these (thio)urea-substituted systems dramatically improves catalyst activity and selectivity without altering the sense of stereoinduction observed, that is, 9-*epi*-DHQU and 9-*epi*-DHQT promote the formation of the same antipode of **4** as DHQU (and DHQ), whereas 9-*epi*-DHQDU furnishes the same product enantiomer as DHQDU (and DHQD).

This is in marked contrast to the relative performance of the hydroxy-substituted DHQ and 9-epi-DHQ: epimerization of C9 of the parent dihydroalkaloid led to a marginal increase in enantioselectivity (with inversion of the sense of stereoinduction) and a significant reduction of catalyst activity (Table 1, entries 1 and 2). It is therefore clear that although neither inversion of the C9 stereocenter nor (thio)urea substitution alone endow the parent alkaloids DHQ and DHQD with significantly improved catalytic properties (in the context of the addition reaction studied), a combination of both modifications results in a remarkable enhancement of catalyst efficacy and enantioselectivity.

We then turned our attention to the question of catalyst scope. The use of either 9-epi-DHQT or 9-epi-DHQDT allowed the conversion of both activated (**6–8**) and deactivated (**9–11**) β-nitrostyrenes (Table 2, entries 1–10) into their corresponding Michael adducts **14–19** in excellent yields (91–95%) and enantioselectivities (87–99% *ee*) at convenient reaction temperatures between ambient temperature and −20°C. Although we did not observe a strong correlation between the electronic properties of the substrate and the enantiopurity of the product, in general, relatively deactivated olefins gave rise to products of marginally higher enantiopurity than more-electrophilic analogues. Alkyl-substituted nitroolefins were also found to be compatible with 9-epi-DHQT; the unhindered **12** proved unproblematic and even the traditionally challenging substrate **13** (which is inert towards a binary bifunctional catalyst system, Table 2, entry 13)[22] underwent conversion into **21** with attenuated enantioselectivity (75% *ee*).

9-*epi*-DHQT and 9-*epi*-DHQDT are characterized by excellent catalytic activity at 2–5 mol% loadings and convenient reaction temperatures, and are also comparable in terms of efficacy, scope, and enantioselectivity to benchmark metal-based systems.[20] At higher concentrations catalytic asymmetric addition can be conveniently carried out at unprecedented catalyst loadings without compromising either efficiency or enantioselectivity, as exemplified by the synthesis of **16** from **8** in excellent yield and enantioselectivity promoted by 9-*epi*-DHQT (0.5 mol%) at 0°C (Scheme 2, compare with Table 2, entry 4).

Scheme 2. Catalysis by 9-epi-DHQT at low catalyst loading.

The dependence of catalytic efficiency and selectivity on both the presence of (thio)urea functionality and the relative stereochemistry at C8/C9 strongly implies that these modified cinchona alkaloid systems operate through a bifunctional mechanism, that is, quinuclidine-moiety-assisted generation of the de-protonated malonate nucleophile and its addition to a single face of the (thio)urea-bound nitroolefin electrophile. A preliminary selectivity principle based on the results presented in Table 1 is outlined in Figure 1. An examination of models and MM2 calculations[23] indicate that **A** is a reasonable representation of the least strained conformation of the active and selective catalyst 9-epi-DHQU in which the bulky alkyl groups at the C9 stereogenic centre avoid steric interactions with each other and with the carbonyl group of the urea functionality.[24] In this conformation it would be expected that the nitroolefin would bind (through both oxygen atoms)[25] as shown in pretransition state (TS) assembly **B** (Figure 1) to minimize

contact with the large catalyst substituents, thus allowing the proximal Brønsted basic aliphatic heterocycle to bring about enolate generation at the *Si* face of the electrophile, leading to the formation of (*S*)-**4** (Figure 1, **B** and Table 1, entry 7).

A similar MM2 examination of DHQU identifies **C** as the minimum-energy conformer, which would clearly be ill suited to efficient bifunctional catalysis and would be expected to furnish the opposite enantiomer to that observed experimentally (Figure 1, **C** and Table 1, entry 4,). We therefore propose that bifunctional catalysis involving DHQU may proceed predominantly through a minor conformer represented by **D**, in which the bifunctional catalyst components are more suitably oriented to cooperate catalytically and to generate the product enantiomer observed. The catalyst components, however, are still poorly situated relative to the catalytically active components of 9-epi-DHQU in terms of both proximity of the quinuclidine ring to the aryl urea and the ability of the catalyst to bind the nitroalkene selectively.[26]

In summary we have developed a new class of highly active and selective (thio)urea-substituted cinchona alkaloid based catalysts for the addition of dimethyl malonate to nitroalkenes. A systematic investigation into the effects of the relative stereochemistry at C8 and C9 of these materials on catalyst performance has implicated bifunctional catalysis and revealed that C9 epimeric catalysts are remarkably more efficacious in terms of rate and selectivity than analogues of
Figure 1. Selectivity model. A: Proposed catalytically active conformation of 9-epi-DHQU (MM2). B: Possible pre-TS assembly for enantioselective addition to **3** promoted by 9-epi-DHQU. Communications

"natural" cinchona alkaloid stereochemistry. Highly active 9-*epi*-DHQT and 9-*epi*-DHQDT (which are readily available from DHQ and DHQD - see Supporting Information) have been identified as efficient and enantioselective catalysts with substrate-scope and selectivity profiles on a par with current benchmark literature systems and can be conveniently employed at relatively low catalyst loadings (0.5–5 mol%). Studies to determine the solution-state structure of these materials and to explore their potential as promoters of a variety of reactions susceptible to the influence of bifunctional catalysis are underway.

[21] The prefix "*epi*" usually refers only to inversion of configuration at a single stereocenter, that is, no functional-group interconversion is implied. The term is adopted in this case for convenient identification of the relative stereochemistry of the catalyst at C8/C9.

[22] To the best of our knowledge only Deng et al. (ref. [9]) have thus far successfully selectively converted this hindered substrate by using 20 mol% 6′-demethylated quinine.

[23] MM2 force-field energy-minimization calculations were carried out with CS Chem3D Std v.4.0 software. Conformers were minimized to a minimum RMS gradient of 0.02.

[24] The catalysts were obtained as amorphous solids, and several attempts to recrystallize these materials were unsuccessful. Conformation **A** is in very good agreement with structural data associated with other (thio)urea-based catalysts in the literature which incorporate a chiral methine group adjacent to the (thio)urea functionality.[12e, 13b]

[25] B. J. Hay, T. K. Firman, B. A. Moyer, *J. Am. Chem. Soc.* **2005**, *127*, 1810.

[26] This would account for the observed product stereochemistry, and the decrease in catalyst efficiency and selectivity associated with DHQU relative to 9-*epi*-DHQU. However, it is acknowledged that alternative rationales are possible, for example, reversal of binding selectivity relative to 9-epi-DHQU, etc. It is envisaged that ongoing structural studies will provide more detailed insight into the catalytic behaviour of these C9 diastereomers.

Biosensors

A Sensitive Colorimetric and Fluorescent Probe Based on a Polythiophene Derivative for the Detection of ATP

Chun Li, Munenori Numata, Masayuki Takeuchi, and Seiji Shinkai*

The design and construction of chemo- and biosensors for recognizing biologically important small molecules and anions has received considerable attention in recent years.[1] The anion adenosine triphosphate (ATP) is known to be a key player in bioenergetics in all biological systems, and thus it is important to be able to monitor easily the concentration of ATP in aqueous solution. Although several intriguing strategies have been developed to detect ATP, such as synthetic host–guest receptors,[2] peptides,[3] and RNA aptamers,[4] it remains a challenge to find new approaches that could improve the simplicity, selectivity, and sensitivity of ATP detection.

Recently, a new sensory technology based on conjugated polymers has been developed in view of their signal-amplification effect, and thus is sensitive to very minor perturbations.[5] In particular, water-soluble conjugated polymers provide a unique platform for the development of chemosensors for biologically relevant targets.[6] For example, we and others have successfully prepared interpolymer complexes between water-soluble polythiophene (PT) derivatives and biomacromolecules such as DNA,[7] polypeptides,[8] and polysaccharides.[9] The induced conformational changes of PTs can be followed by absorption, emission, and circular dichroism (CD) spectroscopic methods, which provides the means for implementation of these systems as sensors. Moreover, nucleobases and ATP have been demonstrated to be versatile building blocks for the construction of supramolecular aggregates.[10] Thus, we thought that if ATP can form some supramolecular complexes with conjugated polymers and induce changes in their conformation and mode of aggregation, the perceived structural changes of conjugated polymers would be useful not only for spectroscopic detection but also for rapid visual sensing. Herein, we report a water-soluble cationic polythiophene derivative that displays colorimetric and fluorescent responses to ATP through electrostatic and hydrophobic cooperative interactions. To the best of our knowledge, water-soluble conjugated polymers

have not been applied to ATP sensing previously; this is the first observation of a colorimetric probe based on a conjugated polymer for ATP that operates in aqueous solution at physiological pH.

Poly(3-alkoxy-4-methylthiophene) was chosen as a model conjugated polymer to study the viability of this approach because its conformation is sensitive to external stimuli as a result of the presence of sterically demanding side chains (i.e. the 4-methyl group).[11] Therefore, the changes in the π–π* transitions that arise from conformational alterations in the PT backbone upon the formation of a complex are convenient to monitor by using absorption and fluorescence spectroscopy. Water-soluble PT derivative, **1**, was synthesized as

$O(CH_2)_3\overset{+}{N}(CH_3)_3Cl^-$

1
reported previously.[9] Titration of **1** with ATP in water at 20°C was monitored by absorption spectroscopy. As shown in Figure 1, the absorption maximum of **1** in water appears at
Figure 1. Variation in the absorption spectra of **1** (1.0×10^{-4} M) in water with increasing concentrations of ATP as indicated.

around 400 nm and is associated with a random-coil conformation of the PT derivatives.[11] Upon adding increasing amounts of ATP, the absorption maximum is gradually red-shifted to 538 nm with an observed dramatic color change from yellow to pink-red. This distinct shift and the appearance of two vibronic bands are characteristic of the aggregation of the PT backbone.[11, 12] These results indicated promise that water-soluble **1** could be used as a colorimetric sensor for ATP.

To validate the specificity of the PT derivative toward anionic guests, the changes in the absorption spectra of **1** in water upon addition of biologically important anions such as adenosine monophosphate (AMP), adenosine diphosphate (ADP), and uridine triphosphate (UTP), as well as chloride, carboxylate, phosphate, and triphosphate ions (as sodium salts) were studied (see Supporting Information). After addition of an equimolar amount of these anions to aqueous

Supporting information for this article is available on the WWW under http://www.angewandte.org or from the author.

solutions of **1**, most of the solutions remained yellow with $\lambda_{max} < 435$ nm except for those that contained ADP and UTP, which gave orange solutions with shifts of the absorption maxima to 435 and 461 nm, respectively. The most remarkable effect was noted, however, upon addition of ATP, which gave a pink-red solution (Figure 2). Note, the dramatic color
Figure 2. Changes in the color of solutions of **1** (1.0×10^{-4} M) in water induced by the addition of equimolar amounts of various anions.

change of **1** upon addition of ATP provides a very simple means for naked-eye detection of ATP in aqueous solution. Figure 3 shows the dependence of A_{535}/A_{400}, the ratio of the
Figure 3. The dependence of the relative absorbance of **1** (1.0×10^{-4} M) at 535 and 400 nm (A_{535}/A_{400}) on the different anions at various concentrations in pure water. ATP (■); UTP (●); $P_3O_{10}^{5-}$ (▲); $P_2O_7^{4-}$ (▼); ADP (◆); AMP (+); Cl^-, $H_2PO_4^-$, HPO_4^{2-}, PO_4^{3-}, HCO_3^-, and CO_3^{2-} ions all have a negligible effect (see lowest line with overlapping unfilled symbols).

absorbance of **1** at 535 nm (π-stacked aggregates) and 400 nm (random coil), on the addition of different amount of various anions. It is clear from these results that the most striking effects are observed for ATP, and hence they confirm that the water-soluble derivative **1** is selectively responsive to ATP.

The analysis of ATP in biological systems is commonly carried out in the presence of alkali and alkali-earth metal cations. Therefore, we also studied the influence of the metal ions Na^+, K^+, Ca^{2+}, and Mg^{2+} (as their chloride salts) on the properties of **1** in solution (see Supporting Information). It was found that the absorption bands of **1** do not show any significant shift upon addition of these cations even when they are present in 20-fold excess. It is known that ATP has an

intrinsic metal-binding affinity with respective binding constants of 9554 M^{-1} (Mg^{2+}), 3722 M^{-1} (Ca^{2+}), 13 M^{-1} (Na^+), and 8 M^{-1} (K^+).[13] To study the possibility of analytical interference from these cations, the influence of these cations (20-fold excess with respect to the repeating unit **1**) on the binding of ATP to **1** was also investigated (see Supporting Information). The introduction of monovalent cations (Na^+, K^+) revealed little influence on the binding of ATP with **1**, whereas the presence of Mg^{2+} and Ca^{2+} suppressed to some extent the formation of the supramolecular complex as a result of their stronger binding (larger binding constants) with ATP relative to the monovalent cations. However, this does not interfere with the analytical determination of ATP by optical and visual detection.

To elucidate the mechanism behind the remarkable color change observed for **1** in the presence of ATP, the absorption spectra of **1** in the absence of anionic guest but in the presence of an equimolar amount of AMP, ADP, or ATP, or the presence of phosphate, pyrophosphate, triphosphate, UTP, or ATP were compared in Figure 4. As shown in Figure 4a, the absorption maximum at 400 nm of **1** is red-shifted to 416, 435, and 504 nm upon the stepwise addition of an equimolar amount of AMP, ADP, and ATP, which indicates that the number of negative charges on the anion plays a crucial role in promoting the formation of a supramolecular aggregate of **1**. However, only the presence of inorganic oligoanionic triphosphate ion does not induce a distinct change in the color of the solution of **1** and no supramolecular aggregate is
Figure 4. Absorption spectra of **1** (1.0×10^{-4} M) in water in the absence of anionic guest (——) and a) in the presence of an equimolar amount of AMP, ADP, or ATP, or b) in the presence of an equimolar amount of phosphate, pyrophosphate, triphosphate, UTP, or ATP. All spectra were extracted from the titration curves.

formed in this mixture (Figure 4b). It is also important to consider the effect of different nucleotides on the aggregation structure of **1**. As can be seen in Figure 4b, the presence of nucleotides uridine and adenosine is indispensable for accelerating the formation of a π-stacked supramolecular complex. In particular, the presence of the more hydrophobic nucleobase adenine leads to more efficient formation of supramolecular aggregates,[14] and thus displays the most pronounced color change which is noticeable even to the naked eye. Although further studies will be needed to address the molecular mechanism behind this event, some preliminary considerations concerning the origin of the color are discussed next. The electrostatic interaction between the negative charges in the triphosphate group and the positive charge on the ammonium group in **1** promotes planarization of the PT backbone upon addition of increasing amounts of ATP, and above a critical concentration efficient π–π-stacking interaction between **1** backbones is induced by the synergistic effect that arises from the hydrophobic interaction between adenine units (see Supporting Information).[15,16] Simultaneously, these interactions shift the π–π* transition to longer wavelengths and lead to a color change from yellow to pink-red. To further confirm that the sensory response is due to interpolymer π-stacking aggregation, the absorption spectrum of **1** in the aggregated state (solid film cast from aqueous solution of **1**) was also measured (see Supporting Information). The resultant pink-red solid film exhibited characteristic absorption bands that are similar to those observed for **1** in aqueous solution in the presence of ATP, which supports the viewpoint that the addition of ATP promotes the aggregation of **1**.

To emphasize the biological importance and to assess the viability of this approach for the detection of ATP at physiological pH values, we subsequently examined the sensing ability of water-soluble **1** toward ATP in an aqueous solution containing HEPES (2-[4-(2-hydroxyethyl)-1-piperazinyl]ethanesulfonic acid) buffer (10 mM, pH 7.4; see Supporting Information). In the absence of anionic guest, the absorption maximum of **1** in HEPES buffered solution shows a slight red shift (12 nm) relative to that observed in unbuffered aqueous solution and appears at 412 nm. This difference may be due to the size-dependent effects of counterions as reported previously.[17] Upon further addition of ATP, the absorption maximum is red-shifted gradually to 476 nm and is accompanied by the appearance of two shoulders at 536 and 583 nm. Unlike the large shift of 138 nm toward the red region as observed in aqueous solution, a relatively small red shift (64 nm) is detected in solution of **1** in HEPES buffer due to the competitive binding of HEPES anions with **1**. Despite this, it does not prevent the analytical determination of ATP with **1** (see Supporting Information) which indicates that **1** can be applied as a satisfactory ATP sensor in aqueous solution at physiological pH values.

It is known that conformational changes and interchain interactions play decisive roles in controlling the emissive properties of conjugated polymers that have been applied in some fluorescence sensory systems.[18] Given the high sensitivity of fluorometric methods relative to absorption spectroscopy, it is expected that fluorometry will extend the detection limit of ATP. The yellow, random-coiled form of **1** is fluorescent and exhibits an emission band around 536 nm upon excitation at 445 nm (see Supporting Information). Upon addition of increasing amounts of ATP, the emission intensity decreases gradually and a slight red shift and broadening of the band is observed which indicates that fluorometric detection of ATP binding is possible. Of the analytes studied here, the fluorescence quenching of **1** (5.0×10^{-6} M in 10 mM HEPES buffer at pH 7.4) is most sensitive to binding with ATP; that is, an 84% decrease in intensity at the emission maximum was observed in the presence of an equimolar amount of ATP, whereas only 12% quenching of the fluorescence was detected upon addition of an equimolar amount of AMP (Figure 5). These results indicate that the
Figure 5. Fluorescence quenching of **1** (5.0×10^{-6} M) by AMP, ADP, and ATP at various concentrations in 10 mM HEPES buffered solution at pH 7.4. The fluorescence quenching $Q = [(I_0 - I)/I_0] \times 100\%$; I_0 is the fluorescence intensity at 529 nm of a solution of **1** (5.0×10^{-6} M); I is the fluorescence intensity at 529 nm of a solution of **1** (5.0×10^{-6} M) in the presence of different amounts of the analytes ATP (□: $\lambda_{ex} = 445$ nm), ADP (○; $\lambda_{ex} = 435$ nm), and AMP (△; $\lambda_{ex} = 435$ nm).

quenching of fluorescence is much more effective in the presence of ATP than with the use of AMP or ADP and that the detection limit can be extended to the order of 10^{-8} M.

In conclusion, we have developed a novel colorimetric and fluorescent sensor for ATP that operates in aqueous solution. The present findings will not only extend the application of water-soluble conjugated polymers but also provide a new approach for facile monitoring of ATP based on the different mechanisms discussed above. Therefore, we expect that the present system will be applicable to routine cellular assays after the rational design of the substituted groups (e.g. the introduction of zwitterionic groups or poly(ethylene glycol) groups) in polythiophenes to improve the membrane permeability of the probe, and further research along this line is currently in progress.

[14] Guanosine triphosphate (GTP), which bears a purine base, can also form a supramolecular complex with **1**, which results in a similar change in color of the solution from yellow to pink-red. However, the presence of ATP can be efficiently distinguished from GTP by a chiroptical method as the two supramolecular complexes with **1** give opposite induced circular dichroism pattern (see Supporting Information).

[16] The differences between the ^{1}H NMR spectra (D$_2$O) of the adenosine moiety in ATP and the complex ATP/**1** further support this conclusion. In the complex, the 8-H and 2-H protons in the adenine moiety and the 1′-H proton in the D-ribose moiety shift to higher field and is accompanied by broadening of these peaks relative to those for "free" ATP in solution, indicating the significant contribution of π–π stacking between adenosine moieties.

Protein Analysis

Differential Receptors Create Patterns That Distinguish Various Proteins**

*Aaron T. Wright, Michael J. Griffin, Zhenlin Zhong,
Shawn C. McCleskey, Eric V. Anslyn,* and
John T. McDevitt**

The term "protein-detecting array" has been coined to describe an analytical device consisting of a series of protein receptors.[1] Classically, such an array consists of highly selective protein-binding agents. Unfortunately, the creation of synthetic receptors with high affinity and specificity for proteins is particularly challenging owing to their molecular complexity. However, there has been recent success in creating selective synthetic receptors for assorted peptides.[2]

An alternative to the use of highly selective receptors is to employ differential receptors.[3] This method uses an array of receptors having good affinity, but not necessarily high selectivity, for a particular target. When functioning in tandem the combined response of the receptors creates a pattern that is diagnostic for each analyte. Because the response of the receptor array does not necessarily rely on specific recognition interactions between substrate and analyte, highly challenging analytes can be targeted.

Very few groups have used differential receptors for the analysis of biomolecules.[3] Hamilton et al. recently reported the use of a 35-member receptor library of tetraphenyl porphyrin derivatives, functionalized with different amino acids resulting in charges varying from +8 to −8, for the detection of charged proteins. Eight members of the library were used to detect four charged proteins, ranging from acidic ferredoxin (pI = 2.75) to highly basic cytochrome C (pI = 10.6). Fluorescence quenching patterns composed from the responses of the eight receptors correlated with the charge complementarity between the receptors and proteins.[4] Until our current report, differential receptor arrays had not found use in distinguishing classes of proteins.

Our group's approach to differential sensing is to create libraries of receptors that are biased towards particular analyte classes. Using this approach, we have shown that a

microchip-based array incorporating a combinatorial library of receptors[5] is effective in differentiating nucleotide phosphates with an indicator-displacement assay.[6] We now report the development of a library of differential receptors biased towards proteins and glycoproteins. When combined with an indicator-uptake visualization assay and principal component analysis (PCA), the library gives differentiation of proteins and glycoproteins, as well as subtle differentiation within each protein class.[7]

To differentiate proteins and glycoproteins, we designed and synthesized library **1**, which incorporates one of 19

1
R^n are amino acids
natural amino acids (cysteine excluded) at each of three sites on two different binding arms, by using combinatorial chemistry.[8] This created a library with 19^3 (6859) unique members. The peptide arms provide sites for molecular recognition of proteins by means of ion pairing, hydrogen bonding, and the hydrophobic effect. The boronic acids provide effective sugar binding sites because these groups rapidly and reversibly form cyclic esters with diols in aqueous media.[9] The hexasubstituted benzene scaffold acts as a spacer and assists in the creation of a binding cavity.[10] Our expectation was that each receptor would show differential binding with proteins based on the variance in the peptide arms, and that the boronic acids would assist in differentiation of proteins from glycoproteins.

We used a 7 × 5 array consisting of 29 randomly selected resin beads from library **1** and six acylated resin blanks. Each bead was placed in a micromachined chip-based array platform (see the Supporting Information) that has been previously described.[11] Protocols for the delivery of protein and indicator, and for acidic and basic washes? have been detailed previously. The patterns created by the array of receptors are obtained by measuring the intensity of transmitted red, green, and blue light for each bead using a charge-coupled device attached to a customized reader.[12]

In order to create diagnostic patterns for each protein, a signaling protocol was incorporated. Previous work utilized

indicator-displacement assays; however, at the low protein concentrations used in this study it was more advantageous to evaluate the rate of indicator uptake. Our indicator-uptake signaling protocol allowed us to use protein concentrations (355 µM) nearly 60 times less than that in our previous work with nucleotide phosphates (20 mM).[6] We incorporated the commercially available indicator bromopyrogallol red (**2**) for the indicator-uptake colorimetric analysis. This indicator forms reversible cyclic esters with the boronic acids of the receptor.
Our experimental protocol starts with a delivery of 5 mL of a protein solution (355 µM in HEPES buffer) at a flow rate of 0.25 mL min^{-1}. This is followed by washing with buffer for 3 min (25 mM HEPES, pH 7.4, 1.0 mL min^{-1}) and then delivery of **2** (3.0 µM in HEPES buffer, 1.0 mL min^{-1}). After each analysis, the protein and indicator were washed from the array with NaOH (150 mM) and HCl (300 mM) rinses. This allowed for repeated use of the array. A 12-bit image was captured every 2 s during indicator uptake. For each receptor bead in the array the green-channel absorbance ($\lambda = 550$ nm) was plotted versus time and a slope was garnered. Effective absorbance values were obtained by calculating the negative log of the ratio of the green-channel intensity of each bead to the green-channel intensity of a blank bead.[11]

Ovalbumin, fetuin, lysozyme, bovine serum albumin (BSA), and elastin were used for this study. These choices were made to challenge our design principles by grouping proteins of similar properties. The characteristics of the proteins span a variety of molecular weights, glycosidic properties, and isoelectric points (pI). The molecular weights of ovalbumin and fetuin are similar, as are those of elastin and BSA. The pI of ovalbumin, BSA, and fetuin are similar, as are those of lysozyme and elastin (Table 1).

2

Figure 1. Indicator-uptake curves from three beads are represented from a trial with BSA. The slope from 49 to 403 s for each resin-bound receptor is taken as part of a cumulative slope pattern for each protein. A_{eff} is the effective absorbance. See the text for an explanation of the measurement procedure.

In PCA, the first principal component (PC) axis is calculated to lie along the line of maximum variance in the original data set. Subsequent orthogonal axes are calculated to lie along lines of diminishing levels of variance. In this study, the first four PC axes effectively satisfied the Kaiser criterion, which states that as many factors can be extracted as variables that have eigenvalues greater than one.[14] Figure 2
Figure 2. PCA score plot for each protein trial. Percentages on the PC axes define the weight of those axes to the overall pattern. Spacing between proteins demonstrates the recognition capability of the resin-bound receptors. (● lysozyme, ● elastin, ● ovalbumin, ● fetuin, ● BSA)

Table 1: Characteristic protein data.

Protein	M_w [kDa]	pI	Glycoprotein?
ovalbumin	44–45	4.6	yes
fetuin	48.4	4.5–4.9	yes
lysozyme	14	9.6–11	no
BSA	66	4.7–5.2	no
elastin	60	9.3–10.2	no

Four trials were performed for each protein.[13] The indicator-uptake slopes were calculated for each receptor bead over the time during which the dye passed through the array (49 to 403 s). An illustration of the differences in indicator uptake from different resin-bound receptors can be seen in Figure 1. For each trial a slope was measured for each bead (blanks not included). Because of the large number of slopes calculated from each trial, the dimensionality of the data set was simplified using PCA.

shows a two-dimensional PCA plot which effectively separates the different protein classes. As illustrated, there is differentiation between proteins and glycoproteins, which was a primary goal of this study. However, because four PC axes are outside the range of error it was possible to generate a three-dimensional PCA plot that further separates the proteins. Figure 3 shows an expanded PCA plot using PC axes 1–3. This demonstrates that the array of receptors adequately separated proteins from glycoproteins, and to a lesser extent even separates proteins within the classes. The fact that we used a random selection of receptors to achieve these results illustrates the power of our method. More than likely any one of these 29 receptors would not have been a good receptor for a particular protein; however, when functioning in tandem, the array works well. Further, any 29 receptors could presumably be used to obtain analogous patterns for the proteins. PC axis 4 (4.7%) could have also been used for further discrimination in another plot.
Figure 3. PCA score plot for each protein trial (● lysozyme, ● elastin, ● ovalbumin, ● fetuin, ● BSA). The additional dimension further separates the proteins.

A control was performed using a 7×5 array with six blanks and 29 resin beads derivatized only with tripeptides that were obtained from a combinatorial library synthesized with 19 natural amino acids (cysteine excluded). Using this array of tripeptide beads, no separation of analytes occurred. This control illustrates that some design must be incorporated into the receptors to bind certain analyte classes, and that simple random receptors are inefficient. These results do not strictly demonstrate that the boronic acids bind to glycoproteins and not standard proteins. More likely the boronic acids interact with surface epitopes on both protein classes but to different extents. Yet, if differential formation of covalent bonds with the boronic acids was the only factor in the discrimination between protein classes, then because they are the only binding moiety present in every receptor we would expect no differences within each protein class. Therefore, both the boronic acids and the variable peptide arms of the receptors are critical in the identification and discrimination of proteins and glycoproteins.

Though we significantly reduced the analyte concentrations from those in our previous report with nucleotide phosphates, the protein concentrations (355 μM) are still relatively high for practical analysis. Reduction to practical concentrations (nM) was accomplished with differential receptors of higher affinity. In other work we have also shown that an analysis cell that recycles the analyte solution through the array leads to extremely sensitive assays.[15]

The PCA plot (Figure 2 and Figure 3) demonstrates similarities between ovalbumin and fetuin, and similarities between elastin and lysozyme. Yet, even the proteins in similar groups are separated. The proximity of ovalbumin and fetuin is reasonable as both are glycoproteins with similar pI values, and both likely interacted with the boronic acid moieties. Further, elastin and lysozyme have similar pI values. Therefore, the separation in our analysis is not simply a result of charge differences. Interestingly, molecular weight also did not play a large role in the patterns exhibited. BSA is likely separated from the others because it has a different pI than elastin and lysozyme and is not a glycoprotein. The differentiation between similar proteins is likely due to specific contacts between the receptors and proteins that are cross-reactive and subtly discriminatory.

Factor loading values are calculated in PCA to determine the magnitude of the contribution of an original variable to the formation of a PC axis. Variables with loading values approaching −1 or 1 have a dominant role in the formation of a PC axis. Because PC axis 1 described the most variance, five beads with high loading values on PC 1 and two beads with low loading values were selected for receptor characterization (Table 2) using Edman degradation. The sequencing results do not show any obvious homologies. Yet, the lack of any homology is a lesson in itself: differential sensing schemes can be successful and may even benefit from a wide variety of structurally diverse receptors.

Table 2: Factor loadings and sequencing results for principal component 1.

Tripeptide sequence	Factor loadings (PC 1)	Bead number
Ala-Ser-Asp	0.984	12
Ser-Lys-Gly	0.963	9
Arg-Lys-Lys	0.951	15
Gly-Asp-Ser	0.932	2
Asp-Leu-Val	0.928	22
Lys-Arg-Met	0.774	23
Gly-Gln-Gln	0.722	6

In summary, we have shown that the use of an array of differential receptors can differentiate between classes of proteins, and even between very structurally similar proteins. This separation did not arise from charge differences or molecular weight differences, but rather from specific contacts between receptors and proteins giving discriminatory patterns. We plan to expand this general approach to the qualitative analysis of complex mixtures of proteins.

SiGe$_2$ and Ge$_3$: Cyclic Digermenes that Undergo Unexpected Ring-Expansion Reactions**

*Vladimir Ya. Lee, Hiroyuki Yasuda, Masaaki Ichinohe, and Akira Sekiguchi**

The chemistry of cyclic compounds composed of heavier Group 14 elements represents one of the most fascinating topics of modern organometallic chemistry. Since the first reports on the preparation of heavy cyclopropane analogues by Masamune et al. in 1982–1983,[1] the chemistry of these unusual compounds has been greatly developed in all respects, including synthesis, structure, and reactivity. The first examples of heavy cyclopropene analogues were synthesized only recently, during the last decade.[2] Since then, several representatives of these highly challenging compounds, which combine the properties of heavy cyclopropanes and heavy alkenes in one molecule, have been reported.[3]

Apart from the homonuclear heavy cyclopropenes, consisting of identical Group 14 elements, several heteronuclear analogues containing different heavier Group 14 elements can also be imagined. However, of all the possible combinations only two heteronuclear heavy cyclopropenes have been synthesized by the Würtz-type coupling reaction, namely 3*H*- and 1*H*-disilagermirenes, which feature endocyclic Si=Si and Si=Ge bonds, respectively.[4] Herein, we report the synthesis of two cyclic, three-membered-ring digermenes: the first 1*H*-siladigermirene, a heteronuclear cyclopropene with one Si and two Ge atoms, and a novel 1*H*-trigermirene derivative.

As the target compound 1*H*-siladigermirene, in contrast to 3*H*-disilagermirene,[4] could not be prepared by the Würtz coupling reaction, we developed a new synthetic protocol that involves a coupling reaction of 1,1-dilithiosilane R$_2$SiLi$_2$[5] with tetrachlorodigermane RCl$_2$Ge−GeCl$_2$R in toluene (R = SiMe*t*Bu$_2$). This reaction quickly results in the formation of two products, tetrakis(di-*tert*-butylmethylsilyl)-1*H*-siladigermirene (R$_4$SiGe$_2$, **1a**) and disilene R$_2$Si=SiR$_2$ (**2a**),[6] in a 2:1 ratio (Scheme 1). It is interesting that among the various compounds that one can imagine as the products of this reaction, namely 1,4-disila-2,3-digermabuta-1,3-diene, 2,4-disila-1,3-digermabicyclo[1.1.0]butane, and 1*H*-siladigermirene, only the last compound was formed. The isolation of disilene **2a** as the side product provides evidence for the

Scheme 1. Synthesis of the 1*H*-siladigermirene **1a** and the 1*H*-trigermirene **1b**. E = Si, Ge; R = SiMe*t*Bu₂.

initial formation of the intermediate cyclic 2,3-dichlorosiladigermirane (**3a**) followed by a rapid lithium–chlorine exchange reaction between **3a** and a second equivalent of R₂SiLi₂, finally resulting in the formation of **1a** and **2a** in a 2:1 ratio.[7] The 1H-siladigermirene **1a** represents the first SiGe₂ hybrid heavy analogue of cyclopropene featuring a skeletal Ge=Ge double bond.

Compound **1a** exhibits very simple ^{1}H and ^{13}C NMR spectra with only two sets of signals for the protons of the Me and *t*Bu groups. In the ^{29}Si NMR spectrum of **1a**, the skeletal Si atom resonates at high field ($\delta = -110.6$ ppm), as expected for tetrahedral Si atoms incorporated in a three-membered-ring system. Dark red crystals of **1a** were isolated that were highly sensitive to air and moisture. The X-ray crystal structure analysis[8] proved that **1a** was an unsaturated three-membered ring with a Ge=Ge double bond length of 2.2429(6) Å (Figure 1). The remaining two sides of the SiGe₂ isosceles triangle are made up of Si–Ge single bonds (2.4167(10) Å). These skeletal bond lengths are characteristic for three-membered rings of heavier Group 14 elements. As expected, the Ge=Ge double bond has a highly pronounced *trans*-bent configuration with a bending angle of 51.0(2)°.[9]
Figure 1. ORTEP plot of the crystal structure of **1a**; the thermal ellipsoids are shown at the 30% probability level and hydrogen atoms are omitted. Selected bond lengths [Å] and angles [°]: Ge1-Ge2 2.2429(6), Si3-Ge1 2.4168(10), Si3-Ge2 2.4165(10), Ge1-Si4 2.3995(11), Ge2-Si5 2.3943(11), Si3-Si6 2.3993(13), Si3-Si7 2.4033(13); Ge2-Ge1-Si3 62.34(11), Ge1-Ge2-Si3 62.36(3), Ge1-Si3-Ge2 55.30(2). The torsional angle Si4-Ge1-Ge2-Si5 is 51.0(2)°.

By employing the same synthetic approach, we were able to prepare the corresponding Ge₃ analogue, tetrakis(di-*tert*-butylmethylsilyl)-1*H*-trigermirene (**1b**), by the reaction of dilithiogermane R₂GeLi₂[10] and tetrachlorodigermane RCl₂Ge–GeCl₂R in toluene (Scheme 1). As with **1a**, compound **1b** was formed along with R₂Ge=GeR₂ (**2b**) in a 2:1 ratio.

The reactivity of the new cyclic digermenes **1a** and **1b** proved to be very interesting. Compounds **1a** and **1b** readily react with an excess of CH₂Cl₂ at room temperature to produce the new four-membered-ring compounds, *trans*-2,4-dichloro-1,1,2,4-tetrakis(di-*tert*-butylmethylsilyl)[1,2,4]siladigermetane (**5a**) and *trans*-1,3-dichloro-1,2,2,3-tetrakis(di-*tert*-butylmethylsilyl)[1,2,3]trigermetane (**5b**), respectively, as the result of ring expansion (Scheme 2).
Scheme 2. Reaction of **1a** and **1b** with CH₂Cl₂ along with the proposed mechanism for the formation of [1,2,4]siladigermetane **5a** and [1,2,3]trigermetane **5b**. R = SiMe*t*Bu₂.

Surprisingly, the ^{1}H NMR spectra of **5a** and **5b** display markedly downfield-shifted resonances for the skeletal methylene protons: $\delta = 2.79$ and 2.98 ppm, respectively.[11] This unusual feature might be attributed to a hyperconjugative σ(C–H)–σ*(Ge–Cl) interaction, which would result in a downfield shift of the signal of the CH₂ protons. The crystal structure analysis of **5a**[8] demonstrates a folded SiGe₂C four-membered ring (folding angle 33°) with long skeletal Si–Ge bonds of 2.475(2) and 2.547(3) Å (typical values 2.384–2.462 Å[12]), which could be due to steric congestion around the Ge1-Si2-Ge3 unit (Figure 2). The long Ge–Cl bonds of 2.229(2)–2.236(2) Å are another interesting feature, as they exceed the normal values of 2.08–2.15 Å.[12] The formation of **5a** and **5b** may involve initial 1,2-addition of a molecule of CH₂Cl₂ across the Ge=Ge bond of **1a** and **1b** to form the intermediate cyclopropane-type derivatives **4a** and **4b**,[13] followed by intramolecular insertion of the methylene unit into the neighboring endocyclic Ge–Ge bond (Scheme 2). Indeed, calculations at the B3LYP/6-31G(d) level with the GAUSSIAN 98 program on model compounds of **5a** and **4a** with R=SiH₃ showed that the final four-membered ring **5a** is 41.7 kcal mol⁻¹ more stable than the intermediate three-membered ring **4a**.

We found that CH₂Cl₂ is a unique reagent with respect to its reactivity toward the heavy cyclopropene analogues **1a** and **1b**. For example, CCl₄ reacts with **1a** and **1b** to form the

Figure 2. ORTEP plot of the crystal structure of **5 a**; the thermal ellipsoids are shown at the 30% probability level and hydrogen atoms are omitted. Selected bond lengths [Å] and angles [°]: Si2-Ge1 2.547(3), Si2-Ge3 2.475(2), Ge1-C1 1.998(10), Ge3-C1 1.956(10), Ge1-Cl1 2.229(2), Ge3-Cl2 2.236(2); Ge1-Si2-Ge3 73.88(6), Si2-Ge3-C1 90.0(3), Ge3-C1-Ge1 99.5(4), C1-Ge1-Si2 87.0(3).

corresponding dichloro derivatives 2,3-dichloro-1,1,2,3-tetrakis(di-*tert*-butylmethylsilyl)siladigermirane (**3a**) and 1,2-dichloro-1,2,3,3-tetrakis(di-*tert*-butylmethylsilyl)trigermirane (**3b**), instead of the ring-expansion products (Scheme 3).[14]
Scheme 3. Reaction of **1 a** and **1 b** with CCl$_4$ with formation of 2,3-dichlorosiladigermirane **3 a** and 1,2-dichlorotrigermirane **3 b**. R = SiMe*t*Bu$_2$.

The reaction with CHCl$_3$ results in complicated product mixtures. The ring-expansion reaction with CH$_2$Cl$_2$ is general for all heavy cyclopropene analogues of the type R$_4$EE$'_2$ (R = SiMe*t*Bu$_2$; E, E' = Si, Ge). Thus, the previously reported 1*H*-trisilirene R$_4$Si$_3$[2b] as well as the 3*H*- and 1*H*-disilagermirenes R$_4$GeSi$_2$[4] smoothly react with CH$_2$Cl$_2$ to produce four-membered rings that are isostructural to **5a** and **5b**.

Experimental Section

1a: A mixture of (*t*Bu$_2$MeSi)$_2$SiLi$_2$—prepared from 1,1-bis(di-*tert*-butylmethylsilyl)-2,3-bis(trimethylsilyl)-1-silacycloprop-2-ene
(500 mg, 0.98 mmol) and Li (35 mg, 5.00 mmol) in THF (4 mL)—and *t*Bu$_2$MeSi-GeCl$_2$-GeCl$_2$-SiMe*t*Bu$_2$ (200 mg, 0.33 mmol) was placed in a reaction tube with a magnetic stirrer bar. Dry, oxygen-free toluene (4 mL) was introduced by vacuum transfer, and the dark green reaction mixture was stirred for 1 h at room temperature. After the inorganic salts were removed by filtration and the solvent was removed under vacuum, the residue was taken up in hexane and separated by column chromatography on silica gel (eluent: hexane) in a glove box. Recrystallization of the appropriate fraction from pentane at −30 °C produced pure **1a** as dark red crystals (68 mg, 26%), m.p.: 193–195 °C; ^{1}H NMR (300.1 MHz, [D$_6$]benzene, TMS): δ = 0.43 (s, 6H), 0.53 (s, 6H), 1.21 (s, 36H), 1.30 ppm (s, 36H);

^{13}C{^{1}H} NMR (75.5 MHz, [D$_6$]benzene, TMS): δ = −3.9, −2.1, 22.8, 23.4, 29.8, 31.2 ppm; ^{29}Si{^{1}H} NMR (59.6 MHz, [D$_6$]benzene, TMS): δ = −110.6 (cyclic Si), 5.8 and 40.8 ppm (substituent Si); UV/Vis (hexane): λ_{max} (ε) = 470 (1200), 403 (1000), 311 (2400), 236 nm (21 800 M^{-1}cm^{-1}); elemental analysis (%) calcd for C$_{36}$H$_{84}$Ge$_2$Si$_5$: C 53.87, H 10.55; found: C 54.06, H 10.33.

1b: Compound **1b** was prepared from (*t*Bu$_2$MeSi)$_2$GeLi$_2$ and *t*Bu$_2$MeSi-GeCl$_2$-GeCl$_2$-SiMe*t*Bu$_2$ in 22% yield as dark red crystals; m.p.: 188–190 °C; ^{1}H NMR (300.1 MHz, [D$_6$]benzene, TMS): δ = 0.46 (s, 6H), 0.54 (s, 6H), 1.23 (s, 36H), 1.29 ppm (s, 36H); ^{13}C{^{1}H} NMR (75.5 MHz, [D$_6$]benzene, TMS) δ = −3.8, −1.9, 22.7, 23.7, 29.8, 31.0 ppm; ^{29}Si{^{1}H} NMR (59.6 MHz, [D$_6$]benzene, TMS): δ = 17.0, 39.1 ppm; UV/Vis (hexane): λ_{max} (ε) = 457 (700), 407 (700), 324 (2400), 234 nm (13 600 M^{-1}cm^{-1}); elemental analysis (%) calcd for C$_{36}$H$_{84}$Ge$_3$Si$_4$: C 51.04, H 9.99; found: C 50.71, H 9.77.

5a: A mixture (319 mg) of 2-siladigermirene **1a** and disilene **2a** (2:1) was placed in a reaction tube with a magnetic stirrer bar. Dry, oxygen-free CH$_2$Cl$_2$ (1 mL) and hexane (1 mL) were introduced by vacuum transfer, and the reaction mixture was stirred for 3 h at room temperature to give a dark blue solution. After removal of the solvents under vacuum, the residue was separated by column chromatography on silica gel (eluent: hexane) in a glove box. Two fractions were collected: the first blue fraction (**2a**) and the second pale yellow fraction (**5a**). After removal of the solvent under vacuum, the second fraction was recrystallized from hexane at −30 °C to give pure **5a** as colorless crystals (173 mg, 71%), m.p.: 152–154 °C; ^{1}H NMR (300.1 MHz, [D$_6$]benzene, TMS): δ = 0.46 (s, 6H), 0.79 (s, 6H), 1.20 (s, 18H), 1.21 (s, 18H), 1.24 (s, 18H), 1.31 (s, 18H), 2.79 ppm (s, 2H, CH$_2$); ^{13}C{^{1}H} NMR (75.5 MHz, [D$_6$]benzene, TMS): δ = −4.8, 1.1, 22.5, 23.1, 23.5, 24.3, 29.8, 30.0, 31.4, 31.8, 42.6 ppm; ^{29}Si{^{1}H} NMR (59.6 MHz, [D$_6$]benzene, TMS): δ = 21.5 and 28.6 (substituent Si), 30.7 ppm (cyclic Si); elemental analysis (%) calcd for C$_{37}$H$_{86}$Cl$_2$Ge$_2$Si$_5$: C 50.07, H 9.77; found: C 49.81, H 9.82.

5b: Compound **5b** was prepared from a mixture of **1b** and **2b** in 69% yield as colorless crystals; m.p.: 149–152 °C; ^{1}H NMR (300.1 MHz, [D$_6$]benzene, TMS): δ = 0.46 (s, 6H,), 0.84 (s, 6H), 1.201 (s, 18H), 1.203 (s, 18H), 1.23 (s, 18H), 1.30 (s, 18H), 2.98 ppm (s, 2H, CH$_2$); ^{13}C{^{1}H} NMR (75.5 MHz, [D$_6$]benzene, TMS): δ = −4.9, 1.3, 22.9, 23.3, 23.5, 24.2, 29.8, 30.0, 31.2, 31.6, 44.9 ppm; ^{29}Si{^{1}H} NMR (59.6 MHz, [D$_6$]benzene, TMS): δ = 27.7, 31.0 ppm; elemental analysis (%) calcd for C$_{37}$H$_{86}$Cl$_2$Ge$_3$Si$_4$: C 47.68, H 9.30; found: C 47.74, H 9.32.

[7] The dichloride **3a**, independently synthesized by the reaction of **1a** with CCl_4, immediately reacts with an equivalent amount of R_2SiLi_2 to form exclusively **1a** and **2a** in a 2:1 ratio.

