eq. (1)].

$$RSO_2 \diagup\!\!\!\diagdown + ArSO_2X + CO \xrightarrow[V\text{-}40]{} \underset{R}{\overset{O}{\diagdown\!\!\!\diagup}} X + \diagup\!\!\!\diagdown SO_2Ar \quad (1)$$
Radical carboxylations were reported by Kharasch et al. in the 1940s,[6] but no significant progress in this area was made in the subsequent 50 years. Direct radical carboxylation of alkyl radicals with carbon dioxide is an extremely difficult process because decarboxylation is a greatly favored process.[7] Thus, radical carboxylations using highly reactive radical trapping agents such as oxalyl acid derivatives[8] and *S*-phenyl chlorothioformate[9] have recently been reported along with an indirect approach involving carbonylation and iodine atom transfer.[10] For the synthesis of thiol esters, radical reactions of aldehydes with disulfides are used.[11]

To uncover efficient radical-trapping agents of acyl radicals,[12,13] we screened several phenylsulfonyl derivatives as shown in Table 1. When 4-phenoxybutyl allyl sulfone (**1**) was treated with phenylsulfonyl bromide (**2b**) in the presence of V-40 (1,1′-azobis(cyclohexane-1-carbonitrile)) as initiator

Table 1: Radical carbonylation of alkyl allyl sulfone **1** (R = PhO(CH₂)₄) with arylsulfonyl derivatives **2**.

$$RSO_2\diagup\diagdown + PhSO_2X \xrightarrow[\text{V-40, 100 °C, 12 h}]{\substack{\text{50 atm CO} \\ \text{0.03 M heptane}}} \underset{3}{R\overset{O}{\diagup}X} + \underset{4}{R\text{-}X}$$

[a] Isolated as the methyl ester.

under pressurized CO (50 atm, 0.03 M, autoclave) in heptane at 100 °C for 12 h, 4-phenoxybutyl bromide (**4b**) was obtained in 75 % yield along with recovery of the starting material **1** (20 %) while no acid bromide was obtained. The use of phenyl benzeneselenosulfonate (**2c**) gave 4-phenoxybutyl phenyl selenide (**4c**) in 84 % yield, whereas the use of phenylsulfonyl chloride (**2a**) yielded a small amount of the acid chloride (10 %). Apparently, phenylsulfonyl bromide and phenyl benzeneselenosulfonate react with the alkyl radical prior to the carbonylation of the alkyl radical, whereas phenylsulfonyl chloride is too unreactive toward the alkyl radical. When the reaction was attempted using phenyl benzenethiosulfonate (**2d**) under the same conditions, a mixture of thiol ester **3d** (75 %) and alkyl sulfide **4d** (12 %) was isolated along with some starting material (7 %). Furthermore, the use of diphenyl disulfide as a trapping agent under the same conditions was not effective and **3d** was obtained in 15 % yield along with 80 % recovery of **1**.

As shown in Scheme 1, the addition of a phenylsulfonyl radical to **1** produces an alkyl radical through the thermal

desulfonylation of the initially generated alkyl sulfonyl radical along with formation of phenyl allyl sulfone (**5**). The alkyl radical can react with CO and/or phenyl benzenethiosulfonate (**2d**) to yield the acyl radical and/or alkyl sulfide **4d**. Therefore, the success of this approach depends critically on obviating the formation of **4d**. To optimize the reaction conditions, the effect of the pressure of CO and the concentration of **1** were investigated (Table 2). As expected, the yield

of thiol ester **3d** was increased at the higher pressure of CO while a lower concentration of **1** led to a reduced yield of alkyl sulfide **4d**. The best result was obtained when the reaction was carried out with **2d** (1.5 equiv) and V-40 (0.2 equiv) as initiator in a pressurized autoclave (95 atm of CO) in heptane (0.01 M) at 100 °C for 18 hours. Furthermore, when the effectiveness of alkyl benzenethiosulfonates relative to **2d** was briefly studied, methyl benzenethiosulfonate was found to be equally effective and slightly more reactive than **2d** [Eq. (2)]. Additionally, we explored the application of the present method to synthetically useful pentafluorophenyl thiol esters [Eq. (3)].[14] Treatment of **1** with pentafluorophenyl benzenethiosulfonate (**7**)[15] under the same conditions afforded pentafluorophenyl thiol ester **8** in 82 % yield along with pentafluorophenyl sulfide **9** (16 %). A similar result was also obtained with **6**.

			EtO₂C, CO₂Et / PhS	59

[a] A: **2d** (1.5 equiv), CO (95 atm), heptane, 100 °C, 18 h; B: **2d** (1.5 equiv), CO (130 atm), heptane, 100 °C, 18 h. TBDPS = *tert*-butyldiphenylsilyl. [b] The numbers in parentheses indicate isolated yields of alkyl phenyl sulfides. [c] Starting material (12 %) was recovered. [d] Some starting material (46 %) was also recovered.

alkyl phenyl sulfide was reduced to some extent to yield an 80:11 mixture of **3d** and **4d** (entry 8). As we anticipated, tertiary alkyl radicals gave more direct addition products (entries 11 and 12). The benzylic radical did not undergo carbonylation and reacted with **2d** to give a benzyl phenyl sulfide in 51 % yield together with the recovery of some starting material (46 %; entry 13). Sequential radical reaction involving cyclization and phenylthio carbonylation afforded the desired product in 90 % yield (entry 14). However, in the case of 6-*exo* ring closure, a 24:59 mixture of two products was obtained in favor of the direct carbonylation product, apparently as a result of the competition between 6-*exo* ring closure and the direct carbonylation (entry 15).[16] When a four-component coupling reaction using **12**, allyl trimethylsilane, CO, and **2d** was carried out under the same conditions, a 4.7:1 diastereomeric mixture of the desired product **14** was isolated in 83 % yield (Scheme 2).[17] Evidently, the electrophilic alkyl radical generated from **12** failed to undergo carbonylation and reacted with allyl trimethylsilane to yield intermediate **13**.

Next, the possibility of a double carbonylation was explored.[18] Reaction of **15** with **2d** and CO yielded acyl radical **17** through carbonylation of the radical intermediate **16**. The subsequent 5-*exo* ring closure of **17** and CO trapping followed by quenching with **2d** afforded thiol ester **18** according to the scheme proposed (Scheme 3). When **15** was subjected to the

conditions (95 atm of CO, 0.01 M solution of **1**). There was no indication of the formation of alkyl sulfide **4d**. In one case, a small amount of the starting material was recovered (entry 6). However, secondary alkyl radicals led to a significant amount of formation of **4d**. As the radical carbonylation of secondary alkyl radicals is less efficient than that of primary alkyl radicals, secondary alkyl radicals would have more chance to react with **5** prior to carbonylation. At 95 atm of CO, a 64:26 mixture of the thiol ester and the alkyl phenyl sulfide was isolated (entry 7). When the same reaction was repeated at a higher pressure of CO (130 atm) for 18 h, the formation of the

Scheme 2. E = CO₂Et.

Communications

Scheme 3. E = CO$_2$Et.

standard carbonylation conditions, **18** was isolated in 66% yield.

In conclusion, we have reported that tin-free radical carbonylation is successfully achieved using alkyl allyl sulfone precursors and have developed a highly efficient method for the synthesis of thiol esters using phenyl benzenethiosulfonate as a trapping agent. This approach provides ready access to other related carbonyl derivatives.

Lewis Acid Catalyzed Asymmetric Cycloadditions of Nitrones: α′-Hydroxy Enones as Efficient Reaction Partners**

Claudio Palomo,* Mikel Oiarbide, Elena Arceo, Jesús M. García, Rosa López, Alberto González, and Anthony Linden

Dedicated to Professor J. Plumet
on the occasion of his 60th birthday

The 1,3-dipolar cycloaddition of nitrones to alkenes[1] is an atom-economic method for the construction of isoxazolidines, which are important precursors of, for example, alkaloids, amino acids, β-lactams, and amino sugars.[2] Typically, an electron-deficient alkene is involved, with the interaction between the LUMO of the alkene and the HOMO of the nitrone being the determinant for the relative orientation of the reactants. However, steric factors often counterbalance the electronic preferences, particularly in β-unsubstituted enoyl (acryloyl) systems, and make regiocontrol challenging.[3,4] Additionally, both *endo/exo* and π-facial selectivity have to be addressed. Although amine activation of enals[5] has emerged as an attractive approach, most methods rely on the use of Lewis acids to activate the enoyl system toward the nitrone counterpart.[3,4,6] However, despite the many applications, success in asymmetric nitrone cycloadditions remains very scarce compared to that reached in the parent Diels–Alder cycloaddition and only a limited number of alkene templates such as *N*-enoyl derivatives of oxazolidinone,[4a–c,6c–6g] thiazolidinethione,[6a] pyrrolidinone,[6b] and pyrazolidinone,[6h] as well as certain alkylidene malonates[6i] have been employed to fulfill this gap. In metal-catalyzed nitrone

cycloadditions, not only are bidentate alkene substrates required but also metal–substrate coordination needs to be notably efficient for optimum selectivity.[7] We report herein that excellent combined levels of regio-, *endo/exo*-, and enantioselectivity may be achieved by using α′-hydroxy enones as new partners for this reaction.

Recent observations from these laboratories in the context of Diels–Alder and conjugate addition reactions have shown the role of α′-hydroxy enones in metal-assisted activation, which likely occurs through formation of 1,4-metal-chelated species as the reactive intermediates.[8] It was argued that such a complexation pattern might be effective in nitrone cycloadditions and hence increase the pool of available templates for this reaction. To evaluate this assumption, initial screening reactions were carried out with the chiral α′-hydroxy enone **1**[9] and nitrone **3a** in the presence of several metal triflates (Scheme 1 and Table 1). Data

[a] Reactions conducted at room temperature in dry CH₂Cl₂, with 1:1:0.1 molar ratio of enone **1**/**3a**/Lewis acid. [b] Determined by ¹H NMR spectroscopy. [c] By-products from nitrone and enone decomposition were detected. [d] Minor isomer corresponds to **4a**; configuration of the major isomer not established. [e] Configuration of the minor isomer not established.

revealed that Cu(OTf)₂ gave the best results and isoxazolidine **4a** could indeed be obtained in high yield and, most notably, with essentially perfect regio- and diastereoselectivity.

Gratifyingly, the chemical efficiency and the high degree of regio- and stereocontrol for this Cu(OTf)₂-mediated reaction was found to be quite general over the range of nitrones **3a–k** examined (Table 2). Nitrones bearing electron-rich, electron-neutral, or electron-poor aryl substituents were tolerated with almost equal efficiency to give isoxazolidines **4a–k** in good yields and with diastereomeric ratios ranging

[a] Reactions conducted on 0.5-mmol scale in dry CH$_2$Cl$_2$, with 1:1:0.1 molar ratio of enone/nitrone/catalyst. [b] Yield of isolated product after column chromatography. [c] Determined by ^{13}C NMR spectroscopy. [d] In the presence of 4-Å molecular sieves and a 1:2:0.2 molar ratio of enone/nitrone/catalyst. [e] Using 5 mol% of Cu(OTf)$_2$. [f] Configuration of the minor isomer not determined.

from 90:10 to greater than 98:2. The reactions were typically carried out in dichloromethane as solvent using 10 mol% catalyst, although a loading of 5 mol% catalyst led to similar results (products **4c** and **4e**). β-Substituted enones also behaved well in terms of both chemical and stereochemical efficiency, although longer reaction times were required.[10] For example, the reaction of enone **2** with nitrones **3a**, **3c**, and **3e** provided cycloadducts **5a**, **5c**, and **5e** in good yields and with remarkable diastereoselectivity.

The scope of the model is further demonstrated in the catalytic, enantioselective 1,3-dipolar cycloaddition of nitrones to simple α′-hydroxy enone **6**[8] (Table 3). A preliminary survey of combinations of privileged ligands and metal salts[11,12] showed that the Evans bis(oxazoline)–Cu^{II} complex **7**

(tBOX/Cu) was most successful in providing the nitrone cycloadducts **8/9** with very high stereoselectivity and with regioisomeric ratios equal to or greater than 90:10. To the best of our knowledge, this represents the highest combined regio- and enantioselectivity observed for β-unsubstituted enoyl substrates.[4,13] As an apparent limitation, however, the reaction of **6** with nitrone **3m** provided low *endo/exo* selectivity, although excellent regio- and enantiocontrol were still attained.

As differently β-substituted, simple hydroxy enones are readily available,[8] the method constitutes a straightforward route to 3,4,5-trisubstituted isoxazolidines of high diastereo- and enantiopurity. For instance, enone **10** reacted with nitrones **3m** and **3n** to give the respective isoxazolidines **11** and **12** with diastereomeric ratios of about 98:2 and enantioselectivities higher than 99% (Scheme 2).
Scheme 2. Enantioselective approach for β-substituted hydroxy enone substrates.

The assigned configuration of adducts **4**, **8**, **5**, and **9** was established by single-crystal X-ray analyses[14] of adducts **4a**, **5a**, **8m**, and **9a** (the configurations of the remaining adducts were assigned by analogy). Additionally, the absolute configuration of **8a** was deduced from comparison of the optical rotation values of elaborated adducts (see below) and by assuming a uniform reaction mechanism.

The potential utility of the method is illustrated in Scheme 3. For example, treatment of adducts **4a**, **4c**, and **4e** with periodic acid afforded the corresponding carboxylic acids **13** in high yields and essentially enantiopure form. Likewise, after addition of methyl lithium to **4a** and subsequent cleavage of the diol with lead tetraacetate, enantiopure acetylisoxazolidine **14** was obtained in 84% yield. Similarly, reduction of **4a** and further scission led to isoxazolidine carbal-

dehyde **15**. In all the above examples, the starting (1*R*)-(+)-camphor was recovered after scission, ready for reuse. On the other hand, the oxidative elaboration of adduct **8a** gave *ent*-**13a** along with acetone as the only by-product, whereas hydrogenolytic opening of **8a** with concomitant *N*-protection (Boc) and further cleavage of the ketol afforded homoserine derivative **16** in two high-yielding steps. Of practical interest, both enantiomers of each isoxazolidine product are readily accessible by appropriate choice of the corresponding approach.

In conclusion, α′-hydroxy enones considerably expand the range of metal-catalyzed 1,3-dipolar cycloadditions of nitrones. Conditions have been set that produce the cycloadducts with very high combined levels of regio- and stereoselectivity. The potential of the method has been demonstrated using camphor-derived α′-hydroxy enone **1** in combination with catalytic Cu(OTf)$_2$, or achiral enones **6** and **10** in combination with the Evans bis(oxazoline)–Cu^{II} catalyst, and by the easy elaboration of the cycloadducts to diversely functionalized di- and trisubstituted isoxazolidines in essentially enantiopure form.

Experimental Section

General procedure for Cu^{II}/tBOX (**7**)-catalyzed 1,3-dipolar cyclo-additions of nitrones to **6**: A flame-dried flask was charged with 2-hydroxy-2-methylpent-4-en-3-one (**6**; 0.114 g, 1.0 mmol) and dry CH$_2$Cl$_2$ (1.5 mL) under N$_2$. The solution was cooled to −20°C, and then freshly dried, powdered molecular sieves (4 Å; 250 mg), a solution of the corresponding nitrone (0.5 mmol) in CH$_2$Cl$_2$ (1 mL), and a solution of **7** in CH$_2$Cl$_2$ (0.05 M, 1 mL) were added consecutively. The resulting mixture was stirred at −20°C until completion of reaction. The reaction mixture was then diluted with 5 mL of ethyl acetate/hexane (1:1), and the solution was directly applied to a short column of silica gel (1.5 cm × 1.5 cm). Elution with a mixture of ethyl

acetate and hexane (1:1), followed by concentration of the collected solution and subsequent purification by column chromatography (silica gel, 1:15 ethyl acetate/hexane), afforded the corresponding cycloadduct.

Tandem Radical-Addition–Aldol-Type Reaction of an α,β-Unsaturated Oxime Ether**

Masafumi Ueda, Hideto Miyabe, Hisako Sugino, Okiko Miyata, and Takeaki Naito*

Conjugate addition of radical species has been recognized as a versatile tool for introducing an alkyl group into the β position of α,β-unsaturated carbonyl compounds,[1] and the subsequent trapping of the intermediate radical species with allyltin compounds has been widely studied.[2,3] Tandem reactions are among the most efficient synthetic methods. However, those that proceed sequentially through ionic species sometimes exhibit problematic drawbacks such as the need for exacting reaction conditions, whereas undesired polymerization may result from tandem radical reactions. A combination of radical and ionic processes may alleviate these problems and could thus be a promising approach. Oshima and co-workers first demonstrated that a tandem radical addition–aldol condensation of enones or enals could be performed via the formation of an intermediate boryl enolate.[4] Other groups have recently reported tandem reactions involving radical and ionic processes for the convenient synthesis of highly complex molecules.[5] However, there are only limited examples which employ enolate intermediates formed by a radical addition reaction. The goal of our work is to develop a highly efficient carbon–carbon bond-construction method by taking advantage of a novel hybrid radical–ionic reaction involving the radical addition to α,β-unsaturated oxime ethers and subsequent ionic trapping of the resulting *N*-boryl enamine by aldehydes.

Building upon our syntheses of α- and β-amino acids by radical addition to oxime ethers,[6] we extended our use of α,β-unsaturated oxime ether **1** bearing Oppolzer's camphorsultam to the synthesis of γ-amino acids (Figure 1). Recent studies on the radical addition to imines showed that aminoboranes were effectively formed by trapping of intermediate aminyl radicals with triethylborane.[7–10] Thus, we expected

that the boryl enamine **2** could be formed by the triethylborane-promoted radical addition to (E)-**1**, if the reaction proceeds regioselectively by path a.

Prior to exploring issues of the tandem process, we first investigated the regioselectivity in the carbon-radical addition to conjugated oxime ether (E)-**1**, which possesses three radicophilic centers (Scheme 1). The addition of ethyl radical
Scheme 1. Radical addition to conjugated oxime ether (E)-**1**. Boc = tert-butyloxycarbonyl.

to (E)-**1** was performed in CH$_2$Cl$_2$ at 20°C for 20 min with triethylborane (Table 1, entry 1). The reaction took place regioselectively at the α position of the carbonyl group (path a as shown in Figure 1) to give the desired product **3a**

Table 1: Alkyl-radical addition to conjugated oxime ether (E)-**1**.[a]

Entry	Initiator	RI	Product	Yield [%][b]	d.r.[c]
1	Et$_3$B	none	**3a**	97	>97.5:2.5
2	Et$_2$Zn	none	–	ND	
3	Et$_3$B	iPrI	**3b**	56	>97.5:2.5
4	Et$_3$B	sBuI	**3c**	69	>97.5:2.5
5	Et$_3$B	tBuI	**3d**	28	>97.5:2.5

[a] Reactions were carried out using RI (30 equiv) and Et$_3$B or Et$_2$Zn in hexane (1.0 M, 5 equiv) in CH$_2$Cl$_2$ for 20 min. [b] Isolated yield of the desired alkylated product (ND = not detected). [c] Diastereomeric ratios were determined by ^{1}H NMR analysis.

in 97% yield without formation of other regioisomers (paths b or c). This is the first example of a regioselective radical addition to a conjugated oxime ether that involves four electrophilic positions. The diastereomeric purity of **3a** was found to be no less than 97.5:2.5 d.r. by ^{1}H NMR spectroscopic analysis of the crude product. The absolute configuration at the newly formed stereocenter was determined to be S by converting the adduct **3a** into the authentic γ-amino acid **4**.[11] The stereochemical preference of this reaction can be rationalized as follows. With regard to the conformation of (E)-**1**, the *anti* (sulfonyl and carbonyl groups) and *s-cis* (carbonyl group and C=C bond) planar rotamer shown in Scheme 1 should be favored over other rotamers. Therefore, the alkyl-radical addition to the *re* (bottom) face is favored, presumably resulting from steric interactions with the axial oxygen of the sulfonyl group.[6c] In marked contrast, the ethylated product **3a** was not formed with the use of diethylzinc as a radical initiator (Table 1, entry 2).[12] The high diastereoselectivities and good chemical yields were observed in the addition of secondary alkyl radicals to (E)-**1** (Table 1, entries 3 and 4). A lower chemical yield was attained with a bulky *tert*-butyl radical, but the reaction still proceeded with high d.r. (>97.5:2.5; Table 1, entry 5). These observations indicate that triethylborane acts as an effective reagent for trapping the intermediate enaminyl radical to form the boryl enamine **2**.

To confirm the formation of boryl enamine **2**, we studied the ^{1}H NMR spectra and the trapping reaction of boryl enamine **2** with D$_2$O (Scheme 2). The ^{1}H NMR spectra of the
Scheme 2. Trapping reaction of boryl enamine with D$_2$O (X = (1R)-camphorsultam).

reaction mixture of **1** with triethylborane in CD$_2$Cl$_2$ suggested the formation of (E)-enamine **2** as shown in Scheme 2. The deuteration of boryl enamine **2** took place at the β position (relative to the carbonyl group) to give the product **5** in 64% yield. Thus, the rationale of the reaction pathway is that the alkyl radical adds to the α position of the carbonyl group in (E)-**1** to form the intermediate radical **A**, which is captured by triethylborane to afford the (E)-boryl enamine **2** and regenerate an ethyl radical.

With these results in mind, we next investigated the tandem radical-addition–aldol-type reaction of an α,β-unsa-

turated oxime ether by using paraformaldehyde (Scheme 3). Triethylborane was added to a mixture of **1** and paraformaldehyde. The resulting products were the ethylated product **3a** and *trans*-γ-butyrolactone **6** in 53 and 44% yields, respectively (Table 2, entry 1). The γ-butyrolactone **6** was presumably
Scheme 3. Tandem radical-addition–trapping reaction of boryl enamine with paraformaldehyde (X = (1*R*)-camphorsultam).

Table 2: Radical–aldol-type reaction of (*E*)-**1** with paraformaldehyde.[a]

| Entry | Lewis acid | T [°C] | Yield [%][b] | | Selectivity[c] |
			6	3a	trans:cis
1	None	reflux	44	53	10:2
2	Me₃Al	20	41	42	10:3
3	Me₃Al	reflux	72	–	10:3[d]

[a] Reactions were carried out with Et₃B in hexane (1.0 M, 5 equiv), Me₃Al in hexane (1.0 M, 1.2 equiv), and (CH₂O)ₙ (1.2 equiv) in CH₂Cl₂. [b] Isolated yield. [c] Determined by ¹H NMR analysis. [d] Enantiomeric purity of the *trans* isomer was found to be 90% *ee* by HPLC analysis.

formed through the diastereoselective addition of ethyl radical to **1**, trapping of boryl enamine **2** with paraformaldehyde, and intramolecular lactonization with concomitant removal of the chiral auxiliary. The relative configuration of the two substituents on lactone **6** was determined by NOE interaction experiments. To the best of our knowledge, this reaction represents the first reported example of the electrophilic trapping reaction of an unstable *N*-boryl enamine generated through a radical process. This tandem reaction was promoted in the presence of Me₃Al (1.2 equiv) as a Lewis acid. The reaction using Me₃Al under reflux gave the desired lactone **6** exclusively in 72% yield (Table 2, entry 3). The enantiomeric purity of *trans*-γ-butyrolactone **6** was found to be 90% *ee* by chiral HPLC analysis. The lower stereoselectivity of the tandem reaction (90% *ee*) than that of the simple ethyl-radical addition (>97.5:2.5 d.r.) was attributed to the higher reaction temperature (reflux) used in the initial radical reaction step.

The utility of this new tandem radical–ionic reaction was tested in the asymmetric synthesis of various types of γ-butyrolactones. Thus, we investigated the reaction with different kinds of aldehydes (Scheme 4). The trapping reaction of boryl enamine **2** with benzaldehyde gave the *trans,trans* isomer **8a** as the major product, accompanied by small amounts of other diastereomers. γ-Butyrolactone **8a** was easily converted into γ-amino acid derivative **9**. Treat-
Scheme 4. Radical-addition–aldol-type reaction of (*E*)-**1** (ratio in parentheses is for the yield of the major isomer to that of all other isomers combined; X = (1*R*)-camphorsultam).

ment of **8a** with benzylamine in the presence of 2-pyridinol gave an acyclic oxime ether which was reduced to the amino acid amide **9**.[13] The electron-donating and electron-withdrawing substituents on the aromatic ring of the aldehyde exhibited no apparent effects on either the chemical yield or the stereoselectivity, and good yields were attained for both **8b** and **8c**. 2-Furfural and cinnamaldehyde also worked well under similar reaction conditions. The *trans,trans* stereoselectivity observed for the reaction can be explained by invoking a six-membered-ring transition state. The sterically more stable conformer of (*E*)-boryl enamine reacted with the Me₃Al-activated aldehyde in such a way that 1,3-diaxial interactions were minimized, and an unfavorable steric interaction with allylic substituents was avoided.[14]

Finally, we examined the tandem reaction involving an addition of isopropyl radical, which occurred by way of an iodine atom-transfer process, followed by an aldol-type reaction (Scheme 5). With the use of isopropyl iodide
Scheme 5. Isopropyl-radical-addition–aldol-type reaction of (*E*)-**1** (ratio in parentheses is for the yield of the major isomer to that of all other isomers combined).

(20 equiv) as radical precursor and benzaldehyde as trapping agent, the tandem reaction of (*E*)-**1** proceeded smoothly to give isopropyl-substituted γ-butyrolactone **10** in 61% yield.

In conclusion, we have developed a hybrid type of reaction that involves a radical addition and an aldol condensation. This tandem reaction of an α,β-unsaturated oxime ether provides a powerful synthetic approach to chiral γ-butyrolactones and γ-amino acids.

Experimental Section

General procedure for radical-addition–aldol-type reaction of α,β-unsaturated oxime ether (*E*)-**1**: Aldehyde (0.148 mmol) and Me₃Al

(1.0 M in hexane, 0.148 mL, 0.148 mmol) were added to a solution of (E)-**1** (50 mg, 0.124 mmol) in CH$_2$Cl$_2$ (5 mL) at room temperature under a N$_2$ atmosphere. Et$_3$B (1.0 M in hexane, 0.62 mL, 0.62 mmol) was then added dropwise to the reaction mixture at reflux. After stirring at reflux for 3 h, the reaction mixture was diluted with saturated aqueous NaHSO$_3$ and then extracted with EtOAc. The organic phase was washed with saturated aqueous NaHCO$_3$ and brine, dried over MgSO$_4$, and concentrated at decreased pressure. Purification of the residue by preparative TLC (hexane/EtOAc 5:1) afforded the desired γ-butyrolactones.

dizers such as lead, mercury, and thallium reagents (Figure 1).[1] They are generally used as stoichiometric oxidants, though it may be possible to carry out oxidations under catalytic conditions. Indeed, oxidative fluorination reactions with a catalytic amount of iodobenzene difluoride
Figure 1. Hypervalent iodine(III) reagents. PIDA = phenyliodine diacetate; PIFA = phenyliodine bis(trifluoroacetate); HTIB = (hydroxy-(tosyloxy)iodo)benzene; PDAIS = poly(diacetoxyiodo)styrene; PBTIS = poly(bis(trifluoroacetoxy)iodo)styrene.

or 4-iodotoluene difluoride were reported in which the reoxidation of the iodine groups of iodoarenes was carried out electronically.[2,3] However, to our knowledge, a catalytic system for the formation of other bond types has not yet been reported. This is probably due to the lack of efficient procedures for the reoxidation of organoiodine(I) to hypervalent iodine(III) species[4–8] in the reaction system. Although new preparative methods that use sodium periodate (NaIO$_4$),[6] chromium trioxide (CrO$_3$),[7] and dimethyldioxirane[8] have been reported, they remain unsatisfactory in terms of product yield, ease of operation, and other aspects.

We have recently developed environmentally friendly, recyclable hypervalent iodine(III) reagents **1a–c** with high reactivities.[9] In its synthesis, we realized the need to prepare **1a** with nearly quantitative yield to make it a practical recyclable reagent; we also found that only an oxidation system using *meta*-chloroperbenzoic acid (*m*CPBA)[10] in dilute acetic acid/dichloromethane was suitable for this purpose. This interesting aspect prompted us to explore the possibility of these adamantane-based recyclable reagents as catalysts by combination with *m*CPBA as a stoichiometric chemical oxidant.

Herein, we demonstrate oxidative transformations with catalytic amounts of hypervalent iodine(III) reagents, which enable versatile C–O and even C–C bond formations. Relying on the previous conditions

to synthesize **1a**, we first examined the oxidative spirocyclization reaction of the phenol **5a**[11] with 0.1 equivalent of phenyliodine diacetate (PIDA), which gave disappointing results (Table 1, entry 1). Therefore, the reaction conditions were optimized. With **3a** instead of PIDA, a catalytic reaction was observed (entry 2). As the amount of trifluoroacetic acid (CF$_3$CO$_2$H) increased, the catalytic efficiency increased (entries 2 and 3). In the absence of **3a**, no reaction was observed. Interestingly, the rapid conversion of **5a** was observed in these cases. The nature of the acids and the presence of water were also influential (entries 4–7). The hypervalent iodine(III) reagent **3d** gave the best results of those examined (entries 10 and 11). It was possible to decrease the amount of **3d** to as low as 0.01 equivalent without a significant loss in catalytic efficiency (entry 11). The spirocyclization of **5a** using **3d** with other cooxidants such as peracetic acid,[4] sodium perborate,[5] NaIO$_4$,[6] and CrO$_3$[7] were not successful.

A proposed catalytic cycle is depicted in Scheme 1. First, **3d** forms the hypervalent iodine(III) active species **A** (which occurs under the stated reaction conditions, although a certain

[a] 0.1 equiv PIDA was used. [b] 1 g mmol^{-1} **5a**. [c] Prepared from 0.1 equiv 2,4-difluoroiodobenzene in situ. [d] Prepared from 0.1 equiv 4-iodoanisole in situ. [e] 50 equiv CF$_3$CO$_2$H was used.

degree of **3d** formation was observed in the absence of these phenol derivatives). The intermediate **A** transforms phenol **5a** into **6a** with concomitant formation of 4-iodotoluene (**4**), which then regenerates **A** by the action of *m*CPBA. The effect of the methyl group in the aryl substituent of **3d** might be to accelerate the conversion of **4** into **A**. With 0.05 equivalent of **4** instead of **3d**, the spirocyclization of **5a** also occurred with nearly the same efficiency (2 h, 72% yield). This result strongly supports the formation of **4** during the catalytic cycle.

The results of the oxidation of a series of phenol

Table 2: Spirocyclization reaction of various phenol derivatives with a catalytic amount of **4**.

[a] 0.05 equiv **1b** was used instead of **4**. [b] 1.05 equiv *m*CPBA was used.

derivatives with a catalytic quantity of **4** are shown in Table 2. This procedure imparts more versatility to the catalytic reaction, as the initial preparation of hypervalent iodine(III) reagents could be avoided. Thus, the oxidative transformations of various phenol derivatives proceeded smoothly in good yields with short reaction times. The recyclable reagent **1b** was also usable in this catalytic reaction (entry 2). After reaction completion, **2** was recovered nearly quantitatively in this case by taking advantage of its insolubility in methanol. Although further exploration is required, this catalytic approach was extended to other

Scheme 2. Intermolecular C−C bond-formation reaction catalyzed by **3a**.

oxidative bond-formation reactions such as those of C−C bond formation[12] (Scheme 2).

In summary, we have established the efficient catalytic reactions of hypervalent iodine(III) reagents at room temper-ature by using *m*CPBA as an effective chemical cooxidant. These catalytic approaches have the following characteristics: rapid conversion (short reaction time), high catalytic effi-ciency, and no need for the preparation of hypervalent iodine(III) reagents. As **2** was also usable in the catalytic reaction, it has the advantage of the net recycling capacity of **1b**, considering the loss in the preparation of **1b** from **2**. The catalytic use of hypervalent iodine(III) reagents is our highly desirable goal. The application of other effective cooxidants with these hypervalent iodine(III)-catalyzed reactions is now in progress.

Experimental Section

Typical experimental procedure with **1b**: Compound **1b** (92.4 mg, 0.05 mmol) was added to a stirred solution of 3-(4-hydroxyphenyl)-propionic acid (**5a**; 166 mg, 1.0 mmol), trifluoroacetic acid (114 mg, 1.0 mmol), and *meta*-chloroperbenzoic acid (≈69% purity, 224 mg, ≈1.05 mmol), in CH₂Cl₂ (3 mL) at ambient temperature under a nitrogen atmosphere. The mixture was stirred for 2 h under the same reaction conditions while the reaction was monitored by TLC. The aqueous work-up was successive with saturated NaHCO₃ (20 mL), sodium thiosulfate (15 mL), and then the organic phase was evaporated to dryness. MeOH (10 mL) was added to the residue, and the resulting suspension was filtered to separate **2** from the product. The recovery of **2** was nearly quantitative. The filtrate was evaporated and subject to column chromatography (SiO₂/*n*-hexane/AcOEt) to give 1-oxaspiro[4.5]deca-6,9-diene-2,8-dione (**6a**)[11c] as a white powder (121 mg, 74%).

first examples of cyclodiphosphinophosphonium **3** and cyclo-triphosphinophosphonium **4** cations (Scheme 1). Isolation of these new frameworks is surprising in light of the exclusive formation of **5** over possible tetra- and hexaphosphorus derivatives with phenyl substituents at the phosphorus
Scheme 1. Prototypical *catena*-polyphosphinophosphonium cation frameworks.

Small Cyclopolyphosphinophosphonium Cations: Systematic Development of Fundamental *catena*-Phosphorus Frameworks**

Neil Burford,* C. Adam Dyker, Mike Lumsden, and Andreas Decken

Recognizing that catenation of carbon is principally responsible for the diversity and extent of organic chemistry, the "diagonal relationship" between carbon and phosphorus in the Periodic Table is often quoted[1,2] in the discussion of the numerous catenated polyphosphines[2–6] and polyphosphorus anions.[2–4,7–12] *catena*-Phosphorus cation systems are less well developed despite the classical chemistry of phosphonium salts, but the pioneering contributions of Schmidpeter and co-workers[13–15] and Schmutzler et al.[16] have highlighted new aspects of structure and bonding that prompt the establishment of a comprehensive polyphosphinophosphonium series. Our high-yielding and facile methods for the synthesis of the prototypical phosphinophosphonium **1**,[17] diphosphinophosphonium **2**,[18] and cyclotetraphosphinophosphonium **5**[18] cations have now been applied to the preparation of the

centers.[18] Derivatives of **3** and **4** provide representative frameworks that complete a series of the smallest cyclopolyphosphinophosphonium cations **3–5**, and their characterization is pivotal in the systematic development of fundamental phosphorus chemistry.

^{31}P NMR spectra of reaction mixtures containing (P*t*Bu)$_3$ (**6a**) with excess MeOTf show quantitative formation of [(P*t*Bu)$_3$Me][OTf] (**3a**-OTf; Figure 1a and Scheme 2a). The spectrum can be approximated as an AMX[19] spin system and is consistent with the solid-state structure of **3a**-OTf (Figure 2a), thus demonstrating stereoselective methylation of **6a** at either of the *syn*-configured centers to give a racemic
Figure 1. ^{31}P NMR spectra at 101.3 MHz: a) mixture of MeOTf (2 equiv) and (P*t*Bu)$_3$, which shows the approximate AMX pattern of **3a**-OTf; b) mixture of MeOTf (2 equiv) and (PCy)$_4$, which shows the approximate A$_2$MX pattern of **4a**-OTf; c) experimental (top) and simulated (inverted) AB$_2$X pattern of pure **4b**-OTf.

Scheme 2. Preparation of cyclopolyphosphinophosphonium cations. OTf = trifluoromethanesulfonate, Cy = cyclohexyl, TMS = trimethylsilyl.
Figure 2. Representative structural views of the cations in a) **3a**-OTf, b) **4a**-OTf, and c) **4b**-OTf. Ellipsoids are given at the 50% probability level. Hydrogen atoms are omitted for clarity.

mixture rather than the *meso* isomer. Similarly, the homocyclic tetraphosphorus core is maintained in the formation of [(PCy)$_4$Me][OTf] (**4a**-OTf) from (PCy)$_4$ (**7**) and MeOTf (Scheme 2b), and the ^{31}P NMR spectrum of the reaction mixture can be approximated as an A$_2$MX spin system (Figure 1b). Thus, methylation occurs at one of the four equivalent phosphorus atoms in the all-*trans* configuration of **7**, which is confirmed by the solid-state structure of the

meso isomer **4a** (Figure 2b). The reaction of **6a** with 1.5 equivalents of PMe$_2^+$ (formed in situ from Me$_2$PCl and TMSOTf, see Scheme 2c) gives [(P*t*Bu)$_3$PMe$_2$][OTf] (**4b**-OTf) almost quantitatively through a PMe$_2^+$ bond insertion/ring expansion process. The complicated ^{31}P NMR spectrum of **4b**-OTf (Figure 1c) was simulated at 101.3 MHz (Figure 1c, inverted) and at 202.6 MHz as a second-order AB$_2$X spin system and is consistent with the symmetric *meso* structure of **4b** observed in the solid state (Figure 2c). There is no evidence for the existence of the diastereomeric isomers of **4b**, thus indicating a stereospecificity of the reaction that can be rationalized in terms of "PMe$_2^+$" insertion into the *syn*-configured P–P bond at the less-hindered face of **6a**,[20] as observed in similar insertions of "PCl" and "PBr".[21]

Examples of cations based on framework **4** have been previously postulated on the basis of elemental analysis[22,23] and ^{31}P NMR data;[24] however, we provide herein the first confirmation of structural types **3** and **4**. The solid-state structural features of **3a**-OTf, **4a**-OTf, and **4b**-OTf are listed in Table 1 along with the comparative parameters of [P$_5$Ph$_6$][OTf] (**5a**-OTf), **6a**, **7**, and (PPh)$_5$. The methylated, four-coordinate P1 center in **3a** is significantly distorted with the C-P1-P angles exhibiting the widest range (108.6–133.2°) of the compounds listed in Table 1 (Figure 2a). Whereas the endocyclic angles in **3a** are similar to those in the neutral precursor **6a**, the plane defined by C1,P1,C2 is twisted by 72.49(6)° with respect to the plane of the three phosphorus atoms (ideally 90°) because of the steric interactions of the *syn* substituents. The greater steric imposition of the *tert*-butyl substituents in **4b** relative to that of the cyclohexyl substituents in **4a** is indicated by both the greater planarity of the P$_4$ ring in **4b** (P-P-P-P torsional angles: **4a**: 23.6–24.2°, **4b**: 10.3–10.5°; c.f. (P*t*Bu)$_4$: 24.5°, **7**: 31.4°) and a greater distortion of the tetrahedral geometry at P1 in **4b**, in which a larger range of C-P1-P angles and a smaller C-P-C angle are adopted (Table 1). In this context, the cyclohexyl substituent at P1 in **4a** minimizes steric interactions by twisting to enable a *gauche* conformation of the α-hydrogen atom of C2 and the methyl substituent (C1).

The P–P distances are remarkably regular in neutral, anionic, and cationic compounds, although the four-coordinate phosphorus centers of the cations typically form slightly shorter P–P bonds (bold values in column 3 of Table 1). Interestingly, the P–P distances between the three-coordinate phosphorus centers in the cations are somewhat longer than those in the neutral cyclopolyphosphines. Consistent with the trend in P–P distances, the shortest P–C bonds within a given cation involve the phosphonium center (bold values in column 2 of Table 1).

Table 1: Selected distances [Å] and angles [°] for **3a**-OTf, **4a**-OTf, and **4b**-OTf, and the comparative features of **5a**-OTf, **6a**, **7**, and (PPh)₅.[a]

[a] Numbers in square brackets denote atom labels and the values in bold are those that involve the four-coordinate phosphorus center (av. = average value). [b] This work. [c] The average of two crystallographically independent molecules.

In a preliminary study of reactivity, reaction mixtures that contain **4a**-OTf and PMe₃ show the characteristic A₂B pattern of (PCy)₃ (**6c**) in the ³¹P NMR spectra.[27] In addition, two new doublets (δ = 15.4 and −38.2 ppm, ¹*J*(P-P) = 295 Hz) are assigned to the new phosphinophosphonium cation in [Me₃P-PMeCy][OTf] (**1a**-OTf), and a low-intensity sharp signal at δ = −67 ppm is assigned to **7** (Scheme 3). The

Scheme 3. Phosphenium abstraction from **4a**.

abstraction of MeCyP⁺ from **4a** by PMe₃ effects a ring contraction and, in conjunction with a previous methylation step, highlights a synthetically viable transformation from cyclotetraphosphine (PR)₄ to cyclotriphosphine (PR)₃. In addition, the reversibility of the phosphenium P−P insertion is observed (by ³¹P NMR spectroscopic analysis) in the reaction of **4b** with PMe₃, which slowly gives **6a** and [Me₃P-PMe₂]-[OTf] (**1b**-OTf).

In summary, the application of methylation or phosphenium insertion reactions to cyclopolyphosphines has enabled the characterization of a family of small cyclopolyphosphinophosphonium monocations. The high-yielding preparations

of cyclodiphosphinophosphonium **3** and cyclotriphosphino-phosphonium **4** cations are facilitated by the appropriate imposition of substituent steric strain in the starting cyclo-polyphosphines. The phosphenium abstraction induced by PMe₃ and ring contraction provides further systematic development of these fundamentally important *catena*-phosphorus frameworks.

Experimental Section

Small-scale reactions were carried out in a glove box with an inert N₂ atmosphere. Solvents were dried on an MBraun solvent-purification system and stored over molecular sieves prior to use. (P*t*Bu)₃[28] and (PCy)₄[29] were prepared according to literature methods. All the reported ³¹P NMR parameters were derived by computer simulation, as all compounds exhibited some degree of second-order character.

3a-OTf: MeOTf (0.08 mL, 0.71 mmol) was added dropwise to a solution of (P*t*Bu)₃ (0.096 g, 0.36 mmol) in fluorobenzene (4 mL). The reaction mixture was filtered after 15 min. Slow diffusion of hexane vapors into the filtrate at −25 °C gave colorless crystals; yield = 0.14 g (0.32 mmol, 87 %). M.p. 121–125 °C; elemental analysis (%) calcd for C₁₄H₃₀F₃O₃P₃S: C 39.3, H 7.1; found: C 39.5, H 7.0; ¹H NMR (500.1 MHz, CDCl₃, 298 K): δ = 3.6 (dd, *J*(P,H) = 13 Hz, *J*(P,H) = 8 Hz, 1H), 1.6 (d, ³*J*(P,H) = 22 Hz, 3H), 1.4 (d, ³*J*(P,H) = 17 Hz, 3H), 1.6 ppm (d, ³*J*(P,H) = 17 Hz, 3H); ³¹P NMR (101.3 MHz, CDCl₃, 298 K): AMX spin system, δA = −110.3, M = −50.8, X = −20.4 ppm, *J*(A,M) = −123, *J*(A,X) = −334, *J*(M,X) = −317 Hz; FTIR (nujol, ranked intensities): $\tilde{\nu}$ = 1399 (9), 1260 (1), 1151 (2), 1030 (4), 904 (5), 800 (10), 751 (8), 638 (3), 572 (7), 516 (6) cm⁻¹.

4a-OTf: MeOTf (0.095 mL, 0.84 mmol) was added dropwise to a mixture of (PCy)₄ (0.25 g, 0.55 mmol) in CH₂Cl₂ (5 mL). The reaction mixture was filtered after 90 min, and removal of the solvent in vacuo gave a white solid that was recrystallized at −25 °C from fluoroben-

zene by vapor diffusion of hexane over 3 days; yield = 0.15 g (0.23 mmol, 43%). M.p. 175–177°C; elemental analysis (%) calcd for $C_{26}H_{47}F_3O_3P_4S$: C 50.3, H 7.6; found: C 50.4, H 7.3; ^{1}H NMR (500.1 MHz, CDCl$_3$, 298 K): δ = 2.6 (m, 1H) 2.4 (d, J(P,H) = 12 Hz, 3H), 2.4 (m, 2H), 1.7–2.1 (m, 20H), 1.1–1.5 ppm (m, 21H); ^{31}P NMR (202.6 MHz, CDCl$_3$, 298 K): A$_2$MX spin system, δA = −69.8, M = −56.2, X = 10.1 ppm, ^{1}J(A,M) = −122, ^{1}J(A,X) = −230, ^{2}J(M,X) = −17 Hz; FTIR (nujol, ranked intensities): $\tilde{v}$ = 1284 (4), 1246 (1), 1158 (5), 1083 (3), 926 (9), 883 (8), 754 (10), 636 (2), 572 (7), 527 (6) cm^{-1}. Crystals suitable for X-ray diffraction were obtained by vapor diffusion of fluorobenzene/hexane at room temperature.

4b-OTf: A solution of PMe$_2$Cl (0.044 mL, 0.55 mmol) and TMSOTf (0.10 mL, 0.67 mmol) in CH$_2$Cl$_2$ (3 mL) was added dropwise to a solution of (PtBu)$_3$ (0.098 g, 0.37 mmol) in CH$_2$Cl$_2$ (3 mL). The solvent was removed in vacuo after stirring of the reaction mixture for 45 min, and the resulting white solid was washed with portions of hexane (2 × 4 mL). The product was recrystallized from fluorobenzene by diffusion of hexane vapor into the solution at room temperature over 5 days; yield = 0.095 g (0.20 mmol, 54%). M.p. 112–114°C; elemental analysis (%) calcd for $C_{15}H_{33}F_3O_3P_4S$: C 38.0, H 7.0; found: C 38.5, H 6.9; ^{1}H NMR (500.1 MHz, CDCl$_3$, 298 K): δ = 2.7 (d, ^{2}J(P,H) = 14 Hz, 1H), 2.4 (dt, J(P,H) = 13 Hz, J(P,H) = 8 Hz, 1H), 1.5 (m, 6H), 2.7 ppm (d, ^{3}J(P,H) = 14 Hz, 3H); ^{31}P NMR (101.3 MHz, CDCl$_3$, 298 K): AB$_2$X spin system, δA = −28.2, B = −24.2, X = −2.1 ppm, ^{1}J(A,B) = −143, ^{1}J(B,X) = −251, ^{2}J(A,X) = 28 Hz; FTIR (nujol, ranked intensities): $\tilde{v}$ = 1304 (6), 1267 (2), 1224 (7), 1155 (3), 1032 (4), 957 (8), 914 (9), 638 (1), 573 (10), 517 (5) cm^{-1}.

X-ray crystallographic analysis: Data was collected on Bruker AXS P4/SMART 1000 diffractometer using ω and θ scans with a width of 0.3°, a exposure time of 10 s at 173 K, and a detector distance of 5 cm. The data were reduced (SAINT)[30] and corrected for absorption (SADABS).[31] Structures were solved by direct methods and refined by full-matrix least squares on F^2 (SHELXL).[32] All non-hydrogen atoms were refined anisotropically. **3a**-OTf: $C_{14}H_{30}F_3O_3P_3S$; colorless, plates, crystal size 0.40 × 0.40 × 0.10 mm^3, monoclinic, space group $P2_1/n$, a = 13.6318(9), b = 10.5918(7), c = 15.487(1) Å^3, β = 104.084(1)°, V = 2168.9(2) Å^3, Z = 4, μ = 0.405 mm^{-1}; λ(Mo$_{K\alpha}$) = 0.71073 Å, 2$\theta_{max.}$ = 53.8°, collected (independent) reflections = 14573 (4869), R_{int} = 0.0213; 337 refined parameters, R_1 = 0.0487, wR_2 = 0.1056 for all data, max./min. residual electron density = 0.646/−0.476 e Å^{-3}. **4a**-OTf: $C_{26}H_{47}F_3O_3P_4S$, colorless parallelepiped, crystal size 0.275 × 0.20 × 0.175 mm^3, triclinic, space group $P\bar{1}$, a = 11.4946(7), b = 11.5640(7), c = 14.0822(9) Å^3, α = 110.984(1), β = 102.476(1), γ = 106.868(1)°, V = 1561.62(17) Å^3, Z = 2, μ = 0.352 mm^{-1}; λ(Mo$_{K\alpha}$) = 0.71073 Å, 2$\theta_{max.}$ = 52.2°, collected (independent) reflections = 10965 (6795), R_{int} = 0.0195; 522 refined parameters, R_1 = 0.0475, wR_2 = 0.0964 for all data, max./min. residual electron density = 0.491/−0.247 e Å^{-3}. **4b**-OTf: $C_{15}H_{33}F_3O_3P_4S$, colorless parallelepiped, crystal size 0.40 × 0.275 × 0.25 mm^3, tetragonal, space group $I4_1/a$, a = 25.6452(11), b = 25.6452(11), c = 14.7549(8) Å^3, V = 9703.9(8) Å^3, Z = 16, μ = 0.432 mm^{-1}; λ(Mo$_{K\alpha}$) = 0.71073 Å, 2$\theta_{max.}$ = 54.7°, collected (independent) reflections = 33323 (5547), R_{int} = 0.0293; 367 refined parameters, R_1 = 0.0445, wR_2 = 0.0809 for all data, max./min. residual electron density = 0.414/−0.237 e Å^{-3}.

CCDC-271727–271729 (**3a**, **4a**, and **4b**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Optical Absorption and Structure of a Highly Symmetrical Neptunium(v) Diamide Complex**

Guoxin Tian, Jide Xu, and Linfeng Rao

The neptunium(v) cation, NpO_2^+, contains Np in its most stable oxidation state under a wide range of conditions in aqueous media. Because of its low positive charge, NpO_2^+ does not form strong complexes with ligands so it is difficult to separate neptunium from high-level nuclear wastes by using traditional extracting agents that are effective for separating other actinides.[1] Also, the low tendency of NpO_2^+ to undergo hydrolysis and sorption makes it highly mobile in the subsurface, raising concern in the migration of this radionuclide in the environment.[2]

The absorption spectrum of NpO_2^+ is dominated by a band in the near-IR region with a fairly high intensity ($\varepsilon \approx 390\,M^{-1}\,cm^{-1}$ at 980.2 nm). This band, as well as a weaker band at 1024 nm, follows Beer–Lambert behavior and is often used to quantitatively determine the concentration of NpO_2^+ in solution.[3] The position and intensity of these bands are also affected by the coordination environment of NpO_2^+ and are frequently used to study the complexation behavior of NpO_2^+.[4,5] The absorption band of the free $[NpO_2(H_2O)_n]^+$ ion at 980.2 nm is usually shifted to longer wavelengths when NpO_2^+ forms complexes with ligands that replace the water molecules in the primary hydration sphere. For a series of structurally related ligands, the magnitude of the shifts in the wavelength appears to increase as the binding strength of the ligand is increased. For example, in the 1:1 complexes of NpO_2^+ with dicarboxylates, the stability constants and the shifts in wavelength ($\log\beta$ and $\Delta\lambda$ in nm) are 1.29 and 3.7 for glutarate,[6] 1.47 and 4.5 for succinate,[6] 2.63 and 7.2 for malonate,[7] and 3.79 and 8.4 for oxalate.[7] Formation of 1:2 complexes with these ligands shifts the absorption band to even longer wavelengths.[4,6,7] The molar absorptivities of the bands vary in the range from 250 to $390\,M^{-1}\,cm^{-1}$.[4,6,7] The underlying mechanism that allows the transitions and the origin of the intensities remain unclear. Theoretical calculations suggest that the absorption band at 980 nm is a 5f→5f electric-dipole transition, which is forbidden by Laporte's rule, and that the intensity of the transition depends on the symmetry of the Np^V species.[8] The results of theoretical calculations are enlightening but need to be tested by comparison with experimentally observed spectra of Np^V complexes with different ligands.

In an effort to develop efficient extractants for the separation of actinide ions including Np^V, we have found that tetraalkyl-3-oxa-glutaramide, L^1, displays a good ability

L^1 L^2 L^3
R = *i*Bu, Bu, *n*Oct   R = *n*Oct
to extract Np^V ions.[9] To obtain insight into the complexation of Np^V with diamide ligands, a simple water-soluble homologue of L^1, tetramethyl-3-oxa-glutaramide (L^2), was synthesized and studied by optical absorption spectroscopy in aqueous solution.

Figure 1a shows the absorption spectra obtained during spectrophotometric titrations of Np^V with L^2. As the concentration of L^2 was increased, the intensities of the absorption bands at 980 and 1024 nm that belong to the free NpO_2^+ cation decreased and new bands appeared at 987 and 1037 nm, which correspond to the formation of a 1:1 complex of Np^V with L^2, $[NpO_2(L^2)^+]$. As the concentration of L^2 was further increased, the intensities at 987 and 1037 nm decreased but no new absorption peaks appeared at longer wavelengths. These changes in the spectra are different from those for Np^V complexes with many other ligands for which the decrease of the absorbance of the first complex is accompanied by the appearance of new absorption band(s) of successive complexes at longer wavelengths.

The variation of the spectra in Figure 1a is interpreted with the assumption that two complexes of Np^V with L^2 form in solution successively but that the second complex, $[NpO_2(L^2)_2^+]$, does not absorb in that wavelength region. This assumption is consistent with the factor analysis of the spectra using the Hyperquad2000 program;[10] the formation constants of the $[NpO_2(L^2)]^+$ and $[NpO_2(L^2)_2]^+$ complexes are calculated to be $23.7 \pm 0.5\,M^{-1}$ and $295 \pm 6\,M^{-2}$, respectively. The deconvoluted spectra for free NpO_2^+ and the $[NpO_2(L^2)]^+$ complex are shown in Figure 1b.

The $[NpO_2(H_2O)_n]^+$ ion also has absorption bands of much lower intensity in the visible region that render its usual green-blue color. Figure 2 shows that the intensities of the bands at 430, 476, and 616 nm decrease and the spectra tend to become flat and featureless as the concentration of L^2 increases, which suggests that the $[NpO_2(L^2)_2]^+$ complex does

Figure 1. a) Spectrophotometric titrations in the near-IR region of Np^V with L^2. [Np] = 2.66 mM; [L^2] = 0–336 mM; optical path: 1.0 cm. b) Deconvoluted absorption spectra of NpO$_2^+$ (——) and the [NpO$_2$(L^2)]$^+$ complex (- - - -); [NpO$_2$(L^2)$_2$]$^+$ does not absorb in this region.
Figure 2. Spectrophotometric titrations of Np^V with L^2 in the visible region. [Np] = 2.66 mM; [L^2] = 0–336 mM; optical path: 1.0 cm.

not absorb in the visible region. In fact, the initial green-blue color of the solution of [NpO$_2$(H$_2$O)$_n$]$^+$ gradually faded as the concentration of L^2 was increased and became almost colorless at the end of titration.

These results are consistent with the theoretical calculations by Matsika et al.[8] For the f^2 electronic configuration of NpO$_2^+$, all of the excited states up to 23000 cm^{-1} (corresponding to $\lambda \approx 430$ nm) contain two f electrons and display the gerade parity in the ground state.[8] Thus, all the excitations at low energies should be electric-dipole forbidden by Laporte's rule. This rule is followed if NpO$_2^+$ is in a coordination environment where a center of inversion exists. However, if the ligands that surround the NpO$_2^+$ are arranged so that the center of inversion is destroyed, Laporte's rule does not apply and the f→f transitions are allowed. The successive complexation of Np^V with L^2 and the accompany-

ing changes in symmetry and absorption spectra are best illustrated by Scheme 1.

The free NpO$_2^+$ cation contains five molecules of H$_2$O in the equatorial plane[11] to result in a structure without a center of inversion. As a result, the f→f transitions are allowed and
Scheme 1. Successive complexation of [Np^{V}O$_2$(H$_2$O)$_5$]$^+$ with L^2 and the accompanying changes in symmetry and absorption bands (corresponding ε values in M^{-1}cm^{-1} are given in parentheses).

absorption bands at 980 and 1024 nm are observed. For the same reason of absence of a center of inversion, the first complex, [NpO$_2$(L^2)]$^+$, does absorb light, but the energies of the absorption bands are red-shifted (987 and 1037 nm). However, the second complex, [NpO$_2$(L^2)$_2$]$^+$, could be highly symmetrical with a center of inversion, wherein each L^2 ligand supplies three oxygen atoms to coordinate NpO$_2^+$ in the equatorial plane. This complex is expected to display no absorption in the near-IR region (Figure 1). The same discussions apply to the change of absorption bands in the visible region (Figure 2) because all the bands up to 23000 cm^{-1} originate from f→f transitions as shown by the theoretical calculations by Matsika et al.[8]

A comparison of the absorption spectra between the complexes of Np^V and L^2 (Figures 1 and 2) and those between Np^V and oxalate (C$_2$O$_4^{2-}$) complexes (Figure 3) further demonstrates the dependence of f→f transitions on the symmetry of the coordination environment of Np^V. It is known that the Np^V oxalate complexes, [NpO$_2$(C$_2$O$_4$)]$^-$ and [NpO$_2$(C$_2$O$_4$)$_2$]$^{3-}$, with a coordination number of five in the equatorial plane of NpO$_2^+$, do not have inversion centers.[12] There are three water molecules and one bidentate oxalate ligand in [NpO$_2$(C$_2$O$_4$)]$^-$, and one water molecule and two bidentate oxalate ligands in [NpO$_2$(C$_2$O$_4$)$_2$]$^{3-}$. As a result, the f→f transitions in both complexes should be allowed. This is indeed the case as shown by the absorption spectra in Figure 3. For the spectra in both the near-IR and visible regions, distinctive absorption bands are seen for [NpO$_2$(H$_2$O)$_n$]$^+$, [NpO$_2$(C$_2$O$_4$)]$^-$, and [NpO$_2$(C$_2$O$_4$)$_2$]$^{3-}$. The successive complexation of Np^V ion with oxalate ion and the accompanying changes in symmetry and absorption spectra are illustrated in Scheme 2.

To obtain structural information for the [NpO$_2$(L^2)$_2$]$^+$ complex and test the assumption based on the theoretical calculations discussed above, single crystals of the complex were prepared from solution and X-ray diffraction data were collected (Figure 4).[13] The perchlorate salt, [NpO$_2$(L^2)$_2$]ClO$_4$, crystallized in a highly symmetrical tetragonal space group, *I4/mcm*. The neptunium atom sits at the crossover

point of three mirror planes that lie perpendicular to each other. The two L^2 ligands are coplanar and are mirror images of each other. The O=Np=O moiety is perfectly linear and symmetrical, with an angle of 180° and Np=O distances of 1.729 Å. The f→f transition in this highly symmetrical complex with a center of inversion is forbidden according to the theoretical calculations. In fact, the crystals and solutions of [NpO$_2$(L^2)$_2$]ClO$_4$ are almost colorless, drastically different from the green-blue colors of most reported Np^V compounds. We believe that the [NpO$_2$(L^2)$_2$]$^+$ complex in solution has the structure shown in Figure 4. Attempts to collect the diffuse reflectance spectra of [NpO$_2$(L^2)$_2$]ClO$_4$ in the solid state were

Figure 4. ORTEP drawing (30% probability ellipsoids) of [NpO$_2$(L^2)$_2$]$^+$. For clarity, the perchlorate anion is not shown.

unsuccessful owing to the limited availability of the solids and the complications involved in the experimental setup for handling the transuranic elements.

The structure of [NpO$_2$(L^2)$_2$]$^+$ (Figure 4) provides guidance in the design of better ligands to complex Np^V. The distance between the two carbon atoms of the terminal methyl groups is 4.01 Å, implying that significant steric hindrance would be present if the methyl groups are replaced by bigger and/or bulkier alkyl groups such as the octyl or *iso*-butyl groups in L^1, which is used as an extractant for the separation of actinides. The bigger alkyl groups in L^1 are mainly for enhancing its solubility in organic solvents. However, the structure of [NpO$_2$(L^2)$_2$]$^+$ suggests that asymmetric amide groups such as *N*-methyl-*N*-octyl (L^3) could be used, guaranteeing the solubility of the ligand in organic solvents as well as improving the complexation and thus the extraction of Np^V by reducing the steric hindrance in the Np^V complex. Also, the structural parameters of [NpO$_2$(L^2)$_2$]$^+$ help with the design of hexadentate amide ligands with a rigid backbone connecting the diamide ligands. Complexation of such ligands with Np^V should be enhanced due to a lower preorganization energy and a larger entropy effect.

In conclusion, we have synthesized, studied the optical absorption properties, and characterized the molecular structure of a highly symmetrical Np^V diamide complex, [NpO$_2$(L^2)]$_2$$^+$. This is the first neptunium complex that has been characterized by single-crystal X-ray diffraction with a synchrotron radiation source. The correlation between the optical absorption properties and the symmetry of Np^V complexes in solution was experimentally demonstrated and confirms the theoretical calculations of the optical spectra of 5f elements. The identified structure of [NpO$_2$(L^2)$_2$]$^+$, while helping to interpret the optical absorption spectra also suggests approaches for the rational design of ligands to improve the binding ability with Np^V and the separation of neptunium from nuclear wastes.

Experimental Section

Spectrophotometric titrations were performed on a Cary 5G UV-Vis-NIR spectrophotometer (Varian). Initial solutions of (NpO$_2$)(ClO$_4$) (V_0 = 2.50 mL, [Np] = 0.5–3 mM, I = 1M NaClO$_4$, pH 5–7) in a 1-cm

quartz cuvette were titrated with solutions of L^2 or oxalate ion (0.2–1M). After each addition of the titrant (0.05–0.140 mL), the absorption spectrum was collected from $\lambda = 400$–1150 nm at 0.2-nm intervals.

Single crystals of $[NpO_2(L^2)_2]ClO_4$ were prepared from 0.05M $(NpO_2)(ClO_4)$ (0.2 mL) and 0.5M L^2 by slow evaporation in a hood. A small crystal (20–80 μm) was immerged in Paratone-N oil and sealed inside a quartz capillary (i.d. = 0.3 mm). Precautions, including coating the capillary with a thin layer of protective resin, were taken to ensure the containment of radioactive neptunium. The capillary was mounted in a brass pin on the goniometer, which was then transported from the radiochemistry laboratory in a closed container to the Advanced Light Source (ALS), thus minimizing the amount of alignment required once at the diffractometer. Crystallographic data were collected at 255 K in less than one hour using a Bruker Platinum 200 detector at the Small-Crystal Crystallographic Beamline 11.3.1 at the ALS of Lawrence Berkeley National Laboratory.

Imido Complexes

On the Mechanism of the Reaction of Organic Azides with Transition Metals: Evidence for Triplet Nitrene Capture**

Mahdi M. Abu-Omar,* Catherine E. Shields, Nicola Y. Edwards, and Rebecca A. Eikey

Organic azides (RN_3) have received extensive attention recently because of their central role in several "spring-loaded" reactions that have been dubbed "click chemistry".[1–4] In organometallic chemistry, azides have been used

Communications

extensively for the preparation of imido (M=NR) complexes, in which dinitrogen is released as byproduct.[5,6] As part of our interest in developing nitrene (NR) transfer to organic substrates by transition-metal catalysis, we have used aryl azides, which are quite stable and easy to make,[7,8] to prepare mononuclear terminal imido complexes of manganese(v) and chromium(v) corroles.[9,10] Despite many known reactions of organic azides with transition metals, little is known about the reaction mechanism. Organoazido metal complexes have been proposed to initially form for coordinatively unsaturated metal complexes.[11–14] However, only in two instances have such complexes been characterized and shown to proceed to the imido product upon heating or photolysis, presumably via a four-membered metallacycle.[15–17] Herein we report a novel mechanism for the reaction of aryl azides with manganese corroles in which the metal does not form an organoazido complex.

Encouraged by the successful synthesis of terminal imido manganese(v) complexes from mesityl azide and trichlorophenyl azide,[9] we explored the utility and generality of this reaction (Scheme 1). We noted that *ortho* substitution is mandatory, as is thermal or photochemical activation. Phenyl azide with substituents in the *para* position as well as the electron-withdrawing sulfonyl azide did not produce imido metal complexes.

Results presented herein and the scope of the reaction (Scheme 1) gave valuable insight into the mechanism of the reaction of organic azides with transition-metal corroles. Our mechanistic proposal is presented in Scheme 2. On thermal or photochemical decomposition of aryl azide, singlet nitrene is formed and dinitrogen extruded.[18,19] The singlet nitrene then decomposes along two pathways. The first is cyclization to azepine **B** via azirine **A** as a steady-state intermediate.[20] The
Scheme 2. Mechanism of the reaction of organic azides with [Mn^{III}(tpfc)].

ultimate fate of the azepine is polymerization.[19] However, in highly dilute solutions, polymerization of **B** is suppressed and it reverts to singlet nitrene, which relaxes by intersystem crossing (isc) to the lower-energy triplet state.[21] The final thermodynamic product is azo compound **C**, assumed to form by dimerization of triplet nitrene.[22] This second pathway, isc of singlet nitrene to triplet, is responsible for the formation of the imido manganese complex in our system and is most consistent with the observed scope of the reaction (Scheme 1) and kinetic data, as detailed below.

Ortho substituents are mandatory for the formation of imido metal complexes in this system. This is in agreement with results showing that singly *ortho*-substituted singlet aryl nitrenes cyclize away from the substituent,[23] and *ortho* methylation increases the rate of intersystem crossing.[21] Furthermore, the lack of reaction with fluorinated phenyl azides and sulfonyl azide is consistent with these substituents destabilizing the open-shell singlet nitrene.[24] Indeed, under our reaction conditions only starting material was recovered with these substrates (Scheme 1).

The kinetics of imido metal formation were studied in detail for the reaction of mesityl azide (MesN$_3$) with [Mn^{III}-(tpfc)]. Changes in the UV/Vis spectra for a typical reaction are displayed in Figure 1. The disappearance of the bands at
Scheme 1. Scope of the reaction of aryl azides with transition-metal corroles.
Figure 1. UV/Vis spectral changes for the reaction of [Mn^III(tpfc)] (15 μM) with mesityl azide (2.1 mM) in toluene at 80°C recorded every 6 min.

479 and 609 nm and appearance of the band at 536 nm are indicative of a change in the oxidation state from Mn^III to Mn^V. The tight isosbestic points at 510 and 565 nm demonstrate clean conversion without significant accumulation of an intermediate.

The progress of the reaction was monitored at 536 nm with [Mn^III(tpfc)] limiting and MesN_3 in excess. The experimental reaction rate was found to be first-order in mesityl azide (Figure 2) and exhibited a complex dependence on the concentration of the manganese complex. A simplified rate law that includes the reaction steps described in Scheme 2 is given in Equation (1).

$$\frac{dc_{[Mn^V imide]}}{dt} = \frac{k_1 k_P c_{[Mn(tpfc)]} c_{MesN_3}}{k_P c_{[Mn(tpfc)]} + k_d c_{^3NMes}} \tag{1}$$

Under conditions where $k_P c_{[Mn(tpfc)]} \gg k_d c_{^3NMes}$, the rate law simplifies to $dc_{[Mn^V=NR]}/dt = k_1 c_{MesN_3}$ and the rate is zeroth-order in the concentration of the manganese corrole. However, as the reaction proceeds and [Mn(tpfc)] is consumed, the above assumption is no longer valid and the kinetics divert from zeroth order. This expectation is consistent with the time profiles shown in Figure 2A, which are linear over the initial 30% of the reaction (ca. 0.02 ΔOD) and deviate from zeroth order in the later stages. The experimental time profiles do not fit an exponential pseudo-first-order equation (see Supporting Information). Furthermore, under no circumstance would the reaction rate be independent of the metal concentration if an organoazido adduct was formed initially or the metal corrole reacted directly with the organic azide. Similar kinetic behavior was observed when reaction progress was followed at 479 nm, which corresponds to the disappearance of the Mn^III reactant (see Supporting Information).

The observed kinetics were successfully modeled with the kinetic simulation program KINSIM.[25,26] Figure 3A shows the simulated time profiles for [Mn^III(tpfc)], [Mn^V(tpfc)], azo compound, azepine, and polymer arising from the azepine. The rate constants used in association with Scheme 2 as the reaction mechanism are given in the caption of Figure 3. The rate constant for the thermal decomposition of mesityl azide
Figure 2. A) Time profiles for the reaction of [Mn(tpfc)] (15 μM) and mesityl azide (3, 5, and 12 mM) in toluene at (80.0 ± 0.2)°C. The linear fit is over the initial 30% of the reaction to illustrate zeroth-order kinetics that deviate from linearity in the later stages of the reaction. B) A plot of the initial rate V_i versus the mesityl azide concentration showing first-order dependence on the azide concentration.

(k_1) was determined experimentally herein (Figure 2B); the rate constant for intersystem crossing (k_{isc}) was taken from published data,[27] and the rate constants for triplet nitrene dimerization to give the azo compound (k_d) and for polymerization of azepine (k_2) were set to the diffusion limit ($8.0 \times 10^9 M^{-1} s^{-1}$). The remaining three rate constants were floated to give the best fit to the experimental profiles. The agreement between experimental and simulated kinetics is illustrated in Figure 3B and the Supporting Information. It is worth noting that formation of the azo compound sets in after the initial 30% of reaction, which agrees with the observed kinetic behavior (see above). Nevertheless, GC-MS analyses of reaction mixtures at the end of the reaction show only azide, and only at longer decomposition times is the azo compound detected (see Supporting Information). This apparent contradiction is most likely due to low concentrations of the azo compound (below the GC-MS detection threshold) on the reaction timescale (2 h).

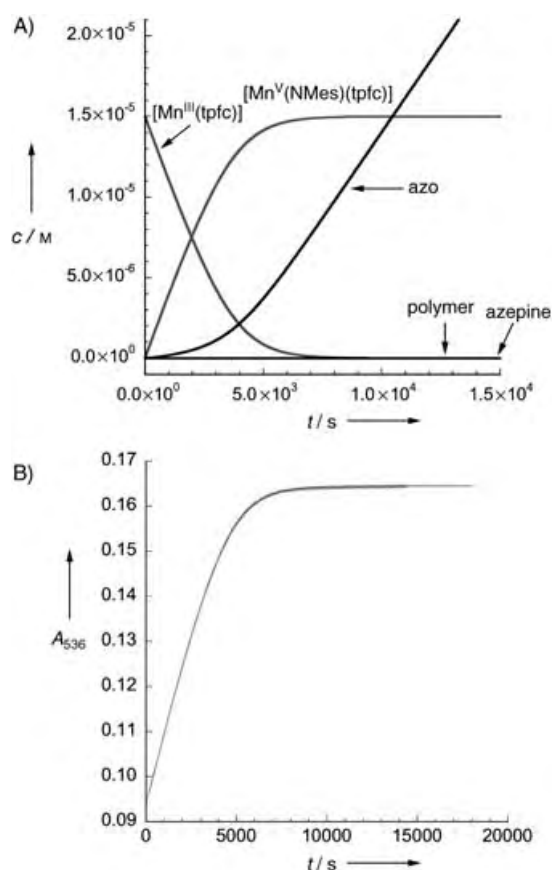
To date, the reaction of organic azides with transition-metal complexes to give imido metal compounds has been accepted to proceed via an organoazido metal intermediate. While this mechanism holds true in many instances and has been demonstrated in a couple of reaction systems, it is not exclusive.[15–17] We have described herein a new mechanism


Figure 3. A) Time profiles simulated by the program KINSIM for the reaction of [Mn^{III}(tpfc)] with mesityl azide according to Scheme 2. Simulation conditions: $c_{[Mn^{III}(tpfc)]} = 15$ μM, $c_{MesN_3} = 5.3$ mM, $k_1 = 8.3 \times 10^{-7}$ s^{-1}, $k_{isc} = 2.0 \times 10^7$ s^{-1},[27] $k_r = 1.0 \times 10^{10}$ s^{-1}, $k_{-r} = 1.0 \times 10^7$ s^{-1}, $k_2 = k_d = 8.0 \times 10^9$ M^{-1} s^{-1}, $k_p = 2.0 \times 10^6$ M^{-1} s^{-1}. B) Simulated (gray) and experimental (black) data for the formation of [Mn^V(NMes)(tpfc)] from the reaction of 15 μM [Mn(tpfc)] and 5 mM mesityl azide.

for the reaction of a manganese corrole with aryl azides to give imido metal complexes. In this mechanism, the transition-metal complex captures a triplet nitrene formed by thermal or photochemical activation of the organic azide. The compelling evidence presented for this mechanism is 1) complex dependence of the kinetics on metal concentration with zeroth order over 30% of the reaction), 2) the kinetics have been modeled successfully for the reaction mechanism described in Scheme 2, and 3) substituents in both *ortho* positions (Me or Cl, but not F) are required. Contrary to conventional wisdom that highly reducing metal complexes are needed for a reaction with organic azides, we have demonstrated that effective imido metal formation via nitrene capture does not require a highly reducing center. Investigations into harnessing this mechanistic paradigm for selective nitrene transfer under thermal or photochemical catalysis are in progress.

Experimental Section

Compounds were prepared and handled by standard vacuum-line and glove-box techniques. Toluene and acetonitrile were predried over molecular sieves and distilled over CaH$_2$ prior to use. When required, solvents were deoxygenated by freeze/pump/thaw cycles. Deuterated solvents were purchased from Cambridge Isotopes and used without further purification. All other solvents and reagents were of reagent grade and used as received. The syntheses of H$_3$(tpfc),[28,29] [Mn-(tpfc)],[30] [Cr(tpfc)(py$_2$)],[31] [Mn(tpfc)(NMes)][9] (Mes = 2,4,6-(CH$_3$)$_3$C$_6$H$_2$), [Mn(tpfc)(NAr)][9] (Ar = 2,4,6-Cl$_3$C$_6$H$_2$), [Mn(tpfc)-(NAr′)][10] (Ar′ = 2,6-Cl$_2$C$_6$H$_3$), [Cr(tpfc)(NMes)],[10] and [Cr(tpfc)-(NAr)][10] followed previously described methods. All azides were prepared by using the Sandmeyer reaction or slight variations thereof.[7,8] Azo compounds were compared to authentic samples. Photolysis experiments were carried out with a Hanovia Model 673A-0360 550 W medium-pressure mercury arc lamp. Rate measurements were carried out by conventional UV/Vis spectroscopy on a Shimadzu UV-2501 spectrophotometer equipped with a temperature-controlled cell holder. Formation of [Mn^V(NMes)(tpfc)] was monitored at 536 nm, $c_{[Mn(tpfc)]} = 15$ or 30 μM, and $c_{MesN_3} = 2.0$–12.0 mM at (80 ± 0.2)°C.

done little to unravel the role of morphology in the energy-transfer process. Even nearfield scanning optical microscopy, which has been used to study polymer blends at the sub-100-nm scale,[10,11] lacks the spatial resolution in most cases to study individual morphological regions that can be as small as a few nanometers.

Herein, we take an alternative approach by using single-molecule spectroscopy (SMS) to study energy transfer across a molecular interface in isolated, single diblock polymer DMOS-co-MEH chains (DMOS = 2-dimethyloctylsilyl-1,4-
Conjugated Polymers

Single-Molecule Studies of Electronic Energy Transfer in a Diblock Conjugated Polymer**

John K. Grey, Doo Young Kim, Young Jong Lee, Jose J. Gutierrez, Nam Luong, John P. Ferraris, and Paul F. Barbara

Electronic energy transfer across a molecular interface between two dissimilar conjugated polymers in a blend is a critical process for many promising optoelectronic device strategies.[1–9] Owing to the short range of electronic energy transfer, this process should in principle be strongly modulated by molecular-scale morphology in the interfacial regions of polymer blends. The most common approach for characterizing energy transfer in polymer blends, namely, ensemble fluorescence measurements, is obscured by morphological and kinetic heterogeneity of these materials and thus has

phenylenevinylene; MEH = 2-methoxy-5-(2′-ethylhexyloxy)-1,4-phenylenevinylene) comprised of an energy-donor block (DMOS, $\lambda_{\text{max}}^{\text{em}} = 490$ nm) and an energy-acceptor block (MEH, $\lambda_{\text{max}}^{\text{abs}} = 500$ nm). The sizes of these molecules (≈ 10 nm) make them excellent models for developing a detailed understanding at the molecular level of energy transfer between a molecular interface of two dissimilar polymers. SMS has been used effectively to study intramolecular energy transfer in bi- and multichromophoric dendrimers,[12–15] end-capped polymers,[16,17] and conjugated homopolymers.[18,19] The SMS approach reported here provides detailed information at the molecular level on how energy transfer is influenced by polymer morphology within a single diblock polymer chain.

Figure 1 shows ensemble fluorescence spectra (solid lines) for DMOS (a) and MEH (b) homopolymers at $T = 298$ K dissolved at high dilution in a polymethyl methacrylate (PMMA) polymer host. These spectra were obtained by summing single-molecule spectra for isolated polymer chains. For comparison we also show absorption spectra (dotted lines) for the homopolymers which were acquired in dilute liquid solutions (solvent) rather than in polymer thin films because of the weak absorption of the latter. These data indicate that excitation wavelengths of 415 nm and 488 nm selectively excite DMOS and MEH, respectively, and also demonstrate a good spectral overlap of the emission bands of DMOS and the absorption bands of MEH which is important for promoting energy transfer by the Förster mechanism (the dominant mechanism for conjugated polymers).[20,21]

Analogous ensemble spectra for the DMOS-co-MEH diblock polymer are shown in Figure 1c. The emission spectra of DMOS-co-MEH (single molecules and ensembles) are well-modeled by a sum of MEH- and DMOS-like spectral components and do not show evidence of excimer emission between the two blocks. It is apparent from the spectrum of the diblock polymer in Figure 1c (solid line, $\lambda_{\text{ex}} = 415$ nm) that energy transfer occurs from the DMOS block to the MEH block with an overall efficiency of approximately 75%. The spectrum obtained upon excitation at 488 nm (dashed line) in Figure 1c demonstrates, as expected, that direct

Figure 1. Absorption spectra recorded on dilute solutions (·····) and emission spectra from dilute thin-film ensembles (——) of a) DMOS, b) MEH, and c) DMOS-co-MEH. Ensemble spectra were obtained by summing single-molecule spectra for each polymer. Excitation wavelengths are indicated by arrows on the respective absorption bands (DMOS $\lambda_{ex} = 415$ nm; MEH $\lambda_{ex} = 488$ nm). Part (c) shows the dependence of the emission spectra from the DMOS-co-MEH ensemble at 298 K on the excitation wavelength: $\lambda_{ex} = 415$ nm (——); $\lambda_{ex} = 488$ nm (----).

Figure 2. a) Typical single-molecule spectra for DMOS-co-MEH excited at 415 nm, b) histogram of peak wavelengths of 210 single DMOS-co-MEH molecules, and c) sub-ensemble spectra excited at 415 nm. Sub-ensemble spectra were sorted according to their wavelength distribution ranges (labeled 1, 2, and 3), which correspond to 1) DMOS (500–530 nm), 2) blue MEH (540–560 nm), and 3) red MEH (570–600 nm).

excitation of the MEH block does not lead to uphill energy transfer from the MEH block to the DMOS block.

Further insight into the energy-transfer process was gained in a molecule-by-molecule analysis of the spectroscopy of DMOS-co-MEH. Typical spectra for single isolated DMOS-co-MEH molecules excited in the donor DMOS block at 415 nm are shown in Figure 2a. Single-molecule spectra were acquired individually over approximately 3-minute periods, during which time the spectra did not vary, which indicates that spectral diffusion and photochemistry are not complicating factors for these measurements. A histogram (Figure 2b) of the peak wavelength for the DMOS-co-MEH molecules reveals three distinct classes: 1) 490–530 nm, 2) 535–560 nm, and 3) 570–605 nm. Sub-ensemble spectra (Figure 2c) for the different classes were generated by sorting the spectra according to the peak wavelength. Class 1 corresponds to almost pure DMOS-like emission ($\lambda_{max}^{em} = 505$ nm). Class 2 ($\lambda_{max}^{em} = 550$ nm) and 3 ($\lambda_{max}^{em} = 590$ nm), in contrast, closely correspond to the previously reported blue- and red-light-emitting morphological forms of the MEH homopolymer[19,22] and thus imply efficient DMOS-to-MEH energy transfer.

It is informative to directly calculate the distribution of apparent energy-transfer efficiencies for the diblock single molecules. This has been determined by fitting the blue edge of each spectrum to a model DMOS spectrum and then using the amplitude of the donor spectrum to determine the fraction (f_D) of the donor intensity for each spectrum. Figure 3a shows a histogram of apparent energy-transfer efficiencies ($1-f_D$)[23] for all DMOS-co-MEH single molecules excited at 415 nm. The results clearly demonstrate that

Figure 3. a) Apparent energy-transfer efficiencies ($1-f_D$) for single DMOS-co-MEH molecules excited at 415 nm. b) Schematic diagrams illustrating energy transfer to red-light-emitting MEH sites in the diblock polymer: left) cascading energy transfer to blue-light-emitting MEH followed by emission and intrachain energy funneling to red—light-emitting MEH sites; right) direct energy transfer to red MEH. Spectroscopic states are represented by solid horizontal lines, and energy-transfer and emission transitions are shown as vertical dotted and solid lines with arrows, respectively.

the energy-transfer process in the diblock conjugated polymer sample is highly heterogeneous. The molecules that show a low energy-transfer efficiency (< 0.1) in the histogram consist mostly of diblocks that exhibit DMOS-only emission and closely correspond to class 1 in Figure 2c. Successive SMS scans of the same region of the sample using excitation alternatively at 415 and 488 nm demonstrated that these molecules contain extremely short MEH blocks, which lead to the lower efficiency of energy transfer. Thus, the major factor responsible for the low efficiency of energy transfer for a diblock molecule is a short MEH (acceptor) block. Presumably, energy transfer is slower for the shorter MEH block molecules owing to a smaller number of effective acceptor chromophores.

Two-color (415 nm/488 nm) excitation experiments were also carried out on the individual homopolymers to measure the contribution of "cross-talk" to the observed energy-transfer efficiencies by exciting MEH at 415 nm. The relative excitation efficiency of DMOS and MEH blocks excited at 415 nm was found to be greater than 9:1, which demonstrates that energy transfer rather than direct excitation is the dominant mechanism for the excitation of MEH. The data were not corrected for the small contribution from direct excitation.

It has recently been shown that MEH homopolymer chains can be roughly classified into blue- and red-light-emitting chains. The red-light-emitting single molecules have been shown to comprise a small number of low-energy "red" chromophores, due to chain–chain contacts, which act as acceptors of electronic energy from the much greater number of blue chromophores.[19,24] In contrast, the blue-light-emitting morphological forms of MEH lack red chromophores and thus directly emit from the blue chromophores. One of the main results of this study is that the presence of the DMOS block induces folding of the MEH block which leads to a larger fraction of red-light-emitting MEH sites in the diblock polymer, as compared to the MEH homopolymer. Over 70% of all single diblock polymer molecules studied exhibit high apparent efficiencies of energy transfer (> 0.8), with the MEH red-light-emitting form (class 3 in Figure 2c) being the dominant emitting species. It should be emphasized that the efficiency of energy transfer from DMOS to MEH is close to unity for a majority of both red- and blue-light-emitting molecules. The red and blue forms differ, however, in the ultimate sink for excitation energy, that is, the red or blue MEH chromophores. The reason for a larger fraction of red sites in the diblock case has not been established, but we speculate that it may be due to a co-collapse of both blocks to favor a more collapsed chain conformation, and hence a larger number of chain–chain contacts.

The possible photophysical processes pathways following excitation of the donor block at 415 nm which lead to the red-light-emitting forms are illustrated in Figure 3b. $S_{n,D}$ ($n = 0, 1$) represent the donor states and $S_{n,A}$ represent acceptor states, with the blue and red forms denoted with b and r subscripts, respectively. Interestingly, the fraction of red-light-emitting molecules is a factor of four greater than that observed for an MEH homopolymer of the same molecular weight as the MEH block in the DMOS-co-MEH diblock polymer

(Figure 4). The origin of the greater number of red-light-emitting molecules for the diblock sample relative to the homopolymer samples is revealed in low-temperature SMS studies on diblock and homopolymer samples. Figure 4 shows the distributions of peak wavelengths and sorted sub-ensem-

Figure 4. Histograms of peak wavelengths (left) and sorted sub-ensemble spectra (right) for a) MEH ($M_W = 186$ kDa), b) MEH ($M_W = 1000$ kDa), and c) DMOS-co-MEH (MEH block $M_W = 186$ kDa), excited at 488 nm at around 20 K. The dotted vertical lines show the peak wavelength positions of the red- and blue-light-emitting forms of MEH in the diblock polymer as well as the polymers of different molecular weights.

ble spectra of blue- and red-light-emitting species for MEH homopolymer samples ($M_W = 186$ kDa and 1000 kDa, panels a and b, respectively) and single DMOS-co-MEH molecules (MEH block $M_W = 186$ kDa, panel c) excited at 488 nm at around 20 K. Blue-to-red ratios for the 186-kDa MEH homopolymer and the DMOS-co-MEH diblock polymer are around 4:1 and 1:1, respectively, with the latter being similar to the high-molecular-weight MEH homopolymer sample ($M_W = 1000$ kDa, Figure 4b). This establishes that the MEH region of the diblock in fact contains higher number of red sites on average than an MEH homopolymer of the same length. The significantly better spectral resolution achieved at low temperature allowed for a precise, quantitative determination of the relative yields of the blue and red emission bands for MEH.

Unfortunately, the experimental data did not allow us to establish whether energy transfer from DMOS to red chromophores of MEH proceeds predominantly by a cascading or a direct mechanism (see Figure 3). If the MEH block has very few red chromophores per MEH block, as suggested by experiments on pure MEH,[19] the cascading mechanism would be expected to be more rapid as it involves energy transfer from DMOS to blue chromophores in the first step.

In this report, single-molecule spectroscopy on diblock donor/acceptor polymers has been used to show that energy

Communications

transfer across a polymer–polymer interface can be highly heterogeneous as a result of morphological features at the interface. Furthermore, the results demonstrate that the morphology of the chains that comprise the diblock can differ substantially from the morphology of the separate homopolymers.

Experimental Section

Dilute thin-film samples of poly(2-methoxy,5-(2′-ethylhexyloxy)-*p*-phenylenevinylene)-co-poly(2-dimethyloctylsilyl-*p*-phenylenevinylene) (DMOS-co-MEH; $M_W = 312$ kDa, polydispersity index: 1.18) were prepared according to a reported procedure,[19] and the synthesis and characterization of DMOS/MEH are described in detail in the Supporting Information. Typically, samples were diluted in a solution of PMMA (3% w/w) in toluene and spin-cast onto glass substrates to yield films of approximately 100-nm thickness. Samples were then coated with either gold or aluminum (≈ 200 nm) to prevent oxygen and water from diffusing into the PMMA layer. Single molecules were excited with the doubled output (415 nm) of a Ti:sapphire laser centered at 830 nm, and the 457.9 nm and 488 nm lines of an argon-ion laser and images and spectra were obtained from a confocal scanning microscope apparatus described elsewhere.[19] Excitation intensities were approximately 200 W cm^{-2}.

2-Deoxyribonolactone Lesions in X-ray-Irradiated DNA: Quantitative Determination by Catalytic 5-Methylene-2-furanone Release**

*Marina Roginskaya, Yuriy Razskazovskiy, and William A. Bernhard**

The C1′-oxidized abasic DNA lesion 2-deoxyribonolactone (dL, **1**) has attracted significant attention in recent years owing to its potential mutagenicity, which is associated with

the ability of lesion **1** to misincorporate nucleotides during DNA synthesis, its resistance to base-excision-repair (BER) enzymes, and its ability to form cross-links with BER enzymes efficiently.[1] Lesion **1** is produced in model systems by the action of a number of DNA-damaging agents such as copper(I)phenanthroline,[2] other metal complexes,[3] enediyne antibiotics,[4] as well as by UV light,[5] photosensitization,[6] and ionizing radiation.[7] However, the formation of **1** in vivo and its biological effects have been poorly documented. Until recently, lesion **1** in model systems has been identified primarily by detection of its low-molecular decomposition product 5-methylene-2-furanone (5-MF, **3**).[2b,8] Only recently has a method for the selective detection of **1** been developed based on its reactivity with biotinylated cysteine.[9]

Lesion **1** is relatively unstable; decomposition of **1**, which is significantly accelerated by heating or alkaline treatment, results in strand scission and release of **3** (Scheme 1).[10–12]

Scheme 1. Decomposition of **1**.

Decomposition of **1** is a two-step process: β elimination of the 3'-phosphate fragment forms butenolide **2**, and δ elimination of the 5'-phosphate fragment produces **3** as the final product. The product **3** is unstable at basic pH values and hence cannot be detected upon alkaline decomposition of **1**.

In our recent paper[8] we demonstrated that **3**, a characteristic decomposition product of **1**, is released from X-irradiated calf thymus DNA upon postirradiation treatment with DNA-phosphate-binding catalysts such as spermine. We hypothesized that **1** is a precursor to **3** in irradiated DNA and suggested that the yield of **1** in DNA can be quantified by using the yield of released **3**.

Herein we report the isolation of dL-containing tetramers from X-irradiated d(CGCG) and d(pCGCG) films, with the dL lesions corresponding to all four positions of the $d(C_1G_2C_3G_4)$ tetramer. We demonstrate that these dL-containing tetramers undergo catalytic decomposition with quantitative release of **3**. These results provide proof that lesion **1** is the major, perhaps only, precursor to **3** in irradiated highly polymerized DNA.

Figure 1 shows the HPLC profiles of d(CGCG), X-irradiated as a "dry" film and then dissolved in water for analysis. In the absence of heat, a group of products that do not contain strand breaks but presumably contain modified nucleotides were observed with a retention time of 16–23 min (Figure 1B). Furthermore, peaks are observed for the free bases C and G and for phosphate fragments produced as a result of immediate strand scission.

Figure 1. HPLC profiles of the solution of X-irradiated d(CGCG) film (ammonium acetate (40 mm), pH 6.8, spermine (10 mm)). A) 20 min at 90°C with spermine; B) no heat. Peaks for products **4–7** are shown with arrows. HPLC conditions: C18 μ-Bondapack 8 mm × 100 mm Radial Pak cartridge (Waters) washed with ammonium acetate (40 mm) as running phase and methanol as eluent (1–16.5% methanol over 30 min, linear gradient, 2 mL min⁻¹).

Upon heating of the same solution in the presence of spermine (10 mm), a number of peaks corresponding to non-strand-break d(CGCG) lesions disappear. These changes are accompanied by the growth of peaks corresponding to products of strand scission, d(pGCG), d(CGCp), d(CGp), d(pCG), d(pG), and d(Cp), as well as free bases C and G (Figure 1A). This observation indicates that at least some of the non-strand-break products are latent lesions, which undergo catalytic decomposition to give strand scission. Also, the release of **3** was observed (Figure 1A), and is shown below to be a result of the decomposition of dL-containing products.

Each of the four products **4–7** (see peaks in Figure 1B), have been identified as a tetramer containing dL located at one of the four numbered positions in $d(C_1G_2C_3G_4)$ (see Scheme 2). These products were isolated as individual compounds by semipreparative HPLC and purified through several rounds of HPLC fractionation. MALDI-TOF analysis of the isolated compounds supports the assignments to dL structures **4–7**. Similarly, a 5'-phosphorylated tetramer **8**, which contains the terminal dL at position 1 of $d(pC_1G_2C_3G_4)$ (see Scheme 2), was isolated from the X-irradiated d(pCGCG) film and identified by using MALDI-TOF and decomposition patterns. Additional evidence is provided by the characteristic decomposition patterns of the dL-containing tetramers **4–8** (see Figures 2 and 3).

The patterns of the thermal decomposition of **4–8** are shown in Scheme 2. Thermal decomposition of **5**, **6**, and **8** under conditions analogous to those used for the release of **3** from X-irradiated highly polymerized DNA[8] is illustrated in Figure 2. It can be seen from Figure 2C that **8** and its product d(pGCG) have overlapping retention times in the reversed-phase (RP) HPLC chromatogram; therefore, ion-exchange chromatography was applied to resolve the peaks for **8** and d(pGCG) (Figure 2D).

Scheme 2. Structures and decomposition patterns of dL-containing oligonucleotides isolated from X-irradiated d(CGCG) and d(pCGCGp) films.

Figure 2. Thermal decomposition of **5**, **6**, and **8**. Reaction mixtures contained 50 mM sodium acetate buffer, pH 5.2, 10 mM spermine (added before or after heating). A–C: RP HPLC; a) 20 min at 90 °C with spermine; b) as a) but heated without spermine; c) no heat. HPLC conditions: Gemini C18 4.6 mm × 250 mm analytical column (Phenomenex) washed with ammonium acetate (40 mM) as running phase and acetonitrile as eluent (1–8 % acetonitrile over 20 min, nonlinear gradient type 5 in the original Water's definition). D: Ion-exchange HPLC; a) 20 min at 90 °C with spermine; b) no heat. HPLC conditions: Dionex DNAPac PA-100 column washed with ammonium acetate-(40 mM)/ acetonitrile (10 %) running phase and a solution of NaCl as eluent (5–250 mM NaCl over 20 min, linear gradient, 1 mL min⁻¹).

All dLs shown in Figure 2 (**5**, **6**, and **8**) are heat-resistant at pH 5.2 in the absence of a catalyst (see panels b of Figure 2 A–C). Furthermore, **5**, **6**, and **8** readily decompose with release of **3** upon heating under the same conditions but with spermine (10 mM) added. Thus these dLs show decomposition patterns analogous to irradiated calf thymus DNA.[8] All dLs in

Figure 2 undergo quantitative decomposition; **3** and its corresponding phosphate fragments are formed in nearly stoichiometric ratios (with the exception of d(Cp) for **5**). These results show that the yield of **3**, released upon catalytic treatment of dL-containing oligonucleotides, correlates well with the yield of its dL precursor.

The 5′-terminal dL **4** undergoes about 80 % conversion upon heating for 20 min at 90 °C with spermine (10 mM) at pH 5.2 (Figure 3 A a), while its 3′-terminal analogue **7** is stable
Figure 3. Thermal decomposition of **4** (A) and **7** (B). A) sodium acetate buffer (50 mM), pH 5.2, spermine (10 mM); a) 20 min at 90 °C with spermine; b) as a) but heated without spermine; c) no heat; HPLC conditions: as in Figure 2 A–C. B) ammonium acetate (40 mM) buffer, pH 6.8, spermine (50 mM) a) 30 min at 90 °C with spermine; b) no heat; HPLC conditions: Luna C18 4.6 mm × 250 mm analytical column (Phenomenex) washed with ammonium acetate (40 mM) and acetonitrile as eluent (1–9.6 % acetonitrile over 20 min, linear gradient, 1 mL min⁻¹).

under these conditions (results not shown). Significant decomposition of **7** required more prolonged heating at pH 6.8 (30 min or more, Figure 3 B, a). The optical absorption of the butenolides **9** and **10** (see Scheme 2) supposedly formed upon decomposition of **4** and **7** respectively, is apparently too weak at 254 nm to be detected under the conditions of this study.

The total yield of dL was estimated for the X-irradiated films of d(pCGCGp) (Figure 4). All four types of dL formed from d(pCGCGp) release **3** upon thermal catalytic decomposition; the yield of **3** therefore, is assumed to correlate with the total yield of dL. This assumption is justified by the quantitative release of **3** upon decomposition of phosphorylated dL-containing tetramers and by the stability of **3** under the experimental conditions employed (at slightly acidic pH values).[8] The inset in Figure 4 shows the dose dependence for the formation of **3**; the radiation yield of **3**, $0.0103 \pm 0.0004\ \mu mol\,J^{-1}$, was obtained from the slope of the linear fit to the experimental data. This yield is 3.4-fold lower than the
Figure 4. Release of **3** from the solution of the X-irradiated d(pCGC-Gp) film. The reaction mixture containing ammonium acetate buffer (40 mM), pH 6.8, and spermine (10 mM) was heated 25 min at 90°C. The inset shows the dose dependence of the release of **3**. HPLC conditions: Gemini C18 4.6 mm × 250 mm analytical column (Phenomenex) washed with 40 mM ammonium acetate as a running phase, with acetonitrile as eluent (4–9.6% acetonitrile over 20 min, gradient type 5, 1 mL min⁻¹).

coinjection of a corresponding reference compound. The yields of released products were quantified from HPLC peak areas as previously described.[14] For the measurements of the radiation yield of **3** released from d(pCGCGp), the yield of **3** was quantified by co-injection of a known amount of authentic **3**.

Thermal decomposition of 2-deoxyribonolactones: Typically, the reaction mixture (200 µL) of the dL-containing tetramer (50 µL), (≈20–50 µM final concentration), sodium acetate (50 mM), and spermine (10 mM) at pH 5.2 was heated for 20 min (unless otherwise stated) at 90°C and then cooled to 4°C. For thermal decomposition without spermine, the spermine was added after the reaction mixture was heated and cooled. These conditions have been optimized in our previous work for the maximum release of **3**.[8] As shown herein, the loss of **3** owing to its decomposition and/or side reactions does not exceed 10% under the experimental conditions employed.

yield of **3** obtained for the X-irradiated films of calf thymus DNA[8] subjected to analogous post-irradiation treatment. This degree of variation is not surprising given the large differences in the primary and tertiary structures of d(pCGCGp) when compared with genomic DNA.

In conclusion, we have demonstrated that catalytic decomposition of dL isolated from X-irradiated d(CGCG) and d(pCGCG) films quantitatively produces **3**. This finding supports our earlier hypothesis that **1** is the major, perhaps only, precursor of **3** released from X-irradiated highly polymerized DNA.[8] Our data suggest that quantification of the yield of **3** released upon catalytic decomposition of dL can be applied as a method for selective quantitative detection of lesion **1** in DNA.

Experimental Section

Details of the isolation and characterization of dL-containing oligonucleotides are included in the Supporting Information. The product **3** used as a reference compound in HPLC experiments was synthesized according to a published procedure.[13] All the DNA oligonucleotides used in this study were purified by semipreparative RP HPLC. The "dry" films containing the oligonucleotides (≈500 µg) were prepared from aqueous solution (200 µL) dried over saturated NaOH (5% relative humidity) on a microscope glass slide and then subjected to vacuum overnight.

X-irradiation of the films: A Phillips tube (tungsten anode) operated at 55 kV and 20 mA, giving a dose rate of 163 kGy h⁻¹, was used as the X-ray source. The dose rate was measured with radiochromic films (Far West Technology, Inc.). Typically, the DNA films were irradiated to a dose of ≈330 kGy. For the measurements of the radiation yield of **3** released from d(pCGCGp), the d-(pCGCGp) films were irradiated to doses from 100 to 326 kGy. Immediately upon irradiation, the films were dissolved in H₂O (200 µL), transferred into microcentrifuge tubes, and stored at −20°C until used.

HPLC analysis: Typically, the reaction mixture (200 µL) containing the oligonucleotide (50–200 µg) was injected. All HPLC experiments were performed at 30°C and pH 6.8, with UV detection at $\lambda = $ 254 nm. The retention times of the products were determined by

Ruthenium(II) Terdentate CNN Complexes: Superlative Catalysts for the Hydrogen-Transfer Reduction of Ketones by Reversible Insertion of a Carbonyl Group into the Ru−H Bond**

Walter Baratta,* Giorgio Chelucci, Serafino Gladiali, Katia Siega, Micaela Toniutti, Matteo Zanette, Ennio Zangrando, and Pierluigi Rigo

Dedicated to Professor Fausto Calderazzo on the occasion of his 75th birthday

Pincer ECE (E = N, P) transition-metal complexes, in which the terdentate ligands contain two stable five-membered cyclometalated rings, have reached a high level of sophistication and appear extremely attractive for both catalytic and stoichiometric reactions.[1] The great interest in pincer ligands arises from the high level of control over the reactivity and the stereochemistry that they impose around the metal center as a result of their electronic properties and geometric restrictions. These factors afford highly selective transformations and lead to some unique species of relevance for the investigation of elementary processes.[2] In spite of the great attention afforded to ruthenium for its versatility in catalysis,[3] no examples of terdentate ruthenium CNN catalysts have been reported thus far. It is worth noting that CNN complexes are expected to have significantly different reactivity compared to the NCN analogues, mainly because of the different geometrical disposition of the σ-donor carbon atom.

Recently, we have shown that 2-(aminomethyl)pyridine (ampy) shows a high ligand acceleration effect in transfer hydrogenation[4] catalyzed by ruthenium(II) complexes with phosphane ligands. Thus, complete reduction of many ketones in 2-propanol is quickly achieved with the cyclometalated

[**] This work was supported by the Ministero della Ricerca Scientifica e Tecnologica (MURST).

complex [RuCl(CO)(CP)(ampy)] (CP = (2-CH$_2$-6-MeC$_6$H$_3$)PPh$_2$), with turnover frequencies (TOF values) up to 6.3×10^4 h^{-1}, whereas the derivatives *cis*-[RuCl$_2$(PP)-(ampy)] (PP = diphosphane) lead to TOF values up to 4.0×10^5 h^{-1} and *ee* values up to 94% by using chiral diphosphanes.[5] Since it is well known that 2-phenylpyridine readily gives access to orthometalated CN ruthenium complexes,[6] we decided to investigate the coordination chemistry of the related 6-(4′-methylphenyl)-2-pyridylmethylamine with the aim of obtaining terdentate CNN complexes. We report herein on novel complexes of formula [RuX(CNN)(dppb)] (X = Cl, H; dppb = Ph$_2$P(CH$_2$)$_4$PPh$_2$), which are remarkably active catalysts for transfer hydrogenation that afford TOF values up to 2.5×10^6 h^{-1} with very low loading of catalysts (0.005–0.001 mol%) compared to the most active systems reported.[2f,7] Evidence is provided that the reduction of the ketone proceeds through the formation of a Ru^{II}–alkoxide complex by insertion of the carbonyl group of the substrate into the Ru−H bond of a ruthenium(II) hydride formed as an intermediate from the chloride complex **1**.

Treatment of [RuCl$_2$(PPh$_3$)(dppb)] with an equimolar amount of 6-(4′-methylphenyl)-2-pyridylmethylamine in 2-propanol at reflux in the presence of NEt$_3$ affords the thermally stable orthometalated ruthenium(II) complex **1**[8] in high yield [Eq. (1)].

$$[\text{RuCl}_2(\text{PPh}_3)(\text{dppb})] \quad + \quad \text{(aminomethylpyridine)} \quad + \quad \text{NEt}_3 \quad \longrightarrow \quad \mathbf{1} \tag{1}$$

The signals for the diastereotopic NCH$_2$ protons in the ¹H NMR spectrum are at $\delta = 4.12$ and 3.72 ppm with $^2J(\text{H,H}) = 15.5$ Hz. The doublet at $\delta = 52.5$ ppm with a $^3J(\text{C,P}) = 2.7$ Hz in the ¹³C NMR spectrum corresponds to the CH$_2$N group which is shifted downfield relative to the free ligand ($\delta = 48.2$ ppm), thus indicating coordination of the NH$_2$ group to the metal center. Finally, the signal for the orthometalated carbon atom appears as a doublet of doublets at $\delta = 181.8$ ppm with $^2J(\text{C,P}) = 16.3$ and 7.8 Hz, which is strongly shifted downfield[6a,9] relative to the free ligand ($\Delta\delta = 54.8$), thus allowing the former formulation to be established unambiguously in solution. The X-ray analysis carried out on a single crystal of **1** shows a severely distorted octahedral environment around the ruthenium center comprising the orthometalated terdentate pyridine ligand, the diphosphane, and a chloride ligand (Figure 1).[10]

The two N1-Ru-C1 and N1-Ru-N2 bond angles in the five-membered rings are rather small, (80.32(13) and 76.45(12)°, respectively) because of the geometrical constrains of the terdentate ligand. The Ru−N2 bond length of 2.246(3) Å is significantly longer than the Ru−N1 bond (2.046(3) Å) because of the *trans* influence exerted by the aryl group. The terdentate ligand presents coplanar atoms with the exception of the CH$_2$NH$_2$ group, the carbon and amino nitrogen atoms of which are displaced by −0.13 and 0.53 Å,

Figure 1. ORTEP representation of complex **1**. Thermal ellipsoids are at 40% probability, the labeling scheme of the phenyl carbon atoms is omitted for clarity. Selected coordination bond lengths [Å] and angles [°]: Ru-C1 2.057(4), Ru-N1 2.046(3), Ru-N2 2.246(3), Ru-P1 2.252(1), Ru-P2 2.287(1), Ru-Cl1 2.495(1); N1-Ru-C1 80.32(13), N1-Ru-N2 76.45(12), N2-Ru-P1 102.59(8), N1-Ru-P2 173.00(8), C1-Ru-P2 103.60(10), N2-Ru-P2 98.74(8), P1-Ru-P2 94.85(4), P1-Ru-Cl1 173.29(3), C1-Ru-N2 155.40(12), C1-Ru-P1 85.78(9), N1-Ru-P1 91.20(8).

respectively, from the mean plane. Related terdentate Pt^{II} and Pd^{II} complexes obtained from 6-phenyl-2-(2-aminoiso-propyl)pyridine have recently been reported.[11]

Complex **1** has been found to display an exceptionally high catalytic activity in the reduction of a large number of ketones (0.1m) with 2-propanol as the hydrogen donor and in the presence of NaOH (2 mol%) [Eq. (2)].

$$\text{(Eq. 2)}$$

R, R' = alkyl, aryl
Acetophenone is quantitatively reduced to 1-phenylethanol in five minutes using a substrate/**1** ratio of 20000:1 with a remarkably high TOF value of 1.1×10^6 h^{-1} at 50% conversion (Table 1). Subsequent addition of further amounts of the ketone (two times) results in complete reduction, thus suggesting that the stability of the complex results from the rigid framework built up by the association of the robust terdentate ligand with the chelating diphosphane, and consequently catalyst deactivation is significantly retarded.

Complex **1** can also be generated in situ from [RuCl$_2$-(PPh$_3$)(dppb)] and the functionalized pyridine ligand (1:2 molar ratio) in 2-propanol and it shows the same activity as the isolated compound. In contrast, the in situ prepared analogue of **1** bearing N(CH$_3$)$_2$ instead of the NH$_2$ group

shows low activity for acetophenone (Ru 0.005 mol%, NaOH 2 mol%, 7% conversion after 1 h) under identical experimental conditions, thus suggesting that the high performance of **1** is in someway related to an assistance of the NH group in the catalytic cycle. Interestingly, complete reduction (98%) is achieved in 1 h with a substrate/**1** ratio of 100000:1 (TOF = 5.2×10^5 h^{-1}), and experiments at lower catalyst loading (0.0005 mol%) led to a turnover number (TON) of 1.7×10^5. These results are of particular relevance for large-scale synthesis since hydrogen-transfer catalysts are usually used in the range of 1–0.01 mol% as a consequence of their easy deactivation, with TOF values lower than 10^5 h^{-1}. As shown in Table 1, alkyl–aryl, dialkyl (cyclic and linear), and diaryl ketones are rapidly (minutes), quantitatively, and chemo-selectively reduced to alcohols with TOF values in the range 5.0×10^5 to 2.5×10^6 h^{-1} with 0.005 mol% of **1**. The high performance of **1** means that this protocol allows the preparation of alcohols on a gram scale using very low amounts of catalyst.[12]

It is generally accepted that the role of the base in ruthenium-catalyzed hydrogen-transfer reactions is to generate hydrides, which are the catalytic active species.[13] In agreement with this, we have found that reaction of **1** with sodium isopropoxide in a 2-propanol/toluene solution affords the orange hydride complex **2**[14] through elimination of acetone on evaporation of the medium [Eq. (3)].

$$\text{(3)}$$
The ^{31}P NMR spectrum of **2** displays two doublets at $\delta = 65.7$ and 34.6 ppm with a relatively small $^2J(P,P)$ coupling constant of 17.2 Hz. The resonance of the hydride in the ^{1}H NMR spectrum appears as a doublet of doublets at $\delta = -5.58$ ppm with $^2J(H,P) = 89.1$ and 26.4 Hz, which is consistent with the presence of *trans* and *cis* phosphorus atoms.[15] An IR band of medium intensity appears at $\tilde{\nu} = 1743$ cm^{-1} corresponding to the Ru–H species and this low-frequency shift is in agreement with the strong *trans* influence of the phosphane ligand.[16] It is noteworthy that addition of hydride **2** (1 mol%) to acetophenone and 2-propanol (1:1 molar ratio) in C$_6$D$_6$ leads, at room temperature and within a few minutes, to an equilibrium mixture in which 1-phenylethanol and acetone are formed. Hydride **2** is a catalyst of impressive activity in 2-propanol at reflux which leads to complete conversion of acetophenone in a few minutes with TOF values ranging from 4.8×10^4 h^{-1} (**2** 0.01 mol%, in the absence of any additional base) to 8.0×10^5 h^{-1} (in the presence of a tenfold excess of NaO*i*Pr).

Complex **2** reacts promptly with an equimolar amount of benzophenone in C$_6$D$_6$ at 20°C to give the alkoxide–amine complex **3**[17] through insertion of the ketone into the Ru–H bond (Scheme 1).
Scheme 1.

Table 1: Catalytic reduction of ketones (0.1 M) with **1** (0.005 mol%) and NaOH (2 mol%) in 2-propanol at 82°C.

Ketone	Alcohol	Conversion [%][a]	min	TOF [h⁻¹][b]
(acetophenone)	(1-phenylethanol)	98	5	1.1×10^6
(3-methoxyacetophenone)	(1-(3-methoxyphenyl)ethanol)	98	2	1.9×10^6
(3-chloroacetophenone)	(1-(3-chlorophenyl)ethanol)	99	1	2.5×10^6
(cyclopentanone)	(cyclopentanol)	99	5	1.2×10^6
(cyclohexanone)	(cyclohexanol)	97	2	1.5×10^6
(2-heptanone)	(2-heptanol)	99	10	5.0×10^5
(unsaturated ketone)	(unsaturated alcohol)	97	5	7.0×10^5
(4-chlorobenzophenone)	(4-chlorobenzhydrol)	98	10	5.3×10^5

[a] The conversion was determined by GC or ¹H NMR analysis. [b] Turnover frequency (mol of ketone converted into alcohol per mol of catalyst per hour) at 50% conversion.

The ^{31}P NMR spectrum of **3** shows two doublets at $\delta = 57.0$ and 37.3 ppm with $^2J(P,P) = 34.2$ Hz; this coupling constant is slightly smaller than that of **1** ($^2J(P,P) = 38.3$ Hz). The proton signal for the RuOCH moiety appears as a doublet at $\delta = 4.80$ ppm (0°C in [D$_8$]toluene) with $^4J(H,P) = 3.7$ Hz, whereas one broad resonance shifted downfield to $\delta = 5.30$ ppm arises from one proton of the amine group, which may suggest an NH···O hydrogen bond interaction that stabilizes the alkoxide **3**. The ^{13}C NMR peak of the OCH moiety in C$_6$D$_6$ appears at $\delta = 80.1$ ppm and it is shifted downfield relative to free benzhydrol ($\delta = 76.1$ ppm), a result

which is in agreement with other metal alkoxides.[18] NMR spectroscopic studies show that heating a solution of **3** in [D$_8$]toluene above 70°C results in reversible generation of both the ketone and the hydride **2**.

The alkoxide **3** is sensitive to protic compounds and the corresponding alcohol adducts are observed in the presence of alcohols.[19] Addition of benzhydrol (2 equivalents) to **3** results in the formation of the species **4** (^{31}P NMR: $\delta = 55.0$ and 42.8 ppm, with $^2J(P,P) = 34.2$ Hz), according to the equilibrium shown in Scheme 1 (**3/4** ca. 1.5:1). Heating the solution results in an increase of **3**, and coalescence of the signals for **3** and **4** is observed at about 60°C. Elimination of benzhydrol has been observed with more acidic compounds such as water or carboxylic acids.[20] It is worth noting that a ^{31}P NMR spectroscopic study of the reaction of **1** with Na*i*OPr in 2-propanol/toluene to give the hydride **2** shows two doublets at $\delta = 54.3$ and 44.6 ppm, with $^2J(P,P) = 34.2$ Hz. These values are close to those of **4**, thus suggesting the formation of a similar adduct between the ruthenium isopropoxide and 2-propanol. A variable temperature NMR study shows that heating this solution above 40°C leads to an equilibrium reaction between the Ru-isopropoxide and the hydride **2**, whose concentration can also be increased by elimination of acetone through evaporation (in agreement with the reaction of benzophenone shown in Scheme 1).

While the insertion of unsaturated compounds into the Ru–H bond has been thoroughly studied, examples of the formation of Ru–alkoxides by reaction of ketones are rare and restricted to ketoesters or to substrates containing an additional electron-withdrawing group.[21] The reverse reaction, that is, β-hydrogen elimination,[22] provides one of the

most practical routes to metal hydrides. The reversibility of this process, however, has been clearly established only for [Re$_3$(μ-OiPr)$_3$(OiPr)$_6$],[23a] although spectroscopic evidence has been collected at low temperature for [OsCl-(OCH(CD$_3$)$_2$)(CO)(PiPr$_3$)$_2$].[23b] Recently, the NH-assisted reversible insertion of CO$_2$ into the Ru–H bond to give the formate–amine species has been reported by Koike and Ikariya.[24] Interestingly, spectroscopic evidence of ruthenium–alkoxide–amine species has been obtained starting from ruthenium–amide complexes and alcohols.[25]

The results of the study on the stoichiometric reactions of the CNN complexes, together with the influence of the alkoxide concentration on the catalytic activity of the hydride **2**, provide strong support to the formation of a discrete intermediate Ru–alkoxide species in the course of the catalytic transfer hydrogenation of ketones. As this fact cannot be explained by the concerted outer-sphere mechanism first proposed by Noyori and co-workers for ruthenium catalysts containing ligands with NH donor groups (metal–ligand bifunctional catalysis),[4b, 26] an alternative mechanism for this process may be envisioned as follows. The catalytically active Ru–isopropoxide species, which is formed from **1** and sodium isopropoxide, equilibrates with hydride **2**. Insertion of the ketone into the Ru–H bond of **2** provides a new ruthenium alkoxide, such as **3**. The latter, on exchange with 2-propanol, delivers the reaction product and regenerates the Ru–isopropoxide complex, thus closing the catalytic cycle. Although the classical ketone insertion into the metal-hydride bond and the β-hydrogen elimination pathways,[4e, 27] involving a *cis* vacant site (that is, through dissociation of the NH$_2$ moiety), cannot be ruled out, it is more likely that both elementary steps occur through hydrogen-bond assistance of the NH$_2$ group, without NH proton transfer. For example, the development of an NH···O=C interaction between the amine and the incoming ketone may at the same time activate the substrate towards the nucleophilic attack and provide the ketone with the correct orientation for the hydride transfer to be feasible. The resulting alkoxide anion might then migrate from the hydrogen to the metal center, possibly through a three-centered reaction mechanism, to afford the Ru–alkoxide intermediate. Thus, the formation of the Ru hydride from the Ru alkoxide may occur through the reverse pathway. Strong hydrogen bonding between the substrate, catalyst, and solvent probably plays a key role in the overall process. Theoretical studies on the mechanism of the transfer hydrogenation with Ru/NH catalysts show that ruthenium methoxide–amine complexes are the most stable species along the reaction pathways.[26b, 28]

Finally, it is worth noting that our approach can be easily extended to the high-speed enantioselective transfer hydrogenation. Thus, when [RuCl$_2$(PPh$_3$)(dppb)] is treated with the chiral derivative of 6-phenyl-2-pyridylmethylamine with a *t*Bu group on the CHNH$_2$ arm (*R* enantiomer), rapid conversion of *o*-methoxyacetophenone into (*S*)-*o*-methoxy-α-phenylethanol is observed (Ru 0.05 mol%, TOF = 6.0×10^5 h^{-1}, *ee* = 87%), in agreement with the non-hemilabile behavior of the NH$_2$ function of the CNN ligand.

In summary, we have shown that terdentate [RuX-(CNN)(PP)] (X = Cl, H) complexes are highly efficient catalysts in transfer hydrogenation involving 2-propanol to afford quantitative reduction of different ketones with very low loading and in a short time. Reduction of ketones apparently takes place by insertion of the substrate into the Ru–H bond, thus leading to a Ru^{II} alkoxide. The reversibility of this step has been observed in the case of the stoichiometric reaction of complex **2** with benzophenone. This fact provides strong evidence that a Ru alkoxide derivative is most probably an intermediate in the formation of the hydride **2**, the putative active catalyst, from the relevant chloride **1**. As the structure of the terdentate pyridine ligand is well suited for a modular synthetic approach, which allows for a fine tuning of the stereoelectronic properties of the CNN complexes, this new class of ruthenium derivatives holds the promise for a broad application in organometallic chemistry and in homogeneous asymmetric catalysis.

Experimental Section

1: [RuCl$_2$(PPh$_3$)(dppb)] (1.17 g, 1.36 mmol) was added to a solution of 2-propanol (15 mL) containing 6-(4′-methylphenyl)-2-pyridylmethylamine (300 mg, 1.51 mmol) and NEt$_3$ (1.9 mL, 13.6 mmol). The mixture was refluxed for 2 h and the yellow precipitate was filtered, washed with methanol, and dried under reduced pressure. Yield: 810 mg (78%).

2: Compound **1** (516 mg, 0.679 mmol) was suspended in toluene (10 mL) and a solution of NaOiPr (0.1 M, 1.00 mmol) in 2-propanol (10 mL) was added. The solution was concentrated after 1 h at 60°C, stirred at room temperature, and after addition of toluene, filtered over celite. The filtrate was evaporated and the solid was precipitate from toluene and filtered, to afford a bright orange product which was dried under reduced pressure. Yield: 395 mg (80%).

3: Benzophenone (45 mg, 0.247 mmol) was added to a suspension of **2** (160 mg, 0.220 mmol) in toluene (2 mL), and the solution was stirred for 15 min. The solution was then concentrated and pentane added. This afforded a dark yellow precipitate which was filtered and dried under reduced pressure. Yield: 140 mg (70%).

Typical procedure for the catalytic hydrogen-transfer reaction: Complex **1** (3.0 mg, 4.0 μmol) was dissolved in 2-propanol (8 mL). The ketone (2 mmol) was dissolved in 2-propanol (19 mL) and the solution heated to reflux under argon. Addition of NaOH (0.1 M, 400 μL) and the solution containing the catalyst **1** (200 μL) resulted in the reduction of the ketone starting immediately. The yield was determined by GC or NMR analysis (ketone:**1**:NaOH = 20000:1:400; ketone 0.1 M).

the transient formation of an enolate (enol) that can be halogenated to generate the desired product. The crucial enolization process can be efficiently promoted through 1) coordination of chiral Lewis acids with 1,3-dicarbonyl compounds;[6] 2) formation of an enamine intermediate derived from the reaction between a secondary chiral amine and enolizable aldehydes and ketones;[7] 3) attack of a chiral nucleophile on a ketene intermediate to generate a zwitterionic enolate;[8] and 4) ionic association of a phase-transfer catalyst with the enolate.[9]

Recently, chiral tertiary amines have been successfully applied in various organocatalytic transformations, acting as chiral-base catalysts.[10] However, this concept has not yet been applied to asymmetric halogen–carbon bond-forming reactions. Herein, we describe a new effective approach that uses a cinchona alkaloid derivative as a chiral base for promoting the enolization of 1,3-dicarbonyl compounds and the subsequent highly enantioselective electrophilic α-chlorination and α-bromination of the enol derivative [Eq. (1)].

Despite the considerable recent advances, the development of a novel halogenation system of 1,3-dicarbonyl compounds that displays satisfactory selectivity as well as generality is still in high demand, as the reported Lewis acid catalyzed asymmetric chlorinations and brominations of β-

Organocatalytic Asymmetric α-Halogenation of 1,3-Dicarbonyl Compounds**

Giuseppe Bartoli,* Marcella Bosco, Armando Carlone, Manuela Locatelli, Paolo Melchiorre,* and Letizia Sambri

The enantioselective construction of carbon–halogen stereogenicity belongs to the topical area of current asymmetric catalysis[1] by virtue of the fact that halogen atoms attached to a chiral stereocenter can serve as a linchpin for further stereospecific manipulations.[2] Moreover, optically active halogen-containing compounds are increasingly important targets in drug discovery and material sciences.[3] Despite this, different efficient catalytic asymmetric halogenation strategies have been developed only in the last few years.[1a,b] To date, the most notable advances have been made in the α-halogenation of carbonyl compounds by using mild and stable sources of electrophilic halogens. All the reported asymmetric catalytic methodologies, from the first Lewis acid catalyzed asymmetric α-fluorination of β-keto esters reported by Hintermann and Togni,[4] to several highly practical metal-free (organocatalytic)[5] approaches, involve

keto esters are efficient only with selected substrates.[6a–c] The organocatalytic halogenation presented herein is effective with both cyclic and acyclic β-keto esters and with cyclic β-diketones to afford highly optically enriched α-halogenated compounds (up to 96% *ee*) in good yields using inexpensive benzoylquinidine (BQd) as the catalyst and easy-to-prepare polyhalogenated quinolinones as new sources of the halogen.

To verify the feasibility of such an organocatalytic asymmetric halogenation strategy, we examined the reaction of ethyl 2-oxo-cyclopentanecarboxylate **1a** with *N*-chlorosuccinimide (NCS, **3a**) as the halogen source in the presence of some cinchona alkaloid derivatives as the chiral-base catalyst. Representative results of the extensive screening of reaction conditions are listed in Table 1. Several solvents were inves-

[a] Experimental conditions (0.4-mmol scale): open-air reactions run in undistilled solvent (0.1 M) using a 1:1.2 ratio of **1a** to **3**, and 5 mol% of catalyst. [b] (DHQ)₂PYR = hydroquinine 2,5-diphenyl-4,6-pyrimidinediyl diether, (DHQD)₂PHAL = hydroquinidine 1,4-phthalazinediyl diether, (DHQ)₂AQN = hydroquinine anthraquinone-1,4-diyl diether. See Supporting Information for structures of catalysts. [c] Conversion determined by ¹H NMR spectroscopy of the crude mixture. [d] Determined by GC analyses on commercially available chiral stationary phases; the absolute configuration reported in parentheses was determined by comparison of values of optical rotation with those reported in the literature. [e] Number in parenthesis indicates yield of the isolated product **2a**. [f] Reaction carried out with 1 equivalent of NaHCO₃. [g] Reaction carried out with 1 equivalent of NaHCO₃ in toluene (0.25 M).

tigated, and toluene was selected as the solvent of choice, although ethereal solvents afforded analogous results (see Supporting Information for details).

In the initial studies, benzoylquinine (BQ, **4a**) proved to be the most promising catalyst among the chiral amines tested by affording the *R* chloro derivative **2a** in moderate enantio-

meric excess (60% *ee*, Table 1, entry 6). However, a slight decrease in enantioselectivity was observed when the BQ-catalyzed reaction was performed at −78°C (entry 7). We speculated that, under these reaction conditions, the uncatalyzed background reaction of the enol form effectively competes with the stereoselective pathway, even at low temperature. Thus, the primary goal was to employ a less-reactive, finely tuned chlorinating agent that displays a minimal rate of background reaction with the substrate **1a**.
Along these lines, a series of electrophilic halogens was screened, employing BQ (**4a**) as the catalyst (entries 8–11). The trichloroquinolinone **3d**, which is easily prepared from 8-hydroxyquinoline and 3 equivalents of *tert*-butylhypochlorite, gave the best result, with the product **2a** obtained in 79% *ee*. The structurally related chlorinating agent **3e** provided the same stereochemical outcome with a significant decrease in reactivity. Performing the reaction at −78°C in the presence of **3d** led to a dramatic increase in enantioselectivity, albeit at the expense of reactivity (95% *ee*, entry 12), which indicates that under these conditions the discrimination between the background reaction and the asymmetric catalyzed chlorination was maximized.[11] Importantly, the capacity of the trichloroquinolinone **3d** to function in highly enantioselective enolate halogenations is disclosed here for the first time.[12]

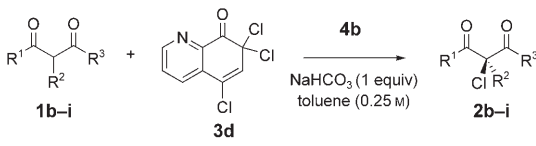
Halogen transfers involving quinolinone **3d** are expected to release stabilized aromatic phenolate anion **5** in a thermodynamically favorable process (Figure 1). We envis-


Figure 1. Halogen transfer from quinolinone **3d** to **1a** catalyzed by BQ (**4a**).

aged that the plausible tight ionic association of **5** with the protonated chiral amine catalyst may affect the efficiency of the system. We reasoned that an inorganic base that is able to facilitate the proton transfer from the protonated chiral amine (BQ-H⁺) to thus regenerate the active catalyst without promoting a racemic chlorination path could have a beneficial effect on the reaction rate.[13] With this consideration in mind, a survey of reaction conditions was performed which revealed that the BQ-catalyzed asymmetric chlorination of **1a** was accelerated by using 1 equivalent of NaHCO₃ in a more concentrated solution (toluene, 0.25 M; Table 1, entries 13–14).[14] Noteworthy, when the "pseudoenantiomeric" BQd (**4b**) was used as catalyst the opposite enantiomer (*S*)-**2a** was obtained in significantly higher enantiomeric excess (entry 15). Such a selectivity allowed the reaction to be performed at higher temperature without affecting the optical purity of the product, which was isolated in quantitative yield (95% *ee*, entry 16).

The superior levels of induction and efficiency exhibited by BQd (**4b**) in the presence of NaHCO₃ (1 equiv) and toluene (0.25 M), prompted us to select these conditions to

examine the scope of the 1,3-dicarbonyl substrates in this asymmetric chlorination protocol. As highlighted in Table 2, cyclic β-keto esters **1b–d** were all converted into the corresponding chloro derivatives in fairly good yields and with excellent optical purity (Table 2, entries 1–3). The

Last, the extension of the presented organocatalytic protocol to asymmetric brominations was evaluated. We presumed that the newly synthesized tribromoquinolinone **6** (Figure 2), structurally related to the chlorinating agent **3d**, might have been a useful source of bromine for the organo-

asymmetric chlorination of different substituted acyclic β-keto esters also afforded the desired products with good enantioselectivity, although a decreased reactivity was observed (entries 4–6). In the presence of a more-reactive substrate such as **1g**, the possibility to perform the reaction at low temperature allowed the generation of the chlorinated adduct **2g** in high optical purity (89% *ee*, entry 6).[15]

We next investigated the efficiency of the method with β-diketones, a particularly challenging class of substrates for which, to our knowledge, just one example of low-enantioselective chlorination has been reported.[6b] Reactions of cyclic diketones **1h–i** proceeded smoothly to give the expected products with moderate enantioselectivity (entries 7–8).

Figure 2. The organocatalytic asymmetric bromination of β-keto esters **1b,f** in the presence of 1.2 equivalents of **6** as the halogen source (toluene (0.25 M), −78°C, 30 h) to afford **7b** and **7f**.

catalytic enantioselective α-bromination. Proof-of-principle was provided through BQd-catalyzed reactions of β-keto esters **1b** and **1f**: the corresponding bromo derivatives **7b** and **7f** were obtained in good yields and with good enantioselectivity (up to 84% *ee*, Figure 2).[16] Further studies to improve the efficiency and the applicability of the organocatalytic enantioselective bromination reaction are ongoing in our laboratories.

In summary, we have developed the first organocatalytic asymmetric α-chlorination and α-bromination reactions of 1,3-dicarbonyl compounds by using an inexpensive chiral amine as the catalyst and a mild, operationally simple protocol that allows direct access to highly enantiomerically enriched halogen-containing compounds. The use of polyhalogenated quinolinones as new sources of halogen electrophiles was essential to achieve high enantioselectivity.

[10] For recent examples, see: a) T. B. Poulsen, C. Alemparte, S. Saaby, M. Bella, K. A. Jørgensen, *Angew. Chem.* **2005**, *117*, 2956; *Angew. Chem. Int. Ed.* **2005**, *44*, 2896; b) H. Li, Y. Wang, L. Tang, F. Wu, X. Liu, C. Guo, B. M. Foxman, L. Deng, *Angew. Chem.* **2005**, *117*, 107; *Angew. Chem. Int. Ed.* **2005**, *44*, 105; c) S. Saaby, M. Bella, K. A. Jørgensen, *J. Am. Chem. Soc.* **2004**, *126*, 8120; d) M. Bella, K. A. Jørgensen, *J. Am. Chem. Soc.* **2004**, *126*, 5672; e) H. Li, Y. Wang, L. Tang, L. Deng, *J. Am. Chem. Soc.* **2004**, *126*, 9906.

[11] The uncatalyzed background chlorination reaction of **1a** was demonstrated to proceed to different extents depending on the chlorinating agent; that is, under conditions of 1:1 **1a/3**, in toluene for 3 h at room temperature, the conversion of **1a** is 100% with **3a**, 58% with **3c**, and 12% with **3d**.

[12] It was reported that the use of trichloroquinolinone **3d** in the asymmetric catalytic α-chlorination of acid halides resulted in poor chemical and optical yields; see reference [8b].

[13] For a similar system in which the proton transfer from the protonated benzoylquinine to $NaHCO_3$ represents a key step of catalysis, see the α-chlorination of acid halides in reference [8b].

[14] The beneficial effect of $NaHCO_3$ on reactivity is more appreciable with less-reactive substrates such as linear β-keto esters. The effects of various bases on the asymmetric halogenation were evaluated (see Supporting Information).

[15] The absolute configurations of **2a–b** and **2e** were determined to be *S* by comparison of the specific optical rotations with those reported in the literature. All other absolute configurations were assigned by analogy. Although it is premature to provide a detailed mechanistic explanation at this level, the sense of stereochemical induction suggests the formation of a BQd–enolate ionic complex in which the *Re* face is effectively shielded by the chiral organocatalyst.

[16] The use of different brominating agents such as *N*-bromosuccinimide and 2,4,4,6-tetrabromo-2,5-cyclohexadione resulted in very low enantioselectivities.

Structural Dualism in the Zwitterionic 7-RR′NH-*nido*-7,8,9-C$_3$B$_8$H$_{10}$ Tricarbollide Series: An Example of Absolute Tautomerism**

Mario Bakardjiev, Josef Holub, Drahomír Hnyk, Ivana Císařová, Michael G. S. Londesborough, Dmitry S. Perekalin, and Bohumil Štíbr*

Tautomerism, which is a dynamic equilibrium between two or more alternative structures of a single species, has been observed for many organic compounds. The commonest case of tautomerism, known as prototropy, is when the electrofuge (a leaving group that does not carry away the bonding electron pair) is a proton. This phenomenon is typical for compounds that contain a functional group that is able to donate a proton, and another functional group which is able to accept it, the functional groups must be in the same molecule and in close enough proximity to one another. The tautomerisation equilibrium is in all cases transmitted by a common anion. The most renowned textbook example of tautomerism is the equilibrium between the keto and enol forms of acetylacetone (Scheme 1).[1] The tautomerisation constant, defined as $K_T = $ [enol]/[keto], is in this case 3.6 for neat acetylacetone.[1]

Herein we report a unique example of what we would like to term "absolute tautomerism" in the "zwitterionic" tricarbollide series in which a compound adopts one of two different tautomeric forms, either zwitterionic 7-RR′NH-7,8,9-C$_3$B$_8$H$_{10}$ (**Z1**) or neutral 7-RR′N-7,8,9-C$_3$B$_8$H$_{11}$ (**N1**; where R,R′ = H or alkyl groups), depending on the properties of the solvent used.