[8] Crystal structure analyses of **1a** and **5a**: The single crystals were grown from saturated solutions in hexane. The diffraction data were collected at 120 K on a MacScience DIP2030 Image Plate Diffractometer employing graphite-monochromated $Mo_{K\alpha}$ radiation ($\lambda = 0.71070$ Å). Crystal data for **1a** ($C_{36}H_{84}Ge_2Si_5$): $M_r = 802.66$, monoclinic, space group $P21/c$, $a = 24.1020(6)$, $b = 11.6190(9)$, $c = 17.7300(16)$ Å, $\beta = 110.206(4)°$, $V = 4659.6(6)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.144$ g cm^{-3}, GOF = 1.008. The final R factor was 0.0544 ($R_w = 0.1611$ for all data) for 7455 reflections with $I_o > 2\sigma(I_o)$. Crystal data for **5a** ($C_{37}H_{86}Cl_2Ge_2Si_5$): $M_r = 887.59$, monoclinic, space group Cc, $a = 23.1270(16)$, $b = 12.4550(14)$, $c = 17.8730(19)$ Å, $\beta = 109.567(6)°$, $V = 4850.9(8)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.215$ g cm^{-3}, GOF = 0.999. The final R factor was 0.0580 ($R_w = 0.1548$ for all data) for 3834 reflections with $I_o > 2\sigma(I_o)$. The structures were solved by direct methods and refined by full-matrix least-squares methods using the SHELXL-97 program. CCDC 273374 (**1a**) and 273375 (**5a**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

The molecular mechanisms of the commonly employed hydrolases involve nucleophilic attack onto the carbonyl group of carboxylic acids or their derivatives.[1,2] As this group is a planar entity, any stereochemical alterations of the substrate caused by enzymatic catalysis are impossible, and as a consequence, enantiomers of the transformed substrate and product are usually homochiral (with the exception of prochiral or *meso* esters), that is, they have the same absolute configuration. Although the stereochemical features of the substrate, such as stereogenic centers (in racemates) or enantiotopic groups (in prochiral or *meso* compounds), are "recognized" by the enzyme, which gives rise to differences in k_{cat} and/or K_M values, they remain unchanged during catalysis.

Biocatalysts, which elicit the more complex potential to affect the stereochemistry of the substrate in a controlled fashion during catalysis, are rather rare and encompass haloalkane dehalogenases,[3] epoxide hydrolases,[4] and (alkyl) sulfatases.[5,6] In each case, a $C(sp^3)$ atom could potentially be involved in the catalysis and therefore open the possibility of stereocomplementary pathways. These enzymes do not only display enantioselectivity (through the transformation of one substrate enantiomer faster than the other) but also stereoselectivity (with retention or inversion of configuration). This therefore makes them important catalytic tools for the development of so-called enantioconvergent processes in which each enantiomer from a racemic mixture is transformed into the same product through independent pathways, that is, through retention and inversion of configuration.[7] As a consequence, a racemate can be

converted, in principle, into a single stereoisomeric product without the occurrence of an undesired stereoisomer.

Sulfatases catalyze the hydrolytic cleavage of the sulfate ester bond (Scheme 1). Depending on the enzyme subtype, the stereochemical course of sulfate ester hydrolysis can be
Scheme 1. Enzymatic stereodivergent hydrolysis of sulfate esters catalyzed by sulfatases.

controlled by an appropriate enzyme. On the one hand, inverting sulfatases[8,9] were shown to act on sec-alkyl sulfate esters by breaking the C–O bond of the sulfate ester, which resulted in inversion of configuration (Scheme 1, pathway A). However, nothing is known about their mechanism of action. Based on limited knowledge of the stereospecific and enantioselective hydrolysis of alkyl sulfate esters,[8] we recently reported an inverting alkyl sulfatase (termed "RS2") from *Rhodococcus ruber* DSM 44541.[10–12] Although the enzyme exhibited absolute stereospecificity through strict inversion of configuration of simple sec-alkyl sulfate esters, its enantioselectivity was less than perfect and its substrate tolerance was rather narrow. These limitations could be circumvented through the use of aerobically grown sulfur metabolizers. In particular, *Sulfolobus* spp., which exhibited not only enhanced enantioselectivities but also a broader substrate spectrum,[13] showed a stereoselectivity identical to that of "RS2", that is, inversion of configuration was observed.

To exploit the full potential of the enzymatic hydrolysis of alkyl sulfate esters, stereocomplementary sulfatases that act with retention of configuration were needed. In contrast to inverting sulfatases, the mechanism of action of retaining sulfatases is well understood (Scheme 2).[14,15] The mechanism

was elucidated during structural studies on human aryl sulfatase A[16] and was shown to proceed through cleavage of the S–O bond.[17] The latter is effected by nucleophilic attack of an aldehyde hydrate (formed from a Cys or Ser residue by post-translational modification[18]) onto the sulfur atom; the result is liberation of the corresponding alcohol and retention of its stereochemistry (Scheme 2).[19]

The same principle of catalysis was shown to occur in sulfatases from *Pseudomonas aeruginosa*[20] and *Klebsiella pneumoniae*.[21] As the natural substrates of these enzymes are believed to be glycosyl and aryl sulfate esters,[16] nothing is known about their enantioselectivities. Our search for a suitable microbial source for retaining (alkyl) sulfatase activity was led by the fact that all known sulfatases that act through the above-mentioned mechanism have the canonical sulfatase consensus motif C/S-X-P-X-R-X$_4$-T-G.[18,22,23,27] This sequence motif encompasses sulfatases from mammals, lower eukaryotes, and prokaryotes,[24] but is absent in the inverting alkyl sulfatase RS2 from *Rhodococcus ruber*.[25]

A recently published complete genome sequence of the marine planctomycete *Rhodopirellula baltica* DSM 10527 (formerly denoted as *Pirellula* sp. 1)[26,27] revealed the existence of an unexpectedly high number of 110 genes putatively encoding sulfatases. It is believed that, in *R. baltica*, these enzymes play a vital role in the metabolism of sulfated carbohydrates, such as chondroitin. Of the 110 potential sulfatase sequences, 85 show the conserved "core" of the sulfatase consensus motif C-X-P-X-R, which is required in post-translational modification to render activated sulfatase proteins. Furthermore, each of the 85 sequences contains the adjacent "auxiliary" part of the consensus motif, X$_4$-T-G, either fully conserved or only slightly modified. This part of the sulfatase consensus motif has been implicated in modulating the efficiency of the post-translational modification step.[24] According to the sequence–function relationships proposed for both eukaryotic and prokaryotic sulfatases,[20,22,24] the 85 putative sulfatases from *R. baltica* were expected to act through retention of configuration.

To prove this hypothesis, a set of sec-alkyl sulfate esters, rac-**1a**–**9a** and the primary sulfate ester **10a** were screened by using resting whole cells of *R. baltica* DSM 10527 (Table 1). In general, the enantiopreference was shown to be R, that is, R enantiomers were preferentially hydrolyzed from the racemate, while S enantiomers remained untouched.

R. baltica displayed excellent activities on linear (ω-1)-sulfate esters rac-**1a**–**3a** (Table 2, entries 1–3), which were readily accepted as substrates. Surprisingly, even sterically demanding sulcatyl sulfate (rac-**4a**), which was accepted by neither sulfatase RS2 nor *Sulfolobus* spp., was converted with good rates. Concerning the
Scheme 2. Schematic representation of the mechanism of action of retaining (aryl) sulfatases.

[a] No conversion. [b] Opposite absolute configuration due to a switch in Cahn—Ingold priority (CIP) assignment of R^1 and R^2.

Table 2: Hydrolysis of sulfate esters using glucose-grown *Rhodopirellula baltica* DSM 10 527.

Entry	Substrate	Conversion [%]	Product	*ee* [%]	Enantioselectivity (*E* value)
1	*rac*-**1a**	16	(*R*)-**1b**	>99	>200
2	*rac*-**2a**	13	(*R*)-**2b**	>99	>200
3	*rac*-**3a**	18	(*R*)-**3b**	>99	>200
4	*rac*-**4a**	11	(*R*)-**4b**	>99	>200
5	*rac*-**5a**	n.c.	–	–	–
6	*rac*-**6a**	n.c.	–	–	–
7	*rac*-**7a**	3	(*R*)-**7b**	48	3
8	*rac*-**8a**	10	(*R*)-**8b**	29	2
9	*rac*-**9a**	6	(*S*)-**9b**[a]	42	3
10	**10a**	26	**10b**	n.a.	n.a.

[a] Absolute configuration is *S* owing to a switch in CIP priority rules, however, it is homochiral to (*R*)-**1b**–**4b**, **7b**, **8b**. n.c. = no conversion; n.a. = not applicable. *E* values were calculated from $E = \{\ln[1-c(1+ee_p)]\}/\{\ln[1-c(1-ee_p)]\}$ where c = conversion and ee_p = enantiomeric excess of product.

enantioselectivities, all four substrates (Table 2, entries 1–4) showed perfect *E* values (>200) and the corresponding *R* alcohols **1b**–**4b** were obtained with excellent *ee* values (>99%). However, in the case of phenyl-substituted substrates (Table 2, entries 5 and 6), no conversion was observed. As R^1 and R^2 became similar in size, yielding near-symmetrical compounds (Table 2, entries 7–9), the enantioselectivities decreased as was observed in previous studies on inverting sulfatases.[9,10,13] As *R. baltica* has more than 100 genes that encode putative sulfatases, it is not surprising that the primary sulfate ester **10a** was readily converted as well.

Stereochemical analysis of the products suggested that the hydrolysis pathway proceeded with retention of configuration. For unambiguous proof, enantiopure (*R*)-2-octyl sulfate was used as the substrate, which yielded (*R*)-2-octanol

without racemization in >99% *ee*; analogously, enantiopure (*S*)-2-octyl sulfate remained untouched. Screening of the extracellular medium did not show any activity, which suggests that these sulfatases are intracellular. Using *R. baltica* grown on various C sources—glucose, chondroitin sulfate A,[28] and chondroitin sulfate C—did not lead to significant differences in either activity or selectivity, thus indicating that no enzyme induction takes place. This suggests that the observed activity can, most likely, be associated with a "broad-spectrum sulfatase" rather than with separate primary- or *sec*-alkyl sulfatases.

In summary, the first highly enantioselective *sec*-alkyl sulfatase that acts with strict retention of configuration was detected in *R. baltica* DSM 10527 through a sequence-similarity approach. The use of this sulfatase in combination with a stereocomplementary inverting enzyme from *Sulfolobus* spp. in a deracemization strategy is currently being investigated.[29]

One-Pot Reaction Cascades Using Star Polymers with Core-Confined Catalysts**

Brett Helms, Steven J. Guillaudeu, Yu Xie, Meredith McMurdo, Craig J. Hawker, and Jean M. J. Fréchet**

An attractive feature of dendritic systems, and possibly other highly branched polymers, is their ability to encapsulate and isolate various functional groups within the interior of the molecule.[1] In many applications, from light harvesting to catalysis, the benefit derived from site isolation is typically the preservation of both the structure and activity of moieties that would normally be sensitive to quenching or deactivation if used as small molecules.[2] Site isolation as such has been used since the work of Patchornik and co-workers with so-called "wolf and lamb" reactions, in which otherwise incompatible reagents on large heterogeneous particulate solid supports were used in mixed-bed reactors to perform multiple steps of a reaction sequence.[3] More recent investigations of sol–gels with encapsulated opposing reagents have made the concept of "wolf and lamb" reactions emerge as a powerful tool to probe site-isolation effects in cross-linked solid materials.[4] To our knowledge, this concept has never been applied to soluble molecular reagents, such as star polymers, although their synthetic accessibility relative to dendrimers makes them attractive targets for practical applications. Herein, we report a one-pot reaction cascade performed with two different star polymers, each containing a different catalytic group confined in its core. To demonstrate the synthetic utility that site isolation affords, we have devised a "wolf and lamb" test, in which otherwise incompatible acid and base catalysts are employed to effect the overall transformation. Our results clearly show that encapsulation of both acidic and basic groups within highly branched, yet fully soluble, multiarm star polymers suppresses their mutual deactivation, thus allowing for a sequence of acid and base reactions to be performed in succession (Figure 1). Thus, the concept of "wolf and lamb"

Figure 1. Acid- and base-containing star polymers with non-interpenetrating highly cross-linked cores.

reactions, previously limited to immiscible solid reagents, has now been demonstrated successfully with reactive moieties attached to well-defined and sterically restricted locations within soluble synthetic macromolecules that are comparable in size to many proteins.

The preparation of highly branched multiarm star polymers with a narrow polydispersity has been an active area in polymer science as these materials provide quick access to globular macromolecules that bear some crude resemblance to the more structurally perfect dendrimers. Although syntheses of dendrimers have been well documented, it is only recently that techniques have been put forth to prepare well-defined star polymers without resorting to living anionic methods.[5] We recently reported an "arm-first" approach based on nitroxide-mediated living free-radical polymerization.[6]

Star polymers that contain analogues of *para*-toluenesulfonic acid (PTSA) groups at the core were prepared by using the arm-first approach. A low-molecular-weight polystyrene macroinitiator **1** was prepared in bulk from an α-hydrido-alkoxyamine initiator and styrene at 125 °C (Scheme 1; size-exclusion chromatography (SEC) with THF: $M_n = 6250$, $M_w = 6730$, polydispersity index (PDI) = 1.07).[7] Star polymers were then obtained by using a 1:4:10 ratio of **1**, divinylbenzene (DVB), and a mixture of co-monomers (styrene and the functional monomer phenyl 4-styrenesulfonate (**2**) in 3:2 ratio). The phenylsulfonate esters were saponified with KOH in methanolic THF and then acidified to generate the active form of the catalyst. The star polymers **3** thus obtained were of high molecular weight (SEC with THF: $M_n = 66150$, $M_w = 78530$; multiangle laser light scattering (MALLS): $M_n = 221200$, $M_w = 260200$) and narrow polydispersity (PDI = 1.19). Further examination of the SEC traces of **1** and **3** indicates clean conversion to the macromolecule without any low-molecular-weight polymer contaminants (Figure 2a), which is critical to achieve catalyst isolation. Elemental analysis of the sulfur content of **3** revealed 0.45 mmoles of sulfonic acid groups per gram of polymer, or approximately 100 residues per star polymer. These values correspond to 3–4

acidic groups per arm for the 35–40-arm star polymer or 7–8 wt %.

Similarly, star polymer **6**, which contains amine moieties, was synthesized by the arm-first method from an *N*-isopropylacrylamide (NIPAAm) macroinitiator **4** (SEC with *N,N*-dimethylformamide (DMF): $M_n = 4450$, $M_w = 5890$, PDI = 1.32) and a styrene monomer **5** that contains a pendant 4-(dialkylamino)pyridine catalyst (Scheme 1). The same optimized ratio of 1:4:10 was used for the polymerization of **6** (SEC with DMF: $M_n = 59160$, $M_w = 110210$, PDI = 1.86; MALLS: $M_n = 526300$, $M_w = 640800$), with the co-monomer portion composed of styrene and **5** in a 1:1 ratio. Although the SEC data with DMF as the solvent (Figure 2b) indicate a less-controlled star polymerization and a higher molecular weight for **6** (approximately 100 arms per star) relative to **3**, we were satisfied with the absence of contamination by low-molecular-weight species and proceeded with the catalytic experiments. The catalyst loading for **6** was evaluated by using UV spectroscopy with 4-(dimethylamino)pyridine (DMAP) as the reference compound in CHCl$_3$ ($\lambda_{max} = 260$ nm), with subtraction of any background absorbance from the poly-NIPAAm-core-(PS-co-DVB) star polymer. An upper value of 0.63 mmoles of **5** per gram of polymer was measured which corresponds to approximately 350 catalytic groups per star polymer or 3 or 4 residues per arm. Therefore, the DMAP-
Scheme 1. Synthesis of star polymers that contain core-confined PTSA analogues or 4-(dialkylamino)pyridines.

like residues constitute up to 5–7% of the weight in the polymer.

The chemical transformations targeted for this system were the acid-catalyzed deprotection of 4-nitrobenzaldehyde dimethyl acetal and the nucleophilic amine-catalyzed Baylis–Hillman reaction of 4-nitrobenzaldehyde with methyl vinyl ketone (MVK) (Scheme 2).[8] As control experiments, reac-
Scheme 2. One-pot-reaction cascade involving sequential acid-catalyzed acetal hydrolysis followed by the amine-catalyzed Baylis–Hillman reaction.

tions were performed in the absence of any catalysts; with DMAP and PTSA; with non-polymer-bound DMAP and **3**; and with non-polymer-bound PTSA and **6** (Table 1).

Table 1: Catalytic results for the reaction cascade using acid and amine catalysts.

Entry	Acid catalyst[a]	Amine catalyst[a]	Yield of **8** [%][b]	Yield of **9** [%][b]
1	**3**	**6**	34	65
2	**3**	DMAP	9	0
3	PTSA	**6**	6	0
4	PTSA	DMAP	3	0
5	**3**	**11**	<1	0
6	**10**	**6**	<1	0
7	none	none	0	0

[a] Reaction conditions: 10 mol% acid and amine catalysts were used. $[7]_0 = 0.50$ M in DMF with H_2O (1 equiv) and MVK (4 equiv). The reaction mixtures were heated at 70°C in sealed vials for 36 h. [b] Yields are based on GC-MS measurements with decane as the internal standard. The values represent an average of three runs.

Complete hydrolysis of the acetal was observed over the course of a few hours when the reaction was performed with **3** and **6**, and at the end of the experiment 65% of the aldehyde had been converted into the Baylis–Hillman adduct. When either of the small-molecule catalysts DMAP or PTSA were added to **3** or **6**, respectively, only partial hydrolysis of the acetal was observed (Table 1, entries 2 and 3), which was also the case when PTSA and DMAP were added (entry 4). Finally, the acetal appears to be stable to hydrolysis when no catalysts are used (entry 7).

Given that a Baylis–Hillman adduct did not form in any of the entries except those in which both **3** and **6** were used, we reason that when the small molecules DMAP or PTSA are added to **3** and **6**, respectively, they can penetrate the cores of the star polymers and deactivate the acidic and basic groups through salt formation. The absence of reactivity for the resulting salt is confirmed by entry 4. The partial hydrolysis observed in entries 2 and 3 points to the difficulty of titrating the exact amount of catalyst in each internally cross-linked star polymer for a given reaction.

To examine further the site-isolation properties of these polymers, acid- or amine-containing diblock copolymers were synthesized from the same macroinitiators and functional monomers used in the preparation of **3** and **6** (Scheme 3). The
Scheme 3. Synthesis of diblock copolymers containing PTSA analogues or 4-(dialkylamino)pyridines.

acid-containing polymer **10** (SEC with THF: $M_n = 8170$, $M_w = 9090$, PDI = 1.11, 0.73 mmol of sulfur per gram polymer) and amine-containing polymer **11** (SEC with DMF: $M_n = 6980$, $M_w = 10050$, PDI = 1.44, 0.55 mmol of catalyst per gram polymer) were prepared to best resemble the star polymers in terms of composition but not architecture. When either of these diblock copolymer catalysts was used along with the complementary star polymer (namely, **3** with **11** or **10** with **6**, entries 5 and 6, respectively), the reaction cascade did not proceed. This result implies that the linear polymers can penetrate the corona of the star polymers with the same deleterious effects as either PTSA or DMAP, thus confirming our hypothesis that the catalysts must be confined to the sterically restricted core of the star polymers before the advantages of site isolation can be realized.

Thus, we have shown that core-confined groups in these high-molecular-weight, yet fully soluble, star polymers appear to be site isolated as is observed with moieties at the core of dendrimers. As a result of this site isolation, sequential catalysis of a "wolf and lamb" two-step reaction using catalytic species that are normally incompatible with each other is possible. This ability to generate a pathway by which a cascade of reactions is enabled is reminiscent of biological systems in which a series of discrete reactions performed by different enzymes is used to create a wide range of chemical functionality and diversity through the combination of a few simple steps.

Experimental Section

3: The polymerization mixture containing polystyrene macroinitiator **1** (1.93 g, 0.355 mmol; SEC with THF: $M_n = 6247$, $M_w = 6728$, PDI = 1.07), DVB (336 mg, 1.42 mmol; 55 wt%), styrene (221 mg, 2.13 mmol), and phenyl 4-styrenesulfonate (**2**; 369 mg, 1.42 mmol)

in DMF (7.28 g) was heated at 125 °C for 16 h. The reaction mixture was diluted with CH$_2$Cl$_2$ and precipitated on addition to *i*PrOH. Fractionation from benzene using methanol gave a solid, which was reprecipitated to give 2.54 g of the star polymer (89%). The star polymer (250 mg, 1.25 µmol) was treated with KOH (250 mg, 4.45 mmol) in MeOH/THF (9:1) at 50 °C for 16 h, acidified with H$_2$SO$_4$, and precipitated on addition to *i*PrOH to give a white solid (215 mg, 87%). ^{1}H NMR (500 MHz, CDCl$_3$): δ = 7.5–6.9 (br, Ar-H), 6.8–6.3 (br, Ar-H), 2.1–1.7 (br, -C(Ar)*H*-), 1.7–1.2 ppm (br, -CH$_2$-); IR (thin film): $\tilde{v}$ = 3600–3200, 3081, 3059, 3025, 2924, 2850, 1942, 1873, 1804, 1746, 1730, 1713, 1687, 1600, 1584, 1492, 1452, 1413, 1372, 1217, 1179, 1155, 1126, 1069, 1030, 1006, 907, 834, 758, 699, 667 cm^{-1}; SEC with THF: M_n = 66150, M_w = 78530, PDI = 1.19; MALLS: M_n = 221200, M_w = 260200.

6: The polymerization mixture containing polyNIPAAm macroinitiator **4** (280 mg, 69.4 µmol; SEC with DMF: M_n = 4453, M_w = 5888, PDI = 1.32), DVB (66 mg, 0.279 mmol; 55 wt%), styrene (36 mg, 0.344 mmol), and 4-(dialkylamino)pyridine monomer **5** (93 mg, 0.345 mmol) in DMF (1.35 g) was heated at 125 °C for 16 h. The reaction mixture was diluted with CH$_2$Cl$_2$ and precipitated on addition to cold diethyl ether. Fractionation from acetone using hexanes gave the solid, which then reprecipitated to give 120 mg of the star polymer (33%). ^{1}H NMR (500 MHz, CDCl$_3$): δ = 8.3–8.0 (br, Py-H; Py = pyridine), 7.1–6.2 (br, Ar-H, -N*H*-*i*Pr), 4.2–3.9 (br, -C*H*(Me)$_2$), 3.8–3.5 (br, N-CH$_2$-CH$_2$-O), 3.2–2.9 (br, N-CH$_3$), 2.5–2.3 (br, Ar-CH$_2$-O), 2.3–1.8 (br, -C(Ar)*H*-, -C(C=O)*H*-, -CH$_2$-), 1.8–1.5 (br, -CH$_2$-), 1.4–0.8 ppm (br, -CH(C*H*$_3$)$_2$); IR (thin film): $\tilde{v}$ = 2965, 2928, 1664, 1608, 1598, 1529, 1453, 1384, 1366, 1211, 1171, 1129, 989, 910, 804, 763, 701 cm^{-1}; SEC with DMF: M_n = 59160, M_w = 110210, PDI = 1.86; MALLS: M_n = 526300, M_w = 640800.

Analytical Methods

Interfacing Capillary Electrophoresis and Electrothermal Atomic Absorption Spectroscopy To Study Metal Speciation and Metal–Biomolecule Interactions**

Yan Li, Xiu-Ping Yan,* and Yan Jiang

Metallomics is a new field in the study of biometals and is related to genomics, proteomics, and metabolomics.[1] Trace metals in the environment may be adopted by biological systems to assist in the syntheses and metabolic functions of genes (DNA and RNA) and proteins. These metals may be beneficial or may pose a risk to humans and other life forms.[1–9] To establish metallomics as an integral biometal science, more robust and information-rich trace- and ultra-trace-chemical speciation analyses are needed for adequate risk or benefit assessments and to determine distributions of metals in humans, human blood serum, seawater, and even biological cells. Metal speciation is an important research subject in metallomics because the bioavailability and toxicity of metals on a molecular basis depends on their chemical state. Different species of the same metal be considered as essential, innocuous, or toxic.[1–9] Another important research subject in metallomics is the interaction between metal species and biomolecules, which is significant for biochemistry, biology, medicine, pharmacy, nutrition, agriculture, and environmental science.[1–9]

Communications

Hybrid approaches are currently preferred for the study of metal speciation and metal–biomolecule interactions in numerous techniques developed to date.[6–9] The use of high-resolution separation methods in combination with highly sensitive detection techniques is necessary to improve the accuracy of the detection of metal speciation and metal–biomolecule interactions. The importance of capillary electrophoresis (CE) for such purposes has grown rapidly in the past decade, primarily as a result of its potential flexibility and easy implementation, high resolution, minimal sample and reagent consumption, and rapid and efficient separations with only minor disturbances of the existing equilibrium between the different species.[6,10–12] The use of inductively coupled plasma mass spectroscopy (ICP-MS) or optical emission spectroscopy (ICP-OES) as online detection techniques for CE promises substantial improvements in the sensitivity of the methods and in the identification and quantification of multispecies systems.[6]

Herein we report a new hybrid technique for nanoliter trace-metal speciation and metal–biomolecule interaction studies based on online coupling of CE to electrothermal atomic absorption spectroscopy (ETAAS). ETAAS provides high detection capability with low instrumental and operational costs. However, the discontinuous nature of ETAAS makes it troublesome when used in combination with continuous-flow systems and departs from the concept of monitoring continuously the chromatographic eluent.[13] We have developed a method for real-time ETAAS detection of the CE effluent by the direct interface of CE with ETAAS. The analysis was conducted on a laboratory-made thermospray interface, with no need for external heat sources or postcolumn derivatization steps. The features of this new hybrid technique are its simplicity, low instrument and running costs, easy operation, high sensitivity and selectivity, as well as its environmentally friendly nature.

The schematic setup of the CE–ETAAS hybrid system is shown in Figure 1. It includes a capillary electrophoresis system, a thermospray interface, and a graphite furnace. It is crucial for the interface to serve as a link that can harness the full potential of the separation method and the detector. ETAAS is sufficiently sensitive for speciation analysis, but graphite furnaces are not designed for continuous operation. Direct coupling of ETAAS to CE involves a number of problems because of the stepwise operational characteristic of the commercially available atomizers and because only a small volume can be injected into the furnace.

In view of above problems, a thermospray interface was designed to allow the real-time ETAAS monitoring of individual species separated by CE. A commercially available graphite tube and conventional ETAAS operating procedures were modified slightly to enable real-time detection of the CE effluent. First, the dosing hole of the graphite tube was enlarged to allow the tight attachment of a hollow graphite cap (1.0 mm i.d.), into which the thermospray vaporizer was inserted. The graphite cap behaved as a good heat-transfer medium for the vaporizer. A small gap was left between the vaporizer and the graphite capsule for carrier gas (argon) to flow through, thus enabling the delivery of the locally generated vapor into the graphite tube. Second, because the
Figure 1. Schematic diagram for the new hybrid technique of capillary electrophoresis coupled online with electrothermal atomic absorption spectroscopy through a thermospray interface (not to scale).

original dosing hole of the graphite tube was blocked by the thermospray interface, two more holes (1.0 mm i.d.) were made symmetrically beside the original dosing hole in the graphite tube to serve as hole for exhaust gas. The distance between the dosing hole and the hole for exhaust gas was 6.0 mm.

To demonstrate the applicability of the developed hybrid technique for ultra-trace-element speciation, mercury and cadmium were chosen as target elements as they are highly dangerous metals, with an accumulative and persistent character in the environment. To ensure sufficient time for monitoring individual metal species in the CE effluent, the graphite furnace was programmed with seven successive thermostatic steps in the gas stop mode at an appropriate constant temperature for 99 s (the maximum time allowed) for each step. The temperature of the graphite furnace was set at 600 °C for the efficient atomization of mercury species. In this case, the lifetime of the graphite tube was 400 h. For cadmium speciation, the temperature of the graphite furnace was set at 1000 °C as a compromise between the lifetime of the graphite tube (≈ 70 h) and the sensitivity of the method. The lifetime of the graphite tube decreased markedly when the temperature of the graphite furnace rose above 1200 °C.

In view of the complete introduction of CE effluent into the graphite tube, running electrolyte may influence the real-time ETAAS detection, depending on the nature of the element of interest. The goal herein was to achieve adequate resolution of the target species and to ensure subsequent detection without interference. Phosphate and borate buffers were suitable for mercury, but led to serious interferences for real-time ETAAS detection of cadmium at 1000 °C. Ammonium acetate (NH_4Ac) was preferred for cadmium speciation owing to its easy decomposition. As a running electrolyte with higher salt content causes undesirable blocking at the tip of the thermospray vaporizer after continuous heating for a long time, the concentration of the electrolyte should be as low as

possible, but should be enough to ensure good resolution and reproducibility for CE separation.

As shown in Figure 2A, three mercury species of methylmercury (MeHg^I), phenylmercury (PhHg^I), and inorganic mercury (Hg^{II}) were treated by baseline separation with CE
Figure 2. A) Electropherograms of a) GBW (E) 080393 (simulated natural water); b) GBW (E) 080393 spiked with of Hg^{II}, PhHg^I, and MeHg^I (100 µg L^{-1} each); c) the extract of a certified reference material (DORM-2, dogfish muscle); d) the extract of DORM-2 spiked with of MeHg^I, PhHg^I, and Hg^{II} (100 µg L^{-1} each); e) a standard mixture of MeHg^I, PhHg^I, and Hg^{II} (100 µg L^{-1} each). B) Electropherograms of Cd^{II} and [Cd(edta)]$^{2-}$ for a) Cd^{II} (89 nmol L^{-1}), pH 6.8; b) a standard mixture of Cd^{II} (89 nmol L^{-1}) and EDTA (40 nmol L^{-1}), pH 1.0; c) a standard mixture of Cd^{II} (89 nmol L^{-1}) and EDTA (40 nmol L^{-1}), pH 3.0; d) a standard mixture of Cd^{II} (89 nmol L^{-1}) and EDTA (40 nmol L^{-1}), pH 6.8; e) a standard mixture of Cd^{II} (89 nmol L^{-1}) and EDTA (160 nmol L^{-1}), pH 6.8.

in a 50 cm × 75 µm i.d. fused-silica capillary at 20 kV by using 15 mmol L^{-1} phosphate buffer at pH 6.8. The detection limit of the developed hybrid technique for mercury speciation was independent of mercury species. With an injection of 200 nL of sample solution in the hydrodynamic method, the detection limit ($S/N = 3$) of the mercury species was 14.8 ± 0.7 µg L^{-1} (as Hg). The developed method was validated by analyzing two certified reference materials GBW (E) 080393 (simulated natural water, National Research Center for Standard Materials, Beijing, China) and DORM-2 (dogfish muscle, NRCC, Ottawa, Canada). Both the quantified Hg^{II} content (97 ± 2 µg L^{-1}, $n = 5$) in GBW (E) 080393 and the methyl mercury content (4.28 ± 0.21 µg g^{-1}) in DORM-2 by using a simple external calibration method based on peak-area measurements are commensurate with the certified values (100 ± 4 µg L^{-1} for Hg^{II} in GBW (E) 080393, and 4.47 ± 0.32 µg g^{-1} for methylmercury in DORM-2).

The developed hybrid technique was also applied to the study of the effect of the pH value on the reaction of Cd^{II} with disodium ethylenediaminetetraacetate (EDTA). As shown in Figure 2B, Cd^{II} and [Cd(edta)]$^{2-}$ were well separated by CE in a 50 cm × 75 µm i.d. fused-silica capillary at 20 kV when using NH$_4$Ac buffer (5 mmol L^{-1}) at pH 8.0. The peak area of Cd^{II} increased, whereas that of [Cd(edta)]$^{2-}$ decreased as the pH value decreased from 6.8 to 1.0 owing to the coalescence of H$^+$ with EDTA. The peak of Cd^{II} disappeared in the presence of excess EDTA at pH 6.8 (Figure 2Be).

The usefulness of the developed hybrid technique for the study of metal–biomolecule interactions was demonstrated by taking Cd^{II}/bovine serum albumin (BSA) and Hg^{II}/DNA as model systems. For this purpose, experiments were performed to obtain a series of incubation-time-dependent electropherograms of Cd^{II} and Cd–BSA adduct for a mixture solution of Cd^{II} (0.2 µmol L^{-1}) and BSA(0.1 µmol L^{-1}) (Figure 3A). Baseline separation of Cd^{II} and Cd–BSA adduct was carried out by CE in a 50 cm × 75 µm i.d. fused-silica capillary at 20 kV in the presence of 5 mmol L^{-1} of NH$_4$Ac-Tris buffer (pH 7.40) as running electrolyte. It was found from Figure 3A that about 55 % of the Cd^{II} was bound to BSA within 12 h and that the binding reaction between Cd^{II} and BSA reached equilibrium after 48 h. Hereafter no variations in the concentrations of Cd^{II} and Cd–BSA adduct were observed at various Cd^{II}/BSA molar ratios. The kinetics and binding constant for the interaction of Cd^{II} with BSA were evaluated from the time-dependent peak areas of Cd^{II} and Cd–BSA adduct. We assume that the interaction of Cd^{II} and BSA results in pseudo-first-order kinetic properties at the initial stage of incubation. The apparent kinetic rate constant (k) was then calculated by polynomial approximation of the concentration–time plots according to Equation (1).[14]

$$\ln \frac{C_{Cd}^b}{C_{Cd}^0} = -kt \tag{1}$$

C_{Cd}^0 and C_{Cd}^b are the initial molar concentration of Cd^{II} and the concentration of Cd–BSA adduct, respectively. The kinetic rate constant for the interaction of Cd^{II} and BSA was found to be independent of BSA concentration (zero-order kinetics for BSA). The value of k at various initial molar

A)

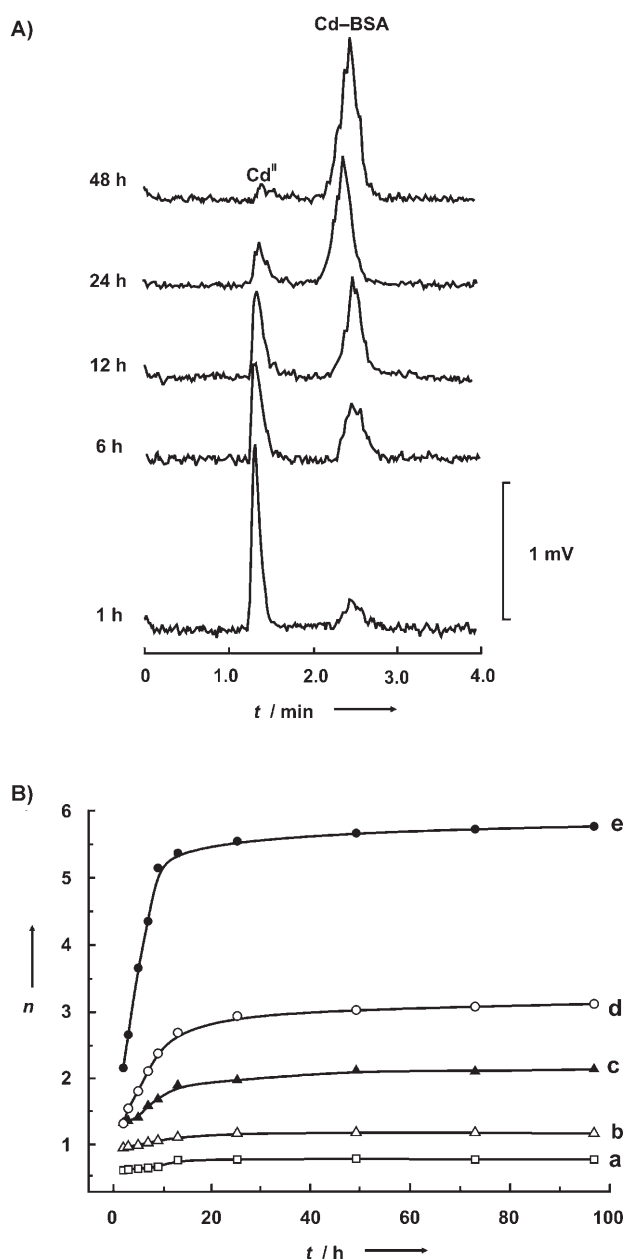
B)


Figure 3. A) Incubation-time-dependent electropherograms of Cd^{II} and Cd–BSA adduct for the binding of Cd^{II} (0.2 µmol L^{-1}) with BSA (0.1 µmol L^{-1}). Baseline separation of Cd^{II} and Cd–BSA adduct was achieved by capillary electrophoresis in a fused-silica capillary (50 cm × 75 µm i.d.) at 20 kV by using NH$_4$Ac–Tris buffer (pH 7.40; 5 mmol L^{-1}) as running electrolyte. B) Number of cadmium atoms binding per BSA molecule at variable incubation time. Initial Cd^{II}/BSA molar ratio (initial Cd^{II} concentration of 0.2 µmol L^{-1}): a) 1:2; b) 1:1; c) 2:1; d) 4:1; e) 10:1.

ratios (0.5, 1, 2, 4, and 10) of Cd^{II}/BSA with an initial Cd^{II} concentration of 0.2 µmol L^{-1} at 37°C was determined to be $(1.108 \pm 0.065) \times 10^{-3}$ min^{-1}.

The determination of Cd–BSA binding constant (K_b) was based on the bimolecular reaction between the donor (Cd^{II}) and the acceptor (BSA). If the concentration of BSA was kept constant, but different concentrations of Cd^{II} were added in the mixture, the value of K_b could be estimated by using a linear regression of a Scatchard plot.[15] based on the following expression [Eq. (2)]:

$$\frac{C_{Cd}^b}{C_{Cd}^f} = -K_b\, C_{Cd}^b + C_{BSA}\, K_b \qquad (2)$$

In Equation (2), C_{Cd}^b and C_{Cd}^f are the concentrations of bound Cd^{II} (i.e. Cd–BSA adduct) and Cd^{II}, and C_{BSA} is the concentration of the binding site on the BSA. The number of Cd atoms bound per BSA molecule (n) was calculated from the change in the peak areas of Cd^{II} and Cd–BSA adduct based on Equation (3):[14]

$$n = \frac{C_{Cd}^0}{C_{BSA}^0}\, \frac{S_{Cd}^b}{S_{Cd}^f + S_{Cd}^b} \qquad (3)$$

In Equation (3), C_{Cd}^0 and C_{BSA}^0 are the initial concentrations of Cd^{II} and BSA, respectively, S_{Cd}^f and S_{Cd}^b are the peak areas of Cd^{II} and Cd–BSA adduct, respectively. As such, the binding constant of Cd^{II} with BSA was estimated to be 2.68×10^7 L mol^{-1}, and the number of binding sites was 3.4 after incubation for 12 h. The evolution of Cd-BSA binding as a function of incubation time at various initial molar ratios of Cd^{II} to BSA is illustrated in Figure 3B. In the presence of excess Cd^{II}, the reaction proceeds more rapidly and the protein is attached to Cd to a higher degree, as expressed by a growing number of Cd^{II} bound per BSA molecule. The number of Cd atoms bound per BSA molecule increased more rapidly with higher molar ratios of Cd^{II} to BSA as the incubation time increased to 12 h. The number of Cd^{II} species bound per BSA molecule increased very slowly with increase of incubation time over a 12-h period. These results indicate that both strong and weak binding sites on the BSA molecule might contribute to the interaction of Cd^{II} with BSA in the presence of excess Cd^{II}. It was found that BSA binds up to 5 mol of Cd^{II} per mol of the protein when incubated with Cd^{II} in tenfold excess. The Cd^{II}/BSA stoichiometry ratio is greater than 3.4:1 and might be ascribed to the high affinity of soft Cd^{II} to some potential binding sites on BSA.

Representative electropherograms of the mixture of Hg^{II} and salmon sperm DNA are shown in Figure 4. Hg^{II} was well resolved from Hg–DNA adduct. The electropherograms show that Hg^{II} decreased, whereas the bound Hg–DNA increased with increasing concentration of DNA, as was clearly reflected by the variations in peak areas of Hg^{II} and the Hg–DNA adduct. The K_b value for the binding of Hg^{II} with DNA is 5.12×10^6 L mol^{-1}, and the number of binding sites is 0.2 for an initial DNA concentration of 2 mg L^{-1} (corresponding to a base-pair concentration of 3.4 µmol L^{-1}) after incubation with various concentrations of Hg^{II} for 1 h. Detailed studies are underway in our laboratory to determine the interactions of different mercury species with DNA, improve our understanding of the kinetic and thermodynamic properties, and to evaluate the relevant binding parameters, the damage of different mercury species to DNA, and the potential toxicity and environmental effects.

In summary, ETAAS was employed for the first time as a real-time CE detector. The combination of species separation by CE with direct ETAAS detection is suitable for elemental speciation. The technique could be used in investigations of
Figure 4. DNA-concentration-dependent electropherograms of Hg^{II} and Hg–DNA adduct for the binding of Hg^{II} (1 µmol L^{-1}) with DNA at various concentrations (µmol L^{-1}): a) 0.84; b) 1.7; c) 3.4; d) 6.8. Baseline separation of Hg^{II} and Hg–DNA adduct was achieved by capillary electrophoresis in a fused-silica capillary (50 cm × 75 µm i.d.) at 20 kV by using Tris–HAc buffer (pH 7.40; 50 mmol L^{-1}) as running electrolyte.

the thermodynamic equilibrium between the coexisting species and to determine the kinetics and stoichiometry of the binding reaction between metal species and biomolecules with good selectivity and high sensitivity.

Experimental Section

Certified reference materials DORM-2 (dogfish muscle; NRCC, Ottawa, Canada) and GBW (E) 080393 (simulated natural water; NRCSM, Beijing, China) were analyzed to check the accuracy of the developed hybrid technique for speciation analysis. An acid-leaching procedure was employed for extraction of mercury species from biological materials:[16] Briefly, hydrochloric acid (5 mL, 5 mol L^{-1}) was added to the certified reference material DORM-2 (0.3 g) in a 10-mL centrifuge tube. The mixture was then placed in an ambient ultrasonic bath for 10 min. After extraction, the suspension was centrifuged at 3500 rpm for 10 min, and the supernatant was transferred to a 10-mL flask. The supernatant was neutralized with NH$_3$H$_2$O and adjusted to pH 4.8–5.0 with phosphate buffer, then diluted to volume with doubly deionized water.

To simulate physiological conditions, NH$_4$Ac–Tris buffer (5 mmol L^{-1}) containing 100 mmol L^{-1} NaCl at pH 7.40 was used as the incubation solution. For the kinetic experiment, the reaction mixtures were incubated at 37 °C for more than 6 days, and aliquots were continuously taken from the same sample for analysis.

Polypyrrole Nanowires

Polypyrrole Nanowires Grown from Single Adsorbed Polyelectrolyte Molecules**

Vera Bocharova, Anton Kiriy,* Hartmut Vinzelberg, Ingolf Mönch, and Manfred Stamm

One-dimensional nanostructures of conductive polymers (CPs) have attracted a great deal of interest as building blocks for future miniaturized nanoelectronic devices[1] and highly sensitive chemical[2] or biological sensors.[3] Several "template-less" approaches to 1D superstructures of CPs based on the self-assembly of conjugated polymers, oligomers, or monomers have been reported recently.[4] Other methods for the synthesis of CP nanowires involve chemical or electrochemical oxidative polycondensation in "hard tem-

Supporting information for this article is available on the WWW under http://www.angewandte.org or from the author.

plates" (such as zeolites, track-etched polymeric membranes, and porous alumina),[5] or "soft templates" (surfactant micelles or liquid-crystalline phases).[6] However, for various applications, CP nanowires must be properly integrated into circuits. Therefore, at least one additional step is required, such as the release of the nanowires from the templates and/or their positioning in the device.

Polymer chemistry offers a fascinating world of structures of different architecture, composition, and functionality. The use of single polymer molecules as templates constitutes a highly promising strategy to generate nanoparticles with desired size, shape, location, and with specific properties.[7] Like macroscopic objects, single molecules of polyelectrolyte (PE) can be stretched and aligned under external forces[8] (such as centrifugal or capillary forces and electric or shear fields) and can be immobilized onto surfaces by simple procedures like casting or printing.[9] Single DNA molecules have recently been used for the fabrication of metallic[10] and conductive polymer (polyaniline, PANI) nanowires.[11] In the latter case, DNA molecules were covalently attached to a Si surface and activated with aniline, which was then polymerized. However, the PANI nanowire networks produced in this way have rather low conductivity, even when doped.[11] This low conductivity is the result of a very limited quantity of PANI being formed along the template. This restriction is governed by the quantity of aniline that can be attracted by DNA during the activation step owing to electrostatic and hydrophobic interactions. The oxidative degradation of DNA templates has been proposed by some authors[11b] as a possible factor that decreases the continuity and thus the conductivity of the DNA–PANI nanowires. We therefore assumed that the use of chemically robust synthetic PE molecules might benefit the fabrication of more conductive nanowires. Herein, we report the use of single molecules of negatively charged synthetic polyelectrolyte (polystyrene sulfonic acid, PSA) to grow continuous and conductive polypyrrole (Ppy) nanowires through selective "electroless" deposition of Ppy along PSA molecules.

Spin-coating of a PSA solution onto mica or a thermally oxidized Si wafer at high rotation speed results in stretching and alignment of the PSA chains (Figure 1 a and Supporting Information). In initial experiments, mica-deposited PSA templates were incubated in pyrrole (Py) monomer solution, then rinsed with deionized water to remove unattached Py and placed in a solution of ammonium persulfate (APS) to polymerize the Py attached to the templates. The resulting product appears in AFM images as a 1D sequence of apparently separated clusters 2–4 nm in height (Figure 1 c). These structures are considerably higher than bare PSA molecules (≈ 0.5 nm),[8] which clearly reflects the formation of Ppy clusters along the PSA molecules.

To produce more continuous and thicker Ppy nanowires, we performed electroless deposition of Ppy.[12] PSA chains were deposited onto substrates in the stretched conformation and were then treated with aqueous solution of Py and APS for up to 60 s (for details, see Experimental Section and Supporting Information). AFM investigations revealed the successful formation of PSA–Ppy nanowires with diameters that vary from a few to hundreds of nanometers depending on
Figure 1. a) Topographic AFM image of short ($M_W = 403$ kg mol^{-1}) PSA molecules. b) AFM image of Ppy nanoparticles formed from the placement of aqueous solutions of Py and APS onto mica-immobilized PSA templates ($M_W = 403$ kg mol^{-1}) for 20 s. c) AFM image of Ppy nanoparticles formed from the incubation of mica-immobilized long ($M_W = 6940$ kg mol^{-1}) PSA molecules in Py monomer solution followed by rinsing with water and oxidation with APS. d) Surface image from the same procedure as in b), but with the use of long ($M_W = 6940$ kg mol^{-1}) PSA templates. e),f) Cross-sections along the dashed lines in c) and d), respectively. g) Surface image from the same procedure as in d), but with an APS concentration fivefold smaller.

the polymerization time (Figure 1 c,d). As expected for the template method, the aspect ratio of the nanowires (≈ 7 and ≈ 100 for the nanowires in Figures 1 b and d, respectively) is dependent on the contour length of the PSA molecules. The resulting nanowires, however, are somewhat shorter than the corresponding templates (usually by a factor of 1.5–3, depending on the polymerization time). The observed partial shrinkage of the nanowires is the result of attractive interactions between hydrophobic segments of Ppy, which

can be avoided if the PSA templates are properly fixed to the substrate.