Almost a decade ago we reported the synthesis of the zwitterionic (**Z**) compounds 7-RR′NH-7,8,9-C$_3$B$_8$H$_{10}$ (**Z1**) (where R,R′ = H,H (**1a**); H,*t*Bu (**Z1b**); Me,Me (**Z1c**)); Me,*t*Bu (**Z1d**)). The NMR spectra for this series in CD$_3$CN

show typical patterns consistent with the structural formulation **Z1**.[2] Having the zwitterionic character of these compounds in mind, we initially did not attempt NMR spectroscopic measurements in proton nontransferring (PNT) solvents (such as CDCl₃) because of suspected insolubility. Serendipitously, however, we ventured to do so and to our surprise we found that not only are these compounds soluble in CH₂Cl₂ or CHCl₃, but that their NMR spectra (in CDCl₃) show entirely different NMR patterns (for compounds **N1b** and **Z1b** see Figure 1) that are fully consistent with the
Figure 1. Stick diagrams showing chemical shifts and relative intensities in the ¹¹B (all signals), ¹H (signals from cage CH groups), and ¹³C NMR (signals cage C atoms) spectra for the tautomeric pair 7-*t*BuNH₂-7,8,9-C₃B₈H₁₀ (**Z1b**) and 7-*t*BuNH-7,8,9-C₃B₈H₁₁ (**N1b**). For numbering scheme see **Z1** in Scheme 2

neutral tautomeric form of constitution 7-RR′N-7,8,9-C₃B₈H₁₁ (**N1**). It should be emphasized that in homogeneous solvent solutions all **Z1**→**N1** conversions are quantitative (at least K_T approaches infinity) with no sign of equilibrium between individual **Z1** and **N1** tautomers detectable in the NMR spectra. As shown in Scheme 2 (path 1) the tautomeric
Scheme 2. The formation and interconversions of the 7-RR′NH-7,8,9-C₃B₈H₁₀ (**Z1a–Z1d**) and the corresponding 7-RR′N-7,8,9-C₃B₈H₁₁ tautomers (**N1a–N1d**). 1) dissolution in PNT solvents (such as, CHCl₃, CH₂Cl₂, C₆H₆); 2) crystallization from PT solvents (EtOH/water, acetone/water); 3) proton sponge/CH₂Cl₂ or NaH/Et₂O; 4) protonation (H₂SO₄, CF₃COOH, HCl) in PT solvents; 5) protonation (H₂SO₄, CF₃COOH, HCl) in PNT solvents. See text for details. C is CH (for C8 and C9), vertices without letters are BH.

conversion is achieved by a simple transfer of an N−H proton to a position bridging B10–B11. Conversely, the **N1** tautomers can also be quantitatively converted into **Z1** tautomers by simple crystallization from proton transferring (PT) solvents (such as EtOH/H₂O, acetone/H₂O) or by dissolution in acetonitrile (path 2).

In the case of nonhomogeneous solvent mixtures (see Figure 2) the addition of CH₃CN to a CDCl₃ solution of **N1b** expectedly leads to a classical equilibrium between the **Z1b** and **N1b** tautomers, the equilibrium being defined by the tautomeric constant $K_T = [\text{Z1b}]/[\text{N1b}]$ (where [**Z1b**] and [**N1b**] are equilibrium concentrations of the zwitterionic and neutral tautomers, respectively). It can be seen from Figure 2 that by adding CH₃CN to a CDCl₃ solution of **N1b** the concentration of the **Z1b** tautomer rapidly grows, and at a CH₃CN volume fraction of approximately 0.25, the **N1b** tautomer disappears from the solution ([**N1b**] = 0), there are no signals corresponding to the **N1b** tautomer in the ¹¹B and ¹H NMR spectra. This result suggests that at that critical CH₃CN concentration K_T is equal to or approaching infinity.

It is reasonable to suppose that in these tautomeric conversions the proton transfer between the two proton
Figure 2. Plot of experimental K_T values versus volume fraction $CH_3CN/CDCl_3$ for the equilibrium between **Z1b** and **N1b** tautomers. At around 0.25 (dotted line) K_T approaches infinity and only one tautomer (**Z1b**) is present in the solution. $K_T = [\textbf{Z1b}]/[\textbf{N1b}]$.

accepting centers, the N-atom and the cage B10–B11 bond, occurs through common anions of type $[7\text{-}RR'NH\text{-}7,8,9\text{-}C_3B_8H_{10}]^-$ (**1**⁻). These anions can be prepared independently by treatment of both tautomers, **Z1** and **N1**, with NaH in Et_2O or proton sponge (PS) in CH_2Cl_2/hexane mixtures (Scheme 2 (path 3)). Conversely, acidification (HCl, CF_3COOH) of the anions **1**⁻ (Na⁺ salts) in PT solvents (water, acetonitrile) generates tautomers **Z1** (path 4)), while acidification of the PS⁺ salts with H_2SO_4 in CH_2Cl_2 leads exclusively to tautomers **N1** (path 5)).

Figure 1 summarizes the NMR patterns for the tautomeric pair **Z1b/N1b**. The remaining compounds from the corresponding **Z1/N1** series exhibit very similar NMR spectroscopic behavior, which we will report elsewhere in a full paper.

The **Z1**-type compounds are derivatives of the $[7,8,9\text{-}C_3B_8H_{11}]^-$ ion, while their **N1** tautomers are derivatives of the neutral tricarbollide $7,8,9\text{-}C_3B_8H_{12}$.[2,3] Significant differences between the **Z1** and **N1** tautomers are seen in their ¹¹B NMR spectra, and arise from the presence of the hydrogen atom bridging the B10–B11 bond in **N1**. However, the ¹H and ¹³C NMR spectra for cage CH and C units are also remarkably different.

The different **Z1** and **N1** tautomers can also be isolated in the solid state. For example, **Z1b** and **N1b** differ in their melting points (148/136 °C, respectively) and, moreover, the structure of pure **Z1b** (Figure 3[4]) and **Z1d**. OCMe₂[2] tautomers were determined by single-crystal X-ray diffraction analysis.

Unfortunately, we have not been able to grow crystals of **N1** compounds, therefore the structures for the simplest tautomeric pair, **Z1a** and **N1a**, were geometrically optimized[5,6] at the RMP2(fc)/6-31G* level (see Figure 4 and Figure 5). Ignoring variances in H-N-H angles, the main difference (0.094 Å) between them was found for the respective B10–B11 bonds.
Figure 3. ORTEP representation of the crystallographically determined molecular structure of $7\text{-}t\text{BuNH}_2\text{-}7,8,9\text{-}C_3B_8H_{10}$ (**Z1b**). Figure 4. RMP2(fc)/6-31G* optimized geometry of $7\text{-}NH_3\text{-}7,8,9\text{-}C_3B_8H_{10}$ (**Z1a**). White spheres B, black spheres C. Selected bond lengths [Å] and angles [°]: B1-B2 1.775, B1-B3 1.733, B1-B4 1.761, B1-B5 1.790, B1-B6 1.822, B2-B3 1.779, B2-B6 1.760, B2-C7 1.710, B2-B11 1.804, B3-B4 1.754, B3-C7 1.744, B3-C8 1.739, B4-B5 1.766, B4-C8 1.731, B4-C9 1.737, B5-B6 1.761, B5-C9 1.720, B5-B10 1.788, B6-B10 1.790, B6-B11 1.785, C7-C8 1.508 C7-B11 1.602, C8-C9 1.516, C9-B10 1.625, B10-B11 1.729, C7-N 1.491; C7-C8-C9 108.3, C8-C7-N 117.9, H-N-H (mean) 108.3, H-N-C7 (mean) 110.3. Calculated $\delta(^{11}B)$ chemical shifts (B3LYP/6-31G*//RMP2(fc)/6-31G*) versus experimental (CD₃CN, data from ref. [2]): calcd/exp: B6 −10.8/−15.5, B10 −13.7/−15.5, B11 −19.7/−17.8, B5 −20.8/−18.5, B4 −20.8/−20.2, B2 −23.1/−23.1, B3 −23.8/−23.1, B1 −44.7/−47.1 ppm.

Considering the readiness of interconversion between the **Z1** and **N1** tautomers, a minimal difference in their calculated structure energies might be anticipated. However, the RMP2(fc)/6-31G* calculations on the "free" molecules of **Z1a** and **N1a** in vacuo reveal that the neutral **N1a** tautomer is 22.34 kcal mol⁻¹ more stable than **Z1a**. Including the solvent
Figure 5. RMP2(fc)/6-31G* optimized geometry of 7-NH$_2$-7,8,9-C$_3$B$_8$H$_{11}$ (**N1a**). White spheres B, black spheres C. Selected bond lengths [Å] and angles [°]: B1-B2 1.756, B1-B3 1.772, B1-B4 1.777, B1-B5 1.760, B1-B6 1.800, B2-B3 1.753, B2-B6 1.780, B2-C7 1.689, B2-B11 1.796, B3-B4 1.765, B3-C7 1.700, B3-C8 1.720, B4-B5 1.753, B4-C8 1.730, B4-C9 1.695, B5-B6 1.777, B5-C9 1.685, B5-B10 1.804, B6-B10 1.793, B6-B11 1.792, C7-C8 1.532, C7-B11 1.667, C8-C9 1.515, C9-B10 1.657, B10-B11 1.823, C7-N 1.438; C7-C8-C9 116.7, C8-C7-N 115.6, H-N-H (mean) 107.6, H-N-C7 (mean) 110.3, B10-H$_b$ and B11-H$_b$ 1.312. Calculated δ(^{11}B) chemical shifts (B3LYP/6-31G*//RMP2(fc)/6-31G*) versus experimental (CDCl$_3$): calcd/exp: B2 3.6/3.9, B5 −5.3/−5.7, B3 −16.9/−16.0, B11 −19.4/−19.5, B4 −21.6/−21.0, B10 −22.2/−22.1, B6 −26.2/−27.0, B1 −35.0/−36.2.

polarity effects in the calculations shows a gradual decrease in the difference between the two tautomers from 6.31 in CHCl$_3$ to 3.32 in CH$_2$Cl$_2$, to 0.15 kcal mol^{-1} in MeCN. Nevertheless, the experimental observation of a rapid conversion of **N1a** into **Z1a** upon only small polarity change indicates that **Z1a** is stabilized by some specific interaction with acetonitrile (most probably, hydrogen bonding). The mass spectra of both **Z1** and **N1** show essentially the same fragmentation patterns, which indicates that the **Z1**→**N1** conversions proceed under the conditions of the mass-spectrometric experiment.

As far as we are aware, the isolation of pure tautomers of type **1** represents the first example of absolute tautomerism, and thus introduces a new type of structural dualism to chemistry.

Experimental Section

Typical experiments outlined below for compound **1b** are generally applicable to all compounds of constitution **1**.

Z1b: Compounds **Z1b** (102 mg, 0.5 mmol, prepared as reported earlier[2]) and **N1b** (102 mg, 0.5 mmol) were re-crystallized from a hot EtOH/H$_2$O mixture to give 100 mg (98%) of **Z1b**. For **Z1b**: For ^{11}B and ^{1}H NMR spectra see ref. [2] ^{13}C NMR (125.8 MHz, CD$_3$CN, 295 K): δ = 65.0 (s, 1 C, *t*Bu), 60.9 (br, s, 1 C, C7), 35.6 (br, s, 1 C, C8), 34.1 (br, s, 1 C, C9), 27.4 ppm (q, ^1J(C,H) = 129 Hz, 3 C, *t*Bu).

N1b: Compound **Z1b** (205 mg, 1 mmol) was dissolved in CH$_2$Cl$_2$ or CHCl$_3$ (10 mL). Diffusion in of hexane vapors led to crystallization to yield 158 mg (77%) of crystalline **N1b**. Further amount of **N1b** (42 mg, 21%, total yield of **N1b** 98%) was obtained by evaporation of mother liquors. For **N1b**: m.p. 136°C; ^{11}B NMR (128.3 MHz, 25°C, CDCl$_3$): δ = 2.8 (d, ^1J(B,H) = 159 Hz, 1 B; B2), −6.2 (d, ^1J(B,H) = 162 Hz, 1 B; B5), −15.2 (d, ^1J(B,H) = 171 Hz, 1 B; B3), −19.7 (d, ^1J(B,H) ≈ 170 Hz, 1 B; B4), −20.7 (d, ^1J(B,H) ≈ 140 Hz, 1 B; B11), −22.1 (d, ^1J(B,H) ≈ 150 Hz, 1 B; B10), −25.9 (d, ^1J(B,H) = 150 Hz, 1 B; B6), −37.2 ppm (d, ^1J(B,H) = 152 Hz, 1 B; B1), all theoretical [^{11}B–^{11}B] cross-peaks are observed; ^{1}H{^{11}B} NMR (400 MHz, 25°C, CDCl$_3$): δ = 3.88 (s, 1 H; H8), 3.01 (s, 1 H; H2), 2.73 (s, 1 H; H9), 2.48

(s, 1 H; H5), 2.17 (s, 1 H; H11), 2.00 (s, 1 H; H4), 1.89 (s, 1 H; H3), 1.83 (s, 1 H; H10), 1.1 (s, 2 H; H1, H6), −2.27 ppm (s, 1 H; μH); ^{13}C{^{1}H NMR (100.2 MHz, CDCl$_3$, 295 K): δ = 69.1 (s, 1 C, *t*Bu), 54.9 (br, s, 1 C, C7), 39.2 (br, s, 2 C, C8, C9), 31.1 (s, 3 C, *t*Bu); C$_7$H$_{21}$B$_8$N (205.73): elemental analysis calcd (%) C 40.87, H 10.29; found C 40.64, H 10.12. A solution of PSH$^+$**1b**$^-$ (50 mg, 0.12 mmol; PS = proton sponge) in CH$_2$Cl$_2$ (10 mL) was treated dropwise with concentrated H$_2$SO$_4$ (0.5 mL) under cooling and stirring. The CH$_2$Cl$_2$ layer was collected, shaken with water (2 × 20 mL), dried over CaCl$_2$, and evaporated to afford 12 mg (84%) of **N1b**, which was identified by NMR spectroscopy.

1b$^-$: A solution of compounds **Z1b** or **N1b** (102 mg, 0.5 mmol) in Et$_2$O (20 mL) was treated with NaH (ca. 50 mg, 2 mmol) under stirring at room temperature for 12 h. The mixture was then filtered under anaerobic conditions, the filtrate evaporated, and the residual solid dried at room temperature for 24 h to give Na$^+$**1b**$^-$·OEt$_2$ (145 mg, 96%) as white crystals. For Na$^+$**1b**$^-$·OEt$_2$: m.p. > 350°C (decomp.); ^{11}B NMR (128.3 MHz, 25°C, CD$_3$CN): δ = −15.4 (d, −, 1 B; B6), −16.8 (d, −, 2 B; B10,11), −17.7 (d, −, 1 B; B5), −18.9 (d, −, 1 B; B4), −23.5 (d, ^1J(B,H) = 161 Hz, 1 B; B3), −25.3 (d, ^1J(B,H) = 146 Hz, 1 B; B2), −48.0 ppm (d, ^1J(B,H) = 138 Hz, 1 B; B1), all theoretical [^{11}B–^{11}B] cross-peaks observed; – indicates couple constants that could not be determined ^{1}H{^{11}B} NMR (400 MHz, 25°C, CD$_3$CN): δ = 3.61 (s, 1 H; NH), 3.39 (t, 2 H; Et$_2$O), 2.31 (s, 1 H; H9), 1.77 (s, 1 H; H8), 1.45 (s, 1 H; H3), 1.38 (s, 1 H; H4), 1.30 (q, 3 H; Et$_2$O), 1.29 (s, 1 H; H10 or H11), 1.12 (s, 9 H; *t*Bu), 0.96 (s, 1 H; H5), 0.93 (s, 1 H; H6), 0.92 (s, 1 H; H10 or H11), 0.77 (s, 1 H; H2), −0.16 ppm (s, 1 H; H1); C$_{11}$H$_{30}$NB$_8$ONa (301.83): elemental analysis calcd (%) Na 7.62; found Na 7.56. A solution of compound **N1b** (50 mg, 0.24 mmol) in CH$_2$Cl$_2$ (10 mL) was treated with proton sponge (ca. 50 mg, 2 mmol) hexane (20 mL) was carefully layered onto the surface of the solution. After allowing the solution to stand for 24 h, the crystals were isolated by filtration, washed with hexane, and vacuum dried to give 91 mg (90%) of PSH$^+$**1b**$^-$, which was identified by NMR spectroscopy.

[5] The calculations used the Gaussian03 program package (ref. [6]) and were performed on a PC (FujitsuSiemens). The structures were optimized first at the RHF/6-31G* level without symmetry restrictions (C_1). Second-derivative analysis, carried out at the same level, determined the nature of the stationary points. The minima were characterized with zero imaginary frequencies. Final optimization at the RMP2/6-31G* included the effect of electron correlation. The calculation of the solvation effects on energy were performed for these geometries at the same level of theory using the PC (personal computer) model. The ^{11}B NMR spectroscopy chemical shifts were calculated at B3LYP/6-31G* level by the GIAO method. The complete data are available from the authors.

Heterocycles

Synthesis of Enantiopure Carbohydrate Mimetics by Lewis Acid Catalyzed Rearrangement of 1,3-Dioxolanyl-Substituted 1,2-Oxazines**

Ahmed Al-Harrasi and Hans-Ulrich Reißig*

*Dedicated to Professor Helmut Vorbrüggen
on the occasion of his 75th birthday*

Enantiomerically pure 3,6-dihydro-2H-1,2-oxazines, which are easily available by [3+3] cyclization of lithiated alkoxyallenes with aldonitrones,[1] are versatile intermediates for the stereoselective synthesis of a range of highly functionalized compounds. All these products, including polyhydroxylated pyrrolidines, stereodefined amino polyols, and substituted tetrahydrofuran derivatives,[2] are interesting because of their potential biological activities, for example, as glycosidase inhibitors.[3] While trying to deprotect 1,2-oxazine *syn*-3 with Lewis acids we found that a rearrangement to tetrahydropyran-bridged bicyclic 1,2-oxazine **4** occurred in moderate yield (Scheme 1).[2b] Thereby the acetonide protecting group of *syn*-3 was incorporated into product **4**. Herein we report that:

● this reaction proceeds quite generally with suitably substituted 3,6-dihydro-2H-1,2-oxazines as starting materials,

● the obtained enantiopure bicyclic products can be converted stereoselectively into numerous polyhydroxylated amino-substituted pyran derivatives,

● in a similar manner, highly functionalized oxepane derivatives are accessible.

The resulting products may be regarded as carbohydrate mimetics,[4] which are potentially important building blocks for the synthesis of biologically active compounds, for example, oligosaccharide analogues.

The stereodivergent addition of lithiated alkoxyallene **1** to the D-glyceraldehyde-derived nitrone **2** gives either *syn*- or *anti*-configured **3** in excellent yield (Scheme 1).[1] The unex-

Scheme 1. Reaction conditions: a) THF, −78 °C, 2 h (*syn*-3: 76 %); b) **2** + Et$_2$AlCl, Et$_2$O, then add to **1**, −78 °C, 2 h (*anti*-3: 84 %); c) SnCl$_4$ (3 equiv), CH$_3$CN, −30 °C→RT, 6 h (**4**: quant.); d) Me$_3$SiOTf (0.05 equiv), CH$_2$Cl$_2$, −30 °C→RT, 6 h (**5**: 79 %); e) *t*BuMe$_2$SiOTf (3 equiv), CH$_2$Cl$_2$, room temperature, 20 h, then NEt$_3$, 0 °C, 15 min (**6**: quant.); f) *t*BuMe$_2$SiOTf (3 equiv), CH$_2$Cl$_2$, room temperature, 20 h, then NEt$_3$, 0 °C, 15 min (**7**: 93 %). Bn = benzyl; TBS = *tert*-butyldimethylsilyl; Tf = trifluoromethanesulfonyl.

pected cyclization of *syn*-3 to **4**, which was first observed in moderate yields in the presence of BF$_3$·OEt$_2$, was optimized by using a range of Lewis acids and screening the reaction conditions. Although the rearrangement could be accomplished with different Lewis acids, dibutylboron triflate, trimethylsilyl triflate, and tin tetrachloride proved to be the best promoters.[5] The conversion of *syn*-3 into bicyclic product **4** proceeded quantitatively with SnCl$_4$ in acetonitrile.

We propose that the mechanism of this reaction involves the coordination of the Lewis acid to the "outer" dioxolane oxygen atom (O-1) of *syn*-3, followed by ring opening of the acetonide unit and intramolecular attack of the generated carbenium ion at the enol ether unit of the 1,2-oxazine ring. Cleavage of the (trimethylsilyl)ethyl group—most probably to give ethene and Me$_3$SiX species[6]—affords the central carbonyl group of the resulting bicyclic compound **4**. This rearrangement can be classified as an intramolecular aldol-type addition of an acetal to an enol ether[7] or as a Prins reaction.[8]

The rearrangement can also be triggered by catalytic amounts of trimethylsilyl (TMS) triflate.[9] Treatment of *syn*-3 with 0.05 equivalents of this mild Lewis acid led to TMS-protected derivative **5** in 79 % yield. To introduce the more stable *tert*-butyldimethylsilyl protecting group, *syn*-3 was treated with *t*BuMe$_2$SiOTf (3 equiv) and then with triethyl-

Communications

amine to generate bicyclic product **6**. In a similar manner the rearrangement of diastereomeric 1,2-oxazine *anti*-**3** led to protected bicyclic 1,2-oxazine **7** (Scheme 1). This compound can also be obtained by SnCl$_4$-induced rearrangement followed by silylation (80% yield). As diastereomeric heterocycles *syn*- and *anti*-**3** are enantiopure,[10] this should also hold for the corresponding bicyclic products **4**–**7**.

The incorporation of the acetonide unit into products **4**–**7** suggested that other "protecting" groups can be employed in the starting material to obtain differently substituted bicyclic compounds. Therefore *syn*-configured 1,2-oxazines **8**, **10**, and **12**, which contain cyclopentanone-, cyclohexanone-, and benzaldehyde-derived acetals, were synthesized in analogous procedures (Scheme 2).[11] As expected, treatment of **8** with
Scheme 2. Reaction conditions: a) SnCl$_4$ (3 equiv), CH$_3$CN, −30°C → RT, 6 h; b) tBuMe$_2$SiOTf (3 equiv), NEt$_3$, CH$_2$Cl$_2$, 0°C, 1 h, (yields over two steps: **9**: 86%, **11**: 70%, **13**: 77%); c) tBuMe$_2$SiOTf (3 equiv), CH$_2$Cl$_2$, room temperature, 20 h, then NEt$_3$, 0°C, 15 min, (**11**, **13**: quant.).

tin tetrachloride followed by *O*-silylation gave spiro compound **9** in very good overall yield. For 1,2-oxazines **10** and **12** the one-step procedure with *tert*-butyldimethylsilyl triflate as promoter was chosen, leading directly to the protected rearrangement products **11** and **13** in excellent yields. The configuration at the acetal carbon atom of compound **12** did not affect the outcome: the pure *R*-configured bicyclic product **13** was obtained from both diastereoisomers (or a mixture of the two).[12] This can be expected if a carbenium ion with an equatorial aryl group is involved in the cyclization process. The *anti*-configured compounds underwent similarly efficient rearrangements.[5]

The bicyclic products presented contain an N−O bond whose cleavage should give access to highly functionalized enantiopure pyran derivatives. With ketones such as **6** this ring fission was not successful. However, after reduction of the carbonyl group of **6**, **9**, or **11** with NaBH$_4$ the resulting diastereomerically pure alcohols **14**–**16**, respectively (or their *O*-protected derivatives),[5] could be opened smoothly. Hydrogenolysis with hydrogen and palladium on charcoal did not only cleave the ring of the 1,2-oxazine but also removed the *N*-benzyl group to give primary amines **17**–**19** in good to very good yields (Scheme 3).[13] Debenzylation can be avoided by using the milder reducing agent samarium diiodide.[14] Secondary amines **20**–**22** were obtained after short reaction time in almost quantitative yields. These two reduction steps were used to convert phenyl-substituted bicyclic compound **13** into pyran derivative **23**, which contains five stereogenic centers.[15]
Scheme 3. Reaction conditions: a) NaBH$_4$, EtOH, 0°C, 4 h, (**14**: 97%, **15**: 98%, **16**: 70%); b) H$_2$, Pd/C, MeOH, room temperature, 1 d, (**17**: 72%, **18**: 96%, **19**: 99%, **23**: 64% over two steps); c) SmI$_2$, THF, room temperature (**20**: quant., **21**: 93%, **22**: 95%).

Several options are available to generate different configurations of the tetrahydropyran derivatives. Bicyclic 1,2-oxazine **7** (derived from *anti*-**3**) was reduced with NaBH$_4$ and subsequent ring opening with samarium diiodide led to *trans,trans,trans*-**24** (Scheme 4). Hydrogenolysis gave the
Scheme 4. Reaction conditions: a) NaBH$_4$, EtOH, 0°C, 4 h (82%); b) SmI$_2$, THF, room temperature (72%); c) DEAD, PPh$_3$, *p*-nitrobenzoic acid, benzene, room temperature, 6 h, (81%); d) NaN$_3$, MeOH, 55°C, 2 d, (78%); e) SmI$_2$, THF, room temperature (**25**: 81%); f) H$_2$, Pd/C, MeOH, room temperature (**26**: quant.). DEAD = diethylazodicarboxylate.

expected *N*-debenzylated product.[5] With bicyclic compound **14** as an example, it was demonstrated that Mitsunobu reaction[16] allows an inversion of configuration of the secondary hydroxy group and hence the synthesis of *all-cis*-substituted carbohdrate mimetics. Both methods of reduction provided the expected products **25** and **26** in good yields.

Further stereodefined pyran derivatives synthesized from bicyclic compounds **4** and **6** are presented in Scheme 5.
Scheme 5. Reaction conditions: a) MsCl, NEt₃, CH₂Cl₂, 0 °C, 4 h, (quant.); b) NaBH₄, EtOH, room temperature, 3 h, (85%); c) NaN₃, DMF, 90 °C, 6 h, (73%); d) H₂, Pd/C, MeOH, room temperature, 3 days, (**27**: 81%); e) NaBH₄, EtOH, 0 °C, 4 h, (97%); f) MsCl, NEt₃, CH₂Cl₂, 0 °C, 4 h, (quant.); g) KSAc, DMF/toluene, 60 °C, 6 h, (**28**: 64%); h) Me₃SO⁺I⁻, *n*BuLi, −78 °C→RT, 12 h, (**29**: 70%). Ms = mesyl, DMF = *N*,*N*-dimethylformamide.

Mesylation of the primary hydroxy group of **4**, followed by reduction of the carbonyl group with NaBH₄ and introduction of an azido group, generated a new precursor for the reductive ring opening. Hydrogenolysis furnished pyran derivative **27** with an intact azido functionality which may be used for further transformations.[17] Starting from **6**, a thioacetate group can be installed by nucleophilic attack at the corresponding mesylate, resulting in the bicyclic 1,2-oxazine **28** in good overall yield. Treatment with trimethyl-sulfoxonium iodide stereoselectively transformed **6** into tricyclic compound **29**, which contains an epoxide moiety. Products **27–29** and their precursors offer new options for the preparation of highly functionalized enantiopure tetrahydropyran derivatives that can serve as carbohydrate mimetics.

In first experiments we examined whether rings larger than pyrans can be formed by using the rearrangement presented herein. Schemes 6 and 7 show the reaction pathways that led to enantiopure oxepane derivatives in a highly diastereoselective and surprisingly effective manner. The reaction of nitrone **30** (which was easily prepared from D-isoascorbic acid[18]) with lithiated alkoxyallene **1** provided compound **31** with high *syn/anti* selectivity. In the presence of SnCl₄ in acetonitrile, 1,2-oxazine **31** afforded the desired rearrangement product, which after protection of the primary
Scheme 6. Reaction conditions: a) THF, −78 °C, 2 h, (**31**: 49%, *syn/anti* = 97:3); b) SnCl₄ (3 equiv), CH₃CN, −30 °C→RT, 6 h, (76%); c) *t*BuMe₂SiOTf (3 equiv), NEt₃, CH₂Cl₂, 0 °C, 1 h, (**32**: 92%); d) NaBH₄, EtOH, 0 °C, 4 h, (71%); e) H₂, Pd/C, MeOH, room temperature, 1 day, (**33**: 82%).
Scheme 7. Reaction conditions: a) THF, −78 °C, 2 h, (**35**: 71%, *syn/anti* > 97:3); b) SnCl₄ (3 equiv), CH₃CN, −30 °C→RT, 6 h, (55%); c) *t*BuMe₂SiOTf (3 equiv), NEt₃, CH₂Cl₂, 0 °C, 1 h, (**36**: 97%); d) NaBH₄, EtOH, 0 °C, 4 h, (93%); e) H₂, Pd/C, MeOH, room temperature, 1 day, (**37**: 70%).

hydroxy group gave bicyclic product **32** in good overall yield. Reduction with NaBH₄ followed by hydrogenolysis yielded oxepane derivative **33**, whose constitution and configuration was confirmed by X-ray crystallographic analysis. In the same manner, the stereoisomeric oxepane derivative **37** was prepared from the diastereomeric nitrone **34** (derived from L-ascorbic acid)[18] via intermediates **35** and **36**.[19] Preliminary experiments proved that suitably substituted 1,2-oxazines as precursors opened a route to oxacyclooctane derivatives (oxocanes) in moderate yields.[5]

Our results show that Lewis acid induced rearrangements of 3,6-dihydro-2*H*-1,2-oxazines with 1,3-dioxolanyl substituents and subsequent transformations lead to a variety of polyhydroxylated amino-substituted pyran and oxepane derivatives in an efficient and stereocontrolled manner.[20] The obtained enantiopure oxygen-containing heterocycles can easily be protected selectively (and orthogonally). There-

Communications

fore these analogues of aminodesoxy sugars should be of high interest for integration into oligosaccharides.[4,21] Their lipophilicity should be strongly influenced by the nature of alkyl groups R^1 and R^2 (Scheme 2). These compounds also have potential as starting materials for the synthesis of carbohydrate-based β- or γ-amino acids (sugar amino acids) and they can therefore provide novel peptide analogues.[22] The pyran derivatives **6** and **7** can be easily prepared in gram scale and hence they are also candidates for stereodefined scaffolds for the synthesis of polyfunctionalized compounds. This concept has been successfully applied to several carbohydrate derivatives.[23]

[6] Ethene was trapped with bromine during this conversion.[5] The rapid fragmentation of the residue R seems to be quite important for the smooth cyclization to compounds **4–7**. With the 4-methoxy-substituted analogue of *syn*-**3** similar reactions were observed but owing to the persistence of the methyl group the outcome was more complicated. Details will be presented in a future publication.

Natural Product Synthesis

A General Sultone Route to the Pamamycin Macrodiolides—Total Synthesis of Pamamycin-621A and Pamamycin-635B**

*Petra Fischer, Ana Belén García Segovia,
Margit Gruner, and Peter Metz**

In memory of Udo Gräfe

The pamamycins (**1**) are a class of 16-membered macrodiolide homologues that have been isolated from various *Streptomyces* species (Table 1).[1,2] Besides displaying pronounced autoregulatory, anionophoric, and antifungal activities, several members of this family have been shown to be highly active against Gram-positive bacteria including multiple antibiotic-resistant strains of *Mycobacterium tuberculosis*.[1a,3]

We have recently accomplished a total synthesis of pamamycin-607 (**1a**)[4,5] by extensive application of sultone methodology.[6] To facilitate more detailed studies of structure–activity relationships with respect to the antimycobacterial action of the pamamycins, we decided to utilize our sultone route to (n)actic acids and analogues[7] for the preparation of selected higher homologues of **1a** as well. A major problem that had to be addressed in this context was the enantioselective synthesis of the smaller hydroxy acids incorporated in **1** featuring $R^5 \neq H$. Whereas the smaller fragment of pamamycin-607 (**1a**) with $R^5 = H$ could be

[*] Dipl.-Chem. P. Fischer, MSc A. B. García Segovia, Dr. M. Gruner, Prof. Dr. P. Metz

readily assembled by regioselective opening of an enantiomerically pure terminal epoxide with lithiated furan,[4,8,9] an alternative protocol was required for efficiently securing the key hydroxyalkylfuran needed for targets with $R^5 \neq H$. Here we report a solution to this problem that eventually led to a straightforward route to pamamycin-621A (**1b**)[10–13] and pamamycin-635B (**1e**)[13a,14] using a sultone approach.

Following the strategy that was successful for **1a**,[4] the pamamycins **1b** and **1e** were at first retrosynthetically disconnected to give the silylated larger hydroxy acid **2** and benzyl esters **3a** and **3b**, respectively (Scheme 1). Acid **2** had
Scheme 1. Retrosynthetic analysis of **1b** and **1e**. TBS = *tert*-butyldimethylsilyl

already been used as the larger fragment in our synthesis of **1a**, and the smaller hydroxy acid corresponding to **3a** also occurs in the pamamycins **1c**, **1d**, **1f**, and **1g**. Very recently, we found that our published route to **1a**[4] can be further streamlined by employing the more easily accessible benzyl ester of the smaller fragment epimeric at C2′, since the final macrolactonization is accompanied by complete epimerization at C2′.[2] As a consequence, we felt that use of **4a,b** instead of **3a,b** might be a viable alternative for a related route to pamamycin-621A (**1b**) and pamamycin-635B (**1e**) as well.

Benzyl esters **3a,b** and **4a,b** were synthesized enantioselectively as illustrated in Scheme 2 and Scheme 3. Addition of butyl Grignard to 2-acetylfuran (**5**) followed by acid-catalyzed dehydration of the resulting tertiary alcohol under

Scheme 2. Sultone route to hydroxy esters **12a,b**. a) BuMgBr, Et$_2$O, reflux; b) cat. HCl, CH$_2$Cl$_2$, reflux, 58% from **5**, E/Z = 93:7; c) 1. IpcBH$_2$, THF, −25°C, 2. Ac$_2$O, pyridine, CH$_2$Cl$_2$, RT→reflux, 87% **10a**, 86% **10b**; g) PhSH, BF$_3$·Et$_2$O, CH$_2$Cl$_2$, RT, 79% **11a**, 80% **11b**; h) Raney Ni (W2), 50 bar H$_2$, EtOH, RT, 59% **12a**, 58% **12b**. IpcBH$_2$ = monoisopinocampheylborane.
Scheme 3. Synthesis of the smaller fragment surrogates **3a,b** and **4a,b**. a) 2 N NaOH, RT (for **13a**) or 90°C (for **13b**), 100% **13a**, 79% **13b**; b) 1. 2,4,6-trichlorobenzoyl chloride, Et$_3$N, THF, RT, 2. DMAP, toluene, reflux, 65% **14a**, 11% **15a**, 68% **14b**, 14% **15b**; c) BnOLi, BnOH, THF, RT, 59% **3a**, 40% **3b** (yield based on recovered starting material); d) LiAlH$_4$, Et$_2$O, RT→reflux, 70% from **3a**; e) BnOH, 10 mol% Bu$_2$SnO, 160°C, 93% **4a**, 100% **4b**. DMAP = 4-(N,N-dimethylamino)pyridine.

Benzyl esters **3a,b** featuring the relative configuration at C2′ present in **1b** and **1e** were prepared in a three-step sequence[9] from methyl esters **12a,b** (Scheme 3). After saponification of **12a,b** and Yamaguchi lactonization[20,21] of hydroxy acids **13a,b**, the C2′-epimerized lactones **14a,b** were isolated as the major products, which was revealed by 2D NOESY investigation of both lactone diastereomers. Lactone **14a** was recently isolated from *Streptomyces globisporus* and exhibited significant antibacterial activity.[22] Subsequent cleavage of the medium-sized lactones **14a,b** with the lithium alkoxide prepared from benzyl alcohol[4,23] gave isomerically pure **3a,b**.

The absolute configuration of **3a** and hence **3b** was proven by comparison of the optical rotation data of the known diol **16**,[13a] which was derived from **3a**, with literature values.[24] On the other hand, dibutyltin oxide catalyzed transesterification[25] of **12a,b** with benzyl alcohol directly provided **4a,b** in excellent yields.

Yamaguchi coupling[20] of the silylated larger hydroxy acid **2** with the naturally configured smaller building block **3a** (1.2 equiv) for **1b** effi-

equilibrating conditions delivered olefin **6** as a mixture of isomers (E/Z = 93:7, Scheme 2). Asymmetric hydroboration[15] of this mixture with monoisopinocampheylborane derived from (+)-α-pinene (91% ee) followed by oxidative workup led to the desired *anti* alcohol **7** (81% ee according to chiral GC) and some of the *syn* isomer in 76% combined yield. Treatment of this mixture with vinylsulfonyl chloride induced a smooth domino esterification/intramolecular Diels–Alder reaction[6,8,16,17] to give the pure *exo* sultone **8** (≥99% ee according to chiral HPLC) after chromatographic purification and recrystallization. Application of the reaction sequence[7,8,18] domino elimination/alkoxide-directed 1,6-addition,[19] sequential ozonolysis/cyclization, Lewis acid catalyzed hydroxy/phenylthio exchange, and domino reductive elimination/hydrogenation converted sultone **8** to methyl esters **12a,b**.

ciently furnished the doubly protected seco acid **17** (Scheme 4). After desilylation and reductive debenzylation, modified Yamaguchi macrolactonization[23] of **19** (1.3 × 10^{-3} M) at room temperature in dichloromethane gave a high yield of pamamycin-621A (**1b**).[11,26,27] Since utilization of **4a** instead of **3a** for fragment coupling promised a shortcut to **1b**, we decided to explore such a simplified approach as well. Intermolecular Yamaguchi esterification of **2** with **4a** (1.2 equiv) provided the coupling product **20** in high yield. Desilylation followed by debenzylation proceeded uneventfully to give seco acid **22**. Most gratifyingly, Yamaguchi macrolactonization of **22** (1.2 × 10^{-3} M) under Fleming conditions[23] again afforded pamamycin-621A (**1b**)[11,26,27] as the single macrodiolide product in 64% yield. Thus, as was noted for the corresponding ring closure to give **1a**,[2] the cyclization of **22** is accompanied by complete epimerization at C2′ under
Scheme 4. Final steps of the synthesis of pamamycin-621A (**1b**) and pamamycin-635B (**1e**). a) 1. 2,4,6-trichlorobenzoyl chloride, Et$_3$N, THF, 0°C→RT, 2. **3a**, DMAP, toluene, RT, 94%; b) aq. HF, MeCN, RT, 97% **18**, 95% **21**, 95% **24**; c) H$_2$, 10% Pd/C, THF, RT, 100% **19**, 84% **22**, 100% **25**; d) 2,4,6-trichlorobenzoyl chloride, DMAP, MS 4 Å, CH$_2$Cl$_2$, RT, 78% **1b** from **19**, 64% **1b** from **22**; e) 1. 2,4,6-trichlorobenzoyl chloride, Et$_3$N, THF, 0°C→RT, 2. **4a**, DMAP, toluene, RT, 88%; f) 1. 2,4,6-trichlorobenzoyl chloride, Et$_3$N, THF, 0°C→RT, 2. **4b**, DMAP, toluene, RT, 78%; g) 1. 2,4,6-trichlorobenzoyl chloride, Et$_3$N, THF, 0°C→RT, 2. DMAP, toluene, reflux, 57%. MS = molecular sieves.

these conditions. Encouraged by the facile lactonization of **22** to **1b**, we directly applied such a streamlined sequence to access pamamycin-635B (**1e**). However, seco acid **25** readily obtained after coupling of **2** with the non-naturally configured smaller building block **4b** (1.4 equiv) and subsequent deblocking proved to be reluctant to cyclization under the modified Yamaguchi conditions used for **1b**. This is probably a result of the increased steric shielding imparted by the C2′ ethyl group. To our delight, Yamaguchi macrolactonization[20,21] of **25** performed by separate mixed-anhydride activation of the acid function and subsequent reflux in toluene under high dilution in the presence of 4-(N,N-dimethylamino)pyridine eventually afforded pamamycin-635B (**1e**)[14,27,28] as the sole macrodiolide product in 57% yield.

In summary, a short and highly stereoselective access to the smaller fragment surrogates **3a,b** and **4a,b** of the pamamycins **1b-g** has been developed by means of asymmetric hydroboration and application of sultone methodology. Using benzyl esters **3a** and **4a**, the first total synthesis of the macrodiolide antibiotic pamamycin-621A (**1b**) has been accomplished, while the first total synthesis of pamamycin-635B (**1e**) was achieved using benzyl ester **4b**. Further synthetic work in this area and investigations on the biological activity of the pamamycins will be reported in due course.

Activation of a Zinc-Bound Ethyl Group by Formation of a Zn-C$_{Et}$-Ba Moiety and Crystal Structure of [{(Me$_3$Si)$_2$N}Ba(thf)Zn$_2$(μ-Et)(μ$_3$-PSi*t*Bu$_3$)$_2$]$_2$ with Bridging Ethyl Substituents**

Matthias Westerhausen,* Gerhard Sapelza, and Peter Mayer

The organometallic chemistry of the heavy alkaline-earth metals has been studied for many decades. However, despite the enormous efforts to prepare and structurally characterize such compounds only very few crystal structures of organobarium compounds are known. More than 60 years ago Gilman and Woods reported that the addition of diethylzinc drastically increases the reactivity of dialkylbarium towards benzonitrile.[1] However, up to now most of these compounds remain poorly characterized because of their poor solubility in common organic solvents (highly ionic metal–carbon bond), poor yields (side reactions, necessity of metal activation prior to use), poor purity, and reactions with the solvent (ether cleavage). Within the last decades several procedures have been developed for the preparation of σ-bonded alkylbarium compounds.[2] The majority of these derivatives contain α-bound aryl[3] and trialkylsilyl groups[4] for stabilization. These compounds found wide use as polymerization initiators,[5] but their structures were determined only quite recently.[6,7] In order to avoid side reactions the substituents bear no β-hydrogen atoms. In addition ab initio calculations predict bent structures for solvent-free monomeric dimethylbarium.[8] Even though Cherkasov and co-workers[9] reported reactions of diethylbarium with vinylalkynes, the resulting products were identified solely after protolysis reactions. Here we present an example of activation of a zinc-bound alkyl group by formation of an interaction with a barium center.

The reaction of dialkylzinc with tri(*tert*-butyl)silylphosphane in an equimolar ratio yields quantitatively dimeric alkylzinc tri(*tert*-butyl)silylphosphanide (**1**; Scheme 1). The deprotonation of **1** in THF by addition of [(thf)Ba-{N(SiMe$_3$)$_2$}$_2$]$_2$ yields (thf)$_4$Ba[(RZn)$_2$(PSi*t*Bu$_3$)$_2$] (**2**) (metalation). Also the reaction of **1** with barium metal in THF gives **2** (transmetalation reaction). However, if the reaction is

Scheme 1.

Figure 1. Molecular structure of **2a**. Symmetry-related atoms (*x*, 0.5−*y*, *z*) are marked with apostrophes. The ellipsoids are set at a probability of 50%. For clarity reasons the CH_2 groups of the THF ligands and all hydrogen atoms are omitted. Selected bond lengths (pm): Ba−P 313.9(1), Ba−O1 272.9(6), Ba−O2 269.4(6), Ba−O3 275.1(5), Zn1−P 235.8(1), Zn1−C1 197.5(8), Zn2−P 237.2(1), Zn2−C2 199.3(7), P−Si 220.9(2).

Figure 2. Molecular structure of **3**. Symmetry-related atoms (1−*x*, −*y*, −*z*) are marked with apostrophes. The ellipsoids are set at a probability of 50%. For clarity both the Si-bound alkyl groups and the hydrogen atoms are omitted. Selected bond lengths (pm): Ba1−P1′ 323.2(5), Ba1−O1 269(2), Ba1−N1 255(1), Ba1−P2333.9(4), Si5−N1 167(1), Si6−N1 171(1), Zn1−P2 224.1(5), Zn1−P1 223.8(5), Zn2−P2 242.6(5), Zn2−P1′ 242.7(4), Zn2−C49 204(1), P1−Si1 226.7(7), P2−Si2 226.4(6).

performed in toluene and an excess of THF is avoided, the barium atom must be sterically saturated intramolecularly, and the reaction of **1** (R = Me, Et) with [(thf)Ba{N(SiMe₃)₂}₂]₂ leads to compound **3** (Scheme 1). The main difference between these reactions is that in the synthesis of **2** all bis(trimethylsilyl)amido groups react as the deprotonation reagent, whereas for the formation of **3** two ethyl and two amido groups deprotonate the phosphanides. This observation can be explained by a prior activation of the ethyl substituents by formation of Ba-C_{Et}-Zn three-center two-electron bonds or by agostic interactions between the C−H σ bonds and the barium cation as observed in **3**. In contrast to the reaction performed in toluene, the formation of such bonds in **2** is not necessary because in THF the barium atom always remains sterically saturated by solvent molecules.

Whereas in **2** the distorted octahedral coordination sphere of the heavy alkaline-earth metal atom is completed by four THF molecules (Figure 1), in **3** the barium atom displays the coordination number of 5. Here, the Ba atom is shielded by the bulky bis(trimethylsilyl)amido group, one THF ligand, and the neighboring P-bound tri(*tert*-butyl)silyl substituents (Figure 2). Furthermore, a zinc-bound ethyl group assumes a bridging position. Thus the central cage consists of a distorted $Ba_2C_2P_4Zn_4$ cuboid. The distortions result from the nearly trigonal-planar environment of the zinc atom (angle sum 348.8°). The other two-coordinate zinc atom, Zn1, shows short Zn1−P bonds 224 pm in length.

The Ba−C bond length of 337.9(5) pm in **3** is very large compared to those of known organobarium compounds; also the Zn−C bond of 204 pm is elongated. In zincates such as ($η^6$-toluene)₂Ba[Zn(CH₂SiMe₃)₃]₂[10] and its thermolysis product [Ba₄Zn₆(CH₂SiMe₃)₈(CHSiMe₃)₆][11] shorter Ba−C bonds of 302.8(5)/305.5(5) pm and 299.4(4)/320.0(4) pm, respectively, have been observed. For ([18]crown-6)Ba(C≡C-SiPh₃)₂ extremely short Ba−C distances of 285.3(3) pm have been reported,[12] whereas in (dme)Ba[C(SiMe₃)₂(SiMe₂OMe)]₂ values of 304.9(2) pm were found.[7] The Ba−C distances in **3** are in the upper range of those in molecules with π-bonded ligands having significant charge delocalization[13, 14] or with side-on coordinated alkene moieties.[15]

A comparison of the Ba−P distances of **3** (323.2(5) and 333.9(5) pm) with those of **2a** (313.9(1) pm) shows elongated bonds despite the smaller coordination number. This fact can be attributed to the bulkiness of the substituents. However, the Ba−O distances of the two compounds are similar.

The importance of such an activation of the alkylzinc moiety can be seen from the observation that, for example, alkylzinc amides and phosphanides are stable and form amine

and phosphane adducts rather than undergo deprotonation reactions.[16] The enhancement of the reactivity of organometallic compounds by formation of heterobimetallic derivatives has often been observed.[1,17] In **3** a kinetic stabilization by shielding of the Ba-C$_{Et}$-Zn moiety of the barium-bound ethyl group with large substituents enabled the structure elucidation by X-ray diffraction. Thus far, the characterization of compounds with alkylbarium moieties has been limited to α-phenyl- and α-trialkylsilyl-substituted derivatives and to the identification of protolysis products. It is very likely that the structural feature described here plays a key role in the activation of zinc-bound alkyl groups. In ether solvents where the alkaline-earth metal atom remains coordinatively saturated by Lewis bases throughout the reaction the alkylzinc moiety shows a strongly reduced reactivity towards H-acidic substrates.

Experimental Section

All manipulations were carried out in an anhydrous argon atmosphere. The solvents were thoroughly dried and distilled under argon. The starting compounds H$_2$PSitBu$_3$[18] and [(thf)Ba(N(SiMe$_3$)$_2$)$_2$]$_2$[19] were prepared according to literature procedures. In the elemental analysis the carbon content is low as a result of carbonate formation during combustion.

2a (Procedure 1): A solution of H$_2$PSitBu$_3$ (0.47 g) in 10 mL of toluene was treated with 1 mL of a 2 M solution of dimethylzinc in toluene. A solid precipitate of **1a** formed (m.p. 174°C; ν(P-H) = 2308 cm^{-1}; ^{31}P NMR (109.365 MHz, [D$_8$]toluene, −80°C, AA'XX'): δ(^{31}P) = −232.4, ^1J(P,H) = 257, ^2J(P,P) = 60, ^3J(P,H) = 5, ^4J(H,H) < 1 Hz). This compound was dissolved by addition of 5 mL of THF. After addition of [(thf)Ba(N(SiMe$_3$)$_2$)$_2$]$_2$ (0.6 g, 1 mmol) in 10 mL of THF, this solution was stirred for several hours at room temperature. Then all volatile materials were removed under vacuum, and the residue was dissolved in 3 mL of THF. At 5°C colorless crystals of **2a** (0.3 mmol, 30%) precipitated.

2a (Procedure 2): Compound **1a** was prepared as described above and dissolved by addition of 5 mL of THF. After the addition of barium metal (0.17 g, 1.2 mmol), the solution was stirred for three days. Then the volume was reduced to a third of the original volume. At 5°C colorless crystals of **2a** (0.21 mmol; 21%) formed. No melting point was observed. ^{1}H NMR (270.166 MHz, [D$_6$]benzene, 20°C): δ = −0.13 (s, ZnCH$_3$), 1.34 ppm (s, tBu); ^{13}C NMR (100.526 MHz, [D$_6$]benzene, 20°C): δ = −3.5 (ZnCH$_3$), 24.4 (s, CMe$_3$), 32.4 ppm (s, CMe_3); ^{29}Si NMR (53.674 MHz, [D$_6$]benzene, 20°C): δ = 26.7 ppm (pseudo-t, AA'X, |J(AX)+J(A'X)| = 25.0 Hz); ^{31}P NMR (109.365 MHz, [D$_6$]benzene, 20°C): δ = −183.8 (s); IR: ν̃ [cm^{-1}] = 1495w, 1479vs, 1441w, 1419vw, 1390s, 1366m, 1300vw, 1260vw, 1246vw, 1185m, 1073vs, 1005s, 965w, 934w, 867vw, 844vw, 819vs, 727vw, 694vw, 671vw, 628m, 615m, 567w, 508w, 469m, 460m; Elemental analysis (C$_{42}$H$_{92}$BaO$_4$P$_2$Si$_2$Zn$_2$, 1047.34 g mol^{-1}): calcd: C 48.16, H 8.85; found: C 47.10, H 8.47.

Crystal data for **2a**·toluene:[20] C$_{49}$H$_{100}$BaO$_4$P$_2$Si$_2$Zn$_2$, 1139.54 g mol^{-1}, monoclinic, $P2_1/m$ (no. 11), a = 1100.96(8), b = 2543.8(1), c = 1117.98(7) pm, β = 104.984(8)°, Z = 2, $ρ_{calcd}$ = 1.251 g cm^{-3}, μ = 1.558 mm^{-1}, λ = 0.71073 Å, T = 200(2) K, 3.8° < 2θ < 51.8°, 5734 independent reflections, R_{int} = 0.072, 3346 observed reflections ($I > 2σ(I)$), 285 parameters, $wR2$ = 0.1010, s = 0.84, min./max. residual electron density −0.44/0.61 e Å^{-3}.

3: For the preparation of **1b** a 1 M solution of diethylzinc in hexane (2.0 mL, 2.0 mmol) was added to a solution of H$_2$PSitBu$_3$ (0.47 g, 2.0 mmol) in 15 mL of toluene. (**1b**: m.p. 181°C; ν(P-H) = 2304 cm^{-1}; ^{31}P{^{1}H} NMR ([D$_8$]toluene): δ(^{31}P) = −231.5). [(thf)Ba(N(SiMe$_3$)$_2$)$_2$]$_2$ (0.6 g, 1 mmol) was added and the solution stirred for an additional

three days. After reduction of the volume and storage at 5°C yellow crystals of **3** (0.32 mmol; 65%) precipitated. No melting point was detectable. ^{1}H NMR: (270.166 MHz, [D$_6$]benzene, 20°C): δ = 0.32 (s, SiMe$_3$); 0.34 (q, CH$_2$, ^2J(H,H) = 7.3),1.28 (s, tBu); 1.37 ppm (t, CH$_3$); ^{13}C NMR (67.933 MHz, [D$_6$]benzene, 20°C): δ = 5.3 (s, SiMe$_3$ and ZnCH$_2$), 6.0 (s, CH$_3$), 24.0 (s, C$_q$), 32.1 ppm (t, tBu, $^2J_{P,C}$ = 20.0 Hz); ^{31}P NMR (109.365 MHz, [D$_6$]benzene, 20°C): δ = −245.0 ppm (s); IR: ν̃ [cm^{-1}] = 1477m, 1441vw, 1415vw, 1384m, 1357vw, 1249s, 1179w, 1012s, 932s, 876s, 817vs, 758m, 665w, 603m, 564m, 506m, 479w, 459m. Elemental analysis (C$_{86}$H$_{186}$O$_2$N$_2$P$_4$Si$_8$Ba$_2$Zn$_4$, 2165.2 g mol^{-1}): calc: C 47.70, H 8.65, N 1.38; found: C 45.43, H 8.62, N 1.45.

Crystal data for **3**:[20] C$_{86}$H$_{186}$Ba$_2$N$_2$O$_2$P$_4$Si$_8$Zn$_4$, 2165.20 g mol^{-1}, triclinic, $P\bar{1}$ (no. 2), a = 1194.19(6), b = 1788.8(1), c = 2711.7(2) pm, α = 90.325(3), β = 90.773(3), γ = 105.701(3)°, Z = 2, $ρ_{calcd}$ = 1.290 g cm^{-3}, μ = 1.724 mm^{-1}, λ = 0.71073 Å, T = 200(2) K, 7.2° < 2θ < 48°, 11723 independent reflections, R_{int} = 0.057, 9248 observed reflections ($I > 2σ(I)$), 903 parameters, $wR2$ = 0.2280, s = 1.10, min./max. residual electron density −1.27/1.65 e Å^{-3}.

Metal@MOF: Loading of Highly Porous Coordination Polymers Host Lattices by Metal Organic Chemical Vapor Deposition**

Stephan Hermes, Marie-Katrin Schröter,
Rochus Schmid, Lamma Khodeir, Martin Muhler,
Arno Tissler, Richard W. Fischer, and
Roland A. Fischer

Standing out from the vast majority of metal organic coordination polymers is the class of highly porous basic zinc carboxylates developed by Yaghi and co-workers.[1] Its prototype is MOF-5 (MOF = metal organic framework), in which {Zn_4O} building blocks are linked together by terephthalate bridges to form a zeolite-like, cubic framework.[2] The extremely high specific surface area[2] of up to 4500 $m^2 g^{-1}$ and a pore volume of 0.69 $cm^3 cm^{-3}$ (for MOF-177), which has not been surpassed by any other crystalline substance, and thermal stability (up to 350 °C) opens up fascinating perspectives for the supramolecular host–guest chemistry.[3] Applications for these materials in miniaturized fuel cells and convenient gas-storage devices (for H_2, CH_4), as gas sensors and for gas separation, as catalyst materials, and also for molecular electronics are emerging.[4]

A report on the quantitative inclusion of C_{60} and large polycyclic dye molecules (e.g. Astrazon Orange R) into the cavities of MOF-177 single crystals attracted our attention.[5] Could these MOF host lattices also be suitable to efficiently and selectively absorb typical metal organic chemical vapor deposition (CVD) precursors, provided these were volatile (gas absorption) or very soluble in nonpolar hydrocarbons and had matching size and shape to fit into the cavity? The release of the metal atoms of the precursors imbedded in the

cavities should then lead to "naked" metal-nanoclusters of a size regime otherwise difficult to access (1–2 nm) that are trapped in a novel and presumably only weakly interacting chemical environment.

When pure, freshly synthesized MOF-5 gently dried at 110 °C (to remove embedded solvents)[2] was exposed to the vapor of the auburn palladium-precursor $[(\eta^5\text{-}C_5H_5)Pd(\eta^3\text{-}C_3H_5)]$ (**1**)[6] in static vacuum (1 Pa) at 293 K in a tightly sealed Schlenk-tube, the originally colorless to light beige microcrystalline MOF-5 material turned dark red within 5 min. Surprisingly, while the palladium adsorption is not reversible, the corresponding charging with pentacarbonyl iron $[Fe(CO)_5]$ is. The quantitative desorption occurs at 0.01 Pa (dynamic vacuum, 298 K, IR control).

The three-dimensional crystalline order of the MOF-host lattice remains unchanged after loading with **1**, as shown by the comparison of the powder X-ray diffraction (XRD) pattern before and after adsorption. The analysis of the IR and ^{13}C magic-angle spinning (MAS) NMR solid-state spectra (see Supporting Information) reveal the presence of intact molecules of **1** in the MOF. The elemental analysis data suggest a formal inclusion of exactly four molecules per cavity (Figure 1, Table 1).

The molecular volume of the precursor can be calculated from the structural data[6] with Gaussian98[7] as 196.6 Å^3. The palladium precursors **1** thus fill 36.3 % of the elemental cell, which amounts to 45.3 % of the pore volume. Analogously, other typical metal organic precursors for metal deposition

Figure 1. MOF-5 cage (blue/yellow) with four incorporated $[(\eta^5\text{-}C_5H_5)Pd(\eta^3\text{-}C_3H_5)]$ (**1**) precursors (red). The elemental cell of the crystalline MOF-5 contains eight cavities of this kind.

are absorbed unchanged, for example, $[(\eta^5\text{-}C_5H_5)Cu(PMe_3)]$ (**2**)[8] and $[(CH_3)Au(PMe_3)]$ (**3**)[9]

As expected, size and form selectivity are very high. For example, with **2** which is only slightly more space demanding than **1** and **3** only two instead of four embedded molecules are found, even though then only 28 % of the pore volume is filled with precursor molecules **2**. The only slightly larger copper precursor $[Cu(OR)_2]$ (R = CH(CH_3)CH_2NMe_2)[10] with a volume of 327.5 Å^3 (principal axes of the circumscribed ellipsoids 8.3, 10.4, 6.4 Å) is not absorbed by MOF-5 in which the pore opening diameter is 8 Å, whereas it will be absorbed by isoreticular IR-MOF-8[4] in which the pore opening diameter is approximately 9.5 Å.

As the partial pressure of the precursors is comparatively very low (< 1 Pa at 298 K) the question of maximum loading of the cavities remains open. Solution penetration proved to be far less efficient than loading the empty cavities through the gas phase. The driving force for the exchange by diffusion of the solvent molecules in the cavity against the precursor molecules is weak. Note that highly reactive precursors such as ZnEt$_2$ or TiCl$_4$ will destroy the MOF-5 material immediately upon contact at room temperature.

If the inclusion compound **1**@MOF-5 is treated with H$_2$ gas, the reddish powder will turn to black immediately at −35 °C, indicating the reduction to palladium. GC/MS analysis of the components desorbed into the H$_2$ stream (293 K, 2 h) that are condensable at 77 K indicates the presence of cyclopentane and propane as the expected by-products (catalytic hydrogenation of the ligands). Furthermore, we found plenty of other species formed as a result of C–C couplings, C–H activation, isomerization, and (partial) hydrogenation of the ligands and their C–C coupling products. The obtained material Pd@MOF-5 is thus highly reactive and extremely air sensitive (glowing/calcination).

The XRD pattern (Figure 2) of a capillary probe prepared under argon displays a broad reflection (full width at half maximum (FWHM) = 5.4°) at 40.99° 2θ, which indicates palladium nanocrystallites of the dimension 1.4 (±0.1) nm (profile analysis with Topas P 1.0, Pseudo Voigt). The shift of the 2θ angle to slightly bigger values, corresponding to a shrinking of the Pd–Pd distance, is also characteristic for small metal particles.[11] The particle size is also confirmed by TEM data (Figure 2).

The characteristic reflections for the MOF-5 framework in the XRD of the Pd@MOF-5 samples prepared by H$_2$ reduction (Figure 3) are significantly reduced or completely missing, whereas the typical high Langmuir surface areas of approximately 1600 m^{2}g^{-1} are still obtained. A noteworthy hydrogenation of the terephthalate ligands of the lattice

Table 1: Loading parameters of precursors **1–3** in MOF-5.

Precursor	Molecules per cavity	Elemental analysis [measured/calculated]			Volume precursor [Å^3][a]		Allocation of pore volume [%][c]
		M [%]	C [%]	H [%]	Per molecule	Per elemental cell MOF-5[b]	
1	4	26.4/26.3	41.5/41.5	3.14/3.2	196.6	6291	45.3
2	2	10.7/10.8	40.4/40.7	3.4/3.4	242.6	3882	28.0
3	4	40.8/41.0	23.4/24.9	3.4/3.1	159.3	5098	36.7

[a] Calculated with Gaussian98[14] (B3 LYP/SDD). [b] The elemental cell of MOF-5 consists of eight cavities. [c] The framework of MOF-5 occupies only 20 % of the volume of the elemental cell ($V = 17343.6$ Å^3).[2]
Figure 2. Powder diffraction patterns of a) MOF-5, b) photolytically generated Pd@MOF-5, c) Pd@MOF-5 (reduction by H_2). The 2θ values characteristic for palladium are highlighted. The enlargement shows the shift to higher 2θ values, typical of small particles; d) TEM image of photolytically generated Pd@MOF-5.
Figure 3. Powder diffraction patterns of a) MOF-5 b) photolytically generated Cu@MOF-5, c) Cu@MOF-5 (after methanol catalysis test, reduction by H_2), d) TEM image of Cu@MOF-5 (sample in (b)).

structure can be excluded on the basis of the IR data. We assume that only the long-range order of the host lattice is faulty. The existence of, for example, a defect or layer structure with 2D-order could be possible. The compound Pd@MOF-5 proved to be a moderately active catalyst for the hydrogenation of cyclooctene (coe) which was chosen as test reaction[12] (Table 2).

We also found catalytic activity for the material Cu@ MOF-5 which was obtained by reduction of **2**@MOF-5 in hydrogen stream at 150°C (1 h). With 70 $\mu mol_{MeOH} g_{cat.}^{-1} h^{-1}$ methanol production from synthesis gas (rapid test at normal pressure[13]) Cu@MOF-5 matches the standard of our recently reported novel supported mesoporous catalysts Cu/ZnO@ MCM-41/48 (Table 2) prepared by metal organic CVD.[14] The specific copper surface of approximately 6 $m^2 g^{-1}$ (at 13.8 wt% Cu) proved to be stable. According to the XRD data (Figure 3) there are copper particles in the range of 3–4 nm as well as an intact MOF-5 framework. The Langmuir surface area was determined to be 1100 $m^2 g^{-1}$ (after catalysis tests). This activity of Cu@MOF-5 is surprising as the promotion of copper by zinc or ZnO_x species[13,15] normally essential for catalysis is, in this case, apparently not necessary, or is provided in a novel way by the MOF-5 framework stabilizing the copper particles and not collapsing under the catalysis conditions (220°C, CO/H_2). These observations confirm our earlier assumption, namely that the complicated metal–support interaction in the case of Cu/ZnO could imply a local interfacial phenomenon of Cu-O-Zn species that apparently does not require a well-developed (nano)crystalline ZnO phase.[14]

Thermal transformation of **3**@MOF-5 (190°C, 4 h, H_2 stream) into Au@MOF-5 leaves the crystalline host lattice completely intact (XRD and Langmuir) as also found for Cu@MOF-5 but in contrast to Pd@MOF-5. TEM data (Figure 4) show polydisperse gold particles in a range of 5 to 20 nm. Apparently the gold atoms or gold clusters (or nuclei) primarily formed by decomposition of **3** are more mobile in the open MOF structure than the copper or palladium clusters and thus bigger aggregates are formed within the pores and a diffusion of gold particles to the outer surface also takes place, which accounts for the large gold particles of around 20 nm found outside the pores. Analogously this phenomenon was found for Au@MCM-41 and, as in our case, attributed to a very weak gold-particle–support or wall interaction.[16]

The highly porous Au@MOF-5 material proved to be inactive for catalytic CO oxidation. The gold nanoparticles spread through the intact MOF-5 lattice and at the surface of the MOF-crystallites apparently lack the strong metal–support interaction or promotion (Au/TiO_2, Au/ZnO)[17] necessary for this catalytic effect.

Table 2: Catalytic performance of different metal@MOF-5 systems.

Catalyst	Production rate		Metal surface	wt% metal	
	[$\mu mol_{MeOH} g_{cat.}^{-1} h^{-1}$]	[$\mu mol_{MeOH} m_{Cu}^{-2} h^{-1}$]	[$m_{Cu}^2 g_{cat.}^{-1}$]	wt% Cu	wt% Zn
Cu@MOF-5	70	11.1	6.3	13.8	29.0[a]
Cu/ZnO@MCM-41	19	4.1	4.6	6.9	10.4
Cu/ZnO@MCM-48	130	22.4	5.8	10.6	21.9
	[$mmol_{COA} g_{cat.}^{-1} h^{-1}$][b]	[$mmol_{COA} m_{cat.}^{-2} h^{-1}$][b]	[$m_{Pd}^2 g_{cat.}^{-1}$]	wt% Pd	
Pd@MOF-5	47.34	1.42	33.3	35.6	
	[$\mu mol_{CO_2} g_{cat.}^{-1} h^{-1}$]	[$\mu mol_{CO_2} m_{Au}^{-2} h^{-1}$]	[$m_{Au}^2 g_{cat.}^{-1}$]	wt% Au

[a] Zinc content of the MOF lattice and not additionally incorporated into MOF-5. [b] COA = cyclooctane.

Communications
Figure 4. Powder diffraction patterns of the systems a) MOF-5
b) Au@MOF-5 (after reductive treatment with hydrogen at 190°C)
c) TEM image of Au@MOF-5.

An alternative, and very gentle path to metal@MOF materials with a persistant, crystalline host lattice is the UV photolysis of the intermediate inclusion compounds **1–3**@ MOF-5 at room temperature (water cooling) under inert gas (Ar, He) or vacuum. GC/MS analysis of the gaseous by-products in the case of photochemically generated Pd@ MOF-5 merely shows cyclopentadiene as well as three further products of composition C_8H_{10} and $C_{10}H_{12}$. For Cu@MOF-5 $C_{10}H_{12}$ (fulvalen) as well as PMe_3 are found. TEM images (Figure 2 and Figure 3) reveal very small palladium and copper clusters (1–2 nm).

Our results show that metal organic chemical vapor deposition offers novel perspectives for the host–guest chemistry of porous coordination polymers. Nonaqueous colloid chemistry of metal and semiconductor nanoparticles is likewise based on metal organic precursor chemistry.[18,19] Thus, MOF-5 and related solid-state materials will have lots to offer as moderately temperature stable "crystalline solvent cages" for the analysis of the chemical and physical properties of "naked" inorganic nanoparticles of all kinds, even beyond the scope of heterogeneous catalysis.

Experimental Section

Metal@MOF-5: Thermal metal organic CVD (MOCVD) loading: a sample of the freshly synthesized,[2,4] pure solvent free MOF-5 template (50 mg) was placed in a Schlenk tube together with precursor (**1–3**; 100.0 mg) in a separate glass boat and warmed in static vacuum (1 Pa) for 3 h to 343 K (for **2** and **3**), or left at room temperature (for **1**). Samples of the thus obtained well defined intermediates **1–3**@MOF-5 (40 mg) were then reduced under H_2 at 23°C (30 min) for Pd@MOF-5 or at 150°C (1 h) for Cu@MOF-5 and 190°C (2 h) for Au@MOF-5. Cooling in vacuum (10^{-3} mbar) to room temperature (2 h) removed traces of the gaseous decomposition products (control by IR and ^{13}C-/^{31}P-MAS-NMR).

Photo MOCVD loading: Samples of the intermediates **1–3**@ MOF-5 (30 mg) synthesized as described above where photolysed in an inert gas stream (Ar, He) for 2 h at 25–30°C (Hg high-pressure lamp, 500 W, Normag TQ718) and traces of remaining ligand fragments were removed in vacuum as described above.

The specific surface ($S_{Langmuir}$) of the empty MOF-5 and the samples metal@MOF-5 was determined by application of the Langmuir surface model in the pressure range $p/p_0 = 0.1$–0.3 at $T =$

77.36 K. The copper surface area of Cu@MOF-5 and its methanol synthesis activity was determined as described elsewhere in detail.[16] A mixture of 72% H_2, 10% CO, 14% CO_2, and 14% He was used as synthesis gas. For tests on Au-catalyzed CO oxidation see ref. [20]. For the determination of the Pd surface and details on cyclooctene hydrogenation see ref. [21].

Further experimental details can be found in the Supporting Information.

The linear dianionic $(P_nR_n)^{2-}$ species were first obtained by Issleib et al. by reduction of cyclooligophosphanes *cyclo*-(P_nR_n) with alkali metals.[1] The chain length of the $(P_nR_n)^{2-}$ fragments can be controlled by the stoichiometry of the reaction.[1,2] Subsequently, it was shown that ^{31}P NMR spectroscopy can serve as a valuable tool to establish the identity of the resulting alkali metal salts $M_2(P_nR_n)$.[3,4] Moreover, the alkali metal compounds K[*cyclo*-(P_3tBu_2)],[2] K[*cyclo*-(P_5Ph_4)],[5] and Li[*cyclo*-(P_ntBu_{n-1})] $(n = 3–5)$[6,7] have also been described. However, these compounds were not isolated in pure form.

In spite of the established syntheses of alkali metal oligophosphanides, they have only been used sporadically in the synthesis of main group or transition metal complexes.[8–13] Significantly, transmetalation of $K_2(P_4tBu_4)$ with halides of Si^{IV}, Ge^{IV}, and Sn^{IV} leads to five-membered cyclic species *cyclo*-$(P_4tBu_4ER_2)$ (R = organic substituent or Cl; E = Si, Ge, Sn).[8] In contrast, the $(P_nR_n)^{2-}$ chains do not remain intact in transmetalations of $K_2(P_2tBu_2)$ with $[NiCl_2(PMe_3)_2]$, and of $M_2(P_nPh_n)$ $(n = 2–4)$ with $[Cp_2M'Cl_2]$ (M' = Ti, Zr, Hf).[9,10] Recently, the renaissance of oligophosphanide chemistry has been spurred by the targeted synthesis of Na[*cyclo*-(P_5tBu_4)], which displays highly versatile coordination chemistry,[14,15] and by the simplified syntheses of alkali metal oligophosphanediides $M_2(P_nR_n)$ $(n = 2–4)$,[16–18] which have enabled detailed structural investigations thereof.[16–20] In the context of our ongoing studies on the synthesis of metal complexes containing oligophosphanide ligands,[14–21] we now report the synthesis and structural characterization of $[Cu_4(P_4Ph_4)_2(PCyp_3)_3]$ (**1**; Cyp = *cyclo*-C_5H_9), which to our knowledge is the first copper(I) complex with an oligophosphanediide ligand.

One major difficulty in the transmetalation of alkali metal oligophosphanediides is their high reducing ability, which often leads to reduction of the metal halide employed and the formation of thermodynamically stable neutral cyclooligophosphanes. Thus, only a black precipitate, consisting of elemental copper and NaCl according to X-ray powder diffraction, and the cyclophosphanes *cyclo*-(P_nPh_n) $(n = 4–6)$ or *cyclo*-(P_4tBu_4), respectively, were formed in the reaction of two equivalents of CuCl with $[Na_2(thf)_4(P_4Ph_4)]$ (**2**) or $K_2(P_4tBu_4)$. However, no reduction was observed in the reaction of **2** with $[CuCl(PCyp_3)_2]$ [1:2; Eq. (1)]. Instead, $[Cu_4(P_4Ph_4)_2(PCyp_3)_3]$ (**1**) was isolated as air-sensitive orange crystals in 66% yield.

Copper Oligophosphanides

Synthesis and Molecular Structure of the Cu4P8 Cage Compound [Cu4(P4Ph4)2(PCyp3)3]**

Robert Wolf and Evamarie Hey-Hawkins*

Linear and cyclic oligophosphanide anions $(P_nR_n)^{2-}$ $(n = 2–4)$ and *cyclo*-$(P_mR_{m-1})^-$ $(m = 3–5)$ are an attractive class of ligands displaying a plethora of potential coordination modes.

$$[Na_2(thf)_4(P_4Ph_4)] \quad (2)$$

$$\xrightarrow[\text{− 2 NaCl, − 2 Cu}]{\text{2 CuCl}} 4/n \; cyclo\text{-}(P_nPh_n)$$

$$\xrightarrow[\text{− 2 NaCl}]{\text{2 [CuCl(PCyp}_3)_2]} 1/2 \; [Cu_4(P_4Ph_4)_2(PCyp_3)_3] \quad (\mathbf{1})$$

$$(1)$$

An X-ray crystal structure analysis revealed that **1** exists in the solid state as a solvate with 3.5 molecules of toluene in the asymmetric unit. A tetranuclear aggregate of four Cu⁺ ions with two $(P_4Ph_4)^{2-}$ dianions is observed (Figure 1),[22] and
Figure 1. Solid-state molecular structure of **1** (without hydrogen atoms and toluene molecules).

three of the Cu⁺ cations are additionally coordinated by tricyclopentylphosphane ligands. Thus, three distinct coordination environments can be distinguished for copper. Two of the cations (Cu1 and Cu4) are each coordinated by two terminal phosphorus atoms of different $(P_4Ph_4)^{2-}$ chains and a tricyclopentylphosphane molecule. These attain a trigonal-planar coordination geometry (sum of angles around Cu1: 359.28°; around Cu4: 359.16°). This results in the formation of a "crownlike" ten-membered $[Cu_2(P_4Ph_4)_2]^{2-}$ macrocycle which coordinates two further copper ions through two terminal phosphorus atoms of the same P_4 chain and one internal phosphorus atom of the other P_4 chain. Thus, a unique Cu_4P_8 cage arrangement is formed (Figure 2).
Figure 2. Core structure of **1** (only Cu and P atoms are shown).

In contrast, the formation of four- to eight-membered Cu_nP_n rings is generally observed in other Cu^I phosphanido complexes.[23,24] Of the two remaining copper ions, Cu2 is additionally coordinated by a tricyclopentylphosphane molecule and therefore displays a distorted tetrahedral coordination environment, while the fourth copper cation (Cu3) is coordinated in a trigonal-pyramidal fashion (sum of angles around Cu3: 343.60°). The higher coordination number of Cu2 is reflected in its rather long Cu—P bonds (d(Cu2–P2,P5,P8,P12) = 2.316(2)–2.403(2) Å) compared to the remaining Cu—P bond lengths (d(Cu—P) = 2.239(2)–2.320(2) Å). These differences apart, the Cu—P bond lengths

of the anionic and the neutral P donors are in a similar range and compare well with those found in other copper phosphanides,[23,24] copper polyphosphides,[25] and related Cu^I coordination compounds.[26]

The P—P bond lengths are in the usual range for single bonds [d(P—P) = 2.180(2)–2.241(2) Å].[27] Although the P_4 chains are in a *syn* arrangement they display rather large torsion angles compared to the structure of $[Na_2(thf)_5(P_4Ph_4)]$ (**2**·thf) (**1**: P1-P2-P3-P4 62.90°, P5-P6-P7-P8 −67.17°; cf. P1-P2-P2′-P1′ 32.1° in **2**·thf).[16] This appears to be a consequence of the coordination of an internal phosphorus atom to copper in each of the ligands, and underlines the structural flexibility of the $(P_4Ph_4)^{2-}$ ligands as they adapt to the coordination requirements of the metal atoms.

The composition of **1** is additionally supported by NMR spectroscopic investigations, C,H analysis, and mass spectrometric measurements. Due to its high mass the molecular ion was not observed in the LDI-MS spectrum, but dominant fragment ions were reproducibly detected which, according to their characteristic isotopic patterns, are derived from the parent molecule by loss of organic substituents (Ph, Cyp) and tricyclopentylphosphane units. As expected, the ¹H NMR spectrum of **1** displays overlapping resonances for the cyclopentyl groups, the phenyl substituents, and the toluene molecules, which are also present in the solid-state structure of **1**. After drying in vacuum it still contains about 1.5 equivalents of toluene. This is indicated both by the C, H analyses and by the ratio of aliphatic and aromatic resonances in the ¹H NMR spectrum.

The room-temperature ³¹P{¹H} NMR spectrum is extremely complex, displaying several broad peaks of varying intensity. This is not entirely surprising considering that an unsymmetric spin system of 11 different phosphorus nuclei would be expected if the solid-state structure of **1** were to remain in solution. However, the spectrum becomes even more complicated at −80°C and shows numerous severely broadened multiplets in the regions between $\delta = +20$ and 0 ppm, −10 and −30 ppm, −70 and −105 ppm, as well as a broad symmetric multiplet at +44.1 ppm. This indicates that line broadening at higher temperatures is not exclusively caused by coupling between phosphorus and the quadrupolar $^{63}Cu/^{65}Cu$ nuclei, but that a fluxional process also plays a key role. Although the exact nature of this process is still unclear, it appears unlikely that the molecular structure of **1** is retained in solution. This is in contrast to the behavior of alkali metal tetraphosphanediides, the solid-state structures of which are generally retained in solution.[16,17]

In summary, the copper(I) tetraphosphanediide complex $[Cu_4(P_4Ph_4)_2(PCyp_3)_3]$ (**1**) has been synthesized and structurally characterized. In the solid state, it displays a twelve-membered Cu_4P_8 cage arrangement with an unprecedented coordination mode of the $(P_4Ph_4)^{2-}$ ligands involving one internal and two terminal phosphorus atoms of the P_4 chain. The synthesis of **1** demonstrates that in principal such complexes are readily accessible by transmetalation of the respective alkali metal tetraphosphanediides. In future work, the preparation of other copper oligophosphanido complexes will give further insight into the solution structures of such species. Furthermore, it is well known that Cu^I phosphanido

complexes often react differently to their alkali metal counterparts.[24] Therefore, it will be of great interest to explore the reactivity of **1** with electrophiles and its utility in the synthesis of other homo- and heterometallic oligophosphanido complexes.

Experimental Section

All experiments were performed under an atmosphere of dry argon. The NMR spectra were recorded on a Bruker AVANCE-DRX-400 spectrometer. The mass spectra were recorded on an Applied Biosystems 4700 spectrometer by using the laser desorption ionization (LDI) technique. The IR spectra were recorded on an Perkin-Elmer System 2000 FTIR spectrometer in the range 350–4000 cm^{-1}. All solvents were purified by distillation, dried, saturated with argon, and stored over potassium mirror. [Na$_2$(thf)$_4$(P$_4$Ph$_4$)] (**2**) was synthesized according to the literature procedure;[16] all other reagents were obtained from commercial sources and used as supplied.

1: A colorless solution of [CuCl(PCyp$_3$)$_2$] (0.99 g, 1.72 mmol), prepared from CuCl and 2 equiv of PCyp$_3$ in toluene (10 mL), was added to a yellow to orange solution of **2** (0.66 g, 0.86 mmol) in THF (6 mL) at −80°C. The resulting orange suspension was allowed to warm to room temperature. A clear orange solution formed on stirring overnight. This was concentrated to ca. 10 mL and layered with 20 mL of *n*-hexane. A fine, colorless powder (NaCl) formed on storage at +5°C for several days. This was removed by filtration and the filtrate was evaporated to dryness. The orange residue was carefully dissolved in 6 mL of warm toluene. Orange, crystalline needles formed on storing the clear orange solution at +5°C for several days. This solid was isolated and dried in vacuo. Under vacuum the compound loses toluene and contains ca. 1.5 equiv of toluene after evacuating for ca. 25 min at 10^{-2}–10^{-3} torr. Yield: 0.56 g (66% ref. to **1**·1.5C$_7$H$_8$); m.p. 152–153°C (red oil); ^{1}H NMR (400.13 MHz, C$_6$D$_6$, 25°C, TMS): $\delta = 0.85$ (br, 1.5H, C$_5$H$_9$), 1.2–1.8 (br m, 79.5H, C$_5$H$_9$), 2.11 (s, 4.5H, CH$_3$ from toluene), 6.8–8.8 ppm (m, 47.5H, Ph); ^{13}C{^{1}H,^{31}P} NMR (100.16 MHz, C$_6$D$_6$, 25°C, TMS): $\delta = 21.08$ (s, CH$_3$ in toluene), 25.16–30.47 (s, CH$_2$ in C$_5$H$_9$), 34.83–35.49 (s, CH in C$_5$H$_9$), 123.58–149.09 ppm (s, Ph); ^{31}P{^{1}H} NMR (161.9 MHz, C$_6$D$_6$, 25°C): $\delta = +32.5$ (br s), +18.2 (t, $J_{P,P} = \pm 72$ Hz), +10.0 (br s), +5.35 (t, $J_{P,P} = \pm 48.0$ Hz), +2.9 (br s), −20.4 (br m), −23.8 (br m), −71.2 (br m), −88.8 ppm (br m); IR (KBr): $\tilde{\nu} = 3129$ (vw), 3046 (m), 2951 (s), 2865 (s), 1941 (w), 1871 (w), 1801 (w), 1649 (w), 1576 (m), 1474 (m), 1448 (m), 1430 (m), 1299 (m), 1261 (m), 1179 (w), 1125 (m), 1089 (m), 1066 (m), 1024 (m), 908 (m), 804 (m), 736 (s), 694 (m), 485 cm^{-1} (m); MS (LDI): m/z (%): 1061.7 (100) [M−2PCyp$_3$−2Cyp−2Ph−2H]$^+$, 963.5 (50) [M−3PCyp$_3$−2Ph]$^+$; elemental analysis (%) for C$_{103.5}$H$_{133}$Cu$_4$P$_{11}$ ($M = 1972.10$): calcd: C 63.04, H 6.80; found: C 63.12, H 6.69.

[22] Structural data of **1**: C$_{117.5}$H$_{149}$Cu$_4$P$_{11}$, $M = 2156.20$, triclinic, space group $P\bar{1}$, $a = 16.165(1)$, $b = 17.199(2)$, $c = 21.460(2)$ Å, $\alpha = 91.475(9)$, $\beta = 91.334(9)$, $\gamma = 110.077(7)$°, $V = 5599.0(7)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.279$ Mg m^{-3}, $\mu = 0.953$ mm^{-1}, $\theta_{max} = 26.03$°, $R = 0.0508$, $Rw = 0.1229$. The data were collected on a STOE IPDS diffractometer ($\lambda_{Mo_{K\alpha}} = 0.71073$ Å, $T = 207(2)$ K), 20533 independent reflections, 1154 parameters, 94 restraints, max. residual electron density 1.168 e Å^{-3}. A numerical absorption correction was carried out with X-red (STOE & Cie GmbH, Darmstadt), and the structure solution with direct methods (G. M. Sheldrick, SHELXS-97, Program for Crystal Structure Solution, University of Göttingen, **1997**). Cu, P, and C atoms were refined anisotropically (G. M. Sheldrick, SHELXL-97, Program for the Refinement of Crystal Structures, University of Göttingen, **1997**). The structure contains 3.5 molecules of toluene in the asymmetric unit, some of which are heavily disordered. One toluene molecule that could not be refined satisfactorily was eliminated by using the program SQUEEZE implemented in PLATON (P. V. D. Sluis, A. L. Spek, *Acta Crystallogr. Sect. A* **1990**, *46*,

194). The positions of the H atoms were partially located on the Fourier difference map and partially calculated on idealized positions. CCDC 270972 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Cover Picture

Bruce H. Lipshutz* and Bryan A. Frieman

The innate stability of the extraordinarily reactive and enantioselective reagent [{(R)-(−)-DTBM-segphos}CuH] (whose structure is shown in the cover picture) is revealed in the Communication by Lipshutz and Frieman on page 6345 ff. Although there have been many advances in ligand-accelerated catalysis of hydrosilylations, these reactions invariably require the preparation of the catalyst prior to use owing to their limited shelf-life. This new reagent represents the first asymmetric "CuH in a Bottle".
Monolayers on SiO_2
Self-assembled monolayers offer an ideal platform for the functionalization of silicon oxide surfaces. Their formation and modification as well as the generation of patterns are the themes of the Review by B. J. Ravoo, D. N. Reinhoudt, and S. Onclin on page 6282 ff.
Tridehydrobenzenes
In their Communication on page 6306 ff., W. Sander et al. discuss the matrix isolation and spectroscopic characterization of 1,2,3-tridehydrobenzene. The triradical has a $^2A_1$ ground state.
Hydrogenation Catalysts
H. Grützmacher et al. present a four-coordinate rhodium(I)amide in their Communication on p. 6318 ff. The complex heterolytically cleaves H_2 activating it for the hydrogenation of ketones and imines.

Highlights

Asymmetric Catalysis

A direct hit! The asymmetric 1,3-dipolar cycloaddition of azomethine ylides (from imines **A**; EWG = electron-withdrawing group) and electrophilic alkenes **B** using chiral metal complexes in substoichiometric amounts provides a direct stereoselective synthesis of pyrrolidine or proline derivatives. The successful ligand/metal cation couples are rationalized on the basis of recently published results.

Electron-Transfer Reagents
A question of potential! Clean reduction by dissolving base metals can be effected by employing redox catalysts of appropriate oxidation potential. The traditional use of aromatic hydrocarbons as redox catalysts has now been expanded by application of Me$_3$Fe^{II}Li and related ate complexes. The scheme shows, for example, the catalytic cycle for the reductive cleavage of phenylsulfonamides with magnesium.

Reviews

Engineering on the nanometer scale:
Nanoscale control over surface properties
is of paramount importance in bottom-up
approaches to nanofabrication, which will
revolutionize nanoelectronics and bio-
technology in the near future. Self-
assembled monolayers can form an ideal
platform for nanofabrication on silicon
oxide (see picture). Their formation, deri-
vatization, and patterning are discussed.

Anthracis* Tetrasaccharide—Creation of an
Anthrax Vaccine Candidate

A split decision: Efficient heterolytic hydrogen splitting is achieved with novel tetracoordinate rhodium(I) amides. This reaction is reversible, and DFT calculations imply that the cleavage is a one-step process with a relatively low activation barrier. Ketones and imines are hydrogenated by the amide complexes without the need for further additives.
The filled/filled repulsion model can be used to explain qualitatively the trends in the acidity of the coordinated NH groups, the redox potentials of the amides, and the UV/Vis absorptions in different aggregates between a counter cation, $[M(solv)_n]^+$, and the first stable diamido rhodate(1−) anion (see structure and space-filling model), which was synthesized by using the tetradentate diamino diolefin ligand (S,S)-trop$_2$dpen.
Outstanding in the electric field: Bundles of helical peptides undergo stochastic switching in response to the applied bias polarity as observed by STM. This behavior results from a conformational change between the α-helical (left) and 3$_{10}$-helical (right) states and affects the overall helix length. The interaction of the helical dipole moment with the applied electric field determines the preferred conformation of the peptides.
Building bridges: α-Conotoxins (C1–C3, C2–C4 disulfide pairing) adopt a globular conformation, whereas χ/λ-conotoxins (C1–C4, C2–C3 disulfide pairing) fold into a ribbon conformation. Amidation of the peptide C terminus has been shown to influence the folding (see picture) and hence the biological activity of conotoxins.

Contents

Heme recognizes genes: As a step towards the electronic control of reading DNA code at a molecular level, heme and DNA recognition can be linked through protein folding (see picture). Through the conversion of an engineered DNA-binding cytochrome into a heterodimer, the sequence-specific DNA recognition can be controlled by heme recognition and the oxidation state of the iron center.
New binding sites: Calcium(II) binding to the dimeric protein S100A13 triggers key conformational changes, thus creating two symmetrical copper(II)-binding sites between the helices of the monomers (see picture). These solvent-exposed binding sites are unique among the S100 proteins.
[(R)-(DTBM-segphos)CuH]

Bottled for freshness: [{(R)-DTBM-segphos}CuH] (see formula; DTBM = 3,5-di-tert-butyl-4-methoxy) generated in situ represents the first reported copper hydride reagent that can be stored and used over time without loss of activity in several types of asymmetric hydrosilylation reactions.
Structural perfection up to the fifth generation of a polyphenylene dendrimer has been achieved by inserting p-terphenyl spacers into the arms of each branching unit (see picture). The stiff, monodisperse macromolecules with diameters up to 22 nm were synthesized in a stepwise manner, during which the topology of the branching units was controlled. Dendrimers containing up to 1368 phenyl rings with high porosity were generated.
The arrangement of the spins of adjacent helical cobalt–oxygen chains that form the backbone of the framework (see figure) of a microporous coordination polymer lead to metamagnetic behavior. When the polymer is heated, the metal center loses a coordinated water molecule and alters its coordination geometry from octahedral to square-pyramidal, although the framework remains stable.

Tasty tubes: Multiwalled carbon nanotubes functionalized with fluorescein isothiocyanate and amphotericin B (AmB) have been shown to be rapidly internalized by mammalian cells (see picture) without the toxic effects typically displayed upon treatment with AmB. Furthermore, the modified drug exhibits a higher antifungal activity than native AmB.
self-supported
binol/La catalyst
(S)-binol   La^{III}

Bridging the gap: Heterogenized Shibasaki's binol/La catalyst is synthesized by a self-supporting strategy through the reactions of multitopic ligands with La(OiPr)$_3$ (see picture). The catalyst shows high activity and enantioselectivity, and can be reused in the asymmetric epoxidation of α,β-unsaturated ketones.
Natural not always best: Novel *N*-aryl urea and thiourea derivatives of dihydrocinchona alkaloids serve as efficient catalysts for the asymmetric addition of dimethyl malonate to a range of nitroalkenes. Catalytic activity and selectivity depend strongly on the relative configuration at C8/C9. Catalysts with "non-natural" inverted configuration at C9 display excellent activity and enantioselectivity at loadings as low as 0.5 mol%.

Contents

From amber to red: The water-soluble polythiophene derivative **1** forms a supramolecular complex with ATP (adenosine triphosphate) through electrostatic and hydrophobic cooperative interactions which results in a color change of the aqueous solution from yellow to pink-red (see photo; AMP/ADP = adenosine mono-/diphosphate). Besides naked-eye detection of ATP, the detection limit may be extended to 10^{-8} M by using fluorometry.
Pattern formation: Analysis with an array of differential receptors such as **1** rather than specific receptors leads to patterns for various proteins and glycoproteins that can be examined by principal component analysis. This allows for the direct recognition of large substrates for which the creation of synthetic specific receptors would be very difficult.
R^n are amino acids
The heavy cyclopropene analogues 1*H*-siladigermirene R$_4$SiGe$_2$ (**1a**) and 1*H*-trigermirene R$_4$Ge$_3$ (**1b**) have been obtained, and the X-ray crystal structure of **1a** shows that it forms an isosceles triangle with a highly *trans*-bent endocyclic Ge=Ge bond (bending angle 51.0(2)°). The interaction of **1a** and **1b** with CH$_2$Cl$_2$ unexpectedly affords the unusual four-membered-ring compounds **2a** and **2b** as a result of ring expansion (see scheme: E = Si, Ge; R = SiMe*t*Bu$_2$).
Hydrolytic enzymes: The marine planctomycete *Rhodopirellula baltica* DSM 10527 displays high stereo- and enantioselective alkyl sulfatase activity towards (±)-*sec*-alkyl sulfates with retention of configuration through cleavage of their S—O bond (see scheme; pathway B), whereas inversion of configuration is observed upon cleavage of the C—O bond (pathway A).

My stars! Star polymers that contain otherwise incompatible acid or base catalysts, such as *para*-toluenesulfonic acid or 4-(dialkylamino)pyridines moieties, at their sterically restricted cores (see scheme) are readily prepared. Homogeneous catalysis using these star polymers can perform reaction cascades in the same pot and is demonstrated with an acid-catalyzed deprotection and the nucleophilic amine-catalyzed Baylis–Hillman reaction.
Happy couples: A new hybrid technique, capillary electrophoresis combined with online detection through electrothermal atomic absorption spectroscopy, allows the study of metal speciation and metal–biomolecule interactions, important aspects of metallomics. Advantages include complete sample introduction, nanoliter sample and reagent consumption, real-time detection, high sensitivity, and low cost.
Conductive polypyrrole (Ppy) nanowires (see picture) can be grown from single adsorbed synthetic polyelectrolyte molecules by oxidative polycondensation of pyrrole. The location and length of the Ppy nanowires are defined by the location and length of the adsorbed single-molecule templates. The diameter of the Ppy nanowires varies from a few to hundreds of nanometers and can be adjusted by varying the reaction conditions.
A flexible host: The use of pyridyl-substituted cyclotriveratrylene ligands coupled with geometrically accommodating silver centers has resulted in the isolation and structural characterization of a compact $[M_2L_2]$ molecular capsule and an $[M_4L_4]$ tetrahedral prism (see structure). The former incarcerates two coordinated CH_3CN molecules while the latter has an unusual star-burst shape and also acts as host for CH_3CN molecules.

Contents

Overall charge unchanged: Disulfide bonds in gaseous polypeptide cations can be cleaved efficiently by ultraviolet photodissociation (UVPD) at 157 nm (see scheme). Unlike electron-capture dissociation, UVPD cleaves S—S bonds without overall charge reduction in the product ions. This cleavage is suggested to be a result of electronic excitation caused by the absorption of photons of 7.9 eV.
Blueprints for an inhibitor: The de novo molecular design program SPROUT was used in conjunction with the X-ray crystal structures of the bacterial enzymes DdlB and VanA to produce a novel enzyme-selective inhibitor template. Following short and efficient synthesis and in keeping with the design predictions, the resulting inhibitor showed useful levels of enzyme-selective inhibition.
Interconversion of organonitrogen oxides: Nitrosyl, nitrosoalkane, and hydroxylamido(1−) ligands are interconverted on an organoruthenium platform (see structure and scheme). These stepwise and sequential reactions provide insights into the mechanism of the biological nitrite–ammonia interconversion, a major process in the inorganic nitrogen cycle in which nitric oxide, nitroxyl, and hydroxylamine have been invoked as intermediates.
The tail end: The Rh-catalyzed selective functionalization of commercial linear low-density polyethylene (LLDPE) with boron reagents is demonstrated. Subsequent oxidation and transformations of the boron-containing polymer yields materials that contain a variety of polar functionalities, such as hydroxy, amino, and formyl groups, at the termini of the side chains (see scheme).

Sun sensitivity: A charge-transfer sensitizer with an ion-complexing moiety formed by oxyethylene side groups (see picture) is used in a solid-state dye-sensitized solar cell. Lithium coordination to the dye backbone produces under realistic conditions photovoltages of nearly 900 mV and efficiencies of 3.8%.
Four-gone confusion! An assembly of four N-confused porphyrinatosilver(III) subunits (see structure; N blue, Ag olive-colored, C silver/red) placed on the perimeter of a cyclic structure that comprises two silver(I) ions is effectively formed from a bis(N-confused porphyrin) free base and a silver(I) salt.

Obituary

Christopher S. Foote (1935–2005): Singlet Oxygen

Christopher Spencer Foote, professor of chemistry at the University of California, Los Angeles (UCLA), passed away at the age of 70 on June 13, 2005.

Born in Hartford, Connecticut, Foote grew up in an intellectual environment. His father was the editor of the local newspaper, while his mother was a descendant of the Benjamin Sillimans (father and son), who were eminent chemists at Yale University. Foote graduated from Kingswood School in West Hartford, Connecticut, and obtained a Bachelors degree in chemistry from Yale University in 1957. He spent the following year as a Fulbright scholar with G. O. Schenck at the University of Göttingen in Germany. In retrospect, this year in Germany clearly set the stage for his life's work. Foote's first scientific paper, on the "Photosensitized Autooxidation of Menthofuran", with Schenck as a coauthor, was published in *Angewandte Chemie* in 1958.[1]

Foote took "time off" from the study of photooxygenation reactions to obtain a PhD: He joined the research group of R. B. Woodward at Harvard University in 1958 and graduated in 1962 with a thesis entitled "Angle Strain and Solvolytic Reactivity in Bridged Bicyclic Systems." Immediately after leaving Harvard, Foote joined the chemistry faculty at UCLA. It was here that he returned to the study of photooxygenation reactions, establishing the lifelong program for which he is now recognized. Foote was associated with UCLA throughout his entire academic career. He attained the rank of full professor in 1969 and served as department chairman from 1978 to 1981.

Foote arguably established his career with two communications of his results that appeared in *J. Am. Chem. Soc.* in 1964.[2] In these reports, he proposed that the lowest excited electronic state of molecular oxygen, singlet molecular oxygen, $O_2(a^1\Delta_g)$, was the pertinent reactive intermediate in a solution-phase dye-sensitized photooxygenation reaction. In effect, Foote was confirming a hypothesis originally made by H. Kautsky in 1931 which was subsequently dismissed by, among others, G. O. Schenck. The final sentence in the latter of these two communications was, "Further experiments are in progress"; a statement that essentially presaged the next 40 years of his life.

Foote's primary research interest centered on reactive oxygen species, with singlet oxygen being the most prominent.[3,4] Despite its reactivity and short lifetime in condensed phases, singlet oxygen displays many selective reactions, some of which are synthetically useful. The reaction with dienes to form endoperoxides is still one of the most selective and mild reactions to form these types of compounds. The singlet-oxygen-mediated formation of allylic hydroperoxides from unsaturated hydrocarbons and the oxidation of sulfur-, nitrogen-, and phosphorus-containing compounds have important biological ramifications. Indeed, singlet oxygen is an acknowledged intermediate in processes that result in cell death, a phenomenon that forms the basis for photodynamic therapy, a medical procedure used to destroy undesired tissue in the treatment of cancer, for example. Likewise, the process of ageing involves the destruction of key biochemical compounds by reactive oxygenating species.

The mechanistic aspects of these oxygenation reactions are often complex, involving one or more reactive intermediates. One of Foote's scientific achievements was to methodically elucidate many of these reaction mechanisms. It was through these studies that he established his reputation as the foremost authority on the reactions of singlet oxygen. In his latter years, Foote expanded his research program to include studies on the photophysical properties of fullerenes.

Foote's research covered a broad spectrum of science. Although formally an organic chemist, his interests and tools ranged from biology to physics and from experimental to computational. He was a cross-disciplinary chemist of the highest level. In addition to an extensive list of research publications, Foote was coauthor of a textbook now in its fourth edition.[5] He was president of the American Society for Photobiology during 1988–89 and was a senior editor of *Accounts of Chemical Research* during the last 10 years of his life. In 1994, the American Chemical Society acknowledged his contributions with the Arthur C. Cope Scholar Award.

Foote always allowed members of his research group to pursue their own ideas, thereby creating a stimulating environment for the large number of graduate students and postdoctoral fellows for whom he served as mentor (the authors of this article are two of his former PhD students). He was very tolerant and patient when listening to research presentations, but always asked sharp questions at the end. In his private life, Foote particularly enjoyed music. He was a noted fan of Bach and never tired of Wagner's "Der Ring des Nibelungen". He had the amazing nose of a good old-fashioned qualitative organic chemist; one that could readily distinguish an aldehyde from a ketone. This characteristic was frequently put to good use in distinguishing a good merlot from a bad merlot.

It was a privilege and a pleasure to have known and worked with Chris. His brilliance, insight, companionship, and warmth will be missed. Christopher S. Foote passed away having earned the deep-seated respect of his colleagues. No higher award can be achieved.

Highlights

Catalytic Enantioselective 1,3-Dipolar Cycloaddition Reaction of Azomethine Ylides and Alkenes: The Direct Strategy To Prepare Enantioenriched Highly Substituted Proline Derivatives**

Carmen Nájera* and José M. Sansano*

*T*he interest in asymmetric synthesis is continuously increasing owing to the continuous demand for enantiomerically enriched molecules. The main challenge in this area is to create the maximum number of stereogenic centers in one reaction step by employing the minimum number of reagents. From both an economic and a synthetic point of view, asymmetric catalysis[1] can constitute a powerful tool, especially for pericyclic reactions, where the relative and absolute configuration of several carbon atoms can be established almost simultaneously.

One example is the 1,3-dipolar cycloaddition of azomethine ylides (from imines **A**) and alkenes **B**,[2] which allows the stereoselective synthesis of pyrrolidines or proline derivatives **C** (Scheme 1). Among such molecules of type **C**, which can be obtained through longer and more sophisticated routes, are very important pharmaceuticals and natural alkaloids, organocatalysts, and building blocks in organic synthesis.[3] In this cycloaddition, the particular struc-
Scheme 1. EWG = electron-withdrawing group.

ture of the azomethine ylide promotes a characteristic frontier molecular orbital (FMO) controlled reactivity with alkenes, which can lead to the formation of four stereocenters with high stereoselectivity. There are several procedures for generating azomethine ylides, of which the metalation of imino esters **A** is the most widely used in organic chemistry.[2a,c] The benefits of the in situ preparation of metalloazomethine dipoles from α-imino esters **A** in basic media, such as working at room temperature with a highly coordinated transition state and starting from easily available compounds, make this reaction much more attractive (Scheme 1).

The asymmetric version of this 1,3-dipolar cycloaddition reaction can be accomplished following different strategies: a) by attaching a chiral auxiliary to the imino (R¹) or to the electron-withdrawing group (EWG¹) of the

dipole **A**; b) by attaching a chiral auxiliary to the EWG² of the alkene **B**; c) by employing a chiral Lewis acid capable of chelating both components **A** and **B**. According to the last strategy, and considering all of the previous advantages of these metalloazomethine ylides, Grigg and co-workers employed a stoichiometric amount of the catalytic system ephedrine derivative **1**/cobalt(II) chloride in the reaction of the dipole precursor **3** with the dipolarophile **4** (Y = CO₂Me, used as solvent) giving an excellent *ee* in the case of the enantiomer **5a** with total *endo*-selectivity (Scheme 2, Table 1).[4,5] However, the stoichiometric catalyst formed by bisphosphine **2**/AgOTf (Tf = trifluoro-
Scheme 2. R¹ = 2-naphthyl, R²: see Table 1; **4** as solvent when Y = CO₂Me, Bn = benzyl.

Me	SO₂Ph	2	AgOTf	84	5a′, 70

[a] 100 mol%.

methanesulfonyl) afforded the other enantiomer, *endo*-**5a′**, albeit with lower enantioselection.[5] The high enantiomeric excesses obtained in these examples can be justified, presumably, by the presence of the compact transition states **6** and **7**, respectively.

Despite these attractive precedents, the first asymmetric catalytic 1,3-dipolar cycloaddition reaction, in which substoichiometric amounts of a chiral metallic complex were used, was not described until 2002.[6] Zhang and co-workers screened several chiral bisphosphine ligands such as, binap ((*R*-) or (*S*)-2,2′-bis(diphenylphosphanyl)-1,1′-binaphthyl), Me-DuPhos ([(−)-1,2-bis-(2*R*,5*R*)-2,5-dimethylphospholano]benzene), PennPhos (*P,P′*-1,2-phenylenebis(*endo*-2,5-dialkyl-7-phosphobicyclo[2.2.1]heptane) and bicp ((*R,R*)- or (*S,S*)-2,2′-bis-(diphenylphosphanyl)dicyclopentane), with silver acetate, and obtained very poor enantioselectivities and even diastereoselectivities, in the cyclization reaction of imino esters **3** and dimethyl maleate.[6] However, Trost's ligand **8**[7] provided a promising higher enantioselectivity; the weak interaction of the nitrogen atom of the bisamide seems to be very important in the assembly of the

chiral ligand with the silver cation (Scheme 3).[6]

A similar ligand **9**, which incorporates an additional element of planar chirality (two ferrocene units), was designed to impart different steric and stereoelectronic properties on the product (Scheme 3). The best results for the *endo*-**10** adducts were obtained with these ligands when the aryl group was 3,5-dimethylphenyl and dimethyl maleate was used (Table 2).[6] Surprisingly, the adduct **10** was also formed in good yield and noticeable enantiomeric purity when the substituent R¹ of the

Table 2: Asymmetric catalytic 1,3-dipolar cycloaddition using substoichiometric amounts of a chiral metal complex (see Scheme 3).

R¹	Dipolarophile	Yield [%]	ee [%]
Ph	methyl maleate	87	87
4-(NC)C₆H₄	methyl maleate	90	86
2-Naph[a]	methyl maleate	98	97
*i*Pr	methyl maleate	82	70
Cy[b]	methyl maleate	82	81
Ph	methyl acrylate	90	60
Ph	*tert*-butyl acrylate	85	93
Ph	NMM[c]	87	79

[a] Naph = naphthyl, [b] Cy = cyclohexyl, [c] NMM = *N*-methyl maleimide.

precursor **3** was a cyclohexyl or isopropyl group. In previous work, it has been pointed out that the Michael-type addition reaction of the dipole to the electrophilic alkene is the expected pathway and, normally, no further cyclization occurred when R¹ is an alkyl substituent.[8] Very good enantioselection was also exhibited by the

dipolarophile *tert*-butyl acrylate (Table 2).[6]

However, it has been demonstrated that chiral bisphosphine ligands form a more suitable complex with copper triflate than with silver acetate. Komatsu and co-workers observed reverse *exo*-selectivity using chiral bisphosphine/copper(II) triflate at −40°C.[9] In most of the cases, the *exo/endo* ratio exceeded 95:5 using *N*-phenylmaleimide (NPM), the higher enantioselection being achieved with the catalytic systems formed by (*R*)-binap **11** or (*R*)-SegPhos **12**/copper(II) triflate (Scheme 4). With other dipolarophiles, such as dimethyl fumarate or fumaronitrile, the *endo*-adduct (e.g. **14**) was formed in higher proportion (Table 3).

The authors proposed a plausible mechanism for the cycloaddition reaction and for the explanation of the obtained diastereoselection (Scheme 2) by which the azomethine ylide **15** would be generated under basic media, and in turn this would react with NPM to give the *exo*-

(R)-binap **11**   *(R)*-SegPhos **12**
Scheme 4. R¹: see Table 3, R²=H; SegPhos = (4,4′-bi-1,3-benzo-dioxole)-5,5′-diylbis(diphenylphosphane).

transition state **16**, because here the steric interactions between NPM and the bisphosphine ligand are less than in the *endo*-transition state **16** (Scheme 5). This hypothesis was also supported by ZINDO calculations.[9]

Focusing on the silver(I)-catalyzed enantioselective cycloaddition developed by Zhang and co-workers, Schreiber and co-workers studied the catalytic 1,3-dipolar cycloaddition reaction of azomethine ylides with a series of chiral monophosphines bearing a donor group; the P,N-ligand quinap **17** is an

[a] By using 10 mol% of the catalyst system **17**/Ag^I.

excellent chelating molecule for the silver cation (see chelate **7** in Scheme 2).[10] The catalyst loading (3 mol%) was very similar to that reported in previous examples (see above). When substrates **3** were allowed to react with *tert*-butyl acrylate, *tert*-butyl crotonate, and *tert*-butyl cinnamate (Scheme 6, Table 4), the enantioselectivities achieved were very high. Nevertheless, the reaction between the imino ester **3** and dimethyl maleate furnished compound **19** in 60% *ee*. In all these cycloadditions the *endo*-selectivity was overwhelmingly predominant, except when *tert*-butyl cinnamate was employed as dipolarophile. In addition, α-substituted esters **3** (incorporating methyl, isobutyl, benzyl, and 3-indolylmethyl groups) were also evaluated in this transformation using a catalyst loading of 10 mol%; proline derivatives **19** with a quaternary carbon atom in the α-position were obtained in high yields and very good *ee* values.

The same enantioselection and yields were achieved by Carreira and co-workers with the ligand O-(S)-pinap **18** under the reaction conditions detailed in Table 4 (R^1 = 4-(NC)C$_6$H$_4$),[11] namely 3 mol% of the catalytic mixture **18**/AgOAc was employed at −40 °C. This result also confirmed the efficient coordination of the silver cation to the chiral moiety of (S)-quinap **17** and O-(S)-pinap **18**, as was shown in the model **7** (Scheme 2).

Jørgensen and co-workers demonstrated that chiral bisoxazolines **20–22** (Scheme 7) were suitable ligands for the standard 1,3-dipolar cycloaddition reac-

(S)-*t*Bu-box **20**   (R)-Ph-box **21**

tions of azomethine ylides and electrophilic alkenes when zinc(II) triflate, rather than copper(II) triflate, was used as Lewis acid.[12] The reaction of the imino ester **3** in basic media with several dipolarophiles occurred at room temperature with excellent diastereoselectivity (*endo*-products **23** were exclusively formed) in very good yields and very high *ee* values, although an improvement of the enantioselectivity was observed when the reaction was carried out at −20°C (Scheme 8, Table 5). The
Scheme 8. R¹, R³: see Table 5, R² = H.

catalyst loading employed in this reaction is higher than that employed in the previously described cases. These reaction conditions were independent of the quantity of base used and were very sensitive to the bulkiness of the substituents anchored to the dipolarophile (the *ee* value decreased when *tert*-butyl acrylate was used as the dipolarophile). Based on the absolute configuration of the *N*-tosylated adducts **23** (determined by X-ray structure analysis), the authors proposed an intermediate **24** in which the azomethine ylide coordinates with the Zn^{II}-*t*Bu-box catalyst to form an 18-electron complex with a tetrahedral arrangement of the ligand around the metal center (Scheme 8).[12]

In summary, if we evaluate all these aspects we determine that the metal-catalyzed 1,3-dipolar cycloaddition re-

action of azomethine ylides is a very difficult reaction because too many parameters have to be controlled. For example, the coordination between the metal center and the chiral ligand has to be stronger than the coordination of the metal center and the 1,3-dipole; however, the interaction with the final pyrrolidine should be weaker to allow the regeneration of the chiral catalyst. The chiral domain must differentiate the two enantiotopic faces of the 1,3-dipole on attack of the dipolarophile. The substituents of the imine and the ester groups, as well as the structure of the electron-deficient olefin are crucial for the course of the enantioselection. Finally, the solvent and the temperature play important roles in fine-tuning this asymmetric reaction and have to be considered carefully.

The five contributions described previously[6,9–12] constitute very good pieces of chemistry, each of which has some intrinsic drawbacks that need to be corrected. Which ligand/metal cation couple can ensure a very good enantioselection? From the work done so far, it is seen that N,P-ligands/Ag^I, P,P-ligands/Cu^{II}, and N,N-ligands/Zn^{II} are, a priori, suitable combinations for this enantioselective cycloaddition. The perfect asymmetric reaction, for which yields and enantiomeric enrichment are excellent, independent of the structure of the 1,3-dipole and dipolarophile, has not been reported yet. A fast reaction, at room temperature, in the presence of a recoverable chiral ligand without any significant loss of efficiency or activity of the catalyst system, is very desirable. Thus, this area remains fascinating and much work still has to be done in the pursuit of the perfect catalytic system.[13]

Redox Catalysts for Reduction with Base Metals

*Reinhard W. Hoffmann**

Reduction of organic compounds by dissolving base metals (short: dissolving metal reduction) is one of the established methods in functional group interconversion.[1] Organic chemists traditionally use lithium ($E° = -3.28$ V),[+] sodium ($E° = -2.95$ V), magnesium ($E° = -2.60$ V), sodium amalgam ($E° = -1.80$ V), or zinc ($E° = -1.00$ V) as reductants, which allows a rather coarse differentiation between various reducible groups in a substrate. A major step forward in the field of dissolving metal reduction was the development and progress made by Yus and Ramon[2] on the redox catalysis[3,4] by naphthalene ($E° = -2.50$ V) or di-*tert*-butylbiphenyl ($E° = -2.70$ V) of reductive metalations with lithium metal. This provided convenient reduction procedures,[5] at potentials less negative than those of sodium or lithium metal (Scheme 1).[6]

In fact, the metal reductions with naphthalene or di-*tert*-butylbiphenyl were so convenient, that different redox catalysts, which might allow access to other regimes of redox potentials have hardly been explored. In this regard the report[7] is remarkable that organometallic ate complexes such as Me₃FeLi, Me₃CoLi, or Me₃MnLi are useful catalysts for the reduction of various functional groups by magnesium metal. Their oxidation potentials ($E° = -2.55$ to -2.65) fall in between those of naphthalene and di-*tert*-butylbiphenyl.

Scheme 1. Reductive cleavage of *p*-toluenesulfonamides with naphthalene as electron transfer catalyst.

These compounds have for example, been applied (10 mol% in THF) to mediate the reductive cleavage of sulfonamides by magnesium metal (Table 1).

This reduction reaction is apparently based the catalytic cycle given in Scheme 2. This and related reductive cleavage reactions[7] appear to proceed by electron transfer and not by group transfer,[8] other-

wise rapid turnover in a catalyzed reaction would be difficult to explain. It is fortunate that the trimethyl metal(III) intermediate **1** is sufficiently long-lived to maintain the catalytic cycle, rather than to decompose by homolysis of the metal–carbon bond [9] or by reductive elimination.[10]

But what could be important about the use of metal ate complexes as electron transfer catalysts? First of all, it underscores that efficient catalysts for electron transfer reactions may be found outside the trodden paths of aromatic and heteroaromatic compounds.[11] When redox catalysts with a rather negative oxidation potential had to be sought, it seems quite rational to look
Scheme 2. Proposed catalytic cycle for the reductive cleavage of phenylsulfonamides.

(tetrahydroisoquinoline, SO₂Ph → H)	100	83	83

among the electron-rich organometallic compounds and ate complexes.[12] It was, however, by no means obvious to examine the trialkyl ferrates(II)[13] or the related manganates(II) or cobaltates, which had hitherto not attracted much attention in chemistry. The fortunate aspect of this choice is that the reactivity of these reagents can be tuned by way of the metal and ligand.[14] Thus, a change from Me_3FeLi to $(tBuO)_3FeK$ provides a catalyst with a more positive oxidation potential ($E° = -1.90$ V), which allowed a high-yielding pinacol coupling of aromatic aldehydes (Scheme 3).[7]
Scheme 3. Example of ligand tuning in the metalate-catalyzed reduction of benzaldehyde by magnesium metal.

The unexpected move from aromatic systems to the metal ate complexes as redox catalysts for dissolving metal reduction leads one to ask, which molecular properties besides possessing the "right" oxidation potential a compound should have to function as an efficient electron transfer catalyst.[3] In the end, the catalyzed process should be faster than the noncatalyzed direct electron transfer from the stoichiometric metal to the substrate. The catalyst is therefore required to provide a fast two-stage electron transfer, that is, the electron transfer rates to and from the catalyst should be high. This brings the Marcus theory into focus:[15] The electron transfer rate is increased when the reorganization energy on electron transfer remains small. Hence systems, in which the reduced and oxidized state have essentially the same molecular geometry, are favored.[16] In fact, BP86/SV(P) calculations indicate for the trimethylferrate system **1** that upon electron transfer changes in bond length remain less than 0.01 Å and changes in bond angles less than 2°.[17] As far as solvent reorganization goes, the valence electrons in the redox catalyst should be in

delocalized orbitals which do not cause a marked solvation in either the reduced or the oxidized state. The shape of the frontier orbitals is also of consequence: spatially extended and spatially directed frontier orbitals allow a better overlap between the partners during electron transfer and affect, via the electronic matrix coupling element H_{AB}, the rate of the electron transfer.[18] Besides these intrinsic factors that make a good electron transfer catalyst, there are also nontrivial external factors of importance: Obviously both the oxidized and reduced state should have sufficient kinetic stability that they persist long enough to permit reversible electron transfer and turnover. Second, reducing agents with a high-lying HOMO are likely not only to be strong reductants but also good nucleophiles. A reagent with a predominant nucleophilic reactivity such as $[Na_2Fe(CO)_4]$[19] might therefore have a handicap if considered as an electron transfer catalyst.

From these considerations it becomes clear that the trimethylferrates(II) will not be the only candidates for efficient redox catalysts in dissolving metal reductions. Just staying with iron, inorganic chemistry has provided remarkable redox catalysts such as **2** or **3** (Scheme 4), which appear to have so far been overlooked by the organic chemistry community.
Scheme 4. Examples of potential redox catalysts for metal reductions by sodium or magnesium.

The cyclopentadienyl–Fe^{II}–arene complexes (**2**) are readily prepared and soluble in organic solvents.[20] They are reversibly reduced to neutral cyclopentadienyl–Fe^{I}–arene complexes at potentials between -1.1 to -1.9 V,[21] and have already been applied as redox

catalysts in the reduction of nitrate ions.[22] This bodes well for their application as redox catalysts in the dissolving metal reduction of a variety of organic substrates.

The iron–sulfur cubane clusters[23] **3** are perhaps a little bit more difficult to handle on account of their air-sensitivity. These[24] and the related $MoFe_3S_4$ double cubane clusters[25] offer reversible redox systems that span redox potentials in the $+0.13$ to -1.61 and the -0.7 to -2.1 V range. The clusters **3** have been applied as redox catalysts in the reduction of acridine derivatives by sodium dithionite.[26] Overall the series of compounds **2** and **3** should allow the choice of an appropriate redox catalyst anywhere in the potential range of interest for group selective reduction in organic chemistry. Potential applications have been delineated by Semmelhack and Heinsohn,[27] who devised a series of different ester protecting groups, which can be removed selectively by controlled potential electrolysis in the -0.6 to -2.1 V range (Scheme 5).
Scheme 5. Chemoselective cleavage of reducible esters by controlled potential electrolysis.

Rather than relying on controlled potential electrolysis, which many organic chemists consider as inconvenient, dissolving metal reduction with a redox catalyst of appropriate reduction potential should effect the same results. A cautionary word regarding chemoselectivity by electrochemical methods (or catalyzed metal reduction) should be added. Electrochemical reduction will not only occur when it is thermodynamically downhill. Rather an uphill reduction may occur, when the substrate is reduced to a radical anion that undergoes a rapid follow-up reaction such as an irreversible decomposition. This particularly holds for the reductive cleavage of protective groups that occurs by bond breaking in the intermediary radical anion.

The results and possibilities referred to here suggest that the field of dissolving metal reduction no longer should be considered as a static and ripe technology. Rather it appears that a renaissance in the development of versatile synthetic methods is forthcoming in this area of chemistry.

Engineering Silicon Oxide Surfaces Using Self-Assembled Monolayers

Steffen Onclin, Bart Jan Ravoo, and David N. Reinhoudt**

Angewandte
Chemie
*A*lthough a molecular monolayer is only a few nanometers thick it can completely change the properties of a surface. Molecular monolayers can be readily prepared using the Langmuir–Blodgett methodology or by chemisorption on metal and oxide surfaces. This Review focuses on the use of chemisorbed self-assembled monolayers (SAMs) as a platform for the functionalization of silicon oxide surfaces. The controlled organization of molecules and molecular assemblies on silicon oxide will have a prominent place in "bottom-up" nanofabrication, which could revolutionize fields such as nanoelectronics and biotechnology in the near future. In recent years, self-assembled monolayers on silicon oxide have reached a high level of sophistication and have been combined with various lithographic patterning methods to develop new nanofabrication protocols and biological arrays. Nanoscale control over surface properties is of paramount importance to advance from 2D patterning to 3D fabrication.

From the Contents

1. Introduction

The term "self-assembling monolayer" was coined in 1983 in *New Scientist*[1] in an anonymous report describing the work of Lucy Netzer and Jacob Sagiv on the chemically controlled layer-by-layer self-assembly of multilayer films.[2] The self-assembly of adsorbates on an appropriate surface has been known since 1946, when Zisman and co-workers reported the formation of monomolecular films of long-chain hydrocarbons carrying polar groups on a variety of polar surfaces.[3,4] Although these films are extremely thin (typically ca. 2 nm), they are able to completely change the surface properties. However, the versatility of these adsorbed monolayers was not realized until 1978, when Polymeropoulos and Sagiv proposed their use for measuring electrical conduction between two metal surfaces.[5] In 1980, Sagiv published the first article demonstrating the formation of well-defined organosilane monolayers on SiO$_2$ by direct adsorption (that is, self-assembly) from solution.[6]

Self-assembled monolayers (SAMs) are highly ordered two-dimensional structures that form spontaneously on a variety of surfaces. Several reviews have discussed this subject.[7–10] The most common adsorbate/substrate combinations are alkylsilanes on oxide surfaces,[6] and sulfur-containing molecules on gold.[11] Although the latter combination has received the most attention, presumably because of the ease of preparation, alkylsilane monolayers on oxide surfaces such as SiO$_2$ possess some advantageous features. The covalent nature of the assembly process results in them displaying superior stability, which allows extensive handling and further modification steps without deterioration of the monolayer. Moreover, these SAMs are compatible with silicon technology and permit the use of optical techniques, such as fluorescence spectroscopy, as read-out methods.

Since the pioneering work of Sagiv and co-workers in the 1980s,[2,6,12–19] the field of SAMs on SiO$_2$ surfaces has grown exponentially. SAMs are not merely a method to passivate surfaces, but constitute ordered molecular platforms that can be employed in surface patterning and bottom-up nanofabrication techniques. However, in contrast to the increasing sophistication of the molecular architectures based on SAMs, the actual mechanism of monolayer formation remains a subject of debate. Many studies have been carried out to elucidate this process, but the results are often conflicting.

In this Review the mechanism of monolayer formation will be discussed, followed by an overview of the chemistry that has become available to derivatize monolayers. Much of this chemistry is exploited for applications, such as (bio)-chemical sensing. Particularly important for the application of SAMs in areas such as nanotechnology and biological array formation has been the development of (soft) lithographic methods, which can be used to address and modify selected parts of the surface in a controlled manner. These methods greatly facilitate the preparation of high-density chemical patterns on a surface, which in turn are available for further functionalization by, for example, self-assembly. In this way, SAMs form well-defined platforms for nanofabrication, where a 2D pattern is expressed and amplified in a 3D functional structure. An overview of the techniques available for surface patterning is presented and future applications of SAMs are discussed.

2. Self-Assembled Monolayers on Silicon Oxide

The development of analytical tools for the study of SAMs has been impressive in the last two decades. The methods that are used most frequently are listed briefly here. It should be

noted that a satisfactory characterization of films with a thickness of just a few nanometers can only be obtained by combining several of these techniques, each providing specific information. Contact angle goniometry provides information on the polarity, roughness, and order of a SAM.[7] Ellipsometry is a common optical technique for the determination of the thickness of thin films.[7,20] Detailed information on the elemental composition of SAMs can be gathered by X-ray photoelectron spectroscopy (XPS),[21] which probes the kinetic energy of the inner or valence electrons ejected by an incident photon with a known energy $h\nu$. An alternative technique to study the composition of a monolayer is secondary ion mass spectrometry (SIMS).[22,23] SIMS uses a beam of high-energy "primary" particles (ions) to bombard the SAM and analyses the ionized "secondary" particles that are emitted. Fourier transform infrared spectroscopy (FT-IR) can be employed to determine the molecular packing and orientation as well as to identify functional groups in SAMs.[22] It is mainly used in three spectroscopy modes: attenuated total reflection,[24] grazing angle,[25] and Brewster angle.[25] The electron-density profile of thin films can be probed by X-ray reflectivity, which can be used to determine the film thickness.[26] The technique of choice to measure surface topology, nanoscale structures, and molecular as well as atomic scale lattices is atomic force microscopy (AFM),[27] which measures the repulsive and attractive forces between a very sharp tip (radius 10–100 nm) and the sample surface.

2.1. Mechanism of Formation

There has been considerable debate on how SAMs are formed on SiO$_2$. Especially in the late 1980s and 1990s, when the field started to grow rapidly, many fundamental studies were performed to establish a clear picture of the mechanism of monolayer formation and to formulate procedures that would guarantee reproducibility. It soon became apparent that several parameters are important in monolayer formation and, in particular, the role of water has been investigated thoroughly. The first SAM of octadecyltrichlorosilane (OTS) molecules was reported by Sagiv.[6] He recognized that water adsorbed on the surface was necessary to hydrolyze the chlorosilane and assumed that the hydrolyzed molecules would undergo condensation reactions with the surface hydroxy groups[28] and other OTS molecules to form a polymerized network of molecules in which each OTS molecule is covalently anchored to the surface.

This view on the self-assembly process had to be adjusted when Finklea et al. discovered that organized monolayers of OTS could also be formed on a gold surface, that is, a surface devoid of hydroxy groups.[29] They concluded that self-assembly occurs on the adsorbed water film on the gold substrate and that the silane head groups are incorporated into a two-dimensional cross-linked network of Si-O-Si bonds. This view was later confirmed by Allara et al.[30] The observation of a lower roughness of silanized wafers compared to unmodified wafers, as observed in X-ray reflectivity experiments by Silberzan et al., also indicated that not all molecules are individually linked to the surface, but rather form a cross-polymerized network of molecules with only a few bonds to the surface.[31] This scenario was supported by the IR studies of Tripp and Hair:[32,33] they found in a low-frequency IR study that the adsorbed species form few, if any, Si-O-Si bonds with the surface.

Commonly, the surface is activated prior to the self-assembly to clean the surface and maximize the number of silanol groups at the surface.[28] There are several methods to achieve this, but usually strong acids or an oxygen plasma are employed. This procedure renders the surface hydrophilic and prone to the formation of a thin water layer. There is a general consensus that trace amounts of water are essential for the formation of well-packed monolayers. Several studies even reported that the quality of SAMs increases with the degree of hydration of the substrate.[24,32,34–36] SAMs formed on dry SiO$_2$ surfaces are generally of poor quality. IR data suggested that a uniform film containing disordered alkyl chains was formed.[24] Tripp and Hair showed that a solution of OTS in carbon tetrachloride does not react at all with the surface in the absence of moisture.[32,37] Rye et al. compared the saturation coverage of octadecyldimethylchlorosilane (ODMS) and OTS.[38] The ODMS coverage on hydrated surfaces was approximately one third of the OTS coverage. In contrast, when the substrates were vacuum-baked prior to self-assembly the saturation coverages were comparable. Rye et al. attributed this to coupling reactions being limited to the surface hydroxy groups.

Steffen Onclin was born in 1975 and studied chemical engineering at the University of Twente (The Netherlands). From 2000 to 2004 he worked in the Laboratory of Supramolecular Chemistry and Technology on his PhD Thesis on supramolecular nanotechnology. In October 2004 he received his PhD from the University of Twente. Since February 2005 he has been working as a project manager at Ciba Speciality Chemicals.

Bart Jan Ravoo was born in 1970 and obtained his graduate and postgraduate degrees in chemistry from the University of Groningen (The Netherlands). From 1999 to 2002 he held a Newman Scholarship at the University College Dublin (Ireland). In 2002 he was appointed as assistant professor at the University of Twente. His main research interest is self-assembly and molecular recognition in water and at the dynamic interface between water and (soft) surfaces. His research interests include the development of functional SAMs, soft lithography, and nanofabrication.

The same authors proposed a model of a growing crystallite resulting from the reaction of an alkyltrichlorosilane with oxidized silicon covered by a thin water layer.[38,39] The model, shown in Figure 1, is controversial. The model

= van der Waals radius for hydrocarbon chain
Figure 1. Model of a growing monolayer crystallite resulting from the reaction of an alkyltrichlorosilane with a silicon oxide surface.[39]

shows alkyl chains that are forced into proximity by the covalent bonds of the Si-O-Si framework and not by the interaction of the alkyl chains. A distance of 3.5 Å between nearest neighbor Si atoms was used in the construction of the model and the circles around the hydrocarbon chains represent the van der Waals radius for linear hydrocarbons

(2 Å). Rye et al. claimed that the steric crowding imposed on the alkane chains can be reduced by a tilt of the chains relative to the surface normal. However, in a modeling study by Stevens it was shown that cross-polymerization, which was considered an essential element in the formation of stable SAMs on SiO$_2$, cannot occur for monolayers at full surface coverage.[40] The reason for this is because of steric effects.

A fundamental inconsistency in the organization in a monolayer as proposed in Figure 1 is that the covalent bonds in the Si-O-Si network (3.2 Å) are substantially shorter than the van der Waals diameters for C atoms (3.5 Å). The steric overlap is even larger when the hydrogen atoms of the hydrocarbon chain are also taken into account. Moreover, complete cross-polymerization would yield an area per chain of around 11 Å^2, which is not possible and not observed. Instead, the experimentally observed area per chain of 21–25 Å^2[26,41–45] is more consistent with the area per chain of 20–24 Å^2 that was found for hexagonally close-packed Langmuir–Blodgett layers of OTS,[46,47] thus indicating that SAMs on SiO$_2$ are very similar to Langmuir–Blodgett layers.

Kajiyama and co-workers compared OTS monolayers prepared by the Langmuir–Blodgett method and the chemisorption method,[48] and found that OTS molecules in the Langmuir monolayer were less tilted (ca. 8–10°) than in the chemisorbed layers (15–17°). The Langmuir monolayers are also slightly better ordered, as concluded from the spacing of the molecules. The molecular packing of chemisorbed monolayers was discussed earlier.[49] Taking into account the overall experimental evidence furnished by IR and X-ray scattering data collected strictly from the same film specimens, they proposed a dynamic structural model that can reconcile the steric limitations imposed by the packing of perpendicularly oriented hydrocarbon tails with the apparent formation of extended lateral siloxane (-Si-O-Si-O-) chains. More recently, further evidence in support of this model was put forward in a semiquantitative experimental evaluation of the intra- and interlayer modes of bonding in organosilane multilayers.[50] The hydrocarbon chains in these highly ordered multilayers adopt an essentially perpendicular orientation (that is, no significant tilt) with a maximum molecular area of 20 Å^2. Thus, it seems reasonable to conclude that SAMs of alkylsilanes on SiO$_2$ are very similar to Langmuir–Blodgett layers and that the reduced ordering of the SAMs can be explained by a certain degree of cross-polymerization. This most likely accounts for the fact that no long-range order is observed.

Recently, Wang et al. reported a method to grow ultrasmooth OTS monolayers on native SiO$_2$.[51] By comparing the deposition of OTS under "dry" and "wet" conditions, they concluded that growth occurs by different mechanisms. In dry, hydrophobic solvents, when water is only present as a thin layer on the surface and not in solution, true monolayers could be grown with a root-mean-square roughness of about 1 Å in two days, which is a much longer deposition time than usually applied. Under "wet" conditions OTS condensed into flat aggregates in solution which subsequently adsorbed onto the substrate. Since the aggregates are preformed in solution, they cover the substrate much faster than under "dry" conditions, but are not able to form a smooth monolayer.

David N. Reinhoudt was born in 1942 in The Netherlands and obtained a PhD in chemistry in Delft in 1969. From 1970 to 1975 he worked at Shell on the crown ether research program. He was appointed as a part-time professor at the University of Twente in 1975 and as a full professor in 1978. He is now in charge of the Laboratory of Supramolecular Chemistry and Technology, scientific director of the MESA$^+$ Institute for Nanotechnology, and chairman of the Board of NanoNed, the Dutch program for Nanotechnology. He is the author of more than 750 scientific publications and patents.

The role of solvents on the self-assembly process was systematically investigated by McGovern et al.,[52] and by Hoffmann et al.[20] McGovern et al. found that aromatic solvents such as toluene, which are able to extract significant amounts of water from the substrate, yielded the densest OTS films in one hour and postulated that hydrolysis of OTS took place in solution rather than at the surface, as had commonly been assumed until then. In the second study, kinetic information on the monolayer growth in different solvents was obtained by in situ ellipsometry measurements. Different solvents resulted in differences in the rate of monolayer growth of up to a factor of 50.