Close inspection of the AFM images shows that thin nanowires ($\varnothing < 5$ nm) are still sequences of isolated Ppy clusters, although the nanowires become quasi-continuous (the clusters are closely packed) if their diameter exceeds 10 nm. The clusters are localized predominantly along the PSA chains, which indicates a rather high selectivity of the deposition.

In general, growth of Ppy nanowires can be realized according to two schemes: 1) precipitation of hydrophobic Ppy nanoparticles preformed in solution onto the hydrophobic PSA–Py complex, and 2) growth of Ppy from the PSA–Py complex.[13] We performed a set of experiments to decide which scheme is realized in our case. For this, we prepared colloidal dispersions of Ppy by mixing solutions of Py and APS followed by quenching with excess sodium bisulfite (SBS) as a reducing agent. The colloids prepared in this manner were placed on a substrate with pre-adsorbed PSA template molecules. However, the formation of Ppy nanowires was never observed in these experiments regardless of the activation time, size, and concentration of Ppy colloids used. Thus, the prerequisite for nanowire growth is the presence of both Py monomer and oxidizing agent in solution. This result clearly excludes the "grafting-to" and supports the "grafting-from" scheme for Ppy nanowire formation.

Varying the reaction conditions influences the morphology of the Ppy nanowires. With excess oxidant, the resulting nanowires display a relatively smooth morphology (Figure 1c,d). In contrast, a lack of oxidant leads to the formation of "hairy nanowires" that resemble "molecular brushes"[14] (Figure 1g). These observations are consistent with the "grafting-from" scheme of Ppy growth.[15]

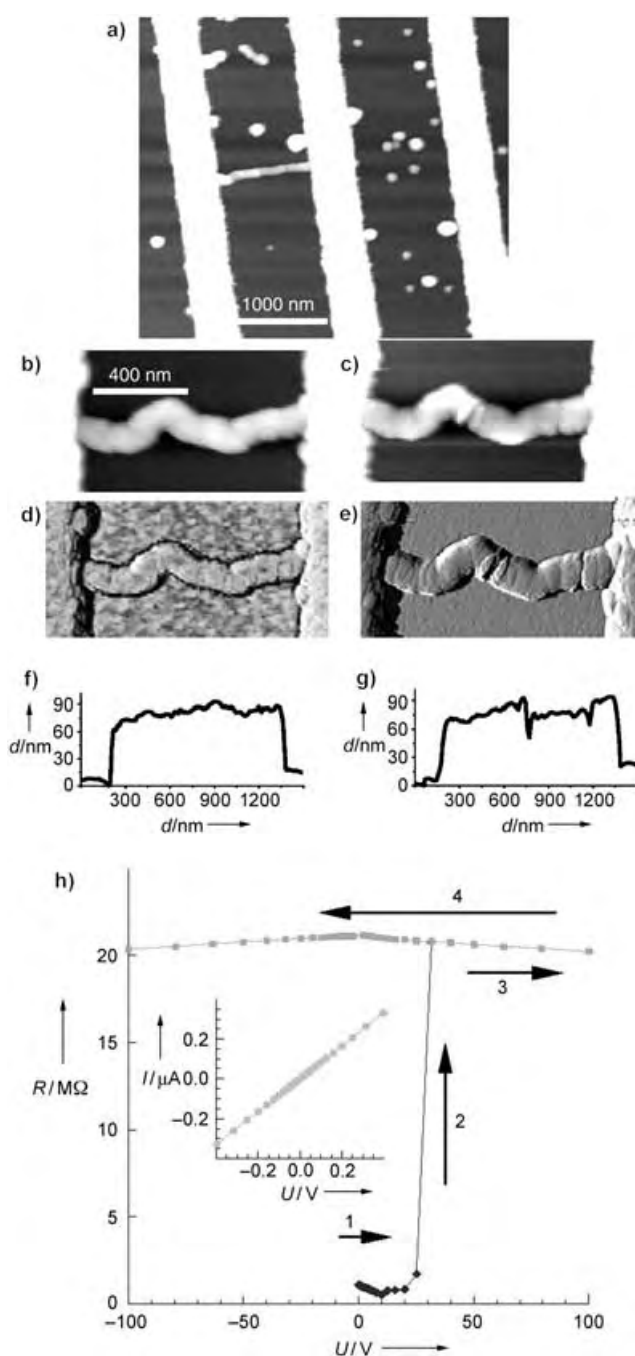
Electrical characterization was performed for the larger Ppy nanowires (Figure 2). For this, Ppy nanowires 50–60 nm thick were grown onto devices with gold micro-electrodes (the distance between the electrodes was 1 μm). The amount of PSA–Ppy nanowires produced was adjusted to allow only a few Ppy nanowires to bridge the electrodes; the other nanowires remained disconnected. This allowed us to measure the dc conductivity of individual nanowires. After deposition, the device was carefully investigated by AFM, and the amount, location, and size of all nanowires was noted. These electrical measurements revealed the resistance of a single nanowire to be ≈ 0.6–1.5 MΩ, which corresponds to a conductivity of ≈ 1–3 S cm^{-1}. This rather high conductivity approaches the conductivity of Ppy in bulk.[16] The nanowires display a linear current–voltage dependence (Figure 2h, inset), which reflects good contacts between the nanowires and the electrodes and good connectivity of the Ppy clusters along the PSA molecule. To break a certain nanowire, we slowly increased the potential between the electrodes until an abrupt increase in resistance was observed. The significant resistance increase after this procedure (from 1.1 to 21 MΩ for the nanowire in Figure 2b) proves that the measured conductance is indeed caused by this particular nanowire. On the other hand, AFM inspection of the broken nanowires reveals the formation of gaps (usually one or two per broken


Figure 2. a) AFM topography image of a representative Ppy nanowire with a resistance of ≈ 1 MΩ. b),c) High-magnification topography and d),e) phase AFM images of the pristine Ppy nanowire bridging two microelectrodes. The intact nanowire shown in b) and d) was broken by applying a high voltage (25 V; c) and e), respectively). f),g) Cross section profiles of the nanowires in images b) and c), respectively. h) Room-temperature resistance–current characteristics of the pristine nanowire with a resistance of 1.1 MΩ; numbered arrows indicate the sequence of increasing (1–3, ◆) and subsequent decreasing (4, ■) voltage. The same nanowire after breakage with high voltage displays a resistance of ≈ 21 MΩ. (Inset: demonstration of the linear I–U dependence of the pristine nanowire at low voltage.)

wire, Figure 2b–g). An even more pronounced decrease of the conductance (the resistance increased from a few MΩ to a

Communications

few GΩ) was observed when the nanowires were mechanically broken by movement of the AFM tip operating in contact mode (Supporting Information).

Finally, we evaluated the possibility of using Ppy nanowires as active elements in sensors. In general, the conductivity of Ppy can be modulated by changing the doping level: the conductivity is high in an oxidized (doped) state and low in a reduced (de-doped) form. Alternatively, Ppy in the reduced form can be doped by acids and de-doped by bases. As expected, the Ppy nanowires synthesized by oxidative polycondensation display a rather high conductivity that changes only slightly upon further exposure to acidic (HCl) or basic (NH_3) vapors. To make the conductivity of the Ppy nanowires sensitive to acids and bases, they were reduced by rinsing with an aqueous solution of $NaBH_4$ ($1 \, g \, L^{-1}$), which resulted in an increase in resistance from 1–5 MΩ for doped nanowires to more than 1 GΩ for the de-doped wires. In the reduced state, the nanowires reversibly change their resistance upon exposure to HCl and NH_3 vapors from several MΩ to a few GΩ.[17]

In conclusion, we have developed a simple chemical route to conductive Ppy nanowires by the grafting of Ppy from isolated synthetic polyelectrolyte molecules. The location and length of the synthesized Ppy nanowires are defined by the location and length of adsorbed single-molecule templates. The diameter of the nanowires can be varied from a few nanometers to hundreds of nanometers by adjusting the polycondensation time and concentration of the reagents. The dc conductivity of individual Ppy nanowires approaches the conductivity of Ppy in bulk. This result opens up broad opportunities for the fabrication of electronic devices and sensors at a molecular level.

Experimental Section

Polystyrene sulfonic acid (PSA; $M_w = 6940 \, kg \, mol^{-1}$, PDI = 1.3; $M_w = 403 \, kg \, mol^{-1}$, PDI = 1.3) was purchased from the Polymer Standards Service, Mainz, Germany. Ammonium persulfate (APS), pyrrole (Py), and all other chemicals were purchased from Aldrich.

Ppy nanowires: Stretched PSA molecules were deposited from aqueous solution ($0.01 \, g \, L^{-1}$) onto clean Si wafers or freshly cleaved mica by spin-coating at high speed (10000 rpm). Py ($3 \, g \, L^{-1}$, 50 μL) and APS ($30 \, g \, L^{-1}$, 50 μL) in deionized water were placed for a limited time (10–60 s) onto the substrates with predeposited PSA molecules. Afterwards, the samples were rinsed with water, dried, and examined by AFM (NanoScope IV-D3100, Digital Instruments, Santa Barbara, USA) in tapping mode. The diameter of the Ppy nanowires was dependent on the polymerization time and was found to be < 10, 10–30, and 30–60 nm for polymerization times of 15, 30, and 60 s, respectively. "Hairy nanowires" were produced with a similar procedure in which the only difference was a lower concentration of APS ($6 \, g \, L^{-1}$).

For electrical measurements (Keithley 236 Source-Measure Unit), 18-finger gold micro-electrodes (step height: 50 nm; width: 500 nm; separation: 1 μm) were fabricated by photolithography on a Si wafer with an insulating SiO_2 layer (300 nm).

Host–Guest Systems

Capsules and Star-Burst Polyhedra: An [Ag₂L₂] Capsule and a Tetrahedral [Ag₄L₄] Metallosupramolecular Prism with Cyclotriveratrylene-Type Ligands**

Christopher J. Sumby and Michaele J. Hardie*

Cyclotriveratrylene (CTV) is a macrocyclic host molecule that strongly favors a crown conformation, which gives it a bowl shape with a shallow molecular cavity.[1] Indeed, despite CTV being known for over 40 years, the alternative saddle conformation has only recently been isolated by the rapid quenching of a hot solution or melt,[2] or within a novel CTV-based cryptophane.[3] The bowl-shaped CTV is a cyclic trimer which has a distinctly spiked, pyramidal aspect. We wish to exploit this characteristic to create self-assembled capsules and polyhedra through the formation of metallosupramolecular assemblies. These would likewise have a spiked aspect that allows for significantly more internal space than could be afforded from a similar flat or flexible ligand. A range of spectacular polyhedral structures have been reported from the self-assembly of metal salts with multifunctional ligands.[4] CTV itself is not a good molecular component for such assemblies as it lacks predictable coordination sites for transition metals, hence we have synthesized a number of CTV analogues with pyridyl groups at the upper rim for use as ligands for these types of assemblies as well as coordination networks.[5] Notably, a number of crystalline hydrogen-bonded assemblies feature tetrahedral clusters of CTV hosts arranged in a back-to-back fashion,[6] which excludes the possibility of forming an assembly with internal space. Likewise a 3D coordination polymer with a C_3-substituted CTV derivative also shows this back-to-back stacking.[7] Self-assembled complexes of CTV-related host molecules that do show an internal space would result from the head-to-head association of host molecules. Examples are currently restricted to a dimeric [Pd₃L₂] capsule that has been characterized in solution by Shinkai and co-workers.[8] This

capsule results from the assembly of a trisubstituted CTV derivative possessing rigid pyridyl arms with *cis*-protected Pd salts. Covalently linked cryptophanes, where two CTV fragments are linked in a head-to-head fashion by organic spacers, are well established.[9]

Other bowl-shaped host molecules have been shown to form both capsule assemblies and more complicated polyhedral structures. Capsule structures assembled from hydrogen bonds or coordination chemistry are known with calixarenes and calixresorcinarenes.[10] Considerably more complicated assemblies such as a cyclic trimer,[11] cyclic hexamers,[12] a tetrahedron,[11b] a snub cube,[13] icosahedron,[14] and a cuboctahedron[15] have also been reported from similar tetrameric molecular hosts.

We report herein a new type of [M₂L₂] dimeric capsule with a CTV-related host molecule in the complex [Ag₂(tris(3-pyridylmethylamino)cyclotriguaiacylene)₂(CH₃CN)₂]·2PF₆· 4CH₃CN, along with the first example of a discrete polyhedral cluster larger than a dimeric capsule assembled with a CTV-related host molecule. This latter complex [Ag₄(tris(4-pyridylmethylamino)cyclotriguaiacylene)₄(CH₃CN)₄]·4BF₄· 7CH₃CN·2.8H₂O features a tetrahedral metallosupramolecular prism with a novel stellated "star-burst" aspect to the assembly.

The precursor 3,8,13-triamino-2,7,12-trimethoxy-10,15-dihydro-5H-tribenzo[a,d,g]cyclononene (**1**) has been previously reported,[16] and can be converted into the tris(pyridylmethylamino)cyclotriguaiacylenes **2** and **3** in good yields by reaction with the appropriate pyridinecarboxaldehyde, followed by reduction with sodium borohydride (Scheme 1).
Scheme 1.

Reaction of ligand **2** dissolved in acetone with AgPF₆ in CH₃CN gives the crystalline complex [Ag₂(**2**)₂-(CH₃CN)₂]·2PF₆·4CH₃CN (**4**), whose structure was determined by X-ray crystallography.[17] The metal complex [Ag₂(**2**)₂(CH₃CN)₂]²⁺ is a dinuclear, dimeric species with a capsulelike structure (Figure 1). The centrosymmetric capsule forms through the head-to-head coordination of two ligands to two Agᴵ centers to give an [M₂L₂] capsule rather than the [M₃L₂] capsule reported by Shinkai and co-workers. The Agᴵ center is coordinated by a terminal acetonitrile ligand at an Ag–N distance of 2.347(3) Å, and three pyridyl groups at Ag–N distances of 2.322(3), 2.346(2), and 2.247(2) Å in a distorted tetrahedral geometry.

The conformation and directionality of twist of the pyridyl arms of ligand **2** are all similar, and directed above the

molecular cavity of the ligand. This arrangement means that the Ag^I centers are likewise located above the molecular cavity which results in the capsule having an equatorial region that is pinched inwards. Each coordinated acetonitrile ligand is directed into the cavity of a molecular host. Such host–guest associations between a host and coordinated acetonitrile have been previously observed for silver–CTV complexes.[18] The two specific host–guest interactions observed in this structure may be a factor favoring the formation of an [M$_2$L$_2$] capsule over the [M$_3$L$_2$] species.

^{1}H NMR spectroscopic analysis of the dimeric capsule suggests a species related to the solid-state structure may be present in solution. Addition of one equivalent of a silver salt to a solution of **2** results in subtle, but significant, changes to the ^{1}H NMR spectrum: in particular, the splitting of the signal for the methylene spacer of the pyridyl arms of **2** into two doublets and the considerable upfield shift of the H2 proton of the pyridyl ring. The former change is likely to originate because of restricted rotation of the pyridyl arm of **2** upon coordination, while the latter may result from internalization of the pyridyl H2 within a capsule or related species. However, the [Ag$_2$(**2**)$_2$(CH$_3$CN)$_2$]$^{2+}$ capsule characterized by X-ray crystallography has C_2 symmetry but in solution the ligand (**2**) possesses C_3 symmetry—that is, only one set of signals are observed. Thus, either a fluxional process which is fast on the NMR timescale is simplifying the expected spectrum for the [Ag$_2$(**2**)$_2$(CH$_3$CN)$_2$]$^{2+}$ capsule, or another species such as an [Ag$_3$(**2**)$_2$]$^{3+}$ cage or an [Ag(**2**)]$^+$ complex where the ligand is a tripodal tridentate donor is present in solution. Rapid crystallization (ca. 20 min) of the [Ag$_2$(**2**)$_2$-(CH$_3$CN)$_2$]$^{2+}$ capsule occurs from acetonitrile solution when the silver salt used is silver(I) cobalt(III) bis(dicarbollide) (Ag[Co(C$_2$B$_9$H$_{11}$)$_2$]) which indicates there is some form of preorganization of the structure in solution.

Titration of **2** with Ag[Co(C$_2$B$_9$H$_{11}$)$_2$] leads to a significant upfield shift of the pyridyl H2 signal when up to one equivalent of the silver salt is added. The upfield movement

of the resonance then stabilizes before undergoing a downfield shift as more than 1.5 equivalents of Ag[Co(C$_2$B$_9$H$_{11}$)$_2$] are added. The pyridyl H6 proton signal mimics this behavior, but undergoes a significantly less-pronounced upfield shift, while the signals for the more remote pyridyl H4 and H5 move progressively downfield throughout the titration. In an additional set of experiments, crystals of **4** prepared in acetonitrile were redissolved in [D$_6$]acetone or CD$_3$NO$_2$, but signals for the incarcerated acetonitrile, disappointingly, could not be observed. These results suggest that while a related [Ag$_2$(**2**)$_2$]$^{2+}$ capsule may be present in solution, other species, including the originally anticipated [Ag$_3$(**2**)$_2$]$^{3+}$ capsule, and possibly a 1:1 complex, are also likely solution structures. ES-MS results demonstrate the presence of a 1:1 complex in solution, thus suggesting that the ligand may in fact act as a tripodal tridentate donor in solution. This 1:1 complex then dimerizes upon crystallization to generate the [M$_2$L$_2$] capsule. Further solution studies will be discussed in a future full paper that demonstrates the generality of this capsule-related topology with other tetrahedral transition-metal ions.

Use of the 4-substituted ligand **3** in place of the 3-substituted ligand **2** has a profound effect on the type of metallosupramolecular prism isolated. Reaction of **3** with one equivalent of AgBF$_4$ in CH$_3$CN gives the crystalline complex [Ag$_4$(**3**)$_4$(CH$_3$CN)$_4$]·4BF$_4$·7CH$_3$CN·2.8H$_2$O (**5**). The crystal structure of **5** was determined by single-crystal techniques.[17] Complex **5** contains a [Ag$_4$(**3**)$_4$(CH$_3$CN)$_4$]$^{4+}$ metallosupramolecular prism in which the Ag^I centers form the vertices of a slightly distorted tetrahedral prism, with Ag···Ag separations along the tetrahedron edges ranging from 8.29 to 10.33 Å. Four tris(4-pyridylmethylamino)cyclotriguaiacylene ligands form the faces of the [M$_4$L$_4$] tetrahedral prism (Figure 2).

There are four independent ligands within complex **5**, and each shows a noncrystallographic C_3 symmetry. The conformation of each ligand is similar, with the plane of each pyridyl arm at approximately 90° to the plane of the core arene group to which it is attached. All pyridyl arms are directed inwards in relation to the ligand core. This conformation allows for formation of a convergent, discrete structure, rather than a polymeric structure which would result from an *exo* pyridyl arm conformation. Each molecule of **3** bridges between three Ag^I centers. There are four crystallographically independent Ag^I centers, and each is coordinated by pyridyl groups from three different molecules of **3** and an acetonitrile ligand. The Ag–N$_{py}$ and Ag–NCMe interatomic distances range from 2.216(13) to 2.328(13) and 2.390(18) to 2.60(3) Å, respectively, and the metal geometries are distorted tetrahedral, distorted trigonal pyramidal, or have a geometry in-between these extremes. Three of the four Ag^I centers have their terminal acetonitrile ligand directed *exo* from the tetrahedral

Figure 2. Tetrahedral metallosupramolecular prism $[Ag_4(3)_4(CH_3CN)_4]^{4+}$ from the X-ray crystal structure of **5**. Thin lines highlight the tetrahedral prism formed by the Ag^I centers (shown as spheres).

structure, in which the calixresorcinarene ligands act as the vertices of a metallosupramolecular tetrahedron, has been reported by Beer and co-workers.[11b] Aside from the final two examples, these tetrahedra feature ligands with a flat trigonal core. Where the structure of **5** differs from these examples is in having a pyramidal ligand defining the triangular faces of the tetrahedron, which gives the assembly a spiked starlike aspect, somewhat akin to stellations of a prism.[26] Figure 3a highlights this "star-burst" aspect of **5** and shows the tetrahedron of Ag^I ions and the centers of the lower rim -$(CH_2)_3$- plane of the ligands. This "star-burst" topology engenders the structure with a greater internal volume than a tetrahedron of equivalent dimensions formed with a planar trigonal ligand.

Overall, the $[Ag_4(3)_4(CH_3CN)_4]^{4+}$ prism is a molecular host for five molecules of acetonitrile. Four of these acetonitrile guests form host–guest interactions, each with an individual ligand, in which the hydrophobic methyl group is directed into the molecular cavity. Distances between the methyl carbon atom of the guest and the lower rim -$(CH_2)_3$- plane of the host ligand range between 3.74 and 3.86 Å. The fifth acetonitrile molecule is disordered across two positions with 65% occupancy as the *endo* CH$_3$CN molecule coordinated to Ag(3) and 35% occupancy as a guest in the middle of the assembly (Figure 3b).

The tetrahedral prisms pack together in the crystal lattice with various π-stacking interactions apparent. These include face-to-face interactions between core arene groups at centroid separations of 3.56 Å and edge-to-face interactions between pyridyl CH groups and core arene groups at C–H⋯centroid separations of 2.40 Å (C⋯centroid distance 3.3 Å). The additional solvent molecules and BF$_4^-$ counterions fill spaces created by the packing of the prisms. These sites are approximations of the tetrahedral and octahedral interstitial holes displayed by close-packing spheres, which are created as $[Ag_4(3)_4(CH_3CN)_4]^{4+}$ has a roughly spherical surface. Note that $[Ag_4(3)_4(CH_3CN)_4]^{4+}$ does not genuinely close pack as it is not truly spherical; distortions are such that each $[Ag_4(3)_4(CH_3CN)_4]^{4+}$ unit is in proximity to 11 others rather than the 12 expected of a genuinely close-packed array.

prism, and one, Ag(3), has the terminal acetonitrile molecule directed into the prism. The geometry of Ag(3) is closest to trigonal pyramidal with the acetonitrile ligand forming a long bond (Ag–N: 2.60(3) Å) in the capping position.

Tetrahedral metallosupramolecular prisms have been reported by a number of researchers, with most examples having an [M$_4$L$_6$] stoichiometry where the six ligands define the edges of the tetrahedron.[19] There have been fewer examples of tetrahedral metallosupramolecular assemblies where the ligand defines a face of the tetrahedron. These are a [M$_8$L$_4$] distorted tetrahedron from Fujita and co-workers,[20] a distorted [M$_{12}$L$_4$] tetrahedron reported by Robson and co-workers,[21] a handful of [M$_4$L$_4$] tetrahedra with triscatecholate ligands,[22,23] an [M$_4$L$_4$] tetrahedron formed from a disk-shaped tridentate ligand,[24] and an [M$_4$L$_4$] tetrahedron with a podand borate ligand.[25] Additionally, a flattened tetrahedral

Communications

We have reported herein the first structural characterizations of metallosupramolecular cages incorporating ligands derived from the molecular host CTV. In the first case, the additional flexibility engineered into our ligand system over that reported by Shinkai and co-workers, coupled with the geometrically more accommodating silver centers have resulted in the isolation and structural characterization of a more compact [M₂L₂] molecular capsule which incarcerates two coordinated CH_3CN guests. The utilization of the more-divergent 4-pyridyl ligand **3** led to the formation of a significantly expanded stellated tetrahedron with an internal space capable of accomodating five CH_3CN guest molecules. This dichotomy of structures observed presents the intriguing possibility that by tailoring the size of the guest we can control the formation of various metallosupramolecular cages with this ligand system.

[26] Stellations arise from extending the edges of a polyhedron so that they intersect to form a star. A tetrahedron cannot strictly show a stellation as the extended edges of a tetrahedron never meet. Often the overall effect of stellation is to produce pyramidal faces in place of flat faces; hence this prism is reminiscent of a stellated prism. For an example of a complex with a stellated structure, see: E. C. Constable, C. E. Housecroft, M. Neuburger, S. Reymann, S. Schaffner, *Chem. Commun.* **2004**, 1056–1057.

of proteins. The problems addressed by the top-down approach include verification of the protein sequence, localization of errors in DNA-predicted sequences, de novo sequencing, as well as the analysis of pre- or posttranslational modifications (PTMs). However, such PTMs as disulfide bonds still remain a challenge for traditional MS/MS techniques that utilize vibrational excitation (VE), as they break peptide bonds preferentially in protonated polypeptides and leave the disulfide bonds intact.[3] As a result, information on the primary sequence is limited to parts of the protein that is not constrained by disulfide bonds. This restriction complicates primary sequence elucidation and limits the utility of automated database searches. The problem of disulfide bonds is solved conventionally by their reduction and alkylation[4] prior to MS/MS measurements. However, the additional step involving solution-phase chemistry, including subsequent purification, greatly increases the analysis time and the risk of sample loss. Another approach is to use an alternative ion-dissociation strategy. Chrisman and McLuckey have shown that VE of deprotonated polypeptides induced by collisionally activated dissociation (CAD)[5] breaks disulfide bonds with high efficiency.[6] However, CAD of peptide anions often produces complicated mass spectra that, together with backbone cleavages, contain significant amounts of neutral mass losses and rearrangement products which make such MS/MS spectra of limited value for sequencing. Electron-capture dissociation (ECD)[7] stands alone in its ability to cleave S−S bonds preferentially in peptide polycations (Scheme 1).[3] A

Facile Disulfide Bond Cleavage in Gaseous Peptide and Protein Cations by Ultraviolet Photodissociation at 157 nm**

Y. M. Eva Fung, Frank Kjeldsen,* Oleg A. Silivra, T. W. Dominic Chan, and Roman A. Zubarev*

Disulfide bonds formed between cysteine residues stabilize the native structure of many proteins.[1] These covalent cross-linkages are part of the tertiary structure and introduce conformational constraints to the polypeptide architecture, thus improving the thermodynamic stability. Mass spectrometry has become increasingly important in the characterization and identification of proteins as a result of its capability for highly specific measurements on relatively small amounts of analyte. Protein characterization and identification relies on database searches using primary sequence information obtained by tandem mass spectrometry (MS^n or MS/MS). The top-down approach[2] applied to intact proteins ions is an efficient MS/MS method which is potentially suited for the high-throughput characterization

$$R^1H_m^{m+}-CH_2-S-\vdots-S-CH_2-R^2H_n^{n+} \xrightarrow{\text{ECD, e}^-} R^1H_m^{m+}-CH_2-SH + \cdot S-CH_2-R^2H_{(n-1)}^{(n-1)+}$$

Scheme 1. Charge reduction by cleavage of the disulfide bond with ECD.

drawback of this technique is that the capture of a low-energy electron by multiply charged polypeptides results in charge reduction prior to bond cleavage, which in turn leads to a charge decrease in one of the two fragments. As species need to contain at least one charge to be detectable in mass spectrometry, the charge reduction in ECD can lead to a loss of information.

Previously, when magnetic sector instruments were widely used, high-energy CAD (HE CAD) was utilized to produce cleavage of numerous disulfide bonds in peptides.[8] The abundance of this fragmentation channel compared to low-energy CAD has been explained by electronic excitation. Today, HE CAD can only be found in TOF/TOF instruments that are more suitable for peptides than for proteins, and for which MS^n abilities are limited above $n = 2$. Therefore, a fragmentation technique is needed that is suitable for MS^n of protein cations and that would not involve charge reduction.

We have assumed that if the HE CAD efficiency for cleavage of a disulfide bond is indeed a result of electronic excitation, a similar effect could be expected upon irradiation of polycations with ultraviolet (UV) light. Indeed, irradiation of desorbed cations with light of wavength 337 nm in matrix-assisted laser desorption ionization (MALDI) studies[9] results in partial reduction of the S−S bonds in situ.[10] The

wavelength of maximum absorption for the S—S bond in, for example, cystine (Cys-S-S-Cys) is approximately 150 nm.[11] Therefore, one may expect an efficient cleavage of the S—S bond upon UV photodissociation (UVPD) at 157 nm. This cleavage would compete with the backbone fragmentation of peptide monocations reported by Reilly and co-workers that resulted in unusual cleavage of the backbone C_α—C bonds (a, x-type fragments).[12] The fragmentation of the peptide backbone in that study was explained as a result of electronic excitation of the polyamide bonds as a consequence of absorption of photons of 7.9 eV.

Herein, we have tested the above assumption and present evidence of a facile cleavage of both intra- and intermolecular disulfide bonds in peptide and protein polycations by UVPD at 157 nm. Figure 1 presents a comparison of the MS/MS spectra obtained with CAD, ECD, and consecutive UVPD and CAD (UVPD/CAD) of a peptide dimer linked by an intermolecular disulfide bridge. The CAD mass spectrum (Figure 1a) of the $[M+3H]^{3+}$ ions contains only a few (ten) **b**- and **y**-type fragment ions (in b ions, the charge is retained on the N-terminal side of the peptide, and in y ions on the C-terminal side).[13] However, there was no evidence for cleavage of the disulfide bond. In contrast, ECD (Figure 1b) produced abundant signals corresponding to free monomers

and thus to cleavage of the S—S bond. Charge reduction meant that only singly charged peptide monomers were observed, thus rendering them useless for MS³ by ECD, as electron capture would neutralize them and their products. UVPD at 157 nm (Figure 1c) also cleaved the disulfide bond, and led to both singly and doubly charged peptide monomers. The efficiency of the dissociation of the S—S bond (defined as the ratio of the released monomer abundances divided by the total ion abundance) by UVPD at 157 nm was 1.2% compared to 2.3% with ECD. However, UVPD at 157 nm was implemented on a linear ion trap that was approximately 100 times more sensitive than the Fourier transform analyzer on which the ECD mass spectrum was obtained. Thus, the twofold loss of efficiency was more than compensated by the huge advantage in sensitivity. Furthermore, the efficiency of the S—S bond cleavage in UVPD increases as the positive charge decreases (data not shown).

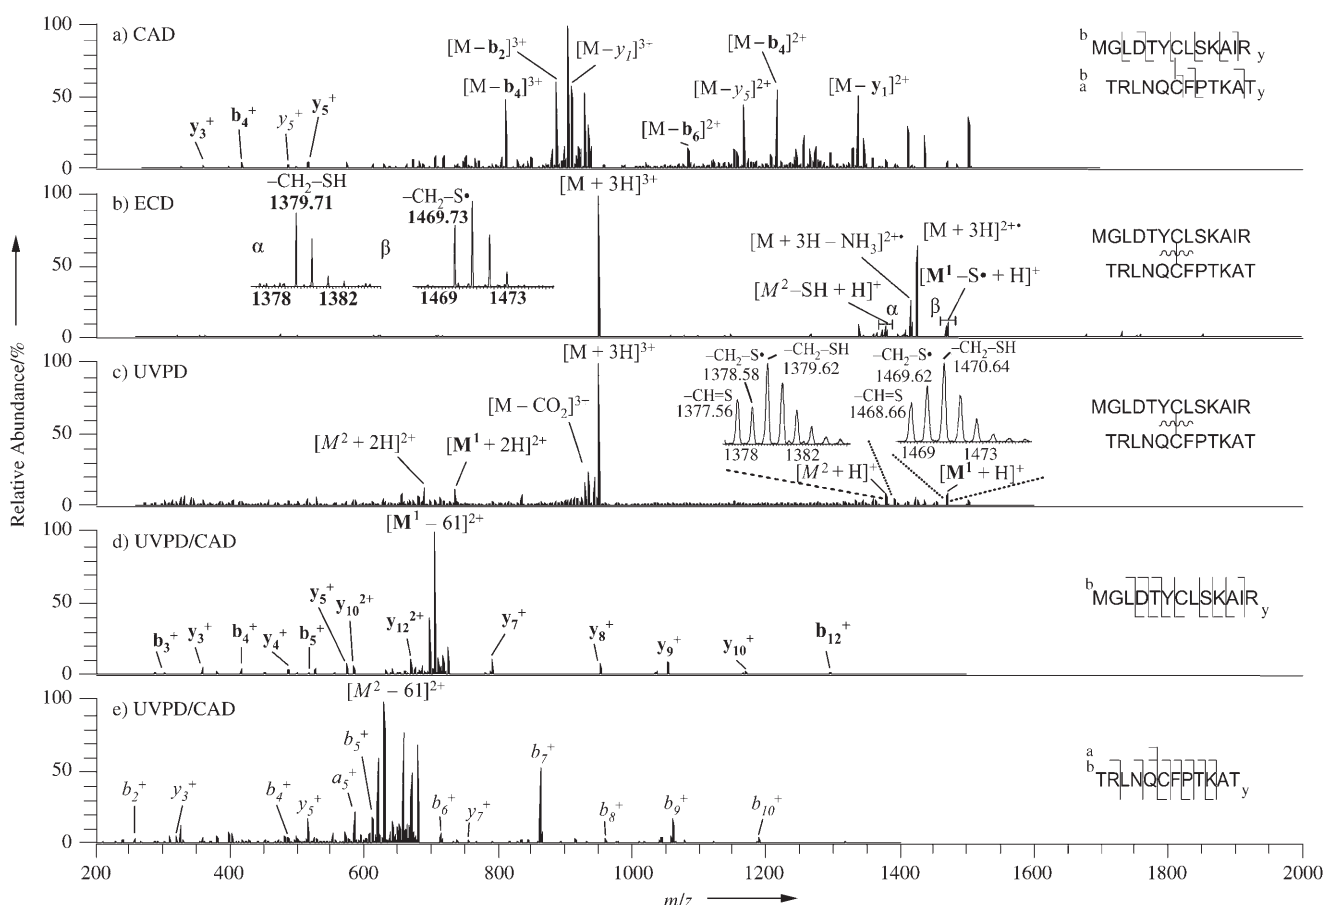
Only limited information on the sequence of the peptide dimers was obtained in MS² with UVPD at 157 nm, as the S—S bond was cleaved at a higher rate than the peptide backbone. Therefore, the released doubly charged peptide monomers were isolated and subjected to MS³ by CAD (Figure 1d and e), which resulted in extensive fragmentation of the backbone (> 60% sequence coverage). The same procedure was carried


Figure 1. a)–c) Tandem mass spectra of a disulfide-bridged peptide dimer, **M**¹-S-S-M^2; where **M**¹ = MGLDTYCLSKAIR and M^2 = TRLNQCFPTKAT. Fragments from **M**¹ are marked in bold and that from M^2 are marked in italics. The fragmentation techniques were: a) CAD, b) ECD, c) UVPD at 157 nm, d) CAD of isolated $[M^1+2H]^{2+}$ after UVPD at 157 nm of **M**¹-S-S-M^2 trications; e) CAD of isolated $[M^2+2H]^{2+}$ after UVPD at 157 nm of **M**¹-S-S-M^2 trications. The identities of the $[M^{1,2}-61]^{2+}$ peaks in (d) and (e) are currently under investigation.

out on singly charged peptide monomers, which increased the overall sequence coverage to 96%, with only one interresidue bond not cleaved. The combined sequence information of all the disulfide-linked peptide dimers studied is summarized in Figure 2.

Figure 2. a) Fragmentation schemes of three trications of disulfide-bridged peptide dimers resulting from UVPD/CAD at 157 nm.

Figure 3. CAD mass spectra of isolated isotopic ions after UVPD at 157 nm of dications of the TRLNQCFPTKAT peptide corresponding to masses of a a) monoisotopic signal and b) the first isotopic signal.

We hypothesize that UVPD breaks disulfide bonds by homolytic cleavage induced by electronic excitation. This process should result in two complementary fragments with radicals localized on each of the sulfur atoms ($R^1CH_2S^{\bullet}$/$R^2CH_2S^{\bullet}$). However, the isotopic pattern observed for the sulfenyl radical (see inset of Figure 1c) was much broader than the theoretically calculated distribution. To investigate this effect further we isolated separately two isotope components of the UVPD-released doubly charged TRLNQCFPTKAT peptide monomer and fragmented them by CAD (Figure 3a and b, respectively). Only the cysteine-containing fragment ions exhibited a mass difference of 1 Da between the two spectra—other fragment ions were of the same mass. This result implies that the mass difference of 1 Da between the two monomeric ions was not exclusively the consequence of stable isotopes (for example, ^{12}C versus ^{13}C), but also the result of the presence of two different species ($R^1CH_2S^{\bullet}$ and R^1CH_2SH). Similarly, isolation and MS/MS of the isotope 1 Da below the monoisotopic signal confirmed the identity of these ions as $R^1CH{=}S$ (data not shown).

Thus, three mechanisms for the cleavage of disulfide bonds in UVPD at 157 nm were proposed (Scheme 2). Electronic excitation by photon absorption can lead to rapid cleavage of the disulfide bond and formation of two sulfenyl radicals $R^1CH_2S^{\bullet}$ and $R^2CH_2S^{\bullet}$ (path a). If fragment separation is delayed because of noncovalent bonds between the monomers, the proximity of the two radical peptide chains

can result in intermolecular hydrogen transfer. This process leads to reactions (path b or path c) where either abstraction of a H atom by a peptide monomer from the other monomer forms sulphydryl or thioaldehyde (-CH_2SH or -$CH{=}S$) functional groups. Alternatively, absorption of a photon by a dimer leads to intramolecular hydrogen rearrangement, with an H atom attacking the S—S bond, as has been suggested for ECD.[3,14] Additional evidence for this latter mechanism comes from the observation of abundant loss of H atoms from irradiated precursor ions (data not shown), thus indicating that hydrogen abstraction and rearrangement do play a significant role in UVPD at 157 nm.

The ability of UVPD at 157 nm to cleave intramolecular disulfide bonds was tested on the peptide RLCADTPICGK with a disulfide bridge between the two cysteine residues. Figure 4 shows the CAD spectrum (Figure 4a) and the UVPD spectrum (Figure 4b) for comparison. While CAD yielded only three b and one y ions with no cleavage of the disulfide bond, UVPD generated a series of a-type (a_2–a_{10}) fragment ions (a ions correspond to cleavage of a C_α–C backbone bond with the charge retained on the N-terminal side) and two d-type fragment ions (d_n ions form from radical a_n ions by loss of side-chains from the C-terminal residue), all as a consequence of cleavage of the disulfide bond. The observation of a-type fragment ions in UVPD at 157 nm was in agreement with the results obtained by Reilly and co-workers.[12] Two other peptide ions with intramolecular disulfide bonds gave similar fragmentation (data not shown).

Moving from model peptides to biologically relevant proteins, we applied UVPD at 157 nm to human insulin, a 5.9-kDa molecule containing polypeptide chains A and B linked by two disulfide bonds, and with one S—S bond within the
Scheme 2. Suggested reaction pathways for the cleavage of the disulfide bond by UVPD at 157 nm.
Figure 4. Tandem mass spectra of dications of the peptide RLCADTPICKGK with an intramolecular disulfide bridge, obtained with: a) CAD and b) UVPD at 157 nm.

A chain (Figure 5). Previously, ECD of 6+ ions have released free A and B chains, but only the B chain gave a MS^3 spectrum.[3] Here, UVPD of $[M+6H]^{6+}$ ions (Figure 5a) yielded predominantly the quadruply charged B chain and doubly charged A chain by simultaneous cleavage of both intermolecular disulfide bonds. CAD on the isolated 4+ charged B chain (Figure 5b) gave abundant *b* and *y* fragment ions covering 59% of the sequence. CAD was performed on 2+ charged A-chain ions (Figure 5c) to determine whether the intramolecular S–S bond in the A chain was also cleaved. This experiment yielded *b* and *y* ions covering 85% of the

sequence. Observation of seven fragments arising from backbone cleavages between the two cysteine residues confirmed the breakage of the intramolecular S–S bond. Thus, the UVPD/CAD combination provided the most complete top-down sequence verification of a protein with three S–S bonds to date.

In summary, we have demonstrated the ability of UVPD at 157 nm to cleave both intra- and intermolecular disulfide bonds without charge reduction in peptide and protein cations. This methodology is expected to be useful in de novo sequencing of polypeptides. As a note of caution, competition with backbone cleavages in UVPD complicates identification of complementary fragment pairs arising exclusively from cleavage of the S–S bond in de novo sequencing. This problem can be addressed by first performing CAD of the intact protein to reveal complementary pairs arising from cleavage of the backbone. While classical reduction of the S–S bond in solution may still provide a clearer answer, the faster UVPD approach that avoids time- and sample-consuming wet chemistry will be preferred in many cases. As photons are not affected by electromagnetic irradiation, UVPD can easily be adapted to different types of mass analyzers, which broadens the application range of this technique.

Experimental Section

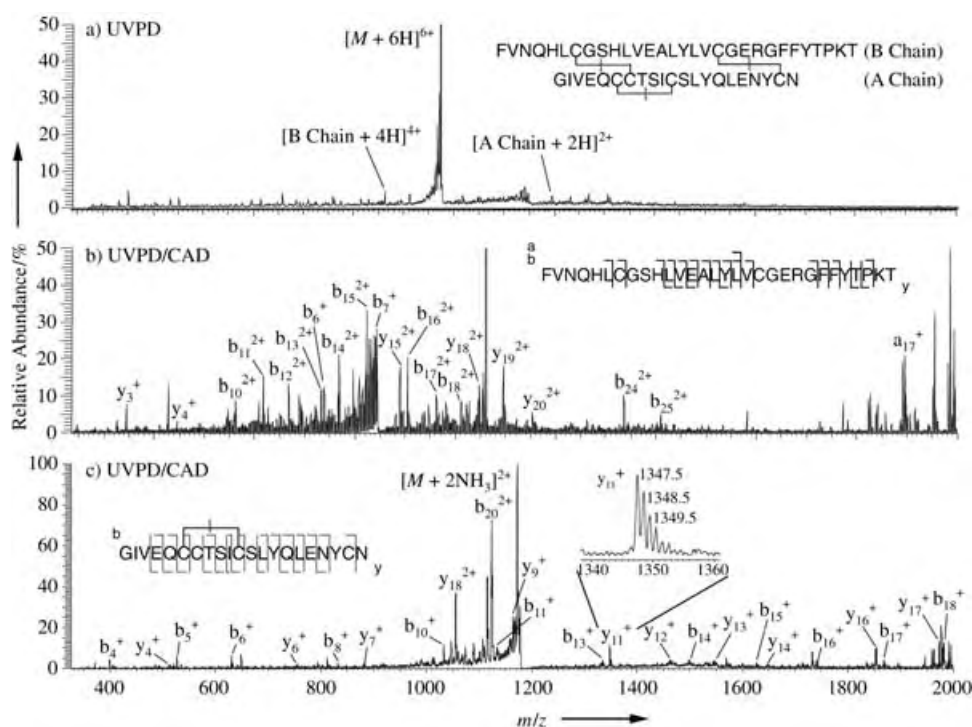
Cysteine-containing peptides were synthesized by automated solid-phase synthesis using the 9-fluorenylmethoxycarbonyl (Fmoc) protection strategy on a research-scale ResPep peptide synthesizer (Intavis AG, Gladbach, Germany). The oxidation of the cysteine residues was performed on 0.5 mg of peptides in a solution of DMSO (20 μL) in 20 mM NH_4HCO_3 (aq, 80 μL) for two days at RT. Human insulin (Sigma, St Louis, MO) was used without further purification. Mass-spectrometric experiments were performed on a linear ion trap mass spectrometer (Thermo Electron, San Jose, CA) equipped with a nanoelectrospray interface operated in the positive ion mode. Oxidized peptides were diluted in a solvent containing acetic acid/methanol/water (2:49:49, v/v/v) to approximately 10^{-6} M and electrosprayed. An excimer F_2 UV laser at 157 nm (Excistar S500, Tuilaser, Germering, Germany) was connected with the mass spectrometer by means of a CaF_2 window on-axis with the ion trap. Unfocused laser pulses (15 ns, 1 mJ) with a repetition rate of 500 Hz were passed through a 1.5-mm collimator installed in front of the window. Isolated precursor ions were irradiated for 3 to 9 ms with UV light. ECD experiments were performed on a 7 Tesla FT mass spectrometer (Thermo Electron AG, Bremen, Germany) equipped with an indirectly heated cathode as an electron source. The electron irradiation in ECD lasted for 70 ms.


Figure 5. a) Mass spectrum of human insulin 6+ ions obtained by UVPD at 157 nm, b) CAD spectrum of $[M+4H]^{4+}$ ions of the B chain released in UVPD at 157 nm from 6+ insulin ions, c) CAD spectrum of $[M+2H]^{2+}$ ions of the A chain released in UVPD at 157 nm from 6+ insulin ions. The inset shows the isotopic distribution of y_{11} ions (Ile–Cys bond cleaved) confirming breakage of the disulfide bond.

covalent linear glycan polymer that consists of alternating *N*-acetylglucosamine (GlcNAc) and *N*-acetylmuramic acid (MurNAc) residues, the latter of which have an appended pentapeptide chain. In addition to the transglycosylase and transpeptidase enzyme families, the biosynthesis of peptidoglycan involves a number of ATP-dependant ligases (namely the Mur ligases). These catalyze the assembly of the pentapeptide moiety through the successive addition of L-Ala, D-Glu, *m*-dpm or L-Lys, and D-Ala–D-Ala to UDP-MurNac by MurC, MurD, MurE, and MurF enzymes, respectively (*m*-dpm = *meso*-diaminopimelic acid; UDP = uridine-5′-diphosphoryl). An additional ATP-dependant enzyme, D-Ala–D-Ala ligase (DD-ligase) is responsible for supplying the D-Ala–D-Ala dipeptide, which is the substrate for MurF.

Inhibition of any of these essential enzymes in either Gram-positive or Gram-negative organisms leads to the loss of cell shape and integrity followed by bacterial death.[2–4] The emergence of bacterial strains that are resistant to all antibiotics in current clinical use has created an urgent need for the development of new inhibitors of peptidoglycan biosynthesis enzymes and, in particular, those that act on targets that have not been previously exploited.