The study of partially formed monolayers is helpful to understand the self-assembly process and was a topic of controversy during the 1980s and early 1990s. Sagiv and co-workers proposed that monolayers are formed through islands, as suggested by IR data on partially formed SAMs,[14,17] while others concluded that disordered, homogeneous, but incomplete monolayers are formed.[26,42,53–55] Both processes are illustrated in Figure 2.
Figure 2. Schematic representation of island-type growth and homogeneous growth of SAMs.

Eventually, it was shown by AFM that OTS monolayers grow via islands that are virtually perpendicular to the substrate surface.[56] Perfluorinated trichlorosilanes also grow via island formation,[57] and alternate phases depending on the deposition conditions.[58] In contrast, shorter-chain molecules do not show island growth.[56] Several AFM studies revealed that the deposition process strongly depends on parameters such as solvent,[59] solution age,[60–62] water content,[51,60,61,63] deposition time,[62–64] and temperature.[65–68] Vallant et al. observed both homogeneous growth and island-type growth depending on the water content and age of the silane solution.[60] Island-type growth was found to be strongly favored with increasing water content or age of the solution. This result is indicative of the formation of larger preorganized aggregates of siloxanes in solution. However, Wang and Lieberman recently showed that even in the absence of traces of water in solution, the self-assembly process still proceeds via island-type growth.[51] The reason that this was not observed in other studies is probably the slow kinetics. Wang et al. claim that they observed monolayer islands after 18 h of deposition time in the absence of water,

while deposition times of only seconds to a few hours are common. Figure 3 shows a tapping-mode AFM image of a partial OTS film on oxidized silicon, which clearly shows the growth of an OTS monolayer via islands.
Figure 3. Tapping mode AFM image ($20 \times 20\ \mu m^2$) of a partial OTS film on oxidized silicon.[67]

The formation of monolayers appears to proceed through a number of stages. A combined lateral force microscopy (LFM) and sum-frequency generation (SFG) spectroscopy study by Liu et al. showed OTS adsorption from solution and the beginning of island formation during the initial stage. This process was followed by a dramatic change in the conformation of the alkyl chain within the film from a disordered to an ordered, mainly all-*trans* conformation, with only a small increase in surface coverage.[63] The final stage is a much slower adsorption process to form a complete monolayer. Balgar et al. observed two regimes: a nearly linear growth up to a coverage of about 75 %, followed by slow saturation at higher coverages.[64]

Despite the complex mechanism of monolayer formation, and its dependence on many parameters, several studies reported first-order Langmuir adsorption kinetics by using analytical techniques such as in situ attenuated total reflection infrared spectroscopy (ATR-IR),[69] in situ AFM,[61] X-ray reflectivity,[70] and in situ ellipsometry.[20] Recently, a simple two-dimensional model for the growth of alkylsilane monolayers on hydroxylated surfaces was proposed.[71] The model, which takes into account the weak and strong bonding interactions of the aggregating species, was able to reproduce characteristics such as island-type growth and first-order Langmuir adsorption kinetics. In addition, it provides an explanation for the observed deviations from the first-order Langmuir adsorption kinetics in various ex situ studies.[64,72]

The observation that monolayer formation depends on temperature was reported in the very first paper on monolayer self-assembly.[3] A thorough account reporting the existence of a critical temperature above which monolayers are not produced followed as early as 1947, in the second classic paper published by Zisman and co-workers on the formation of such monolayers.[4] These observations were

"rediscovered" 45 years later by Silberzan et al.[31] who also found that lower temperatures favor the chemisorption, which may seem paradoxical at first sight. Several research groups have studied this phenomenon by monitoring the surface tension and confirmed that a critical temperature, close to ambient temperature for OTS, exists for the formation of high-quality SAMs.[73–75] As the critical temperature was found to depend on the length of the alkyl chain, these studies related the critical temperature to the triple point observed in the phase diagram of Langmuir layers at the air–water interface. Silberzan and co-workers confirmed the analogy to Langmuir films by AFM studies.[65,72] Island-type growth takes place below the critical temperature, while islands were not observed for depositions above the critical temperature. However, Rye reported that a much simpler and more straightforward correlation exists between the melting points of alkanes and the observed critical temperature.[39]

Time-resolved AFM studies by Carraro et al. indicated three distinct mechanisms, depending on deposition temperature: island growth at low temperatures, homogeneous growth at high temperatures, and a mixed regime at intermediate temperatures.[66] Later, they reported an experiment that showed reversible structural change of the same partial OTS monolayer as a function of temperature at constant coverage.[67] They concluded that the highly mobile monolayer exists in a hydrogen-bonded state at the surface and is closely related to the equilibrium state of Langmuir films at the air–water interface.

Recently, the interplay between water and temperature on the growth of OTS submonolayers was investigated.[76] Dynamic light scattering studies revealed the formation of aggregates in solution with a hydrodynamic radius of approximately 200 nm for all examined water concentrations and temperatures. However, formation of the aggregates was faster at higher water contents and lower temperatures. In addition, a characteristic temperature was found above which such aggregates could no longer be detected, and which was higher for higher water concentrations.

2.2. Stability of the Self-Assembled Monolayers

Part of the attractiveness of SAMs on SiO₂ stems from their stability, which is a vital issue in applications. The stability is caused by partial in-plane cross-linkage of the molecules and possible covalent anchoring to the substrate. SAMs of OTS are stable in air up to about 150 °C,[17,77–80] after which irreversible changes occur in the monolayer structure. Perfluorinated SAMs appear to be even more resistant towards thermal decomposition:[78,81] Srinivasan et al. reported that $1H,1H,2H,2H$-perfluorodecyltrichlorosilane coatings remain intact even up to 400 °C.[78] The stability toward various chemicals is also remarkable: OTS SAMs can be washed with organic solvents, hot (tap) water, or detergent solutions without detectable damage to the layer.[82,83] Their stability in boiling solvents such as chloroform and water is good,[84] but when exposed to 2.5 M sulfuric acid in boiling dioxane or 48 % aqueous HF the layers were damaged significantly, as witnessed by reduced ellipsometric thick-

nesses.[85] Wasserman et al. found that exposure of tetradecyltrichlorosilane SAMs to 0.1 N HCl for more than 40 h did not affect the monolayer, but immersion in 0.1 N NaOH resulted in immediate degradation.[86] This lack of stability in basic media was attributed to the hydrolysis of Si−O bonds close to the surface.

One of the first applications where SAMs on SiO₂ were thought to play a key role was in boundary lubrication in, for example, magnetic storage devices. As early as in 1993, the tribological properties of alkylsilane films on solid substrates were investigated.[87] The friction of coated interfaces was lower compared to the friction of bare interfaces, and the lifetime of the lubricated interfaces increased with increasing chain length.[87,88] Srinivasan et al. examined the potential of SAMs for the reduction of adhesion in microelectromechanical systems.[78] They found a reduction in adhesion by more than three orders of magnitude upon applying an OTS coating, while fluorinated SAMs reduced it further by a factor of four. The mechanical strength of octadecyltriethoxysilane (OTE) layers on mica has been investigated by scratching studies with an AFM tip.[89] No mechanical wear was observed for loads up to 300 nN when a large tip radius was used. When sharper tips were used a load of about 10 nN was sufficient to displace the OTE monolayer. *n*-Alkanethiols on Au were removed with a smaller force (ca. 5 nN) using the same sharp tip. However, a more recent study questioned the mechanical stability of OTS SAMs on SiO₂.[90] Lower friction coefficients for monolayer-coated surfaces were reported, as well as a poor load-carrying capacity and antiwear ability. This report concluded that OTS SAMs could only be potential boundary lubricants at low loads.

3. Chemical Diversity of Self-Assembled Monolayers on Silicon Oxide

SAMs on SiO₂ provide molecularly defined platforms for chemical derivatization. Potential applications range from the control of surface properties to the fabrication of sensors and biochips as well as their use in nanotechnology. Progress in the development of these fields partly depends upon the ability to functionalize SAM surfaces with suitable groups. Two constraints determine the utility of SAMs on SiO₂ for the creation of functionalized surfaces: 1) the range of functionalities that can be tolerated in the self-assembly process to yield stable and ordered SAMs, and 2) the scope of chemical modifications of the monolayer that can be achieved.

An efficient reaction in solution is not necessarily successful on a solid substrate. The reactivity of immobilized reactants can be significantly reduced as a consequence of steric constraints, transport limitations, solvation effects, charge, and dipole effects.[91] Therefore, the extent of reaction in a SAM depends strongly on the location of the reaction center: When it is located on the incoming reagent, the transition state does not experience much steric limitation, while if it is confined to the surface the reaction center is severely crowded by immobilized neighbors. Acid/base properties of surface-confined molecules can also differ significantly from those in solution.[92–95] Important factors might be

the polarity of the surface, interfacial electrostatic fields, and the local structure of the solvent.

3.1. Self-Assembly of Functionalized Alkylsilanes and Chemical Transformations at the Monolayer Surface

The most straightforward way to prepare a functionalized SAM is by using an ω-substituted alkylsilane. In general, chlorosilanes are preferred over alkoxysilanes since they are more reactive. However, the reactivity of chlorosilanes severely limits the range of functional groups that can be introduced in this manner. The preparation of ω-functionalized alkyltrichlorosilanes is facilitated by using trialkoxysilanes as synthetic intermediates, as was reported by Barness et al.[96] These offer superior stability with respect to synthetic operations and can be converted into trichlorosilanes by reaction with trichloroacetyl chloride.

The first functionalized SAM was reported by Netzer and Sagiv, and contained vinyl groups that could be transformed into terminal hydroxy groups by hydroboration and oxidation.[2] Other reactions on these layers generated carboxylic acid, and bromo-terminated films.[86] A nice example of surface chemistry with these carboxylic acid monolayers was shown by Sagiv et al.[97] The carboxylic acids were used to form a bilayer with octadecylamine through electrostatic/hydrogen-bonding interactions. Exposure of the bilayer to microwaves resulted in the formation of imides (Scheme 1).

More recently, vinyl SAMs have been covalently coupled to zwitterionic phosphorylcholine groups.[98] Such monolayers are biocompatible and prohibit the deposition of enzymes and proteins. In addition, vinyl monolayers can be modified with adenine, and subsequently zeolite crystals functionalized with thymine were assembled at that surface through adenine–thymine hydrogen bonding.[99] Tillman et al. prepared monolayers incorporating phenoxy groups and methyl esters, of which the latter were reduced to the corresponding alcohols by LiAlH$_4$.[82, 83, 100] Other functional groups incorporated into monolayers include methyl ether,[101] acetate,[101] thiocyanate,[102] α-haloacetate,[103] (trimethylsilyl)ethynyl,[104] and thioacetate,[102] which can be reduced to thiols.[105]
Scheme 1. Microwave-induced imide formation in SAMs.[97]

A convenient starting point for chemistry on monolayers is provided by bromo-terminated SAMs.[69,101,106,107] Bromides can be quantitatively replaced by azide groups, which in turn are reduced to ω-amino SAMs,[102,108] or can be used to tether to a fullerene molecule.[109] In addition, bromides have also been replaced by other anionic nucleophiles such as thiocyanate and thiolate.[110] These reactions did not go to completion, most likely because of steric congestion and because thiocyanates and thiolates are less nucleophilic than azides.

An alternative method to obtain amino-terminated SAMs is by self-assembly of cyanide monolayers.[69,102] These SAMs can be reduced in one step using $LiAlH_4$ or BH_3.[102] Such amino-terminated SAMs form an important platform for reaction with functionalized molecules. Ordered and well-defined layers are obtained when amino-terminated SAMs are prepared by reduction of azides or cyanides.[102,108,111] Aminosilane films prepared in one step, on the other hand, are completely disordered.[112] XPS and IR measurements indicated that this is probably a result of interaction of the amino group with the SiO_2 surface.[112,113] Nevertheless, aminosilanes, and particularly 3-aminopropyltrialkoxysilanes (APS), have been used extensively as adhesion promoters and the well-known reactivity of amines has been exploited for the introduction of various functionalized molecules. APS layers were used to covalently bind fullerenes,[114,115] chromophores,[116,117] and fluorophores,[118,119] and to coordinate to a zinc porphyrin.[120] In addition, photoresponsive spiropyran molecules were covalently attached to an APS layer and used to induce reversible changes in wettability upon switching to a more polar zwitterionic merocyanine isomer, triggered by the absorption of UV light.[121,122] Other reactions on amino-terminated SAMs will be discussed in Sections 3.3 and 3.4.

SAMs exposing sulfanyl groups are potentially interesting because of their ability to coordinate to noble metals. The self-assembly of (mercaptopropyl)trimethoxysilane (MPTMS) has been reported,[91,123] and the preparation of colloidal gold multilayers using MPTMS as a linker molecule has been investigated.[124] This layer-by-layer growth method yields uniform colloidal Au multilayers. More recently, MPTMS layers have been oxidized to produce sulfonic acid functionalized silica that can be used as a catalyst in esterification reactions,[125] and MPTMS monolayers have also been used for electroless plating of Ag.[126]

Homogeneous epoxy-terminated SAMs have been reported by Luzinov et al. to serve as templates for the chemical tethering of polymer layers.[127] These layers can serve as functionalized surfaces and react with various amino-derivatized molecules. Kulak et al. attached an APS layer to zeolite crystals and found that the modified crystals assembled as monolayers on an epoxide SAM.[128] The zeolite layer remained intact after sonication, thus indicating that strong linkages were formed between each crystal and the substrate. Furthermore, epoxide layers were used to immobilize per-6-amino-β-cyclodextrin on SiO_2, which led to a surface exposing host molecules.[129]

The immobilization of polymers at a surface is a convenient way to tailor the surface properties of inorganic materials. One way to accomplish this is by the immobilization of initiators for the in situ generation of grafted polymers. Rühe and co-workers prepared layers of polystyrene and a per-fluorinated polymer in a controlled manner and with high graft densities by using SAMs carrying azo initiators.[130,131] A particular interesting development in this area has been the use of a "living" free-radical process at the surface to prepare accurately controlled polymer brushes.[132–135] Advantages of this "living" polymerization include the control of molecular weight and polydispersity and the wide variety of monomers amenable to the process. In this way, surface-attached block and random copolymers can be formed for applications such as the precise tuning of surface properties and the preparation of responsive surfaces.[133,135]

Tailoring surface properties using SAMs does not necessarily require polymers. Surfaces with very low surface free energies are generated by self-assembly of fluorinated silanes,[57,101,136,137] while poly(ethylene glycol)-carrying silanes are widely used to prepare SAMs that resist the nonspecific adsorption of biomolecules.[138–140]

3.2. Formation of Multilayers

Whereas a SAM is only a few nanometers thick, many practical devices require the formation of high-quality, close-packed, and highly ordered films with thicknesses of a few hundred nanometers to several micrometers.[83] The growth of highly ordered multilayers is necessary to extend the two-dimensional structure of SAMs to the third dimension. Multilayer formation was studied for the first time by Netzer and Sagiv.[2] They described the conversion of an olefin-terminated SAM into a hydroxy-terminated surface, which could be used to deposit a second layer of olefinic silanes. However, hydroboration of the olefin was not quantitative and led to increasing disorder in the subsequent layers. An improvement of this strategy was reported in which the reduction of methyl esters to alcohols by $LiAlH_4$ was used,[83] which led to the construction of ordered assemblies of up to 25 discrete monolayers. A methodology to produce hydroxy-terminated siloxane-anchored SAMs and multilayers, which takes advantage of the photolysis of a nitrate-functionalized SAM for the formation of surface hydroxy groups without any reagents, was later reported.[141] This photoconversion allowed the photopatterning of films and subsequent construction of multilayers.

An alternative procedure to yield multilayer assemblies involves the immobilization of a boronate-protected trichlorosilane, which can be hydrolyzed conveniently with water/ethanol to a diol, after which the process can be repeated.[142] A different approach, reported by Yam and Kakkar,[143] involved acid-base hydrolysis of aminosilanes with dihydroxy-terminated molecules. The layer-by-layer construction methodology used $Si(NEt_2)_4$ and rigid, rodlike diols, and led to relatively close-packed multilayered structures.

Hydrogen bonds can also be used instead of covalent coupling to stabilize the three-dimensional structure of the multilayer. Maoz et al. oxidized an olefinic SAM to the corresponding carboxylic acid before the next silane layer was assembled on top.[49,144,145] Lateral cross-coupling of the silane

head-groups provided structural robustness and a self-healing capability to the films. Noncovalent multilayers were also reported by Mallouk and co-workers.[146, 147] They used the strong electrostatic and coordinative interaction between phosphonates and Zr^{4+} ions for the formation of multilayers.

Marks and co-workers prepared thin-film nonlinear optical (NLO) materials consisting of self-assembled chromophore-containing multilayer structures.[148–154] They reported the formation of an acentric monolayer by self-assembly of a trimethoxysilane-functionalized azobenzene chromophore from solution. A siloxane capping layer was subsequently formed, which stabilized the structure by cross-linking and provided hydroxy groups to start a new cycle (Figure 4). The advantages of this approach to prepare NLO materials are the high chromophore concentration of the SAM and its robustness as a consequence of the covalent bonds.
Figure 4. NLO materials obtained by self-assembly of chromophoric superlattices.[154] Self-assembly of the chromophore yields a hydrophobic surface. Treatment with octachlorotrisiloxane ($Si_3O_2Cl_8$) results in deprotection and in the formation of a robust polysiloxane capping layer approximately 0.8 nm thick.

3.3. Sensor Layers

One field of increasing interest in which SAMs are employed extensively is (bio)chemical sensing. Immobilization of sensor systems implies the transition from solution to the solid state, which offers a convenient way to couple sensing systems to the macroscopic world through read-out functions. Furthermore, immobilized sensors usually have faster response times, are easier to handle, and may be recycled. Most sensor functionalities in SAMs were developed for gold surfaces, with read-out techniques such as electrochemistry, surface plasmon resonance, and AFM.[25]

Fluorescence spectroscopy has advantages over electrochemical methods, as there is no need for reference electrodes or additional electrolytes.[155] Moreover, molecules labeled with fluorescent probes are easily prepared or commercially available and can even be visualized individually. Fluorescence spectroscopy is extensively used in biological sensing (see Section 3.4), where it is applied in, for example, DNA chips and protein microarrays to gain information at the nucleic acid or protein level. The reason for the limited use of fluorescence spectroscopy on gold lies in the strong quenching effect of the gold substrate on the fluorescence of nearby molecules,[156] thus making oxide surfaces such as SiO_2 the surface of choice for the immobilization of fluorescent sensing molecules.[157–161]

One of the first immobilized sensors was reported by de Silva et al.[162] The sensor consisted of an anthracene fluorophore covalently connected to an APS layer. The fluorophore could behave as a pH probe depending on the protonation state of the amino group. Porphyrins linked to an APS layer were reported by McCallien et al.[163] After attachment to the substrate, zinc was inserted and the interaction of the zinc porphyrins with amino ligands was investigated by UV/Vis spectroscopy. Porphyrins could also be immobilized through reaction of a vinyl or hydroxyethyl group of a porphyrin with a sulfanyl-terminated monolayer, thus providing a simple and direct method for attaching porphyrins on solid substrates.[164] UV/Vis measurements were used to monitor the coordination of carbon monoxide to various metal porphyrins.

Sensing by host–guest interactions on the SiO_2 surface has been reported by several research groups. Fullerenes were attached to silica gel to investigate binding affinities of potential hosts such as calixarenes and cyclodextrins.[165] Cyclodextrins (CDs) constitute a class of receptor molecules that have been studied extensively in solution. CD films were prepared to monitor the interactions with various guest molecules,[129, 166, 167] and in an elegant experiment Flink et al. monitored the interaction of β-CD hosts with monolayers of dansyl adsorbates by polarity-dependent fluorescence.[168] Recently, we reported a procedure that yields densely packed β-CD monolayers, and it was shown that the binding properties of the CDs were retained when they were assembled at a surface.[111] A monolayer bearing preorganized binding sites for metal ions was reported by van der Veen et al. (Scheme 2).[155] They used a calix[4]arene receptor modified with ligating groups and two pyrene fluorophores. The immobilized receptor site showed selectivity for Na^+ over other alkali-metal ions. The complexation of Na^+ ions could be monitored by a decrease in monomer emission and an increase in excimer emission.

Although the fluoroionophore shown in Scheme 2 was found to be a good receptor for Na^+ ions, the use of preorganized recognition sites brings forth certain disadvan-
Scheme 2. Immobilized Na$^+$-selective fluoro-ionophore which shows a change from the monomer emission to excimer emission upon complexation of Na$^+$ ions.[155]

tages: It requires lengthy syntheses and results in disordered monolayers as a result of the bulkiness of the receptor molecule. Therefore, a new approach was developed more recently.[169,170] It relies on the immobilization of ligating functionalities on an amino-terminated SAM, without any preorganization. A small library containing various simple ligating and reporter molecules was made, and the response to different metal ions was measured. The results showed that selectivity for different metal ions depended on the surface functionalization. The same approach was used by Brasola et al. to develop a fluorescence nanosensor for Cu^{2+} ions on silica particles, the only difference being the immobilization of ligating and reporter molecules in one step, instead of linking them to a preformed monolayer.[171]

3.4. Immobilization of Biomolecules

The attachment of biologically active molecules to surfaces is of considerable importance for the development of biological microarrays, such as DNA chips and protein microarrays.[172,173] DNA chips are promising for obtaining information on nucleic acid levels and sequences in a fast, simple, and cheap way, and are developed for use in large-scale genotyping and gene-expression profiling.[172] Protein microarray technology is valuable in the pharmaceutical industry for the acceleration of drug target and diagnostic biomarker discovery.[173] Crucial to the development of these small-molecule microarrays is the ability to selectively attach molecules to the surface under mild conditions and at the same time avoid nonspecific interactions. Moreover, the reactions should be compatible with a wide variety of functional groups that occur in biologically relevant molecules. To meet these requirements, extensive research has

been performed to expand the immobilization techniques on surfaces. Recently, an overview of different reactions that have been studied with monolayers on Au and SiO$_2$, with the emphasis on immobilization of biomolecules, was reported.[174]

The formation of amine-terminated SAMs on glass surfaces allows immobilization of biologically important molecules in both a covalent and a noncovalent way. Cells stick to the SAMs through electrostatic interactions between the positively charged ammonium groups and the negatively charged cell membrane.[175] This simple electrostatic adsorption has also been used to link short oligonucleotides to a positively charged amino-functionalized SAM.[176] This method produced a stable oligonucleotide monolayer with a density that approached a two-dimensional close-packed array.

Several mild methods have been developed to covalently couple biological molecules to the glass surface. Successful reactions include N,N′-dicyclohexylcarbodiimide (DCC) coupling of pepsin,[91] 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) coupling of DNA,[177] the immobilization of p-nitrophenyl chloroformate activated dextrans,[178] reaction of compounds containing acidic protons with diazobenzilidene-functionalized glass slides,[179] and a photoaffinity reaction.[180] Many research groups have employed a two-step approach, where the amine-functionalized SAM was derivatized with a linker molecule after self-assembly to increase the reactivity of the monolayer. Heterobifunctional reagents such as N-succinimidyl-6-maleimidocaproate react with APS monolayers to expose the maleimide functionality, which in turn can be used in a Michael addition with sulfanyl groups.[181–183] A critical feature of this methodology is the resistance to nonspecific adsorption, which was attributed to the hydrophilicity of the maleimide functionality.[183] It has also been

shown that the same heterobifunctional molecule could be attached to a sulfanyl-terminated SAM.[184] In this case it was utilized to link an amine-containing, fluorescently labeled oligodeoxynucleotide probe to the surface for hybridization experiments. A slightly different approach to attach DNA covalently to glass surfaces was reported by O'Donnel et al.[185] They applied a heterobifunctional cross-linking agent to incorporate an iodoacetamido group, which was treated with a reduced oligodeoxynucleotide presenting free sulfanyl groups.

As was mentioned before, resistance to nonspecific adsorption is a critical issue when designing microarrays. Sekal et al. described a method to prepare monolayers that are resistant to nonspecific protein adsorption and present primary amino groups for derivatization.[186] By treating an APS layer with glutaraldehyde and subsequently with 2,2′-(ethylenedioxy)bis(ethylenediamine) they were able to incorporate ligands and protein-sensitive fluorescent reporter groups, and used these monolayers for the detection of protein–ligand interactions.

Efficient surface silylation reactions can be complicated by formation of inhomogeneous layers, poor surface coverage, and instability to frequent regeneration steps.[187] To overcome these problems, Benters et al. developed a method for generating highly homogeneous activated silicon oxide surfaces that can be applied to the efficient coupling of oligonucleotides to produce DNA microarrays.[187] The method involves the initial formation of an APS layer, which is activated by a homobifunctional linker such as 1,4-phenylenediisothiocyanate (DITC), and then allowed to react with a starburst dendrimer containing 64 primary amino groups at the periphery. The attached dendritic molecules are subsequently activated and cross-linked with a homobifunctional spacer to display a surface with high coverage and decreased steric hindrance, and that is resistant against repeated regeneration procedures. Recently, layers obtained by this procedure and APS layers were derivatized with appropriate phosphane groups to immobilize azido-functionalized biomolecules by Staudinger ligation.[188, 189] This coupling strategy affords rapid immobilization and offers the advantage that it is compatible with unprotected functional groups, which are often required for interactions in biological systems.

Epoxy-terminated SAMs can react with molecules bearing amino groups. In this way it was possible to bind cyclopeptides to the glass surface for use as a molecular receptor[190] and to determine binding constants between an immobilized tripeptide and vancomycin using confocal fluorescence detection.[191] Hydrolysis of an epoxide-functionalized SAM yields a diol-functionalized SAM, which was used to develop a biosensor of immobilized nucleic acid aptamers to detect nonlabeled targets such as proteins.[192]

Another relatively simple coupling strategy involves the reaction of aldehyde-modified glass surfaces with amine-containing molecules. The aldehydes react readily with primary amines of proteins or DNA to form a Schiff base linkage.[177, 193] This strategy was applied to prepare libraries of peptidyl coumarins in microarrays. It was demonstrated that the immobilized peptides were accessible for proteolytic cleavage.[194]

Other reported strategies to attach biological molecules to SiO_2 surfaces involve the reactions of sulfanyl-terminated SAMs with disulfide-modified oligonucleotides or heme proteins,[195, 196] iodopropyl monolayers with sulfanyl-containing proteins,[197] alcohols with a silyl chloride surface,[198] and bromoacetamide SAMs with phosphorothioate-functionalized oligonucleotides.[199]

4. Engineering the Silicon Oxide Surface Using Self-Assembled Monolayers

The development of methods to control surface chemistry on the 1–100-nm length scale is a fundamental challenge in nanoscience and nanotechnology because it opens up new possibilities in fields ranging from molecular electronics to biomedicine and catalysis.[200] SAMs offer an ideal platform for engineering surfaces on a molecular level, provided that techniques are developed to pattern or assemble SAMs with high resolution and fidelity.

4.1. Spacing of Chemical Functionalities

The positioning of chemical groups at regular intervals on a surface is of technological importance to localize adsorption and tune surface coverage, for example. The density of probe molecules is a critical issue in the design of DNA and protein chips. A facile method to achieve low surface coverage of functional groups is by preparing multicomponent SAMs so that chemical functionalities are diluted in an "inert" matrix of other molecules, which might be either unfunctionalized or carry a different functionality. Several approaches have been described in the literature, of which the most widely used involves competitive chemisorption, that is, the treatment of a surface with a mixture of adsorbates. Although the composition and properties of mixed monolayers are not at all straightforward, numerous binary monolayers have been prepared, as listed by Fadeev and McCarthy in Ref. [201].

Fan et al. stimulated phase separation in a binary monolayer by using two very different alkylsilane amphiphiles—one with strong cohesive interactions and one able to form hydrogen bonds—to generate a surface with nano-islands of a chemical functionality.[202] The surface composition was analyzed by AFM, which showed pronounced differences in height and friction for the two components. The phase behavior of multicomponent SAMs could be used as an effective "latent image" to generate features on the surface by wet etching.[203] This difference in etch resistence was achieved by the assembly of molecules with different chain length, and it was proposed that regions of more densely packed molecules were more etch resistant than regions of less coherent packing. Mixed SAMs can be conveniently used to control the surface free energy, as was shown in an elegant experiment by Lee et al.[204] They used different ratios of hydroxy and methyl groups to tailor the surface free energy of silicon substrates, and found that in this way they could

6292   www.angewandte.org

Angew. Chem. Int. Ed. **2005**, *44*, 6282–6304

control the growth modes of atomic layer deposition (ALD) of TiO$_2$.

An alternative approach for the preparation of "mixed surfaces" involves reaction of partially silanized surfaces with a second silane. As mentioned earlier, SAMs on SiO$_2$ grow through an island growth mechanism, thus offering the possibility to fill partial monolayers of one component with another. Recent examples have reported small domains of OTS islands filled with bromine-terminated[205] and amino-terminated SAMs.[206] Fadeev and McCarthy have used a very bulky silane for deposition, and found by size-exclusion contact angle hysteresis measurements that nanopores with a cross-section of about 0.5 nm^2 were still present at the surface, and accessible to probes of smaller dimension.[201] In this way uniformly mixed binary monolayers were generated (Figure 5).

ers, monolayers, and multilayers of trichlorosilane-terminated carbosilane dendrons with a phenyl group at the focal point were reported by Cai and co-workers.[207,208] Dendrons bearing carboxy groups at the periphery and a protected amine at the focal point were assembled on an amino-terminated SAM through multiple ionic interactions.[209] AFM and fluorescence measurements indicated the formation of a close-packed layer with spacings between the amino functional groups of 24–34 Å.

SiO$_2$ surfaces with spacially separated functionalities are relatively easily prepared by the methods described above, without the use of expensive machinery. The process is flexible, useful on a large scale, and not restricted to flat surfaces. However, a significant drawback of these approaches is that only homogeneous surfaces can be generated and the functionalities cannot be positioned or patterned accurately, as is required for the bottom-up construction of nanosized functional entities.

4.2. Patterning Self-Assembled Monolayers with Photons and Particles

4.2.1. Photolithography

Photolithography on SAMs relies on the absorption of radiation in the exposed regions of the monolayer which undergo photocleavage to yield surface residues. The use of less expensive equipment, compared to, for example, electron beam lithography (see Section 4.2.2), makes this a popular method to create patterned SAMs, but the feature sizes that can be achieved are diffraction-limited.

Irradiation with light in the deep UV region has been used extensively to remove SAMs in exposed regions. This leaves an activated surface that can be used for numerous post-patterning processes. SAMs of different chemical functionalities were deposited for the immobilization of fluorophores,[210] for cell adhesion,[211] and to control the surface potential.[212,213] The remaining SAMs have been used as a mask for wet chemical etching to fabricate microstructures on Si substrates[214,215] and as a template for Pd adhesion and subsequent electroless deposition of ZnO.[216] The exposed areas could be used as templates for electroless plating of Ni,[210,215] and for the deposition of TiO$_2$ films.[217] Recently, photocatalytic lithography of alkylsilane SAMs was reported using UV light and TiO$_2$ to rapidly and homogeneously remove the SAM by the generation of highly reactive oxygen species.[218]

Instead of completely removing the monolayer, photolithography can also be used to create patterns with different chemical functionalities. Some research groups have reported photodeprotection of protected amino groups, after which the exposed areas could be selectively developed by the adsorption of fluorescent particles.[219,220] A very elegant example is the combination of photolithography with the immobilization of biomolecules for the generation of, for example, DNA chips.[221] Pioneering work in this field was conducted by Fodor and others.[222–225] They used light-directed, spatially addressable parallel synthesis to build arrays for rapid DNA analysis. The pattern of illumination through a mask, using

Figure 5. Schematic representation of a two-step silanization procedure.[201]

A different strategy to achieve the positioning of chemical functionalities on a surface comprises the self-assembly of large molecules carrying only one type of functional group. Focally functionalized dendrons appear to be particularly suitable molecules for this method (Figure 6). Sub-monolay-

Figure 6. Schematic illustration of the concept of using large molecules to control the spacing between functional groups at a surface.

light to remove photolabile protecting groups from selected areas, determines which regions of the surface are activated for coupling. The first set of building blocks, each bearing a photolabile group, is exposed to the surface but reacts only with the patterned areas. The substrate is subsequently illuminated through another mask for deprotection and coupling with a second building block. The steps of masking/irradiation and coupling are repeated to introduce various oligomers. The patterns of the masks and the sequence of reagents define the ultimate sequences synthesized, and their locations on the surface are known.

Other chemical transformations have been shown by the research groups of Dressick and Sugimura. Dressick and co-workers were able to transform 4-(chloromethyl)phenyl chromophores into phenylaldehyde groups, which in turn could be reduced to amines.[226] Sigimura et al. showed that OTS SAMs decomposed gradually upon exposure to UV light in a vacuum to generate carboxilic acid groups that were successfully treated with functionalized and fluorinated silanes.[214,215] Surface wettability could also be controlled using photolithographic methods. In a series of publications Beebe and co-workers reported cunning experiments to control liquid flow inside microchannels.[227–229] Surface free energies were patterned by use of SAMs in combination with photolithography (Scheme 3). They could confine the flow of aqueous liquids to the hydrophilic pathways, provided that the pressure was maintained below a critical value.

Photolithography has recently been applied in a constructive procedure.[230] Direct writing with a laser allowed the formation of sub-200 nm oxide patterns on H-terminated Si. Exposing these substrates to a solution containing OTS molecules resulted in selective growth on the oxide patterns.

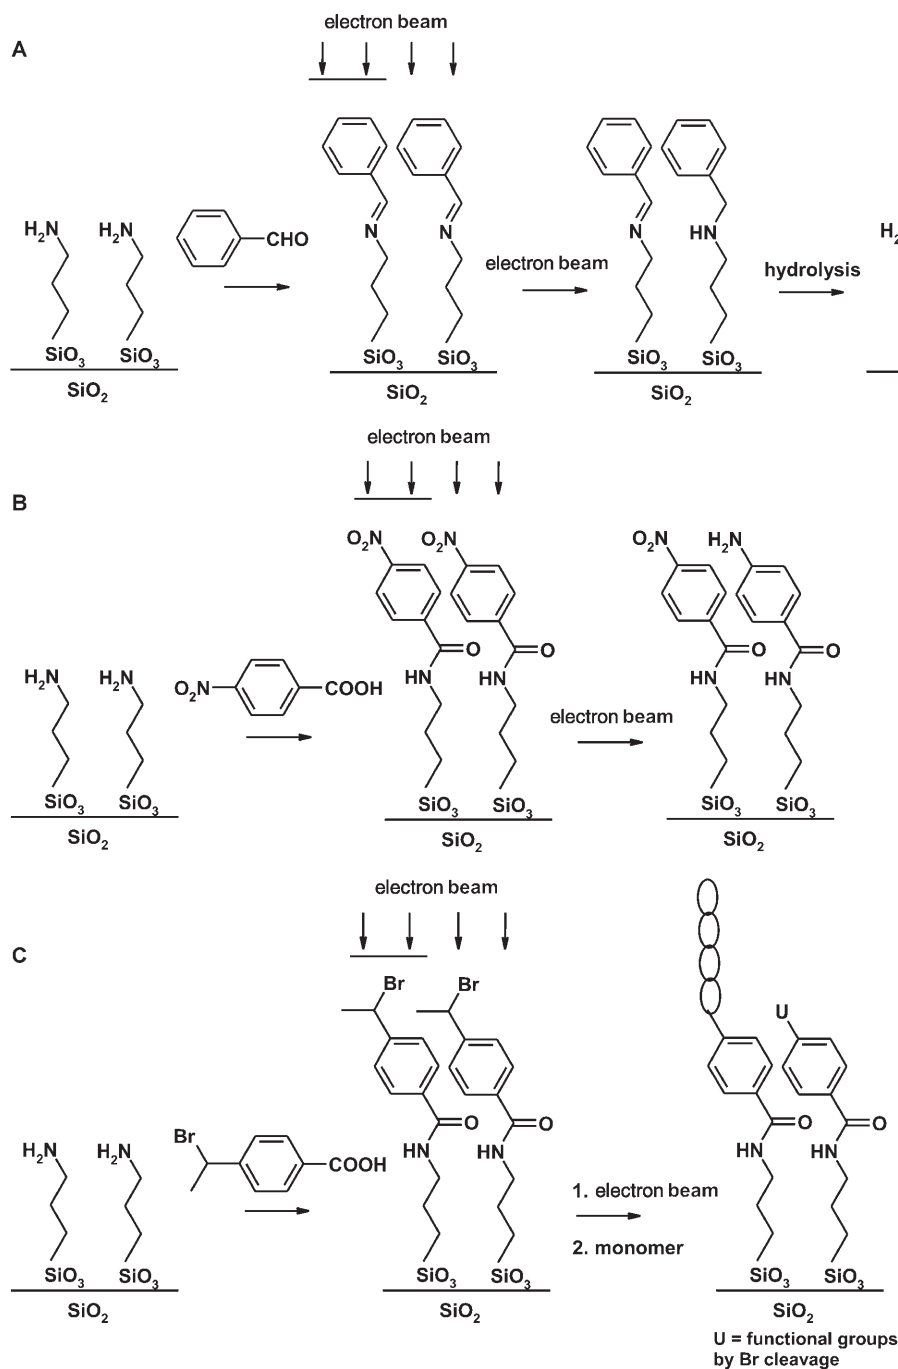
4.2.2. Electron Beam Lithography

SAMs are candidates for very high resolution resists in electron beam lithography. Since the feature size generated with electron beam lithography depends on the thickness of the resist, the monomolecular thickness of SAMs could reduce back scattering of electrons and provide ultrahigh-resolution electron beam patterning. It has been shown that patterns of several tens of nanometers could be created in OTS and perfluorinated SAMs on SiO_2, and that the patterns could be transferred into the substrate by wet-etching techniques.[231–233] Patterns smaller than 10 nm could also be attained by using scanning electron microscopy (SEM) with a small beam diameter.[234] A different development of the created patterns was reported by Marrian et al.[235] Low voltage electron beam lithography was used to pattern films and the patterns were applied as templates for the electroless
Scheme 3. UV photolithography to fabricate hydrophilic patterns inside microchannels.[227]

plating of thin Ni films. Linewidths down to about 20 nm were observed after plating.

There have been several reports that combine electron beam lithography with functionalized SAMs. Craighead and co-workers patterned amino-terminated SAMs and developed the patterns by exposing them to palladium colloids and coated polystyrene fluorescent spheres.[236] The colloids and spheres adhered only to unexposed areas of the monolayers. Other studies employed the deposition of aminosilanes through a poly(methylmethacrylate) (PMMA) mask or an unfunctionalized SAM that was patterned by electron beam lithography.[237–239] In this way colloidal particles and carbon

nanotubes were deposited selectively on the amine-modified parts of the substrate.

Recently, electron beam irradiation was used to induce chemical transformations in monolayers. Park and co-workers studied several procedures to prepare patterned amino- and bromo-terminated SAMs, and verified the reactivity by attaching biotin/streptavidin groups,[240] or amplified the patterns vertically by radical polymerization.[241] The transformations are shown in Scheme 4. The induced transformations have been employed to direct adsorption of gold nanoparticles.[242] In addition, sub-50 nm patterns were prepared in SAMs with embedded disulfide bonds.[243] Phenyl-3-


Scheme 4. Chemical transformations of SAMs with a low-energy electron beam.[240,241]

(trimethoxysilylpropyl)disulfide monolayers were patterned with electron beam lithography, which generated 3–4-Å deep and 30-nm wide trenches. XPS indicated the cleavage of the disulfide bonds to sulfhydryl groups, and the resulting chemical patterns could be developed by reaction with *N*-(1-pyrene)maleimide. Even smaller chemical patterns were obtained by a combination of electron beam lithography and gas-phase silanization.[244] It was shown that monolayers with varying chemical functionalities could be formed through nanoholes in a PMMA mask. After removing the mask, a monolayer of different functionality was deposited, and generated well-defined nano-islands as small as 20 nm of one chemical functionality in a matrix of another.

4.2.3. Ion-beam and X-ray Lithography

Ion-beam and X-ray lithography are methods that have been less frequently used to pattern SAMs on SiO$_2$. Patterning with low-energy ion beams usually employs shadow masks because of the difficulty of focusing such sources. However, high-energy focused ion beams (FIBs) should result in nanometer-scale patterns, as it is possible to attain beam diameters as small as 8 nm.[245] FIBs have already been used to write 10-nm wide features in thin PMMA films.[246] A vinyl-terminated monolayer was selectively deposited in ion-beam-etched regions of a methyl-terminated SAM with a resolution of 1–3 μm.[247] Ada et al. have studied in detail the interaction of low-energy ions with organosilane SAMs, and were able to create 300-nm wide gaps by employing FIB.[248] Smaller feature sizes were reported by exposing monolayers to low doses of slow, highly charged ions, such as Xe^{41+} and Th^{73+}.[249] AFM images showed craters from single ion impacts with diameters of 50–63 nm. Equally small features have also been reported by Whitesides and co-workers by utilizing a beam of neutral Cs atoms.[250]

Irradiation with soft X-rays through a mask can be a convenient method for chemical patterning of monolayers. Reported transformations include the loss of halogens in halogenmethylphenylsilyl layers,[251,252] and the cleavage of nitro groups in nitro-substituted aromatic SAMs.[253] La et al. used masks with nanometer-sized features to develop sub-100 nm patterns, as evidenced by AFM.[254] The patterns could be derivatized by attachment of fluorescently labeled oligonucleotides. Irradiation of OTS layers resulted in the formation of oxygen-containing groups such as OH and C(O)H.[255] Pattern transfer of features with dimensions as small as 150 nm into the underlying substrate were obtained by reactive ion etching using thin films of Ni selectively deposited onto the exposed areas of the OTS SAM.

Recently, it was shown that hybrid patterning strategies allow for the fabrication of defect-free nanopatterns of block copolymers.[256] A photoresist on top of a phenylethyl monolayer was patterned with 45–55-nm-sized features by interferometric lithography using extreme UV light, and the pattern was transferred into the underlying SAM by chemical modification using soft X-rays. After removing the photoresist, poly(styrene-*block*-methylmethacrylate) (PS-*b*-PMMA) was spin-coated onto the patterned SAM and annealed. It was found that the PMMA block preferentially wetted the modified regions of the surface, and thus domain structures were formed analogous to the SAM patterns, as observed by SEM (Figure 7).
Figure 7. SEM image of 48-nm wide PS and PMMA domains formed by selective absorption on a SAM patterned by a combination of UV and X-ray lithography.[256]

4.3. Soft Lithography

Soft lithography[257] is the collective name for a set of lithographic methods including replica molding, microcontact printing (μCP), and micromolding using a patterned elastomer as a mold, stamp, or mask to transfer a pattern.[258] Soft lithography offers advantages over other lithographic methods for the patterning of nonplanar substrates, unusual materials, or large areas.[258] Of these techniques, μCP has been employed most frequently for the facile (sub)micron patterning of surfaces. μCP relies on the inking of an elastomeric (usually PDMS) stamp with suitable molecules. When the stamp is brought into contact with a substrate, the molecules are transferred from the stamp to the substrate in the regions of contact. μCP was initially developed for the patterning of gold surfaces with alkanethiols, and even today the bulk of the literature comprises patterning of this surface with these adorbates.

Reports regarding μCP on SiO$_2$ surfaces have been rather limited. This situation might be explained by the inherent sensitivity of trialkoxy- and especially trichlorosilanes, and the lower edge resolution of silanes on SiO$_2$ relative to thiols on gold.[259] Although Whitesides and co-workers reported that printed OTS SAMs were only partly etch resistant, later studies showed that printed patterns could be transferred into the underlying silicon substrate,[260] even with feature sizes as small as 80 nm.[261] Detailed studies by Nuzzo and co-workers indicated that close-packed OTS monolayers were formed after only 30 s of printing while it took minutes to form a densely packed monolayer by deposition from solution.[262] They also found that stable SAMs were formed, but that patterning at dimensions less than a few micrometers resulted in the spreading of OTS in regions that had not been in

6296   www.angewandte.org

Angew. Chem. Int. Ed. **2005**, *44*, 6282–6304

contact with the stamp. µCP with docosyltrichlorosilane resulted in more accurate transfer to the substrate, and these films had an improved etch-resistance.[263]

Amplification of a printed pattern can also be achieved in a different manner. Harada et al. amplified a printed vinyl-terminated pattern by selectively attaching a Ru complex, which reacted with norborene derivatives to give thin polymer films.[264] The contrast in wettability between clean SiO$_2$ and a printed OTS pattern enabled the confinement and alignment of molecules.[265] After printing, the remaining hydrophilic parts of the substrate were covered with a thin polyelectrolyte layer, onto which biological macromolecules and liquid crystals could be confined. This process afforded a straightforward way to create microchannels on a surface.

The majority of the work concerning µCP of SAMs on SiO$_2$ involves deposition of metals. Printed monolayers can serve as a resist for chemical vapor deposition of copper,[266] or deposition of SnCl$_2$ from solution, which serves as a nucleation point for electroless plating of Ag.[267]

Instead of printing a monolayer, it is also possible to print onto a monolayer assembled from solution. Hidber et al. used an amino-terminated SAM as an adhesion promoter to print (sub)micron patterns of Pd colloids.[268] The immobilized colloids served as a catalyst for the electroless deposition of copper, and yielded (sub)micrometer-scale copper lines on an insulating surface. Recently, Reinhoudt and co-workers introduced supramolecular µCP, which is shown schematically
Figure 8. Schematic representation of supramolecular microcontact printing (µCP). Cyclodextrin host monolayers are patterned by µCP of suitable guest molecules.[269, 270]

in Figure 8.[269–271] In this method, guest molecules that bind through multiple supramolecular interactions were printed onto a densely packed monolayer of cyclodextrin receptor molecules on SiO$_2$ (or gold). The patterns were characterized by AFM, XPS, and confocal microscopy. Control experiments showed that the ink molecules bind to the receptor surface

through specific host–guest interactions. One advantage of this method is that the stability of the assemblies can be tuned by the number of interactions between the guest molecules and host monolayer.

Sulfanyl-terminated MPTMS SAMs can be employed as adhesion promoters for noble metals.[272] In nanotransfer lithography a gold-coated PDMS stamp is used to transfer thin but stable gold layers onto the monolayer (Scheme 5). In a series of publications Delamarche et al. described an elegant process to produce NiB stuctures and metal nano-wires on glass substrates.[273–277] They combined the adhesive properties of an amino-terminated SAM to bind Pd/Sn colloids, which were used to initiate electroless deposition of NiB. Then, copper was electroplated and patterned by µCP using a protective layer of thiol molecules. The pattern was subsequently etched into the copper and NiB by two wet etching techniques. This process was developed to provide a new and potentially cost-effective way for the fabrication of gate layers in thin-film transistor (TFT) LCDs, and could even be applied on a macro (38 cm) scale.

Nanoimprint lithography (NIL)[278] was recently advocated as a powerful alternative to µCP of organosilanes.[279] A PMMA polymer template obtained by NIL directs the assembly of a SAM from the gas phase to the uncovered area of the substrate while preventing the formation of a SAM in the covered area. After removal of the polymer, SAM patterns are obtained that may be filled with other silanes. NIL-patterned SAMs are useful in nanofabrication, for example, to direct adsorption of particles or deposition of metal electrodes on SAMs (Figure 9).

4.4. Scanning Probe Lithography

Scanning probe microscopy can visualize surface topography and surface chemistry at the submolecular level. In addition, probe tips can be used to manipulate atoms and molecules on surfaces, and in this mode the technique is often referred to as scanning probe lithography.[280] Sugimura et al. were among the first to combine a scanning probe tip with self-assembly on SiO$_2$ surfaces to create nanoscale patterns. They have used a scanning tunneling microscope tip for local anodization of a Si-H surface to SiO$_2$ in the presence of an organosilane vapor.[281] This resulted in the formation of monolayer features of 20 nm that showed a resistance to chemical etching. Other studies from the same authors reported patterning of a homogeneous monolayer by apply-

Figure 9. Nanofabrication using SAMs patterned by nanoimprint lithography. Applications: a) Polymer removal, evaporation of a second silane, and selective attachment of functionalized particles. b) Selective attachment of functionalized particles, and polymer removal. c) Metal evaporation and metal lift-off.[279]

ing a bias voltage to the probe tip, effectively removing the monolayer from the probe-scanned regions. Next, the exposed regions were filled with SAMs of different chemical composition to regulate the surface potential or selectively assemble proteins at a spatial resolution on the nanometer scale.[282,283] A different method for nanometer-scale patterning was obtained by field-induced oxidation (FIO) using a conductive cantilever.[284] Surface hydroxy groups, necessary for monolayer formation, were removed and monolayer formation was suppressed when FIO was employed locally on an oxide surface in a dry nitrogen atmosphere. In this way, a line structure of an OTS SAM as narrow as 22 nm could be fabricated. In contrast, OTS SAMs formed on the entire surface when FIO was performed under humid conditions.

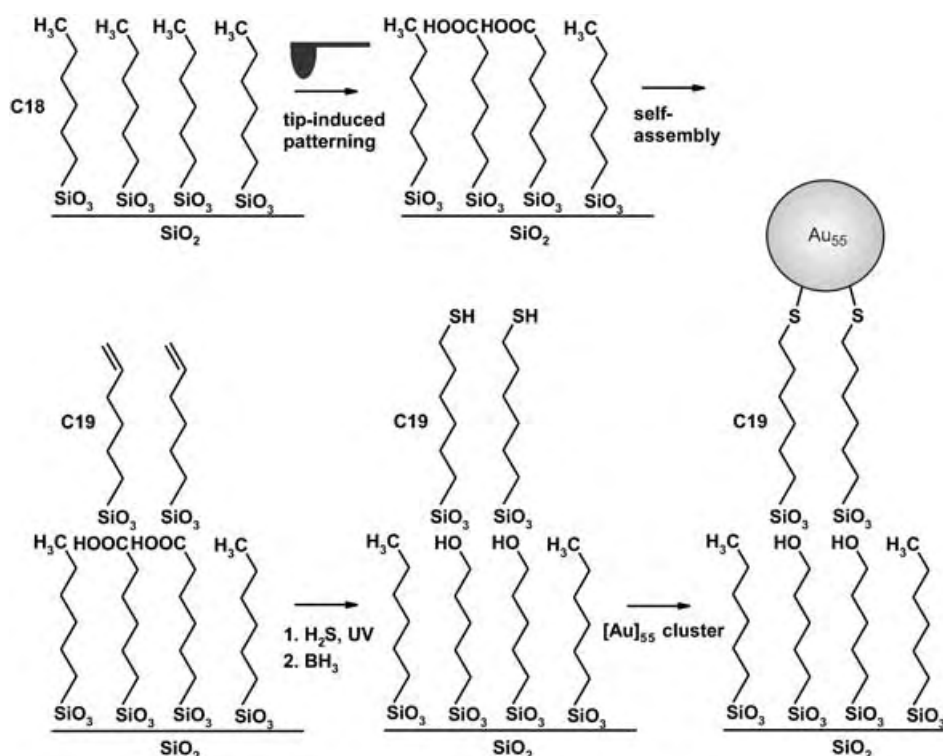
4.4.1. Constructive-Nanolithography

Constructive nanolithography was introduced by Sagiv and co-workers.[285] It involves nondestructive surface patterning by means of an electrical

bias to a conducting AFM tip operated under ambient conditions, followed by template-controlled self-assembly. The versatility of this approach was demonstrated in several systems where vinyl-terminated and OTS SAMs were locally electrooxidized to prepare patterned bilayers,[286] self-assembled metal islands,[285,287] metal nanoparticles,[288–290] and nanowires.[289] Features with sub-50 nm dimensions could be fabricated by using this method. A schematic representation of the organosilane template pattern and the self-assembly of $[Au_{55}]$ clusters on the template is displayed in Scheme 6. This methodology could be used for the nanometer to millimeter range by employing electrooxidation with a rigid metallic stamp.[291] Recently, other research groups have applied local probe oxidation of SAMs for functionalization with cationic gold nanoparticles, quaternary ammonium salts, and polymers.[292,293]

A few years before Sagiv and co-workers introduced constructive nanolithography, a similar approach was presented by Schultz and co-workers, who made use of a catalytic probe.[294] In this elegant experiment an alkylazide monolayer was reduced to its corresponding amine by a catalytic Pt coated AFM tip. The amino groups were then covalently modified with fluorescently labeled beads and imaged under a confocal microscope.

4.4.2. Dip-Pen Nanolithography

Dip-pen nanolithography (DPN)[200,295] uses an inked AFM tip to deposit molecules on a substrate. This technique, which is believed to rely on the transport of molecules from


Scheme 6. Schematic representation of constructive nanolithography, in which tip-induced electrooxidation and subsequent self-assembly on the written template are employed. In this case $[Au_{55}]$ clusters were assembled.[288]

6298   www.angewandte.org

Angew. Chem. Int. Ed. **2005**, *44*, 6282–6304

the tip to a surface through a water meniscus, has been used to generate structures with line widths as small as about 10 nm (Figure 10a). Reported examples have dealt almost exclusively with the writing of thiol inks on gold substrates, or the use of metal salts for the electrostatical assembly on appropriately biased silicon substrates.
Figure 10. a) Schematic representation of dip-pen lithography (DPN). b) Fluorescence image of DPN-generated labeled antirabbit IgG structure on SiO$_2$.[301]

Thus far, silane-based inks have rarely been used, mainly because of the incompatibility of chloro- and alkoxysilane groups with the water meniscus that mediates ink transport. Ivanisevic and Mirkin used hexamethyldisilazane to write organic patterns on SiO$_2$ with sub-100 nm dimensions.[296] Two recent articles, however, demonstrated that it is possible to write with trialkoxysilane-based inks. Pena et al. wrote APS and MPTMS lines of nanometer dimensions, but were not able to further derivatize the formed structures.[297] They explained this lack of reactivity by the formation of multilayers through hydrogen bonding. These results were contradicted in a study by Jung et al.,[298] who claimed that DPN with reactive silanes is possible if proper measures against polymerization are taken. Writing at low humidity resulted in the formation of 110-nm-wide MPTMS lines, which were successfully treated with biotin and fluorescently labeled streptavidin.

An alternative method to write functionalized structures on the SiO$_2$ surface constitutes writing on functional monolayers. Reinhoudt and co-workers recently demonstrated supramolecular DPN where an AFM tip is inked with suitable guest molecules and the substrate is a β-cyclodextrin host monolayer.[270] Sub-500 nm patterns, based on host–guest interactions, were written and imaged by confocal microscopy

and AFM. Covalently anchored nanoscale patterns of oligonucleotides and maleimide-linked biotin were written onto MPTMS SAMs.[299,300] It was found that nanoscale patterning of maleimide-linked biotin was facilitated by the addition of small amounts of non-ionic surfactant to the biotin ink. An increase in the wettability of the substrate is thought to cause this phenomenon.

The direct writing of proteins on modified SiO$_2$ surfaces has been reported.[301] A negatively charged surface was used to bind proteins electrostatically (Figure 10b), and proteins were covalently bound by writing on a preformed aldehyde-terminated monolayer. Some modifications to the writing process had to be made. First, an AFM tip coated with poly(ethylene glycol) (PEG) was used to minimize protein adsorption and to reduce the activation energy required for protein transport from the tip to the surface. In addition, it protects the protein from denaturation on the tip surface. Second, it was found that high humidity is a prerequisite for writing with high-molecular-weight molecules. Patterning was performed at relative humidities between 60 and 90%, whereas low humidities were sufficient for writing with low-molecular-weight trialkoxysilanes.

5. Summary and Outlook

Since the first report on SAMs on SiO$_2$ in 1980, many studies have investigated the mechanism of monolayer formation, which has led to a better understanding of the principles underlying this self-assembly process. It has become clear that factors such as solvent, temperature, water content, deposition time, and age of the adsorbate solution play a crucial role in the self-assembly process. Small variation of one or more of these factors can result in very different assembly properties, and several studies appear to have conflicting outcomes. An illustrative example is the temperature at which the self-assembly takes place: Lower temperatures favor island growth, while at higher temperature homogeneous growth has been observed. In addition, several studies have shown that the assembly process is not so much covalent in nature as had been assumed for a long time. Adsorbate molecules that covalently attach to the surface are scarce, and in-plane polymerization of the adsorbates might lead to decreased order instead of a close-packed monolayer. These results indicate that the monolayers have Langmuir-like features, as was elegantly demonstrated by reversible temperature-dependent island-growth formation of submonolayers.[67]

Chemical derivatization of SAMs on SiO$_2$ is essential for many potential applications. Two factors determine the versatility of functional SAMs on SiO$_2$: the range of functionalities that are tolerated in the self-assembly of stable and ordered SAMs, and the scope of chemical post-modifications that can be achieved. Not all functional groups can be conveniently introduced in the self-assembly process because of the inherent reactivity of the trichloro- or trialkoxysilanes that are used for chemisorption. In addition, functional groups might interact with the polar surface, thus resulting in the formation of disordered monolayers. For these

reasons chemical postmodifications have been studied in depth and a wide range of surface chemistry is nowadays available for further derivatization of the SAMs. Selective attachment of compounds to the surface under mild conditions, while avoiding nonspecific interactions, is crucial particularly for the development of bioanalytical surfaces. These reactions should be compatible with a wide variety of functional groups that occur in biologically relevant molecules. Bifunctional coupling agents are often used to meet these requirements.

Positional control of surface chemistry on the nanoscale allows the development of arrays containing a high density of chemical information. The chemical information can then be translated into high-density functional surfaces, such as proteins or DNA chips, or be exploited as a platform for building nanosized functional materials (for example, by self-assembly). The ability to pattern surfaces with chemical information is therefore of prime importance. Electron beam lithography, and especially photolithography, have been the principal techniques for the patterning of surfaces for many years, but soft and probe lithographic techniques have recently witnessed a tremendous development. The main advantages of these methods include the use of inexpensive equipment, the high (sub-100 nm) resolution, and the possibility to prepare positive patterns under mild conditions.

The logical extension of surface patterning is to express and amplify a 2D pattern into a 3D structure. This is a requirement for the bottom-up fabrication of nanoscale devices. Taking nature as a source of inspiration, it is expected that self-assembly techniques will play a major role in nanofabrication. Striking examples of this trend have already been published by Sagiv and co-workers, who used self-assembly techniques to translate a chemical pattern into nanostructures of colloidal gold,[288] and by Mirkin and co-workers, who employed an AFM tip to write protein structures on a SAM.[301] It is expected that this trend from 2D to 3D will be continued in the next decade, while the focus of research in this area will shift more and more toward the nanofabrication of devices.

Communications
1,2,3-Tridehydrobenzene, a novel triradical derived from benzene, was isolated and spectroscopically characterized in cryogenic neon matrices. The IR spectra are in accordance with a $^2A_1$ ground state, whereas the $^2B_2$ excited state is 1–2 kcal mol^{-1} higher in energy and not observed under these conditions. For more information, see the Communication by W. Sander and co-workers on the following pages.

1,2,3-Tridehydrobenzene**

Sugumar Venkataramani, Michael Winkler, and Wolfram Sander

In memory of Orville Chapman

Didehydrobenzenes (benzynes) **1** are well-established reactive intermediates in organic synthesis that have been the target of a large number of mechanistic studies.[1–3] The singlet–triplet splittings in the three isomers **1a–c** were
determined by negative-ion photoelectron spectroscopy to be 37.5 ± 0.3, 21.0 ± 0.3, and 3.8 ± 0.5 kcal mol^{-1}, respectively.[4] These values indicate that the stabilizing interactions of the radical centers in the singlet ground states of **1** decrease in the order *ortho > meta > para*. This bonding interaction results in a shortening of the 1,2-bond (the formal triple bond) in **1a** and a trapezoid deformation with a comparatively short C1–C3 distance (205 ± 5 pm) in **1b**.[5–8]

The addition of a third radical center to form tridehydrobenzenes **2** results in more-complicated electronic structures with several close-lying low-spin (doublet) and high-spin (quartet) states. In a recent computational study, Krylov and co-workers found that all three isomers **2a–c** prefer low-spin
doublet ground states with partial bonds between the radical centers.[9] Again, the adiabatic energy difference between high-spin and low-spin states (i.e. the doublet–quartet splitting) can be taken as a measure of the interaction between the three unpaired electrons in the low-spin states. According to these calculations, **2a** has a $^2B_2$ ground state, and the doublet–

quartet splitting is as high as 2.1–2.2 eV, the largest in the series of the tridehydrobenzenes.[9]

Thermodynamic data for 1,3,5-tridehydrobenzene **2c** were determined by Wenthold and co-workers by means of collision-induced dissociation in a flowing afterglow apparatus.[10] According to these measurements, **2c** is best described as a phenyl radical that interacts only weakly with a *meta*-didehydrobenzene unit on the opposite side of the ring. None of the three isomers had so far been isolated or spectroscopically characterized. Herein we describe the matrix isolation and IR spectroscopic characterization of 1,2,3-tridehydrobenzene (**2a**). We selected 3-iodophthalic anhydride (**3**) and 1,2,3-triiodobenzene (**4**) as photochemical precursors for **2a** [Eq. (1)].[11,12]
Phthalic anhydrides have frequently been used to generate **1a** and its derivatives in inert gas matrices.[13–15] Iodoarenes, on the other hand, undergo photochemical or thermal cleavage of the C–I bond and are thus precursors for aryl radicals and diradicals.[15–17] A general problem in the matrix photolysis of iodoarenes is the rapid thermal recombination of the aryl radicals with the iodine atoms which thus lowers the yield of the radicals. In several instances the yields of radicals increased when the photolysis was carried out in neon matrices at 3 K instead of in the more-common argon matrices at 10 K. As this matrix effect is as yet not well understood or predictable, we investigated the photolysis of **3** and **4** in argon, nitrogen, and neon matrices.

Photolysis of **3**, matrix-isolated in argon at 10 K, with the 308-nm light of a XeCl excimer laser produced CO_2, CO, and 3-iodo-1,2-didehydrobenzene **5** as the major product [Eq. (2)]. The latter exhibits strong IR absorptions at $\tilde{\nu} = 1387$, 1076, 848, 754, and 473 cm^{-1}, in good agreement with the values calculated at the B3LYP/6-311G(d,p) level of theory (Table 1). A further product is 3-dehydrophthalic anhydride (**6**), which again was identified by comparison of its IR spectrum with DFT calculations. In nitrogen the yield of radical **6** is lower, and benzyne **5** is formed almost exclusively (besides CO_2 and CO).

Continuous irradiation at $\lambda = 308$ nm in argon or nitrogen at 10 K did not lead to **2a** or other C_6H_3 isomers. Irradiation at shorter wavelength ($\lambda = 248$ nm) resulted in the formation of several ring-opened alkyne products with characteristic C≡C-H stretching vibrations at $\tilde{\nu} \approx 3300$ cm^{-1}. Hexatriyne (**7**) was tentatively identified as one of these products.

Irradiation of **3** in neon at 3 K with $\lambda = 308$ nm produced the same major products **5** and **6** as in argon. However, the yield of radical **6** was now higher than in argon. Irradiation of this matrix, which contained **5** and **6**, at shorter wavelength (248-nm KrF or 193-nm ArF excimer lasers) resulted in a decrease in the intensity of all the IR bands assigned to these species and in the appearance of several new absorptions.[18] Three of these bands ($\tilde{\nu} = 1698$, 753, and 524 cm^{-1}; Table 2)

IR signals. However, the principal products are now terminal alkynes formed by opening of the benzene ring. These results clearly indicate that a new, labile compound with properties expected for triradical **2a** was generated and isolated in a neon matrix at 3 K.

To assign the three IR signals conclusively to **2a**, extensive quantum-chemical calculations at various levels of theory were performed (Table 3).[19] Two low-lying doublet states have to be considered that arise from single occupation of the

disappeared upon warming the neon matrix from 3 K to 8 K (annealing to allow diffusion of small trapped species) or upon broad-band UV irradiation at $\lambda > 350$ nm (Figure 1). Simultaneously, iodobenzyne (**5**) was formed as the principal product. Furthermore, radical **6** disappeared and some starting material **3** was reformed, thus confirming that radical recombination with iodine atoms takes place under these conditions. Prolonged irradiation at $\tilde{\nu} = 193$ nm also led to the disappearance of the newly formed

[a] A negative value indicates that the $^2B_2$ level lies below $^2A_1$. Electronic contributions $[E_e(^2A_1) - E_e(^2B_2)]$ are given in parenthesis. [b] UBLYP/cc-pVTZ geometries and ZPVE corrections. [c] UB3LYP/cc-pVTZ geometries and ZPVE corrections.