As part of a structure-based design and synthesis program for the discovery of new enzyme inhibitors, we previously described the computer-aided molecular design, synthesis, and biological evaluation of novel inhibitors of the ligase responsible for D-Glu attachment, MurD.[5] Other research groups, using either library-screening methods or substrate-inspired approaches, have also reported useful inhibitors of the MurC[6–8] and MurD[6,9,10] ligases. A phosphinate-based transition-state isostere of DD-ligase has also been reported.[10]

The structure-based design of small-molecule enzyme inhibitors is a powerful tool in drug discovery, particularly if an X-ray crystal structure of the target enzyme is available. For cases in which the X-ray crystal structure includes a substrate or a known inhibitor, a substrate-inspired approach can be adopted; classical molecular modeling techniques can be used to alter the structure of the co-crystallized substrate, and a new molecule with enhanced enzyme-binding affinity can be produced. To identify different inhibitor structure types, the technique of virtual high-throughput screening (VHTS) can also be applied to the crystal structure of the enzyme in an attempt to identify new "hits" by docking the 3D structures of molecules contained in a database.[11]

However, both techniques have a number of drawbacks. The substrate-inspired approach requires a suitable enzyme–substrate co-crystal structure. Furthermore, the structures of the designed molecules will necessarily be biased toward that of the original co-crystallized small molecule, which, as is the case for many natural enzyme substrates, may not possess drug-like properties and may not be an ideal starting point. Although suitable databases allow the design of molecules by the VHTS method to focus on drug-like fragments, this technique is limited by the size and diversity of the small-molecule database; even databases that consist of millions of compounds constitute only a small fraction of the available "diversity space".

A De Novo Designed Inhibitor of D-Ala–D-Ala Ligase from *E. coli*

Recent reports involving the application of de novo design indicate that this approach is a powerful alternative to these classical drug discovery approaches.[12–15] Through the use of only structural features present within the enzyme, new inhibitor designs can be built up sequentially according to the requirements of the targeted binding site. Therefore, in principle, de novo design should be a far more useful technique than VHTS, because a good de novo design program will examine structure space many orders of magnitude larger than that of most virtual libraries currently in use for this purpose. Herein, we report the application of the de novo molecular design program SPROUT[16] to the design of a novel inhibitor of DD-ligase from *E. coli*. We also describe the development of an efficient synthesis of this novel inhibitor and the enzymological characterization of its interaction with DD-ligase and a related enzyme.

SPROUT[16] is a powerful suite of software modules for de novo structure-based molecular design. SPROUT has modules for 1) characterizing regions within a protein, 2) detecting "hot-spots" in which ligand atoms are expected to form strong interactions with the protein, 3) docking molecular fragments to these sites, 4) joining these fragments with a molecular backbone to give a complete ligand, and 5) ranking the set of predicted ligands by criteria that include predicted binding energy, structural complexity, and synthetic accessibility.

In *E. coli*, there are two isoforms of DD-ligase (DdlA and DdlB) encoded by the genes *ddlA* and *ddlB*, with similar kinetic characteristics. The crystal structure of *E. coli* DdlB complexed with a phosphorylphosphinate inhibitor and resolved to 2.3 Å has been used to propose a catalytic mechanism for the formation of D-Ala–D-Ala.[17] To use a de novo approach for the discovery of novel DD-ligase inhibitors, we applied SPROUT to the X-ray crystal structure[18] of DD-ligase encoded by *ddlB* from *E. coli*.

The active site contains two distinct D-alanine binding sites; the N-terminal site is a high-affinity site with strict substrate specificity, whereas the C-terminal site is a lower-affinity site showing lower substrate specificity.[19] A phosphonate-based transition-state isostere is included in the crystal structure of DdlB, located within the active site. It makes direct contacts with essentially all of the residues implied by the catalytic reaction mechanism[17] (Figure 1).

To design a structurally simple inhibitor which was predicted to show high affinity for the enzyme, we wished to use only a small number of these contacts in our SPROUT design strategy. Examination of this active site with SPROUT indicated that use of the side chains of residues R255 and E15, the C$^\alpha$ backbone N—H group of G276, and the magnesium ion Mg331 should result in relatively simple designed molecular templates. Additionally, SPROUT analysis revealed the presence of a small hydrophobic region (which is not used by the phosphonate isostere) between the phenolic ring of Y216 and the alkyl side chain of L282 that we also wished to use for inhibitor design. During this work, it became apparent that the design of a molecular template which allows good contacts to be made to all these sites would require a rigid small-ring framework; the cyclopropyl-based amino acid **1**
Figure 1. a) The bonding interactions between the phosphonate-based isostere and DdlB based on the crystal structure; b) view of the DdlB active site.

(Figure 2) was selected from the many suggestions that arose from the SPROUT design iterations.

One of us recently reported the X-ray crystal structure of the closely related ligase VanA co-crystallized with the same phosphinate-based isostere as described above for DdlB.[20] In addition to the DD-ligases, VanA is present in certain vancomycin-resistant enterococci and is responsible for the formation of D-alanine–D-lactate. This unit is then incorporated into the pentapeptide chain, and it is the resulting lactate-containing peptide that binds poorly to vancomycin. We were aware that although the overall topology of the active sites of VanA and DdlB were very similar, there are also important differences, particularly in the hydrophobic region bordered by L282 and Y216 in DdlB (corresponding to R317 and H244 in VanA). We therefore used SPROUT to produce a model of our designed inhibitor **1** within the active site of VanA (Figure 3). This revealed that the three designed hydrogen-bonding contacts to E15 (E16 in VanA), R255 (R290 in VanA), and G276 (G311 in VanA) as well as binding to the magnesium ion were possible for the inhibitor **1** bound within the active site of VanA. However, VanA possesses a

much narrower hydrophobic region between H244 and R317 than the equivalent region in DdlB (between L282 and Y216) due to protrusion of the imidazole ring of VanA H244 into the cavity (Figure 3). In fact, SPROUT analysis of the inhibitor **1**–VanA complex indicated that this inhibitor should bind only very poorly to VanA. Following synthesis, we therefore planned to measure the affinity of inhibitor **1** with both DdlB and VanA and test the selectivity of our inhibitor predicted by these computational studies.

A short synthesis of cyclopropane **1** was developed and is summarized below (Scheme 1). Ring opening of the readily available racemic lactone **2**[21] followed by halogen exchange and oxidation afforded aldehyde **3**. Olefination with phosphorane **4** followed by catalytic reduction of the double bond with concomitant *N*-deprotection and final ester hydrolysis yielded the desired inhibitor **1** as an inseparable 1:1 mixture of diastereomers.[22]

Enzymological evaluation[23] of designed inhibitor **1** was performed with recombinant *E. coli* DdlB and VanA enzymes. In keeping with our modeling predictions, this molecule (as a diastereomeric mixture) inhibits the activity of DdlB with an apparent K_i value of 12.5($\pm$0.1) μM, whereas it

had no inhibitory activity against VanA. The apparent K_i value of cycloserine for DdlB, a known inhibitor of this enzyme, was 1.4 μM. Clearly, the designed template is for a single enantiomer of absolute stereochemistry shown in Figure 2. In these proof-of-principal studies, however, we chose to perform biological evaluation with a readily available diastereomeric mixture containing this designed template along with equimolar amounts of three other stereoisomeric versions of this inhibitor. Therefore, although the measured binding affinity of this mixture to DdlB is very encouraging, it is likely that the actual designed enantiomer **1** is an even more potent inhibitor of DdlB. It should be noted that the production of inhibitors that are active at the low micromolar concentration range after pure de novo design is quite typical of the current state of this approach; of course, inhibitors active at this level provide an excellent starting

Communications

point for further optimization. Development of more accurate functions for the estimation of binding affinity remains a key requirement for further progress in the de novo design of even more potent inhibitors.

In summary, it appears that SPROUT-based de novo design holds tremendous potential for the rapid discovery of selective inhibitors of DdlB and related enzymes. We believe that this approach is complementary to the use of high-throughput screening and is particularly attractive for cases in which such screening methodology is not available or in which access to large collections of library compounds of sufficient molecular diversity is limited.

N-Methylhydroxylamido(1−)- and Nitrosomethaneruthenium Complexes Derived from Nitrosyl Complexes: Reversible N-Protonation of an N-Coordinated Nitrosoalkane**

Satoshi Kura, Shigeki Kuwata,* and Takao Ikariya*

Nitric oxide (NO), nitroxyl (HNO), and hydroxylamine have been invoked as key intermediates in the biological multi-electron reduction of nitrite to ammonia, which is a fundamental process in the inorganic nitrogen cycle in nature. The reaction is catalyzed by a certain type of nitrite reductase that contains heme moieties at its active site.[1] Within this context,

the electrochemical reduction of nitrite to ammonia by coordination compounds of iron and its congeners ruthenium and osmium has been studied extensively.[2] In these systems, however, the exact formulation and coordination mode of the intermediary nitroxyl and hydroxylamine complexes are not known. Indeed, interconversion of these partially reduced nitrogenous species, including their organic derivatives such as nitrosoalkanes (RNO), on late transition-metal centers remains unexplored[3–8] compared with that on the early transition metals.[9,10] In an early example, Roper and co-workers[3] reported the reversible protonation of the nitrosyl complex [Ir(NO){P(C$_6$H$_5$)$_3$}$_3$] by HCl to afford the hydroxyl-amine complex [IrCl$_3$(NH$_2$OH){P(C$_6$H$_5$)$_3$}$_2$]. Although the nitroxyl complex [IrCl(HNO-κ*N*){P(C$_6$H$_5$)$_3$}$_3$] has recently been characterized as an initial protonation product in this transformation,[4] the second protonation site of the nitroxyl complex, for example, is still unclear. We now describe the stepwise transformation of nitrosylruthenium complexes to nitrosoalkane and *N*-alkylhydroxylamido(1−) complexes, as well as the facile interconversion of the latter two species.

The thermolysis of the linear nitrosyl complexes [Cp*Ru(NO)(CH$_3$)(NC$_5$H$_4$Ar-2)](OTf) (**1a**, Ar = C$_6$H$_5$; **1b**, Ar = 4-CH$_3$C$_6$H$_4$; Cp* = C$_5$Me$_5$)[11] gave mixtures of the two isomeric *N*-methylhydroxylamido(1−)-κ^2*N,O* complexes **2** and **3** (Scheme 1). Fortunately, all of these isomers, except

Figure 1. Structures of a) **2b** and b) **3b** with 30% ellipsoids. Hydrogen atoms except that for the hydroxylamido group are omitted for clarity. Selected interatomic distances [Å] for **2b**: Ru(1)−O(1) 2.042(3), Ru(1)−N(1) 2.057(3), Ru(1)−N(2) 2.081(3), Ru(1)−C(22) 2.075(4), N(1)−O(1) 1.379(4), N(1)−O(2) 2.869(5). For **3b**: Ru(1)−O(1) 2.040(2), Ru(1)−N(1) 2.042(2), Ru(1)−N(2) 2.087(3), Ru(1)−C(22) 2.073(3), N(1)−O(1) 1.370(3), N(1)−O(2) 2.982(4).
Scheme 1. Synthesis of **2** and **3**.

for the phenylpyridine derivative **3a**, could be isolated by adjusting the reaction conditions and subsequent workup procedure. The solid-state structures of the tolylpyridine derivatives **2b** and **3b** are depicted in Figure 1.[12] The two isomers **2b** and **3b** have the same stereochemistry around the Ru atom but are differentiated by the relative orientation of the Cp* and methyl groups with respect to the three-membered RuNO ring; these groups lie on the same side of the RuNO plane in **2** and on the opposite side in **3**. The N−O distances (1.380(5) and 1.377(4) Å) are unexceptional for hydroxylamido(1−) complexes.[9,14,15] Although the hydroxylamido(1−) H atom could not be located in the difference Fourier map, close contacts (ca. 2.9 Å) of the N atom and the

triflate O atom in both crystals clearly indicate the presence of an amine proton hydrogen-bonded to the OTf⁻ counterion. The presence of the amine proton was also deduced from the IR spectra, which display an NH stretching band around 3140 cm^{-1}. In the ^{1}H NMR spectra, the amine proton in **3** is observed at around δ = 8.6 ppm as a quartet split by the *N*-methyl protons with a $^3J_{H,H}$ coupling constant of 4.4 Hz;[16] the corresponding signal of **2** is overlapped by the aryl resonances around δ = 7.8 ppm. These observations confirm the formulation of the Ru^{IV} hydroxylamido(1−) complexes **2** and **3**. To the best of our knowledge, **2** and **3** are the first fully characterized hydroxylamido(1−) complexes of a late transition metal.[5,7]

It should be noted that samples of isolated **2** and **3** undergo slow isomerization to give mixtures of **2** and **3**. The disappearance of the ^{1}H NMR signal of the amine proton upon treatment of **2** or **3** with D$_2$O suggests that the isomerization takes place by a deprotonation–protonation sequence that involves the amine proton. Dissociation of the M−N bond followed by inversion at the N atom[17] seems less plausible because **2** and **3** were found to be inert towards various two-electron donor ligands such as CO, phosphanes, and alkynes at room temperature.

In the formation of **2** and **3** from **1**, the nitrosyl ligand undergoes an intramolecular methylation and protonation coupled with the cyclometalation of the coordinated arylpyridine. Evidence for the stepwise transformation of the nitrosyl ligand was obtained from separate experiments. Treatment of the ruthenacyclic complexes [Cp*Ru(NO)(C_6H_3R-C_5H_4N-κ^2N,C)](OTf) (**4a**, R = H; **4b**, R = CH_3)[11] with an equimolar amount of CH_3Li afforded the Ru[II] nitrosomethane-κN complexes **5** as the main product, although the yields of isolated product were unsatisfactory due to the difficulty in separating them from small amounts of uncharacterized by-products (Scheme 2). The X-ray crystal structure analysis of
Scheme 2. Transformation of **4** into **2** and **3** via **5**.

the phenylpyridine derivative **5a** revealed the N-coordination of the nitrosomethane ligand (Figure 2).[12] The N—O distance of 1.264(13) Å is much shorter than those in the hydroxyl-amido(1−) complexes **2b** and **3b**. The nitrosomethane ligand, the Ru atom, and the centroid of the Cp* ligand are coplanar to maximize the π back-donation to the nitrosomethane
Figure 2. Structure of **5a** with 30% ellipsoids. Hydrogen atoms are omitted for clarity. Selected interatomic distances [Å] and angles [°]: Ru(1)−N(1) 1.914(7), Ru(1)−N(2) 2.067(7), Ru(1)−C(22) 2.068(7), N(1)−O(1) 1.27(1), N(1)−C(11) 1.47(1); Ru(1)−N(1)−O(1) 125.2(6), Ru(1)−N(1)−C(11) 124.0(6), O(1)−N(1)−C(11) 110.7(7).

ligand, as observed in the isoelectronic complex [Cp*Ru-(C_6H_5)(C_2H_5NO-κN){P(CH_3)$_2$(C_6H_5)}].[18]

As expected, subsequent protonation of the nitrosomethane complexes **5** with a slight excess of triflic acid gave isomeric mixtures of the hydroxylamido(1−) complexes **2** and **3**. Despite the rich coordination chemistry of nitrosoalkane,[19] protonation of well-defined nitrosoalkane (or nitroxyl) ligands on late transition-metal centers is extremely rare. The only precedent we are aware of is the O-protonation of the nitrosobenzene complex [Os(NO)Cl(C_6H_5NO-κ^2N,O)-{P(C_6H_5)$_3$}$_2$], the product of which was characterized only by IR spectroscopy.[7] Furthermore, the reverse reaction, namely deprotonation of isomeric mixtures of **2** and **3**, regenerated the nitrosomethane-κN complexes **5**. The formation of the nitroxyl-κN derivatives **5** contrasts sharply with the deprotonation of the hydroxylamido(1−)molybdenum complex [Mo(NO)(terpy)(H_2O)(H_2NO-κ^2N,O)]$^{2+}$, which forms a nitroxyl-κ^2N,O complex.[20]

The overall transformation shown in Scheme 2 has close relevance to the biological reduction of nitrite (Scheme 3). In the biological system, alternating proton and electron transfer
Scheme 3. a) Consecutive proton and electron transfer to the nitrosyl intermediate proposed for the mechanism of cytochrome *c* nitrite reductase. b) Sequential reduction of the nitrosyl ligand at the {Cp*Ru(C_6H_3R-C_5H_4N-κ^2N,C)} chromophore.

is thought to convert the nitrosyl intermediate into the heme-bound nitroxyl and hydroxylamine.[1c] On the other hand, the nitrosyl ligand on the ruthenium complexes **4** is reduced upon methylation and subsequent protonation. The electrons for this reduction are formally supplied by the methyl anion in the first step, and by the Ru[II] center in the nitrosomethane complexes **5** in the second step, to give the hydroxyl-amido(1−) ligand in the Ru[IV] complexes **2** and **3**. Similarly, the reaction in Scheme 1 can be considered as the migratory insertion of the nitrosyl ligand in **1** into the Ru−CH_3 bond[10,21] followed by an aromatic C−H bond activation and subsequent proton migration to the resultant nitrosomethane ligand. It should be emphasized that related electron–proton chemistry of the nitrosyl ligand has been observed only in some early transition-metal complexes.[14,22]

In summary, we have demonstrated that organic derivatives of the possible intermediates in the inorganic nitrogen cycle, with various formal oxidation states of nitrogen ranging from +3 (NO$^+$) and +1 (RNO) to −1 (RNHO$^-$), can be stabilized, structurally characterized, and converted into each other on an organometallic platform. Reversible N-protonation of the nitrosoalkane ligand, which results in the formation of the unprecedented hydroxylamido(1−)ruthenium complexes **2** and **3**, is particularly noteworthy because it

sheds light on the detailed mechanism of the biological nitrite–ammonia conversion at a late transition-metal center. The reactions described herein also feature a facile aromatic C−H bond activation in **1** to give the high-valent, yet stable, Ru^{IV} center in **2** and **3**, and the isomerism of the novel *N*-methylhydroxylamido(1−) complexes of a late transition metal.

Regiospecific Side-Chain Functionalization of Linear Low-Density Polyethylene with Polar Groups**

Chulsung Bae, John F. Hartwig, Hoyong Chung, Nicole K. Harris, Karen A. Switek, and Marc A. Hillmyer*

The incorporation of polar functional groups along the backbone of polyolefins can significantly alter the physical properties and increase the utility of these commodity materials.[1,2] A polar functionality can improve the interaction of these materials with other polymers and their adhesion to metals or glass. Moreover, functional groups in a polymer chain can serve as initiation sites for the formation of graft copolymers.[2] Thus, polyolefins with polar groups have been a target for polymer synthesis.[2–4]

We recently reported the synthesis of such materials by conducting selective, catalytic functionalization of the pendant methyl groups of a model atactic amorphous polybutene of moderate molecular weight[5] and of commercial polypropylenes of various tacticities.[6] Both polybutene and polypropylene contain an abundance of accessible methyl groups. In contrast, commercially important linear low-density polyethylenes (LLDPEs), generated from ethylene and an alpha-olefin, such as octene, contain a small population of methyl groups. Because the yields of the borylation of ali-phatic C–H bonds depend on the population of methyl groups in the system,[7] the extension of the functionalization of polybutene and polypropylene to the functionalization of amorphous polybutene to LLDPE is challenging. Moreover, these polyolefins have been converted into materials with boronic esters and alcohols, but not into materials with groups such as amines or carbonyls which would be useful for generating ionic polymers or graft copolymers. We have recently met these challenges. Herein, we report the regiospecific functionalization of an ethylene–octene copolymer using pinacolborane (HBpin) or bis(pinacolato)diboron (B$_2$pin$_2$) as reagent in the presence of a rhodium catalyst, and the conversion of the resulting borylated polymer into a family of materials with hydroxy, amino, and formyl groups at the termini of the hexyl side chains.

As with the borylation of small alkanes,[8] the rhodium-catalyzed reactions of HBpin and B$_2$pin$_2$ at 150–200 °C with a copolymer **1** of ethylene (87 mol %) and 1-octene (13 mol %) which has a number-average molecular weight (M_n) of 112 kg mol^{-1} and a polydispersity index (PDI = M_w/M_n) of 1.9,[9] produced the corresponding polymer with boryl groups at the termini of the side chains. The isolated **1**-Bpin was then oxidized with NaOH/hydrogen peroxide in a mixture of THF and H$_2$O to give the corresponding polymer **1**-OH with hydroxy groups at the termini of the side chains (Scheme 1).

Both **1**-Bpin and **1**-OH were characterized by NMR spectroscopy. The borylated material **1**-Bpin gave rise to a

Scheme 1. Regiospecific functionalization and subsequent oxidation of linear low-density polyethylene (LLDPE).

Supporting information for this article is available on the WWW under http://www.angewandte.org or from the author.

broad peak in the ^{11}B NMR spectrum at $\delta = 34$ ppm for the alkyl–Bpin moiety and a resonance in the ^{1}H NMR spectrum at $\delta = 0.75$ ppm for the methylene groups adjacent to the Bpin units. The ^{13}C NMR spectrum contained two signals of low intensity at $\delta = 24.9$ and 82.8 ppm from the Bpin groups. DEPT ^{13}C NMR spectroscopy confirmed that these signals corresponded to methyl and quaternary carbon atoms.

After treatment of **1**-Bpin with basic hydrogen peroxide, no signals for an alkyl–Bpin moiety were observed in the ^{1}H and ^{13}C NMR spectra, consistent with complete conversion of **1**-Bpin into the hydroxylated material **1**-OH. The ^{1}H NMR spectrum contained a triplet at $\delta = 3.64$ ppm, and the ^{13}C NMR spectrum contained a singlet at $\delta = 63.2$ ppm for the methylene group that lies alpha to the hydroxy group. An attached proton test confirmed the assignment of the signal at $\delta = 63.2$ ppm as a methylene resonance. The relative intensities of the ^{1}H NMR signals of the hydroxymethyl methylene protons and of the unfunctionalized methyl groups of the side

chains were used to calculate the fraction of side chains that were functionalized with hydroxy groups (Table 1 and Table 2).

Data on the molecular weight and degree of functionalization of polymers generated from **1** are summarized in Table 1 (HBpin) and Table 2 (B$_2$pin$_2$). Size-exclusion chromatography (SEC) data show that the borylation and hydroxylation processes do not lead to a significant change in the molecular weight or polydispersity of the parent polymer **1**. Thus, the rhodium-catalyzed reaction and subsequent oxidation led to the addition of a polar functionality without causing significant chain scission or coupling between polymer chains as typically observed in the free-radical modification of polyolefins.[10, 11]

We defined the efficiency of the functionalization reaction as the ratio of hydroxy groups in the polymer to the boron reagent added initially. As complete conversion of **1**-Bpin into **1**-OH is supported by the disappearance of resonances for alkyl–Bpin in the NMR spectra, we assume that the reported OH efficiency is also representative of the initial efficiency of the addition of Bpin. Reactions of **1** with HBpin in the presence of [Cp*Rh(η^4-C$_6$Me$_6$)] and [Cp*Rh(C$_2$H$_4$)$_2$] (Cp* = pentamethylcyclopentadiene) occurred with similar efficiencies, whereas reactions with [Cp*RhCl$_2$]$_2$ led to incorporation of less boron into the polymer (Table 1, entries 1–3). Reactions of B$_2$pin$_2$ catalyzed by [Cp*Rh(η^4-C$_6$Me$_6$)] led to **1**-Bpin

with a higher concentration of boryl groups in the polymer than reactions catalyzed by [Cp*RhCl$_2$]$_2$ or [Cp*Rh(C$_2$H$_4$)$_2$] under otherwise identical conditions (Table 2, entries 1–3) and showed more effective functionalization than those with HBpin as the boron reagent. Therefore, the combination of B$_2$pin$_2$ reagent and [Cp*Rh(η^4-C$_6$Me$_6$)] catalyst was chosen to study the effects of solvent, temperature, and the ratio of boron to hexyl side chains (Table 2, entries 3–11). Reactions performed at 150 °C in cyclooctane generated a polymer with the highest concentration of functionalized hexyl side chains, which could be controlled by varying the ratio of B$_2$pin$_2$ to side chain without adversely affecting the molecular parameters under the optimized conditions (Table 2, entries 3, 5, 7, and 10). For example, the degree of functionalization increased by a factor of two when the ratio of B$_2$pin$_2$ to hexyl groups was increased from 0.3 to 0.7, but a further increase in the ratio of diboron reagent to hexyl groups from 0.7 to 1.0 did not increase the percentage of functionalized side chains. The maximum percentage of side chains that we were able to functionalize with hydroxy groups was about 20% (Table 2, entries 7 and 10).

We also explored the conversion of the selectively hydroxylated LLDPE into materials with other types of polar functionality. At this time, no method to directly convert an alkyl pinacolboronate into an alkylamine or aldehyde is known. Thus, we developed conditions to convert

the hydroxylated polymers into materials with formyl and amino groups. Although several reactions of stoichiometric reagents are available for the oxidation of alcohols to aldehydes, we chose the catalytic route with water as the only byproduct as shown in Scheme 2. The conversion of 1-
Scheme 2. Conversion of 1-OH to formyl- (1-CHO) and amino-functionalized (1-NHBn, 1-NHPMB) LLDPEs.

OH (Table 2, entry 5) into the aldehyde-containing polymer 1-CHO proceeded with molecular oxygen in the presence of $Pd(OAc)_2$ under the mild conditions reported for low-molecular-weight alcohols by Nishimura et al.[12] and without adversely affecting the molecular parameters (Table 3). As

Table 3: Molecular weight data for formyl- and amino-functionalized LLDPEs.

Entry	M_n [kg mol^{-1}][a]	PDI
1-OH	102	2.1
1-CHO	105	1.8
1-NHBn[b]	67.0	2.1
1-NHPMB[b]	49.9	2.1

[a] Measured by SEC relative to polystyrene standards (THF as eluent at 40°C). [b] M_n and PDI measured from an initial solution of polymer in toluene, eluted with THF at 40°C.[13]

with the hydroxy groups of 1-OH, the aldehyde groups in 1-CHO were easily identified by NMR spectroscopy. Resonances for a formyl hydrogen center and a methylene group alpha to an aldehyde were observed as a singlet at $\delta = 9.77$ ppm and a triplet at $\delta = 2.42$ ppm in the ^{1}H NMR spectrum and as resonances at $\delta = 202.4$ and 44.0 ppm, respectively, in the ^{13}C NMR spectrum. The formyl group was also detected by the C=O stretching band at $\tilde{v} = 1711$ cm^{-1} in the IR spectrum.

We converted the hydroxylated polymers into amino-substituted polymers by an iridium-catalyzed amination of alcohols.[13] The reaction of polymer 1-OH with benzylamine ($BnNH_2$) and p-methoxybenzylamine ($PMBNH_2$) in toluene at 140°C for 48 h in the presence of 2.5 mol% of $[Cp*IrCl_2]_2$,

relative to the hydroxy groups, and K_2CO_3 as the base (Scheme 2) formed a polymer with benzylamino and p-methoxybenzylamino groups in place of hydroxy groups at the termini of the functionalized side chains. The ^{1}H and ^{13}C NMR spectra of the product polymers 1-NHBn and 1-NHPMB showed an absence of resonances from a methylene group alpha to the oxygen atom. The ^{1}H NMR spectrum of 1-NHBn contained new singlet and triplet methylene resonances at $\delta = 3.79$ and 2.62 ppm, and the ^{13}C NMR spectrum contained two new resonances at $\delta = 54.1$ and 49.6 ppm for the methylene units of the benzyl group and the methylene unit of the side chain alpha to the nitrogen center. ^{1}H and ^{13}C NMR data for 1-NHPMB were similar but displayed a ^{1}H NMR resonance at $\delta = 3.77$ ppm and a ^{13}C NMR resonance at $\delta = 55.4$ ppm for the methoxy groups.

Molecular-weight data from SEC of these amino-substituted polymers are included in Table 3. The PDI values and peak shapes of 1-NHBn and 1-NHPMB are similar to those of 1-OH, suggesting that chain scission and chain coupling have not occurred. However, the average molecular weights of the 1-NHR polymers relative to polystyrene standards are significantly lower than those of the starting hydroxylated polymer 1-OH. We presume that the M_n values of the amine-functionalized polymers are lower owing to a combination of changes in the solubility[14] and the hydrodynamic volume of the polymer from the addition of the amino groups, and that unfunctionalized polystyrene standards do not provide an appropriate representation of the molecular weight of the material with basic groups.

In summary, we have demonstrated that functionalization of a commercial linear low-density polyethylene can be accomplished through the rhodium-catalyzed borylation of alkanes and subsequent oxidation without significantly altering the molecular weight of the starting polymer. Moreover, the hydroxy groups can be further modified to generate polymers with formyl and amino groups at the termini of the side chains.

oxidized dye to a hole-transporting organic molecule or polymer takes place, where the hole is transported to and collected at the counter electrode.[3] The fundamental advantage of this system over two-component systems[4–7] is that the electron- and hole-transporting components are spatially separated by the dye molecules, which hugely suppresses charge recombination and allows efficient charge collection through microns-thick material.[8] Furthermore, the efficiency of such devices has been found to dramatically improve with the addition of various additives to the hole-transporting material, with the most efficient devices incorporating specific quantities of ionic salts and electrochemical dopants. This "cocktail" of additives has been fine-tuned and optimized for the current system.[2] However, the precise function of each component is, as yet, not fully understood.[9] Herein, we report a new charge-transfer sensitizer with an ion-complexing moiety formed by oxyethylene side groups. Lithium coordination to the backbone of this dye induces a striking improvement in the photovoltage and performance, with voltages of nearly 900 mV regularly achieved and efficiencies improved from 3.2 to 3.8% (under 100 mW cm^{-2} simulated air mass (AM) 1.5 solar conditions) for the lithium-coordinating sensitizer as compared with a noncoordinating analogue. A staggering record efficiency of 4.6% is achieved under 10 mW cm^{-2} simulated AM 1.5 illumination. Our supramolecular approach to the self-assembly of functional components[10, 11] opens new avenues to control charge separation and recombination at the interface, and gives us a more comprehensive understanding of the mechanisms occurring within this class of solar cells.

The chemical structures of the dyes used for sensitization are shown in Scheme 1. Z907 is an amphiphilic ruthenium

Ion-Coordinating Sensitizer in Solid-State Hybrid Solar Cells**

Henry J. Snaith,* Shaik M. Zakeeruddin,
Lukas Schmidt-Mende, Cédric Klein, and
Michael Grätzel

The solid-state dye-sensitized solar cell is one of the most promising organic-based device concepts which demonstrates solar-power conversion efficiencies in excess of 4%.[1,2] The basic strategy of this hybrid system is that light is absorbed in a dye to form an excited electronic state, termed an exciton. Electron transfer takes place from the excited dye molecule to an inorganic semiconductor, where it is transported to and collected at an electrode. Subsequent hole transfer from the

Scheme 1. Structures of the sensitizing dyes used: a) K51 (tetraethylene oxide side chains) and b) Z907 (nonyl side chains).

complex with one proton and one sodium ion,[12] and K51 is an analogue of Z907, in which the hydrophobic alkyl chains have been replaced with ion-coordinating triethyleneglycol methyl ether (TEG) groups. A brief description of the synthetic procedure for this novel sensitizer (K51) is provided in the Supporting Information and will be published in detail elsewhere.[13] The light absorption of the K51 and Z907 dyes is almost identical, both in solution and when adsorbed on a TiO$_2$ nanoporous film.

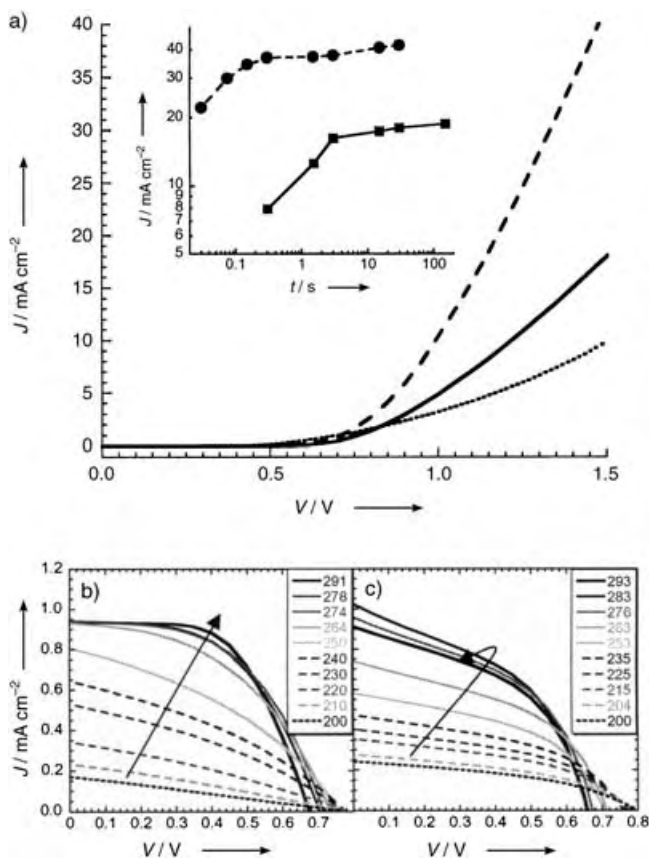
Figure 1 a shows the current density–voltage (JV) curves in the dark for dye-sensitized solar cells. The dark current for the K51 device at 1.5 V bias is over ten-times larger in the presence of Li ions than in their absence. There is no color


Figure 1. a) Current density (J) measured in the dark versus applied bias (V) for a dye-sensitized solar cell with K51 dye in the absence of Li triflate (••••, ×10), K51 dye with Li triflate (——), and Z907 dye with Li triflate (-----). Inset: current density at 1.5-V applied bias versus scan time from 0 to 1.5 V with the Z907 device (-----, ●) and the K51 device (——, ■). b,c) Current density–voltage characteristics for K51 device (b) and Z907 device (c) under illumination from a halogen lamp (20 mWcm^{-2}) and at 200–300 K (see legends; the arrows indicate increasing temperatures). These measurements were performed in the Laboratory of Optoelectronics of Molecular Materials (LOMM), EPFL.

change of the hole-transporting material 2,2′,7,7′-tetrakis(*N*,*N*-di-*p*-methoxyphenylamine)-9,9′-spirobifluorene (Spiro) upon the addition of Li salt, which suggests that no electronic doping takes place. The increased current density could be a consequence of the formation of a dipole at the Au electrode.[14] However, this would require the bulky triflate anion (negatively charged) to migrate to the gold electrode to improve the hole-injection characteristics, which is unlikely. A more reasonable explanation is that the ions in the "electrolyte" can redistribute to balance the space charge, and higher current densities are sustainable as hole transport will no longer be under the "space-charge-limited" regime.[15] In effect, the addition of the ionic salt dramatically improves the hole mobility in the organic material. Significantly, the

current density through the Li-doped Z907 device is approximately three times that of the Li-doped K51 device, although the initial ionic concentration in both devices is identical. The current density through Li-doped devices varies with the scan rate, with slower scans giving higher currents (this is constant for undoped devices). Notably, this is much more pronounced for the K51 device. The inset to Figure 1 a shows the current density at 1.5 V versus scan time (from 0 to 1.5 V) for the K51 and Z907 Li-doped devices. The current for the Z907 device reaches a plateau after approximately 300 ms, whereas the K51 device does not plateau until after 3 s. The increase in current density with time is likely to be a result of the finite time taken for the ions to redistribute and balance the space charge within the device.[15] The only difference between the Z907 and K51 devices is the ion-coordinating side chains, so this is direct evidence that a large proportion of the ions are immobilized on the surface of the K51 dye molecules.

Figure 1 b and c show the JV characteristics of the K51 and Z907 devices over a range of temperatures under illumination. The short-circuit current increases with temperature up to around 280 K. The increase in short-circuit current over the lower temperature region is consistent with the temperature dependence expected for the hole mobility in an organic hole transporter,[16] with the holes being "frozen" in the device at low temperatures. The fill factor increases with temperature over the entire range studied, but increases most rapidly from around 250 K. An increase in fill factor is consistent with reduced series resistance within the cell;[17] this is likely to be because the ions become more mobile at these higher temperatures.[18] This finding demonstrates that the function of the mobile ions in the hole-transporter material is to facilitate a low series resistance, fast charge extraction, and thus a large fill factor.

A striking difference between the two devices is that the short-circuit current remains high over the higher range of temperatures for the K51 device, whereas it drops for the Z907 device with a peak at approximately 280 K. There are two competing temperature-dependent factors which influence the short-circuit current. First, an increased charge mobility will increase the short-circuit current by increasing the charge-diffusion length[19] and increase the fill factor through reducing the series resistance.[17] Second, the charge-recombination rate increases with temperature.[20] An increased charge-recombination rate will reduce the short-circuit current through reducing the charge-diffusion length[19] and reduce the open-circuit voltage as it reduces the chemical potential gradient which is sustainable within the device.[21,22] For the Z907 device, it appears that the increasing recombination rate becomes dominant at higher temperatures, which results in a drop in short-circuit current at these temperatures. However, for the K51 device the increased mobility appears to be dominant over the temperature range studied. The tethering of the Li ions to the interface is likely to "coulombically" retard recombination by screening the electrons in the TiO$_2$ from the holes in the Spiro, thus increasing the activation energy for recombination and retaining a high photocurrent at higher temperatures. This effect appears to be a dominant factor over the increased charge mobility in the Spiro, as the Z907 device, which incorporates the free Li ions,

exhibits much higher charge-transport characteristics. This finding has implications in the use of dual-conductive (ion and hole) materials in these solar cells, as the immobilization of ions at the surface seems beneficial.[23,24]

Figure 2a shows the transient decay of the open-circuit voltage for various devices. An estimate of the overall charge

	lifetime/ms
K51	0.45
Z907	0.32
K51/no Li	0.03
no dye/Li	0.01
Figure 2. a) Transient open-circuit voltage measurements (normalized values) of a Li-doped K51 device (●, ——), a Li-doped Z907 device (□, -----), a K51 device in the absence of both Li and tbp (△, •••••), and a device with only Sb-doped Spiro (no dye, Li, or tbp) (■, −•−•). The inserted table gives the charge lifetimes (τ_{rec}) calculated from the V_{oc} decay measurements by fitting the decays as $\exp(-t/\tau_{rec})$. b) Open-circuit voltage versus temperature for the same devices as in (a); the symbols are the data points and the lines are linear fits to the data. tbp = 4-*tert*-butylpyridine, rec = recombination, oc = open circuit.

lifetime in these devices can be obtained by simply fitting a monoexponential decay to the curves (see table inset to Figure 2a). Charge lifetimes derived in this manner have been shown to give very similar values to those obtained by intensity-modulated photovoltage spectroscopy.[25,26] As we might expect, the presence of the dye at the interface increases the charge lifetime (from 10 to 30 μs) as compared to that of a pristine TiO$_2$ film coated with Spiro. Addition of free Li ions (Z907 device) dramatically increases the charge lifetime tenfold to 320 μs; this effect has been observed by Kruger et al.[9] with transient absorption spectroscopy. Furthermore, the charge lifetime is increased to 430 μs by tethering the ions to the dye backbone (K51 device). This result is consistent with the above analysis of the *JV* data.

Figure 2b shows the open-circuit voltage as a function of temperature for the same devices. The open-circuit voltage

drops with increasing temperature over the range studied for all devices. Koster et al. have derived the relationship between open-circuit voltage (V_{oc}) and absolute temperature (*T*) for organic PPV:PCBM (PPV = poly(*p*-phenyleneviny-lene); PCBM = [6,6]-phenyl-C$_{61}$-butyric acid methyl ester) bulk heterojunction photovoltaic devices.[27] We believe the solid-state dye-sensitized solar cell to be a very similar system, with the only important difference being that there is a dye molecule at the interface between the two components where all excitons are formed. Koster et al. studied the metal–insulator–metal picture where the material composite is considered to be one intrinsic semiconductor, with the valance band corresponding to the highest occupied molecular orbital (HOMO) of the hole-transporting polymer, and the conduction band corresponding to the lowest unoccupied molecular orbital (LUMO) of the electron-withdrawing component (PCBM), with a corresponding energy gap (E_{gap}). The relationship is shown in [Eq (1)] where γ is the

$$V_{oc} = \frac{E_{gap}}{q} - \frac{kT}{q}\ln\left(\frac{(1-P)\gamma N_c^2}{PG}\right) \qquad (1)$$

Langevin recombination constant, N_c is the effective density of states, *G* is the generation rate of bound electron–hole pairs, *P* is the dissociation probability of bound electron–hole pairs, and *k* is Boltzmann's constant. For the system studied herein, we consider *G* to be the rate of generation of electrons in the TiO$_2$ by electron transfer from the photoexcited dye molecule with the hole remaining on the dye, and *P* to be the probability of hole transfer from the dye molecule to the Spiro.

The linear fit to the data in Figure 2b is the relationship we would expect from Equation (1), with the *y* axis intercept at zero temperature giving E_{gap}. It is clear that if the active layer in the solid-state dye-sensitized solar cell can be considered as a single semiconductor material, the exact nature of the interface between the components is critical in determining the electronic structure of such a material. For a TiO$_2$ and Spiro composite E_{gap} should be approximately 0.6 eV.[1,28] This value is close to that obtained for the device with no dye molecule (0.56 eV), which demonstrates that Equation (1) correctly describes the temperature dependence of the open-circuit voltage for this system. However, the derived value of E_{gap} rises to 1.0 eV when the TiO$_2$ is sensitized with dye molecules, and further to 1.1 eV when Li is added to the Z907 device, and to 1.2 eV with surface-tethered Li ions in the K51 device.

To understand this trend we must consider what the definition of an "energy gap" is in this nanocomposite material. There is no direct transition for an electron in the conduction band of TiO$_2$ to the HOMO level of Spiro, but there is a spatial and energetic barrier in the form of the dye molecule. For this material we should consider the energy gap to be the energy required to move an electron from the HOMO of the Spiro to the conduction band of TiO$_2$, thus overcoming the barrier presented by the dye molecule. If this is so, the potential barrier is clearly susceptible to changes in local conditions, with the addition of Li and, more importantly, the coordination of Li ions to the dye molecule

Communications

increasing the barrier height. This results in a widening of the quasi energy gap, with the most important implication being that the fundamental limit of the open-circuit voltage ($qV_{oc,max} = E_{LUMO}$(electron transporter) $- E_{HOMO}$(hole transporter)) is no longer true, as V_{oc} has an additional contribution (or at least the energy levels can be further offset) because of the exact nature of the interface. This further "energy-level offset" is likely to be influenced by the dipole moment which will be present at the interface; the ion-coordinating dye molecule will act as a dipole at the surface, and cause a downward shift in the vacuum level of the Spiro with respect to that of the TiO$_2$.[29–31] This shift will force the HOMO level of the Spiro further from the conduction band of the TiO$_2$, thereby increasing the quasi energy gap and thus the open-circuit voltage. The introduction of a surface dipole in "flat-junction" TiO$_2$ solar cells has previously been shown to increase the open-circuit voltage in such devices.[31]

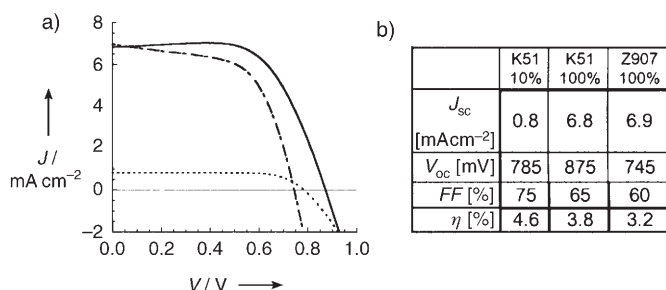
Figure 3 shows the current density–voltage characteristics for the devices sensitized with the K51 and Z907 dyes, measured under simulated AM 1.5 sunlight at 100 mW cm^{-2}.


Figure 3. a) Current density–voltage characteristics under simulated AM 1.5 solar conditions (100 mW cm^{-2}) for a full device containing K51 sensitizing dye (——) and Z907 sensitizing dye (–•–•). Also shown is the K51 device illuminated by 10 mW cm^{-2} simulated sunlight. b) The standard device performance parameters calculated from the JV data.

	K51 10%	K51 100%	Z907 100%
J_{sc} [mA cm^{-2}]	0.8	6.8	6.9
V_{oc} [mV]	785	875	745
FF [%]	75	65	60
η [%]	4.6	3.8	3.2

The current densities are similar for the two devices, but both the fill factor and open-circuit voltage are improved for the device sensitized with the K51 dye, which leads to an improved efficiency of 3.8% as opposed to 3.2% for the Z907 dye. Furthermore, at 10 mW cm^{-2} the efficiency of the K51 device is as high as 4.6%, which demonstrates the potential of this system.

In summary, the presence of mobile ions in the hole-transporting material is important as it enables hole transport to take place beyond the space-charge-limited current regime, dramatically improving the material characteristics. Control of the nature of the interface between the TiO$_2$ and the Spiro, by coordination of Li ions to the dye backbone, tailors the electronic structure of the composite system to be more favorable for photovoltaic operation. Our findings open new avenues to control charge separation and recombination at the interface of inexpensive bulk-junction solar cells, and this work will pave the way for a whole new class of multifunctional sensitizer molecules.

Experimental Section

The dye-sensitized solar cells were fabricated, and the standard device measurements were performed, by identical methods to those used by Schmidt-Mende et al.[2] The additives and concentrations used in a full device were Li triflate (1×10^{20} cm^{-3} in the solid film), 4-*tert*-butyl pyridine (tbp; 17 μL mL^{-1} in chlorobenzene), and antimony salt as the electrochemical dopant (0.03 M relative to Spiro). These additives were predissolved in the Spiro solution prior to coating of the sensitized TiO$_2$ film. Tbp was used to help dissolve the Li triflate in the Spiro solution. It has been shown to cause considerable changes to the operation of the device;[9] however, here we always used tbp in conjunction with Li triflate and consider it as one additive for the purposes of analysis. Low-temperature current density–voltage measurements were performed under high vacuum in the dark and under illumination from an unfiltered halogen lamp with an optical output of 20 mW cm^{-2}. Transient photovoltage measurements were performed by illuminating the devices with a Nd:YAG laser filtered to give a low intensity (532 nm, 30 Hz, 6-ns pulse width), superimposed upon a large-bias, red-filtered (>630 nm), white-light illumination from a xenon lamp (≈ 500 mW cm^{-2}), by a similar method to that described by of O'Regan and Lenzmann.[32]

phyrin **1**[5] is particularly attractive owing to its unique structure, which allows multimodal coordination of the confused pyrrole to metal ions,[6] and its reactivity. The exposed position of the external nitrogen atom (N2) makes this fragment of molecule susceptible to interactions with metal ions.[7]

4: Ar = *p*-Tol

Metalloporphyrinoids

Synthesis and Characterization of a Cyclic Bis-silver(I) Assembly of Four 2-Aza-21-carbaporphyrinatosilver(III) Subunits**

Piotr J. Chmielewski*

Porphyrins and metalloporphyrins constitute a class of building blocks for the construction of multicomponent 2D and 3D molecular arrays that are being considered as possible biomimetic models, catalysts, or materials for the transport of charge, molecules, and ions. Covalent[1] as well as coordination linkages[2] have been exploited in the design of a variety of discrete porphyrin assemblies. Recently, special attention has been given to systems built up of directly linked porphyrins with strongly interacting aromatic subunits,[3] which represent some of the most promising candidates for potential applications.

Porphyrin analogues[4] exhibit many distinct features that can be exploited in the construction of novel molecular and supramolecular systems. Among them, the N-confused por-

Supporting information for this article is available on the WWW under http://www.angewandte.org or from the author.

Recently, we reported the synthesis of the dimeric N-confused porphyrin **2** (Ar = phenyl, *p*-tolyl (*p*-Tol)),[8] which is a unique isomer that preserves the basic skeleton of a directly β–β-linked bis(porphyrin).[9] The cyclic assemblies **3**, whose synthesis and characterization are presented herein, exemplify a new type of carbaporphyrinoid array that consists of both covalent and coordinating links between the subunits. Owing to the steric factors imposed by *meso*-aryl substituents, the bipyrrolic fragment adopts a cisoid conformation in **2** but deviates strongly from planarity. Such an arrangement determines the coordination mode of this fragment, which, unlike the planar bipyrrole system present in corroles,[10] is preorganized to coordinate two metal ions rather than to form a chelate ring.

Reaction of bis(carbaporphyrinoid) **2** with AgX (X = BF₄⁻ or CF₃SO₃⁻) was carried out at room temperature in THF for 30 minutes. After evaporation of the solvent, the residue was dissolved in CH₂Cl₂, and washed with water to remove the excess of silver(I) ions and the acid liberated upon insertion of the metal. The composition and molecular structure of **3** was established on the basis of ESI-MS, NMR

spectroscopy, and single-crystal X-ray analyses. Owing to the dicationic character of the complex, the dominant peak in the mass spectrum corresponds to the dication ($m/z = 1657$, 100%) with a characteristic half-unit isotopic pattern. The fragmentation peak at $m/z = 1549.5$ (47%) reflects liberation of the dimeric fragment **4**.

The solid-state structure of **3a**-(OTf)$_2$ (OTf = CF$_3$SO$_3^-$) presents an assembly of four 2-aza-21-carbaporphyrinatosilver(III) subunits,[11] which are organized on the perimeter of a ten-membered ring that contains two silver(I) ions (Figure 1). The assembly of the axially chiral[8] dimeric subunits **4** on the bis-silver(I) template may lead to the formation of diastereomers. However, only *S,S* and *R,R* enantiomers are observed in the crystal structure (see Supporting Information). Although both monovalent silver centers are two-coordinate, the N-Ag-N fragments are far from linear, being bent outwards with an angle of 147.0(3)°. This is likely due to the geometric constraints imposed on the ring by the

structure of the bipyrrolic moiety. The relatively short distance between the bridging silver atoms Ag3–Ag3* (3.107(2) Å) suggests that an "argentophilic" interaction[12] stabilizes the assembly. Such interactions have been shown to influence the outcome of several supramolecular assemblies, and their importance has been crystallographically investigated.[13] The distances within the macrocyclic core (Ag1-C21: 1.974(9); Ag1-N22: 2.030(9); Ag1-N23: 2.052(7); Ag1-N24: 2.027(8) Å) are slightly shorter than those observed in monomeric neutral silver(III) complexes of **1**,[11] an O-confused porphyrin derivative,[14] or the so-called "true" carbaporphyrin.[15] The distances between the external nitrogen atoms and the bridging silver ions (Ag3-N2: 2.175(8); Ag3-N26: 2.169(8)) are typical for the monovalent silver complexes.[13g]

As a consequence of the crystal-packing forces, the molecule displays only twofold symmetry in the solid state. In contrast, the effective symmetry of the molecule in solution is fourfold, as inferred from the ^{1}H NMR spectra which reveal only one set of signals (Figure 2 a, b). The spectra support the stereoselectivity of the formation of the assembly, as diastereomers are expected to exhibit different ^{1}H NMR spectra. Owing to the nonplanar character of the system and freezing of rotation of the *meso*-aryl substituents, each proton of the subunit in **3** is represented by a unique signal and can be assigned on the basis of 2D NMR experiments (see Supporting Information). Analysis of the chemical shifts and interprotonic through-space interactions observed in NOESY or ROESY experiments allowed a model to be built that has the same molecular topology as the solid-state structure of **3a** but which displays fourfold symmetry.

A neutral diamagnetic bis-silver(III) complex **4** can be obtained by treating a solution of **3** in chloroform with either an aqueous solution of sodium halogenide or with a solution of tetraalkylammonium bromide in chloroform to remove bridging silver(I) ions.[16] Protonation of **3** with one equivalent of trifluoroacetic acid or the addition of pyridine (500-fold excess) breaks the assembly reversibly. The process can be fully reversed upon addition of water or by evaporation of the solvents. Thus, reconstruction of **3** is possible as long as silver(I) ions are present in the solution.

A slow exchange reaction can be observed upon mixing of the solutions of **3a** and **3b** to result, after 20 h at room temperature, in an equilibrium of starting complexes and a mixed-ligand species **3c** that can be identified by ESI-MS (observed: $m/z = 1602.4$; calcd: $m/z = 1601.7$) and ^{1}H NMR spectroscopy (Figure 2 d). Formation of **3c**, which exhibits twofold symmetry, indicates the lability of the system but also provides additional support for the preservation of the tetrameric structure in solution.

The charge on the external nitrogen atom of the confused pyrroles strongly influences redox properties of the metal ion that is coordinated in the macrocyclic core.[7f,17] Thus, it can be expected that
Figure 1. Molecular structure of the assembly **3 a**. Top: ORTEP view with thermal ellipsoids scaled at the 30% probability level (hydrogen atoms, triflate anions, and solvent molecules are omitted); bottom: wire-frame representation of the structure with all aryl substituents omitted for clarity.
Figure 2. Fragments of the ¹H NMR spectra (CDCl₃, 298 K) of the assemblies a) **3a**, b) **3b**, c) **3a** + **3b** immediately after mixing, and d) **3a** + **3b** 40 h after mixing (some of the new features, attributed to the mixed-ligand species **3c**, are indicated by ■). Signal assignments of the most upfield-shifted *meso*-aryl protons in **3a** and **3b** are presented in (a) and (b), with numbers indicating *meso* positions.

coordination of the Ag^I cation to the external nitrogen atom destabilizes the trivalent silver center in each subunit to allow the reduction of the metal. Such a reduction process has not been observed to date for any of the carbaporphyrinoid silver(III) complexes. In cyclic voltammograms of **3a** and **3b** (CH₂Cl₂ solutions; tetrabutylammonium perchlorate as the supporting electrolyte; glassy carbon as a working electrode; all data are referenced to ferrocene/ferrocenium internal standard), a pair of two-electron couples ($E_{1/2} = -1100$ mV, $\Delta E_{ac} = 40$ mV, $E_{1/2} = -1230$ mV, $\Delta E_{ac} = 46$ mV for **3a**; $E_{1/2} = -1055$ mV, $\Delta E_{ac} = 40$ mV, $E_{1/2} = -1175$ mV, $\Delta E_{ac} = 46$ mV for **3b**) is attributable to a stepwise reduction of silver(III) centers in the strongly interacting covalently linked subunits.[8,18] Each reduction step takes place at the same potential in two nondirectly connected, and thus non-interacting subunits, which is accounted for by the two-electron character of the processes. Two overlapping couples observed for **3a** around −1425 mV and those better-resolved for **3b** ($E_{1/2} = -1330$ mV, $\Delta E_{ac} = 36$ mV, $E_{1/2} = -1440$ mV, $\Delta E_{ac} = 30$ mV) reflect reductions of the ligand. For **4** only ligand reductions represented by two couples at −1470 and −1600 mV are observed.

In conclusion, we have shown the very facile diastereoselective formation of a molecular assembly that consists of four carbaporphyrinoids and which is effectively formed despite steric overcrowding imposed by the substituents in the vicinity of the donor sites. It seems that access to the bridging silver–silver fragment is hindered which may stabilize the cyclic structure. Experiments are underway to explore the application of this novel coordination mode of the nonplanar bipyrrolic moiety in the construction of larger redox-active assemblies that consist of covalently linked N-confused porphyrin derivatives.

Experimental Section

3a-(BF₄)₂: 3,3′-Bis(5,10,15,20-tetrakis(*p*-tolyl)-2-aza-21-carbaporphyrin) (**2a**; 20 mg, 0.015 mmol) was dissolved in THF (20 mL) and stirred with silver tetrafluoroborate (10 mg, 0.115 mmol) for 0.5 h. The solvent was then removed by evaporation, and the solid residue was dissolved in dichloromethane (10 mL). The solution was shaken with three portions of water (10 mL each). After separation of the organic phase, the solution was filtered and then the solvent was removed. The solid residue was dissolved in dichloromethane, and the solution was left to crystallize slowly after the addition of hexane to yield the olive-colored product **3a**-(BF₄)₂ (26 mg, 94%). A similar procedure using AgOTf instead of AgBF₄ or **2b** instead of **2a** yielded **3a**-(OTf)₂ or **3b**-(BF₄)₂, respectively. Spectral data recorded in the solution state were independent of the counteranion present in the complex. See Supporting Information for NMR spectroscopic data for **3a** and **3b**.

3a-(BF₄)₂: UV/Vis (CH₂Cl₂): λ_{max} (logε) = 258 (5.23), 313 (5.00), 378 (5.08), 451 (sh), 472 (5.51), 533 (4.80), 596 (4.67), 636 (sh), 686 nm (4.52); ESI-MS: *m/z* calcd for C₁₉₂H₁₃₆N₁₆Ag₆: 1657.7 ($[M]^{2+}$); found: 1657.4; elemental analysis: calcd (%) for C₁₉₂H₁₃₆N₁₆Ag₆B₂F₈·2-(CH₂Cl₂): C 63.70, H 3.86, N 6.13; found: C 63.40, H 3.56, N 6.12.

3b-(BF₄)₂: UV/Vis (CH₂Cl₂): λ_{max} (logε) = 256 (5.19), 323 (sh), 378 (5.08), 452 (sh), 471 (5.47), 531 (4.75), 594 (4.67), 641 (sh), 691 nm (4.48); ESI-MS: *m/z* calcd for C₁₇₆H₁₀₄N₁₆Ag₆: 1545.7 ($[M]^{2+}$); found: 1545.2; elemental analysis: calcd (%) for C₁₇₆H₁₀₄N₁₆Ag₆B₂F₈·2-(CH₂Cl₂): C 62.27, H 3.17, N 6.53; found: C 62.40, H 3.32, N 6.23.

Crystals of suitable quality for X-ray analysis were obtained by slow diffusion of hexane into a solution of **3a**-(OTf)₂ in toluene. Crystal data for **3a**-(OTf)₂: C₂₃₁.₅H₁₇₂N₁₆Ag₆·2 CF₃SO₃, $M_W = 4099.19$, $T = 100$ K, Cu$_{K\alpha}$ radiation, monoclinic, space group $C2/c$, $a = 24.208(4)$, $b = 34.279(4)$, $c = 24.175(4)$ Å, $\beta = 103.35(3)$, $V = 19519(5)$ Å³, $Z = 4$, $\rho_{calcd} = 1.395$ mg m⁻³, $\lambda = 1.54178$ Å, $\mu = 5.485$ mm⁻¹, $F(000) = 8356$, Oxford Diffraction Xcalibur PX with KM4CCD Sapphire detector, $3.19 \leq \theta \leq 68.00°$, 15171 collected reflections, 8504 independent reflections with $I > 2\sigma(I)$, 1104 parameters, $R1(F) = 0.0827$, $wR2(F^2) = 0.2102$, $S = 1.064$, largest difference peak and hole 1.861 and −1.06 e Å⁻³. All non-hydrogen atoms were refined with anisotropic displacement parameters except for those of the disordered solvents, triflate anion, and one *meso*-tolyl ring. Hydrogen atoms were excluded from the geometry of molecules and refined isotropically. The asymmetric unit contains half of the molecule of **3a**, consisting of two subunits linked by a silver ion, one disordered triflate anion, a half molecule of hexane, and one and a half molecules of toluene displaced into six different sites. CCDC 276104 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

4: Complex **3a** (10 mg, 3 μmol) was dissolved in CH₂Cl₂ (20 mL), and the solution was stirred vigorously for 0.5 h with a 1 M aqueous solution of NaBr (10 mL) until the originally olive-colored solution turned red-brown. The layers were then separated, and the organic phase was washed with two 10-mL portions of water. After drying over a small amount of anhydrous K₂CO₃ and filtration, the volume of the solution was reduced to 10 mL, and hexane (5 mL) was added which caused precipitation of **4** as a brown powder (6.1 mg, 65%). ¹H NMR: see Supporting Information; UV/Vis (CH₂Cl₂): λ_{max} (logε) = 254 (5.20), 285 (sh), 323 (5.02), 384(sh), 412(sh), 450 (sh), 468 (5.50), 533 (4.88), 621 (sh), 661 nm (4.45); ESI-MS: *m/z* calcd for C₉₆H₆₈N₈Ag₂: 1549.4 ($[M+1]^+$); found: 1549.5; elemental analysis: calcd (%) for C₉₆H₆₈N₈Ag₂·CH₂Cl₂·C₆H₁₄: C 71.90, H 4.89, N 6.51; found: C 71.94, H 4.78, N 6.22.

[18] Probably as a result of the labile character of the assembly, an irreversible reduction of "free" silver(I) ion takes place to result in the deposition of metallic silver on the surface of the electrode. The appearance of an oxidation peak at 380 mV follows cathodic scans below −950 mV.

Cover Picture

Linked paramagnetic cage complexes could potentially be used as quantum gates for quantum information processing. The cover picture shows such a supramolecular assembly, which consists of two heterometallic octagons (paramagnetic {Cr_7Ni} cages) linked through a metal dimer. The white arrow represents the light input that switches the interaction between the two halves of the quantum gate. For more details see the Communication by M. Affronte, G. A. Timco, R. E. P. Winpenny et al. on page 6496 ff.

Heterogeneous catalysis
In their Review on page 6456 ff. J. M. Thomas et al. describe heterogeneous catalysts with isolated catalytic centers (single-site catalysts). The main focus is on strategically modified mesoporous and microporous structures.
Molecular Switches
A thermally induced, two-step spin crossover in a cyanide-bridged molecular square is described in the Communication by H. Oshio and co-workers on page 6484 ff. Such molecules are suitable building blocks for multistepped molecular switches.
Host–Guest Systems
The polarizable molecular system consisting of H_2O and CH_3OH in a porous crystal of [$Mn_3(HCOO)_6$] is changed into a nonpolarized one by lowering the temperature, as described by H. Kobayashi et al. in their Communication on page 6508 ff.

Highlights

Not only aesthetically appealing: The motif of the double-stranded helix (see picture) is found in DNA, which is able to store and process "information". It inspires scientists to search for ways to mimic not only its fascinating structure but also to develop helical systems with different functionalities and properties, with which one day, likewise, information storage and processing could be achieved.
The unusual suspects: By using a series of ruthenium clusters of the type [{Ru$_3$O(μ-CH$_3$COO)$_6$(CO)L'}(μ-L){Ru$_3$O(μ-CH$_3$COO)$_6$(CO)L''}] (see picture) it has been possible to identify the existence of charge-transfer isomers and establish them as identifiable chemical entities that exist in dynamic equilibrium.

Reviews
Living in isolation: Single-site heterogeneous catalysts offer a widely applicable strategic principle for the design of new mono- and bifunctional catalysts. They combine the merits of homogeneous and heterogeneous processes and permit the preparation of high activity regio-, shape-, and enantioselective solid catalysts. The picture shows a spatially constrained organometallic, Rh^I-based enantioselective catalyst.

Communications

Spinning out: A cyanide-bridged molecular square (see picture) has been isolated and found to undergo thermally induced, two-step spin crossover. Molecules with more than one spin-crossover site are suitable building blocks for multistepped molecular switches.
Unusual octahedral hexamers built up from triangular, corner-linked cobalt trimers (see figure), form the basis of a novel three-dimensional cobalt isophthalate obtained by a solvothermal route. This structure provides a new example of the concept of scale chemistry, in which an {Na$_6$Co$_6$O$_{26}$} "super octahedron" is connected in a classical ReO$_3$ architecture.

The unique structure of a highly ordered pyrolytic-graphite (HOPG) surface is employed as a template to fabricate large random arrays of metal-nanoband electrodes. This process is achieved through selective blocking of the basal-plane HOPG (A) with a polymer film (B), followed by metal coating (C) and cleavage of the metal layer from the HOPG substrate (D; see picture).

Gates leading from cages: Linked paramagnetic cage complexes could potentially be used as quantum gates for quantum information processing. Experiments demonstrate that it is possible to link octanuclear {Cr$_7$Ni} rings through both organic and metal–organic fragments into supramolecular dimers (see structure; Cr green, Ni light green, Cu orange, F yellow, O red, N blue, C black).
Polymer clay for chemists: High strengths and high fracture energies of polymeric hydrogels have been demonstrated by incorporating a substantial amount of nanodispersed inorganic clay during the in situ free-radical polymerization of *N*-isopropylacrylamide. By varying the amount of clay used, mechanical properties as well as the swelling and transparency of the nanocomposite (NC) could be controlled (see picture; NC20 contains more clay than NC5).
Acid test: Macrocyclic compounds that comprise a 9,10-anthracene subunit linked by a *C*$_2$-symmetric peptidomimetic chain (see formula) are useful as fluorescent probes in a pH range of biomedical interest. Changes in the size of the macrocycle (*n* = 3,4,6,8) produce a shift in the p*K*$_a$ values. Experiments with live mouse macrophage cells show the selective localization of the probe in the acidic organelles (see differential interference contrast image).

Simply lowering the temperature changes a polarizable molecular system, which consists of H_2O and CH_3OH inserted into the porous crystal $[Mn_3(HCOO)_6]$ (see structure; Mn pink, C gray, O red), into a nonpolarizable one. Although a large drop in the dielectric constant was observed around 120 K, reminiscent of a liquid↔solid phase transition of the guest molecules, the anisotropy cannot be explained by a simple liquid model of the guest molecules.
The problem of miniaturizing the mixing process is a barrier to the advance of microfluidic technology. Fluorescence lifetime imaging is a powerful technique for the quantitative mapping of mixing in microfluidic systems, providing information essential to the design and evaluation of next-generation devices. With the use of a pulsed laser (B), mixing in a microfluidic cell (A) can be measured with fluorescence (C); a sample image is shown (right).

Keeping nature under control: The internal structure of helical porous protein mimics self-assembled from hybrid dendritic dipeptides is programmed by the stereochemistry of the dipeptide and regulated allosterically. This is the first example of a synthetic helical porous supramolecular structure that is stable both in solution and in the solid state, and that is created by a sequence of events related to those encountered in nature.
Just add CH_3CN and stir! Four building blocks taken in a multicomponent reaction (MCR, see picture; Tf = trifluoromethanesulfonyl) afford a β-aminoacetal adduct, which can be further diversified by post-condensation reactions. The modular character of this approach, the simplicity of the building blocks used, and the structural diversity attained render this process attractive for combinatorial as well as target- and diversity-oriented synthesis.

Artificial α helices prepared by the replacement of a hydrogen bond between residues *i* and *i*+4 with a carbon–carbon bond can stabilize biologically relevant peptides in helical conformations (**1**, internal constraint shaded in gray). α Helices based on hydrogen-bond surrogates that mimic Bak BH3 (**2**, yellow) can bind their expected protein receptor, Bcl-xL (**2**, green), with high affinity and resist proteolytic degradation.
Au natural: A new class of synthesized biomaterials (saccharide–peptide hybrid copolymers shown) are biodegradable, nontoxic, and nonimmunogenic. The cationic saccharide–peptide hybrid copolymers were also shown to be effective in compacting and transferring plasmid DNA into cells.

An efficient and highly diastereoselective intramolecular Diels–Alder reaction is the basis of a concise asymmetric synthesis of the potent antibacterial natural product abyssomicin C (see formula). The complexity of the target structure was reduced to three fragments and required two carbonyl addition reactions to achieve key bond formations.
Abyssomicin C
Illuminating quadruple bonds: The polymeric materials [M$_2$(O$_2$CC$_6$H$_2$-2,4,6-Me$_3$)$_2$(O$_2$C-(Thp)$_n$-CO$_2$)]$_n$ (M = Mo or W (green); Thp = thiophene (S atoms yellow); DMSO molecules also shown) incorporate metal–metal quadruple bonds and form thin films from THF solutions. These films show electroluminescence when deposited on an indium–tin oxide glass-coated plate followed by vapor deposition of aluminum or calcium.

Contents

Cutting Corners: Elaborate triangular arrays of Mn ions are stabilized by the tripodal ligand 1,1,1-tris(hydroxymethyl)-ethane. The self-assembled {Mn$_{32}$} truncated cube (see picture) is further stabilized by end-on-bridging azide ligands and acetate groups. Such stabilization could prove to be useful in the preparation of single-molecule magnets.
Pocket the difference: Highly enantioselective allylic alkylation of simple acyclic ketones is carried out by using a Pd catalyst with a "chiral pocket" ligand **1** (see scheme). The addition of a Lewis acid such as AgBr and the selection of one enolate form over another dramatically affect the enantioselectivity of the reaction.
Surprising rearrangements in a rigid system: A cyclopropyl ring is formed unexpectedly when a trienone substrate is subjected to the Nazarov cyclization (see scheme). The participation of the unconjugated alkene unit present in the substrate might be a consequence of the complete torquoselectivity of the initial electrocyclic closure. A subsequent rearrangement by a homo-1,5-hydrogen shift occurs cleanly to give the final product.

Giving in to templation: Lithium-containing nanostructured transition metal oxides have been prepared by a templating route with preservation of the nanostructure. Both one-dimensional nanowire and three-dimensional mesoporous samples of low-temperature (LT)-LiCoO$_2$ with highly crystalline structures (see image) have been obtained, and these perform better than "normal" LT-LiCoO$_2$ as intercalation electrodes in lithium batteries.
Delocalization in heterocycles: Reaction of hexaphenylstannole with excess lithium gives the dilithium stannole as deep-red crystals. The aromaticity of the dianion was examined by NMR spectroscopy, X-ray analysis (see picture), and calculations. The dianion has considerable aromatic character and is reported to be the first tin-containing carbocyclic aromatic compound.
Thrifty catalysis: Tungsten carbide microspheres with high surface area and CO chemisorption capacity were prepared by heating mixtures of a resorcinol–formaldehyde polymer and ammonium metatungstate. Platinum supported on these microspheres (see electron micrograph) shows higher activity than the commercial catalyst with 20% Pt–Ru (1:1) on C for the electrooxidation of methanol.
Take the rough with the smooth: Conducting silica microspheres with different morphologies—rough, dotted, and smooth (see picture)—have been rapidly synthesized in an ionic liquid under various experimental conditions. The conducting property of the silica particles is attributed to the presence of entrapped molecules of ionic liquid and water.
A phenalenyl-based Kekulé hydrocarbon with singlet biradical character has been isolated and characterized. Strong intra- and intermolecular interactions between the unpaired electrons lead to short π–π contacts and formation of one-dimensional chains (see picture). Thus, wide valence and conduction bands are established, and the compound shows semiconductive behavior.

Contents

Body doubles: An isoelectronic borane analogue of a dinuclear ruthenium–pentalene (C$_8$H$_6$) π complex (see picture) has been prepared and isolated. It is found to be an intermediate in the growth of the borane fragment of a diruthenaborane framework.
Mother-of-pearl has a three-level nanoscopic-to-macroscopic hierarchical architecture, which provides storage for organic molecules at the nanoscale. A material that mimics the hierarchical architecture and nanostorage properties of nacre emerges from the simple crystallization of potassium sulfate and poly(acrylic acid) (see picture).
A facile access to optically active 2-indolyl-1-nitro derivatives, which can be easily transformed into highly valuable compounds such as tryptamines and 1,2,3,4-tetrahydro-β-carbolines, is provided by the first catalytic enantioselective Friedel–Crafts alkylation of indoles with nitroalkenes (see scheme; e.g. R^1 = R^2 = H, R^3 = Ph).
Remarkably stable 2-phosphabicyclo-[1.1.0]butanes (see picture; O red, P violet, W turquoise) were synthesized from the complexed phosphinidene Ph–P=W(CO)$_5$ and cyclopropenes. These compounds undergo valence isomerization to form 3-phosphacyclobutenes via 1-phosphabutadienes at elevated temperatures.

Finding Adiabatically Bound Anions of
Guanine through a Combinatorial
Computational Approach

Enamine–imine transformations of guanine lead to tautomers that support valence anionic states which are adiabatically bound by as much as 8 kcal mol^{-1} (see scheme). The valence anions might be formed by dissociative electron attachment followed by attachment of a hydrogen atom to a carbon atom. Such tautomers might affect the structure and properties of DNA and RNA exposed to low-energy electrons.

Chemical Primer Extension: Efficiently
Determining Single Nucleotides in DNA

Rapid replication: Non-enzymatic primer extension has previously been studied in the context of prebiotic chemistry, but not for practical applications. Reactions with primers featuring a 3′-amino-2′,3′-dideoxynucleotide can be rapid and selective for all four templating nucleobases (see scheme). On a chip with immobilized capture strands, 500 fmol of template suffice for single-nucleotide determinations within 2.7 h.

Corrigendum

Some sentences in the meeting review of ADHOC 2005 in Cologne were incorrect at the time of press.

Page 6102, column 1, line 11 should read: To gain better insights, model systems with well-defined active sites are being developed; on the other hand problems are approached with the aid of kinetic measurements, sophisticated isotope-labeling experiments, molecular probes, and especially computational chemistry which allows the discussion of structure–activity relationships and can either support or reject proposed mechanisms.

Page 6102, column 3, line 6 should read: On the other hand, A. Griesbeck (University of Cologne, Germany) described how $^1O_2$ with the aid of tetraarylporphyrin-loaded polystyrene can be used for ene reactions and [4+2] cycloadditions, and how it can even be "made chiral" through organocatalysts.

Page 6103, column 2, line 7 should read: these effect the oxidation of bromide to bromonium ions, which in turn can be reacted under nonacidic conditions with olefins and aromatic compounds.

Page 6103, column 3, line 5 should read: The latter, however, are apparently stabilized by POM ligands; their use recently afforded the synthesis of a Pt=O complex as described by C. L. Hill (Emory University, Atlanta, USA), and now he reported the isolation and characterization of the first Pd=O complex, $K_9Na_4[(O=Pd^{IV}\text{-}OH)WO(OH_2)L_2]$ (L = $[PW_9O_{34}]^{9-}$).

Page 6103, column 3, line 21 should read: Altogether, there is still great interest in the oxidation of methane, the simplest yet most resistant C1 hydrocarbon source.

Page 6104, column 1, line 27 should read: … R. Hage (Unilever, The Netherlands)…

Page 6104, column 1, line 29 should read: The lecture given by G. Reinhardt (Clariant, Germany) made it clear that there is not, and yet cannot be, a panacea for the bleaching industry.

Page 6104, column 3, line 22 should read: The mechanistic understanding was broadened, refined, and even renewed, and many novel systems have been developed.

Page 6104, column 3, last sentence: The pronounced relation to application was underscored by the fact that this year's meeting was, for the first time, organized jointly by both the industrial and academic spheres as well as through the strong participation and generous support of industry (especially BASF).

The Editorial Office apologizes for the oversight.

Meeting Reviews
A Feast of Supramolecular Chemistry[**]

Daniel-Petru Funeriu*

Just before the distinctly French August holidays, the meeting "Advances in Supramolecular Chemistry" was held in Strasbourg, France, to celebrate the 40th anniversary of Jean-Marie Lehn's laboratory. Eight plenary lectures, rich poster sessions, and a string of cultural and social events made attendance at this meeting memorable and inspiring for some 200 participants. With the contribution of numerous sponsors, the organizing team managed by Nicolas Giuseppone and expertly complemented by Jacline Claudon and Jean-Louis Schmitt succeeded in attracting an exceptional panel of speakers to the esthetic and functional surroundings of the newly built ISIS institute.

On the first day of the meeting, the participants gathered on the top level of the Museum of Modern Art—an inspired choice—where they had the pleasure to meet former colleagues and the invited speakers while enjoying a delightful view of Strasbourg.

The following day, Jean-Marie Lehn opened the scientific session by reviewing the results obtained in his laboratory over the last 40 years (which represents some 600 years worth of research in total)! The first results from the group of the then 25-year-old Lehn were also among the first concerning ab initio studies on organic molecules, with the calculation of energetic barriers for nitrogen and phosphorus inversions and the study of stereoelectronic effects. This topic was followed by studies on ^{14}N nuclear quadrupole relaxation and its use in molecular dynamics. Notably, some of these pioneering results, such as the finding of a second-order transition of quinolein in the liquid phase at 15°C, were only confirmed and published some 20 years later.

Figure 1. Jean-Marie Lehn and his long-term administrative assistant (background).

In 1967, Lehn's earlier interests in *"how a chemist might contribute to the study of […] highest biological functions"* led to the development of the chemistry of cryptands and cryptates in the Strasbourg laboratory. The physical chemistry background of the laboratory was pivotal in the study of the properties of these compounds and, probably, in the genesis of concepts that evolved from these results. The idea that information stored into a molecule can be expressed through an interactional algorithm which is supramolecular in nature flowered into the notion that chemistry can (and should) be seen not only as the science of energy and matter but also as information science. On the basis of Emil Fischer's lock-and-key model, the construction of anion receptors, receptors with multiple binding sites, as well as receptors of organic molecules with transport and catalytic properties substantiated the ensuing, quite natural, emergence of the founding concepts of supramolecular chemistry. The early results in metal-ion-directed self-assembly further anchored this daring conceptualization, which it was at the time, and opened a field of supramolecular chemistry, among which helicates, cages, grids, and higher order assemblies represent many landmarks. Some devices constructed along these principles have had an important practical impact, such as the europium cryptates that are used in screening technologies. The inaugural lecture concluded with a discussion of an area of research that first started in 1994 and is now the main focus of the laboratory: the further exploration of constitutionally dynamic chemical space. The earliest examples from Lehn's laboratory in the field of dynamic combinatorial chemistry, in which the key to Fischer's lock was now self-generated from a multitude of possibilities under the influence of the lock itself, have developed into the field of constitutional dynamic chemistry (CDC), in which reversible bonds (covalent and noncovalent) are used to generate a constitutional diversity that responds in an adaptive process to the pressure of internal or external factors.

On the occasion of such an anniversary, one is usually tempted to look with admiration and sometimes nostalgia to achievements of the past rather than to those yet to emerge in the coming years. In that respect, Lehn's inaugural talk is certainly better described as a scientific appetizer than the cherry on the cake!

In a typically inciting presentation, Helmut Ringsdorf (Mainz) discussed the role of scientists as exchange vectors between science and society, as well as the responsibilities, challenges, and opportunities that they should address in our world of rapid change. The meeting in Strasbourg on supramolecular chemistry, which has crossed the borders

of physics and biology to become supramolecular science, was an ideal setting to discuss the theme of crossing borders between science and society. It was, therefore, only natural in the context of such a meeting to raise the question of *"why is not the responsibility that we, as scientists, feel towards the scientific truth and fairness, transferred to 'the other side', that is, society's evolution?"* Poignant examples of the past, largely illustrating the lack of attitude of German scientists during the emergence of the third Reich, and worrying signs of the present could be considered the data on which Ringsdorf built the case for increased involvement of scientists in the future of society, such as to prevent a *"socio-economic brutalization of Europe and the world in the 21st century"*. In science, Ringsdorf advocated the need for young researchers to exit the gravity field of their mentors (or as he put it, *"to dig their own rivers rather than continuously fishing in their mentor's"*) and take a more courageous approach towards interdisciplinarity. A difficult but also rewarding path, one may add.

Figure 2. Helmut Ringsdorf and Jean-Pierre Sauvage.

Next, David Leigh (Edinburgh) took the spotlight with a presentation of his laboratory's work on rotaxanes and catenanes. Since the first controlled synthesis of these assemblies assisted by metal-ion complexation, templation by ion-pairing and hydrogen-bonding interactions have expanded the repertoire of interlocked molecules so much so that time is ripe to address whether there is more to the field of interlocked molecules than their exotic structure. Leigh

demonstrated how his group has succeeded in relating the unusual molecular-level mechanical features of catenanes and rotaxanes to the emergence of function, particularly the control of directional molecular motion induced by various stimuli. The generally used principle that Leigh's group has brought to the level of art involves the construction of a template unit (a strand in the case of rotaxanes, or macrocycles in the case of catenanes) that contains "stations" with orthogonally modulable affinities for a threaded macrocycle. Then, starting from an initial state in which the threaded macrocycle is bound to the first station, an input signal (such as light or a change of solvent) modifies the relative affinities of the first and second stations which results in a net movement of the threaded macrocycle. By using this principle, his group has succeeded, for example, in moving macroscopic objects against gravity on surfaces.

Henri Kagan (Paris) reviewed the progress in the field of asymmetric amplification, illustrated with recent examples from his laboratory. Kagan disclosed the first example (predicted by the kinetic treatment of the reaction between two enantioimpure reagents by Ugi in 1977) of a kinetic resolution in which a racemic reagent enhances the enantiomeric excess of a partially resolved substrate. By reacting one equivalent of an amine with 67% *ee* with 0.6 equivalents of a racemic acetylation reagent, Kagan's group obtained 0.4 equivalents of the initial amine with 95% *ee* together with 0.6 equivalents of the acetylated compound with 50% *ee*. Kagan concluded a well-guided, in-depth journey into the labyrinths of asymmetric amplification with examples of recent work from his laboratory in combining distinct asymmetric amplification strategies within a single process.

The third day of the meeting was devoted to a visit of the city of Selestat and its humanist library (established in 1452), possibly the most representative humanist library to be preserved intact during the Renaissance. Among the collection of rare books is one of the few

copies of the *"Cosmographiae Introductio"*, produced in nearby Saint-Die, which for the first time coined the term "America". This excursion into universal culture was complemented by a tasty incursion into the local culture: a visit and dinner in one of Alsace's most famous vineyards. The wine-tasting session of the dinner was an enriching experience both for the participants and the wine-producer alike.

In the speech on the morning after the night before, Samuel Stupp (Evanston) presented spectacular examples of macromolecular self-assembled systems, in which an exquisite level of control can be achieved in the micron range by taking advantage of classical molecular recognition codes as well as more subtle ones, such as entropy-limited finite crystallization and steric-crowding-imposed torque. Particularly striking by its implications in medicine was the controlled formation of self-assembled bioactive nanofibers from peptide amphiphiles. The peptides, and thus the external surface of the resulting self-assembled nanofibers, can be engineered to display bioactive epitopes (such as the neurite-guiding epitope IKVAV). Injection of a solution of the IKVAV peptide amphiphile into mice at the site of a spinal-cord injury (where the axons typically cannot penetrate due to reasons of mechanical and chemical signaling) results in spontaneous nanofiber formation. By signaling through the conveniently exposed epitopes, the nanofibers lure the axons into (and through) the site of the injury, consequently re-establishing neuronal contacts. This improves the prognosis in mice that have suffered severe spinal-cord injury.

Javier de Mendoza (Tarragona) drew parallels between art and structural chemistry in describing the advances from his laboratory. Prominent among those are the recent further developments of guanidinium-based receptors for oxo-anion recognition, protein binding, as well as transport into cells. In particular, the binding of chiral bicyclic guanidinium oligomers to p53 protein may be especially important in the future. Other recent developments that Mendoza reported at this meeting were self-assembled rosettes in which ureido-pyrimidinones were used

as multiple-hydrogen-bonding connectors.

Are there unused strings on a supramolecular chemist's violin? Judging by the presentation given by François Diederich (Zürich) about the structural features of orthogonal multipolar interactions and their importance in recognition events, it certainly appears so. Indeed, these interactions (such as C−X···C=O (X = F, Cl, Br, I, OH), C=O···C=O, and CN···CO) appear to have been somehow overlooked and less exploited in the design of molecular interacting partners than hydrogen bonds and ion–ion, ion–dipole, and hydrophobic interactions. Diederich's group, in collaboration with scientists at Roche, undertook a statistical approach and compiled a detailed repertoire of such interactions found through data-mining of crystallographic databases. The results revealed numerous cases of C−X···CO contacts with X···C distances smaller than the sum of their C + X van der Waals radii and C−X···C=O angles close to 90°. Can we predict these "contextual interactions"? Can we harness their proposed potential in molecular design? The answers to these important questions are likely to rely on their difficult but important quantification, for example, as performed by Diederich et al. for the C−F-(CF$_3$)···CO(amide) interaction.

David Reinhoudt (Twente) presented his group's latest results, which make imaginative use of the supramolecular chemistry of cyclodextrins, towards the construction of molecular printboards. By further expanding the knowledge gained in this endeavour, in an approach that combines layer-by-layer assembly with nanoimprint lithography, nanometric islands of Au could be efficiently patterned onto a flat surface. In this approach, Au is sublimed by laser deposition onto a poly(dimethylsiloxane) (PDMS) stamp and a monolayer of thioether-functionalized cyclodextrins is then formed on the Au surface. The resulting Au–cyclodextrin stamp is applied onto a flat surface functionalized with a ferrocene dendrimer. Through the multivalent cyclodextrin–ferrocene dendrimer interactions, the Au layer sandwiched between the PDMS and the cyclodextrin is transferred to the flat surface. Thus, the surface now exposes the Au replica of the stamp, and sandwiched between the surface and the Au lies a monolayer of ferrocene molecules. High-density field-effect transistors can now be fabricated and characterized by using the Au islands as electrical contacts and through the electrical properties of the ferrocenes.

Over the years, the concepts of supramolecular chemistry have been mainly used to build progressively more complex structures. The molecular toolbox that is now available makes it tempting as well as increasingly facile to continue this trend. However, and very importantly so, one common theme of the speakers in the Strasbourg meeting was the emergence of function through structure engineering, both in the biological and the physical sciences. The fact is that function is no longer at the horizon of supramolecular chemistry but has become (at least in the hands of pioneers) it's daily reality. As Reinhoudt stated: *"We are reaching in supramolecular chemistry a phase where structure is not enough: We have to show that we can obtain, by self-assembly, a function as well."* Indeed, most of the speakers did exactly this and very convincingly so, one should add. During this meeting, the question that friends and foes alike have asked — *"What can we do with supramolecular chemistry?"* — received a comprehensive and clear answer, prefiguring a function-focused trend in supramolecular sciences.

With such an event, one could not talk about the science without talking about the people that made it happen. By perfectly illustrating the history and philosophy of the laboratory, and hinting to one of its main sources of success at both scientific and human level, Lehn's concluding remarks about science, art, as well as his former collaborators reinforced the global impression that science and the group, more than the man himself, were the celebrated ones.

Highlights

Artificial Molecular Double-Stranded Helices

*Markus Albrecht**

*H*elicity is a topological motif that is highly attractive from an aesthetic point of view. It can be observed in huge objects like the spiral arms of galaxies and it plays an important role in the world of "string theory".[1] Helical structures, such as those found in the plant kingdom, have inspired architects and artists. For a chemist, helicity is important owing to the wide appearance of helical structures in, for example, quartz,[2] proteins,[3] collagens, and many more natural or artificial fiber-type derivatives.[4]

Since the discovery of the double-stranded helical structure of DNA by Watson and Crick,[5] chemists have been searching for simple linear molecules that are able to form artificial double helices through noncovalent interactions, such as π-stacking, electrostatic interactions, hydrogen bonding, or metal coordination.[6] In naturally occurring DNA the stability of the double helix is attributed to hydrogen bonding between complementary oligonucleotide strands. As an additional stabilizing interaction, the aromatic base pairs display π–π interactions, which are optimized, if the double-strand adopts a helical twist[7] (Figure 1[8]).

In artificial analogues of DNA, the hydrogen bonding interaction between the two strands can be substituted by metal coordination. Shionoya et al. demonstrated this impressively by preparing a heptanucleotide strand with the GXXXXXC sequence (X = hydroxy-
Figure 1. Double-helical DNA (left: C: gray; H: white; N: blue; P: orange; O: red) and a CPK model of the artificial pentanuclear metalla-DNA synthesized by Shionoya et al. (right: Cu: green).[8]

pyridone). Upon addition of copper(II) ions, a double-stranded DNA-type structure is formed, in which the two strands are connected by five copper(II) ions, each possessing a square-planar coordination geometry (Figure 1, right).[9] Metal coordination is frequently used to prepare artificial double helices. There are numerous reports on coordination polymers that exhibit double-helical motifs in the crystal.[10] A special class of well-defined molecular double-stranded helical metal complexes was introduced in 1987 by J.-M. Lehn and was termed *double-stranded helicates*. In these complexes two linear oligodonor ligands wrap around two or more metal centers and thus form a double helix (Scheme 1).[11]

In the first paper on helicates, Lehn and co-workers point out that helicates represent an "*inorganic double helix*, reminiscent of the double-helical structure of nucleic acid".[11] Although on first sight this seems to be a provocative statement, there is some analogy between helicates and DNA with regard to the cooperative self-assembly of the double helix, the noncovalent connection by cations (protons of DNA versus metal cations), and π–π interactions as additional stabilizing effects. If nothing else, at least the double-helical structures of DNA and of helicates are aesthetically appealing.

A class of single-stranded compounds with a helical structure are the helicenes (**A**, Scheme 2).[12] Compound

markus.albrecht@oc.rwth-aachen.de

with additional electrostatic attraction, the formation of double-stranded helices also can be achieved. As shown in Figure 2 (**E**), the chiral sulfur-bridged bisguanidinium strand assembles around dianionic tetrahedral sulfate ions and thus forms an "inverted" helicate-type structure.[15]
Scheme 1. A model of the first double-stranded helicate, which was formed by Lehn et al. from three copper(I) ions and two ligands, which each contain three 2,2′-bipyridyl units. C: gray; H: white; N: blue; O: red; Cu: green.
Figure 2. The "inverted" double-stranded helicate **E** described by de Mendoza et al.[15].

B (Scheme 2) represents an extended helicene, which, owing to the alkyl bridges, possesses some flexibility and which additionally bears some internal nitrogen-donor atoms. Compound **B** forms a double-stranded helicate-type complex upon addition of one or two equivalents of sodium ions.[13] The oligo(pyridine amide) **D** (Scheme 2) adopts a helical conformation owing to intramolecular hydrogen bonding between the amide protons and the pyridine-nitrogen atoms (**C**, Scheme 2). Depending on the concentration and on the temperature, foldamer **D** forms double-stranded compounds owing to attractive π–π interactions between two single strands.[14] In hydrogen-bonded systems

The examples described to date of artificial double helices lack one important feature compared to the natural model DNA. They are not able to store information other than the stereochemistry in the double-strand—information
Scheme 2. Molecules that form helical structures: [6]helicene (**A**) adopts a single-stranded helical structure, whereas **B** yields a double-stranded helicate in the presence of sodium ions. The foldamer **D** forms a helical structure owing to intramolecular hydrogen bonding interactions. Compound **C** dimerizes in solution at high concentration and low temperatures.
Figure 3. Left: The complementary pairs guanine–cytosine, adenine–thymine, amidinium–carboxylate, and the double-stranded helix with complementary amidinium–carboxylate pairing, which was described by Furusho and Yashima. Right: Stereoview of the X-ray structure taken from reference [16].

storage and processing is an important feature of DNA and occurs by a sequential arrangement of complementary base-pairs. The sequence in one strand dictates the sequence of the complementary one. To store information in artificial systems, we have to form the double helices from two strands with complementary binding sites. This can be achieved, for example, by substituting the natural base-pairs guanine–cytosine or adenine–thymine by simple analogues (e.g. amidinium–carboxylate).

Recently, the synthesis of the heterostranded double helix **F** was described, in which different but complementary binding sites were introduced in two different strands (Figure 3). Hereby, a bisamidinium strand and the complementary biscarboxylate strand were prepared by modular approaches. Mixing of the two strands led to the spontaneous formation of an enantiomerically pure double helix, which was characterized by NMR and CD spectroscopy in solution. X-ray stucture analysis revealed that the double-helical structure is maintained in the solid state (Figure 3).[16] Compound **F** is a new type of double-stranded helix, in which two different strands interact by salt bridges between complementary amidinium and carbox-

ylate units. Therefore, for the first time the complementarity between two strands, which is found in DNA, is an important aspect of the noncovalent formation of an artificial double-stranded system. In related future studies this might allow the preparation of sequential strands with complementary binding sites that are either self-complementary or that form hetero-duplexes (as shown in **F**). In the future, an artificial system might result, which contains not only stereochemical[17] but also sequential information. Duplex formation combined with chemical ligation processes might then be able to transfer this information to a new strand. Complementary pairs such as amidinium and carboxylate might take the place held by guanine–cytosine or adenine–thymine in nature. Therefore the preparation of a self-complementary strand with one carboxylate and one amidinium group should be one of the next challenges.

As described herein, naturally occurring double-stranded DNA acts as a model for chemists and motivates us to develop routes to artificial molecular double-stranded helices. Possibilities have to be found to assemble linear molecules to form double-stranded systems with a helical twist. Ideally this

process should proceed stereoselectively. The obtained systems—including those described herein—are still relatively simple compared to nature's wonderful example of DNA. Information storage and processing in double-helical compounds is still a monopoly of nature. However, the introduction of sequential strands in artificial double helices[18] and the use of complementary base-pairs[16] are first steps towards breaking this monopoly in the future.

Electron Transfer

Charge-Transfer Isomers and Mixed-Valence Properties**

Robert J. Crutchley

bridging ligands · charge-transfer isomers ·
cluster compounds · mixed-valence compounds ·
ruthenium

The recent studies of Kubiak and co-workers[1,2] in which they were able to identify the existence of charge-transfer isomers are important contributions to the field of mixed-valence chemistry. The work establishes charge-transfer isomers as identifiable chemical entities that exist in dynamic equilibrium determined by electron transfer on the picosecond time scale.