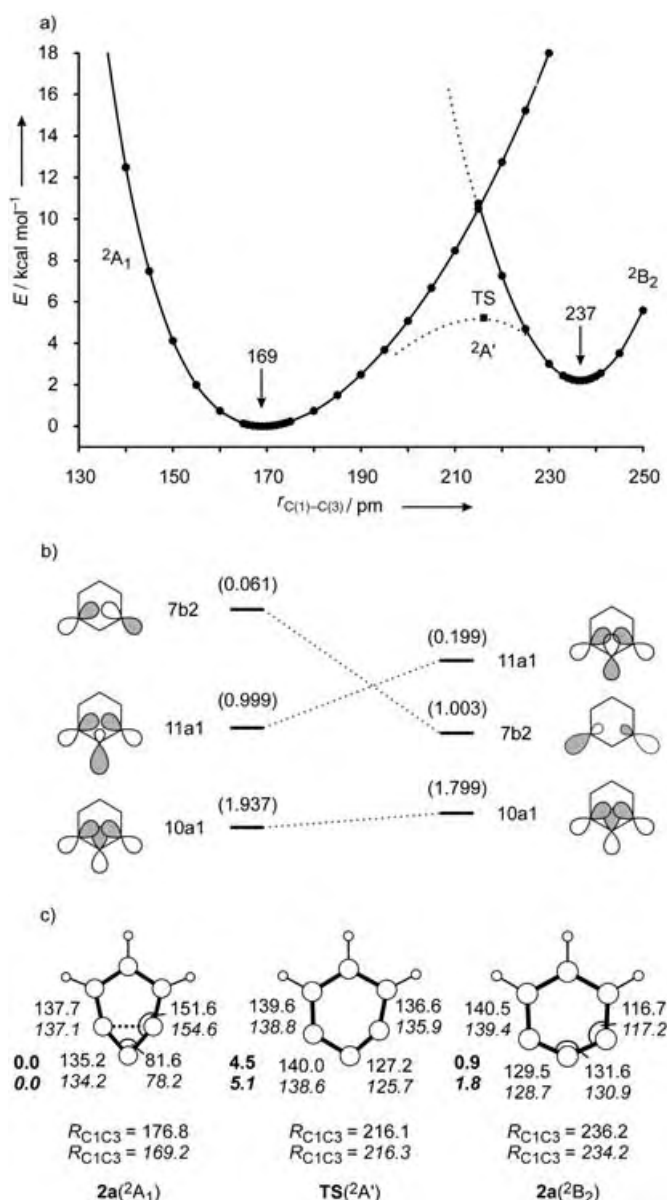
distance of 169 pm, whereas the $^2B_2$ state exhibits a C1–C3 distance of 237 pm, as expected for a benzene derivative. As noted previously,[9] both states exhibit only modest multi-configurational character.[20] Accordingly, the relative energies of both isomers calculated at the DFT level agree favorably with CCSD(T), CAS(9,9)RS2, and CAS(9,9)RS3 calculations. All correlated ab initio calculations as well as DFT indicate a small preference for the $^2A_1$ state, whereas the $^2B_2$ state lies in a shallow minimum slightly higher in energy. Interconversion of both isomers requires a distortion to C_s


Figure 2. a) Energy as a function of the distance of radical centers C1 and C3 calculated at the CCSD(T)/cc-pVTZ//UBLYP/cc-pVTZ level of theory. b) Qualitative orbital energy diagram of the leading configurations of **2a** (CASSCF(9,9)/cc-pVTZ//UBLYP/cc-pVTZ) in the $^2A_1$ ground and $^2B_2$ excited state. Occupation numbers of natural orbitals are given in parenthesis. c) Selected structural parameters (bond lengths in pm, bond angles in degrees) of **2a**($^2A_1$), **2a**($^2B_2$), and the transition state TS ($^2A'$) connecting both isomers (normal print: UBLYP/cc-pVTZ; italics: UB3LYP/cc-pVTZ; bold: relative energies E_0 in kcal mol^{-1}).

Communications

symmetry. The barrier for this process amounts to only 4–5 kcal mol^{-1} (relative to the $^2A_1$ ground state).

A comparison of the three IR signals tentatively assigned to **2a** with the values calculated for the $^2B_2$ and $^2A_1$ isomers at different levels of theory indicates that indeed the more stable $^2A_1$ state of **2a** is formed under the conditions of matrix isolation (Table 2).[21] Vibrational mode 3 at $\tilde{\nu} = 524$ cm^{-1} is in better agreement with $\tilde{\nu} = 522$ cm^{-1} calculated for $^2A_1$-**2a** than $\tilde{\nu} = 441$ cm^{-1} for $^2B_2$-**2a**. Mode 18 at $\tilde{\nu} = 1698$ cm^{-1} is predicted to have no intensity for $^2B_2$-**2a**, but significant intensity (40% relative to the most intense signal) for $^2A_1$-**2a**. Displacement vectors for the three experimentally accessible normal modes of **2a** are shown schematically in Figure 3. Mode 3 corresponds to the intense absorption at around 550 cm^{-1} characteristic of *meta*-didehydrobenzenes which was measured for **1b** (exp.: $\tilde{\nu} = 547$ cm^{-1}; BLYP/cc-pVTZ: $\tilde{\nu} = 535$ cm^{-1}),[7] for various substituted derivatives, and for 3,5-didehydropyridine.[15–17,22]

$\tilde{\nu}3(b2) = 522$ cm^{-1} $\tilde{\nu}6(b1) = 742$ cm^{-1} $\tilde{\nu}18(a1) = 1712$ cm^{-1}
Figure 3. Displacement vectors corresponding to the three experimentally accessible normal modes of $^2A_1$-**2a** (UBLYP/cc-pVTZ).

The photolysis of matrix-isolated **4** as an alternative precursor resulted in only very low yields of products. Flash vacuum pyrolysis (FVP) of **4** at 690°C with subsequent trapping of the thermolysis products in argon at 10 K gave **5** and several ring-fragmentation products such as acetylene and diacetylene. 1,2,3-Tridehydrobenzene was not detected under these conditions.

In summary, our experiments and calculations indicate that 1,2,3-tridehydrobenzene (**2a**) has been isolated and spectroscopically characterized in cryogenic neon matrices at 3 K. The IR spectra are in accordance with a $^2A_1$ ground state, whereas the $^2B_2$ excited state is 1–2 kcal mol^{-1} higher in energy and not observed under these conditions.

[18] One or more by-products with absorptions at $\tilde{\nu} = 2157$, 1721, 1399, and 777 cm^{-1} are only formed upon irradiation at $\lambda = 308$ or 248 nm in neon matrices, but are not observed in experiments with irradiation at $\lambda = 193$ nm. The bands for **2a**, **5**, and **6** can clearly be distinguished from each other and from these by-products by their different increase/decrease rates upon irradiation at different wavelengths in different matrices or upon annealing.

[19] DFT calculations were carried out with Gaussian 98: a) Gaussian 98 (Revision A.7), M. J. Frisch, G. W. Trucks, H. B. Schlegel, G. E. Scuseria, M. A. Robb, J. R. Cheeseman, V. G. Zakrzewski, J. Werner, *Mol. Phys.* **1996**, *89*, 645; the (9,9) active space for CASSCF calculations of **2a** covers the six valence π orbitals of the arene and the three σ orbitals depicted in Figure 2b. The core orbitals were kept frozen in post-(CAS)SCF calculations; Dunning's correlation-consistent basis sets were

used for all computations on **2**: f) D. E. Woon, T. H. Dunning, *J. Chem. Phys.* **1993**, *98*, 1358; g) R. A. Kendall, T. H. Dunning, R. J. Harrison, *J. Chem. Phys.* **1992**, *96*, 6796; h) T. H. Dunning, *J. Chem. Phys.* **1989**, *90*, 1007.

[20] The CI coefficients of the $|..(10a_1)^2(11a_1)^1\rangle$ and $|..(10a_1)^2(7b_2)^1\rangle$ configurations at the CASSCF(9,9)/cc-pVTZ//UBLYP/cc-pVTZ level are 0.925 and 0.861 for the $^2A_1$ and $^2B_2$ wave-functions, respectively.

[21] The structures and IR spectra for both states of **2a** show little dependence on the density functional employed. For consistency with earlier work on 1,3-biradicals, the UBLYP/cc-pVTZ level is discussed. The absolute intensities of the most-intense absorptions for both states ($74\ km\,mol^{-1}$ for mode 6 of $^2A_1$-**2a**, $66\ km\,mol^{-1}$ for the same mode of $^2B_2$-**2a**) are similar, so that the formation of a mixture of both isomers is unlikely. IR spectra of numerous other potential by-products (carbonyl compounds, ring-contraction products, etc.) have been calculated and can be excluded as the carrier of the three traces assigned to **2a**.

Supporting information for this article is available on the WWW under http://www.angewandte.org or from the author.

trations of free valences as well as quantum size effects are more important once the number of atoms falls below a few ten thousand. The preparation and examination of these aggregates is quite challenging because of their high instability.[2] The collision-free environment of a supersonic jet, which provides a "matrix" without effects that arise from the interaction with stabilizing materials, is appealing for the investigation and isolation of pure and mixed-metal or semimetal species. An intense laser-beam can vaporize almost every solid[3] and, in particular, pulsed laser sources can be excellently adapted to pulsed supersonic expansions. Precise information on the geometrical structure as well as the electronic and nuclear magnetic properties of small particles and inorganic clusters formed in the laser-generated plasma can be gained from high-resolution rotational analysis. Fourier-transform microwave (FTMW) spectroscopy combines ideally with pulsed-jet techniques.[4]

Even though laser-ablation of metals and semimetals has found extensive use in mass spectrometry, its combination with rotational spectroscopy is rare: The first attempts using single-target laser-ablation molecular beam FTMW spectroscopy were limited to small inorganic compounds such as metal oxides,[5] halides,[6] and sulfides.[7] Somewhat later, solid organic species such as amino acids[8] or urea were used.[9] However, the study of intermetallic systems is new, to date only one mixed-metal cluster, PtSi[10] in a $^1\Sigma$ closed-shell ground state, has been studied using this combination of techniques. Group 14 selenides and tellurides[11] have only been analyzed by rotational spectroscopy in very hot vapors.

To generate aggregates such as mixed-metal clusters from two solid precursors we designed a new twin-laser ablation source and combined it with a state-of-the-art ultra broadband (2–26.5 GHz) FTMW spectrometer as shown in Figure 1, allowing low frequency measurements to cover the rotational spectra of heavier clusters. This apparatus utilizes a coaxially oriented beam resonator arrangement (COBRA)[13] which provides exceptional (sub-Doppler) resolution and unrivalled sensitivity. Virtually any stable solid compound, even very ductile and reactive alkali metals,[14] can be vaporized by laser-ablation from a pressed target rod and expanded in the supersonic jet.[15] Consequently, the coaxial ablation twin source (CATS) allows the production of a huge variety of clusters by secondary reactions in the plasma prior to the supersonic expansion.

Tellurium selenide is a photoconducting semimetal material that is widely used for optoelectronic devices such as liquid crystal light valves (LCLV).[16] The preparation, study, and application of nanowires, nanotubes, and semiconductor heterojunction nanorods prepared from this material are of current research interest.[17] A prototype building unit in these structures—the diatomic cluster TeSe—is a heteroatomic homologue of the oxygen molecule. In contrast to the oxygen molecule, little is known about TeSe. Thermodynamic properties of TeSe were derived from Knudsen-cell mass spectrometric experiments.[18] Fink et al. observed the rotationally resolved IR-chemiluminescence spectrum in the gaseous state[19] while laser-induced fluorescence experiments on TeSe in the gas phase as well as in inert gas matrices were performed by Ahmed et al.[20] However, precise data on the

Figure 1. FTMW impulse experiment: Species are generated and expanded into a supersonic jet from a coaxial ablation twin source (CATS). Using a coaxially oriented beam-resonator arrangement (COBRA), the molecular systems are coherently excited by an MW pulse and their response is recorded in the time domain. Subsequent discrete Fourier transformation yields the frequency domain. A time-of-flight (TOF) mass spectrometer reassembling the principle Wiley–McLaren arrangement[12] can be lowered onto the jet axis for efficient real-time source optimization towards the desired cluster species.

internuclear potential and quantitative details of the chemical bond, which can be obtained from high-resolution spectroscopy, are unavailable to date.

The study of TeSe started with a coaxial single-target laser-ablation source[6] spectrometer in Valladolid described elsewhere[21] and was continued with the CATS spectrometer in Hannover presented herein. Owing to the extraordinary sensitivity of this technique, it was possible to characterize 43 of the existing 48 isotopologues of TeSe in their natural abundances. 350 rotational transitions $J+1,v\leftarrow J,v$ for $J=0$–6 in the vibrational states $v=0$–6 were recorded and analyzed (see Supporting Information). The extensive analysis of this huge dataset, using the approach of Dunham[22] and Watson[23] for a diatomic vibrating rotor as implemented by LeRoy,[24] will be given in detail in a subsequent publication. From the multi-isotopologue analysis, the rotational constants B_e, the vibration–rotation interaction coefficients $-\alpha_e$, γ_e, and ε_e, and the fourth-order centrifugal distortion constants $-D_e$ can be derived for all isotopologues. With these parameters and using the Bohr theory expansion[25] the individual spectra can be described by Equation (1):

$$v_{J+1,v\leftarrow J,v} = 2\left[B_e - \frac{2P^2}{W_{X1}-W_{X0}} - \alpha_e\left(v+\frac{1}{2}\right) + \gamma_e\left(v+\frac{1}{2}\right)^2 \right.$$
$$\left. + \varepsilon_e\left(v+\frac{1}{2}\right)^3 - D_e(J+1)^2\right](J+1) \tag{1}$$

The additional term $P = \langle v,J_a,\Omega=1\,|\,B(J_a)_+\,|\,v',J_a,\Omega=0\rangle$ accounts[26] for the interaction between the two levels of positive parity, $\Omega=0^+,1^+$, in a $^3\Sigma$ state separated in energy by $W_{X1}-W_{X0}$, which is accurately described for heavy diatomic

species such as TeSe by Hund's case (c).[27] Since finite nuclear-size effects, known for Pb and Tl,[28] should be negligible in this case, such terms are not included. From the spectroscopic constants the equilibrium bond lengths r_e can be calculated and the harmonic vibration frequency ω_e as well as the first anharmonicity constant $-\omega_e x_e$ can be estimated by Equations (2)–(4), with the reduced mass μ:[29]

$$r_e = \sqrt{\frac{h}{8\pi^2 B_e \mu}} \tag{2}$$

$$\omega_e \cong 2\sqrt{-\frac{B_e^3}{D_e}} \tag{3}$$

$$-\omega_e x_e \cong -\left(\frac{-\alpha_e}{3\sqrt{-D_e}} + \sqrt{B_e}\right)^2 \tag{4}$$

The constants ω_e and $-\omega_e x_e$ allow the determination of the Morse potential parameter a and the Morse dissociation energy D [Eq. (5) and Eq. (6)][30]

$$D \cong \frac{h\omega_e^2}{4(-\omega_e x_e)} \tag{5}$$

$$a = \sqrt{\frac{-\omega_e x_e}{B_e}} \tag{6}$$

The results for the most abundant isotopologue are compared to those from Fink et al.[19] in Table 1. As shown, the accuracy for the rotational constants from microwave spectroscopy is two to four orders of magnitude higher. Even the uncertainty in the indirectly determined vibrational

[a] The rotational constant B, the vibration-rotation-interaction coefficients $-\alpha_e$, γ_e, ε_e, the fourth-order centrifugal distortion constant $-D$, the bond length r, the harmonic frequency ω_e, and the first anharmonicity constant $-\omega_e x_e$. [b] The Morse dissociation energy D, the Morse parameter a, and the equilibrium bond length r_e. [c] Standard deviations in parentheses are given in units of the last digit.

parameters is improved, which is generally the case when microwave data, rather than infrared studies, are used for the characterization of heavier diatomics.

The dissociation energy of 293.3 kJ mol^{-1} obtained from Knudsen-cell mass spectrometric experiments is about 25% lower than the Morse dissociation energy D, this is consistent with observations in other systems.[31] Using the higher order anharmonicity contributions that are made available by the spectroscopic data in Table 1, the potential function can be expanded further[22] as shown in Figure 2 where the first term represents the Morse potential. Since the first term is already a good representation and the D_n values are quite small, the
Figure 2. Morse potential (——) and expanded Morse-based potential (- - - -) functions of tellurium selenide for the main isotopologue ^{130}Te^{80}Se.

potential converges rapidly about r_e. However, the corrected dissociation energy $D(1+D_4+D_5) = 409.6$ kJ mol^{-1} is still not supposed to be very reliable since the spectroscopic data sample only the lower region of the potential, where high-order anharmonicities do not contribute. However, in the absence of experiments on near-dissociative states, the Morse dissociation energy D is still valuable as maximum estimate for the dissociation limit.

Omitting contributions from the second term of Equation (1) in the multi-isotopologue analysis was quite unsatisfactory in terms of experimental accuracy, that is, the breakdown of the Born–Oppenheimer approximation is important in this case. This situation strongly indicates the bi-radical nature of the electronic ground state of this cluster, this nature was also discussed for the reasonable large corrections found for PtS.[7] The terms in Equation (1) might be compared with the expression discussed by Watson.[23] The equations are essentially the same giving the relation in Equation (7) with the electron mass m_e, the atomic masses M_i ($i =$ Se,Te), and the isotopologue invariant Born–Oppenheimer breakdown (BOB) mass-scaling correction constants $\Delta^i_{0,1}$ ($i =$ Se,Te).[23]

$$-\frac{2P^2}{B_e(W_{X1}-W_{X0})} = \frac{m_e}{M_A}\Delta^A_{0,1} + \frac{m_e}{M_B}\Delta^B_{0,1} \qquad (7)$$

Both parameters, $\Delta^{Te}_{0,1}$ and $\Delta^{Se}_{0,1}$, have relatively large values as seen in Table 2. By means of Equation (2)–(4) and using

the pure precession approximation $P \cong B_e\sqrt{J_a(J_a+1)}$ with $J_a = S+L = 1$, the BOB analysis of pure rotational spectra provides an estimate for the separation of the $^3\Sigma$-state that is split into a $X0$- and a $X1$-sublevel, or by using Verseth's expression $P \cong B_e\sqrt{2}-\gamma/\sqrt{2}$ can give an estimate of the electron spin-rotation coupling constant γ, provided that the energy separation is known [Eq. (8) and Eq. (9)].[25] This approach gives $W_{X1}-W_{X0} = 1059$ cm^{-1}, which is in fair agreement with the energy separation of 1233.49 cm^{-1} determined from the IR-chemiluminescence spectrum,[19] or $\gamma = -0.01008$ cm^{-1}:

$$W_{X1}-W_{X0} \cong -\frac{4B_e}{\frac{m_e}{M_{Se}}\Delta^{Se}_{0,1}+\frac{m_e}{M_{Te}}\Delta^{Te}_{0,1}} \qquad (8)$$

$$\gamma \cong 2B_e-\sqrt{-B_e(W_{X1}-W_{X0})\left(\frac{m_e}{M_{Se}}\Delta^{Se}_{0,1}+\frac{m_e}{M_{Te}}\Delta^{Te}_{0,1}\right)} \qquad (9)$$

Communications

Owing to the very high resolution of the COBRA-FTMW technique, it is feasible to analyze the narrow hyperfine structure of isotopologues having one or two nuclear spins $I = \frac{1}{2}$, thereby gaining some quantitative insight of the chemical bond. For the $\Omega = 0^+$ component of a $^3\Sigma$ state in the Hund's case (c) limit, the interaction energy[32] for one nucleus in a diatomic molecule ($F = J + I$, $|J - I|$) is given by Equation (10) and Equation (11) in the pure precession approximation. In this case, the unperturbed nuclear spin-rotation interaction constant f is altered by the low lying $\Omega = 1^+$ state. The constant b is averaged over each unpaired electron [Eq. (12) and Eq. (13)] with the molecular g_J-factor on the order of unity and $g_N = \mu/I\mu_N$ being proportional to the magnetic moment μ of the coupling nucleus and the probability $|\psi^2(0)|$ of the electron being found at the nucleus.

$$W_{\mathrm{hfs}} = \frac{1}{2} C_I \{F(F+1) - J(J+1) - I(I+1)\} \qquad (10)$$

$$C_I = f + (b - f)\frac{4B_e}{W_{X1} - W_{X0}} \qquad (11)$$

$$f = 2g_J g_N \mu_N^2 \left(\frac{1}{r^3}\right)_{\mathrm{av}} \qquad (12)$$

$$b = g_N \mu_N \mu_B \left[\frac{16\pi}{3}|\psi^2(0)| - \frac{3\cos^2\theta - 1}{r^3}\right]_{\mathrm{av}} \qquad (13)$$

In Equation (13) the angle θ is taken between the internuclear axis and the radius r from the nucleus to the electron. Our CAS-SCF calculations show that the unpaired electrons in the π^* orbital have contributions of $-0.842p$ and $-0.059d$ from Te and $+0.699p$ and $0d$ from Se. The lack of s character for both nuclei makes $|\psi^2(0)|$ essentially zero, since this probability is negligibly small for p- and d-orbitals. The parameter b is dominated by the second term, which can either be positive or negative or vanishes for a spherical distribution, thus b can become of opposite sign to f, with f assuming the sign of μ. Values of $|b| = 1000$ MHz are not unlikely.[32] However, the measured spin-rotation constants, for example, $C_I(^{130}\mathrm{Te}^{77}\mathrm{Se}) = 45.80(19)$ kHz given in Table 3, are rather large and bear the sign of μ for all isotopologues. An estimate for $f(^{77}\mathrm{Se})$ might be the recently determined $C_I(^{208}\mathrm{Pb}^{77}\mathrm{Se}) = 9.61(30)$ kHz in a $^1\Sigma$ state.[33] Consequently, with $4B_e/(W_{X1} - W_{X0}) \approx 2 \times 10^{-4}$, $b(^{77}\mathrm{Se})$ is estimated to be of the order of 180 MHz, thereby indicating large average values θ for the unpaired electrons in the antibonding π^* orbitals.

In conclusion, this investigation on TeSe proves the power of supersonic-jet FTMW spectroscopy in combination with laser-ablation for research on intermetallic species. Not only spectroscopic parameters and structural information are accessible, but also information on the internuclear potential, electronic structure, and details of the chemical bond of the compound can be gained from high-resolution multi-isotopologue rotational spectra determined with high sensitivity. Even the energy separation of interacting triplet states can be estimated from pure rotational spectra instead of by electronic spectroscopy. Such studies are generally applicable to various metal or semimetal systems. The ability to prepare supersonic jets of these samples and to obtain high-resolution rotational spectra extends the horizon for investigations on the building units of small particles and inorganic clusters that form new materials.

Experimental Section

A stoichiometric mixture of tellurium and selenium powders (Alfa Aesar, 99.96%) was sealed in quartz ampoules under reduced pressure and heated at 800°C for 24 h. Some grams of the ground alloy were mixed with a few drops of acrylic acid based glue, pressed to a rod and dried. Material was ablated from the samples at a repetition rate of 5–20 Hz by the beams of pulsed Nd:YAG-lasers ($\lambda = 1064$ nm, 500 mJ or $\lambda = 532$ nm, 90 mJ) focused on the rod surface in neon (Linde, 3.5) at a stagnation pressure of 5–8 bar. The accuracy of the transition frequencies varies from better than 1 kHz (Hannover) to 5 kHz (Valladolid). For the microwave excitation, a radiation power -8 dBm at 0.4 µs pulse duration was needed to obtain maximum signal-to-noise ratios.

Vaccines

Total Synthesis of Antigen *Bacillus Anthracis* Tetrasaccharide—Creation of an Anthrax Vaccine Candidate**

*Daniel B. Werz and Peter H. Seeberger**

A few letters containing a seemingly inconspicuous white powder killed four innocent people, instilled fear in most Americans for several weeks, and brought the US Postal Service to the brink of collapse shortly after the events of September 11, 2001. The white powder was identified as dormant spores of the Gram-positive soil bacterium *Bacillus anthracis*,[1,2] which are highly resistant to extreme temperatures, radiation, harsh chemicals, desiccation, and physical damage. These properties allow them to persist in the soil for many years.[3] These spores cause anthrax, a serious infection of herbivores and cattle, but infects humans only rarely, except when specially prepared and dispensed as biowarfare agents. If the spores are inhaled, the host is usually killed within days. Three polypeptides that comprise the anthrax toxin play a major role in all stages of infection, from germination to the induction of vascular collapse leading to host death.[4]

Bacillus anthracis, like most bacteria, bears unique oligosaccharides on the surface of the spore for interaction with the host. Specific oligosaccharide antigens can be used to design an antibacterial vaccine for the induction of an immune response.[5] Carbohydrates are evolutionarily more stable than proteins and have been exploited in a series of commonly employed vaccines.[6] Synthetic oligosaccharide vaccines have shown very encouraging results against cancer,[7] malaria,[8] and *Haemophilus influenzae* type b[9] to name just a few.

The structure of tetrasaccharide **1**, which is found on the surface of the exosporium glycoprotein BC1A of *Bacillus anthracis* was elucidated in 2004 (Figure 1).[10] A unique characteristic of this antigen is the nonreducing terminal sugar, the so-called anthrose, which is not even found in closely related species.[10] Tetrasaccharide **1** is therefore a very attractive target for vaccine development and the elucidation

of a highly specific immune response against *Bacillus anthracis*.

Herein, we describe the first total synthesis of tetrasaccharide **2** through a convergent [2+2] approach that facilitates access to analogues and shorter sequences. The terminal pentenyl group can serve as a point of attachment during conjugation to a carrier protein in vaccine development. A straightforward synthesis of the unique monosaccharide anthrose is part of this total synthesis.

Synthesis of the terminal anthrose[10] started from commercially available D-fucose (**3**) (Scheme 1). Acetylation of **3**, followed by immediate protection of the anomeric center with *para*-methoxyphenol (MPOH) and subsequent cleavage of the acetates furnished **4**. A levulinoyl group proved to be the best choice to protect the C2 hydroxy group during installation of the β(1→3) glycosidic linkage in anticipation of its selective removal prior to methylation of *O*2. Thus, reaction of **4** with 2,2-dimethoxypropane and introduction of the levulinic ester at C2 furnished **5**. Removal of the isopropylidene and tin-mediated selective benzylation of the hydroxy group at C3 afforded **6**. The configuration of C4 was inverted by reaction of the hydroxy group with triflic anhydride to install a triflate, which was displaced by sodium azide in an S$_N$2-type fashion to give **7**.[11] Removal of the anomeric *p*-methoxyphenyl group with wet cerium ammonium nitrate was followed by the formation of the anthrose trichloroacetimidate **8** by treatment with trichloroacetonitrile and a catalytic amount of sodium hydride. A completely different, more lengthy approach to the synthesis of an anthrose monosaccharide was reported recently.[12]

Rhamnose building block **13**, which is equipped with a robust participating group at C2 to ensure α selectivity and a readily removable temporary protecting group (Fmoc) at 3-OH was synthesized next (Scheme 2). First, the anomeric

Scheme 2. Synthesis of rhamnose building block **13**. Reagents and conditions: a) Ac$_2$O, pyridine, 12 h, quant.; b) MPOH, BF$_3$·OEt$_2$, acetone, 0°C→25°C, 12 h, 80%; c) NaOMe, MeOH, 12 h, 96%; d) 2,2-dimethoxypropane, BF$_3$·OEt$_2$, acetone, 0°C→25°C, 12 h, 84%; e) NaH, BnBr, DMF, 0°C→25°C, 4 h, quant.; f) HCl (pH 3), MeOH, 50°C, 89%; g) 1,1,1-triethoxyethane, *p*-TsOH (cat.), DMF, 50°C, 50 min; h) AcOH/H$_2$O (4/1, *v/v*), 10°C, 2 h, 98% (two steps); i) FmocCl, pyridine, 25°C, 2 h, 88%; j) CAN, H$_2$O/CH$_3$CN, 25°C, 1 h, 76%; k) Cl$_3$CCN, NaH, CH$_2$Cl$_2$, 25°C, 1 h, 94%. TsOH = *para*-toluenesulfonic acid, DMF = *N,N*-dimethylformamide, Fmoc = fluorenylmethoxycarbonyl.

center was protected with a *para*-methoxyphenol group under the conditions described above to give **10**.[13] Formation of the *cis*-fused acetal and subsequent benzylation afforded **11**. The transformation of the acetal into the corresponding

orthoester and ring opening resulted in the kinetically preferred axial acetate in **12**. The remaining hydroxyl function was protected with an Fmoc group, and the *para*-methoxyphenyl glycoside was cleaved. Subsequent reaction with trichloroacetonitrile in the presence of traces of sodium hydride afforded building block **13**.

The assembly of the tetrasaccharide through a [2+2] approach commenced with the reaction of known building block **14**[14] with 4-penten-1-ol (Scheme 3). The pentenyl

moiety serves at a later stage as a handle for conjugation to a carrier protein in the preparation of the vaccine candidate. Cleavage of the acetate at C2, further glycosylation with **13**, and subsequent removal of Fmoc yielded disaccharide **16**. During the cleavage of the Fmoc group, minor acetate migration ($\approx 10\%$) from the 2-OH to the 3-OH group was observed, but the undesired product was easily removed by column chromatography.

The second disaccharide (Scheme 3 B) was assembled by glycosylation of rhamnose **12**, an intermediate in the synthesis of building block **13**, with the anthrose unit **8**. The levulinoyl group, which ensured β selectivity, was replaced by the final methoxy substituent at C2. The methylation in the presence of acetate proved to be challenging. Even powerful methylating agents such as methyl triflate and diazomethane failed to facilitate the transformation. Satisfying yields were only possible with MeI/Ag$_2$O in the presence of catalytic amounts of dimethyl sulfide. The commonly used maneuver to convert the methoxyphenyl glycoside into the corresponding trichloroacetimidate furnished disaccharide unit **18**.

To complete the total synthesis, the two disaccharide units **16** and **18** were coupled to afford tetrasaccharide **19** (Scheme 4). Sodium in liquid ammonia removed all permanent protecting groups and transformed the azide moiety into an amine, thus achieving global deprotection. The formation of the amide with 3-hydroxy-3-methylbutanoic acid under peptide-coupling conditions[15] led to tetrasaccharide **2**, whose structure was confirmed by comprehensive spectroscopic analysis and comparison with the reported analytical data for **1**.

In conclusion, we have reported a convergent total synthesis of a *Bacillus anthracis* tetrasaccharide antigen ready for conjugation
Scheme 3. Syntheses of disaccharide building blocks **16** (A) and **18** (B). Reagents and conditions: a) 4-pentenol, TMSOTf, CH$_2$Cl$_2$, −20°C, 45 min, 79%; b) NaOMe, MeOH, 4 h, 96%; c) **13**, TMSOTf, CH$_2$Cl$_2$, 0°C, 1 h, 91%; d) piperidine, DMF, 25°C, 30 min, 89%; e) **8**, TMSOTf, CH$_2$Cl$_2$, 0°C, 1 h, 90%; f) hydrazinium acetate, CH$_2$Cl$_2$, MeOH, 25°C, 12 h, quant.; g) MeI, Ag$_2$O, THF, Me$_2$S (cat.), 25°C, 8 h, 73%; h) CAN, H$_2$O/CH$_3$CN, 25°C, 1 h; i) Cl$_3$CCN, NaH, CH$_2$Cl$_2$, 25°C, 1 h 95% (two steps). Heterolytic Splitting of Hydrogen with Rhodium(I) Amides**

Pascal Maire, Torsten Büttner, Frank Breher,
*Pascal Le Floch, and Hansjörg Grützmacher**

Dedicated to Professor Gottfried Huttner
on the occasion of his 68th birthday

The classical mechanisms for the catalytic hydrogenation of C=C double bonds with rhodium(I) or iridium(I) complexes consist of six steps: 1) ligand dissociation from the catalyst precursor, 2) oxidative addition of H_2, 3) olefin coordination, 4) insertion of the coordinated C=C bond in a Rh−H bond, 5) isomerization, and 6) reductive elimination of the product.[1] In the Halpern mechanism,[2] the olefin insertion and in the Brown mechanism the reductive elimination of the alkane is rate-determining.[3] In both mechanisms, a T-shaped 14-electron $[ML_2X]$ complex is the key intermediate which adds H_2 oxidatively in an almost barrierless exothermic reaction. The heterolytic addition of hydrogen across a metal–nitrogen bond was first investigated systematically by Fryzuk and co-workers.[4] In the meantime, this reaction has been recognized as a key step in the very efficient catalytic hydrogenation of unsaturated substrates $RR^1C=X$,[5–7] especially of ketones (X = O), which became known as metal–ligand bifunctional catalysis through the work of Noyori and Morris. This mechanism is different and involves: 1) heterolytic addition of H_2 across the metal–amide bond as the rate-determining step, 2) binding of $RR^1C=X$ in the second coordination sphere of the $MH^{\delta-}-NH^{\delta+}$ unit, 3) "concerted" transfer of $H^{\delta-}$ from the metal atom to the C=X carbon atom and $H^{\delta+}$ from the nitrogen atom to the X center, and 4) product release. In this mechanism no change of the formal oxidation state and no major structural changes in the first coordination sphere of the metal center occur. Combined with the possibility to isolate the species that are directly involved in

the catalytic cycle,[7b, 8] new possibilities for rational catalyst design emerge.

Recently, we isolated rhodium(I) amide olefin complexes with a rigid tetrahedrally distorted square-planar structure.[9] In accord with a calculated high activation barrier (> 29 kcal mol^{-1}), these compounds do not split H$_2$ heterolytically. Here we report the syntheses of rhodium amides with a novel structure. These complexes are easily prepared in a few steps, can be isolated, split H$_2$ heterolytically, and are directly active hydrogenation catalysts for ketones and imines without the need for any additives.

The reaction of bis(5-*H*-dibenzo[*a,d*]cyclohepten-5-yl)-amine (**1**, bis(tropylidenyl)amine, trop$_2$NH)[10a] with [Rh$_2$(μ$_2$-Cl)$_2$(cod)$_2$] (**2**) gives the dinuclear complex [Rh$_2$(μ$_2$-Cl)$_2$-(trop$_2$NH)$_2$] (**3**, Scheme 1).
Scheme 1. Synthesis of rhodium bis(trop)amine complexes **4a,b**, **5a,b**, **6a,b**, and **7a,b**. cod = cycloocta-1,5-diene.

Subsequent reaction with a phosphane leads to the mononuclear complexes [RhCl(trop$_2$NH)(PPh$_2$R)] **4a** (R = Ph) and **4b** (R = 4-MeC$_6$H$_4$ = Tol) in which the phosphane ligand is in the equatorial position and the chloro substituent is in the apical position (these stereochemical assignments are based on the NMR spectroscopic data). The complexes **3** (red crystals) and **4a,b** (yellow crystals) are obtained quantitatively and can be stored in air.

The NH function of the rhodium(I)-coordinated trop$_2$NH ligands is sufficiently acidic (pK_a 15–20 in DMSO)[9,10] to be

fully deprotonated by addition of one equivalent of KO*t*Bu to **4a,b** in THF; this is accompanied by an immediate color change of the reaction solution from orange-red to intense green. Deep green, highly air-sensitive crystals of **5a,b** grew from a 1:1 mixture of THF/toluene which was layered with *n*-hexane. The result of a structure analysis on a single crystal of **5b** is shown in Figure 1.[11]
Figure 1. Structure of **5b**. Thermal ellipsoids are drawn at 30% probability; hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: Rh–N1 2.007(1), Rh–P1 2.316(1), Rh–C5 2.165(2), Rh–C4 2.190(2), Rh–C19 2.174(2), Rh–C20 2.199(2), Rh–ct1 2.058(2), Rh–ct2 2.070(2), C4–C5 1.423(3), C19–C20 1.407(3); N1-Rh-P1 166.18(5), ct1-Rh-ct2 135.81(7), C16-N1-C1 109.5(1), C16-N1-Rh 118.5(1), C1-N1-Rh 119.0(1).

The structure of the neutral amide **5b** is unique among tetracoordinate d^8 rhodium complexes. However, a close relationship exists to the zero-valent 16 valence-electron (VE) [Ru(CO)$_2$(PR$_3$)$_2$] complexes studied by Caulton, Eisenstein, et al.[12] and to the highly reactive transient carbonyls [M(CO)$_4$] (M = Fe, Ru, Os).[13] Indeed, like these species, **5b** adopts a "sawhorse" structure with a N-Rh-P angle of 166.18(5)° and a ct1-Rh-ct2 angle of 135.81(7)° (ct = centroid of the coordinated C=C bond). Comparable angles in [Ru(CO)$_2$(P*t*Bu$_2$Me)$_2$] are: P-Ru-P 165.56(8)°, and C-Ru-C 133.3(4)°.

The amide nitrogen atom N1 has a pyramidal coordination sphere (Σ = 347°). At temperatures below 220 K, sharp and distinct ^{1}H NMR resonances for the inequivalent protons at the olefinic carbon atoms C4/C20 and C5/C19, respectively, are observed, which demonstrates that the sawhorse structure corresponds to the ground-state structure. At room temperature, these NMR resonances collapse to give one broadened singlet, indicating inversion at the nitrogen and rhodium centers, probably via a planar transition state.

The rhodium amides **5a,b** react rapidly and quantitatively with H$_2$ (1 atm) even at −78°C to give the yellow rhodium hydride complexes [RhH(trop$_2$NH)(PPh$_2$R)] (**6a,b**). This reaction is very likely reversible as **6b** reacts with D$_2$ to give

[D$_2$]-**6b** exclusively and, vice versa, [D$_2$]-**6b** reacts with H$_2$ to give **6b**. The latter reaction was monitored by ^{1}H NMR spectroscopy and shows that the intensities of the signals for the NH and RhH protons build up simultaneously. We have no evidence that deuterium labeling occurs at any other position in the molecule. The structure of **6b** was determined by X-ray diffraction (Figure 2).[11]
Figure 2. Structure of **6b**. Thermal ellipsoids are drawn at 30% probability; hydrogen atoms apart from H1 and H2 and one THF solvent molecule are omitted for clarity. One position of the disordered *para*-methyl substituent within the PPh$_2$Tol ligand is shown. Selected bond lengths [Å] and angles [°]: Rh–N1 2.178(1), Rh–P1 2.230(1), Rh–H2 1.59(3), Rh–C5 2.159(1), Rh–C4 2.199(1), Rh–C19 2.158(1), Rh–C20 2.203(1), Rh–ct1 2.057(1), Rh–ct2 2.059(1), C4–C5 1.437(2), C19–C20 1.436(2), N1···O1 3.02; N1-Rh-P1 169.95(3), ct1-Rh-ct2 132.54(5), C16-N1-C1 110.7(1), C16-N1-Rh 116.15(7), C1-N1-Rh 117.36(7).

The structural differences between **5b** and **6b** are very small. In **6b** the Rh–N bond is 9% longer and the Rh–P bond is 4% shorter than in **5b**; the ct1-Rh-ct2 angle is 2% more acute, whereas the N-Rh-P angle is 2% more open. Also the coordination sphere at N1 is not influenced very much (Σ(C-N-C, 2×C-N-Rh) = 344.2°). A THF molecule is coordinated to the NH function (N1···O1 3.02 Å) and indicates, as does the high-frequency ^{1}H NMR shift (δ: 5.56 ppm (**6a**), 5.09 ppm (**6b**)), its acidic character. The hydride ligand H2 in the equatorial position of the trigonal-bipyramidal structure of **6b** causes the typical[14] shift of the olefinic ^{13}C resonances to low frequency (by about 20 ppm) and an elongation of the coordinated C=C bonds.

Solutions of the recrystallized hydrides **6a,b** in THF are stable for at least 24 h. However, impurities provoke the quantitative isomerization to the air-stable yellow complexes **7a,b** in which the hydride ligand adopts the axial position.

The assumption that the amide complexes **5a,b** split H$_2$ heterolytically is supported by DFT calculations with the model complex [Rh(cht$_2$N)(PH$_3$)] (**I**) (cht = cyclohepta-

trienyl, Figure 3).[15] The formation of the hydride **II** is exothermic ($\Delta_R H = -15.8$ kcal mol^{-1}) and proceeds in one step[16] via the transition state **TS-I**. The calculated NBO charges show that the H$_2$ molecule is significantly polarized
Figure 3. DFT[15] computed energies for the heterolytic (shown in black) and oxidative addition (shown in gray) of H$_2$ to the model complex **I**. NBO charges are given for the Rh, N, and the adding H$_2$ molecule in **I**, **TS-I**, and **II**.

($\Delta q^{NBO} = 0.33$ e) in the transition state (compare with $\Delta q^{NBO} = 0.57$ e in the product **II**). The polarity of the Rh^I–N bond varies little throughout this addition process ($\Delta q^{NBO} = 0.94$ e (**I**), 0.91 e (**TS-I**), 0.83 e (**II**)). The "classical" oxidative addition of H$_2$ leading to the rhodium(III) dihydride **III** is an unfavorable endothermic process ($\Delta_R H = 17.9$ kcal mol^{-1}) and has to encompass the transition state **TS-II** which is higher in energy than **TS-I** by 3.4 kcal mol^{-1}.

The isolated crystalline amide **5b** and the hydride **6b** were used in catalytic hydrogenations without any further additives. The conditions and results are listed in Table 1. Under these (not yet optimized) conditions,[17] alkyl- (**8**) and aryl-substituted ketones (**9**) and the imine **10** are completely converted to the corresponding hydrogenated products cyclohexanol, 1-phenylethanol, and *N*-phenylbenzylamine, respectively. The amide **5b** and the hydride **6b** are equally active (see Table 1, entries 2 and 3). Addition of an excess of phosphine does not significantly slow down the catalytic activity. However, at the end of each catalytic run, the axial

Table 1: Hydrogenation of the ketones **8** and **9** and the imine **10** with **5b** or **6b** as catalysts.[a]

Entry	Substrate	Cat.	S/C[b]	t [h]	Conversion [%]
1	**8**	**5b**	100	16	>97
2	**9**	**5b**	100	16	>97
3	**9**	**6b**	100	16	>97
4	**9**	**5b**	1000	1.5	22
5	**9**	**5b**	1000	16	65
6	**10**	**5b**	100	16	>97

[a] THF, 100 bar H$_2$, $T = 298$ K. [b] Ratio substrate/catalyst.

hydride **7b** is the only detectable rhodium- and phosphorus-containing species and this hydride is catalytically inactive. We therefore assume that the formation of **7b** in course of the catalytic reaction is responsible for the incomplete conversion of **9** with low catalyst loadings (Table 1, entry 5).

In summary, rhodium amides with previously unreported structures can be prepared from readily available starting materials. These complexes react cleanly with H_2 which is heterolytically split in a one-step process across the polar Rh—N bond. Both, the amide and hydride can be used directly as catalysts for ketone or imine hydrogenations, which very likely proceed via the metal–ligand bifunctional mechanism.[17] Given that the isomerization of the catalytically active hydride intermediate to an inactive one can be suppressed, efficient new catalysts for hydrogenations are in sight.

Experimental Section

The syntheses of **4a,b** can be performed without any particular precautions. In contrast, the amides **5a,b** must be handled under exclusion of moisture and oxygen. Detailed descriptions of the syntheses and spectroscopic data are given in the Supporting Information.

The reaction of **2** with two equivalents **1** in CH_2Cl_2 gave **3**·CH_2Cl_2, which was obtained as red crystals from the reaction mixture (yield > 90%). Subsequent reaction with PPh_2R (R = Ph or Tol) gave yellow solutions, from which **4a,b** were precipitated by addition of *n*-hexane (yields > 80%; **4a**: R = Ph, **4b**: R = Tol). The reaction of **4a,b** with one equivalent of KO*t*Bu in THF gave a deep green reaction solution, to which was added toluene (50 vol%). After all volatiles had been evaporated under vacuum, the green residue was extracted with THF, filtered, and concentrated. Layering this THF extract with toluene and *n*-hexane (THF/toluene/*n*-hexane = 1:1:10) gave dark green microcrystals of **5a,b** (yields: 80%). Deep green solutions of **5a,b** in THF were treated with H_2 (D_2) gas at 2 atm. Layering of the resulting yellow solutions with *n*-hexane led to the crystallization of the hydrides **6a,b** or [D_2]-**6b** as yellow air-stable platelets (yields > 80%).

NMR data were recorded at 298 K when not specified otherwise: **3**: M.p.: > 250°C (decomp). ^{1}H NMR (400.1 MHz, CD_2Cl_2): $\delta = 5.97$ (dd, $^3J_{H,H} = 9.4$ Hz, $^2J_{Rh,H} = 2.1$ Hz, 4H; CH_{olefin}), 6.20 ppm (d, $^3J_{H,H} = 9.4$ Hz, 4H; CH_{olefin}); ^{13}C NMR (100.6 MHz, CD_2Cl_2): $\delta = 71.4$ ppm (br s, 8C; CH_{olefin}); ^{103}Rh NMR (12.7 MHz, CD_2Cl_2): $\delta = 2992$ ppm (s); UV/Vis (CH_3CN): λ_{max} (ε) = 232 (sh), 289 (45700), 329 nm (sh). **4a**: M.p.: > 260°C (decomp). ^{1}H NMR (300.1 MHz, $CDCl_3$): $\delta = 1.59$ (br, 1H; NH), 5.42 (dd, $^3J_{H,H} = 9.4$ Hz, $^3J_{P,H} = 7.4$ Hz, 2H; CH_{olefin}), 5.66 ppm (ddd, $^3J_{H,H} = 9.4$ Hz, $^3J_{P,H} = 5.8$ Hz, $^2J_{Rh,H} = 1.3$ Hz, 2H; CH_{olefin}); ^{31}P NMR (101.2 MHz, $CDCl_3$): $\delta = 7.7$ ppm (d, $^1J_{Rh,P} = 111$ Hz). **4b**: M.p.: > 260°C (decomp). In $CDCl_3$ solution two conformations (likely due to hindered rotation around the Rh—P bond) in an approximate 2:1 ratio are observed. ^{1}H NMR (300.1 MHz, $CDCl_3$): $\delta = 1.59$ (br s, 1H; NH_{maj}), 1.71 (br s, 1H; NH_{min}), 5.35–5.48 (m, 2H; $CH_{olefin,min}$; and 2H; $CH_{olefin,maj}$), 5.60–5.67 ppm (m, 2H; $CH_{olefin,min}$; and $CH_{olefin,maj}$); ^{31}P NMR (121.5 MHz, $CDCl_3$): $\delta = 6.9$ (d, $^1J_{Rh,P} = 111$ Hz, maj), 7.6 ppm (d, $^1J_{Rh,P} = 111$ Hz, min). **5a**: ^{1}H NMR (400.1 MHz, [D_8]THF, 200 K): $\delta = 4.69$ (ddd, $^3J_{H,H} = 9.0$ Hz, $^3J_{P,H} = 6.2$ Hz, $^2J_{Rh,H} = 1.2$ Hz, 2H; CH_{olefin}), 5.62 ppm (ddd, $^3J_{H,H} = 9.0$ Hz, $^2J_{Rh,H} = 3.3$ Hz, $^3J_{P,H} = 2.9$ Hz, 2H; CH_{olefin}); ^{13}C NMR (100.6 MHz, [D_8]THF, 200 K): $\delta = 76.2$ (d, $^1J_{Rh,C} = 6.7$ Hz, 2C, CH_{olefin}), 84.5 ppm (d, $^1J_{Rh,C} = 14.7$ Hz, 2C, CH_{olefin}). ^{31}P NMR (162.0 MHz, [D_8]THF, 200 K): $\delta = 40.8$ ppm (d, $^1J_{Rh,P} = 124$ Hz); ^{103}Rh NMR (12.6 MHz, [D_8]THF, 200 K): $\delta = 838$ ppm (d, $^1J_{Rh,P} = 124$ Hz); UV/Vis (THF): λ_{max} (ε) = 301 (20000), 352 (10000), 438 (3000),

The hydrogen atoms were placed in idealized positions and included as riding atoms. Crystal structure of **6b**: $C_{49}H_{41}NPRh \cdot 2$ THF, triclinic, space group $P\bar{1}$; $a = 10.935(1)$, $b = 11.864(1)$, $c = 19.658(1)$ Å, $\alpha = 91.408(3)°$, $\beta = 100.019(3)°$, $\gamma = 109.948(3)$; $V = 2350.8(3)$ Å^3; $Z = 2$; $\rho_{calcd} = 1.301$ Mg m^{-3}; crystal dimensions $0.62 \times 0.53 \times 0.43$ mm; diffractometer Bruker SMART Apex; Mo$_{K\alpha}$ radiation, 200 K, $2\Theta_{max} = 82.46°$; 61525 reflections, 29179 independent ($R_{int} = 0.0239$), direct methods; empirical absorption correction SADABS (ver. 2.03); refinement against full matrix (versus F^2) with SHELXTL (ver. 6.12) and SHELXL-97,[18] 471 parameters, $R1 = 0.0471$ and w$R2$ (all data) $= 0.1465$, max./min. residual electron density 2.757/-1.422 e Å^{-3}. The hydrogen atoms were placed in idealized positions and included as riding atoms. The positions of the hydrogen atoms H1 (NH) and H2 (RhH) were obtained from a difference Fourier synthesis, they were refined isotropically. The *para*-methyl moiety of the PPh$_2$Tol ligand was "disordered" due to phenyl/tolyl interchange and had to be split over two positions, which were refined against each other (FVAR = 0.47). Consequently, one hydrogen atom in the *para*-position of a phenyl ring was not included in the refinement. CCDC-264482 (**5b**) and CCDC-264483 (**6b**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

[15] All calculations were carried out within the framework of DFT using the Gaussian 03[15a] set of programs and the B3PW91 functional. This functional employs a combination of exchange terms: exact HF, the Becke 1988 nonlocal gradient correction[15b] and the original Slater local exchange functional.[15c] In addition, it uses the Perdew–Wang 1991 local correlation functional.[15d] The 6-31 + G* basis set was employed for all the atoms connected to the Rh center as well as for the four CH olefinic protons. All the other atoms, except Rh, were calculated using the 6-31G* basis set. A quasirelativistic effective core potential operator was used to represent the 28 innermost electrons of the rhodium atom. The basis set for the metal was that associated with the pseudopotential, with a standard double-ζ LANL2DZ contraction.[15e] Cartesian coordinates of the theoretical structures are given in the Supporting Information. The minimum energy structures were characterized by full vibration frequencies calculations. Natural charges were computed with the NBO program implemented in Gaussian 03.[15f] a) Gaussian 03 (Revision B.04), M. J. Frisch, G. W. Trucks, H. B. Schlegel, G. E. Scuseria, M. A. Robb, J. R. [16] We could not locate any minimum structure with a η^2-bonded H$_2$ molecule as ligand. On the contrary, the heterolytic splitting of H$_2$ by ruthenium(II) phosphane amides is a two-step process including first the formation of a σ-bonded H$_2$ complex followed by an intramolecular proton transfer to the amide nitrogen atom (energy barrier (DFT) from the amide to the transition state for H$_2$ cleavage: 13.4 kcal mol^{-1}).[7b] A one-step heterolytic cleavage of H$_2$ has been calculated for ruthenium(II) arene amides with a transition state at 25.2 kcal mol^{-1} (MP2): M. Yamakawa, H. Ito, R. Noyori, *J. Am. Chem. Soc.* **2000**, *122*, 1466.

[17] The complete catalytic cycle for the hydrogenation of H$_2$C=O with **I** was calculated. The results strongly support the assumption that this reaction follows the metal–ligand bifunctional

mechanism and that the heterolytic H_2-splitting is the rate-determining step. The transfer of $H^{\delta+}$, $H^{\delta-}$ to the $H_2C=O$ molecule, which is bonded in the second coordination sphere at the place where the THF molecule is in **6b**, has only a very small barrier ($E_a = 0.5$ kcal mol^{-1}). However, our experimental set-up did not allow the stirring of the reaction mixtures, which should enhance considerably the turnover frequency. Details concern-ing the calculation of the catalytic cycle are given in the Supporting Information.

Rhodium Complexes

Diamido Rhodates(1−)**

*Pascal Maire, Frank Breher, and
Hansjörg Grützmacher**

*Dedicated to Professor Herbert W. Roesky
on the occasion of his 70th birthday*

The M−N bond in late transition-metal amides[1] is susceptible to a number of useful synthetic transformations.[2] Some years ago, Brunet et al. reported the only known bis-(amido)rhodium(I) complexes, which were characterized in rather complex equilibria in the reaction of $[Rh_nCl_m(PR_3)_l]$ compounds with anilide, MNHPh (M = Li, Na).[3] Based on NMR data, the structure **A** was proposed for {Li(solv)$_x$-[Rh(NHPh)$_2$(PR$_3$)$_2$]} (Scheme 1). In this intimate ion pair,
Scheme 1. The diamido rhodate(1−) **A** reported by Brunet et al.[3], and isolated 18-electron and 16-electron rhodium(I) amides **B** and **C**, respectively (L∩L = tropNH$_2$, bipy).

which is only stable in the presence of an excess of anilide in solution, the NHPh groups are likely rotated such that they are orientated perpendicular to the central plane, and the lone pairs are involved in the complexation of the alkali-metal cation.

Previously, we reported the stable neutral rhodium(I) amides **B** and **C**, which were isolated and fully characterized (see Table 1 for pertinent data). The pentacoordinate 18-electron complex **B** adopts the expected trigonal-bipyramidal structure with the nitrogen atom in an apical position.[4,5] The [Rh(trop$_2$N)(L∩L)] amides **B** (trop$_2$N = bis(5H-dibenzo-[a,d]cycloheptene-5-yl)amide; L∩L = tropNH$_2$, bipy) are reversibly oxidized at about −0.5 V (versus the ferrocenium/ferrocene, Fc$^+$/Fc, couple) to the aminyl radical complexes [Rh(trop$_2$N)(L∩L)]$^{+\cdot}$. Their conjugated acids, [Rh-(trop$_2$NH)(L∩L)]$^+$, have pK_a values of about 19 in DMSO.[5] In the neutral tetracoordinate 16-electron complex [Rh(trop$_2$-dach−H)], **C**, the NR$_2$ group is approximately coplanar with the central plane, which leaves the amide nitrogen lone pair in a perpendicular position (trop$_2$dach = (R,R)-N,N′-bis(5H-dibenzo[a,d]cyclohepten-5-yl)-1,2-diaminocyclohexane; the "−H" indicates mono-deprotonation).[6] This complex is less readily oxidized (−0.34 V versus Fc$^+$/Fc) and the pK_a^{DMSO} of the conjugated acid [Rh(trop$_2$dach)]$^+$ (15.7) is significantly lower than in **B**. We now report the first stable and fully characterized diamido rhodates(1−) and some of their properties. Interestingly, we observe different aggregates between the countercation, [M(solv)$_n$]$^+$ (solv = solvent molecules), and the diamido rhodate(1−) anion.

For this purpose, we used the chiral tetrachelating amino olefin (S,S)-N,N′-bis(5H-dibenzo[a,d]cyclohepten-5-yl)-1,2-diphenyl-1,2-ethylenediamine ((S,S)-trop$_2$dpen = (S,S)-**1**)[6] as ligand (Scheme 2). The reaction of ligand (S,S)-**1** with [Rh(cod)$_2$]OTf was straightforward and gave the orange-red

complex (λ_{max} = 470 nm) (S,S)-**3**. When an orange solution of (S,S)-**3** in THF was treated with one equivalent of KOtBu, the solution immediately turned red to furnish the amide (S,S)-**4** quantitatively. This compound was not isolated but was characterized by NMR and UV/Vis spectroscopy, which show that it is very similar to **C** (see Table 1 for selected data). Subsequently, (S,S)-**4** was further deprotonated under different reaction conditions: a) in THF, b) in the presence of three equivalents of [18]crown-6 (18C6), and c) in the presence of [2.2.2]cryptand (C222) (see Scheme 2). In case (a), an
Scheme 2. Synthesis of the amidorhodium(I) complex (*S*,*S*)-**4**, and the various ion pairs (*S*,*S*)-**5 hip**, (*S*,*S*)-**5 cip**, and (*S*,*S*)-**5 sip**.

intensely deep red solution was obtained. In cases (b) and (c), deep green solutions were obtained. Double deprotonation of (*S*,*S*)-**3** in DMSO as solvent with two equivalents of KO*t*Bu also gave green solutions. The ¹H NMR spectra indicated in each case, that the doubly deprotonated diamido rhodate(1−), (*S*,*S*)-[Rh(trop₂dpen−2H)]⁻ was obtained.

The products obtained under the conditions a)–c) in Scheme 2 were crystallized and the results of the X-ray diffraction studies are displayed in Figures 1–3, respectively.[7] From experiment (a), dark red crystals of the composition (*S*,*S*)-{K[Rh(trop₂dpen−2H)](thf)₃}, (*S*,*S*)-**5 hip**, precipitated (>80% yield) after the reaction mixture had been layered with *n*-hexane. From experiments (b) and (c), dark green needles of the composition (*S*,*S*)-{[K(18C6)(thf)][Rh(trop₂-dpen−2H)]}·0.5 Et₂O, (*S*,*S*)-**5 cip**, and (*S*,*S*)-[K(C222)][Rh(trop₂dpen−2H)]·Et₂O·1.5 THF, (*S*,*S*)-**5 sip**, were obtained from solutions of the respective complexes in THF layered with Et₂O (≥80% yield).

The structure of (*S*,*S*)-**5 hip** is best described as an electrostatically enforced host–guest complex,[8] in which the cationic [K(thf)₃]⁺ fragment is embedded in the ligand framework of the anion (see Figure 1b). The potassium ion has short contacts to the rhodium(I) atom, one amide nitrogen atom, one hydrogen atom in the ethylene bridge, and four carbon atoms of one of the adjacent benzo rings (see

Figure 1a). Such arene–potassium interactions were recently proposed to account for the performance of ruthenium(II) amides as hydrogenation catalysts.[9] Note that the coordination of the K⁺ ion to N2 causes the Rh−N2 bond (2.030(2) Å) to be significantly longer and the N2 coordination sphere to be more pyramidal (sum of angles $\Sigma° = 340.0(2)°$) compared to N1 which binds at a remarkable short distance (1.955(2) Å) to Rh and resides in an almost planar coordination sphere ($\Sigma° = 358.8(2)°$).

In the crown-ether complex (*S*,*S*)-**5 cip**, the [K(18C6)(thf)]⁺ and [Rh(trop₂dpen−2H)]⁻ form a loose contact ion pair; the potassium ion binds at about 3.2 Å in an η²-fashion to one benzo group from the outside of the anion (Figure 2). In the two crystallographically independent molecules in (*S*,*S*)-**5 cip** the slightly shorter Rh−N bond lengths (1.968(4) Å) correlate with a larger sum of bond angles $\Sigma°(N) = 354.5°$ ($\Sigma°(N) = 344.1°$ for the longer Rh−N distances, 1.994(4) Å; averaged data).

In [K(C222)][Rh(trop₂dpen−2H)]·Et₂O·1.5 THF, (*S*,*S*)-**5 sip** (Figure 3), the potassium ion has no direct contact to the anion and is encapsulated by the [2.2.2]cryptand. A "free" diamido rhodate(1−) ion is observed with short Rh−N distances (1.984(3) Å) and flattened coordination spheres at N1 and N2 ($\Sigma°(N) = 349.1(3)°$) compared to the situation in (*S*,*S*)-**3** (R−N 2.09 Å, $\Sigma°(N) = 341.2°$). Taking the average over all structures, the Rh−N distance to an amido nitrogen atom, NR₂, is about 5% shorter than to an amino nitrogen atom, NR₃.

Figure 4 shows the UV/Vis spectra of the cationic complex (*S*,*S*)-**3**, the neutral rhodium amide (*S*,*S*)-**4**, the

filling model of (*S,S*)-**5 cip**.

intimate ion pair (*S,S*)-**5 hip**, and the diamido rhodate(1−) salt
(*S,S*)-**5 sip** in THF. Note the progressively red-shifted absorp-
tion λ_{max} in the series: (*S,S*)-**3**→(*S,S*)-**4** ($\Delta\lambda_{max} \approx 40$ nm), (*S,S*)-
4→(*S,S*)-**5 hip** ($\Delta\lambda_{max} \approx 40$ nm), and (*S,S*)-**5 hip**→(*S,S*)-**5 sip**
($\Delta\lambda_{max} \approx 50$ nm).

We believe that the deep red color ($\lambda_{max} = 545$ nm)
characterizes the host–guest ion pair (*S,S*)-**5 hip**. Furthermore
we assume that (*S,S*)-**5 cip** and (*S,S*)-**5 sip** both dissociate in
solution and the green color ($\lambda_{max} = 598$ nm) indicates the
presence of the solvent separated "free" anion [Rh(trop$_2$-
dpen−2H)]$^-$. ^{1}H NMR spectroscopy did not allow us to
distinguish between both situations, but the ^{103}Rh NMR
resonance signal of a red solution of (*S,S*)-**5 hip** is observed at
$\delta = 580$ ppm, whereas the green solutions of (*S,S*)-**5 cip** and
(*S,S*)-**5 sip** showed $\delta(^{103}$Rh$) \approx 670$ ppm (Table 1).

A cyclic voltammogram (Pt electrode, 0.1M nBu$_4$NPF$_6$/
THF electrolyte at $T = 20$°C, scan rate 100 mV s^{-1}) of a green
solution of (*S,S*)-**5** in DMSO shows a reversible redox wave
for the process (1) at a remarkably low oxidation potential
(−1.09 V, versus Fc$^+$/Fc):

in solution in THF.

(*S,S*)-**3**, (*S,S*)-**4**, (*S,S*)-**5 hip**, and (*S,S*)-**5 sip** (Table 1) can be
interpreted within the concept of filled/filled repulsions
(FFR) elegantly developed by Caulton (see Figure 5).[10,11]

In a pentacoordinate 18-electron rhodium amide **I**, the
lone pair at the amide nitrogen atom undergoes a strong and
repulsive two-center–four-electron interaction with the occu-
pied d$_{xz}$ orbital at the metal center. This orbital is directed
towards the filled p-type orbital at the nitrogen center and is

Communications
Figure 5. Schematic diagram showing the interaction of filled metal located and filled nitrogen located orbitals in a pentacoordinate 18-electron amido complex **I**, a tetracoordinate 16-electron amino amido complex **II**, and a bisamido complex **III** [filled/filled repulsion (FFR) model]. Only the energetically high-lying antibonding orbital interactions based on extended Hückel calculations are presented.

only slightly perturbed by the olefins which lie in the nodal plane (see Figure 5a). In a tetracoordinate 16-electron amino amido complex **II**, the lone pair at N also suffers from a repulsive interaction (seen in the red shift of λ_{max} in (S,S)-**4** compared to that in (S,S)-**3**). However, less so because the filled d_{xz} and d_{yz} orbitals at the metal center are involved in M→L back-bonding into the π^*(C=C) orbitals and are polarized towards the coordinated olefins (see Figure 5b). In that respect, the coordinated olefins contribute to the remarkable stability of late transition metal. Consequently, the strongly destabilized amide **I** is easy to oxidize and the NH function in its conjugated acid has a low acidity (large pK_a). On the other hand, the pK_a value of the NH function of a 16-electron amine complex such as (S,S)-**3**, which gives amide (S,S)-**4** upon deprotonation, is more acidic (by approximately four orders of magnitude). However, double deprotonation of a diamino complex to give a diamido complex **III** gives rise to two destabilizing interactions between the nitrogen lone pairs and the filled d_{xz} and d_{yz} orbitals at the metal center (see Figure 5c). Consequently, λ_{max} is red-shifted to about 600 nm in compounds of type **III**. The facile oxidation of **III** can be taken as a further indication of this destabilization. The pK_a value of the NH function in the amine amide complex of type **II** falls in the region $(21 < pK_a^{DMSO} < 23)$.[12] In the host–guest ion pairs, the destabilizing interaction is diminished (blue shift of λ_{max} $((S,S)$-**5sip**→(S,S)-**5hip**) by about 50 nm) because of the interaction of the nitrogen lone pair with the potassium cation.

Caulton's FFR concept qualifies nicely as a model to interpret the results presented here with a set of structurally very closely related and rare dialkylamine/amide complexes. On the other hand, the fact that the NH functions in d^8 rhodium complexes are remarkably acidic[13] (note that the diamide (S,S)-**5** is even stable in presence of small amounts of methanol or water) and that the Rh–N bond shortens upon deprotonation must await a more deep-sighted (computational) analysis.

Experimental Section

General: Solvents were freshly distilled under argon from sodium/benzophenone (THF, Et$_2$O) or from sodium/diglyme/benzphenone (n-hexane). Air-sensitive compounds were stored and weighed in a glovebox (Braun MB 150 B-G system), and reactions on small scales were performed directly in the glovebox. NMR spectra were recorded on Bruker Avance 400 or 500 systems. The chemical shifts are given as δ values and were referenced against tetramethylsilane (TMS) for ^{1}H and ^{13}C. ^{103}Rh NMR spectra were calibrated with the frequency reference $\Xi = 3.16$ MHz. IR spectra were measured with the attenuated total reflection technique (ATR) on a Perkin-Elmer 2000 FT-IR spectrometer in the range from 4000 cm^{-1} to 600 cm^{-1} using a KBr beam splitter. The UV/Vis spectra were measured with a Perkin-Elmer UV/Vis/NIR Lambda 19 spectrometer in 0.5-cm quartz cuvettes.

(S,S)-{K[Rh(trop$_2$dpen−2H)](thf)$_3$} ((S,S)-**5hip**): To an orange solution of (S,S)-[Rh(trop$_2$dpen)]SO$_3$CF$_3$ ((S,S)-**3**) (84 mg, 0.10 mmol) in THF (2 mL) was added KOtBu (25 mg, 0.22 mmol). The color turned immediately to dark red and the solution was layered with n-hexane (10 mL). Dark red crystals of (S,S)-**5hip** (80 mg, 0.84 mmol; 84%) suitable for x-ray structure analysis grew overnight. M.p. > 130°C (decomp); ^{1}H NMR (400.1 MHz, [D$_8$]THF): $\delta = 3.30$ (d, $^3J_{H,H} = 8.9$ Hz, 2H; CH$_{olefin}$), 3.91 (s, 2H; CH(Ph)(N)), 4.21 (d, $^3J_{H,H} = 8.9$ Hz, 2H; CH$_{olefin}$), 4.35 (s, 2H; CH$_{benzyl}$), 6.60–7.03 (m, 22H; CH$_{ar}$), 7.37–7.45 ppm (m, 4H; CH$_{ar}$); ^{13}C NMR (100.6 MHz, [D$_8$]THF): $\delta = 68.4$ (br, CH$_{olefin}$), 70.8 (CH$_{benzyl}$), 74.5 (d, $^1J_{Rh,C} = 13.0$ Hz; CH$_{olefin}$), 83.4 (CH(Ph)(N)), 123.6–129.0 (CH$_{ar}$), 141.1–148.2 ppm (C$_{quart}$); ^{103}Rh NMR (12.7 MHz, [D$_8$]THF): $\delta = 577$ (s); ATR-IR (neat): $\tilde{\nu} = 3061$ w, 2972 m, 2866 m, 1594 m, 1482 m, 1466 s, 1404 m, 1259 m, 1052 s, 1016 m, 896 m, 750 s, 699 s cm^{-1}; UV/Vis (THF): λ_{max} (ε) = 545 (2210), 339 (7760), 277 nm (25680).