Mixed-valence compounds are generally odd-electron systems and are composed of two or more reduction/oxidation (redox) centers. The odd electron is able to exchange between the two redox centers either by photoinduced or thermal electron transfer depending upon the extent of electronic coupling between the two redox centers. For thermal electron transfer, three absolute conditions arise: no coupling between redox sites and no electron transfer (Class I), weak coupling and electron transfer between redox sites that is dependent upon thermal activation (Class II), and finally strong coupling and activationless electron transfer between redox sites (Class III).[3] Class II and Class III systems are also referred to as valence-trapped and delocalized mixed-valence states, respectively. For mixed-valence systems at the boundary between Class II and Class III behavior,

where electron transfer rates are on the order of solvent relaxation times ($< 10^{-12}$ s), the classification Class II–III has been proposed.[4] The charge-transfer isomers studied by Kubiak and co-workers are of Class II–III.

Of the many mixed-valence systems that have been studied, the vast majority of molecular systems are dinuclear ruthenium complexes and that is because of the stability of the coordination sphere in either Ru^{II} or Ru^{III} oxidation states and the enormous literature resource of ruthenium-complex synthesis. Kubiak and co-workers have extended this series to ruthenium clusters of the type [{Ru$_3$O(μ-CH$_3$COO)$_6$(CO)L′}(μ-L){Ru$_3$O(μ-CH$_3$COO)$_6$(CO)L″}] (Figure 1).
Figure 1. General diagram of the Ru$_3$ dimers, bridging ligand L, and monodentate ligands L′ and L″.

For the above complexes in the neutral isolated state, each trinuclear Ru$_3$ moiety formally contains one Ru^{II} and two Ru^{III} centers (Ru$_3^{III,III,II}$) and the carbonyl ligand is coordinated to the formally divalent center. The cyclic voltammetry of these complexes shows two reversible two-electron oxidation waves at positive potentials and two reversible one-electron waves at negative potentials. The one-electron waves correspond formally to the Ru$_3^{III,III,II}$–Ru$_3^{III,III,II}$/Ru$_3^{III,II,II}$–Ru$_3^{III,III,II}$ and

Ru$_3^{III,II,II}$–Ru$_3^{III,III,II}$/Ru$_3^{III,II,II}$–Ru$_3^{III,II,II}$ one electron couples (i.e. the sequential reduction of one Ru^{III} center on each cluster unit) and are separated from each other in potential, ΔE, because of the stability of the Ru$_3^{III,II,II}$–Ru$_3^{III,III,II}$ mixed-valence state that largely arises for a symmetric complex from the coupling between Ru$_3$ moieties. The Ru$_3$ moieties are separated by a distance that prevents direct orbital overlap and because of this the electronic coupling between Ru$_3$ moieties can only occur by mixing ruthenium orbitals with bridging ligand (L) orbitals in a process referred to as superexchange. As might be expected, the extent of orbital mixing and hence coupling is sensitive to the relative symmetry and energy of the interacting orbitals and this provides a means by which these complexes can be made extraordinarily useful probes of the mixed-valence state. In previous studies,[5] Kubiak and co-workers changed the nature of the bridging ligand L and the monodentate ligands L′ and L″ to purposefully vary the extent of superexchange coupling. Most importantly, the presence of a carbonyl ligand and the infrared spectroscopy of its carbonyl stretch ν(CO) provided an independent probe of the valence state of each Ru$_3$ moiety in the mixed-valence state on the infrared time scale of 10^{-13} s. If the mixed-valence complex is Class III and symmetric (L′=L″ and L possesses a center of symmetry), the two carbonyl ligands will be in identical environments and so only one ν(CO) band will be observed. For a Class II mixed-valence ion, the rate of electron transfer between redox sites is far slower than 10^{13} s^{-1} and so two ν(CO) bands will be

observed. With stronger coupling and faster electron transfer, the two $\nu(CO)$ bands coalesce so that only one average band is observed. Kubiak and co-workers fitted the coalescence of the $\nu(CO)$ bands[5] according to an algorithm[6] in which the electron-transfer rate constant was a variable. The studies convincingly showed that electron-transfer rates k_{et} approach the activationless limit ($k_{et} \approx 10^{12}$ to $10^{13}\,s^{-1}$) in their most strongly coupled systems.

Charge-transfer isomers are mixed-valence complexes which differ only in the location of the odd electron. These isomers cannot be distinguished experimentally in symmetric mixed-valence systems but can be in asymmetric systems. However, the asymmetry in mixed-valence complexes biases the stability of one charge-transfer isomer over the other so that only the most stable charge-transfer isomer is normally observed. This bias in stability can be estimated from the difference in redox couples of isolated Ru_3 moieties (no coupling between moieties) and is referred to as the diabatic free-energy change.[1] It can be accurately calculated by determining the charge-transfer isomer equilibrium constant and hence the adiabatic free-energy change.[1] This latter value includes the effect of coupling on the energy difference between Ru_3 moieties. What Kubiak and co-workers were able to accomplish was to synthesize asymmetric mixed-valence complexes in which the difference in stability between charge-transfer isomers (the adiabatic free energy) was exceedingly small ($\leq 0.0248\,eV$) and the relative populations of charge-transfer isomers in equilibrium sufficiently large to be experimentally measurable. By slightly modifying the complexes in Figure 1, the population of charge-transfer isomers could be established by the asymmetric binding of $^{13}C^{18}O$ and $^{12}C^{16}O$ ligands. Energetic asymmetry was achieved by substituting different L′ and L″ ligands or by binding an asymmetric bridging ligand L. The latter resulted in an elegant and unambiguous experimental identification of charge transfer isomers.

Figure 2 shows the structure and infrared spectroelectrochemistry of two complexes in which the asymmetric ligand, L = methylpyrazine, bridges two Ru_3 moieties and L′ = L″ = pyridine (py).[2] These complexes would be identical were it not for the selective substitution of $^{13}C^{18}O$. The IR spectrum of neutral and doubly reduced complexes shows only two $\nu(CO)$ bands, the higher frequency band is assigned to $^{12}C^{16}O$ while the band at lower frequency is assigned to $^{13}C^{18}O$. A slight shifting to lower frequencies of both bands is seen upon reduction. However, the mixed-valence complex shows four $\nu(CO)$ bands and this occurs because there are two charge-transfer isomers in equilibrium, each with $\nu(^{12}C^{16}O)$ and $\nu(^{13}C^{18}O)$ bands. The bands do not have equivalent intensity because the population of isomers in equilibrium is not the same. For the complex on the left in Figure 2, the basicities of the nitrogen atoms of the methypyrazine bridging ligand suggest that the most stable charge-transfer isomer (the major population) will be the one with most of the electron density on the Ru_3 cluster bonded to $^{12}C^{16}O$. Thus, for the two $\nu(^{12}C^{16}O)$ bands, the band at slightly lower frequency has the greater intensity while the higher frequency band, which appears as a shoulder, is associated with the minor isomer in which most of the electron density is on the Ru_3 cluster bonded to $^{13}C^{18}O$. Similar arguments can be used to rationalize the two $\nu(^{13}C^{18}O)$ bands. Further convincing

proof of the existence of the charge-transfer equilibrium comes from the spectroelectrochemistry of the complex on the right in Figure 2. In this complex, the orientation of the bridging methylpyrazine has been switched so that now the most stable charge-transfer isomer is the one with most of the electron density on the Ru_3 cluster bonded to $^{13}C^{18}O$. This in turn switches charge-transfer isomer populations and $\nu(CO)$ band intensities compared to that of the complex on the left in Figure 2.

In another study[1] of mixed-valence complexes of the type shown in Figure 1, the charge-transfer equilibrium was perturbed by holding the bridging ligand L = pyrazine fixed but varying L′ and L″. Three complexes were examined in which L′ = 4-dimethylaminopyridine and L″ = pyridine (**1**), L′ = pyridine and L″ = 4-cyanopyridine (**2**), and L′ = 4-dimethylaminopyridine and L″ = 4-cyanopyridine (**3**). Cyclic voltammetry of the complexes gave values of ΔE which varied from 310 mV to 410 mV and were considerably larger than those predicted from the differences in intrinsic reduction potentials. This result was appropriately taken as evidence of significant electronic coupling. As discussed above, the substitution of $^{13}C^{18}O$ permitted the charge-transfer equilibrium to be characterized. The adiabatic free-energy differences of the charge-transfer equili-

Highlights

bria varied from 9.3×10^{-3} to 0.025 eV and were considerably smaller although they followed the same trend as the diabatic free-energy differences which varied from 0.1 to 0.23 eV. The relatively small adiabatic free energy is a consequence of the magnitude of electronic coupling between Ru_3 moieties. Applying the potential energy surfaces developed by Sutin[7] to the case of a diabatic free energy of 0.1 eV and reorganizational energy of 1.43 eV, Kubiak and co-workers estimated that the electronic coupling required to achieve a delocalized state is $H_{ad} = 4260$ cm^{-1}. For this delocalized state the adiabatic free-energy difference was calculated to be 0.065 eV. This value is considerably larger than that found for mixed-valence complexes **1–3** which suggests that these complexes should undergo activationless electron-transfer rates. However, the experimental electron-transfer rates range from 0.4 to 8.5×10^{11} s^{-1} which is significantly less than that required for activationless electron-transfer. This result led to the suggestion that these systems are coupled to the solvent or molecular normal modes and that this is an additional barrier to full delocalization. While this may be true, the magnitude of the calculated electronic coupling is also a concern. If $H_{ad} = 4260$ cm^{-1} or 530 mV, the difference in Ru_3 redox couples ΔE should be at least as large as 530 mV but the largest measured by cyclic voltammetry is only 410 mV. This disagreement may be due to antiferromagnetic exchange within the Ru_3 moieties which would reduce the stability of the mixed-valence state. If this is found to be unimportant the choice of parameters or the model itself should be re-examined.

Kubiak and co-workers have made a significant contribution to the field of mixed-valence complexes. By experimentally characterizing charge-transfer equilibria which are established on the picosecond time scale, these researchers have unprecedented access to the chemistry at the transition between localized and delocalized mixed-valence states. The elucidation of their properties has clear application to the purposeful construction of electronic molecular devices.

Heterogeneous Catalysts

Single-Site Heterogeneous Catalysts**

John Meurig Thomas, Robert Raja, and Dewi W. Lewis*
Intellectually, the advantages that flow from the availability of single-site heterogeneous catalysts (SSHC) are many. They facilitate the determination of the kinetics and mechanism of catalytic turnover—both experimentally and computationally—and make accessible the energetics of various intermediates (including short-lived transition states). These facts in turn offer a rational strategic principle for the design of new catalysts and the improvement of existing ones. It is generally possible to prepare soluble molecular fragments that circumscribe the single-site, thus enabling a direct comparison to be made, experimentally, between the catalytic performance of the same active site when functioning as a heterogeneous (continuous solid) as well as a homogeneous (dispersed molecular) catalyst. This approach also makes it possible to modify the immediate atomic environment as well as the central atomic structure of the active site. From the practical standpoint, SSHC exhibit very high selectivities leading to the production of sharply defined molecular products, just as do their homogeneous analogues. Given that mesoporous silicas with very large internal surface areas are ideal supports for SSHC, and that more than a quarter of the elements of the Periodic Table may be grafted as active sites onto such silicas, there is abundant scope for creating new catalytic opportunities.

From the Contents

1. Introduction

It is often explicitly stated, but far more frequently implied, that solid catalysts functioning heterogeneously possess a spectrum of active sites each with their own energetics, activity, and selectivity. The plausibility of this statement is reinforced if the topography of a metal surface such as that depicted in Figure 1 is examined. In this case, atoms located at surface steps or kinks are stereochemically different from one another and less fully coordinated to other atoms than those at terrace sites and flat exterior surfaces.[1] But even at a flat exterior surface (typically the (111) face of a face-centered cubic (fcc) metal such as platinum), there are clearly three distinct adsorption sites—atop, bridge, and hollow—for small molecules such as carbon monoxide to be bound. It is not surprising, therefore, that the enthalpy of adsorption as a function of surface coverage falls, and that a temperature-programmed desorption has several peaks, as these reflect the variety of energetic situations associated with the adsorbed species.[2] This is a situation that is encountered with all metal and alloy catalysts and with a very large number of other catalysts that are continuous solids, including close-packed oxides, halides, and chalcogenides.

Yet, the concept of the catalytically active site, introduced[3] to the literature of catalysis by Taylor eighty years ago, is as widely used as ever; and it has spawned other, heuristically and practically, important notions such as

"active-site engineering" and "active-site modification". Demonstrably, it is easy to comprehend what is meant by the structurally well-defined active site of a metalloenzyme (or any other enzyme) and also by the active site of members of the entire family of homogeneous (i.e. molecular) catalysts in which discrete molecular entities (encompassing the active

site) are dispersed in a fluid phase, usually water. No intellectual or practical problems are encountered when these catalysts are referred to as being of the "'single-site" variety.

So far as heterogeneous catalysts made of metal or alloy are concerned, the nature of the active sites is far less sharply defined than was originally envisaged by Taylor. Taylor advanced reasons for believing that preferential adsorption on a catalyst surface would take place at those atoms situated at peaks, fissures, and other crystalline discontinuities. (In Taylor's days the concepts of kinks, emergent dislocations, and even point-defects had not yet been formulated). Moreover, he inferred that such atoms would also have the highest catalytic activity. In the intervening years it has become clear that preferential adsorption does indeed occur (see Figure 1) at the step and kink sites of solid surfaces. But what is required in a good, catalytically active site is not a high

Figure 1. a) A temperature-programmed spectrum showing three peaks corresponding to progressively stronger bound states at terrace, step, and kink sites of an adsorbate molecule (methylcyclohexanone) at a roughened copper surface.[1] b) Even on a flat surface, such as the (111) face of platinum, there are three distinct sites for a molecule such as CO to be adsorbed. c) The decline in the heat of adsorption with increasing coverage of a flat single-crystal surface arises because of the heterogeneity of sites and mutual repulsion of species adsorbed at neighboring sites (ML = monolayer).[2]

John Meurig Thomas, a former Head of the Department of Physical Chemistry, University of Cambridge and former Director of the Royal Institution of Great Britain, is now Honorary Professor at the Department of Materials Science, Cambridge. A solid-state, materials and surface scientist, he has focused mainly on the design of solid catalysts. For his work on in situ characterization and numerous discoveries in catalysis he has received several awards including the Davy Medal of the Royal Society and the Willard Gibbs medal of the ACS. In 1991, he was knighted for his services to chemistry and the popularization of science.

Robert Raja completed his Ph.D. at the National Chemical Laboratory, Pune, India. In 1997, he was awarded the prestigious 1851 Exhibition fellowship to pursue an independent research program, at the Royal Institution of Great Britain, with Prof. Sir J. M. Thomas. He is currently a Senior Research Associate at the Department of Chemistry, University of Cambridge, where he focuses on the discovery, design, and synthesis of novel microporous and mesoporous solids, for application as heterogeneous catalysts. His recent awards include the IACS "Young Scientist Award" (2004) and the "Barrer Award" (2005).

Dewi Wyn Lewis studied Computer-Aided Chemistry at the University of Surrey. After working for IBM for a year he completed a PhD at the Royal Institution of Great Britain with Prof. Richard Catlow, followed by a postdoctoral position with Prof. Catlow and Prof. Sir J. M. Thomas. He was then Oppenheimer Research Fellow at the University of Cambridge. He was appointed as lecturer (and subsequently senior lecturer) at the Department of Chemistry, University College London in 1998. His research interests encompass computer modeling of materials with an emphasis on microporous solids.

binding energy; rather one of an intermediate value which is such that it optimizes both the residence time of the adsorbate and facilitates its conversion into desirable product species.

With strictly stoichiometric processes (rather than catalytic ones) such as adsorption in general or with surface reactions in a noncatalytic sense, such as thermal oxidation, decomposition, dissolution or gasification, crystalline discontinuities do indeed exhibit enhanced reactivity, and in that

context may legitimately be regarded as active centers.[4] Somorjai's and others[5] work have shown that surface steps and kinks on many metals may indeed function as favored sites for the activation of C–H, H–H, O=O, N≡N, or C≡O bonds under certain circumstances. A major advance in the notion of catalytically active centers in inorganic solids came with the Cossee–Arlman interpretation of Ziegler–Natta catalysts.[6] Working on the plausible assumption that the prismatic faces of α-TiCl$_3$, a vital constituent of such catalysts, inevitably—for thermodynamic reasons—contain a minute fraction of chloride-ion vacancies and hence coordinatively unsaturated titanium ions, Cossee and Arlman showed that these ions are the active centers for the stereoregular polymerization of alkenes. But, for metals and alloys, it has become abundantly clear, thanks to the investigations of Ertl et al.,[7,8] and others, that a great deal of surface mobility (even fluidity) exists under quite thermally mild catalytic conditions. Standing-wave patterns and periodic kinetic oscillations in the oxidation of CO on a Pt surface are pronounced;[9] and chaotic phenomena involving spatio-temporal changes on quite rapid time-scales are frequent occurrences, as are pronounced surface morphological changes brought about as the surface catalytic reactions proceed.[10] It is therefore clear that, at such catalyst surfaces—unlike the situations that prevail for solids in categories A to D in Table 1 (see Section 2)—the concept of a structurally fixed active site is of little value. For such catalysts it is more fruitful to picture them as energetically (and otherwise) multisite catalysts. But where, in other kinds of solid catalysts, one, or a small number of, metal atom(s) is firmly and uniformly anchored to a support (see category A in Table 1) the concept of a single-site catalyst is certainly valid.

There appears, therefore, to be a dichotomy—an ostensible contradiction of facts. On the one hand, it is profitable, for certain types of solid catalysts, to retain the notion of the active site; on the other, the idea of a well-defined active site at a metal surface (where they were conceived by Taylor) seems to be progressively less valid.[11] One of the principal purposes of this Review is to resolve this apparent contradiction. More importantly, it is to identify and classify numerous examples of single-site heterogeneous catalysts—henceforth referred to as SSHC—as they are already playing a significant role in many industrially important chemical processes and are ever-more present in a variety of academic (laboratory-based) situations. Many new developments (and Patents) are continuing to emerge in this hitherto inadequately recognized branch of heterogeneous catalysis. Moreover, single-site heterogeneous catalysts (SSHC) are important for two other reasons which are of profound significance so far as the understanding of the nature of catalysis as well as the design of new catalysts is concerned. First, sophisticated and reliable theoretical computations of the structures, energetics, and kinetics of catalytic conversions may readily be performed on transformations that take place at single-sites, and these, in turn, enable quantitative comparisons to be made between homogeneous and heterogeneous catalysts involving essentially the same active centers. Second, equipped with such quantitative information it becomes possible to evolve strategic principles for the design of improved

catalysts. In other catalytic situations, notably catalysis by metals and most continuous solids, because of the perceived complexity of their mode of action, certain design possibilities cannot even be framed, let alone be constructively implemented.

To fix our ideas, it is prudent to elaborate briefly what we mean by a "single site" in the general context of heterogeneous (solid) catalysts. The "single site" (catalytically active center) may consist of one or more atoms—as will become clear in the discussion and examples given below. Such single sites are spatially isolated from one another, there is no spectroscopic or other cross-talk between such sites. Each site has the same energy of interaction between it and a reactant as every other single site; and each such site is structurally well-characterized, just as the single sites in homogeneous molecular catalysts are.

Herein we give examples of 1) the high regioselectivities of inorganic SSHC enzyme mimics which oxyfunctionalize terminal methyl groups in linear alkanes under mild conditions; 2) the marked shape-selectivity of SSHC in converting methanol (by Brønsted acid catalyzed dehydration) preferentially into ethene and propene; 3) numerous selective hydrogenations with high turnover frequencies (under solvent-free conditions) of polyenes, and also of several enantioselective hydrogenations characterized by high *ee* values; and 4) bifunctional open-structure forms of SSHC in which "isolated" acid centers and "isolated" redox centers cooperatively lead to the in situ production of hydroxylamine (from NH$_3$ and O$_2$), cyclohexanone oxime (from cyclohexanone), and ε-caprolactam (the precursor to nylon-6).

By identifying the reality and usefulness of categorizing certain kinds of solid catalysts as SSHC, a rational strategic principle for the design of new catalysts clearly emerges. Much progress has been made in the design of such catalysts in the past few years. The so-called "uniform heterogeneous catalysts" reviewed[12] by one of us in 1988—where active sites are spatially distributed inside open-structure solids and are freely accessible to reactants—will be seen below to be a special case of the SSHC discussed herein.

2. Four Principal Categories of Single-Site Heterogeneous Catalysts

Table 1 enumerates the four main categories into which SSHC may be conveniently classified. There are subdivisions within some of these categories. For example, in category A, various kinds of supports, to which the catalytic entity containing the single-site are attached, may confer extra activity or selectivity to the SSHC. And both monofunctional and bifunctional catalytic performance may be exhibited by certain examples in category D.

In all four categories there exist structurally well-defined active sites, the precise atomic nature of which may be probed—increasingly nowadays under reaction conditions,[13,14]—by a range of experimental and computational techniques. Such sites are amenable (by pre- or post-synthesis interruption) to controllable, subtle changes in structure that may have far-reaching catalytic repercussions.

Table 1: Four categories of single-site heterogeneous catalysts (SSHC).

A: Individual isolated 1) ions, 2) atoms, 3) molecular complexes, and 4) bimetallic clusters anchored to high-area supports (generally silica).

B: Immobilized asymmetric organometallic species at high-area mesoporous solids, of pore diameters in the range 15 to 500 Å.

C: "Ship-in-bottle" structures, in which isolated catalytic molecular entities (or organometallic complexes) are entrapped within zeolitic cages that are permeable to certain reactants and to some of the potential products.

D: Open-structure, microporous solids (molecular sieves) with pore diameters in the range 3.5 to approximately 10 Å. The isolated active sites, which are uniformly distributed spatially throughout the bulk, are located at or adjacent to ions that have replaced framework ions of the parent structure.

3. Individual Isolated Ions, Atoms, Molecular Complexes, and Bimetallic Clusters as Single-Site Heterogeneous Catalysts

In the four subcategories isolated ions, atoms, molecular complexes, and bimetallic clusters, quite distinct features can be distinguished. First, there are transition-metal-ions grafted on to high-area supports, silica being the most suitable and popular, thereby forming a kind of metal-oxo entity. Second, single atoms of a metal such as palladium may be anchored to a surface structural defect at an oxide support, typically magnesia (MgO). Third, isolated organometallic complexes anchored to silica or alumina surfaces also function as single-site catalysts. Finally, small clusters (all of the same size) of metal atoms or of bimetallic clusters or of their carbides may be anchored securely to mesoporous silica also exhibiting single-site but multinuclear behavior.

3.1. Single-Site Transition-Metal Ions Supported on Mesoporous Silica

From the early days of heterogeneous catalysis, silica has been widely used as a support. Its merits are numerous: it is robust, readily prepared (with high surface area), it does not swell in contact with organic solvents, it has considerable thermal stability as well as structural flexibility and it bonds rather readily to a large number of the elements of the Periodic Table. Moreover, soluble analogues of silica, the so-called silsesquioxanes[15,16] (see, for example, Figure 2) are available, so that it becomes readily possible to characterize new functionalities that are attached to silica surfaces. In addition, the catalytic performance of a hetero ion (e.g. Ti, Fe, Cr) introduced to a silica may be studied both as a homogeneous and as a heterogeneous catalyst.[17]

Twenty-five years ago Basset et al.,[18] extending the earlier studies of others,[19] began a systematic study, which has continued to blossom[20] in which they deliberately set out to functionalize the surfaces of the so-called Aerosil silicas which are nonporous. Their work, often described as surface organometallic chemistry, produces SSHC by appropriately
Figure 2. a) Silsesquioxanes (general formula $(RSiO_{1.5})_n$) are structurally similar to β-cristobalite and β-tridymite, (shown is the structure of $Cy_8Si_8O_{12}$ (Cy = cyclohexyl)). They are, effectively, soluble analogues of silica; and a heteroatom (usually transition metal or Ge) attached to the silsesquioxane simulates the behavior (in solution) of the same, grafted atom attached to mesoporous silica forming the corresponding heterogeneous catalyst. b) Fragment of the crystal structure (schematic) of a Ti^{IV}-cyclopentadienyl complex bound to two silsesquioxane moieties (after F. T. Edelmann et al. ref. [146], c) Actual structure (shown in (b), indicating the isolated nature of the Ti^{IV} center (hydrogen atoms have been omitted for clarity). d) A soluble Brønsted acid site formed from silsesquioxanes.[15b]

functionalizing the residual pendant silanol groups ($\equiv$ SiOH) on the Aerosil silica (surface area typically 200 $m^2 g^{-1}$ and silanol surface concentration of 0.7 ± 0.2 per nm^2, which is equivalent to 0.23 $mol(OH)g^{-1}$). A specific example is the tripodally grafted zirconium hydride, which activates alkanes under mild conditions (Figure 3). Other transition-metal ions have been grafted on to silica by Basset et al.; and their work on grafted organometallic complexes as SSHC, is returned to again in Section 7.5.2.
Figure 3. An isolated site, such as a tripodally bound zirconium hydride at a silica surface, readily activates methane at modest temperatures.[20]

Great scope for the preparation of a variety of single-ion SSHC began once it became readily possible—thanks to discoveries at the Mobil Oil Co.[21] and in Japan (Waseda University and the Toyota Co.)[22]—to prepare mesoporous silica with pore diameters that may controllably fall in the range 20 to 100 Å or more. Later workers produced mesoporous silicas with pore diameters as large as 500 Å. Such silicas possess exceptionally high surface areas (typically 600 to 1000 m^{2}g^{-1}) and their inner and outer surfaces have a profusion of pendant silanol groups (Figure 4), approximately 1–2 per nm^2.
Figure 4. a) A high-resolution electron micrograph of an ordered mesoporous silica where the diameter of the pores is approximately 100 Å and the walls are only a few atoms thick. b) Each pore is lined with pendant silanol ($\equiv$Si-OH) groups; yellow Si, red O, white H.

Corma,[23] Thomas,[24,25] and others[26] were quick to appreciate the advantages that large-pore silicas would confer in facilitating the preparation of single-site, ion-centered heterogeneous catalysts. A significant advance was made when Ti^{IV} active centers were grafted on to the inner walls of mesoporous silica using an organometallic precursor, in particular titanocene dichloride [Ti(Cp)$_2$Cl$_2$] (Cp = C$_5$H$_5$) as was done by Maschmeyer et al.[27] The key steps in the introduction of the isolated, single-site active centers on the inner walls of the so-called MCM-41 silica are shown in Figure 5. The detailed course of this "heterogenization" of a Ti^{IV} active center was followed by in situ X-ray absorption spectroscopy combined with in situ X-ray diffractometry.[28] Density functional theory (DFT) calculations yield important supplementary information: in particular they show that the titanyl group (>Ti=O), once postulated[29] as the active site for epoxidation of alkenes, is energetically unfavorable.

It is to be seen that a tripodally grafted Ti(OH) group constitutes the isolated active site, very resistant to leaching, in this instance. Note that the van der Waals envelopes of the
Figure 5. Experimentally, by in situ measurements,[27a] the course of conversion of a free titanocene dichloride molecule (top right) into a tripodally bound isolated site of $\equiv$TiOH (bottom right) may be followed by X-ray absorption spectroscopy.[28] Note the pronounced "pre-edge" peak signifying four-coordinate Ti^{IV} (bottom left) of the XANES (Ti K-edge) spectra. Bond lengths are extracted from EXAFS spectra, whilst the energetics are from DFT calculations.[27b]

cyclopentadienyl groups attached to the surface bound ("half-sandwich") intermediate, shown in Figure 5, ensure that no two Ti^{IV} active centers are closer than approximately 7 Å (see Figure 6), thereby ensuring the generation of a genuine, isolated, single-site catalyst. (Other methods of introducing Ti^{IV} active centers, involving salts of titanium or in-grown titanium alkoxide additives to the siliceous precursor do not guarantee production of isolated, tetrahedral Ti^{IV} centers and a tendency to form Ti-O-Ti linkages exists with these methods). This catalyst is an exceptionally good epoxidation catalyst using alkyl hydroperoxides as we shall describe in Section 7.2.3.

Other transition-metal ions may be grafted on to mesoporous silicas using the metallocene route, and active centers composed of isolated Mo^{VI}, Cr^{VI}, and VO^{IV} have been described.[30,31]

An altogether different, but equally effective approach has been pioneered by Tilley et al.[32–35] in which a molecular precursor is taken to yield a series of active catalysts on mesoporous (and certain other) supports. The metal ions in question are those of Ti, Cr, Fe, and VO; and the essence of their preparation is that the desired atomic environment aimed at in the final catalyst (e.g. Ti(OSi)$_4$ or Ti(OSi)$_3$) is
Figure 6. The "half-sandwich" surface intermediate (see middle right of Figure 5), with the van der Waals envelope (light blue) surrounding the cyclopentadienyl ligands which ensures that only spatially isolated, tripodal Ti^{IV} sites are formed. EXAFS data show the absence of Ti-O-Ti linkages. Inset: side view, purple Ti, gray C, white H, red O.

Figure 7. The Tilley method[32, 33] of preparing single-site catalysts on mesoporous silica through thermolytic molecular precursors such as $M[OSi(OtBu)_3]_n$.

already present in the thermolytic precursor. Thus, by taking the tris(*tert*-butoxy)siloxy titanium complex (*i*PrO)Ti-$[OSi(OtBu)_3]_3$, the environment ultimately achieved in the single-site catalyst is $Ti(OSi)_3$, and from $Ti[OSi(OtBu)_3]_4$ it is $Ti(OSi)_4$. Typical supports used by Tilley were the high-area mesoporous silicas MCM-41 and SBA-15, the latter being distinctly more thermally stable than the former. The general picture, depicting the production of this type of SSHC is shown in Figure 7. The precursor is bonded to the hydroxy groups of the surface of the silica by protonolysis reactions (Figure 7). For the case of an alkoxy (siloxy) species of the type $M[OSi(OtBu)_3]_n$ (where M = Ti, Fe, Cr,…) this surface-attachment chemistry occurs with loss of HO*t*Bu or HOSi-$(OtBu)_3$, to result in bonding to the surface through M-O-(surface) or Si-O-(surface) linkages, respectively. (Calcination results in the loss of all the carbon and hydrogen, leading to the single-site catalyst of nominal composition MO_x-$(n-1)SiO_2$. All the physical methods of analysis, such as diffuse reflectance UV (DRUV) and EPR spectroscopy carried out on the product suggest that the metal-ion sites (such as Fe^{III} sites) possess distorted tetrahedral geometry. When attempts are made to prepare isolated Fe^{III} sites using $FeCl_3$, $FePO_4$, or $Fe_2(SO_4)_3$ as precursors no success is achieved and calcination almost invariably leads to clusters of iron oxides). Isolated Cu^I species, which are good catalysts for the production of dimethyl carbonate from methanol and CO_2,[34b] may be formed on silica using $[CuOSi(OtBu)_3]_4$ as precursor.

3.2. Supported Isolated Atoms as Single-Site Heterogeneous Catalysts

Recent experimental work has established beyond doubt that a single metal atom of palladium, supported on magnesia (MgO) facilitates the cyclotrimerization of acetylene[36] and
the oxidation of CO by O_2 to CO_2.[37] Heiz and co-workers,[36,37] using mass-selected techniques, prepared single-site active centers such as that shown in Figure 8, in which an F-
Figure 8. An isolated atom of palladium (black) when bound (by charge-transfer) to an F-center at the surface of MgO forms[36] the stable complex $Pd(CO)_2O_2$, Right: top view of F-center. Red O, blue Mg, gray C.

center (that is, an electron trapped at an oxygen anion vacancy) in MgO localizes a single palladium atom, with electronic charge being transferred to the palladium.

When this "single-atom" active site is first exposed to O_2 and then to CO (at 90 K) and then subjected to a linear temperature rise, conversion ensues, the adsorbed gases combine to yield CO_2, and the surplus oxygen is taken up by the F-center, which thereby loses its ability to localize the

palladium. Ab initio computations reveal the optimized structure of the MgO-Pd(CO)$_2$O$_2$ single-site active center with its bound reactants (Figure 9). Heiz et al.[36] have also
Figure 9. a) Computationally optimized structure of the MgO(F-center)-Pd-(CO)$_2$O$_2$ complex.[37] b),c) selected configurations, and d) the potential energy versus time, recorded in an ab initio molecular dynamics (MD) simulation where CO$_2$ is formed from the complex shown in (a). The simulation starts[37] from the transition state shown in (b). The potential energy of the transition state is 0.84 eV above the optimized configuration shown in (a). c) A snapshot at 210 fs, where the formed CO$_2$ is desorbing and the remaining O atom from O$_2$ is moving towards the F-center; black Pd, blue Mg and red O (in MgO), adsorbed O$_2$ is yellow, carbon atoms are gray and their respective oxygen centers are purple and green.

completed a combined experimental and computational study of this model, single-atom version of a SSHC for the cyclotrimerization of acetylene to benzene. In each of these examples of SSHC it is to be noted that, because of the destruction of the F-center during reaction in the first case and the clustering of the Pd atoms to form larger units (Pd$_n$, $3 < n < 30$) in the second, there is no sustained catalytic turnover. In a sense, therefore, this admirable model study, like many in the literature, is concerned with a surface stoichiometric rather than a catalytic reaction.

3.3. Anchored Organometallic Complexes as SSHC

Using the surface organometallic approach, Basset et al.[20] have produced a number of single-site catalysts at nonporous silica surfaces, the molecular complexes thereby anchored being fully characterized by both spectroscopic and chemical methods. Figure 10 shows the single-sites for three powerful examples of metathesis reactions. Basset's group, and especially that of Marks[38–40] (see Section 7.5.2), have also produced single-site, heterogeneous catalysts derived from metallocenes for the polymerization of alkenes.

Microcrystalline α-TiCl$_3$ Ziegler–Natta catalysts, because they have several non-identical atomic environments around the catalytically active centers—the chloride ion vacancy may be a regular site or at a step or corner site—yield polymers
Figure 10. Single-site active centers designed by Basset et al.[20] for heterogeneously catalyzed metathesis reactions.

with broad molecular-weight distributions. Homogeneous metallocene catalysts, on the other hand yield highly uniform homopolymers and copolymers; this arises because of the identical coordination environment of the active site in the homogeneous metallocene catalyst. If the metallocene-type polymerization catalysts could be so anchored as to have only a single kind of active site, this would unite the best qualities of the homogeneous and heterogeneous agents. Recent work, which we now briefly describe, has achieved this desirable goal.

Take first the work of Marks et al.,[38–40] who have used a variety of oxidic supports. Partially dehydroxylated alumina has approximately four Brønsted acidic OH groups, approximately 5.5 Lewis acidic Al^{III} centers, and around 5.5 Lewis basic oxide centers per nm^2 of surface area. The fully dehydroxylated alumina has a much lower Brønsted acidic surface concentration (approximately 0.12), though the concentrations of the other centers remain essentially the same. An even more strongly acidic surface is that of the so-called "superacidic sulfated zirconia." (Recent evidence suggests that this surface is not "superacidic"). When a zirconocene of general formula L$_n$ZrR$_2$ (L is a cyclopentadienyl ligand, and R an alkyl group) approaches the "superacidic" surface, a cationic-like-structure as schematized in Equation (1), forms.

$$L_nZrR_2 + HO\text{-Support} \rightarrow L_nZrR^+ \cdots {}^-O\text{-Support} + RH \qquad (1)$$
This cationic-like-structure, is in effect, an ion pair consisting of a cationic metallocene and a weak conjugate base of a strong Brønsted acid site. The negative charge of the conjugate base is so highly delocalized that coordination to the single-site cationic Zr center is minimal, thereby facilitating access of the alkene to the active site.

Marks et al.[40] have elucidated other, related single-site organometallic electrophiles on "superacidic" sulfated zirconia, including [Cp*$_2$Th(CH$_3$)$_2$] and [CpTi(CH$_3$)$_2$] (Cp* = η^5-C$_5$Me$_5$). And on sulfated alumina, they have shown that protonolysis at the strong surface Brønsted (OH) acidic site again yields a "cation-like" highly reactive (in polymerization) zirconocenium electrophile [Cp*$_2$ZrCH$_3$]$^+$. On a dehydroxylated silica surface no such "cation-like" single-site active center is formed.

Finally, a recent paper by McKittrick and Jones[41] discloses a general method for preparing an isolated titanium-centered polymerization catalyst on porous silica. The essence of the preparation is shown in Scheme 1 and Scheme 2.

Scheme 1.

advantage of the hydrogen bonding of a triflate group to secure the active complex to a silica support.

3.4. Individual, Isolated, Bimetallic Clusters as Single-Site Heterogeneous Catalysts

Along with our colleagues, Johnson et al.[47–50] we have shown that monodisperse mixed-metal cluster carbonylates may be uniformly incorporated inside mesoporous silica and gently decarbonylated to yield the naked clusters, which are anchored securely to the underlying silica (Figure 12). The key point in this case is to recognize that the method of preparation produces 1) clusters that are of the same stoi-

The catalytic performance of the final, site-isolated heterogeneous Ti-centered polymerization catalyst (**8** in Scheme 2) exceeds that of even the homogeneous analogue.

3.3.1. Single-Site Organometallic Complexes Anchored by Noncovalent Interaction

In addition to immobilizing single-site molecular catalysts to solid surfaces by covalent bonding (as done by McKittrick and Jones),[41] it is also feasible, and indeed more convenient, to do so by noncovalent means. Bianchini et al.[42] and we[31,43–45] have taken advantage of the strong hydrogen bonding that secures tripodal attachment of an ionic (or zwitterionic) complex to a silanol-rich silica surface through a triflate[46] or a sulfonate tail (Figure 11, left).[42]

The grafted Rh^I catalyst, [(sulfos)Rh(cod)] (cod = cyclo-octadiene), on silica is an example of SSHC for the hydro-genation of alkenes (in either flow reactors or batch reactors) in hydrocarbon solvents. It also hydroformylates alkenes such as hex-1-ene under solid–liquid conditions. When, however the hydroformylation takes place under solid–gas conditions, the syngas (CO + H$_2$) converts the active catalyst into an inactive species (Figure 11, right), a dicarbonyl derivative is formed {(sulfos)Rh(CO)$_2$}.[42] de Rege et al.[46] have also taken

Figure 12. Top right: a mixed-metal cluster carbonylate [Ru$_{12}$Cu$_4$C$_2$-(CO)$_{32}$Cl$_2$]$^{2-}$ is readily sequestered within the mesopores of silica in the presence of the molecular cation PPN$^+$ (bis(triphenylphosphine)i-minium). The carbonyl groups are held by hydrogen bonds (bottom right) to the silanol-rich inner surface. Upon gentle thermolysis, all the organic components are eliminated (as judged by in situ FTIR) leaving monodisperse mixed-metal Ru$_{12}$Cu$_4$C$_2$ clusters within the mesopores. Top left: individual mixed-metal clusters (shown in red) anchored inside pores (average diameter approximately 35 Å) of the silica sup-port. Bottom left: high-resolution electron micrograph, where each white spot denotes a single mixed-metal cluster.[51]

chiometry and size (monodisperse) and 2) a spatially uniform distribution of the clusters on the inner walls of the high-area mesoporous supports. These statements are supported by nondestructive electron tomographic studies of Thomas, Midgley and co-workers—see Figure 13—where virtual

Figure 13. An axial projection of a 30-nm-thick specimen and five successive 3-nm-thick slices through a scanning electron tomogram[52] of silica-supported $Ru_{10}Pt_2C_2$. (Nanoparticles shown in red, mesoporous silica in gray).

Figure 14. Left: structural information of the $Ru_{12}Cu_4C_2$ nanoparticle hydrogenation catalyst determined from EXAFS analysis.[49] Right: structural information deduced from a combined EXAFS-DFT approach, see ref. [147].

"slices" of the mesoporous silica support are depicted.[51,52] Typically, the size of these clusters falls in the range of 0.5 to 0.8 nm, depending on their precise stoichiometry. They are so small that essentially, all the atoms within each cluster are effectively "surface" atoms. These nanoparticle bimetallic catalysts display very high activities in hydrogenation processes (of many kinds), and are also highly selective.

In Section 7 a number of important, potentially commercial examples, especially in the context of solvent-free processes is given. Turnover frequencies associated with {Pd_6Ru_6} nanoclusters in the hydrogenation of a typical alkene exceed by an order of magnitude those for monoelemental palladium or ruthenium clusters.[48] The structures of these nanoparticle bimetallic clusters are determined (usually under in situ catalytic conditions) by X-ray absorption spectroscopy. Two examples are shown in Figure 14.

Insofar as the reasons for the synergy in catalytic effect between two metals in a bimetallic, nanoparticle cluster is concerned, it is not yet clear what the precise mechanism is. In qualitative terms we know that ruthenium is effective in activating molecular hydrogen and that palladium readily activates an olefinic bond. Furthermore, the recent work of Adams et al.[53,54] sheds some light on this general question. In their study of Pt–Ru carbonyl clusters, they found explicit evidence that Pt–Ru bonds are directly implicated in catalytic

hydrogenation reactions (of alkynes such as substituted acetylenes). Density functional (DFT) calculations, which have already elucidated the detailed structure of mixed-metal cluster carbides such as [$Cu_4C_2Ru_{12}$] (see Figure 14), should in future be able to estimate how many molecules of a particular reactant may be simultaneously catalytically converted at a single cluster. (It is relevant to note that in the work of Heiz et al.[36,37] quoted in Section 3.2 on the cyclotrimerization of acetylene on Pd_n clusters, only one molecule of benzene is liberated (in a temperature programmed reaction) from a supported single-site entity consisting of 1, 2, or 3 atoms of palladium, but two benzene molecules are liberated in clusters of 4, 5, 6 ,or 7 atoms of palladium).

Although not all the atoms in the bimetallic cluster nanoparticles are geometrically equivalent (see Figure 14), nevertheless there is evidence (which needs to be tested further) that the multinuclear bimetallic entities seem to behave as a single-site catalyst in the sense defined in Section 1. (This is reminiscent of some metalloenzymes in which several metal ions are situated at the single-site, catalytically active center).

4. Single-Site Heterogeneous Organometallic Chiral Catalysts

In a comprehensive analysis of the feasibility of effecting enantioselective hydrogenation of prochiral reactants, Brunner[55] stated that "*the limited success of heterogeneous catalysts in enantioselective reactions is due to the fact that on the surface of a heterogeneous catalyst there are many different catalytically active centers. Each of these centers has its own selectivity and the total selectivity is usually low.*" This statement, made in 1996, echoes our introductory remarks in this article. But since 1996 great progress has been made (recently partly reviewed in a special issue of *Topics in Catalysis*)[56] in developing good, efficient, and highly effective SSHC for enantioselective conversions.

First, we recall the relevant background work on non-enantioselective conversions using immobilized organometallic catalysts, see Marks,[38–40] Bianchini[42] and Jones et al.[57] All these cases are based on single-site heterogeneous reactions (polymerizations, hydrogenations, and hydroformylations). We also note the work of Hutchings[58] who, by modifying zeolite-Y with chiral molecules (such as 1,3-dithiane-1-oxide) achieved an efficient chiral preference in the catalytic dehydration of racemic butan-2-ol. We shall see, in Section 7, how a single-site chiral Cr[III](Salen) complex anchored to a silica surface is an effective enantioselective catalyst in the asymmetric ring opening of epoxides.[59]

It is therefore clearly established that single-site heterogeneous chiral catalysts, involving immobilized organometallic (or enantiomeric organic) species are viable propositions. We now show that, using mesoporous silica supports, high-performance single-site heterogeneous chiral catalysts may be conveniently prepared following methods that we have described fully elsewhere,[43–45,57] but which are summarized below. (The drive to prepare enantiomerically pure products for the pharmaceutical, agrochemical, and related industries, such as flavors and fragrances, is partly a response to tightening legislation, but it also reflects an attempt to develop efficient, recyclable catalysts such as SSHC).

We have shown repeatedly that, with mesoporous silica either of the highly ordered but thermally fragile kind (for example, MCM-41 and SBA-15) or non-ordered desiccant-grade commercially available robust (Davison) type[44] each of which have pendant silanol groups, a range of sizeable chiral metal complexes and organometallic moieties may be tethered to the inner walls of the silica. This incorporation is carried out using alkylhalides, amines, carboxylates, or phosphines. The procedure to arrive at single-site, well-isolated asymmetric organometallic active centers on the inner walls only of the mesoporous silica is outlined[49] in Figure 15, where we render the exterior surfaces "neutral" in the sense that the dichlorodiphenyl silane, which functionalizes all the silanol groups at the exterior surfaces, is used under conditions where it cannot diffuse to the interior. Silanols at the interior surfaces are functionalized using trichlorosilane propyl bromide, the ensuing reactions (Figure 16) to tether the chiral organometallic entities being effected through the bromine atom.

When certain kinds of organometallic, chiral catalysts are tethered to the inner walls of the mesoporous silica, it follows that the reactant's (substrate) interaction with both the pore walls and the chiral directing group will be distinct from the interaction it would experience if the chiral catalysts were free (as in the case of a homogeneous catalyst). The confinement of the reactant within the mesopore will lead to a larger influence of the chiral directing group on the orientation of the substrate relative to the reactive catalytic center when compared with the situation in solution. The validity of this strategic principle has been multiply attested in our work[44,57]—see, for example, our reports on allylic amination[60] (of cinnamyl acetate and benzylamine) and on several instances of hydrogenation[44,61]—specific examples are cited later.

The reality of how tethering an asymmetric catalyst at a concave surface boosts the resulting enantioselectivity is
Figure 15. Sequence of steps illustrating how the exterior surface of the mesoporous silica support is rendered inactive and hydrophobic by the attachment of covalently bound Si(Ph)$_2$ groups.[49] Only the silanol groups at the inner surfaces are implicated in the support of the nano-particles (compare Figure 12).

summarized in Figure 17 (see page 6468), where the results of a particular hydrogenation (of (E)-α-phenylcinnamic acid) are compared for the same catalyst (Rh[I]-(S)-(−)-2-aminomethyl-1-ethyl pyrrolidine) tethered in the one case on a concave, and in another on a convex silica.

It is clear that the catalytic performance is enhanced using a concave silica support. We have also shown[44] that non-covalent attachment of the asymmetric catalyst as shown in Figure 18 (i.e. using hydrogen bonding and not covalent bonding; see page 6468) in the manner of Bianchini et al.[42] and de Rege et al.[46] is an effective method of generating well-defined, isolated, and readily accessible single-site active centers for enantioselective conversions (Scheme 3 and Figure 18).

The convenience of using noncovalently tethered chiral organometallic catalysts in the production of fine chemicals and pharmaceuticals has obvious practical merit.[62]

5. Single-Site, "Ship-in-Bottle" Catalysts

Zeolitic supports for so-called "ship-in-bottle" catalysts of the types used by Herron,[63] Raja and Ratnasamy,[64,65]
Figure 16. Two distinct approaches may be used to introduce an anchored chiral (asymmetric) organometallic inside the mesopores.[49]

Vasudevan,[66] Bäckvall,[67] and Jacobs[68] and exemplified in Figure 19 (see page 6469) have long been entertained as being important in situations where it is necessary to prevent an active site entity, such as a metalloporphyrin or metal-molecular complex, from losing its intrinsic catalytic performance because of dimerization or other complicating side-reactions. Such encapsulated catalysts, which are single site, also allow access of only those reactant molecules small enough to diffuse through the windows of the zeolitic cage, and prevent any of those products, which, if formed, are too large, from leaving the reaction environment. In general, however, it is preservation of the single-site (isolated state) catalytic activity that is of paramount importance.

These catalysts, frequently termed zeozymes or enzyme mimics, have yielded encouraging and patentable results in oxyfunctionalizing methane to methanol[64] and propane to isopropanol[65] using oxygen as the oxidant and copper hexadecachlorophthalocyanine ($CuCl_{16}Pc$) as the single-site active center. Because the zeolitic cage distorts the flat $CuCl_{16}Pc$ into a shallow bowl, the latter creates a hydrophobic environment[66] around the central metal atom, thereby boosting catalytic activity.

Jacobs et al.[69] encapsulated *cis*-[Mn(bpy)$_2$]$^{2+}$ complexes (bpy = bipyridine) within the micropores of zeolite Y and used the resulting catalyst for the epoxidation of alkenes with H_2O_2. These reactions proceeded without complications of competing processes, such as the decomposition of the peroxide. High yields of the epoxides of hex-1-ene, cyclo-hexene, dodec-1-ene, and cyclododecene were obtained.

These catalysts are quite robust, and may be repeatedly re-used without loss of activity. Electronic factors are thought to play a key role in the performance of the encapsulated *cis*-[Mn(bpy)$_2$]$^{2+}$,[69] it being argued that the H_2O_2 activates the Mn ions so as to produce a Mn^{IV}=O group, which releases its oxygen in the critical act of addition across the double bond to form the epoxide. Bein et al.[70] also used a "ship-in-bottle" alkene epoxidation catalyst formed inside the cages of zeolite Y when extraframework Mn^{II} cations were complexed with a trimethyl triazocyclononane ligand (tmtacn), the role of the methyl groups being chiefly to protect the amine against oxidation by H_2O_2. In situ ESR measurements show that the catalytically active site is a Mn^{III}-Mn^{IV} dinuclear complex.

The great practical advantages of "ship-in-bottle" SSHC are well illustrated in the recent work of Bäckvall et al.[67] on ruthenium-catalyzed aerobic oxidation of alcohols (where encapsulated cobalt Salophen was the active, single-site catalyst: H$_2$Salophen = 2,2′-[benzene-1,2-diil bis(nitrilomethylidyne)]diphenol. Apart from highlighting the usual advantages of being able to remove and re-use the "ship-in-bottle" catalyst by simple filtration, these workers showed that this SSH catalyst had a higher specific rate than the homogeneous analogue. Moreover the zeolite (bottle) serves as a water acceptor, so that there is no necessity to introduce a separate one, and the zeolite also exhibits shape-selectivity in the oxidation of secondary alcohols.

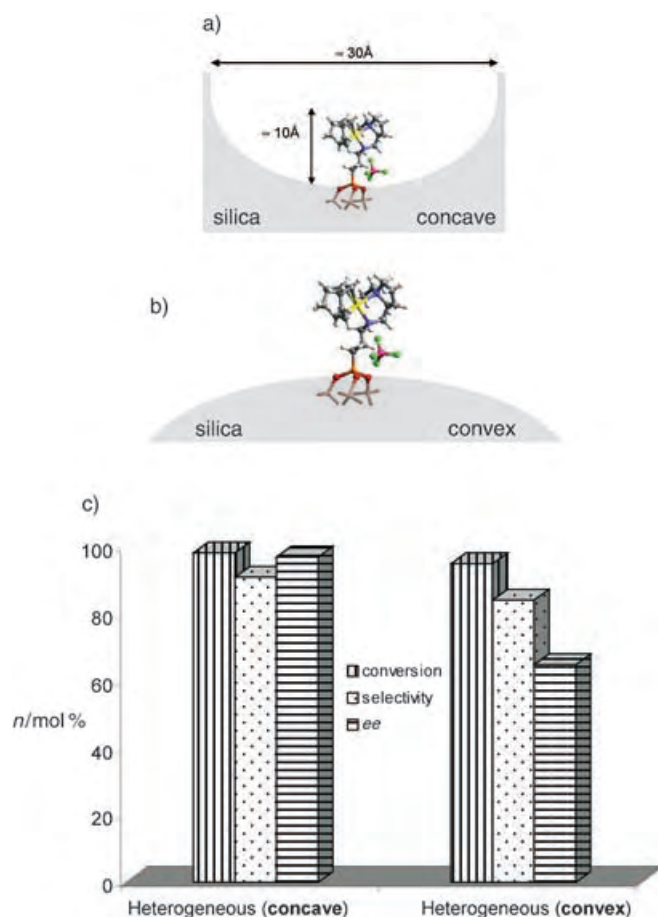
Although not strictly an example of "ship-in-bottle" catalysis in the sense described above, the recent ingenious


Figure 17. Illustration (to scale) of how a spatial constraint is imposed on the asymmetric catalyst when it is anchored at a) a concave surface in contrast to the situation when anchored at a b) convex one. c) The catalytic performance (selectivity and *ee* value in the hydrogenation of *E*-(α)-phenylcinnamic acid) of an asymmetric catalyst is greater in the spatially constrained (a) than in the less constrained (b).[57]
Scheme 3.

strategy adopted by Strukul et al.,[70b] in which they "micro-encapsulate" the enzyme chloroperoxidase within a microporous cage of silica gel, conforms to the principle of site isolation and single-site catalysis. Such catalysts are effective in the enantioselective oxidation of sulfides to sulfoxides with H_2O_2.

6. Single-Site, Open-Structure Solid Catalysts

Unlike bulk metal, alloy, and other binary continuous solid catalysts, the open-structure aluminosilicates (embrac-
Figure 18. A triflate counterion, which is strongly hydrogen bonded to the silanol groups of the silica, holds securely (by ionic forces) the chiral organometallic Rh^I-based cation.[44]

ing natural and synthetic zeolites) as well as open-structure aluminophosphates (AlPOs), particularly framework-substituted variants (MAlPOs where M = Mg, Co, Mn, Zn,…) are prime examples of uniform heterogeneous catalysts. Because the active sites in these catalysts are distributed in a spatially isolated and uniform manner[12] they conform to Langmuir's classic assumption in that the energy released upon the uptake of adsorbate species is constant up to monolayer coverage. This energetic uniformity is seen vividly in the calorimetric work[71] shown in Figure 20 (see page 6470), where there is essentially a constant enthalpy of adsorption of pyridine on the Brønsted acid sites of the so-called pentasil zeolite H-ZSM-5 up until all the sites are neutralized (i.e. up to monolayer coverage of the catalytically active acid centers).

In zeolitic and MAlPO catalysts, the Brønsted active sites, which may be represented as ≡Si−O(H)−Al≡ and ≡M^{II}−O(H)−P≡, respectively, are so far apart spatially—and the higher the Si/Al ratio in the acidic zeolite, $H_xSi_{n-x}Al_xO_{2n}$, or the higher the P/M^{II} ratio in the acidic MAlPO the further apart they are—that they are essentially isolated within the molecular sieve structure, thereby behaving as SSHC as defined in Section 1. An illustration of the nature of the "isolated" Brønsted acid sites of the efficient methanol-dehydration catalyst (to produce light olefins) Co^{II}AlPO-18 is shown in Figure 21 (see page 6470).[72] Also shown in Figure 21 is the isolated "redox" active site generated when the Co^{II} has been converted into the higher oxidation state, Co^{III}. The respective Co−O bond lengths of the acid and redox active centers were determined under in situ conditions by X-ray absorption spectroscopy (XAFS).[28,72]

In the family of single-site acid catalysts MAlPO-18 (M = Co^{II}, Mg^{II}, Zn^{II}, Mn^{II}, …), which shape-selectively convert methanol into light olefins, ethene, propene and traces of butene,[73] the active sites are the protons loosely attached to the oxygen atoms adjacent to the doubly charged M^{II} ions. These metal ions occupy a controllable small percentage (up to about 4 mol%) of the sites normally occupied by framework Al^{III} ions. Likewise, when the transition-metal-ion is raised to a higher oxidation state (e.g.Co^{II}→Co^{III}), the "redox" active centers, which are efficient[74,75] in activating C−H bonds in the presence of molecular oxygen, are again essentially isolated (as borne out by the XAFS data) and

Cu		O	
Al		C	
Si		H	

Figure 19. Views of three examples of "ship-in-bottle" SSHC. a) Pictorial representation of the Co(Salen) adduct inside the supercage of zeolite Y. The complex as its pyridine adduct shows affinity for dioxygen; light blue Co, dark blue N, red O.[63] b) Cobalt phthalocyanine housed within zeolite Y. Owing to spatial restrictions, the guest molecule is distorted, thereby increasing its reactivity and hydrophobicity (from ref. [66]). c) The dimer of copper acetate (in a compressed state with the Cu–Cu distance significantly reduced from its normal value) housed within zeolite Y.[64, 65]

therefore are, by definition, a clear-cut example of SSHC (Figure 22).

The widely used selective oxidation catalyst TS-1,[76] in which some of the silicon atoms that occupy the tetrahedral sites in the siliceous analogue of ZSM-5 are isomorphously replaced by Ti^{IV} ions, is another archetypal example of a SSHC. So also is the (Fe)ZSM-5 catalyst that, in the hands of Panov et al.,[77] has been developed for the selective oxidation of aromatics such as benzene. (In Section 7, we discuss the mechanistic features of TS-1 in the light of the performance of a Ti^{IV}-centered catalyst belonging to category D of Table 1).

6.1. Bifunctional Single-Site Open-Structure Catalysts

Whereas homogeneous catalysts are seldom bifunctional—a recent, unusual example involving allosteric regulation has, however, been reported[78]—it is feasible to design single-site, open-structure catalysts in which a Brønsted acidic site is well-separated from a redox site in a shape-selective nanoporous matrix. The case in question involves[13] another aluminophosphate matrix, known as MAlPO-36, which Raja et al.,[79] were able to modify so as to create both strong Brønsted acid sites (loosely attached protons) adjacent to M^{II} ions such as Mg^{II} or Co^{II} as well as strong redox sites (where Al^{III} is replaced by Co^{III}). Such a catalyst designated $M^{II}M^{III}AlPO$-36 performs well in converting cyclohexanone into its oxime and then into ε-caprolactam in the presence of O_2 and ammonia (Scheme 4).

This sequence of consecutive conversions occurs freely because (see Figure 23, see page 6471): a) hydroxylamine (NH_2OH) is readily formed in situ inside the pores from NH_3 and O_2 at the M^{III} active sites; b) the NH_2OH converts cyclohexanone (**9**) into cyclohexanone oxime (**10**) both inside and outside the pores of the catalyst; and c) likewise, at the Brønsted acid sites **10** isomerizes to ε-caprolactam (**11**) inside the pores of the molecular sieve catalyst.

Recent work[80] in which a systematic variation of the strength of the isolated Brønsted acid sites was introduced (by, for example, keeping a fixed redox site (Co^{III}) and vice versa (keeping a fixed acid site and changing the redox site) has led to a viable industrial method of producing ε-caprolactam, see ref. [148].

6.2. Open-Structure Chiral SSHC

It has not yet proved possible to prepare an open-structure, synthetic zeolite or open-structure MAlPO solid

Figure 20. a) High-resolution electron micrograph of H⁺-ZSM-5 (Si:Al ratio approximately 25:1) inset: computed image. b) Scalar model of the H⁺-ZSM-5 open-structure, showing the isolated Brønsted acid sites (loosely attached hydrogen atoms adjacent to Al^{III} sites). c) The heat of adsorption of pyridine remains essentially constant until all the (single-site) acidic centers are neutralized.[71]
Figure 21. Left: in the open-structure aluminophosphate (AlPO-18) some of the Al^{III} framework ions have been replaced by cobalt ions in a spatially uniform fashion. In the resulting single-site catalyst, Co^{II}AlPO-18, there is Brønsted activity. Right: in the oxidized state Co^{III}AlPO-18 there is redox activity. The bond lengths were determined by in situ XAFS.[72]

Figure 22. a) The Brønsted acidic sites in the open-structure AlPO-18 solid are the loosely attached protons adjacent either to Co^{II} ions that have replaced Al^{III} framework ions or Si^{IV} ions that have replaced P^{V} ions. CoAlPO-18 is a powerful shape-selective dehydration catalyst which converts methanol (top left) into a mixture of ethene and propene (bottom right), just as DAF-4 does.[73b] b) M^{III}AlPO-18 (M^{III} = Mn^{III}, Co^{III}) is a regioselective oxidation catalyst that, in air or O₂, preferentially oxyfunctionalizes the terminal methyl group, as shown for *n*-dodecane.[74]

which possesses intrinsic chirality. It has, however, been possible, as first demonstrated by Hutchings et al.,[58,81] to modify the supercage of an acidic zeolite catalyst (H-Y) so as to create the chiral environment required to favor the formation of one of a pair of diastereoisomeric transition states, which is a necessary condition for enantioselective

conversion. Full details have been given by Hutchings in an earlier review.[58] In essence, by adding a chiral agent (either *R* or *S*) 1,3-dithiane-1-oxide to a zeolite H-Y that has been mildly de-aluminated, a well-defined single-site (Figure 24, left) active center is created which, kinetically enantioselectively resolves (in a gas-phase, acid catalyzed dehydration) racemic butan-2-ol. Hutchings et al.,[82] have also succeeded to effect enantioselective aziridination of alkenes (employing [*N*-(*p*-tolylsulfonyl)imino] phenyliodinane {PhI=NTs}) as the
Scheme 4.
Figure 23. Left: In $M^{II}M^{III}AlPO-36$ (M = Co, Mn), the framework M^{III} ions are the redox-active centers (A_1), whereas the $M^{II}OH$ ions that have ionizable O—H bonds are the Brønsted (B_1) acid sites. Mg^{II} ions in the framework also have neighboring ionizable OH ions (the B_2 sites). Right: In $M^{III}AlPO-18$ all the framework M^{III} ions are again redox active centers: there are no Co^{II} (or Mn^{II}) framework sites. Mg^{II} framework ions again have neighboring (B_2) Brønsted sites.[79]
Figure 24. Left: Isolated active site for the enantioselective dehydration of butan-2-ol catalyzed by zeolite Y that has been premodified with bound dithiane oxide.[58] Right: Aziridination of alkenes using CuHY as catalyst.[58]

nitrogen source, with a single-site Cu^{II}-exchanged zeolite H-Y (see Figure 24, right).

7. A Selection of Examples Illustrating Practical Applications of SSHC

In addition to the examples that have been cited earlier in the description of various categories (summarized in Table 1) of SSHC, we illustrate below further instances encompassing both laboratory (research) scale and industrially used solid catalysts where the single-site active centers are uniformly

distributed, in a spatial sense, over the two-dimensional or three-dimensional surfaces in question. Many of the examples highlighted are of particular value in the general quest for clean technology and green chemistry, with several instances in which the catalysts themselves are environmentally benign and the reactions that they facilitate (involving, for example, oxygen or air instead of nitric acid as an oxidant) even more so.

We shall also illustrate how, 1) recent computational chemical procedures, combined with in situ experimental studies of single-site catalysts, enable us to establish the mechanism of the Ti^{IV}-centered catalytic epoxidation of alkenes and, 2) using functionalized silsesquioxane fragments, direct measurements of catalytic performance may be made of the same active site in both homogeneous and heterogeneous situations.

7.1. Enzyme Mimics

The analogy between the mode of action of enzymes on the one hand, and molecular sieve (open-structure) as well as "ship-in-bottle" catalysts on the other hand has frequently been drawn.[83–87] In each case, cavities in the catalysts impose shape-selectivity that governs the "choice" of reactant species which is to be transformed, and the molecular complementarity and associated factors of the microenvironment at the active site facilitates ensuing chemical conversion. In designing inorganic enzyme mimics,[88–90] the key targets are high activity coupled with high selectivity and an ability to function at ambient temperatures and pressures. In general, inorganic enzyme mimics are thermally and mechanically stable, robust, and are usually readily capable of being regenerated when (through "poisoning" of active sites, for example) their performance diminishes. Moreover, because much is now known about ways of designing the molecular dimensions,[91,92] degree of hydrophobicity,[66] and other features of open-structure inorganic catalysts, genuine inorganic mimics of certain enzymes may be prepared. In addition, a range of highly refined techniques has been evolved to probe, under operating conditions,[13,14,93,94] the behavior of reactant species and the active sites inside the cavities of open-structure inorganic solids.

7.1.1. A Tyrosinase Mimic

Copper-containing monooxygenase enzymes, such as tyrosinase (EC 1.14.18.1) reversibly bind O_2 and catalyze two different reactions—the hydroxylation of monophenols to *ortho*-diphenols (monophenolase activity) and the oxidation of the *ortho*-diphenols to *ortho*-quinones (diphenolase activity) using molecular oxygen as the oxidant. The active site contains a pair of antiferromagnetically coupled copper ions. Even though several homogeneous models of tyrosinase have been proposed, none of them actually catalyzes the conversion of L-tyrosine into L-DOPA (the reaction the enzyme catalyzes), nor has a heterogeneous solid mimic of tyrosinase been reported to date. Raja and Ratnasamy[95,96] have shown that dimeric copper acetate complexes, encapsu-

lated within the microcavities of porous solids (zeolites X, Y, and MCM-22), were effective in converting L-tyrosine into L-DOPA in air (Scheme 5). The catalysts (enzyme mimics) also displayed high substrate specificity (only monophenols were
Scheme 5.

oxidized) and regioselectivity (hydroxylation always occurred at the position *ortho* to the -OH group). A linear correlation was obtained between the concentration of the encapsulated copper acetate dimers (estimated from the integrated intensity of the seven-line ESR spectra) and monophenol conversion, suggesting that these copper acetate dimers are the active sites in the activation of dioxygen.[95] The turnover frequencies for the encapsulated catalysts are higher than their free analogues, suggesting that these copper dimers are well-isolated in the molecular sieve matrix.

7.1.2. Methane Monooxygenase Mimic

Methane monooxygenases are a group of enzymes (molecular mass ca. 300 kD) extractable from methanotropic bacteria. These enzymes are able to hydroxylate methane to yield methanol, an extremely valuable commodity chemical (produced mainly on an industrial scale by steam-reforming of natural gas). Raja and Ratnasamy[64] have shown that "ship-in-bottle" SSHC, consisting of encapsulated complexes of iron and copper phthalocyanine (see Figure 19) in which all or most of the hydrogen atoms have been replaced by electron-withdrawing substituents (halogens or nitro groups) may convert methane in air at 273 K to methanol and formaldehyde as principal products (Scheme 6). The role of
Scheme 6.

the solvent (acetonitrile) is quite important in this conversion, but detrimental to the commercial exploitation of this technology.

7.1.3. Haloperoxidase Mimic

Haloperoxidases, which occur widely in marine organisms, are enzymes which catalyze the oxidation of a halide (Cl$^-$,

Br$^-$, or I$^-$), by hydrogen peroxide, in such as manner as to achieve concomitant halogenation of certain organic substrates. However, in the absence of organic substrates these enzymes convert the halide ions into the molecular halogen (see Scheme 7).[97]
Scheme 7.

[CuCl$_{16}$Pc] complexes, encapsulated within the supercages of zeolites X and Y, are effective for the oxychlorination and oxybromination of a wide range of aromatic compounds, at ambient conditions, using molecular oxygen as the oxidant, in the presence of a suitable alkali halide, such as KBr (Table 2).

Table 2: Oxyhalogenation of aromatic compounds in air using CuCl$_{16}$Pc-Na-X and KBr.[a]

Substrate	T [K]	Conv. [%]	Halogenated products [wt. %]			
			Mono	Di	Tri	Side-chain oxidation
Benzene	338	6.2	100	–	–	–
Toluene	338	16.8	69.5	5.5	–	25.0
Phenol	323	18.1	62.0	25.0	13.0	–
Aniline	338	10.3	63.0	15.5	21.5	–
Anisole	338	6.7	25.5	55.0	19.5	–
Resorcinol	323	18.2	100	–	–	–

[a] Reaction conditions: Catalyst 0.5 g, $t = 10$ h, halide = KBr, air over pressure = 400 psi (1 psi $\approx 6.8 \times 10^{-2}$ atm), solvent CH$_3$CN:H$_2$O 2:1 mol%, Initiator 2 mol% *tert*-butyl hydroperoxide.

The encapsulation of the [CuCl$_{16}$Pc] complex results in *ortho-para* substitution among the halogenated products with virtually no attack at the *meta*-position. Further, the in situ formation of Br$_2$ from KBr (established by spectroscopic methods), and, the pH dependence of the catalytic activity, suggests that the halogenating agent is an electrophilic species.[97, 98]

7.1.4. Hydroxylases

By virtue of their ability selectively to bind a linear alkane and to so orient it with respect to the active oxidant at the active site, the so-called ω-hydroxylases can achieve the remarkable regioselective hydroxylation of terminal methyl groups. Herron and Tolman[99] made significant progress in designing a completely inorganic mimic of the alkane ω-hydroxylases by using encapsulated Pd^0 and Fe^{II} entities inside zeolite A. This "ship-in-bottle" design succeeds in producing hydrogen peroxide from an O$_2$/H$_2$ mixture, but they were unable selectively to functionalize only the terminal methyl group of *n*-octane with this catalyst. Open-structure SSHC (such as M^{III}AlPO-18 where M = Co or Mn) are, however, very effective[74, 75, 100] in preferentially hydroxylating

the terminal methyl groups of linear alkanes (C_nH_{2n+2}, $n = 6$–12) in air or oxygen (see Figure 22 b). Indeed it is also possible with this category of SSHC, provided the degree of substitution of framework Al^{III} ions by M^{III} ions (Co or Mn) is large enough (ca. 10 atom percent), to convert *n*-hexane into adipic acid in air under mild conditions (Scheme 8).[101]

7.2. SSHC for Sustainable Development and Clean Technology

Selective hydrogenation as well as selective oxidation catalysis nowadays loom progressively larger in the general area of clean (green) chemistry and sustainable development.[102, 103]

7.2.1. Solvent-Free Selective Hydrogenation Reactions as Candidates for the Production of Commodity Chemicals

The drive to minimize the use of volatile solvents or replace them with environmentally more benign ones (such as supercritical CO_2) has, as its logical conclusion, the development of catalysts that may effect conversions in a solvent-free

manner.[45, 49] Table 3 enumerates many of the selective hydrogenation processes, leading to much-used commodity chemicals, that are catalyzed by single-site, multinuclear bimetallic nanoparticles. (Note that the turnover frequencies (TOFs) are exceptionally high under relatively mild conditions of temperature and pressure). The selective hydrogenation of benzene to cyclohexene is particularly noteworthy as it opens up a new, environmentally benign route to adipic acid that dispenses with the need to use concentrated nitric acid as an oxidant (and the consequential production of massive quantities the greenhouse gas, N_2O). Cyclohexene, with the "right" catalyst is converted into adipic acid using H_2O_2 as oxidant.[104, 105]

7.2.2. Adipic Acid from Sustainable Sources by Using a Single-Site Supported $Ru_{10}Pt_2$ Nanoparticle Catalyst

With the aid of biocatalysts, muconic acid may be readily produced[106a] from corn, a renewable feedstock. We have discovered[106b] that a single-site $Ru_{10}Pt_2$ multinuclear nanoparticle catalyst supported on mesoporous silica is superior to a variety of comparable catalysts (e.g. Rh/Al_2O_3, Pt/SiO_2, Pd_6Ru_6/SiO_2) in converting muconic acid, in a single-step into adipic acid (see Scheme 9).[106b]

7.2.3. Commercially and Environmentally Important Selective Oxidation Processes that may be Effected by SSHC

A selection of the important selective oxidations that may be effected by a range of isolated (single-site) transition-metal ions grafted into mesoporous silica is shown in Figure 25.[31,33,35,107] The reagents used for the selective oxidations vary according to the reaction and the catalyst in question. Sometimes H_2O_2 is the oxidant,[108] sometimes alkyl hydroperoxides[109] (such as *tert*-butyl hydroperoxide, TBHP) and occasionally oxygen itself (as in the case of the oxidative dehydrogenation of methanol to formaldehyde).

Table 3: Single-step, highly active and selective nanoparticle catalysts for the solvent-free hydrogenation of polyenes.

Catalyst	Reaction	t [h]	TOF [h^{-1}]	Commercial significance
Pd_6Ru_6/SiO_2		8	2012	Polymer intermediates, ketones, and polyesters

$Ru_{10}Pt_2/SiO_2$		6	1790	
Pd_6Ru_6/SiO_2		6	3216	

Epoxidation of alkenes with Ti/SiO$_2$ catalysts is of major industrial importance in the production of fine chemicals and several other commodities.[110] For example, the catalytic conversion of propylene into propylene oxide over Ti/SiO$_2$ in the presence of alkyl hydroperoxides is an industrially important epoxidation process that accounts for an annual production of more than one million tons of propylene oxide world wide. As a result of recent research work,[111,112] there are now real prospects that (renewable) vegetable oils and fats, which are good sources for two widely used unsaturated fatty methyl esters—methyl-(Z)-9-octadecanoate (methyl oleate (**12**)) and methyl-(E)-9-octadecanoate (methyl elaidate (**13**))—may be benignly epoxidized with TBHP using a silica (single-site) catalyst containing Ti^{IV} centers (Figure 26).

In the past, an environmentally unfriendly "peracid" method was used to epoxidize the naturally occurring compounds. Ravasio et al.[112] have also shown that the Ti^{IV}-center single-site catalyst also effectively converts the doubly unsaturated components of soya bean oil into useful epoxides— another important step towards sustainable development.

Ravasio et al.[112] have also shown that the Ti^{IV}-ion SSHC (on silica) is particularly good in epoxidizing terpenes such as

α-terpineol, carveol, and limonene under mild conditions (Table 4).

7.2.4. Other Economically Important Examples of Ti^{IV}-Catalyzed (Single-Site) Selective Oxidations

The open-structure microporous silica known as MFI (the accepted international notation for the framework ZSM-5),[113] when it contains isolated Ti^{IV} ions replacing some of the Si^{IV} tetrahedral sites is known as TS-1, and is an exceptionally good single-site heterogeneous selective oxidation catalyst.[114] Some key processes using H$_2$O$_2$ as oxidant are indicated in Scheme 10.

7.2.5. Mechanism and Energetics of Epoxidation and Comparison between the Heterogeneous and Homogeneous Processes.

Figure 27 shows the kinship that exists between the four-coordinate Ti^{IV} active site for both the corresponding microporous and mesoporous silica frameworks.[115] Using a joint experimental (X-ray absorption) and computational study, in the course of which we could directly probe the environment
Figure 25. Illustration of some of the selective oxidations that may be effected by SSHC formed by anchoring various M^{n+} ions at the surfaces of mesoporous silica.
Figure 26. Both methyl oleate (**12**) and methyl elaidate (**13**) are completely epoxidized using single-site Ti^{IV}-mesoporous silica catalysts and *tert*-butyl hydroperoxide (**14**) as oxidant.[111]

Table 4: Epoxidation of terpenes using Ti^{IV} SSHC on silica[112] under mild conditions.[a]

Substrate	TOF [h^{-1}]	
	Ti$\rightarrow$	Ti$\uparrow$
α-terpineol	2	20
carveol	15	33
limonene	4	20

[a] $T = 85\,°C$; CH$_3$CN (solvent); 30% wt catalyst; TBHP:terpene mol ratio = 1:1. Ti$\rightarrow$ indicates Ti^{IV} ions grafted in (and parallel to) the silica surface and Ti$\uparrow$ Ti^{IV} ions grafted perpendicular to the surface.
Scheme 10.

of the active Ti^{IV} center under steady-state conditions during the actual epoxidation, we could arrive at the pathway and associated energetics for the mechanism of the epoxidation. These are shown in Figure 28.

Coordination of the oxygen atoms of the peroxide to the Ti^{IV} center activates them by increasing their electrophilicity; and the computations reveal that the oxygen atoms may be readily abstracted by the nucleophilic alkenes to form the epoxides. As shown in Figure 28, subsequent loss of the water regenerates the original tripodal (four-coordinate) Ti^{IV} active center. In line with this mechanism, which harmonizes with the independent work of Roesky et al.[116] (on the formation of titanium alkylhydroperoxide), it is not surprising that when
Figure 27. Left: TS-1, a single-site, open-structure selective oxidation catalyst (see Scheme 11) that has the same framework structure as H-ZSM-5 (see Figure 20), except that there are no Al^{III} ions in the framework, only isolated Ti^{IV} sites substitutionally replacing the Si^{IV} centers. Right: The tripodally anchored Ti^{IV} redox sites in a Ti-SiO$_2$ epoxidation catalyst (see Section 7.2.3) in mesoporous silica (compare Figure 5) are very similar to the Ti^{IV} active centers in TS-1.[115]

one of the three silicon atoms, to which, through oxygen, the Ti^{IV} site is attached, is replaced by germanium, there is an increase in the rate of epoxidation.[117]

Experiments with soluble, molecular (homogeneous) analogues of the heterogeneous Ti/SiO$_2$ epoxidation catalyst using the silsesquioxanes: [(c-C$_5$H$_9$)$_7$Si$_7$O$_{12}$TiOXPh$_3$], where X = Si, Ge, or Sn—in which XAFS and kinetic measurements could be carried out in solution—not only confirm that replacement of Si by Ge (or Sn) at the active site enhances the rate of epoxidation, they also show that the turnover frequencies for the "hetero" and "homo" active sites are numerically similar.[117]

7.3. In Situ Generation of Hazardous Reagents by Using Open-Structure SSHC

The in situ production and containment of aggressive and hazardous reagents (as well as the avoidance of the use of ecologically harmful ones) has been much assisted by the design of appropriate open-structure SSHC, such as those consisting of metal-ion-framework-substituted aluminophosphates, MAlPOs (see Section 6). A range of such nanoporous catalysts designed by us has been described previously.[13,100,118] We give two specific examples here: 1) a Baeyer–Villiger process (for the conversion of cyclic ketones to lactones; and 2) the generation of hydroxylamine in the intrapore cavities and channels of bifunctional SSHC (Scheme 11).

In (1), the aggressive permonosulfuric acid (used by Baeyer and Villiger) or methyl rhenium trioxide or any added peroxide is avoided and O$_2$ is used in the presence of (a sacrificial) benzaldehyde (Scheme 11).[119] In (2), ammonia and oxygen generate hydroxylamine at the redox active sites of the bifunctional catalyst (Scheme 12).

The convenience of having a bifunctional open-structure SSHC, such as that shown in Figure 23, commends itself commercially, since this is an extremely direct way of
Figure 28. Catalytic cycle, including calculated energies for the epoxidation of alkenes by catalysts with Ti^{IV} centers. At the right are the observed and calculated radial distribution curve and X-ray absorption spectrum.[115b]
Scheme 11.

generating cyclohexanone oxime, and its isomer, ε-caprolactam, which, on polymerization, yields nylon.[120]

Another example where SSHC has proved valuable is that of the enzyme mimic for haloperoxidase, described in Section 7.1.3. With such a catalyst, the need to add neat halogen to the sphere of reaction is dispensed with.

7.4. Enantioselective Conversions with SSHC

There is an ever-growing need for high-performance, heterogeneous, recyclable asymmetric catalysts, because, as with other areas of catalytic conversion[121] they should surpass their homogeneous analogues so far as the important practical consideration of separation of products is con-

cerned. Of late, many new strategies have been proposed to accelerate the arrival of reliable, robust heterogeneous asymmetric catalysts, and a recent monograph[56] along with other publications[62,122,123] outline various possible strategies for "imprinting" a surface with chirality.

We have already alluded to the ingenious method of Hutchings et al.,[58] who, in turn, refer to the elegant work of Bianchini[42,124] and others especially that of Corma and Garcia[125] and Xiang et al.[126] (who successfully immobilized the Sharpless titanium diethyltartrate system). Herein, for illustrative purposes, we focus on Jacobs's work on the coordination of {Cr^{III}(Salen)} complexes on functionalized silica for the asymmetric ring opening (ARO) of epoxides[127a] and on that of Maschmeyer and Sheldon[127b] on the use of single-site, immobilized [Rh-(MonoPhos)] (MonoPhos is a chiral monodentate ligand). We also summarize the practical advantages of our own approach[43–45,57] to designing constrained (single-site) chiral catalysts.

The heterogeneous ARO of *meso*-epoxides with trimethylsilylazide (TMSN$_3$) catalyzed by a {Cr^{III}-(Salen)} moiety coordinated to an aminopropyl-functionalized (high-area) silica combines good enantioselectivity with high conversions and no tendency for the catalyst to be leached off its support. Thus, in the ring-opening of cyclohexene oxide, under the conditions given in Table 5, conversions are always in excess of 99 % and *ee* values range (in ten successive runs to test leachability) from a low of 65 to a high of 77 %.

Feringa and his colleagues demonstrated[127c] that rhodium complexes with chiral monodentate ligands such as phosphoramidites (MonoPhos) are very powerful tools for reduction, and that homogeneous catalysts based on these ligands are highly enantioselective. Using the specially prepared mesoporous silica known as TUD-1,[127b] into the framework of which isolated Al^{III} ions have replaced some Si^{IV} ions
Scheme 12.

Table 5: Asymmetric ring opening of cyclohexene oxide in the presence of supported catalytically active Cr^{III}(Salen).

2	18	100	67.9	0.8
3	18	100	68.7	0.5
4	18	100	73.3	1.0
5	19	99.3	73.1	1.0

(thereby producing a high-area solid designated AlTUD-1), Maschmeyer, Simons, and co-workers showed that ionically bound Rh-phosphoramidite exhibited excellent enantioselectivity in the asymmetric hydrogenation of methyl-2-acetamidoacrylate (Scheme 13).[127b] The ionic binding procedure of Rege et al.,[46] also used by us,[44] is a rapid, convenient method of generating highly efficient, robust, and recyclable SSHC for enantioselective hydrogenations that may be carried out using water as solvent.
Scheme 13.

So far as the use of our own approach to constrained chiral catalysis is concerned, we emphasize that highly efficient enantioselective hydrogenations, of prochiral molecules that yield products of considerable commercial significance, have been achieved. The following advances have been reported:

1. Two distinct metal centers (Rh^I and Pd^{II}).
2. Three distinct diamino ligands (see Table 6).
3. Two methods of producing the single-site (covalent and ionic) immobilized organometallic centers.
4. Two specific examples of hydrogenation reactions.

The relevant catalytic activities, selectivities, and enantiomeric excesses (*ee* values) for the various homogeneous and heterogeneous Rh^I catalysts are summarized in Table 6 for the asymmetric hydrogenation of methylbenzoylformate (MBF); and the corresponding catalytic performance for the Pd^{II}-based asymmetric catalysts for the hydrogenation of both *E*-(α)-phenylcinnamic acid (PCA) and MBF are shown in Table 7. Several patents,[128–130] based on these constrained, single-site, asymmetric heterogeneous catalysts, have been recently filed by German industry (on behalf of the Inventors).

7.5. Some Miscellaneous Examples

Already in this Review we have cited a number of important examples where single-site, open-structure heterogeneous catalysts hold sway. The majority of zeolites (as well as the growing number of metal-substituted aluminophosphates) used in industry have isolated, single-site active centers. They catalyze a large number of commercially important reactions and also offer ideal testing grounds for fundamental studies. Both these facets are dealt with in Section 7.5.1. In Sections 7.5.2, 7.5.3, and 7.5.4 potential large-scale operations involving hydroformylation, metathesis, and polymerization are outlined.

7.5.1. Solid Acid Catalysts

In all so-called pentasil[83] zeolites (e.g. ZSM-5 and ZSM-11) where the Si:Al ratios are seldom less than 10:1 and often much in excess of this, and in numerous other aluminosilicate and aluminophosphate open-structure solids (such as faujasite (zeolite Y), ferrierite, erionite, and SAPO-34), a huge variety of (Brønsted) acid-catalyzed reactions may be carried out. Several Reviews[131–135] of this vital class of reactions, that embrace both the petrochemical and fine-chemical world, are already available. Table 8 lists some of these reactions.

7.5.1.1. Shape-Selective, Solid-Acid, Single-Site Zeolitic Catalysts and Their Kinship with Enzymes

As mentioned in Section 7.1, the analogy between the mode of action of an enzyme on the one hand and a "ship-in-

[a] The reactions were carried out for 24 h for PCA and 2 h for MBF (see Table 6 for reaction conditions).

Table 8: A summary of the economically significant catalytic conversions effected by single-site, open-structure aluminosilicate and aluminophosphate (zeolitic) solids.[133]

Hydrocarbons produced (sometimes shape-selectively) from acid-catalyzed reactions
Ethyl benzene from benzene and ethene
Xylenes from isomerizations and disproportionation of toluene
Methanol to olefins and methanol to gasoline
Cumene from benzene plus propene
Oligomerization of olefins
Detergent alkylate from benzene plus C_6 to C_{14} olefins
Aromatics from acetylene
Isomerization of methyl naphthalenes
Vinylcyclohexene from butadiene by dimerization

Reactions involving functionalized hydrocarbons
Alkylation of phenol
Ester hydrolysis
Chlorination of chlorobenzene
Alkyl carboxylates from carboxylic acids and olefins
Primary amines from ammonia and olefin
Secondary amines by elimination of ammonia from primary amine
Glycol ethers by ethoxylation of lower aliphatic alcohols
Nitration of chlorobenzene[137,138]

one (HMB)[89] over a H[+] form of (synthetic) ferrierite (Si:Al ratio of 40:1) yields only one product, whereas HMB in acidic solution generates a wide variety of products (Scheme 14a).

Likewise, acetaldehyde[90] is catalytically transformed in acidic solution to a broad distribution of products, whereas within the space-restricting cages of H[+] ferrierite cyclotrimerization occurs with 100% selectivity at ambient temperature (Scheme 14b).

7.5.2. Hydroformylations, Metathesis, and Polymerization Reactions Using SSHC Assembled from Anchored Organometallic Species[134, 136, 139]

Bianchini et al.[42] have shown how to overcome the disadvantages that homogeneous Rh[I] complexes possess by anchoring them, in a single-site fashion, on to a silica surface (see Figure 11). Although hydroformylation (metal-complex) catalysts have been successfully immobilized at silica surfaces their activities and selectivities have not yet reached values high enough to rival those registered by their homogeneous counterparts, which they surpass in ease of separation of products from reactants. The dinuclear rhodium(II) catalyst studied by Maschmeyer et al.[139] is a case in point. In this case, it was possible to pin down the precise structure of the active catalyst from a crystallographic study of the soluble silsesquioxane derivative (Figure 29)

Coperét et al.,[20] using nonporous silica supports were able to immobilize organometallic metathesis catalysts, in which the central atom was either Ta, Mo, W, or Re: examples of such well-defined silica-supported metallocarbenes and carbynes are shown in Figure 10. It is noteworthy that, in contrast to the dirhodium catalyst for hydroformylation, the activities, selectivities, and lifetimes of these SSHC are close to—and in some instances superior—to those of the corresponding homogeneous catalysts.[140–141]

The so-called constrained geometry-inspired catalysts (CGCs) of McKittrick and Jones,[41, 142] mentioned earlier—see Section 3.3 and Scheme 1 and Scheme 2—in which a titanium-based catalyst that is immobilized, site-isolated fashion, at a silica surface exhibits exceptionally good catalytic performance in the room-temperature polymerization of ethene (in the presence of an alkyl aluminum species and a pentafluorophenyl activator). And a text book example of polymerization at a SSHC of the Brønsted acid type is contained in the work of Zecchina et al.[143] These workers showed (using in situ FTIR) that acetylene, methylacetylene, and ethylacetylene interact with the Brønsted acid sites of H-ZSM-5 with the formation of hydrogen-bonded (precursor) species characterized by well-defined IR properties (Scheme 15). These species are then protonated (by the catalyst) to give intensely colored carbocationic species.

a)

b)

Scheme 14.

Scheme 15.

Insertion of the monomer into the first protonation product lead first to oligomeric species with the carbocationic character and then to the polymer (for example, polyacetylene).[144]

Figure 29. Structure of the silsesquioxane-bound dinuclear rhodium(II) complex [Rh$_2$(μ-PC)$_2$(μ-O$_2$CR)$_2$], where μ-PC is a bridging *ortho*-metalated aryl phosphine ligand. This complex, anchored to mesoporous silica, is an efficient catalyst for the hydroformylation of styrene[139] (hydrogen atoms have been omitted for clarity).

Other examples of heterogeneous, single-site catalysts have been reported, but almost invariably none of these has an open-structure of the kind highlighted herein (that is, with three-dimensional surfaces over which the active sites are distributed). A good example is contained in the work of Kaneda et al.,[145] who created monomeric ruthenium species as the active sites at the surface of hydroxyapatite. Such sites are effective in the catalytic aerobic oxidation of alcohols. But, as yet, no one has prepared mesoporous hydroxyapatites possessing an architecture reminiscent of the mesoporous silicas described herein.

8. Summary and Conclusions

The numerous practical and pedagogic advantages of identifying the concept, and aspiring towards the preparation, of single-site heterogeneous catalysts are summarized as follows:

1. They combine the merits of homogeneous and heterogeneous processes, especially in regard to facilitating separation of products from reactants and the recyclability of the catalyst.
2. They yield sharply defined molecular products, and offer great scope for effecting regioselective, shape-selective, and enantioselective reactions.
3. They offer wide scope for the implementation of clean technology and sustainable development in which solvent-free processes, benign reagents (e.g. air as oxidant), and environmentally compatible catalysts are employed, and where hazardous reagents are catalytically formed in situ.
4. Molecular fragments that circumscribe the constituents of the active site in the heterogeneous catalysts are often readily preparable so that direct comparisons between homogeneous and heterogeneous catalysts, with the same active site, may be made (silsesquioxanes as molecular, dispersed catalysts are particularly useful for comparisons with heteroatom silica-based heterogeneous catalysts).

5. They are generally amenable to sophisticated computational approaches (using DFT) so that direct comparisons with experiment are possible (e.g. reaction kinetics).

6. Most importantly, they offer a proven and widely applicable strategic principle for the design of new catalysts and the improvement of existing ones. This principle, applicable to almost all open-structure solids but especially metal-substituted mesoporous silicas and microporous aluminophosphates, applies both to monofunctional and bifunctional catalysts.

A multiplicity of examples, cited above and in earlier articles (see refs. [13, 31, 45, 148]), encompassing a variety of selective oxidations (including the oxyfunctionalization of alkanes and the benign epoxidation of replenishable terpenes and the esters of naturally occurring unsaturated fatty acids), selective hydrogenation of polyenes and unsaturated (prochiral) ketoesters, dehydrations of alkanols, alkylations, allylic aminations, ammoximations, oxyhalogenations, isomerizations, oligomerizations, and polymerization of alkenes and aldehydes, as well as a proven "green" method fo producing ε-caprolactam /th eprecursor of nylon 6)[148] demonstrate the veracity of the above advances. A large fraction of these catalyzed conversions is achieved using open-structure solids, especially metal-substituted mesoporous (15 to 250 Å diameter) silica and microporous (3.8 to 7.5 Å diameter) aluminophosphates, into which, as isolated entities more than a quarter of the elements of the Periodic Table may be incorporated either as well-separated redox or acid–base (or both) active centers. The resulting high-area open-structure and molecularly accessible solids possess, in effect, three-dimensional surfaces over which the active sites are judiciously placed.

Communications

Prussian blue
molecular square

Molecules with many spin-crossover sites
could be used as multistepped molecular switches. The CN-
bridged molecular square [Fe$^{II}_4$(μ-CN)$_4$(bpy)$_4$(tpa)$_4$](PF$_6$)$_4$ (bpy = 2,2'-
bipyridine; tpa = tris(2-pyridylmethyl)amine), a Prussian blue ana-
logue, undergoes thermally induced, two-step spin conversion. For
more information, see the Communication by H. Oshio and co-workers
on the following pages.

Molecular Switches VIP

Two-Step Spin Conversion in a Cyanide-Bridged Ferrous Square**

Masayuki Nihei, Mayumi Ui, Mizuho Yokota, Lingqin Han, Atsushi Maeda, Hideo Kishida, Hiroshi Okamoto, and Hiroki Oshio*

An important route to the development of switches for advanced molecular devices involves changes in magnetic properties at the molecular level.[1] Spin crossover in transition-metal complexes, in which spin-state conversions occur as a result of heat, pressure, or light irradiation, is a key phenomenon for designing molecular switches.[2] Because cyanide-bridged complexes are relatively easy to synthesize and have rich magnetic properties, they have become the focus of this area of research. Prussian blue, which is a ferromagnet with a Curie temperature (T_C) of 5.6 K,[3] and some heterometal analogues that are high-T_C magnets with an ordering temperature up to 372 K are examples of well-known cyanide-bridged metal complexes.[4] Metal ions in cyanometalates typically adopt a low-spin configuration. However, introduction of ligands with weak ligand-field strengths and combinations of heterometal ions afford interesting magnetic properties such as spin crossover,[5] photoinduced magnetism,[6] and superparamagnetism.[7] Furthermore, molecules with more than one spin-crossover site can be used as multistepped molecular switches. Recently, some thermally induced, two-step spin-crossover complexes were reported.[8] However, the number of such systems is still small.[9] We have studied cyanide-bridged molecular squares, $[Fe_2M_2(\mu\text{-}CN)_4(bpy)_8]^{n+}$ (M = late first-row transition-metal ion; bpy = 2,2'-bipyridine), in which cyanide ions bridge four metal ions to form the macrocyclic tetranuclear core.[10] We found that by replacing bpy with tris(2-pyridylmethyl)amine (tpa), the ligand-field strength on the Fe^{II} centers is weakened and the resulting ferrous square, $[Fe^{II}_4(\mu\text{-}CN)_4(bpy)_4(tpa)_2]$-$(PF_6)_4$ (**1**-$(PF_6)_4$), showed two-step spin conversion.