(S,S)-{[K([18]crown-6)(thf)][Rh(trop$_2$dpen)]} ((S,S)-**5cip**): To an orange solution of (S,S)-[Rh(trop$_2$dpen)]SO$_3$CF$_3$ ((S,S)-**3**) (84 mg, 0.10 mmol) in THF (2 mL) was added KOtBu (25 mg, 0.22 mmol) followed by [18]crown-6 (79 mg, 0.3 mmol). The resulting dark green solution was layered with Et$_2$O. Dark green crystals of (S,S)-**5cip** (101 mg, 0.080 mmol; 80%) grew overnight. M.p. > 155°C (decomp); ^{1}H NMR (400.1 MHz, [D$_8$]THF): $\delta = 3.08$ (d, $^3J_{H,H} = 8.9$ Hz, 2H; CH$_{olefin}$), 3.53 (m, 24H; OCH_2CH_2O), 3.96 (s, 2H; CH(Ph)(N)), 3.99 (d, $^3J_{H,H} = 8.9$ Hz, 2H; CH$_{olefin}$), 4.27 (d, $^3J_{Rh,H} = 1.8$ Hz, 2H; CH$_{benzyl}$), 6.56–6.59 (m, 4H; CH$_{ar}$), 6.67–6.94 (m, 18H; CH$_{ar}$), 7.30 (d, $^3J_{H,H} = 7.4$ Hz, 2H; CH$_{ar}$), 7.35 ppm (d, $^3J_{H,H} = 7.4$ Hz, 2H; CH$_{ar}$); ^{13}C NMR (100.6 MHz, [D$_8$]THF): $\delta = 67.6$ (d, $^1J_{Rh,C} = 10.5$ Hz; CH$_{olefin}$), 70.5 (OCH_2CH_2O) 71.3 (CH$_{benzyl}$), 73.5 (d, $^1J_{Rh,H} = 12.8$ Hz, CH$_{olefin}$), 84.6 (CH(Ph)(N)), 122.4–129.7 (CH$_{ar}$), 142.3–148.6 ppm (C$_{quart}$); ^{103}Rh NMR (12.7 MHz, [D$_8$]THF): $\delta = 665$ ppm (s); ATR-IR (neat): $\tilde{\nu} = 2879$ m, 1593 w, 1480 w, 1463 m, 1349 m, 1246 s, 1099 s, 960 m, 835 m cm^{-1}; UV/Vis (THF): λ_{max} (ε) = 598 (2420), 412 (8310), 339 (15360), 275 nm (26370).

(S,S)-{[K(C222)][Rh(trop$_2$dpen−2H)]} ((S,S)-**5sip**): To an orange solution of (S,S)-[Rh(trop$_2$dpen)]SO$_3$CF$_3$ ((S,S)-**3**) (32 mg, 0.038 mmol) in THF (0.5 mL) was added KOtBu (9 mg, 0.08 mmol, 2.1 equiv) followed by [2.2.2]cryptand (30 mg, 0.08 mmol, 2.1 equiv). The resulting dark green solution was layered with Et$_2$O (2.5 mL). Dark green crystals of (S,S)-**5sip** (41 mg, 0.031 mmol; 80%) grew overnight. Crystal structure of (S,S)-**5cip**: Dark green single crystals were obtained from a THF/Et$_2$O solution at room temperature; $C_{120}H_{132}K_2N_4O_{14}Rh_2 \cdot Et_2O$, monoclinic, space group $P2(1)$; $a = 12.842(1)$, $b = 23.010(1)$, $c = 18.969(1)$ Å, $\beta = 101.780(1)°$; $V = 5487.1(5)$ Å^3; $Z = 2$; $\rho_{calcd} = 1.339$ Mg m^{-3}; crystal dimensions $0.60 \times 0.32 \times 0.30$ mm; diffractometer Bruker SMART Apex; Mo$_{K\alpha}$ radiation, 200 K, $2\Theta_{max} = 52.74°$; 40465 reflections, 21957 independent ($R_{int} = 0.0285$), direct methods; empirical absorption correction SADABS (ver. 2.03); refinement against full matrix (versus F^2) with SHELXTL (ver. 6.12) and SHELXL-97, 1326 parameters, 1 restraint, R1 = 0.0457 and wR2 (all data) = 0.1124, max./min. residual electron density 0.775/−0.429 e Å^{-3}. Crystal structure of (S,S)-**5 sip**: Dark green single crystals were obtained from a THF solution which was layered with Et$_2$O at room temperature; $C_{124}H_{140}K_2N_8O_{12}Rh_2 \cdot 3\,THF \cdot 2\,Et_2O$, triclinic, space group $P1$; $a = 12.078(1)$, $b = 14.324(1)$, $c = 21.272(2)$ Å, $\alpha = 80.882(1)$, $\beta = 85.728(2)$, $\gamma = 68.406(1)°$; $V = 3378.1(5)$ Å^3; $Z = 1$; $\rho_{calcd} = 1.270$ Mg m^{-3}; crystal dimensions $0.54 \times 0.48 \times 0.47$ mm; diffractometer Bruker SMART CCD1k; Mo$_{K\alpha}$ radiation, 200 K, $2\Theta_{max} = 56.50°$; 28372 reflections, 25863 independent, direct methods; empirical absorption correction SADABS (ver. 2.03); refinement against full matrix (versus F^2) with SHELXTL (ver. 6.12) and SHELXH-97, 1508 parameters, 22 restraints, R1 = 0.0424 and wR2 (all data) = 0.1106, max./min. residual electron density 0.660/−0.618 e Å^{-3}. For all reported x-ray crystal structures the non-hydrogen atoms were refined anisotropically. Only one carbon atom of a Et$_2$O solvent molecule in (S,S)-**5 sip** had to be refined using the ISOR restraint. The contribution of the hydrogen atoms, in their calculated position, was included in the refinement using a riding model. Upon convergence, the final Fourier difference map showed no significant peaks. CCDC-267206 ((S,S)-**5hip**), CCDC-267207 ((S,S)-**5cip**), and CCDC-272867 ((S,S)-**5sip**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

[8] Because the coordination sphere of the unsaturated [K(thf)$_3$]$^+$ fragment is completed by direct and close contacts within the cavity of the [Rh(trop$_2$dpen−2H]$^-$ ion, we denote (S,S)-**5hip** as a *host–guest* ion *p*air held together by electrostatic forces. Similarly, (S,S)-**5cip** is considered as *c*ontact ion *p*air because the one open coordination site in the [K(18C6)(thf)]$^+$ ion is completed by one contact with the anion, however, outside of its cavity. The ion pair (S,S)-**5 sip** is denoted as a *s*eparated ion *p*air because of the lack of a direct contact between the potassium ion and the anion although the cryptand penetrates the anion in the solid state. For further definitions see, G. Boche, *Angew. Chem.* **1992**, *104*, 742; *Angew. Chem. Int. Ed. Engl.* **1992**, *31*, 731, and references therein. Communications

A Helical Molecule That Exhibits Two Lengths in Response to an Applied Potential[**]

*Kazuya Kitagawa, Tomoyuki Morita, and Shunsaku Kimura**

Molecular devices are expected to play an important role in advanced electronics in the form of molecular diodes,[1] molecular transistors,[2] and molecular switches.[3] However, the electron-transfer mechanism of organic molecules on metal surfaces—the most fundamental aspect of molecular devices—still awaits elucidation.[4–6] In an effort to shed light on this issue, we applied helical peptides as mediators for long-range electron transfer,[7] a scaffold for chromophores to accelerate electron transfer,[8] and a viable system for molecular photodiodes.[9]

Stochastic on–off switching phenomena of molecular conductance in organic molecules have been observed in numerous cases through careful observation by scanning tunneling microscopy (STM).[10–13] These phenomena are considered to be caused by fluctuations in the hybridization of the sulfur atom that accompanies the change in molecular orientation. Our focus is on the use of this mechanism in a molecular memory device, because one bit may be recognized by a change in molecular length. For this purpose, however, the molecule should be able to exhibit two distinct lengths in response to outer stimuli. Herein, we propose helical peptides as an appropriate system for the controlled switching of molecular length on a bulk substrate.

Peptides that contain α-aminoisobutyric acid (Aib) have the unique ability to adopt two different helical structures: an α-helical conformation with a short overall length (1.5 Å for each amino acid residue) and a longer 3_{10}-helical conformation (2.0 Å for each amino acid residue).[14,15] Whereas Boc-(Ala-Aib)$_4$-OCH$_3$ in crystalline form has been reported to adopt a 3_{10}-helical structure, crystals of Boc-(Ala-Aib)$_8$-OCH$_3$ favor an α-helical structure (Boc = *tert*-butoxycarbonyl).[16] This suggests that an intermediate-length dodecapeptide could have dual α-helical and 3_{10}-helical character. The critical chain length which determines the favored helix type may be an octapeptide, because *para*-bromobenzoyl-

(Aib-Ala)$_4$-OCH$_3$ forms an α helix in the crystalline state.[17] However, the critical chain length is expected to be longer (10 or 12 residues) for the present case, in which the peptides immobilized on gold are examined in air or under ultrahigh vacuum (UHV) because less-polar media tends to favor the formation of 3_{10} helices in peptides, whereas media of higher polarity favors the α-helical conformation, as discussed previously.[16]

In an earlier study, we succeeded in single-molecule observations of upright helical peptides incorporated into an alkanethiolate self-assembled monolayer (SAM) by STM.[18] Notably, these helical peptides display a large dipole moment parallel to the helical axis from the C terminus to the N terminus. Therefore, such peptides should be responsive to an applied electric field. Figure 1a illustrates our experimental design with a helical peptide in which the molecular length is modulated with the applied bias. The helical dodecapeptide is immobilized to the gold surface by the N terminus to expose the negatively charged C terminus at the top. The peptide can be contracted to the α helix by placing the STM tip of negative potential on the peptide C terminus. Alternatively, the peptide favors the 3_{10}-helical conformation by the extension force of the STM tip bearing a
Figure 1. a) Conformational change of a dodecapeptide immobilized onto a gold surface by the N terminus. α Helices and 3_{10} helices are stabilized by applying a positive (left) and negative (right) bias, respectively. b) Structures of the two dodecapeptides used for the work reported herein.

positive potential. Indeed, we observed conductance switching for the first time in which the apparent molecular lengths are altered as a function of the polarity of the applied bias through the use of the two helical dodecapeptides (Figure 1 b). For the experiments reported herein, benzyl ester was used instead of *tert*-butyl ester as the protecting group for the C terminus of the SL12B peptide for synthetic purposes. However, as the size of benzyl ester of SL12B is similar to that of a Boc group in the BL12S peptide, the different terminating groups are not expected to affect the length of the peptides on the substrate.

Conformational energies of the peptide Ac-(Leu-Aib)$_n$-OCH$_3$ ($n = 4, 6, 8$) in α-helical and 3$_{10}$-helical conformations are calculated semiempirically. The heats of formation (kcal mol^{-1}) are indicated in the parentheses as follows: Ac-(Leu-Aib)$_4$-OCH$_3$ α helix (-491.759), 3$_{10}$ helix (-492.390); Ac-(Leu-Aib)$_6$-OCH$_3$ α helix (-699.056), 3$_{10}$ helix (-697.146); Ac-(Leu-Aib)$_8$-OCH$_3$ α helix (-907.733), 3$_{10}$ helix (-902.486). The dodecapeptide with the intermediate length exhibits a small energy difference between the α-helical and 3$_{10}$-helical conformations, which suggests that there is facile exchange between the two helical types.

Characterizations of BL12S in solution and in SAMs on gold were carried out similarly to those of the previous report on SL12B.[18] Circular dichroism (CD) studies of BL12SAc in 2,2,2-trifluoroethanol and reflection–absorption spectroscopy (RAS) of the BL12S SAM revealed its α-helical conformation. From the RAS spectrum, the tilt angle of the helical axis from the surface normal was calculated to be 45° (Supporting Information).[7,9,19,20]

We previously observed single molecules or bundles of SL12B incorporated into dodecanethiolate (C$_{12}$) SAMs as bright spots by STM under UHV.[18] BL12S in a C$_{12}$ SAM is also observed as bright spots (Figure 2 a). Notably, time-resolved STM images of the BL12S molecules clearly show switching. Each circle shown in Figure 2 a represents a fixed observation point for the peptide helices. Peptides are observed as bright spots with apparent length differences of 5 Å from the surrounding dodecanethiolate SAM surface (ON state). However, these protrusions stochastically disappeared (OFF state) and reappeared (ON state) over a time span of three to four hours.

The effect of the density of the surrounding alkanethiolate matrix on switching was examined.[10,13] Dodecanethiolate molecules were found to desorb from the gold surface if SAMs were left under UHV ($\approx 10^{-8}$ Pa) for a long period even at room temperature which resulted in a rearrangement of the SAM surface structure.[21] Figure 2 b shows a series of STM images of the SL12B/C$_{12}$ SAM after leaving the sample under UHV for a long period. The striped pattern of the matrix monolayer is clearly observable, indicating that the C$_{12}$ molecules lie down on the surface owing to low surface coverage. Under these conditions, the molecular motion of the peptides is allowed more freedom than that of tightly packed peptides in freshly prepared SAMs. The switching behaviors shown in Figure 2 b, however, occur at a frequency similar to those shown in Figure 2 a; these stochastic switching data are summarized in Table 1. The average number of switching events is nearly the same for the loosely packed
Figure 2. a) STM images of BL12S incorporated into the dodecanethiolate SAM. Images were obtained at a sample bias of 1.4 V and a setpoint current of 2.5 pA. b) STM images of SL12B incorporated into the dodecanethiolate SAM after leaving the sample under UHV for a long period (several days). Images were obtained at a sample bias of -1.3 V and set-point current of 5.0 pA.

Table 1: Summary of stochastic conductance switching events.

| Parameter | Peptide | | | |
	SL12B		BL12S	
Alkanethiol density	tight	loose	tight	loose
Number of samples	9	6	6	9
Observation time [min]	305	306	207	211
Total number of switching events[a]	36	27	19	14
Average number of switching events [min^{-1} (500×500 nm^{-2})]	0.50	0.85	0.55	0.47

[a] The total number of switching events was counted by all changes from ON to OFF and vice versa observed in the STM images between the two successive scans. Each scan required an average of ≈ 6 min. With an observation time of 305 min, ≈ 50 images were recorded.

SAM as it is for the tightly packed SAM. The surrounding C$_{12}$ molecules do not influence the switching behavior, which suggests that the apparent length change is not a result of the change of the molecular orientation as has been reported for oligo(phenylene ethynylene) groups in alkanethiolate SAMs.[10,13]

The variation of the apparent molecular length of BL12S is plotted as a function of time (Figure 3 a). The dodecapep-
Figure 3. a) Time-lapse STM images (first image, upper left; final image, lower right) of BL12S peptide molecules incorporated into the dodecanethiolate SAM; conditions are the same as those reported in Figure 2. b) Measured molecular length (*l*) for each image in part a).

tide shows two apparent molecular lengths, and the switching occurs stochastically in transition between these two states. As the dodecapeptide is allowed to take both α-helical and 3_{10}-helical conformations, the two states may be explained by an α helix representing the ON state, and a 3_{10} helix corresponding to the OFF state. This interpretation is supported strongly by the length difference of 5 Å between the two states (Figure 3b), which is in agreement with the molecular-length difference between an α helix and a 3_{10} helix.

Because both helix types display a large dipole moment along the helical axis,[22] it is expected that the polarity of the applied voltage between the STM tip and the gold substrate influences the STM image of the peptides.[23,24] BL12S was observed by STM under application of the positive sample bias as described above. When the sample bias was inverted from positive to negative, the bright spots of BL12S disappeared within a few scans, but they reappeared with a return to the positive bias (Figure 4a).

If the interaction of the peptide dipole moment with the applied electric field is the origin of this conductance switch-

ing, then SL12B, which has an orientation opposite to that of BL12S and which was immobilized to the gold surface by the N terminus, should also show switching behavior, but with the opposite response to the applied bias polarity. Figure 4b shows the bias dependence of the STM images of SL12B. Indeed, SL12B helices were observed as bright spots at the negative sample bias, but nearly all peptides apparently disappeared from the STM image at the positive bias. Taken together, the dodecapeptides take on a physically elongated state upon application of an electric field in accordance with the direction of the dipole moment. The peptide adopts physically shortened state if the applied electric field is opposite in direction to the dipole moment. It is speculated that under a parallel electric field, the peptides are most stable in a 3_{10}-helical conformation (elongated), and under an opposing electric field direction, the peptides are most stable in an α-helical conformation (shortened; Figure 1a).
The dependence of helical peptide conductivity on the applied bias polarity was further investigated by scanning tunneling spectroscopy (STS) at 77 K. Current–voltage (*I–V*) curves of the C_{12} molecules and the peptide helices in the SAMs are shown in Figure 5. The *I–V* curve of the matrix C_{12}
Figure 5. Current–voltage (*I–V*) curves of dodecanethiolate (thin dotted line), BL12S (thick dotted line), and SL12B (thick solid line) acquired at the temperature of liquid nitrogen (77 K). The lines represent the average of 20–30 individual responses.

molecules shows a featureless monotonic increase in the range from −2 to +2 V.[25,26] On the contrary, asymmetric *I–V* responses are observed for the helices. In the case of BL12S, the current increased more dramatically at the positive sample bias than at the negative bias. On the other hand, the current through SL12B increased more strongly at the negative bias than that at the positive bias. Both results indicate that the current through the helix is enhanced by applying the bias voltage such that the direction of the electric field coincides with the helical dipole moment. Therefore, the *I–V* characteristics of the helices also support the interpretation that the helix dipole moment interacts with the external electric field to convert between α-helical and 3_{10}-helical conformations.

In conclusion, we observed conductance switching of peptide helix bundles by STM. The conductance and the

Figure 4. Sequential STM images of a) BL12S (set-point current of 4.5 pA) and b) SL12B (set-point current of 5.0 pA) incorporated into the dodecanethiolate SAM with alternation of the polarity of the applied sample bias voltage.

apparent molecular length were observed to undergo stochastic changes with time. The conductance of the helix alternated between two states by changing the polarity of applied bias. This novel behavior can be explained by the conformational change between an α helix and a 3_{10} helix. The helical structure is influenced by the applied electric field as a result of the interaction with the large dipole moment of the helix. This means that the apparent molecular length can be regulated by an external stimulus. The precise control of the switching of the helices is now under investigation.

Peptide Conformations

Effect of C-Terminal Amidation on Folding and Disulfide-Pairing of α-Conotoxin ImI**

*Tse Siang Kang, Subramanian Vivekanandan, Seetharama D. S. Jois, and R. Manjunatha Kini**

α-Conotoxins are disulfide-rich neurotoxins isolated from the venom of the marine predatory cone snail. These structurally compact toxins form well-ordered three-dimensional structures through the formation of two crucial disulfide bridges. All currently identified members of the α-conotoxin family exhibit a highly conserved four-cysteine framework, with an absolute preference for folding into the globular form (C1–C3, C2–C4) as the native conformation.[1–3] They specifically bind to nicotinic acetylcholine receptors. Recently, a new family of χ/λ-conotoxin was identified and shown to have conserved the positions of the cysteine residues characteristic of α-conotoxins. However, χ/λ-conotoxins revealed an alternative disulfide-pairing pattern (C1–C4, C2–C3) that results in the ribbon conformation[4–6] and distinct biological activity such as inhibition of the noradrenaline transporter by MrIA conotoxin.[6] Functional assays with the non-native conformations of both α-conotoxin and χ/λ-conotoxin resulted in a tenfold and three-order decrease in activities, respectively.[4,7]

These results indicate that the disulfide pairing and the consequent conformation play a crucial role in the biological potencies of native toxins. To identify the structural features that determine specific disulfide pairing, we analyzed the amino acid sequences of α-[8–19] and χ/λ-conotoxins.[4–6] The α-conotoxins, with the exception of GID conotoxin, have a conserved C-terminal amide, whereas all members of χ/λ-conotoxins bear a free carboxylic acid at the C terminus. Herein we report the influence of C-terminal amidation in the determination of the folding tendencies of ImI α-conotoxin in vitro.

Oxidation of the synthetic ImI conotoxin (termed ImI amide) and the corresponding deamidated analogue (termed ImI acid) was conducted in either folding buffer (100 mM Tris-HCl, 2 mM EDTA, pH 8.5) or denaturant buffer (100 mM Tris-HCl, 2 mM EDTA, 6 M GndCl, pH 8.5) by oxidation with air and a glutathione redox system (Gnd = guanidinium; for detailed protocols, see the Supporting Information). Upon oxidation, each of the synthetic variants folded into three monomeric isoforms that correspond to the three peaks observed in the HPLC chromatograms. Each band contained peptides that were completely oxidized as was verified by a decrease by four mass units, which corresponds to the formation of two disulfide bridges (1351.35 ± 0.47 Da and 1352.65 ± 0.04 Da for ImI amide and ImI acid, respectively). The folding experiments conducted in the presence of redox systems also generated isoforms in similar proportions (Table 1).

Table 1: Oxidation studies of peptide analogues under folding and denaturant conditions.[a]

| | % Total oxidized peptides | | |
	Globular	Ribbon	Beaded
A) Folding buffer			
ImI amide	54.0 ± 0.4	43.0 ± 1.0	3.0 ± 0.6
	(52.1 ± 0.1)	(43.8 ± 0.4)	(4.0 ± 0.2)
ImI acid	30.1 ± 0.6	67.2 ± 0.4	2.7 ± 0.5
	(29.4 ± 0.3)	(67.9 ± 0.1)	(2.8 ± 0.2)
ImI Gly	40.3 ± 0.1	57.6 ± 0.1	2.1 ± 0.03
	(41.5 ± 0.3)	(54.0 ± 0.8)	(4.5 ± 0.5)
B) Denaturant buffer			
ImI amide	48.9 ± 0.1	39.7 ± 0.0	11.4 ± 0.1
	(48.3 ± 0.5)	(38.0 ± 0.4)	(13.7 ± 0.1)
ImI acid	37.6 ± 0.7	44.6 ± 1.8	17.8 ± 2.4
	(50.3 ± 0.3)	(39.8 ± 1.1)	(9.9 ± 0.1)

[a] The results shown in parentheses represent data acquired when the study was performed in the presence of a redox system.

The various isoforms were initially identified by comparison of the retention times of the conotoxin isoforms with the corresponding regiospecifically synthesized globular and ribbon conformations (Figure 1). The dominant isoform of ImI amide coelutes with the globular form. In contrast, the major isoform of the deamidated ImI acid has the same retention time as its ribbon conformation but not its globular form. In folding buffer, ImI amide shows a tendency to fold into the globular conformation. Substitution of the C-terminal amide to free carboxylic acid, however, resulted in
Figure 1. Chromatographic profiles of ImI conotoxin analogues. Comparison of the retention times for the dominant isoform of A) ImI amide B) ImI acid, and C) ImI Gly, with the corresponding regioselectively synthesized isoforms.

a switch in folding preference of ImI acid to that of the ribbon conformation. Thus, it appears that C-terminal amidation plays a pivotal role in the folding tendencies of ImI conotoxin.

In the presence of a denaturant, the overall folding tendencies remained the same as when the peptides were oxidized with air. However, the amounts of disfavored beaded conformation in both variants were found to have increased, and the presence of guanidine resulted in a "normalizing" effect on the lead of the predominant isoform in both variants. We therefore concluded that side-chain interaction has a significant, but non-absolute, role in the folding to the final conformation of ImI peptides.

To further confirm the disulfide pairings and the folding of ImI amide and ImI acid isoforms, we determined their three-dimensional structure by NMR spectroscopy. Figure 2A shows the amide region in the 1D ^{1}H NMR spectrum of the dominant forms of the two variants. The 1D ^{1}H NMR spectrum of the major isoform of ImI amide matches well with that of the force-folded globular conformation. Con-

Figure 2. Structural differences between ImI amide and ImI acid. A) Comparison of 1D NMR spectra of the dominant isoforms of ImI amide and ImI acid with the corresponding globular or ribbon conformations. B) Sequential assignment of 2D NMR ROESY spectra of ImI amide (left) and ImI acid (right).

conformation of ImI acid with that of the native globular conformation of ImI conotoxin (PBD accession code 1G2G). Based on ^{1}H NMR spectra, the solution structure of the isoforms, as well as coelution profiles, we concluded that ImI amide folds predominantly into the globular conformation with C1–C3, C2–C4 disulfide pairings, whereas ImI acid folds preferentially into the ribbon conformation with C1–C4, C2–C3 disulfide pairings. Thus the C-terminal amide has been shown to play a very important role in the determination of the disulfide pairing and resultant protein folding in these two classes of short conotoxins.

Amidation is caused by post-translational oxidative cleavage of a C-terminal glycine residue, and hence we also examined the folding of the precursor peptide with a further C-terminal glycine (termed ImI Gly). ImI Gly, with its free carboxylic acid, folded predominantly into a ribbon conformation (Table 1). Thus, the presence of a negatively charged group appears to favor the ribbon conformation even in the presence of a further C-terminal residue. Although the three sets of peptides fold into different predominant isoforms, the excess of one form over the other is not drastically different, which therefore suggests that the folding may occur through independent pathways. Figures 3C and D show the proposed hydrogen-bonding interactions of the C-terminal regions of ImI amide and ImI acid, respectively. These noncovalent interactions were derived from the averaged 3D structures calculated. The two variants exhibit distinct hydrogen-bonding patterns. It is not clear whether *cis–trans* isomerization of proline or the postulated hydrogen bonds contribute to these folding pathways.

versely, the 1D ^{1}H NMR spectrum of the major isoform of ImI acid corresponds well to that of its ribbon form.

2D ^{1}H NMR spectroscopic experiments for ImI amide and ImI acid yielded good-quality spectra. The TOCSY spectrum obtained for ImI amide was similar to that reported earlier,[20] and the 88 distance constraints derived from its ROESY spectrum fitted well with the reported structure of ImI conotoxin. The 2D NMR ROESY spectrum for ImI acid yielded 110 distance constraints of which the presence of a strong αH–δH ROE between Asp5–Pro6 suggests a *trans* peptide bond between these two residues. Identification of the CβH–CβH ROEs between Cys3–Cys8 and Cys2–Cys12 is indicative of the disulfide-pairing characteristic of the ribbon conformation. The amide regions of the ROESY spectra revealed distinct chemical shift patterns between the globular form of ImI amide and the ribbon conformation that was seen with ImI acid (Figure 2B). Significant differences in chemical shift were observed despite the similarity in amino acid sequences between the analogues. These spectra further support the theory that ImI amide folds preferentially into the globular form and ImI acid into the ribbon conformation.

Figure 3A shows the three-dimensional structure of ImI acid calculated from 2D NMR constraints, the statistics of which are shown in Table 2. The solution structure clearly indicates that ImI acid folds into the ribbon conformation. As the ^{1}H NMR spectra for ImI amide were similar to those reported earlier, we used the structure previously published.[21] Figure 3B shows the superimposition of the ribbon

In several earlier studies, a number of bioactive peptides in nature were shown to have undergone amidation at the C terminus. Such a modification has been shown to have a substantial impact on the biological activities of several of these peptides, presumably owing to the neutralization of negative charges conferred by the carboxylic acid at the C terminus.[22–26] In these cases, however, the C-terminal amide is not known to influence the conformation of the peptides. In earlier reports, post-translational modifications such as γ-carboxylation of glutamate residues have been shown to be important for the folding in P-superfamily

such a system is that when the small molecule simply bridges the protein components, the signaling event is only dependent on the presence or absence of that small molecule. A system in which control is exerted by an external electron transfer or a photochemical event would be more useful for nanotechnology applications. Extending the principle of electron-transfer-triggered folding reactions[17] and learning from natural heme-based sensors,[18,19] we sought to create a macromolecular assembly system that can be controlled by the electronic state of the small molecule — a step towards true electronic control of macromolecular assembly and function.

Previously, we constructed a novel protein that incorporates both cytochrome b_{562} (cyt b_{562}) and the DNA binding basic helix region (BHR) of the leucine zipper transcription factor (bZIP) GCN4.[20] This design created a protein capable of being assembled on a designated template (DNA) that could potentially both carry and control current flow. The novel DNA-binding cytochrome (DBC) exhibits spectral characteristics and heme affinity that is comparable to those of the parent cyt b_{562} and also has the ability to bind DNA sequences based around those recognized by GCN4. This new protein provides the starting point for the creation of a controllable protein-based assembly system in which the parent protein is split into two separate fragments. Each fragment contains one half of the heme binding site and one of the two DNA binding elements that is required for DNA recognition (Figure 1). The assembly of the two protein

Controlling Self-Assembly by Linking Protein Folding, DNA Binding, and the Redox Chemistry of Heme**

D. Dafydd Jones and Paul D. Barker*

Biological molecules are being used extensively as self-assembling materials for the "bottom-up" creation of useful nanoscale structures with non-natural functions.[1–3] New proteins have been created that form linear, branched, and meshed "wires",[4–6] recognize inorganic surfaces,[2,7] assemble and solubilize carbon nanotubes,[8,9] create molecular wires by the organization of conducting materials,[10,11] and generate organized protein networks.[6] As a result of these functions, the ability to control self-assembly processes through an external signal would be very useful. Allowing added ligand molecules to direct assembly is one such method and is used extensively in nature to switch conformational states which then regulates the associated activity. Artificial systems have also been designed in which a small molecule acts as the link between two separate protein components. The problem with

Figure 1. Schematic representation of each system component. The original DNA-binding cytochrome was fragmented to create bhrN12 (residues Met1 to Thr70) and 34Cbhr (residues Met84 to Arg156). DsNC1 is the optimum DNA binding sequence and corresponds to the DNA sequence 5′-caacgATGAcgATGAcggtt-3′ (capital letters designate the potential recognition site).

components is dependent on heme and/or DNA. The oxidation-state-dependent affinity of heme for protein can then be exploited to control the assembly, and conditions can be identified under which DNA binding could be controlled by electron-transfer reactions.

The original design of the single-molecule scaffold[20] has the BHR of GCN4, attached to the termini of the four-helix bundle of cyt b_{562}, thus creating a DBC. The design specifically arranges the conducting material (heme) on a template (DNA), and events that occur at the heme center can be transmitted to the DNA-binding region and vice versa, which

would allow the attenuation of current flow by DNA binding. The DBC binds to specific DNA sequences with a K_D value in the low nM range, but little change in DNA-binding affinity was observed in either the presence or absence of heme, and the affinity was seen to be independent of the oxidation state of heme. We have deconstructed the single protein to create two mutually compatible fragments, bhrN12 and 34Cbhr. Each of these contains one half of the heme-binding site together with one BHR that defines half of the DNA-recognition motif. The two residues that provide axial ligands to the heme iron center, Met7 and His102 (wild-type cyt b_{562} numbering), are separated into the two different molecules in this arrangement. The assembly of these two fragments can be driven by the binding of either heme or DNA and then regenerates an analogue of the original intact complex (Figure 1). The three classes of interaction that become thermodynamically linked in the assembly process are protein–protein, protein—DNA, and protein–heme interactions. As the latter is dependent on the oxidation state of heme, the oxidation state is therefore coupled to the DNA-binding process. The fragments should not self-assemble in the absence of heme or DNA, and the individual halves should not bind heme on their own but can have low affinity for DNA. (In the context of wild-type GCN4, a single BHR can bind its target DNA but with a much lower affinity than the dimeric forms.)[21,22]

In the wild-type cyt b_{562}, the dissociation constant for reduced heme is in the pM range, but rises to 10 nM when the heme is oxidized.[23] In the context of our fragments, the difference in free energy between the two states results in a redox-dependent complex assembly that can be used to influence DNA binding. Titration of bhrN12 and 34Cbhr with ferric heme (2 μM) revealed a low affinity for the cofactor (Figure 2a); $K_D > 27000$ nM ± 3000 is at least 1000-fold higher than that observed for the intact DBC.[20] Under reducing conditions, the bhrN12 and 34Cbhr fragments bind heme with an affinity ($K_D = 435$ nM ± 85 nM) much lower than that of the oxidized form (Figure 2b). In both oxidation states, the spectrum was identical to that of wild-type cyt b_{562}, and the DBC was observed on the addition of 5 equivalents of bhrN12 and 34Cbhr (relative to heme), indicating that the helical bundle had assembled correctly (Supporting Information).

Circular dichroism (CD) spectra of bhrN12 and 34Cbhr suggest that there is little helical structure present when the domains are separated (Supporting Information). Upon mixing of the two components, the CD spectra suggest that no additional structure is induced (Figure 3). The addition of either an equimolar (data not shown) or excess amount of oxidized heme to the mixture of the two proteins, however, results in significant changes in the CD spectrum. The shift in the wavelength of the minimum at 205 nm to 208 nm and the increase in ellipticity at 222 nm are consistent with large increases in the helical content as a result of complex formation. It was not possible to perform the same experiments with the reduced state of heme owing to the absorbance of the reductant required to keep the heme in the reduced state.

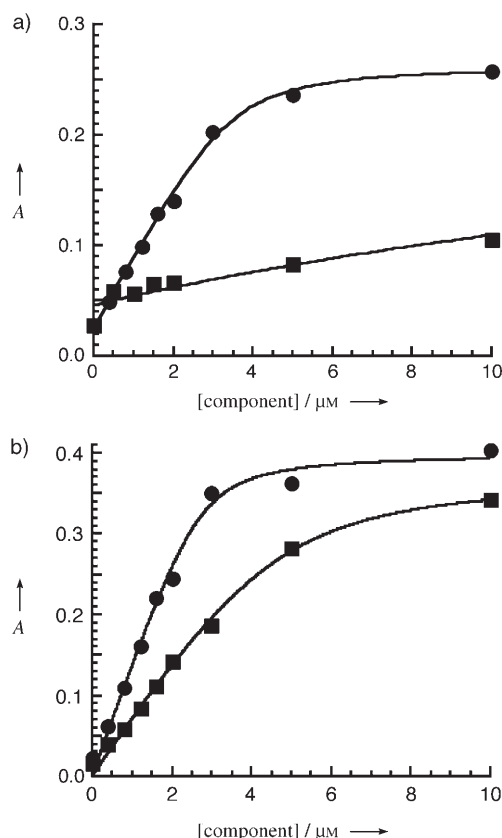
To determine if DNA can influence complex assembly, the optimum double-stranded DNA sequence for the chimera[20]


Figure 2. Determination of heme affinity for bhrN12 and 34Cbhr. Data were extracted at a) 417 nm (oxidizing conditions) and b) 427 nm (reducing conditions) in the absence (■) and presence (●) of dsNC1 DNA (Supporting Information). In all samples, heme concentration remains constant at 2 μM in tris-HCl (20 mM), pH 7.5. BhrN12 and 34Cbhr were titrated in equimolar amounts of 0.4, 0.8, 1.2, 1.6, 2.0, 3.0, 5.0, and 10 μM. When present, dsNC1 DNA was also at the same concentration as bhrN12 and 34Cbhr. Curve fitting was performed as described in the Supporting Information.
Figure 3. Effect of heme on the structure of the protein components. CD spectra of 5 μM each of bhrN12 and 34Cbhr in the absence of any ligand (◇) or in the presence of either 30 μM heme (▲), 5 μM dsNC1 DNA (×), or both 5 μM dsNC1 DNA and 5 μM heme (■). CD spectroscopy methods are outlined in the Supporting Information.

dsNC1 was employed to maximize potential binding. It has been observed that the presence of only one BHR region attached to either the N or C terminus of the intact cyt b_{562} does not promote tight, specific DNA binding.[20] However, the increase in helical content of the fragments in the presence of DNA (Supporting Information) suggests that both the bhrN12 and 34Cbhr fragments bind to DNA alone. This crucial difference should allow DNA to direct the assembly and so influence heme binding.

This is indeed the case, as in the presence of dsNC1 DNA, the affinity of bhrN12 and 34Cbhr for oxidized heme is 100-fold higher (K_D decreases to 207 nM $\pm$ 27) than in the absence of DNA (Figure 2). Under reducing conditions, DNA again increased the affinity of bhrN12 and 34Cbhr for heme, to give $K_D < 3$ nM, which is more than a 100-fold increase in affinity relative to that in the absence of DNA. It is therefore clear that DNA preassembles the bhrN12 and 34Cbhr fragments to generate a heme-binding site. In the presence of different DNA sequences (comparable length to dsNC1, but with no recognition site), tight binding of heme to the fragments was not observed, regardless of the oxidation state (data not shown). These observations suggest that specific DNA binding is required for optimum bundle-assembly enhancement and is reinforced by the changes observed in the CD spectra upon the addition of DNA to the protein fragments, which indicate an increase in helicity (Supporting Information). The increase in the helical signal is consistent with a coil-to-helix transition known to occur upon BHR binding DNA.[24] The CD spectrum in the presence of both DNA and heme together with bhrN12 and 34Cbhr indicates that further structural events occur when the complete quaternary complex is formed (Figure 3). The final spectrum in either oxidation state closely resembles that of the wild-type cyt b_{562}, which suggests that the core of the four-helix-bundle structures are very similar. The specific protein–protein interactions allow precise assembly of the complex thus deterring "off pathway" assembly events such as bhrN12 or 34Cbhr binding heme, despite the presence of the appropriate ligands (Supporting Information). The reduction potential of the DNA-bound, monomeric NCb_{562} protein is close to that of the wild-type cyt b_{562} (180 mV vs. normal hydrogen electrode at pH 7[25]). In general, the potential of cyt b_{562} is very sensitive to the electrostatic environment, and hence the heme bound species in the thermodynamic scheme (Figure 4) may have different reduction potentials. The electrochemical properties of these assemblies are complicated by multiple equilibria and are being studied by direct electrochemical methods.

CD spectroscopy was also used to observe the binding properties of bhrN12 and 34Cbhr with DNA. The traditional gel-shift assay, as was employed for the intact DBC,[20] is not useful when complexes can dissociate during electrophoresis.[22] The changes in the CD spectrum as DNA was titrated against a solution of equimolar concentrations of bhrN12 and 34Cbhr are included in the Supporting Information. Maximum intensity was almost reached at 1 equivalent of DNA. The dissociation constant for DNA binding ($K_D = 186$ nM) is about twofold higher than that observed for the intact apo-, chimeric DNA-binding cytochrome, but is still lower than that
Figure 4. Thermodynamic square based on the calculated K_D values. The K_D values were converted into free energies by using the classical equation $\Delta G° = -RT \ln K_D$. The terms ΔG^T and K_D^T are theoretical values for the bhrN12-heme-34Cbhr complex binding to DNA, calculated by using the determined values of reduced heme for the other three binding equilibria.

observed for the intact DBC binding to a non-optimal DNA-binding sequence.[20]

Measurement of the dissociation constant of DNA from the heme-bound complex has not yet been possible as measurements cannot be made at concentrations well above the K_D value required for the saturated ternary complex between ferric heme and the two fragments. Below the K_D value, binding experiments result in convolution of multiple equilibria, and there is no measurable signal that reports the contribution of each binding event. We are, however, pursuing the use of fluorescently labeled DNA to access this equilibrium constant. The K_D value can be estimated for bhrN12 $\approx$ heme $\approx$ 34Cbhr for DNA through the construction of a classical thermodynamic square (Figure 4). The sum of the free energies of the formation of the quaternary complex (DNA-bound bhrN12-heme-34Cbhr complex; top right corner of Figure 4) from bhrN12 and 34Cbhr should be equal, irrespective of the pathway taken. The calculated standard free energy for the formation of the bhrN12-heme-34Cbhr complex with DNA is -50 kJ mol^{-1}, which translates into $K_D = 1.7$ nM and is independent of the oxidation state of the heme. This value is very close to that of the intact DBC binding to dsNC1 in the absence of nonspecific DNA ($K_D \approx 10$ nM).[20] The magnitude of the changes in the DNA-binding affinity of our proteins in the absence and presence of heme is similar to the changes observed when naturally occurring GCN4 peptides dimerize upon DNA binding.[22] Therefore, we relate heme binding in our system to leucine zipper dimerization in GCN4. The magnitude of the energy of the coupling between DNA and heme binding (two orders of magnitude in K_D) compares favorably with the coupling of small-molecule binding (by maltose-binding protein) with β-

lactamase activity, as was recently reported for a different chimeric protein.[26, 27]

To assess the influence of DNA on protein assembly, equimolar amounts of bhrN12 and 34Cbhr were incubated with varying concentrations of DNA prior to the addition of heme. As the DNA concentration increases to the equivalence point, so does absorbance at 417 nm, therefore indicating complex formation (Figure 5). After the equiva-
Figure 5. DNA as a competitive inhibitor to complex formation. The bhrN12 and 34Cbhr components were present at 1 μM, in the presence of 0.2, 0.4, 0.6, 0.8, 1.0, 1.5, 3.0, or 5.0 μM dsNC1 DNA. Oxidized heme (1 μM) was added as the last component of the mixture, and the system was allowed to equilibrate. Absorbance at 417 nm was used to determine complex assembly (Supporting Information).

lence point, the absorbance begins to decrease, suggesting a decrease in complex assembly. Increasing the DNA concentration beyond that of the protein concentration results in the binding of the protein fragments to different DNA molecules, inhibiting complex assembly. Together with the observation that the binding of DNA alone induces helical structure in bhrN12 and 34Cbhr (Supporting Information), these data suggest the binding of a monomeric BHR peptide to DNA. This is in contrast to our previous result that the complete cytochrome with only one BHR unit attached to either terminus cannot bind DNA.[20] Although we currently have no explanation for this, it is interesting that the loop that links helices 2 and 3 of the wild-type cyt b_{562} is present in the intact DBC, but absent in our current work (having been deleted in making the fragments described herein). Modeling studies suggest that this loop may interact in a negative fashion with the DNA, and our initial study revealed a complex relationship between loop length and DNA affinity.[20] Complete removal of the constraints imposed by this loop (as is the case in our current work) may promote the binding of the fragments to DNA.

The mechanism by which GCN4 binds DNA is dependent on how the whole complex assembles. It is known that GCN4 can bind DNA either as a monomer or as a dimer, but to generate a stable, high-affinity protein–DNA complex, the dimeric form is required.[22] GCN4 can form the dimer through the leucine zipper prior to binding, with the BHR disordered until it binds to DNA,[24, 28] but the dimerization event is thought to be rate-limiting with respect to DNA binding.[22] It has also been reported that certain bZIP proteins bind sequentially as monomers to DNA and then assemble into dimers,[21] whereas other studies have shown that bZIP proteins can bind as monomers.[22, 29] It is therefore not surprising that we have observed evidence of DNA binding of the individual fragments.

We have successfully taken the original design of the DNA-binding cytochrome (DBC) and converted it into a highly cooperative system in which heme and DNA binding influence the self-assembly of the complex. Splitting the complex into two fragments essentially mimics the original GCN4 mechanism, but in this case, a heme-binding domain replaces the leucine zipper. The result is that heme and DNA-binding processes are linked through protein conformation and assembly, which can be controlled electronically. This therefore adds an extra functional component to the toolbox of molecules that could be used in device construction.[3, 30] To avoid heme dissociation during the switching, a covalent linkage between the protein and the cofactor can be introduced into the system,[31, 32] though this will change the relative stabilities of the different assembled states. To compensate for this, heme-iron–ligand mutations[33] will be needed to exaggerate the oxidation-state dependence of assembly. Direct electron transfer between cyt b_{562} and solid-state electrodes is facile,[34] and we are currently investigating the DNA-promoted electrochemistry of these DBCs. Our system therefore has the properties required of a molecular transducer in an electronic device that can control an assembly process. The scaffold in its present forms represents the fundamental core of such a device and can be modified further to change or enhance its character.

Experimental Section

All the materials used are described in the Supporting Information. The bhrN12 and 34Cbhr genes were constructed by using the original DBC as the template. A more-detailed description of fragment construction and purification is in the Supporting Information. Heme-binding affinity was determined spectrophotometrically as outlined in both the figure legends and Supporting Information. Absorbance at 417 nm and 427 nm was used to monitor heme binding to bhrN12 and/or 34Cbhr under both oxidizing and reducing conditions (2 mM sodium ascorbate as the source of reducing equivalents). The heme-binding affinity for bhrN12 and 34Cbhr was determined by extracting the data at the above wavelengths and plotting against component concentration (bhrN12, 34Cbhr, and/or DNA). The data was then analyzed in a manner similar to that used by Bosshard and co-workers for dimeric derivatives of the GCN4 protein.[22] DNA inhibition of complex formation was determined as described in the legend to Figure 5 and in the Supporting Information. CD spectroscopy methods are described in the Supporting Information.

Structural Interplay between Calcium(II) and Copper(II) Binding to S100A13 Protein**

Fabio Arnesano, Lucia Banci, Ivano Bertini,*
Adele Fantoni, Leonardo Tenori, and
Maria Silvia Viezzoli

S100s are dimeric proteins that constitute one of the largest groups in the EF-hand Ca^{II}-binding protein family.[1] The relevance of S100 proteins is shown by their involvement in various human diseases, through a variety of networks of interacting proteins.[1]

Human S100A13 is a ubiquitous protein of 98 amino acids which represents one of the latest members identified in the S100 protein family.[2] S100A13 is involved in the cellular export of interleukin-1α (IL-1α), a potent proinflammatory cytokine, and of fibroblast growth factor-1 (FGF-1), which plays a crucial role in angiogenesis and tissue regeneration.[3] Export is based on the Cu^{II}-dependent formation of multi-protein complexes containing the S100A13 protein, which assemble near the inner surface of the plasma membrane.

The primary sequence indicates that, like most S100 proteins, S100A13 contains a 12-residue canonical Ca^{II}-binding loop (site II) and a 14-residue "pseudo" Ca^{II}-binding loop (site I). The affinity of the two Ca^{II}-binding sites is 1.25×10^5 and $2.5 \times 10^3 \, M^{-1}$, respectively.[4] Consistent with its function and its intracellular location near the inner surface of the plasma membrane, the Ca^{II}-binding affinity of site I of S100A13 is lower ($\approx 10^3 \, M^{-1}$) than that typically found for other S100 proteins ($\approx 10^5 – 10^6 \, M^{-1}$), as it is tuned for the higher local Ca^{II} ion concentration near the membrane.[5]

Herein, we report the structural effects of Ca^{II} and Cu^{II} ion binding to S100A13, and show that binding of two Ca^{II} ions per monomer triggers key conformational changes leading to the creation of two identical and symmetrical Cu^{II}-binding sites on the surface of the protein, close to the interface between the two monomers. These Cu^{II}-binding sites are unique among the S100 proteins, which are reported to bind Cu^{II} or Zn^{II} ions in addition to Ca^{II} ions.[6,7]

The expressed S100A13 was treated with ethylenediaminetetraacetic acid (EDTA) to remove all bound metal ions. Its molecular weight, as measured from electrospray

Supporting information for this article is available on the WWW under http://www.angewandte.org or from the author.

mass spectra (ES-MS), is $11\,340 \pm 1$ Da, which corresponds to residues 2–98 (with the N-terminal methionine residue cleaved). Gel-filtration chromatography gives an apparent molecular mass of $25\,500 \pm 500$ Da, which indicates that the protein is in a dimeric state. Addition of Ca^{II} to the apoprotein (apo), followed by electronic spectroscopy,[4] produced a final species whose molecular weight was greater by 80 Da, thus confirming that the protein contains two bound Ca^{II} ions per monomer (Ca$_2$-S100A13).

The ^{1}H,^{15}N heteronuclear single-quantum coherence (HSQC) NMR spectra showed well-dispersed signals in both dimensions, indicative of a well-folded protein for both apo and Ca-loaded states, with a larger spectral dispersion for the latter (see Supporting Information). The ^{15}N relaxation measurements are consistent with a dimeric state of both forms of the protein in solution. They are characterized by overall rotational correlation times of 13.4 ± 1.2 and 15.0 ± 0.9 ns for the apo and Ca-loaded forms, respectively, and by the same rotational diffusion tensor ($D_\parallel/D_\perp = 1.2$).

Sequence-specific assignment was not complete for the backbone resonances of some of the residues at the C terminus (R^{88}KKKDLKIRKK^{98}) because of the high number of Lys and Arg residues determining extensive signals overlap. These residues experience negative ^{15}N{^{1}H} NOE values, which indicates a mobility faster than protein tumbling. The ^{1}H–^{15}N cross-peaks of residues 22–27 (corresponding to the first Ca^{II}-binding loop between helices α1 and α2) are sensitive to pH and disappear at pH values higher than 6.5 in both forms of the protein. The signals for residues 22–27 appear at lower pH values, but in the apo form they are split in multiple lines, thus indicating multiple conformations in slow exchange on the NMR timescale. This is not the case for Ca$_2$-S100A13, where residues 22–27 are stabilized toward a single conformation by calcium. Therefore, a complete dynamic characterization can be performed for the latter system. In total (residues 2–87), about 89 and 94% of carbon atoms, 90 and 95% of nitrogen atoms, and 86 and 91% of protons were assigned for apo- and Ca$_2$-S100A13, respectively (see Supporting Information).

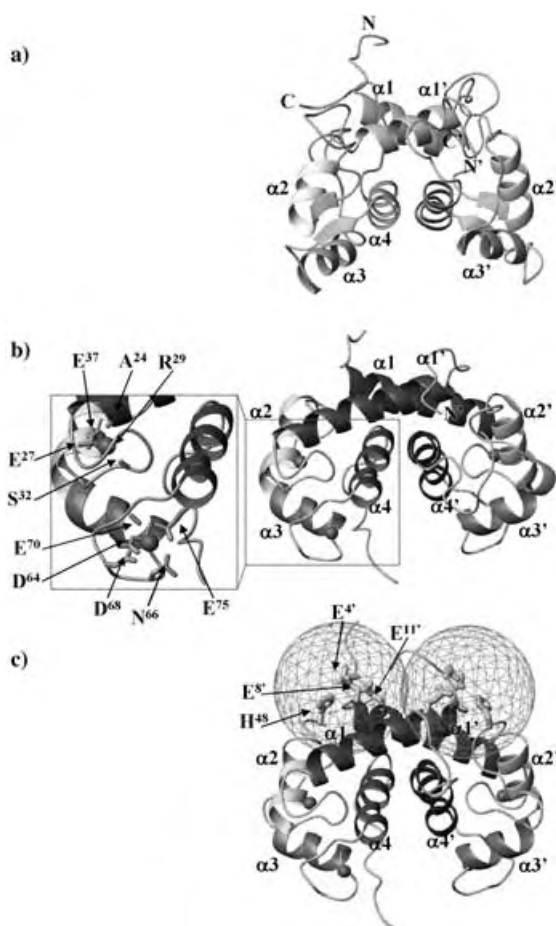
The structures have backbone root-mean-square deviation (RMSD) values to the mean monomeric structure (residues 8–86) of 0.94 ± 0.41 and 0.58 ± 0.09 Å for apo- and Ca$_2$-S100A13, respectively. These values are 1.05 and 0.69 Å, respectively, for the dimer, for which the relative orientation of the two subunits has been experimentally determined through several intermonomer NOEs. The mean structures are shown in Figure 1a and b. A statistical analysis of the quality is reported in the Supporting Information. Both forms consist of homodimers, in which the two monomers are related by a twofold symmetry axis. Each monomer encompasses four α helices and two short β strands, in agreement with the chemical shift index. The two proposed Ca^{II}-binding sites are located between helices α1 and α2, and between helices α3 and α4, respectively (inset of Figure 1b), while a hinge region (residues 45–55) separates α2 from α3. A short antiparallel β sheet is identified within each monomer between residues S^{32} and S^{34} in Ca^{II}-binding site I, and residues E^{70} and K^{72} in site II. The ^{1}H,^{15}N amide chemical-shift differences between apo- and Ca$_2$-S100A13 are larger


Figure 1. Dimeric structures of a) apo-S100A13 and b) Ca$_2$-S100A13 in solution are represented as ribbons, where each helix within a monomer has a different gray scale. Secondary structure elements are indicated. The two Ca^{II}-binding sites and Ca^{II} ligands are shown in the inset of (b). Ca^{II} ions are represented as spheres. c) Two 10-Å spheres are drawn on the structure of Ca$_2$-S100A13, which contain all residues whose signals are broadened beyond detection in the ^{1}H–^{15}N HSQC spectrum of Ca$_2$,Cu-S100A13. The potential Cu^{II} ligands of one site are indicated.

than average ($\Delta\delta_{av}$(HN) > 0.37 ppm) for segments 23–35, 60–70, and 77–82 (see Supporting Information), that is, where the two proposed Ca^{II}-binding sites are located. The extreme N terminus and the last ten residues of the C terminus are poorly defined as a result of their fast internal mobility, revealed by the small or negative ^{15}N{^{1}H} NOE values, which determines the lack of long-range interproton NOE values. Mutational studies have shown that deletion of the basic residues at the C terminus dramatically alters the ability of S100A13 to associate with the acidic protein partner FGF-1,[8] which suggests that the C terminus of S100A13 may become structured upon interaction with FGF-1.

Dimerization occurs through interactions between helices α1 and α4 of both monomers, which form an X-type bundle. At the dimer interface, residues in the hinge between α2 and α3 make contacts with residues near the N terminus of helix α1′ of the other monomer. The aromatic residues Y^{76} and W^{77} in helix α4 also make several contacts with helices α1′ and α4′ of the other monomer. All these interactions align α1

and α4 in opposite directions to α1′ and α4′, respectively, in the dimer. The angle between helices α4 and α4′ ($160 \pm 5°$) in apo-S100A13 is larger than that in Ca_2-S100A13 ($145 \pm 5°$), while helices α1 and α1′ form a similar angle ($155 \pm 5°$). Also, the relative orientation of helices α1 and α2 is similar in the two forms ($125 \pm 5°$). In contrast, the angle between helices α3 and α4 changes by $\approx 40°$. In combination with α4–α4′ reorientation, this latter change has the dramatic effect of placing helix α3 nearly perpendicular to helix α4 ($110 \pm 5°$) in the Ca^{II}-bound structure (Figure 1b), whereas they make an angle of $150 \pm 5°$ in the apo form. The overall structure and the conformational changes induced by Ca^{II} binding are essentially the same as those observed for other S100 proteins.[1,9–11]

One result of the reorientation of helices is the exposure of several residues (see Supporting Information). In the S100 proteins characterized up to now this reorientation exposes a hydrophobic surface,[11] while in S100A13 the majority of the residues that become exposed are positively or negatively charged. They are located at the N termini (E^4, P^5, and E^{14}) and C termini (E^{86}, K^{89}, D^{92}, L^{93}, K^{94}, I^{95}, R^{96}, and K^{97}). Some residues in the hinge between helices α2 and α3 (P^{47}, H^{48}, K^{51}, and D^{52}) also become sizably exposed upon Ca^{II} binding. In particular, residue H^{48} increases its exposure by nearly 40%. However, some residues (mostly hydrophobic) become more buried upon Ca^{II} binding. As a consequence of the decreased exposure of residues 23–27 in Ca_2-S100A13, helix α1 becomes more extended at the C-terminal end, also resulting in a switch of residue packing. All these changes on the surface modify the electrostatic potential of the protein (Figure 2). The protein surface is highly charged in both forms, but the charge distribution appears quite different. In particular, at the dimer interface a more extended and continuous negative patch surrounded by positive charges is observable in Ca_2-S100A13 on top of helices α1 and α1′.

Interaction with Cu^{II} is a key functional aspect of S100A13, as this protein is reported to interact with other proteins in the presence of Cu^{II} ions. Indeed, it is involved in the Cu^{II}-mediated release of FGF1-1 and IL-1α.[3] On addition of a solution of $CuSO_4$ to Ca_2-S100A13 up to a ratio of 0.9:1, an absorption band appears at 720 nm and the ES-MS data indicate a mass increase of 63 Da, still maintaining the two Ca^{II} ions bound per monomer. The EPR spectrum of Ca_2,Cu-S100A13 is characterized by parameters $g_\parallel = 2.35$, $g_\perp = 2.07$, and $A_\parallel = 148 \times 10^{-4}\ cm^{-1}$. These data indicate a type II, pseudotetragonal coordination of Cu^{II} with N and O as donor atoms.[12]

The coupling between the unpaired electron of a type II Cu^{II}, characterized by electronic relaxation times in the range of 10^{-8}–10^{-9} s, and the nuclear spins has a dramatic effect on their nuclear relaxation and consequently on the NMR signal line widths.[13] Addition of substoichiometric amounts of copper to Ca_2-S100A13 results in the disappearance of a number of amide ^1H–^{15}N cross-peaks (residues 3, 4, 7–9, 11, 15, 48, and 49; see Supporting Information). From the location of the disappearing signals and line broadening analysis of the surrounding NH resonances,[13] the copper binding site can be located in a position equidistant from the hinge connecting helices α2 and α3 (residues 44–55) of one
Figure 2. Rotated views of the electrostatic potential surface and ribbon representations of apo- and Ca_2-S100A13. The positively charged, negatively charged, and neutral amino acids are represented in blue, red, and gray, respectively. The putative Cu^{II} ligands are shown in yellow to allow their different degrees of solvent exposure in apo- and Ca_2-S100A13 to be observed.

monomer and the N-terminal region of the other monomer (Figure 1c). The ^{15}N and ^{13}C NMR spectral data, confined in a well-defined region, also clearly indicate that the protein structure is not affected by the copper binding, as it is a secondary structural element, and the overall protein fold is maintained. It might also be possible that there is not a single binding site in the absence of the partner proteins, as some signal broadening occurs on residues located in the C terminus and close to the C-terminal calcium-binding site.

In principle, direct ^{13}C NMR detection offers advantages for the study of paramagnetic proteins because the paramagnetic dipolar contributions to nuclear relaxation depend on the square of the gyromagnetic ratio of the observed nucleus. Thus, going from ^1H to ^{13}C detection guarantees a decrease in relaxation rates of a factor of about 16 ($\gamma_H = 2.67 \times 10^{-8}\ rad\,s^{-1}\,T^{-1}$; $\gamma_C = 6.73 \times 10^{-7}\ rad\,s^{-1}\,T^{-1}$), which therefore decreases the negative effects on the NMR signals arising from the paramagnetic nature of Cu^{II} ions.[14] Also, ^{13}C spectra are more sensitive than ^{15}N and ^1H spectra to even minimal changes of their environment, thus determining their power in monitoring structural perturbations. However, the presence of exchange processes can dramatically affect the ^{13}C signals determining their disappearance. In the CBCACO and CACO experiments[15] acquired on Ca_2-S100A13 in the presence of 0.9 equivalents of Cu^{II} ions (see Supporting Information) it appears that most of the carboxylate side chains of acidic residues disappear, presumably because of

Communications

their interaction with a fractional amount of copper in quasi-slow exchange. The disappearing signals on the backbone, however, are fully consistent with the ^{15}N spectral data, thus confirming that the Cu^{II} ion-binding site involves the N terminus region which is rich in glutamates (disappearance of ^{13}C backbone resonances of 3, 4, 6–9, 11) of one subunit and H^{48}, located in the loop between helices α2 and α3 (disappearance of its Cβ signal) of the other subunit.

The metal-binding site is completely different from that present in a few other S100 proteins where copper or zinc binding has been characterized.[6,7] The sites are different in their location on the protein frame, the nature of the ligand, and accessibility. That of S100A13 is completely exposed to solvent, which is in contrast to the situation in the other proteins where the site is quite buried.[6,7]

In conclusion, results of ^{15}N and ^{13}C NMR experiments have shown that Ca^{II} binding to S100A13 triggers sizable conformational changes, thus creating a novel binding site for Cu^{II} ions on a solvent-exposed location. The opening up of the interhelical angle α3–α4 and the uncovering of H^{48} in Ca$_2$-S100A13 (Figure 2) facilitate Cu^{II} binding at a site bridging the N terminus of one monomer with the hinge of the other monomer. This result suggests that Cu^{II} binding may trigger the interaction with biological partners and provide a mechanism for fine-tuning of the multiprotein complex that involves S100A13.

Experimental Section

The S100A13 recombinant protein was expressed in *Escherichia coli* by using cDNA from human brain, and purified by fast protein liquid chromatography. ^{15}N- and ^{13}C,^{15}N-labeled samples were obtained from cultures grown in labeled Silantes medium. All NMR experiments used for resonance assignment and structure determination were performed on 1.5 mM ^{13}C,^{15}N-S100A13 samples in sodium acetate buffer (20 mM, pH 5.6), and are summarized in the Supporting Information. Structure calculations were performed with DYANA,[16] calculated by using distance and dihedral angle constraints. Restrained energy minimization was then applied to the 25 conformers with the lowest DYANA target function, by using the AMBER 6 package.[17] The ^{15}N backbone longitudinal (R_1) and transverse (R_2) relaxation rates as well as heteronuclear ^{15}N{^{1}H} NOE values were measured as previously described.[18,19] 2D IPAP-CBCACO and CACO experiments based on direct ^{13}C NMR detection[15] were recorded for Ca$_2$-S100A13 and Ca$_2$,Cu-S100A13 on a 500-MHz spectrometer equipped with a TCI cryoprobe. Details on protein expression and characterization, NMR experiments, and structure calculations are available as Supporting Information.

Hydride Reagents

CuH in a Bottle: A Convenient Reagent for Asymmetric Hydrosilylations**

Bruce H. Lipshutz* and Bryan A. Frieman

Copper hydride (CuH), when complexed by the Takasago ligand (*R*)-(−)-DTBM-segphos, (**1**),[1] as shown in Scheme 1
Scheme 1. Formation of [(DTBM-segphos)CuH].

(DTBM = 3,5-di-*tert*-butyl-4-methoxy), is a remarkably reactive yet selective reagent for effecting asymmetric hydrosilylations. Aromatic ketones,[2a] hindered cyclic enones,[2b] aryl imines,[2c] and selected α,β-unsaturated esters and lactones[2d] all react with [{(*R*)-(−)-DTBM-segphos}CuH] (**2**) in the presence of stoichiometric PMHS[3] to afford the corresponding products of asymmetric reduction with excellent *ee* values. Substrate-to-catalyst (S/C) ratios typical of asymmetric hydrosilylations (< 500:1) mediated by other metals (e.g., Rh, Ti, Ru)[4] can be increased substantially, while reaction rates are comparable in many cases, even at much lower temperatures.

Preparation of **2** typically follows either of two procedures: 1) addition of ligand **1** to preformed [{(Ph₃P)CuH}₆] (i.e., Stryker reagent)[5] or 2) in situ formation[6] by using CuCl, NaO*t*Bu, and **1** in the presence of excess silane (PMHS). To simplify handling and to gauge reagent lifetime for potential storage and ease of use, alternatives to its

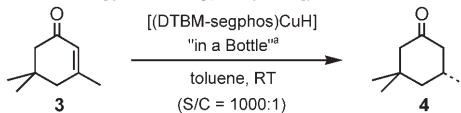
preparation have been investigated. Herein, we report our findings, which suggest that complex **2** is, indeed, quite robust.

Several copper salts were screened as alternatives to CuCl. In particular, those with counterions that are already oxygen-based are, in principle, ready for direct transmetalation with PMHS to CuH. The 1,4-reduction of hindered enone isophorone was used as a test case; results from several experiments are illustrated in Table 1. Each reaction was

Table 1: Survey of copper salt precursors to [(DTBM-segphos)CuH].

Entry	Copper source[a]	*t* [h]	Conversion [%]	*ee* [%][b]
1	Cu(OAc)₂·H₂O	1	100	99
2	CuOPh	1.5	100	99
3	CuCl	2	100	99
4	CuOAc	2	100	99
5	CuCl₂·H₂O	20	17	98
6	Cu(O₂CCF₃)₂·H₂O	20	50	98
7	Cu(OTf)₂	20	25	97
8	[Cu(acac)₂]	20	44	99
9	[Cu(bzac)₂]	20	5	86
10	[Cu(TMHD)₂]	20	67	98
11	Cu(BHT)	20	81	99

[a] acac = acetoacetate; BHT = 2,6-di-*tert*-butyl-4-methylphenol; bzac = PhC(O)CH₂C(O)CH₃; Tf = trifluoromethanesulfonyl; TMHD = 2,2,6,6-tetramethyl-3,5-heptanedione. [b] By chiral capillary GC. [c] From CuCl + NaBHT.

performed under otherwise identical conditions, with a S/C ratio of 200:1. While the *ee* values for all but one case were > 96 %, the extent of conversion over time varied considerably as a function of the counterion. In principle, the counterion should not play a major role, but these data suggest that rates can indeed be affected by this reaction variable. Cu-(OAc)₂·H₂O (Table 1, entry 1) appears to be the best choice to date for several reasons (see below), as also noted recently by others.[7] Copper phenoxide (Table 1, entry 2) was roughly comparable in all respects, an unexpected result in light of prior work from Stryker and co-workers, who found that the replacement of NaO*t*Bu with NaOPh did not lead to a useful catalytic system.[8] The bulky phenoxide from BHT (Table 1, entry 11), on the other hand, in the form of Cu(BHT), led to a far less reactive albeit highly selective precursor to ligated CuH.


The catalyst **2** derived from Cu(OAc)₂·H₂O led to complete reduction of enone **3** to nonracemic ketone **4** in 1 h with > 99 % *ee*. Given the room temperature conditions and high enantioselectivity, this observation encouraged investigation of reagent shelf life, but now with catalyst **2** at a S/C ratio of 1000:1 (vs. 200:1; see Table 1, entry 1). Thus, a 0.001M solution of **2** in toluene was prepared and stored in a bottle at room temperature. This stock solution stored in a refrigerator was monitored over time for yields of isolated product and levels of induction in the reaction of isophorone (1 mmol) added to **2** (1 mL). As shown in Table 2, over a 4-

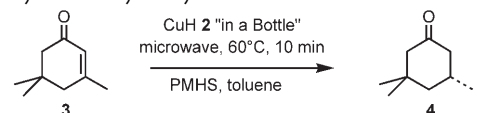
Communications

Table 2: Shelf life of [(DTBM-segphos)CuH]/PMHS.

t [days]	Yield [%][b]	ee [%]
1	88	99
5	87	99
9	88	98
28	86	96
60	87	94

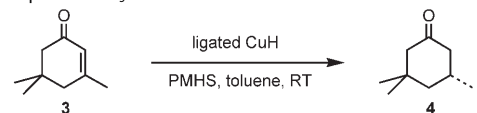
[a] Stored at 4°C. [b] Yield of isolated product.

week period, the enantioselectivity dropped only slightly (from 99 to 96% *ee*). After 2 months, the recorded enantio-selectivity was still $\geq 94\%$ *ee*. To show that the decline in enantioselectivity was likely to be due to adventitious oxygen introduced over time as a result of normal use, a fresh solution of CuH was prepared and stored at room temperature for 14 days without puncturing the Sure/Seal. The CuH in a bottle was tested again on isophorone [Eq. (1)]; no loss in enantio-

selectivity was observed. Thus, we have found that reagent degradation can be minimized by simply switching to a more efficient Oxford Sure/Seal Storage valve cap. With reagent integrity documented at room temperature for a 2-week period, prospects for routine storage and even commercial-ization now exist. Notably, whereas in prior applications the ratio of substrate-to-copper was about 100:1 (i.e., ≈1% CuCl),[2b] in the case at hand the amount of copper present is equal to the quantity of ligand, thus significantly decreasing the extent of transition metal involved.
Treatment of an aryl ketone, acetophenone (**5**), with Cu(OAc)$_2$-derived reagent **2** [Eq. (2)] led to the alcohol **6** with 93% *ee*, essentially identical to that seen previously when using freshly prepared [{(R)-(−)-DTBM-segphos}CuH] derived from CuCl.[2a]


Cinnamate **7** was also exposed to [(DTBM-segphos)CuH] (S/C 1000:1, room temperature). Initially, product ester **8** was obtained with 98% *ee* [86% yield of isolated product; Eq. (3)]. A second experiment under identical conditions (room temperature, 2.5 h) in the presence of reagent **2** that had been stored on the shelf at room temperature over a 2-

week period afforded **8** with essentially the same enantiose-lectivity (99% *ee*) and yield (85%).
Asymmetric hydrosilylations with CuH under microwave conditions are unprecedented in the literature, and are made all the more interesting given the limited thermal stability of this species. Nonetheless, the increased rates normally observed when using this technique might allow rapid conjugate reduction to occur. In the event, even at 1000:1 S/C ratios, reactions run within a microwave reactor at 60°C are close to complete within 10 min without erosion in enantio-selectivity (Table 3).[9]

Table 3: Asymmetric hydrosilylations under microwave irradiation.


S/C	Conversion[a] [%]	ee [%]
500	98	99
1000	95	99

[a] By GC analysis.

The results of the reactions of enoates and cyclic enones at room temperature or above in the presence of the Stryker reagent as the catalytic source of CuH[2b,d] raises the question as to the impact of Ph$_3$P. Achiral [(Ph$_3$P)CuH] could potentially compete in a background reaction, thereby low-ering the *ee* values. The addition of Ph$_3$P (1 equiv) to a solution of [(DTBM-segphos)CuH]/PMHS stored in a bottle caused the *ee* value of the product ketone **4** from the hydrosilylation of isophorone to drop from 99 to 96% (Table 4, entry 2). Alternatively, the addition of ligand **1** (2 equiv) to preformed [(Ph$_3$P)CuH] led to further erosion in enantioselectivity to 95% *ee* (Table 4, entry 3). Thus, the presence of Ph$_3$P has a small but finite effect that detracts from the inherent enantioselectivity imparted by the DTBM-segphos ligand.

Although ^{1}H NMR spectral information on the Stryker reagent is available,[10] the corresponding data for CuH

Table 4: Impact of Ph$_3$P on reactions of **3** with **2**.

Entry	Copper source	CuH/**1**	t [h]	ee [%]
1	[(segphos)CuH] in a bottle (**2**)	1:1	3	99
2	Cu(OAc)$_2$ H$_2$O + **1** + Ph$_3$P (1 equiv)	1:1	5	96
3	[(Ph$_3$P)CuH] + **1** (2 equiv)	1:2	5	95

complexed by a nonracemic bisphosphine ligand has yet to be reported. The spectrum of $[\{(Ph_3P)CuH\}_6]$ in C_6D_6 shows the hydride at $\delta = 3.52$ ppm.[11] Individual spectra of PMHS (Figure 1a) and DTBM-segphos (Figure 1b) in this solvent are shown along with that of $Cu(OAc)_2\cdot H_2O$ in the presence of this ligand (Figure 1c). Upon addition of PMHS, a new peak at $\delta = 2.55$ ppm appears (Figure 1d), which is presumed

Figure 1. ^1H spectrum of $[\{(R)\text{-DTBM-segphos}\}CuH]$.

to correspond to the hydride in reagent **2**. The identical chemical shift is observed for the corresponding reagent complexed with a bitianp ligand (see the Supporting Information).[12] These spectra also show not only that a seemingly discrete species arises from the combination of CuH and DTBM-segphos (or bitianp), but that the presence of Ph$_3$P (as noted previously; see Table 4, entry 3, and the Supporting Information) in reactions at room temperature or above can alter enantioselectivities through competing background reactions that would not otherwise be observed in the presence of DTBM-segphos alone.

In summary, a powerful source of an asymmetric Stryker reagent, copper hydride complexed by Takasago's *(R)*-

DTBM-segphos, has been prepared and documented to be a stable "CuH in a bottle" for easy access and use in asymmetric hydrosilylations.[13, 14] Just as our "cuprate in a bottle" (i.e., (2-thienyl)Cu(CN)Li) introduced two decades ago[15] provides easy access to "higher-order" cuprate species, this reagent combination should encourage many future applications of ligand-accelerated asymmetric CuH chemistry.

[13] Preparation of [(DTBM-segphos)CuH] in a bottle (0.001 M): An oven-dried poly-coated amber glass bottle equipped with a stirrer bar was purged under argon. Under an inert atmosphere (e.g., glove box), $Cu(OAc)_2 \cdot H_2O$ (10 mg, 0.05 mmol) and (R)-(−)-DTBM-segphos (59 mg, 0.05 mmol) were added followed by dry toluene (44 mL), and the reaction mixture was allowed to stir for 2 h at room temperature. PMHS (6 mL, 100 mmol) was added dropwise, and the mixture was allowed to stir for 30 min. The amber bottle was then sealed by using a standard Oxford Sure/Seal top and stored at 0°C.

[14] Typical procedure (isophorone): A solution of [(DTBM-segphos)CuH] "in a bottle" (1 mL, 0.001 M) was added to a 10-mL round-bottomed flask that had been flame dried and purged with argon. Isophorone (3, 150 μL, 1 mmol) was added neat and the reaction was stirred at room temperature until complete (monitored by TLC; 1 h; 4:1 hexanes/EtOAc). The reaction was diluted with THF (5 mL) and then quenched with aqueous NaOH (5 mL, 3 M), after which the mixture was allowed to stir at room temperature for 2 h. After a standard extractive workup, the residue was purified by flash chromatography (4:1 hexanes/EtOAc) to afford the product ketone (R)-4 (123.6 mg, 88%) as a clear oil. The product was analyzed by chiral GC (BDM-75), which indicated an ee value of 99%. The spectral data matched those previously reported.[2b]

the molecule, such as the nature of the molecular density and the location and orientation of the chain ends.[1] Rigidification of the dendrimer, and in some cases, control over the chain-end locations, has come from a variety of approaches,[2] including the use of stiff building blocks such as that of poly(1-3,5-phenylene ethynylene),[3] poly(1-3,5-phenylene),[4] and polyphenylene dendrimers based on pentaphenylbenzene[5] (Scheme 1 a, b, and c, respectively). Beyond a critical
Scheme 1. Stiff, dendritic AB_2 repeat units: a) poly(1-3,5-phenylene ethynylene), b) poly(1-3,5-phenylene), c) poly(4′-4,4″-(3′,6′-diphenyl o-terphenylene)), and d) "exploded" polyphenylene by the extension of each arm by insertion of a linear terphenyl between each set of dashed lines of the general polyphenylene repeat unit shown in (c).

Pushing the Synthetic Limit: Polyphenylene Dendrimers with "Exploded" Branching Units— 22-nm-Diameter, Monodisperse, Stiff Macromolecules**

*Ekaterina V. Andreitchenko, Christopher G. Clark, Jr., Roland E. Bauer, Günter Lieser, and Klaus Müllen**

The majority of effort in dendrimer chemistry has been devoted to constructions with flexible branching units, thereby introducing a variety of conformational aspects into

generation, the convergent synthesis of dendrimers necessitates the use of flexible building blocks or smaller dendrons.[6] To circumvent this limitation, a gradient of branching unit lengths has been employed[7] in the case of a dendrimer with 1-3,5-phenylene ethynylene branching points, thus installing greater volume at the interior of the molecule. A similar size-modulation approach to the branching unit is herein proposed for the enlargement of the parent, polyphenylene dendrimers. Linear enlargement of the arms of the general dendritic repeat unit (Scheme 1d) should directly translate into increased dendrimer radii without requiring a larger core moiety (Figure 1). The synthesis of polyphenylene dendrimers around a tetraphenylmethane core has thus far been limited to the fourth generation[8] because of incomplete conversion at higher generations, presumably the prohibitive result of steric crowding at the chain ends.[9] In light of this observation, a terphenyl spacer was introduced into each arm of the branching unit to decrease the congestion of the chain ends at higher generations (Figure 1). Since the connectivity of the branching points in the dendrimers with extended arms
Figure 1. Scaling of the dendrimer radii for general polyphenylene dendrimers and new "exploded" polyphenylene dendrimers with identical branching-point connectivity but increased branching unit arm length through the use of a 2′,5′-dimethyl-*p*-terphenyl spacer. Second-generation dendrimers for each type are illustrated in greater detail. The iterative illustrations were generated using POV-Ray and are qualitatively similar to the results of MMFF94 molecular mechanics calculations for generations 1–4. The maximum radius was determined by the length of the longest linear oligophenylene arm for each generation.

than 20 nm, which well exceeds the dimension of the narrowly disperse but not monodisperse particles that have been synthesized by self-assembly or multiphase approaches.[10]

The key component in the dendrimer synthesis is the masked AB$_2$ building block 3,4-bis-(2′,5′-dimethyl-4‴-triisopropylsilylethynyl-1,1′:4′,1″:4″,1‴-quaterphenyl-4-yl)-2,5-diphenylcyclopentadienone (**6**; Scheme 2) which bears an active tetraphenylcyclopentadienone and two terminal aryl acetylenes, or Diels–Alder dienophiles, protected with bulky triisopropylsilyl (T*i*PS) groups. While the solubilities of the final dendrimers were not anticipated to be poor, the solubilities of the *p*-terphenyl intermediates were expected to complicate the synthesis. As such, two methyl groups were introduced as side chains from the beginning by using 1-bromo-4-iodo-2,5-dimethylbenzene. An efficient, iterative, selective Suzuki coupling[11] (Scheme 2) using the more-reactive aryl iodide, compared to the aryl bromide, with commercially available 4-trimethylsilylphenylboronic acid was performed to give 4-bromo-2,5-dimethyl-4′-trimethylsilylbiphenyl (**1**). Removal of the trimethylsilyl group with ICl[12] provided 4-bromo-4′-iodo-2,5-dimethylbiphenyl (**2**). The cycle was repeated to obtain 4-bromo-4″-iodo-2,5-dimethyl-1,1′:4′,1″-terphenyl (**4**). The aryl iodide was treated with trimethylsilylacetylene under Sonogashira/Hagihara conditions[13] to afford **5**. The final step was the twofold Suzuki coupling of the remaining aryl bromide with 3,4-bis(4-(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)phenyl)-2,5-diphenylcyclopentadienone to furnish **6**.[14] Chromatographic purification was performed for all steps.

The strategy for the synthesis of the new dendrimers with extended arms (Scheme 3) was directly analogous to the synthesis of the parent polyphenylene dendrimers. Fourfold Diels–Alder reactions of the masked AB$_2$ building block **6** with tetra(4-ethynylphenyl)methane[8] produced the first-generation dendrimer **7** bearing eight T*i*PS chain

is the same as for the parent polyphenylene dendrimers, the radii should be 150% greater than the comparable radii of the parent cases. This situation would enable the stepwise synthesis of a structurally perfect particle with a diameter greater

end groups. Removal of excess **6** was accomplished by chromatographic purification. Removal of the T*i*PS groups with tetrabutylammonium fluoride trihydrate gave the first-generation dendrimer **8** with eight terminal ethynyl units
Scheme 2. quantitatively. After quenching the reaction with water and precipitation in methanol, **8** was ready for subsequent generational growth. The cycle was repeated through to the fourth generation, and a final coupling yielded the fifth-generation dendrimer with 128 T*i*PS chain ends. Removal of excess **6** from the reaction mixture was achieved, beginning with the synthesis of the second-generation dendrimer **9**, by first adsorbing the dendrimer onto silica gel. The adsorbate was washed with acetone until the purple color of the eluent disappeared, and then the dendrimer was extracted with THF and reprecipitated in acetone. Synthetic details for all compounds presented here are included in the Supporting Information.

^{1}H NMR spectroscopic analysis (see Supporting Information) is consistent with the growth of each new generation of dendrimer (**7**, **9**, **11**, **13**, and **15**). The aromatic resonances for the third-, fourth-, and fifth-generation dendrimers (**11**, **13**, and **15**, respectively) were virtually identical, as the resonances from the tetraphenylmethane core were diluted. Resonances for the four inequivalent methyl groups (two closely spaced near $\delta = 2.3$ ppm and two others further separated at $\delta = 2.13$ and 2.10 ppm for **7**) of the repeat unit were nearly unchanged upon deprotection and growth to the next generations, as they are too far from sites of reactivity. Integration of the T*i*PS chain end resonances, relative to both the aromatic backbone resonances and the methyl side-chain resonances, is in agreement with complete conversion into the dendrimer product. Size-exclusion chromatography (SEC)

results (THF; Figure 2) showed a progressive decrease in the elution volume for each subsequent generation (**7**, **9**, **11**, **13**, and **15**), while the decrease in the elution volume was smaller going to the fifth-generation dendrimer **15**;[15] the peak shape confirmed that **15** is smaller than the exclusion limit of the columns. A high-molecular-weight shoulder was present, which gave rise to a broader polydispersity than the earlier generation dendrimers. The shoulder, presumed to be the result of aggregation, has been observed for large generation dendrimers[2c] and was further broadened at higher concentration. Neither ^{1}H NMR spectroscopy nor SEC, however, has the inherent dynamic range to determine whether the final coupling reactions go exclusively to completion (for example, whether the pure dendrimer or a mixture of the dendrimer and nearly complete conversions is produced). MALDI-TOF analysis (using dithranol as matrix, and in some cases, a suitable cationization agent was added) was relied upon to detect the presence of the final dendrimers. The Diels–Alder reactions were stopped when the product molecular ion was the only large molecular ion observed (Table 1). The molecular ions of the desired dendrimeric products were detected for the first three generations, **7**, **9**, and **11**. At higher generation (**13**, Figure 3) an ion corresponding to MALDI fragmentation at the core could be observed (calcd: m/z 16370, found: m/z 16339) in addition to the molecular ion (calcd: m/z 65494, found: m/z 65430). This fragmentation mechanism, removal of one dendron from the core, has been typically observed with polyphenylene den-
Scheme 3. Synthesis of the first- through to fifth-generation "exploded" polyphenylene dendrimers with a tetraphenylmethane core: a, c, e, g, i) *o*-xylene, reflux; b, d, f, h) tetrabutylammonium fluoride trihydrate, THF, RT; a) 85%, b) 76%, c) 96%, d) 75%, e) 87%, f) 75%, g) 64%, h) 58%, i) 65%.

drimers bearing a tetraphenylmethane core.[16] No ions could be observed in the MALDI-TOF spectrum of the fifth-generation dendrimer **15** using dithranol as matrix; however, the MALDI-TOF spectrum obtained using DCTB[17] as matrix (Figure 4) and sufficient laser power to observe any ions showed a weak signal for the molecular ion (calcd: *m*/*z* 134162, found: *m*/*z* 135290). Further proof of the existence of **15** came from the detected ions, which resulted from a large degree of fragmentation and coalescence of the highly reactive fragments with the molecular species. In addition to fragmentation at the core (*m*/*z* 33948, 67980, 101273), an

additional fragmentation pathway was identified at the first branching point away from the core (*m*/*z* 16975, 50971, 84626, 118281, and higher coalescence ions). Increasing the relative amount of matrix or the introduction of cationization agents did not improve the intensity of the molecular ion. The fragmentation is possibly a result of the spectral overlap between the nitrogen laser (337 nm) used for excitation of the matrix and the UV absorbance for the higher generation dendrimers ($\lambda_{max} = 300$ nm). The fourth-generation dendrimer **13** appears to be the limit for efficient generation and detection of the molecular ion without substantial

[a] All MALDI-TOF mass spectra were acquired by irradiating the 1:250 analyte/matrix mixture with a nitrogen laser (337 nm) using dithranol as matrix and optional cationization agent, a trifluoroacetate salt, if specified, except for that of **15** which was acquired using DCTB.[17] [b] SEC was performed at room temperature in THF using SEC columns with 500, 10⁴, and 10⁶ Å porosities and calibrated against narrowly disperse, linear polystyrene (PS) standards. [c] Theoretical radii were determined using MMFF94 molecular mechanics calculations, by evaluating the distance between the central carbon atom and the chain end of the longest linear oligophenylene arm. [d] DLS experiments were performed using a krypton ion laser (647.1 nm), a toluene filled index matching bath, and detected at 60, 90, 120, and 150° with respect to the incident beam and were measured in THF for **7**, **9**, **11**, **13**, and **15** and in toluene for **A**, **B**, and **C**.[8, 16] The hydrodynamic radii were calculated using the Stokes–Einstein equation. [e] TEM samples were prepared by spin-coating 10⁻⁸–10⁻⁹ M CH$_2$Cl$_2$ solutions onto mica substrates and subsequently shadowed with a tungsten/tantalum alloy at high vacuum, followed by deposition of a thin carbon support. The films were floated off the mica substrates onto a water surface and transferred to 600-mesh hexagonal copper grids for imaging. [f] The dendrimer densities were calculating by dividing the molecular mass by the hydrodynamic volume determined from DLS studies, and are substantially lower for the new polyphenylene dendrimer series, which suggests much higher porosities for the same series than those of the general polyphenylene dendrimers.

fragmentation for this family of dendrimers using these experimental conditions.[18] While fragmentation from MALDI is generally regarded as undesired, the iterative nature of the dendrimer, and a clear fragmentation point (such as at the core) enables conclusive evidence to be drawn from such a "digestion." All the detected ions from this MALDI "digestion," combined with the ¹H NMR spectrum of the intact dendrimer **15** unequivocally prove the complete conversion into the fifth generation.

Transmission electron microscopy (TEM; Figure 5, Table 1) and dynamic light scattering (DLS) studies (Table 1) in THF were performed to gauge the sizes of the dendrimers. The TEM samples were obtained by spin-coating dilute CH$_2$Cl$_2$ solutions onto freshly cleaved mica substrates and subsequent shadowing with a tungsten/tantalum alloy by electron-beam evaporation at high vacuum, followed by deposition of a thin carbon support.[8, 19] The fourth-gener-

ation dendrimer **13** showed only filmlike aggregates, but the molecules of fifth-generation dendrimer **15** were well-separated with an average radius of 11.0 nm.[20] There is agreement between the diffusional radius (11.8 nm) and the radius calculated by MMFF94 molecular mechanics (11.0 nm), thus suggesting that the chain ends are not appreciably backfolded and that the shape is preserved in solution. Such agreement, combined with surface accessibility of the chain ends, suggests that the rigid, pentaphenylbenzene branching units provide a conformational stiffness and directionality to the chain ends, similar to that of the parent case.[21] The SEC elution behavior (Table 1) clearly indicates how much more compact the parent polyphenylene dendrimers (**A**, **B**, **C**)[8, 16] are than are the new dendrimers **7**, **9**, **11**, **13**, and **15**. The polystyrene (PS)-

equivalent molecular weights (MWs) are less than the masses determined by MALDI-TOF for the former, and with the exception of the fifth-generation dendrimer, the PS-equivalent MWs are higher than the masses (MALDI-TOF) for the new series, thus indicating there is a very large amount of free volume occupied by solvent. Calculation of the dendrimer density (Table 1) from the hydrodynamic volume for each series revealed that a tenfold greater solvent volume is available in the new dendrimers. The significantly faster decrease in the dendrimer density with increasing generation for the new dendrimer series was the result of having used the same compact core from the general polyphenylene dendrimer series. The consequence of such a low dendrimer density could be a higher propensity for interdigitation, and thus aggregates which are difficult to separate.

Experimental and analytical conditions were found up to the fifth generation that demonstrated the complete conversion into the next generation. The limitations of generating molecular ions with MALDI techniques had precluded

evaluation of growth to a higher generation with complete certainty, but the results are highly encouraging using MALDI "digestion." Perhaps the most compelling synthetic observation is that, unlike the syntheses of the parent polyphenylene dendrimers which necessitated several weeks for the final growth reaction to go exclusively to completion, the reaction conversion for the fifth generation required less than 50 h. This result suggests that the steric demands at the chain ends required by the Diels–Alder cycloaddition are well below any critical threshold, completely unlike that of the parent polyphenylene dendrimers. The control over the topology of the branching units and the high porosity result in efficient growth cycles that lead to structural perfection, even for constructions containing 664 and 1368 phenyl rings (for the fourth- and fifth-generation dendrimers **13** and **15**, respectively). To the best of our knowledge, this is the first report of the stepwise chemical synthesis and proof of a truly monodisperse molecule with a diameter greater than 20 nm. Furthermore, no evidence was observed for the physical encapsulation of the branching unit within the dendrimers during the synthesis, thus suggesting that the cavities within the structures are large and may be exploited as novel hosts for large guests.[22] Efforts are underway to evaluate the stiffness and to clarify the aggregate formation for the fifth-generation dendrimer **15**.

An In Situ High-Temperature Single-Crystal Investigation of a Dehydrated Metal–Organic Framework Compound and Field-Induced Magnetization of One-Dimensional Metal–Oxygen Chains**

Pascal D. C. Dietzel,* Yusuke Morita, Richard Blom, and Helmer Fjellvåg

Metal–organic framework compounds have attracted considerable interest recently because of their eminently promising properties, which make them suitable for applications as gas-storage systems, sensors, and in ion exchange or catalysis,[1] and, more seldom, because of their magnetic properties.[2,3] The diversity of potential applications arises from the possibilities that the range of applicable metals and the appropriate choice of organic linking blocks offer for the intentional or inadvertent design of advantageous compounds. The common feature of most applications is that they necessitate the framework to have a sufficiently large and permanent porosity to be penetrated by guest molecules and ions. As such, coordination polymers have frequently been compared with zeolites, over which they offer a number of advantages. Among these are accessible volumes that are several times higher than for zeolites.[4] A severe disadvantage of an organic–inorganic hybrid compound with respect to zeolites, however, is often the significantly lower thermal stability. For most applications, it is necessary to remove the solvent from the pores, which is usually only achieved at elevated temperatures, and this sometimes leads to the collapse of the long-range order of the framework. Thus, the investigation of the thermal behavior of any novel porous metal–organic framework compound lies at the core of determining its suitability for applications. There have been only a few reports of single-crystal investigations of desolvated microporous metal–organic frameworks,[5] and in only one case was the study conducted in situ.[6] In all of these cases, the connectivities of the framework of the desolvated compound remained unchanged. Here, we report the synthesis and characterization of a microporous cobalt(II)-

containing metal–organic framework. The in situ single-crystal X-ray investigation of its dehydrated form reveals that a water molecule originally coordinated to the metal center is removed as well in the course of the solvent elimination. However, the framework remains stable, with the coordination environment of the cobalt atom changing from octahedral to square pyramidal. The as-synthesized compound orders antiferromagnetically below 8 K, but it subsequently passes through a metamagnetic phase transition to display field-induced ferromagnetic ordering.

The reaction of cobalt(II) acetate and 2,5-dihydroxyterephthalic acid ($C_8H_6O_6$) in a mixture of water and tetrahydrofuran (molar ratio 2:1:556:165) under autogenous pressure at 110°C in a Teflon-lined autoclave (50% filling level) yielded the pink-red, needle-shaped crystalline substance $[Co_2(C_8H_2O_6)(H_2O)_2]\cdot 8\,H_2O$ (**1**). The results of the elemental analysis confirm that the channels are occupied solely by water molecules even though a solvent mixture was used in the synthesis. The crystal structure analysis revealed a three-dimensional coordination polymer with honeycomb topology that contains one-dimensional, solvent-filled channels (Figure 1a). The cobalt atom is coordinated in a distorted octahedral fashion by six oxygen atoms. Five of the oxygen atoms are part of the organic ligand, which utilizes all of its oxygen atoms in coordinative bonds with the cobalt center. The sixth oxygen ligand at the cobalt center comes from a water molecule. Four of the Co−O distances are in the range between 2.03 and 2.06 Å, while the fifth Co−O distance is 2.190(5) Å. The water molecule is *trans* to this bond, and its Co−O bond is also elongated (2.158(7) Å). The hydroxide oxygen atom and one of the carboxylate oxygen atoms coordinate two cobalt atoms each, while the second carboxylate oxygen coordinates only one cobalt atom. This coordination arrangement results in cobalt–oxygen octahedra that are linked by *cis*-oriented edges (Figure 1b) such that the cobalt atoms form a threefold helix parallel to the *c* axis. The framework topology is identical to that recently described for $[Zn_2(C_8H_2O_6)(dmf)_2]\cdot(H_2O)_2$ (dmf = *N,N*-dimethylformamide).[7]

After the hypothetical removal of the noncoordinating solvent molecules in the channels, the empty channels occupy 49% of the total volume of the unit cell, and the average cross-sectional channel dimensions are 11.08×11.08 Å^2. The empty volume increases to 60% if the coordinating water is also removed. The water molecules excluding and including the coordinating water account for 29.2% and 36.6% of the mass, respectively. We found that it was possible to repeatedly dehydrate and hydrate compound **1** by heating to 100°C in a dry argon gas stream and then cooling down and admixing water vapor with the inert gas stream. A dry gas stream at room temperature actually suffices to remove 90% of the water within 43 h. The amount of weight loss during the heating experiments indicates that the coordinatively bound water molecules are also removed. Indeed, this was confirmed by an in situ single-crystal structure determination at 95°C which revealed that the three-dimensional framework actually remains intact upon dehydration. Because of the abscission of the coordinating water molecule, the cobalt center remains in a square-pyramidal coordination environ-
Figure 1. a) Packing diagram of **1** along [001]; b) chains of edge-connected cobalt oxygen octahedra in **1**. Neighboring chains are of opposite handedness; c) square-pyramidal environment of the cobalt center in **2** after removal of the water molecules.

ment (Figure 1c). At the apex of the pyramid is the oxygen atom that used to be *trans* to the vacated water position; the Co−O distance is now significantly shorter than before (2.067(5) Å). The empty coordination site is accessible for molecules from the channels, which is a necessary requirement for the metal to perform catalytic functions.[8]

Plots of the projection of the electron density along the channel direction illustrate the change from the hydrated to the dehydrated framework (surface plots in Figure 2). The
Figure 2. Projection of the electron density along [001] (surface plots) and the final difference electron maps (contour plots; line at 0.0 e Å^{-3}) at a) 25 °C and b) 95 °C. Observed reflections ($I > 2\sigma(I)$) were used for the calculation with the map function of WinGX.[9]

cobalt atoms stand out as the most-intense peaks in groups of three at the corners of the hexagon. Connecting these are the rows of peaks due to the organic ligand. The water molecules in the channel and at the cobalt atoms are clearly distinguishable in Figure 2a, while they are absent in Figure 2b. Some electron density is observed in the center of the channel at 95 °C. This might be due to the inert gas molecules that are bound to occupy the channels now, but the shape of the surface indicates that it is more likely a result of Fourier termination errors accumulating electron density around the element of symmetry. No atoms can be refined in these positions, and the final difference density maps (contour plots in Figure 2) agree well with the chosen structural models. In this context, it is noteworthy to mention that we also measured the crystal at 200 °C and the results were congruent to those obtained at 95 °C. A second crystal that had only been heated to 95 °C yielded identical results to the first crystal. It was subsequently cooled down and stored in a water-vapor-saturated atmosphere, whereupon we could again localize the coordinating water and bulk solvent water molecules.

We confirmed the stability of compound **2** in an inert atmosphere by thermodiffractometry and thermogravimetry studies. The crystallinity of **2** starts to decrease above 200 °C, and final decomposition occurs above 320 °C. A sample heated at 200 °C in argon for a total of 63 h can still take up the entire amount of water. Compound **2** is substantially less stable in air. Decomposition is observed at 234 °C and proceeds rapidly, and the crystallinity of the sample diminishes already above 140 °C. Concurrently, if a sample is dehydrated in air at 150 °C, the amount of water that it can take up again diminishes with the time it has been exposed to this temperature. Apparently, the presence of the oxygen in air promotes the collapse of the framework.

In compound **1**, the shortest metal-to-metal distance within a helical metal–oxygen backbone chain is 3.059(2) Å, while the shortest distance between cobalt atoms in adjacent chains is 7.387(2) Å. Cobalt compounds with such a large anisotropy in metal-to-metal distances have frequently been found to behave as one-dimensional magnetic systems.[10] While measurements of the magnetic susceptibility confirm the $+2$ oxidation state of the cobalt ($\mu = 4.67(13)$ μ_B, $\theta = -6(2)$ K), they do not show any noticeable deviation from three-dimensional behavior. The susceptibility drops off sharply below 8 K, which indicates antiferromagnetic ordering (Figure 3). However, on application of magnetic fields stronger than about 2 T, we observed a field-induced transition to a ferromagnetic-like ordered state.[11] The superexchange pathway in the metal–oxygen chain suggests that the magnetic moments couple ferromagnetically in the chains. The antiferromagnetic long-range order in low magnetic fields then results from the antiparallel alignment of the spins of adjacent chains. It may be the aromatic system of the organic ligand that propagates this further to give a three-dimensional interaction.[12] Stronger magnetic fields can overcome this interaction and induce the ferromagnetic-like state.

In conclusion, we would like to emphasize that metal–organic framework compounds may be very suitable systems to investigate magnetic interactions, even more so since materials with switchable magnetic properties promise to deliver the next revolution in information technology.[13] We have shown that it is possible to remove the solvent from compound **1** whilst maintaining the framework structure intact, even though the cobalt atom also loses its coordinating water molecule and remains pentacoordinate. The resulting compound **2** is stable to above 200 °C in an inert atmosphere.

The stability and the readily available coordination site at the metal atom indicate that it should be worthwhile to investigate the chemical properties of this compound further. This should encompass possible catalytic activity, while its magnetic properties suggest that a more detailed study of its magnetic structure needs to be performed.

Experimental Section

Crystals of compound **1** of a suitable size for a single-crystal structure determination were obtained by reducing the molar ratio of cobalt acetate to ligand to 1:1. They were obtained by combining a solution of cobalt(II) acetate (187 mg, 0.75 mmol) in water (10 mL) and a
Figure 3. a) Molar magnetic susceptibility χ_{mol} as a function of the temperature for compound **1** and various fields (zero-field-cooled: 1000 Oe red, 10^4 Oe blue, 4×10^4 Oe magenta; field-cooled: 1000 Oe green, 10^4 Oe cyan, 4×10^4 Oe yellow); b) magnetization M per cobalt atom $[\mu_B]$ as a function of magnetic field and temperature.

solution of 2,5-dihydroxyterephthalic acid (149 mg, 0.75 mmol) in THF (10 mL) in a Teflon-lined steel autoclave and heating at 110 °C for three days. The crystals were isolated after filtration in 54 % yield (95 mg, 0.2 mmol) with respect to cobalt. Elemental analysis (%): calcd: C 19.52, H 4.47, Co 23.95, O 52.05; found: C 19.60, H 4.38, Co 23.95, O 52.06.

Single-crystal X-ray crystallography: A hemisphere of data was collected on a Bruker D8 diffractometer with an Apex II detector and an Oxford Cryosystems Cryostream Plus device. After data integration with SAINT and semiempirical absorption correction with SADABS,[14] structures were solved by direct methods and refined on F^2 with the SHELX program suite.[15]

Compound **1**: Crystal dimensions $0.02 \times 0.02 \times 0.20$ mm^3, trigonal, space group $R\bar{3}$ (no. 148), $a = 26.1102(19)$, $b = 26.1102(19)$, $c = 6.7192(10)$ Å, $V = 3967.1(7)$ Å^3, $\rho_{calcd} = 1.793$ g cm^{-3}, $Z = 18$, $2\theta_{max} = 50°$, $Mo_{K\alpha}$ radiation, $\lambda = 0.71073$ Å, ω scans, $T = 293$ K, 12 577 reflections collected, 1544 unique reflections, 1093 observed data ($I > 2\sigma(I)$), $R_{int} = 0.115$, $\mu = 1.959$ mm^{-1}, min/max transmission 0.712/ 0.962, 124 parameters, final $R_1(I>2\sigma(I)) = 0.0626$, w$R_2$(all data) = 0.1647, GOF = 1.15, $\Delta\rho_{min} = -0.59$ e Å^{-1}, $\Delta\rho_{max} = 0.73$ e Å^{-1}. Compound **2**: A crystal of dimensions of $0.03 \times 0.03 \times 0.30$ mm^3 was attached carefully oriented and with a minimum of glue to the tip of a capillary to avoid obstructing the channels; it was then slowly heated at 20 °C h^{-1} to 95 °C; trigonal, space group $R\bar{3}$ (no. 148), $a = 25.885(3)$, $b = 25.885(3)$, $c = 6.8058(17)$ Å, $V = 3949.0(12)$ Å^3, $\rho_{calcd} = 1.181$ g cm^{-3}, $Z = 18$, $2\theta_{max} = 50.6°$, $Mo_{K\alpha}$ radiation, $\lambda = 0.71073$ Å, ω scans, $T = 368$ K, 6446 reflections collected, 1598 unique reflections, 1150 observed data ($I > 2\sigma(I)$), $R_{int} = 0.066$, $\mu = 1.89$ mm^{-1}, min/max

transmission 0.590/0.945, 73 parameters, final $R_1(I>2\sigma(I)) = 0.058$, w$R_2$(all data) = 0.209, GOF = 1.24, $\Delta\rho_{min} = -0.76$ e Å^{-1}, $\Delta\rho_{max} = 1.30$ e Å^{-1}.

CCDC 270292 (**1**) and 270293 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

therapeutic molecules.[1–5] In fact, carbon nanotubes (CNTs) have been shown to cross cell membranes easily and to deliver peptides, proteins, and nucleic acids into cells.[6–14] These innovative carriers present a lower toxicity, a fact that boosts their potential for biomedical applications.[1–3,15]

The use of f-CNTs for drug delivery of small molecules (e.g. anticancer, antibacterial, or antiviral agents) is still unexplored. The development of nanovectors able to carry one or more therapeutic agents with recognition capacity, optical signals for imaging, and/or specific targeting is of fundamental advantage, for example, in the treatment of cancer and/or different types of infections.[16] Theoretically, the use of f-CNTs in this approach would require the introduction of different functionalities on the external surface of the CNTs. Multiple functionalization of the tips of CNTs has been reported recently.[17] Although the method is original and interesting, it does not exploit the full surface available on the CNTs for the linking of different molecules, nor has an application for drug delivery been envisaged. We decided to explore an alternative strategy for the introduction of two different and orthogonal functionalizations to CNTs. The orthogonal methodology, which is widely used in organic synthesis, would allow the selection and control of the attachment of active molecules to the sidewalls and tips of the CNTs. This approach enabled us to simultaneously link fluorescent probes to the CNTs for tracking the uptake of material as well as an antibiotic moiety as the active molecule. For this purpose we chose fluorescein and amphotericin B (AmB), respectively. AmB is considered to be the most effective antibiotic in the treatment of chronic fungal infections.[18–20] However, the drug is highly toxic to mammalian cells;[18] one reason for this toxicity can be attributed to the formation of aggregates as a result of the lower solubility of AmB in water.[19] Conjugation of this drug to CNTs could have several advantages: 1) increased solubility of the molecule; 2) decrease in the aggregation phenomena; 3) improved efficacy owing to the internalization capacity of the CNTs; and 4) modulation of the antibiotic activity against different types of cells (mammalian, bacterial, and fungal). Herein we present the first case of AmB covalently linked to a polymeric carrier. Previously, the drug was encapsulated into colloidal or lipid systems owing to the need for slow release;[21] however, high doses are required to elicit the same efficacy as that of AmB alone. The incorporation of CNTs could allow a reduction in the amount of AmB administered. It is easy to control their dimensions and the degree of functionalization. CNTs are particularly promising delivery systems as they are non-immunogenic.[3,10]

The aim of the work described herein was first to explore a new strategy for the double functionalization of CNTs, second, to assess the characteristics of toxicity and uptake of CNTs functionalized with AmB and fluorescein towards mammalian cells, and thirdly, to evaluate the antifungal activity of CNT–AmB conjugates.

It is known that the exposure of CNTs to oxidative conditions (for example, sonication in a mixture of sulfuric and nitric acids) not only cuts the tubes and generates surface defects but can also provide abundant carboxylated sites along their sidewalls.[22,23] To establish the effect of acidic

treatment on both the length of the CNTs and the number of carboxylic groups present, we prepared a series of oxidized multiwalled carbon nanotubes (MWNTs) by applying different acid conditions (Supporting Information).[24,25] The CNT-length distribution was assessed by TEM (Table 1), whereas the loadings were calculated after derivatization of the carboxylic groups (activated as acid chlorides) with Boc mono-protected diaminotriethylene glycol. After removal of the Boc group, the number of free amino groups was measured with a quantitative Kaiser test (Table 1).[9]

Evidently, the length and the loading of the MWNTs strongly depend on the duration of the acid treatment. As expected, the tube length decreases and loading increases with an increase in the duration of oxidation. For our purpose, we selected MWNTs treated for 8 h as they exhibited the most convenient length and loading.

To effect a double, orthogonal functionalization of the CNTs, the oxidized MWNTs **1** were again activated as the acid chlorides and treated with diaminotriethylene glycol (mono protected as phthalimide) (Scheme 1). This protecting group is particularly useful as it is highly stable to harsh acidic conditions and orthogonal to the Boc group, which can subsequently be introduced through 1,3-dipolar cycloaddition to the sidewalls of the MWNTs.[26,27]

MWNTs **2** were structurally characterized by ^{1}H NMR spectroscopy and TEM (Figure 1a). The ^{1}H NMR spectrum of **2** in CDCl$_3$ showed the presence of the Boc group ($\delta = 1.4$ ppm), whereas the phthalimide group gave rise to the signals at $\delta = 7.7$ and 7.8 ppm (Supporting Information). TEM analysis indicated that the lengths of individual MWNTs **2** are consistent with the data reported in Table 1. The stepwise cleavage of phthalimide, followed by removal of the Boc group gave water-soluble MWNTs, whose quantitative Kaiser test showed amino levels of 0.25 and 0.46 mmol per gram of material, respectively. Having ascertained the selective removal of the two protecting groups, we were ready to insert the desired functionalities. We initially removed the phthalimide group in MWNTs **2** with a solution

Scheme 1. a) Neat (COCl)$_2$; Pht-N(CH$_2$CH$_2$O)$_2$-CH$_2$CH$_2$-NH$_2$, dry THF, reflux; b) Boc-NH-(CH$_2$CH$_2$O)$_2$-CH$_2$CH$_2$-NHCH$_2$COOH/(CH$_2$O)$_n$, DMF, 125 °C; c) Hydrated NH$_2$-NH$_2$, EtOH, reflux; d) FITC, DMF; e) HCl 4 M in dioxane; f) Fmoc-AmB, HOBt/EDC×HCl/DIPEA, DMF; 25% piperidine in DMF. BOC = tert-butyloxycarbonyl; DIPEA = diisopropylethylamine; DMF = dimethyl formamide; EDC = N-Ethyl-N'-(3-dimethylaminopropyl)-carbodiimide; FMOC = fluorenylmethyloxycarbonyl; FITC = fluorescein isothiocyanate; HOBt = 1-hydroxybenzotriazole; Pht = phthalimide group.

Figure 1. TEM images of MWNTs **2** (a) and **4** (b).

of hydrazine in ethanol, and the free amino group was then coupled with FITC. The Boc group was then cleaved through the use of HCl (4 M) in dioxane, and AmB (activated at the carboxylic functional group by using HOBT and carbodiimide) was covalently linked to the amino group (Scheme 1). To avoid possible side reactions during the coupling, the NH$_2$ group of the mycosamine moiety of AmB was protected with Fmoc, which was eventually removed with piperidine in DMF (25%) to afford MWNTs **4**. TEM analysis of the conjugate **4** showed a morphology very similar to that of MWNTs **2** (Figure 1b).

The UV/Vis spectrum of MWNTs **4** in DMF exhibit the typical absorption bands of AmB in the range 340–420 nm

Table 1: Chemico physical properties of MWNTs after treatment with strong acid and derivatization of the carboxylic acid functions.

t [h]	Length [nm]	Loading [mmol g^{-1}]
1	1500–4000	0.06
3	1000–2000	0.14
5	200–1000	0.16
8	180–940	0.22
24	160–600	0.26
48	140–500	0.34

and those of FITC at 517 nm (Figure 2). Upon subtraction of the contribution of CNTs to the UV/Vis spectrum of **4**, the ratio between AmB and FITC attached to the tubes was 1.5:1. A similar result was found for the conjugate dissolved in methanol (Supporting Information).
Figure 2. UV/Vis spectra of a) MWNTs **4**, b) **2**, c) AmB, d) FITC in DMF.

To assess the biological properties of the novel, doubly functionalized CNTs, we initially studied the toxicity effects of MWNTs **4** on mammalian cells, tracing its capacity to cross the cell membrane. Human Jurkat lymphoma T cells were incubated with either MWNTs **4** or AmB as the control. The cells were grown at 37 °C in RPMI medium and treated for 1 h with doses of MWNTs **4** increasing from 1 to 40 µg mL^{-1}. Cell viability was analyzed by flow cytometry by staining early and late apoptosis and necrosis with annexin V and propidium iodide (Figure 3). As a positive control, the cells were treated with AmB (10 µg mL^{-1}) alone. The dose of AmB used for the control experiment corresponded to the amount of drug covalently bound to 40 µg mL^{-1} of MWNTs **4**. The conjugation of AmB to CNTs clearly reduces the toxic effects of the antibiotic on mammalian cells. At the highest doses, more than 40 % of the cells died in the presence of AmB, whereas all the cells remained alive upon treatment with MWNTs **4**. We subsequently verified that longer incubation times do not increase the percentage of dead cells. Indeed, all the Jurkat cells remained alive after treatment with MWNTs **4** for 4 and 16 h (Supporting Information). Furthermore, cell uptake of MWNTs **4** was very fast as maximum fluorescence was observed after only 1 h of incubation. This result is in accordance with the behavior of single-walled CNTs previously used as transporters for peptides and proteins.[6–8]

Attachment to CNTs modified the internalization properties of AmB. Jurkat cells incubated with MWNTs **4** at different doses and time points were analyzed by using epifluorescence and confocal microscopy. We found that the
Figure 3. Percentage of early-apoptotic, late-apoptotic, and/or dead Jurkat cells after treatment with MWNTs **4** at different concentrations for 1 h. After incubation and washings, the cells were stained with annexin V and propidium iodide and analyzed by flow cytometry (inset).

internalization of AmB linked to the nanotubes was dose-dependent (Supporting Information). Figure 4 clearly shows that the conjugates pass into the cell cytoplasm. Notably, the MWNTs **4** is mainly localized around the nuclear membrane, but does not cross this barrier.
Figure 4. Epifluorescence (top) and confocal (bottom) microscopy images of Jurkat cells incubated for 1 h at 37 °C with 10 and 40 µg mL^{-1} of MWNTs **4**, respectively. Jurkat cells have an average diameter of 10 µm.

The mechanism of penetration is not mediated by endocytosis because incubation in the presence of NaN$_3$ at 4 °C does not remarkably influence the penetration capacity of MWNTs **4** observed at 37 °C (Supporting Information).[7] We demonstrated that f-CNTs are able to enter the cell by a spontaneous mechanism: they behave like nanoneedles and pass through the cell membrane without causing cell death.[11] This mechanism was recently confirmed by Cai et al., who showed that the nanopenetration of cell membranes seems to be a unique feature of CNTs.[28] Concerning the toxic effects of AmB on mammalian cells, it is thought that this antibiotic destabilizes the cell membrane in a manner similar to the cases of fungi and yeasts.[20] Therefore, the ability of CNTs to internalize AmB rapidly into the cytoplasm of Jurkat cells

remarkably reduces the possibility of disruption of the membrane core. The covalent attachment of AmB to the nanotubes has another clear advantage: it prevents the aggregation phenomena that the drug typically displays in solution. AmB strongly self-associates in aqueous solution and increases the possibility of toxic effects to the cells. In UV/Vis spectra of MWNTs **4** in water and RPMI, we found that the aggregation is lower than that of AmB alone (Supporting Information).[19,29]

Finally, we evaluated the antifungal activity of CNTs, functionalized with AmB, against three species of fungi that are either pathogenic or may opportunistically infect humans. These included collection strains (*Candida parapsilosis* ATCC 90118 and *Cryptococcus neoformans* ATCC 90112) and clinical isolates (*Candida albicans*). In these experiments we used AmB that was covalently linked to ammonium-functionalized multi- and single-walled carbon nanotubes (MWNT-AmB **18** and SWNT-AmB **19**) (Supporting Information). We explicitly chose these types of conjugates to compare the antifungal activity of AmB bound to CNTs directly with that of native AmB, in the absence of the fluorescent probe. The minimum inhibitory concentration (MIC) values were determined after 48 h of incubation with different doses of free AmB, unconjugated CNTs, or CNT–AmB conjugates. As shown in Table 2, ammonium-function-

Table 2: Antifungal activity of CNT–AmB conjugates.

| CNT | Minimum inhibitory concentration (MIC)[a] [μg mL]$^{-1}$ | | |
	C. parapsilosis ATCC 90118	*C. albicans* (c.i.)[b]	*C. neoformans* ATCC 90112
AmB	20	>80	5
SWNT–NH$_3^+$	>80	>80	>80
MWNT–AmB[c] **18**	1.6	6.4	0.8
SWNT–AmB[c] **19**	1.6	13.8	0.8

[a] The MIC corresponds to the lowest concentration of compound that inhibited visible growth of the organism. Results given are mean values of two independent determinations performed in duplicate. [b] c.i., clinical isolate. [c] In this table, the MIC values for MWNT–AmB and SWNT–AmB refer to the amount of AmB in the conjugates (approximately one third by weight).

alized CNTs, free of AmB, were inactive up to the maximal concentration (80 μg mL^{-1}) used against all the microorganisms tested. Conversely, MWNT– and SWNT–AmB were highly effective, indicating that the activity of the drug was not prevented by its covalent binding to both single- and multiwalled CNTs. Interestingly, when equal amounts of free and bound drug are considered, (the actual amount of AmB bound to CNTs is approximately one third by weight), conjugated AmB is definitely more potent than the free drug, particularly against the *Candida* spp. The reason for this increased activity is at present unclear, although an increased solubility of the drug by conjugation to CNTs might explain, at least in part, this finding. Alternatively, or supplementary to an increased solubility, binding to CNTs and the presence of multiple copies of AmB per CNT molecule might favor the interaction of the drug with its target, the fungal membrane. Although further investigations are necessary in this respect, the in vitro results are very promising as they indicate that

appropriate conjugation can increase the effectiveness of AmB while decreasing its toxicity, as shown by the flow cytometric experiments with Jurkat cells (Figure 3). Such a development would increase the clinical use of AmB, which is, at present, limited by its narrow therapeutic index.[30]

In summary, we were successful in preparing CNTs containing both fluorescein and amphotericin B. Our studies revealed that AmB covalently linked to CNTs is taken up by mammalian cells without presenting any specific toxic effect. Furthermore, AmB bound to CNTs preserves its high antifungal activity. Therefore, multifunctionalized CNTs can be envisaged for the delivery of antibiotics to different types of cells by selective transport through the membrane. Finally, the covalent linkage of different drugs to CNTs is an approach that may be used to modulate the therapeutic action of the agent, thus obtaining new conjugates with interesting properties.

might overcome some drawbacks of traditional approaches, such as reduced enantioselectivity or decreased activity in comparison with their homogeneous counterparts.[5–7] With this strategy, the bridged ligands spontaneously coordinate with metal ions to form homochiral metal–ligand assemblies, in which the bridged chiral ligands provide an enantiodiscrimination environment and the metal ions act as the catalytically active centers in asymmetric catalysis.[4,5] In principle, the stereochemical characteristics of the multitopic ligands should have significant impact on the microstructures of the resulting homochiral metal–organic polymers, and thus may exert a profound influence on the enantioselectivity and activity of the catalysis in a given reaction. Therefore, the design and synthesis of multitopic chiral ligands with diverse geometrical features is a central issue in the generation of homochiral metal–organic polymers for heterogeneous asymmetric catalysis (Figure 1).

Heterogenization of Shibasaki's Binol/La Catalyst for Enantioselective Epoxidation of α,β-Unsaturated Ketones with Multitopic Binol Ligands: The Impact of Bridging Spacers**

*Xingwang Wang, Lei Shi, Mingxing Li, and Kuiling Ding**

The use of homochiral metal–organic polymers[1] as heterogeneous catalysts for asymmetric reactions has provided a new strategy for chiral catalyst immobilization,[2–4] which

Figure 1. Schematic representation of the strategy for generation of self-supported enantioselective heterogeneous catalysts by using a) 1D, b) 2D, and c) 3D multitopic chiral ligands with metal ions.

The homogeneous catalytic asymmetric epoxidation of α,β-unsaturated ketones in the presence of Shibasaki's lanthanum catalyst,[8–10] which is based on the 2,2′-dihydroxy-1,1′-binaphthyl (binol) ligand, has provided one of the most convenient approaches to α,β-epoxy ketones among various catalytic systems developed so far.[11–15] Although excellent yields and enantioselectivity have been achieved, a catalyst loading of 5–20 mol % rendered the process less practical. However, the immobilization of this type of catalyst by an organic polymer support or stereoregular polymeric ligands often resulted in a drastic decrease of catalytic activity and enantioselectivity in the catalysis.[16] Herein, we report preliminary results on the heterogenization of Shibasaki's

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

lanthanum catalyst by using multitopic binol ligands bridged by spacers with diverse shapes and sizes. These catalysts are used for the enantioselective epoxidation of α,β-unsaturated ketones, and afford optically active epoxy ketones in excellent yields and enantiomeric excesses.

Three types of multitopic ligands (**1a–i**; Scheme 1) containing different bridging linkers, including linear (**a–d**), bent
Scheme 1. Multitopic ligands employed for the generation of heterogeneous lanthanum catalysts.

(**e–g**), trigonal-planar (**h**), and tetrahedral (**i**) spacers, were designed to investigate the impact of the spatial arrangement of chiral units ((*S*)-binol) on the catalytic properties of their assemblies with the lanthanum ion. Ligands **1b**, **1d**, and **1e** were prepared by following a reported procedure.[4d] The syntheses of other ligands (**1a**, **1c**, and **1f–i**) were achieved by the Pd-catalyzed Sonogashira reactions of a methoxymethyl (MOM)-protected, 6-ethynyl-substituted binol derivative with the corresponding aryl bromides or a MOM-protected, 6-bromo-substituted binol derivative with the corresponding aryl acetylenes, followed by deprotection of the MOM groups of the Sonogashira coupling products by acidic hydrolysis (see Supporting Information).

The heterogeneous catalyst was easily prepared by dropwise addition of a solution of the corresponding multitopic ligand in THF and triphenylphosphine oxide to a solution of La(O*i*Pr)$_3$ under an argon atmosphere. The pale yellow or white (in the case of catalysts **2b**, **2d**, **2e**, and **2i**) solids precipitated immediately. After the mixture had been stirred at room temperature for two hours, the resulting solids were collected by filtration and washed with THF to remove trace amounts of soluble low-molecular-weight species. As exemplified by catalyst **2a** in Figure 2a, these polymeric solids were completely insoluble in THF, and accordingly fulfilled the
Figure 2. a) Self-supported chiral lanthanum catalyst **2a** (yellow solids at the bottom of the test tube) in THF. b) SEM image of the self-supported lanthanum catalyst **2a**; scale bar: 9.7 μm. c) Enlarged SEM image of the catalyst in (b); scale bar: 0.74 μm.

basic prerequisite for heterogeneous catalysis. SEM images showed that these solids were composed of micrometer-sized particles (Figure 2b), and the surface of the particles exhibited a microstructure with nanoscale noncrystalline species (Figure 2c). The powder X-ray diffraction patterns did not

show any obvious peaks in the scanning range of 5–70° (2θ), which further confirmed the noncrystalline morphology of the catalysts (see Supporting Information).

To optimize the reaction conditions, the insoluble homochiral assembly **2a** was then tested as a self-supported heterogeneous catalyst for the enantioselective epoxidation of α,β-unsaturated ketone **3a**. The reaction was carried out at room temperature by using catalyst **2a** (5 mol%) with cumene hydroperoxide (CMHP, 88%) as the oxidant, and THF was selected as the reaction solvent after a preliminary examination of the solvent effect (see Supporting Information). As shown in Table 1, the molar ratio between the chiral

prominent in terms of catalytic activity (Table 1, entry 2 versus entry 8). The use of *t*BuO$_2$H (TBHP) instead of CMHP as oxidant led to a degraded yield and enantioselectivity (Table 1, entry 9). Reduction of the catalyst loading to 1 mol% resulted in a slight drop of the enantioselectivity (Table 1, entry 2 versus entry 10) despite the high yield of product **4a**.

We then turned our attention to investigating the impact of the bridging spacers in the multitopic ligands on the enantioselectivity of the catalysis under the optimized reaction conditions. The heterogeneous catalysts **2b–i**, generated from the reactions of multitopic ligands **1b–i** and La(O*i*Pr)$_3$,

[a] All of the reactions were carried out at 25 °C with 1.5 equivalents of oxidant in **3a** (0.4 mmol) in the presence of MS (80 mg, 4 Å). The catalyst loading was based on the binol/La unit of the assemblies. [b] Yield of isolated product. [c] Determined by HPLC on a Chiralcel OB-H column. [d] Determined by comparison of their optical rotations with those reported in the literature.[8d, 10] [e] In the absence of MS (4 Å).

binol unit and La^{III} was critical for achieving high catalytic activity and enantioselectivity. The ratio of 1:1.05 (binol unit **1a**/La(O*i*Pr)$_3$) turns out to be optimal (for details, see the Supporting Information), and affords the corresponding epoxide (*R,S*)-**4a** in over 99% yield and 97.6% *ee* after a reaction time of 30 min (Table 1, entry 2). In the analogous homogeneous catalyst system, the employment of Ph$_3$PO or Ph$_3$AsO as additive in the reaction system dramatically enhanced the catalytic activity but scarcely influenced the enantioselectivity.[8,9] In contrast to the homogeneous catalytic system, the addition of triphenylphosphine oxide to the heterogeneous catalytic system described herein had a significant impact on both the activity and enantioselectivity of the catalysis (Table 1, entries 2–7 versus entry 1). It seems that Ph$_3$PO is superior to Ph$_3$AsO (Table 1, entries 2–4 versus entries 5–7). The effect of molecular sieves (MS, 4 Å) was also

were subsequently applied to the epoxidation of **3a** with CMHP as the oxidant in the presence of Ph$_3$PO (15 mol%) and MS (4 Å). As shown in Table 1 (entries 11–18), all of the examined catalysts demonstrated excellent catalytic activity, and afforded **4a** in 99% yields in 30 min. The influence of the structure of the spacer on the enantioselectivity of the catalysis was dramatic. For ligands with linear spacers (**1a–d**), shortening the length of the linker between two chiral units generally had a disadvantageous effect on the enantioselectivity (Table 1, entries 11–13 versus entry 2). However, the reduction of the extension angles of the spacers was clearly unfavorable for the enantioselectivity (Table 1, entries 15–16 versus 2; also entry 13 versus entry 14). The catalysts (**2h** and **2i**) composed of planar tritopic (**1h**) or tetrahedral tetratopic (**1i**) ligands with relatively longer spacers also demonstrated high activity and enantioselectivity (91.5–95% *ee*; Table 1, entries 17 and 18). All these facts clearly indicate that both the length and the spatial orientation of the spacers in the multitopic ligands have a significant impact on the enantioselectivity of the heterogeneous epoxidation. It can be concluded that the structural variation of the spacer moieties in the ligands may alter the supramolecular structures of the assemblies and, as a result, affect their catalytic behavior, particularly the enantioselectivity of the catalysis. Given the modular nature of the multitopic ligands, it can be envisioned that both the reactivity and enantioselectivity may be fine-tuned by judicious choice of the spacer part of the ligands.

Encouraged by these preliminary results, the heterogeneous catalysis of the enantioselective epoxidation of a variety of α,β-unsaturated ketones (**3a–h**) was then investigated by using catalyst **2a** with CMHP as oxidant. As shown in Table 2, the reactions proceeded efficiently to give the corresponding epoxides (**4a–g**) in 99% yield with excellent enantioselectivities (94.3–97.6% *ee*, Table 2, entries 1–7), although the electron-withdrawing group at the *para* position of chalcones (Table 2, entries 5 and 6) may reduce the reaction activities. The reactivity and enantioselectivity for

[a] All of the reactions were carried out under the reaction conditions of entry 2, Table 1. The catalyst loading was based on the binol/La unit of the assemblies. [b] Yield of isolated product. [c] Determined by HPLC on a Chiralcel OB-H or AD column. [d] Determined by comparison of their optical rotations with those reported in the literature.[8d, 9b, 10]

the epoxidation of alkyl-substituted α,β-unsaturated ketone **3h** diminished to some extent, and afforded the corresponding epoxide **4h** in 91% yield with 84.9% ee. The performance of the heterogeneous catalytic systems was comparable to that attained with their homogeneous counterparts.[8]

In an effort to identify the heterogeneous or homogeneous nature of the above catalyst system, a supernatant of **2a** in THF was employed for the catalysis of the epoxidation of **3a** under the same experimental conditions. In this case, no product was observed at all after 24 h. This experiment unambiguously demonstrated the heterogeneous nature of the catalytic systems studied. The inductively coupled plasma (ICP) spectroscopic analysis of the supernatant indicated that the concentration of La^{III} was 0.093 ppm, which again supports the heterogeneous nature of the catalyst system.

The remarkable advantage of the self-supported heterogeneous catalysts over their homogeneous counterparts was exemplified by the facile recovery and recycling of catalyst **2a** in the epoxidation of **3a**. After completion of the epoxidation, simple filtration of the reaction mixture under an argon atmosphere allowed the separation of the solid-state catalyst from the product-containing solution. The isolated solids were recharged with THF, substrate (containing 10 mol% Ph$_3$PO), and the oxidant for the next run. As shown in Table 3, catalyst **2a** could be used for at least six cycles in the epoxidation of **3a** without significant loss of enantioselectivity (93.2–96.5% ee), at a cost of slightly reduced activity in the last two runs (95 and 83% yields, respectively). Moreover, the leaching of lanthanum in each cycle during recycling of the catalyst was less than 0.4 ppm, as determined by ICP spectroscopy. In comparison with heterogeneous catalysts with organic polymer supports,[16] the catalyst system described herein represents the best case reported so far in terms of both activity and enantioselectivity.

In conclusion, Shibasaki's binol/La catalyst has been successfully heterogenized by a self-supporting strategy through the reactions of multitopic ligands with La(OiPr)$_3$. The self-supported heterogeneous catalysts showed excellent

activities and enantioselectivities in the catalysis of the epoxidation of α,β-unsaturated ketones. The bridging spacers in the multitopic ligands were found to have significant impact on the enantioselection of the corresponding self-supported catalysts, which demonstrated the importance of the supramolecular structures of the assemblies on their catalytic behavior. This understanding is particularly important in directing the design of chiral metal–organic assemblies for enantioselective catalysis. Research on the application of this conceptually new strategy in the development of other types of heterogeneous asymmetric catalysts is in progress.

Organocatalysis

Urea- and Thiourea-Substituted Cinchona Alkaloid Derivatives as Highly Efficient Bifunctional Organocatalysts for the Asymmetric Addition of Malonate to Nitroalkenes: Inversion of Configuration at C9 Dramatically Improves Catalyst Performance.**

*Séamus H. McCooey and Stephen J. Connon**

Inspired by the efficiency, elegance, and selectivity of enzymatic catalysis, the design of organic molecules capable of the efficient and enantioselective promotion of carbon–carbon bond-forming processes is a formidable challenge which is currently receiving considerable attention.[1] In this context, one of the fundamental enzymatic catalyst competencies that is most difficult to engineer in synthetic systems is bifunctionality; that is, the ability of a catalyst to employ Lewis/Brønsted acidic and Lewis/Brønsted basic functionality synergistically to bring about the activation of both the nucleophilic and electrophilic components of a reaction simultaneously.[2]

Over 20 years ago, Wynberg and Hiemstra[3] reported that cinchona alkaloids were efficient (albeit only moderately selective) bifunctional organocatalysts for the 1,4-addition of thiophenol derivatives to cyclohexenones, and proposed catalyst participation in the deprotonation of the thiol (through the basic quinuclidine alkaloid nitrogen atom) and in the stabilization of the enolate resulting from the 1,4-addition step (through hydrogen bonding with the hydroxy moiety of the catalyst).[4–6]

As Wynberg predicted,[3] the derivitization of cinchona alkaloids[7] with the goal of augmenting hydrogen-bond-donating ability has resulted in an expansion of catalyst scope: Hatakeyama and co-workers reported that the rigid phenolic quinidine derivative **1** promotes highly enantioselective (aza)-Baylis–Hillman reactions,[8] and Deng and co-workers demonstrated that the readily available 6′-demethylated quinine and quinidine alkaloids are considerably more active and selective catalysts for the addition of 1,3-dicarbonyl compounds to β-nitrostyrenes than their natural 6′-methylated analogues.[9,10]

The ability of chiral urea[11] and thiourea derivatives to serve as powerful hydrogen-bond-donating organocatalysts was recently recognized by Jacobsen and co-workers, who developed a suite of thiourea catalysts that promote a diverse range of reactions with excellent enantioselectivity.[12] The compatibility of (thio)ureas with Lewis basic functionality was also demonstrated recently: Takemoto and co-workers have introduced the bifunctional catalyst **2**, which promotes Michael-type[13a,b] and aza-Henry[13c] reactions with high enantioselectivity.[14] Furthermore, we have found that bisaryl(thio)urea derivatives are significantly more efficient "mole-per-mole" promoters of the DABCO-catalyzed Baylis–Hillman reaction than either methanol or water.[15]

We were therefore intrigued by the possibility of modifying the "privileged"[16] cinchona alkaloid structural backbone by substituting the hydroxy group at C9 with an aryl(thio)urea moiety with the aim of augmenting the rigidity, tunability, and hydrogen-bond-donating proclivity of these materials. An additional advantage associated with this strategy is the opportunity to examine the (little studied) effect of inversion of configuration at C9 on catalyst performance. We therefore prepared 9-(3,5-bistrifluoromethylphenyl)urea derivatives of dihydroquinine (DHQ) and dihydroquinidine (DHQD) (DHQU and DHQDU, respectively) together with their C9-inverted analogues (Scheme 1).[17]

The asymmetric Michael addition of relatively acidic carbon pronucleophiles (such as malonates) to nitroolefins is an important C−C bond forming reaction that provides access to synthetically useful enantioenriched nitroalkanes.[18,19] Current bifunctional organocatalytic systems such as **2**[13] and 6′-demethylated quinidine[9] are capable of promoting the reaction with high enantioselectivity at typical catalyst loadings of 10 mol %, and efficient metal-based systems (chiral Mg–bisoxazoline[20a,b] and Ru–amido[20c] complexes at 2–5 mol % loadings) have been reported which require more stringent control of the reaction conditions. This reaction therefore seemed to be an ideal test for the potential activity and selectivity of the novel urea-substituted cinchona alkaloid structures.

The results of initial investigations into the addition of dimethyl malonate to (*E*)-β-nitrostyrene (**3**) catalyzed by cinchona alkaloid derivatives are presented in Table 1. Initial screening studies identified toluene as the optimal solvent for the reaction. The urea-substituted analogues (DHQU and DHQDU) with the stereochemistry of the "natural" cinchona alkaloid were more-selective albeit significantly less-active catalysts than their respective dihydroalkaloid precursors DHQ and DHQD (Table 1, entries 1, 3 and 4, 5) at room temperature. Gratifyingly, the C9 diastereoisomers of these materials (9-epi-DHQU and 9-epi-DHQDU, Figure 1)[21] exhibited decidedly superior activity and enantioselectivity (Table 1, entries 6–8); and gave complete conversion of **3** into nitroalkane **4** with high enantioselectivity at room temperature in the presence of only 2 mol % of catalyst. Further improvement was observed upon the synthesis and evaluation of their thiourea analogues (9-epi-DHQT and 9-epi-DHQDT, Figure 1). Below ambient temperature, **4** could be generated with quantitative conversion and excellent enantioselectivity (Table 1, entries 9–11) at low catalyst loadings. It is noteworthy that inversion of the absolute configuration at C9 in