The reaction of $[Fe(CN)_2(bpy)_2]\cdot3H_2O$[11] with $FeCl_2\cdot4H_2O$, tpa,[12] and NH_4PF_6 in methanol afforded the tetranuclear complex **1**$(PF_6)_4$.[13] X-ray crystal structure analyses were performed at 100, 200, and 300 K, and the molecular structure of **1**$^{4+}$ at 200 K is shown in Figure 1.
Figure 1. ORTEP diagram of **1**$^{4+}$ at 200 K. Average coordination bond lengths [Å] about Fe^{II} ions at 100 K: Fe1 1.958, Fe2 1.976, Fe3 1.958, Fe4 1.963; at 200 K: Fe1 1.954, Fe2 2.154, Fe3 1.955, Fe4 1.965; and at 300 K: Fe1 1.954, Fe2 2.165, Fe3 1.959, Fe4 1.968.

The tetranuclear macrocycle **1**$^{4+}$ is composed of four cyanide-bridged Fe^{II} ions, and the overall geometry is almost square. In the square, two $\{Fe(bpy)_2\}^{2+}$ centers and two $\{Fe(tpa)\}^{2+}$ centers are alternately bridged by four CN^- groups with the carbon atoms coordinated to the Fe^{II} ions in $\{Fe(bpy)_2\}^{2+}$. The Fe^{II} ions have octahedral coordination geometry, and four of the coordination sites are occupied by nitrogen atoms from one tpa or two bpy ligands. The two remaining *cis* positions are coordinated by either carbon or nitrogen atoms from the cyanide groups. The carbon and nitrogen atoms of the cyanide ligands act as π acceptors and σ donors, respectively, and because the cyanide carbon atom has a stronger ligand-field strength,[14] the Fe^{II}−C(cyanide) bond distances become shorter than the Fe^{II}−N(cyanide) distances. The average Fe−C(cyanide) bond length in the $\{Fe(bpy)_2\}^{2+}$ units is 1.916 Å, and the average Fe−N(cyanide) bond length in the $\{Fe(tpa)\}^{2+}$ units is 1.950 Å. Because the coordination bond lengths about Fe^{II} ions differ between the low-spin (LS) and high-spin (HS) states (Δd = 0.2–0.3 Å), the average bond lengths are related to the spin state of the Fe^{II} ions. At 100 K, the average coordination bond lengths involving the Fe^{II} ions are between 1.958 and 1.976 Å in both $\{Fe(bpy)_2\}^{2+}$ and $\{Fe(tpa)\}^{2+}$, and these values are characteristic of LS Fe^{II} ions. At 200 and 300 K, three of the Fe^{II} centers (Fe1, Fe3, and Fe4) stay in the LS state with average Fe^{II} bond lengths the same as the values at 100 K. One of the Fe^{II} ions (Fe2) in the $\{Fe(tpa)\}^{2+}$ moieties forms longer bonds to the ligands (d_{Fe2-N} = 2.154–2.165 Å), characteristic of a HS Fe^{II} ion.

Magnetic susceptibility measurements for **1**-$(PF_6)_4$ were carried out in the temperature range of 5–400 K, and a $\chi_m T$

versus temperature plot is shown in Figure 2. X-ray crystal structure analyses suggest that four Fe^{II} ions in the square are in a LS state below 100 K. The $\chi_m T$ values below 100 K were constant (0.3 emu mol^{-1} K), and the nonzero $\chi_m T$ values are
Figure 2. $\chi_m T$ versus T plot for **1**-(PF$_6$)$_4$.

due to a paramagnetic impurity corresponding to 2.5% of the HS Fe^{II} ($S=2$) species. As the temperature was raised to 200 K, the $\chi_m T$ values increased and reached a plateau value at 3.2 emu mol^{-1} K, which is close to the value (3.0 emu mol^{-1} K) expected for a free HS Fe^{II} ion. The plateau has a width of approximately 100 K and is centered at about 240 K. Upon increasing the temperature, another spin conversion occurred. However, the $\chi_m T$ values did not reach the plateau value (6.0 emu mol^{-1} K) expected for two uncorrelated HS Fe^{II} ions, even at 400 K. The $\chi_m T$ value at 400 K is 4.9 emu mol^{-1} K, which corresponds to 57% of the Fe4 ion being in the HS state. The magnetic susceptibility measurements clearly show the occurrence of a two-step spin conversion in **1**-(PF$_6$)$_4$. Notably, no hysteresis was observed in temperature-dependence measurements of the $\chi_m T$ values.

Reflectance spectra for a single crystal of **1**-(PF$_6$)$_4$ were measured on the (001) plane at 100 and 300 K with unpolarized light (Figure 3). The spectrum at 100 K consists of one sharp (2.13 eV) and two broad (2.3 and 2.6 eV) bands, and a new peak at 1.47 eV appeared with a decrease in the broad bands at 300 K. Absorption data for component molecules were used to assign the reflectance spectra. The LS Fe^{II} ion in [Fe(CN)$_2$(bpy)$_2$] showed a d–d band at 570 nm ($=2.17$ eV),[15] whereas d–d bands for the LS and HS Fe^{II} ions in [Fe(tpa)(L)$_2$]$^{2+}$ (L = CH$_3$CN, CH$_3$OH) were observed at 516 ($=2.40$ eV) and 914 nm ($=1.34$ eV), respectively.[16] MLCT bands for the LS Fe^{II} species appeared in the high-energy region above 3.3 eV.[15,16] The sharp (2.13 eV) and broad (2.3 and 2.6 eV) bands in the reflectance spectrum at 100 K were, therefore, assigned to d–d transitions for the LS iron(II) ions in {Fe(bpy)$_2$}$^{2+}$ and {Fe(tpa)}$^{2+}$ moieties, respectively, and the new band (1.47 eV = 838 nm) at 300 K is due to d–d transitions for HS Fe^{II} species in the {Fe(tpa)}$^{2+}$ moiety. The observed changes in the reflectance spectra are in accord with the magnetic and Mössbauer data.

Selected ^{57}Fe Mössbauer spectra of **1**-(PF$_6$)$_4$ are shown in Figure 4. The Mössbauer spectrum at 50 K is dominated by two LS doublets (four lines in blue), whose Mössbauer parameters (LS1: $\delta = 0.21$ and $\Delta E_Q = 0.66$ mm s^{-1}; LS2: $\delta = 0.43$ and $\Delta E_Q = 0.43$ mm s^{-1}) are characteristic of LS Fe^{II}
Figure 3. Reflectance spectra of **1**-(PF$_6$)$_4$ at 100 and 300 K. $R =$ reflectivity, $E =$ photon energy.
Figure 4. Selected ^{57}Fe Mössbauer spectra of **1**-(PF$_6$)$_4$. Velocity (V) is relative to iron metal. Low-spin pairs in blue and high-spin pair in red. $T_r =$ relative transmission.

species. An additional small doublet (two lines in red, $\delta = 1.13$ and $\Delta E_Q = 2.26$ mm s^{-1}) corresponds to a HS Fe^{2+} species, which is a paramagnetic impurity. The bpy ligand is a strong π acid, and the cyanide carbon atoms act as π acceptors. Furthermore, the LS Fe^{II} ions (Fe1 and Fe3) in the {Fe(CN)$_2$-(bpy)$_2$} centers have smaller isomer shifts than the Fe2 and Fe4 ions in {Fe(NC)$_2$(tpa)} centers. Therefore, the LS1 and LS2 doublets were assigned to the Fe1/Fe3 and Fe2/Fe4 pairs, respectively. The peak-area ratio of the LS1, LS2, and HS doublets is 0.52:0.44:0.04 at 50 K, even though X-ray crystal structure analysis at 100 K showed that all Fe^{II} ions are in LS states. The deviation of the area ratio for LS1 and LS2 is caused by the different Lamb–Mössbauer factors for each LS species.

As the temperature was increased, the LS2 doublet lost intensity, and the HS doublet gained intensity. The ratios of the peak areas for LS1, LS2, and HS doublets became 0.53:0.29:0.18 and 0.56:0.22:0.21 at 160 and 300 K, respectively, meaning that either Fe2 or Fe4 is in a HS state at 300 K. The Mössbauer measurements and X-ray crystallographic analyses suggest the occurrence of a complete spin conversion on the Fe2 ion at 300 K. In summary, **1**-(PF$_6$)$_4$ exhibits a two-step spin conversion with the first step occurring on the Fe2 ion at $T_{sc} = 160$ K (T_{sc} = spin-conversion temperature) and the second step starting to occur on Fe4 at 300 K. Light-induced excited-spin-state trapping (LIESST) experiments are currently underway to explore the possibility of two-step spin conversion by irradiation.

Experimental Section

All procedures were carried out under a nitrogen atmosphere. FeCl$_2$·4H$_2$O (36 mg, 0.18 mmol) in methanol (6.5 mL) was added to a solution of [Fe(CN)$_2$(bpy)$_2$]·3H$_2$O (86 mg, 0.18 mmol) in methanol (13.5 mL), followed by the addition of tpa (52 mg, 0.18 mmol). A methanolic solution (20 mL) of NH$_4$PF$_6$ (118 mg, 0.72 mmol) was added to the dark red solution by diffusion in an H tube to afford dark-red tablets of **1**-(PF$_6$)$_4$. Elemental analysis (%) calcd for C$_{80}$H$_{68}$N$_{20}$F$_{24}$Fe$_4$P$_4$: C 45.48, H 3.24, N 13.26; found: C 45.36, H 3.08, N 13.20.

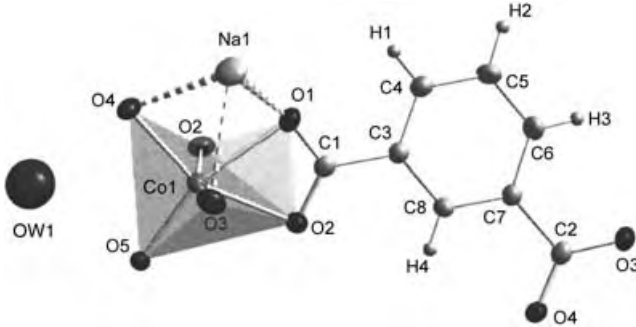
A Three-Dimensional Metal–Organic Framework with an Unprecedented Octahedral Building Unit**


Carine Livage, Nathalie Guillou, Julienne Chaigneau, Pierre Rabu, Marc Drillon, and Gérard Férey*

Among the numerous works devoted to porous hybrid solids, those on structures built up from a chosen inorganic unit reticulated with rigid organic linkers are very topical. The major goal is to control the "design" of the architectures to obtain materials with required properties.[1–5] Interesting architectures have been obtained with tetrameric ZnO_4 units,[6] cuboid zinc silicate cores,[7] and triangular oxo-centered building units with vanadium,[8] zinc,[4] and iron.[9] Recently, a crystalline metal–organic framework (MOF), MIL-100, with a giant cell and a large sorption capacity ($3100\ m^2g^{-1}$) was constructed from this type of triangular unit containing chromium and trimesate ions.[10]

Depending on their architecture, compounds based on polynuclear metallic units offer potential for catalysis, gas storage, or separation. In the search for inorganic "seeds" to grow original 3D networks, we describe here a new hexa-cobalt octahedral building block.[11,12] This type of metal cage could also be useful for magnetic materials with potential applications as molecular magnets.[13,14] The synthetic challenge in this area is to increase and control the degree of nuclearity of the inorganic "clusters" that are responsible for the physical properties. Oligomerization is induced by heating either in solution or in the solid state.[15–17] The title compound, $Na_3[Co_6O(OH)(C_8H_4O_4)_6] \cdot H_2O$ (MIL-104), was synthesized by a classical solvothermal reaction. The hexamers are formed in situ by self-assembly and linked into an original three-dimensional network by the isophthalate dianions.

The structure of MIL-104 is generated by a cobalt atom and a carboxylate on general positions and a sodium ion, water molecule, and oxo-hydroxo oxygen on symmetry elements (Table 1). The metal is octahedrally coordinated to five oxygen atoms of four isophthalate ligands and a μ_3-O ion.

[a] Symmetry code: A: $-x+y-1, -x+1, z$; B: $x-y+1, x+1, -z$.

The geometry is highly distorted, with a narrow O-Co-O angle (60.20(6)°) *trans* to a large one (105.32(7)°), and a short O−O distance (2.188(2) Å) opposite to a long one (3.165(2) Å). This peculiar geometry is always encountered when a carboxylate group binds the metal center in a chelating fashion (Figure 1).[18] The "bite" of the rigid group (ca. 2.1–2.2 Å) is too short for a regular octahedral symmetry. Six octahedra are associated to form a polynuclear "cluster". This
Figure 1. View of the octahedral triangular unit connected by nine isophthalate ions showing the cobalt environment. The 1,3-benzenedicarboxylate ligands adopt two modes of bonding, namely bridging and chelating. The cobalt octahedron presents an important distortion that is attributed to the chelating connection of the organic molecule.

hexameric core is located on an inversion threefold axis and may be easily viewed as the association of two trimers (Figure 2). Each triangle, on a threefold axis, is composed of octahedra sharing a central μ_3-oxygen (Co-μ_3-O-Co 116.33(5)°). At variance to what is usually observed for oxo-centered trimers, the metal atoms are not coplanar with the central oxygen.[8,9] The cobalt "cluster" constructed by the connection through the vertices (six μ_2-O) of two trimers forms an unusual {Co$_6$(μ_3-O)$_2$-(μ_2-O)$_6$(μ_1-O)$_{18}$} super-octahedron (Figure 2).[19,20] Bond valence calculations give a value of 1.5 for the μ_3-O atom.[21] This value, as well as the neutrality of the compound, leads to the statistical half occupancy of the μ_3 site by oxo and hydroxo anions. To the best of our knowledge, this unusual hexanuclear unit has never been observed either in the solid state or in coordination chemistry. This structure can be described as a classical MOF organization, with each hexamer joined by twelve bridging isophthalate ions to six neighboring units, with each metal unit serving as the octahedral node of a

Figure 3. a) Projection of the structure showing one hexameric unit connecting six crystallographically equivalent "clusters" that lie at the corners of an octahedron. Each unit serves as a 6-connecting node of an infinite 3D network. b) View of the inorganic pseudo-cubic network including the sodium cation octahedra. c) Schematic representation of the {Na$_6$Co$_6$O$_{26}$} "super octahedron" highlighting the relationship between the inorganic network and the ReO$_3$ structure.

Figure 2. Schematic representation of the {Co$_6$(μ_3-O)$_2$(μ_2-O)$_6$(μ_1-O)$_{18}$} unit showing its octahedral geometry.

cuboid net (Figure 3a). The connection between two "clusters" is ensured by two nearly parallel bridging isophthalates with weak π–π interactions. In this description, the sodium ions occupy small cavities left free by the hexamers' packing. The alkali-metal cation has a distorted octahedral geometry formed by oxygen atoms of six carboxylate groups, with O-Na-O angles ranging from 68.02(2)° to 132.8(1)° and bond lengths ranging from 2.256(2) to 2.592(2) Å. Taking into account the sodium polyhedron, MIL-104 can also be considered as a 3D inorganic framework with sodium octahedra linking the hexameric units through face-sharing in a pseudo-cubic net (Figure 3b). In fact, each cobalt polyhedron is linked to a sodium ion to form a larger "super octahedron" around the hexamer. The topology here is the same as that found for ReO$_3$, with {Na$_6$Co$_6$O$_{26}$} units as giant octahedra (Figure 3c). Thus MIL-104 provides a new example of scale chemistry.[22]

The temperature variation of the magnetic susceptibility measured in a 500 Oe field is shown in Figure 4.[23] Paramagnetic behavior is observed down to 50 K. A "plateau" is then observed in the χ versus T curve at 0.12 cm^3 mol^{-1} in the range 30–14 K, followed by an increase up to 1.98 cm^3 mol^{-1} at 1.8 K. The fit of the χ^{-1} versus T curve in the high temperature region gives a Weiss temperature, θ, of −118.5 K and a Curie constant of 2.92 K cm^3 per cobalt atom, which agrees well with that expected for high-spin Co^{II} in an octahedral site.[24] The negative sign of θ and the decrease of χT, which tends to zero at 1.8 K, point to the existence of antiferromagnetic exchange interactions. Spin–orbit coupling most certainly also contrib-
Figure 4. Temperature dependence of the magnetic susceptibility of compound MIL-104 recorded in a field of 550 Oe. The inset shows the corresponding variation of the χT product.

Communications

utes to this decay.[24–26] The hexamers are interconnected by large isophthalate bridges and are quite well isolated. Thus, the magnetic behavior is interpreted as being due to antiferromagnetic intrahexamer coupling. Moreover, the presence of a "plateau" in the susceptibility and of a Curie-like tail at low temperature indicate the existence of a residual moment, which might be due to the stabilization of an uncompensated moment by a frustration effect in the triangular cobalt motifs.[26]

In summary, a cobalt isophthalate constructed from a unique {Co$_6$O$_{26}$} cage with octahedral geometry has been prepared. The novelty of the hexanuclear unit illustrates the influence of rigid organic partners upon metal oxide condensation. The great challenge in building-block chemistry is to establish reliable synthetic routes to stabilize desired inorganic motifs.[9,27] Complex inorganic units frequently appear as isolated compounds, and the relationship between "clusters" and synthetic conditions is often unpredictable.[28] For the formation of the title hexamer the crucial point seems to be the distortion of the trimer, which is characterized by an asymmetric linkage of the carboxylate groups: three bridging ones on one side and six nonbridging (intratrimer) ones on the opposite side (Figure 1). Therefore, no steric obstruction limits the condensation increment. On the contrary, with symmetrical triangles (three bridging groups on both side), the association of two trimers through vertices is topologically impossible. However, although it is understandable that chelating carboxylic groups help to induce the formation of the hexamer, the link between synthetic conditions and this type of coordination is far from being understood.[18]

Experimental Section

Preparation of Na$_3$[Co$_6$O(OH)(C$_8$H$_4$O$_4$)$_6$]·H$_2$O (MIL-104):[29] The reactions were carried out in a Teflon-lined autoclave at 180°C for three days under autogenous pressure. The reaction mixture contained CoSO$_4$·7H$_2$O (1.16 × 10^{-3} mol), isophthalic acid (HO$_2$C-(C$_6$H$_4$)-CO$_2$H; 1.73 × 10^{-3} mol), NaOH (3.46 × 10^{-3} mol), and H$_2$O/ethanol (25/75 v/v, 7.5 mL) in a ratio of 1:1.5:3:90. After the mixture was cooled (pH 6), the resulting violet crystals were washed with distilled water. IR (KBr pellet): $\tilde{v}$ = 3580 (w) and 3445 cm^{-1} (s) (oxygen–hydrogen stretch of the water molecules and hydroxy group); 1613 (s), 1559 (s), 1539 (s), 1485 (s), 1457 (s), and 1395 cm^{-1} (s) (symmetric and asymmetric stretching bands of the deprotonated carboxylic functions). Elemental analysis calcd (%) C 39.5, H 1.8, Co 24.3, Na 4.7; found: C 37.8, H 1.8, Co 22.5, Na 5.6. A single crystal was selected for structure determination by X-ray diffraction. Calculated density: 1.973 g cm^{-3}; measured: 1.961(2) g cm^{-3}. The thermal behavior of Na$_3$[Co$_6$O(OH)(C$_8$H$_4$O$_4$)$_6$]·H$_2$O was studied by thermogravimetric analysis under nitrogen. It decomposes through two major processes, namely the loss of water molecules and the combustion of the organic moiety. The first loss appears at around 80°C with the loss of the free water molecules (theoretical loss: 1.2%; observed loss: 1.6%). The structure of MIL-104 is preserved upon dehydration, as proved by X-ray thermodiffraction in air, up to 250°C, which shows only tiny variations of the peak intensities. It reabsorbs water molecules upon cooling. The second weight loss occurs between 450 and 550°C and is characteristic of the combustion of the organic moiety (theoretical weight loss: 59.0%; observed loss: 58.5%).

A violet crystal (1.08 × 0.34 × 0.30 mm^3) was glued to a glass fiber. Intensity data were collected at room temperature with a Siemens SMART diffractometer equipped with a CCD two-dimensional detector (λ(Mo$_{K\alpha1}$) = 0.71073 Å).[30] The structure was solved and refined by full-matrix least-squares techniques, based on F^2, using the SHELX-TL software package.[31] Cobalt, sodium, and oxygen atoms were located by direct methods, and all remaining atoms, including hydrogen atoms, were found by successive difference Fourier maps. All atoms were refined anisotropically, except for hydrogen atoms. The refinement converged to R_1 = 0.0339 and wR_2 = 0.0916 for 2177 unique reflections and 146 parameters.[32]

The Supporting Information contains the atomic coordinates, the atom-labelling scheme, the TGA graph, the X-ray thermodiffraction study, and the magnetization versus field cycle.

Nanotechnology

Fabrication of Random Assemblies of Metal Nanobands: A General Method**

*Michael E. Hyde, Trevor J. Davies, and
Richard G. Compton**

Nanoscale electrodes have several advantages over their macroscopic counterparts: they are well suited to applications that require high sweep rates, low internal-resistance (iR) drops, and low capacitance.[1] A significant disadvantage of such electrodes is, however, that they generate extremely small currents. One useful compromise is to use a band electrode, in which the electrode is small enough in one dimension to give rise to nonlinear diffusion, while its size in the other dimension is increased to maximize the current output. Band electrodes are particularly favored when attempts are made to achieve very low analytical detection limits: the part of the residual current associated with the double-layer charging is lowered in proportion to the surface area of the electrode, while the Faradaic current is not.[2]

Nanoband electrodes are usually fabricated by using one of two general methods. The simpler of these approaches is to generate an insulator-metal-insulator sandwich and then expose one of the edges by polishing or cutting the material. If vacuum-evaporated films are used, extremely narrow bands (potentially down to approximately 1 nm) may be created. However, the technique suffers from some difficulties: the band width is defined by the thickness of the deposited film, which may be difficult to determine accurately. In addition, polishing of such small electrodes is likely to cause significant variations in its final shape, surface area, and so forth. There may be significant doubts about the real surface area of the band even when no polishing step is used.[3] This method is best suited to the creation of single bands.

The other commonly used method involves the use of lithography. In this case, there are two possibilities: First, a metal film may be evaporated on to a substrate, photoresist is applied and patterned lithographically, the unprotected metal is etched, and finally the remaining photoresist is removed.[4] Second, a "lift-off" technique may be employed, in which the photoresist is applied directly to the substrate and patterned.

Fax: (+44) 1865-275-410
E-mail: richard.compton@chemistry.ox.ac.uk

The metal film is then applied on top, and when the remaining photoresist is removed, the corresponding metal film is also removed, thus leaving only the metal attached directly to the substrate.[4] These methods are highly reproducible and allow precise control of the electrode geometry. Recently, band widths and gap widths down to 30 nm have been achieved by using a lift-off procedure combined with high-resolution electron-beam lithography.[5] Lithographic methods, however, require specialized equipment and are relatively complex to implement.

A related approach to the modification of surfaces with conductive bands has been explored by Penner and co-workers,[6–8] who have shown that metal nanowires may be obtained by selective electrodeposition of conducting metal oxides onto the step edges present at highly ordered pyrolytic-graphite (HOPG) surfaces, followed by reduction with hydrogen. (Although the direct deposition of metals onto the step edges is possible and conceptually simpler, the resulting wires are usually of poorer quality for various reasons.[6]) This effect results from the specialized structure of HOPG, which consists of atomically flat basal-plane graphite terraces separated by defects that expose relatively thin (335 pm or multiples thereof) bands of edge-plane graphite. Given the correct deposition potential, these edges are strongly favored because of their much greater electrochemical activity.[9–11]

We have recently extended this methodology in a three-step electrochemical process to generate nanotrenches by using the following procedure:[9] MoO_2 nanowires are deposited on HOPG in a manner similar to that described by Penner and co-workers. A reducing potential is then applied to a solution of 4-nitrobenzenediazonium ions, thus leading to the deposition of a polymeric film on the electrode which has a thickness on the order of 10 nm. (Although the molybdenum oxide deposited under these conditions is in fact a mixture of MoO_2 and MoO_3, it is usually described as MoO_2.[6–9] Herein, we follow this convention to avoid confusion.) Finally, the MoO_2 is dissolved in hydrochloric acid; as with the lithographic "lift-off" procedure, any polymer above the MoO_2 wires is removed at the same time. The result is that the HOPG electrode is covered entirely by an impermeable film except for the step edges, which are uncovered. Herein, we extend this method further through the presentation of a simple, general, and mostly solution-phase method for the generation of assemblies of metal nanobands by using the original MoO_2 nanowires as a template.

The process for the fabrication of these nanoband assemblies is illustrated conceptually in Figure 1. MoO_2 nanowires were electrodeposited onto the freshly cleaved HOPG surface (Figure 1a) using a solution of 1.1 mm sodium molybdate, 1m sodium chloride, and 1m ammonium hydroxide adjusted to pH 8.5 with sodium hydroxide. The mean thickness of the nanowires has been shown to be dependent on the deposition time, thus allowing wires with controlled diameters to be prepared (see below). In the present case, deposition was performed at -1.0 V (versus the saturated calomel electrode (SCE)) for 130 seconds (Figure 1b). An atomic force microscopy (AFM) image of the resulting
Figure 1. Schematic diagram showing the six stages involved in metal-nanoband fabrication: a) freshly cleaved HOPG; b) after deposition of the MoO_2 nanowires; c) after deposition of the DVB (divinylbenzene) polymer film, d) after removal of the MoO_2 nanowires; e) after evaporation of a gold layer onto the surface; and f) after cleavage of the gold layer from the HOPG substrate.

nanowires is shown in Figure 2a. To test the homogeneity of the nanowire coverage, AFM images were collected at several separated points on the electrode; this image (and those presented below) was found to be representative of the whole electrode.

The second step was to cover the remaining exposed carbon again with a layer of polymer. However, a solution of 50 mm divinylbenzene (DVB) and 0.1m tetrabutylammonium perchlorate in acetonitrile was used instead of the solution of 4-nitrobenzenediazonium. DVB has been shown to readily polymerize under oxidation conditions,[12] and we found that
Figure 2. AFM images showing steps in nanoband fabrication: a) MoO_2 nanowires (corresponding to Figure 1b); b) nanotrenches (corresponding to Figure 1d); and c) completed gold nanobands (corresponding to Figure 1f).

application of +1.6 V for 30 s reproducibly generated an even, relatively insulating film (see below), with a thickness of approximately 5–10 nm (Figure 1c).

The nanowires were removed and nanotrenches created by immersion of the HOPG electrode in a stirred solution of 1M hydrochloric acid for 300 s (Figure 1d). An AFM image of these nanotrenches is shown in Figure 2b. The texture of the DVB film is clearly visible when compared with the background HOPG in Figure 1a, and the nanotrenches have a mean depth of approximately 6 nm. It should be noted that the fact that the MoO_2 deposits can be removed in this way implies that the film is somewhat porous, thus allowing the solution of HCl to penetrate. However, the surface is effectively blocked in an electrochemical sense: cyclic voltammetry (CV) in a solution of 1.0 mM $[Ru(NH_3)_6]^{3+}$/1M KCl after DVB-film deposition shows a tiny signal (in proportion to the results obtained from a bare HOPG electrode or metal nanobands). This residual current presumably arises from the slightly porous nature of the film, but is negligible relative to the contribution from the completed nanoband array. The effect of a polymer blocking HOPG electrodes has been previously discussed in greater detail.[9]

The electrode was removed from the acid, rinsed, and dried. A 200-nm-thick layer of gold was then evaporated on top of the nanotrenches under the conditions described in the Experimental Section, and a supporting stub was attached to the gold layer using a cyanoacrylate adhesive (Figure 1e). The HOPG was finally cleaved as close to the gold layer as possible using a knife. The original HOPG block is regenerated, and any thin layer of HOPG that remains on top of the gold layer may be removed with adhesive tape, thus leaving what was originally the underside of the gold layer exposed. We found that the DVB layer adheres preferentially to the gold surface (rather than the HOPG block) and leaves the structure illustrated in Figure 1f, which has exposed gold nanobands surrounded by an insulating layer of polymer. (AFM analysis of the HOPG surface separated from the gold layer showed no sign of nanotrenches, thus confirming that the polymerized DVB deposit adheres to the gold surface.) An AFM image of these bands is shown in Figure 2c. Note that the decreasing height scale in Figure 2a–c shows that the nanobands are somewhat difficult to resolve because of the very small height difference between the DVB layer and the exposed gold surface. This small height difference might be predicted from Figure 1f, as the edges of the bands should in theory be flush with the top of the DVB layer.

To study the nanobands in more detail, a representative band was chosen and examined at a scan range of approximately 800 nm. An AFM image of this band is shown in Figure 3a, along with a section analysis of a line perpendicular to the nanoband axis in Figure 3c. Some important features are apparent: the width of the nanoband is around 180 nm, the maximum height of the nanoband above the polymer layer is approximately 700 pm, and the band has a characteristic "m" shape. The depth of the central "v" is approximately 300 pm, suggesting that this shape is related to that of the original HOPG step edge. The shape of the band may in fact be beneficial in terms of the electrochemical behavior of the electrode, as most of the current flow at a nanoband electrode
Figure 3. A single gold nanoband shown at a scan range of approximately 800 nm. a) AFM image (height). b) Constant-current STM image (height). c) Section analyses perpendicular to the band axis from the AFM (a) and constant-current STM (b) images; note that the actual height of the band is approximately 0.8 nm (estimated by using AFM). d) Constant-height STM image (current).

occurs near the edges. Therefore, a partial reinforcement of the metal thickness at the band edges may decrease the ohmic drop of the nanoband precisely where this drop is required. Next, the sample was analyzed by using scanning tunnel microscopy (STM). Initially, the scan-feedback parameters were increased as much as possible ("constant-current" mode). On typical surfaces (in which the conductivity is uniform), this procedure gives the most accurate reproduction of the real surface. However, we found that in the current case although the texture of the background and the band itself are well resolved, the height of the band is significantly over-reported (Figure 3c). In addition, the STM current appears as in Figure 3d when the feedback parameters are minimized ("constant-height" mode). Together these observations are direct evidence of the presence and relatively much lower conductivity of the DVB film. In constant-height mode, the bias is set high enough for electrons to tunnel through the DVB film. When the tip reaches a nanoband, the much higher conductivity of the gold surface causes the tip to over-compensate, thus moving a large distance away to maintain the same current. For this reason, the absolute heights recorded in the constant-current STM mode should be considered unreliable and have been omitted from the relevant figures. In constant-height mode, the tip remains at a fixed height (irrespective of any surface features) and the tunneling current is recorded. We would clearly expect the gold areas to pass a much greater current at a given bias potential, which is exactly as observed.

In principle, the method described above for the generation of nanobands should be effective for any material that can be evaporated onto the nanotrenches. To test this hypothesis, the procedure was repeated exactly as described above except silver was used instead of gold in the evaporation step. It was found that the resulting nanobands were

impossible to resolve by AFM because of the small height of the bands relative to the roughness of the surface. Again, however, the bands are clearly visible when constant-current STM is used. STM images at two scan ranges are shown in Figure 4. Again, the "m" shape is visible, and the bands shown
Figure 4. Constant-current STM images of silver nanobands at various scan ranges: a) $3 \times 3 \ \mu m^2$ and b) $1 \times 1 \ \mu m^2$.

in Figure 4b have a width of approximately 150 nm, which is consistent with the results for the gold nanobands (given that some variation in nanowire/nanotrench width over the whole electrode is always observed).

As stated above, it should also be possible to control the mean nanoband width by adjusting the length of time for which MoO_2 is deposited, which was tested by repeating the above procedure. However, this time MoO_2 was deposited at −1.0 V for 30 s (see Figure 5a). Finer nanowires were produced with a mean diameter of approximately 80–90 nm, nanotrenches were produced as usual from these wires, and copper was evaporated onto the surface to a depth of 200 nm. After cleavage, again no nanobands could be distinguished by using AFM, but STM clearly revealed their presence (Figure 5b,c). As expected, the bands are narrower than in the two previous cases: the magnified image in Figure 5c shows a typical band with a width of 100 nm.

The nanoband arrays produced by using this method were analyzed voltammetrically. An important parameter for any
Figure 5. a) AFM image of MoO_2 nanowires after deposition for 30 s. b), c) Constant-current STM images of copper nanobands prepared using the nanowires in (a).

type of electrode array is the global coverage Θ as defined by Equation (1):

$$\Theta = \frac{A_{ins}}{A_{array}} \qquad (1)$$

A_{ins} is the area of insulating material and A_{array} is the total surface area of the array. It follows that the area of electrode material is given by $A_{array}(1-\Theta)$. Now consider the case in which we perform cyclic voltammetry at an electrode of material i in a simple one-electron redox couple given by Equation (2):

$$A + e \underset{}{\overset{k^o, \alpha}{\rightleftharpoons}} B \qquad (2)$$

A and B are the oxidized and reduced species, respectively, k^o is the electron-transfer rate constant, and α is the symmetry coefficient for the heterogeneous reaction to give B. The observed response is dependent on a number of system parameters, such as the diffusion coefficient D, the area of the electrode A_{elec}, and k^o. For the purpose of this argument, we label the whole response as $[I-E(k^o)]$. Now consider the case in which we have a nanoband array of material i and global coverage Θ in the same redox couple and $A_{array} = A_{elec}$. Previous investigations have shown that if the spacing between the individual bands is considerably smaller than the diffusion-layer thickness δ, the CV response will be given by $[I-E\{k^o(1-\Theta)\}]$.[10,13] That is, the $I-E$ response of the array will be equal to that of a naked electrode of the same area in the same redox couple but with an electron-transfer rate constant of $k^o(1-\Theta)$.

Figure 6a illustrates a cyclic voltammogram recorded with the gold nanoband array in Figure 2c immersed in a solution of 1.0 mm $[Ru(NH_3)_6]^{3+}/1M$ KCl, in which the scan rate was 1 Vs^{-1}. Overlaid as a dashed curve is the corresponding response for a gold electrode of the same surface area, that is, $A_{elec} = A_{array}$ (in this case the gold electrode was prepared by gold plating a metal slab and was used in the same electrode housing as the array). It is necessary to estimate the proportion of the array surface which is exposed gold to compare these curves meaningfully. To this end, ten STM images, each with a scan range of 5 μm, were collected from randomly selected points on the electrode surface. A custom-written Matlab program was then used to analyze the images by using the following method: the bands appear significantly higher on the surface than the DVB background so the band surface and DVB surface can be differentiated simply by setting an appropriate height threshold and counting the total number of data points above and below this threshold for all the images. In this way, the proportional area of exposed gold was found to be approximately 10%. Although the polymer coverage of the nanoband array was approximately 90%, an $I-E$ response almost equal in magnitude to that of the "naked" gold electrode was observed.

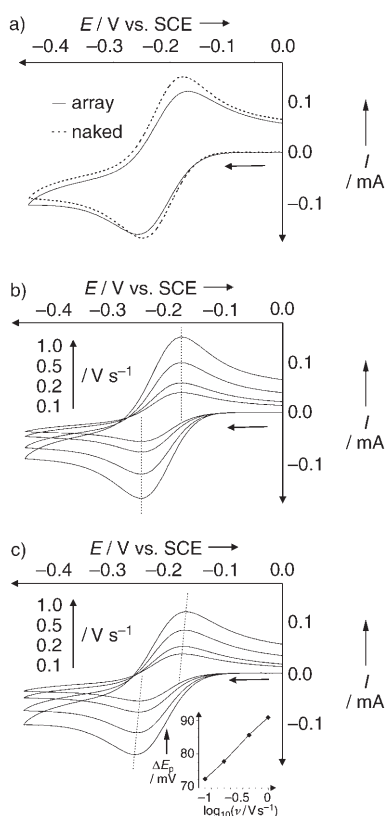
In addition, the peak-to-peak separation for the array was larger than that for the naked electrode. This observation is in complete agreement with the theory discussed above. At 1 Vs^{-1}, the diffusion-layer thickness at the peak potential of the forward scan will be approximately 15 μm.[14] It can be seen from Figure 2c that the spacing between the bands is less


Figure 6. a) Cyclic voltammogram taken at 1 Vs^{-1} in a solution of 1.0 mM [Ru(NH$_3$)$_6$]$^{3+}$/1 M KCl at the gold nanoband array in Figure 2c (solid) and a gold electrode of the same surface area (dashed). b), c) Cyclic voltammograms taken at varying scan rates in a solution of 1.0 mM [Ru(NH$_3$)$_6$]$^{3+}$/1 M KCl at the gold electrode (b) and the gold nanoband array (c).

than 1 μm; therefore, the observed response obtained in Figure 6 is as expected. The fact that the nanoband array with a coverage Θ of approximately 0.9 gives a response almost equal in magnitude to that of the naked electrode indicates that the mass transport to the nanobands must be considerably faster than to the naked electrode. A potential application of this response is illustrated in Figure 6b,c, which shows cyclic voltammograms recorded at various scan rates at the naked gold electrode and the gold nanoband array in the same solution used for the cyclic voltammogram shown in Figure 6a. The [Ru(NH$_3$)$_6$]$^{3+}$/[Ru(NH$_3$)$_6$]$^{2+}$ redox reaction has an electron-transfer rate constant of approximately 0.5 cm s^{-1} at the gold electrodes, thus making it electrochemically reversible at the scan rates employed in Figure 6b.[15,16] Hence, the same peak-to-peak separation ΔE_p (≈ 60 mV) in Figure 6b was observed at all scan rates. In this situation, only thermodynamic data for the redox reaction can be deduced and much higher scan rates would be needed (or smaller electrodes) to deduce reliable kinetic data.[15,16] However, the nanoband array effectively reduces k^o to $(1-\Theta)k^o$, such that the redox reaction now appears to be quasireversible at the scan rates employed, as shown in Figure 6c, in which ΔE_p increases with scan rate. Thus, well-characterized nanoband arrays could have fundamental applications (namely, alternative methods to investigate fast electron-transfer reactions)

in addition to their use in electroanalysis. Also, as well as scanning probe microscopy (SPM) image analysis, a nanoband array could be characterized by using a redox couple of known k^o (for example, determined through a previous microdisk experiment). Subsequent analysis of the nanoband cyclic voltammograms would yield k^o_{eff}, in which $(1-\Theta) = k^o_{eff}/k^o$.

In conclusion, we have demonstrated a method for the generation of large assemblies of metal nanobands (the size of which was only limited by the HOPG block employed). The method has been shown to be effective for the generation of gold, silver, and copper nanobands and may work with any material that can be evaporated onto the electrode surface to form a stable 200-nm-thick layer. Control of the mean nanoband width has also been demonstrated: we have created bands with widths between approximately 90 and 180 nm by varying the deposition time of MoO$_2$. In principle, the method can be readily extended to produce narrower bands simply by decreasing the deposition time further. However, in practice we found this approach somewhat problematic as shorter deposition times tended to produce "patchier" and less-continuous nanowires. Conversely, wider nanobands can be produced by increasing the deposition time. Although not considered in the present study, it should also be possible to vary the nanoband density. The band density is a function of the density of the step edges on the HOPG surface; it could, therefore, be decreased by employing a higher grade of HOPG or increased by using a lower grade.[17] The method for the preparation of a fresh HOPG surface can also effect the edge-step density; for example, McDermott and McCreery found that cleavage of an HOPG surface with a sharp blade results in far less edge steps than the adhesive cleaving technique employed herein.[18]

Experimental Section

All reagents were of the highest grade that was commercially available and were used as received without any further purification. These were sodium molybdate (Aldrich; 98 + %), potassium chloride (Reidel-de-Haen; ≥99.5%), sodium chloride (BDH; AnalaR), ammonium chloride (BDH, GPR), sodium hydroxide (Acros; ≥ 98%), hexaamineruthenium(III) chloride (Aldrich; 98%), sulfuric acid (BDH; AnalaR, sp. gr. 1.84), sodium sulfide (Aldrich; 98 + %), tetrabutylammonium perchlorate (Fluka; puriss electrochemical grade), and DVB (Aldrich; 80%, mixture of isomers). All aqueous solutions were prepared with deionized water with a resistivity of not less than 18.2 MW cm (Vivendi water systems, UK). Solutions of DVB were prepared with acetonitrile (Fischer Scientific; anhydrous synthesis grade). The temperature was 294 ± 2 K for all experiments.

The metal layers were prepared on the HOPG surface by metal-vapor deposition in a BOC Edwards Auto 306 vacuum coater with a Cryo-pumping system (with a base pressure of 2 × 10^{-7} mbar). The metals were evaporated from an alumina-coated molybdenum boat (R. D. Mathis, Long Beach, CA, USA) with a 3.2-V 300-A power supply. The current was controlled so that the rate of deposition on the sample was maintained at about 1 nms^{-1} and monitored with a quartz-crystal microbalance (FTM5 thickness monitor, BOC Edwards), which was mounted adjacent to the sample, both of which were 120 mm from the evaporation source. During the evaporation, the sample was rotated at about 5 rpm around a circle radius of 50 mm centered directly above the source with the pressure maintained below 1 × 10^{-6} mbar. The evaporation was stopped once the film had reached the required thickness, and the system was

allowed to cool to room temperature before venting and removing the sample. Gold and silver were obtained from Alfa (99.99%), and copper was obtained from Goodfellow (99.999%).

Voltammetric measurements were carried out with a μ-Autolab type II potentiostat (ECO-Chemie, The Netherlands). All electrochemical experiments were conducted by using a three-electrode configuration, in which the substrate for the working electrode was basal-plane HOPG. The HOPG was purchased in the form of a $10 \times 10 \times 2$ mm^3 block from SPI Supplies (PA, USA; type SPI-2). The HOPG experiments were conducted by using the HOPG housing, as previously described, which resulted in an exposed electrode area of 0.32 cm^2.[19] The HOPG surfaces were prepared by cleavage with adhesive tape before each experiment. At all times, the counter electrode was a bright platinum wire with a surface area much larger than that of the working electrode. A saturated calomel electrode (Radiometer, Copenhagen, Denmark) was employed as the reference.

All the SPM experiments employed a Multimode SPM (Digital Instruments, now a division of Veeco). A model "J" scanner was used, with a lateral range of 125×125 μm and a vertical range of 5 μm. All the AFM experiments were performed in the tapping mode, with standard silicon probes (Nascatec GMBH part NST-NCHF). STM experiments used Pt/Ir tips (Veeco part PT) at a bias of $+200$ mV in all experiments. All SPM experiments were performed in air.

Linking Rings through Diamines and Clusters: Exploring Synthetic Methods for Making Magnetic Quantum Gates**

Marco Affronte,* Ian Casson, Marco Evangelisti, Andrea Candini, Stefano Carretta, Christopher A. Muryn, Simon J. Teat, Grigore A. Timco,* Wolfgang Wernsdorfer, and Richard E. P. Winpenny*

Those of us interested in polymetallic complexes still strive to control the structures formed, as this is vital if we are ever to exploit their properties. One of the more interesting approaches is to use "templates" to control either the size of clusters[1] or even their shape.[2] Beyond that challenge lies another: how do we assemble cage complexes into materials in a controlled manner? Further motivation to answer this latter question has arisen from theoretical studies,[3,4] which propose that $S = 1/2$ clusters could be used as quantum bits (qubits) in quantum information processing (QIP). Herein, we describe our initial experiments in which we link $S = 1/2$ wheels to each other. Linking two molecules with $S = 1/2$ will allow the study of conditioned dynamics of the magnetization of each molecule and thus let us examine the possibility of implementing quantum gates within molecular clusters.

Previously we reported the first heterometallic octanuclear rings, $[\{NH_2R_2\}\{Cr_7MF_8(O_2CCMe_3)_{16}\}]$ (R = alkyl side chains; $M = Ni^{II}$, Co^{II}, Fe^{II}, Mn^{II}, or Cd^{II}).[5] For QIP, single-qubit operations require an $S = 1/2$ ground state. Among the heterometallic $\{Cr_7M\}$ rings, this condition is met for $M = Ni^{II}$, which therefore represents an appealing candidate.[6] How-

ever, the efficient implementation of a quantum computer requires the creation of a two-qubit quantum gate as pointed out by Loss and co-workers[3,4] and Troiani et al.[7] For such a purpose, it is necessary to have dimers of coupled {Cr₇Ni} rings. As the ring is templated about protonated amine cations, a straightforward method is to use a diamine with a carbon chain of sufficient length so that a {Cr₇Ni} ring can be attached at either end. In initial experiments we found that 1,8-diaminooctane (1,8-dao) and 1,9-diaminononane (1,9-dan) are suitable, while slightly more complex diamines such as 1,3-di(piperidine)propane (1,3-dpp) also produce a pair of linked clusters. Longer diamines are also suitable, such as 1,12-diaminododecane (1,12-dad), but the resulting crystal structures are significantly disordered. The linked clusters, [{1,8-daoH₂}{Cr₇NiF₈(O₂CCMe₃)₁₆}₂] (**1**), [{1,9-danH₂}{Cr₇NiF₈(O₂CCMe₃)₁₆}₂] (**2**), and [{1,3-dppH₂}{Cr₇NiF₈(O₂CCMe₃)₁₆}₂] (**3**) were structurally characterized (Figure 1).[8] The Niᴵᴵ ions in these compounds may be replaced with other metal dications.
Figure 1. Crystal structure of **1** (hydrogen atoms and methyl groups of pivalate groups on rings have been omitted for clarity; Cr green, Ni light green, F yellow, O red, N blue, C black). Selected bond-length ranges: M–F 1.891–1.964, M–O 1.872–2.016 Å. Average estimated standard deviation (av esd): 0.012 Å.

The structure of the heterometallic octanuclear {Cr₇M} rings is a regular octagon of metal ions with each side bridged by one fluoride and two carboxylate ions, as reported previously.[5]. Although it is not possible to distinguish between Niᴵᴵ and Crᴵᴵᴵ sites in a single ring, elemental analysis confirmed the formulation given. The protonated amine head groups hydrogen bond to the fluoride ions within the ring.

We wished to include switchable links between the rings. To this end, we synthesized [{EtNH₂CH₂py}{Cr₇NiF₈(O₂CCMe₃)₁₆}] (**4**; py = pyridine)[8] knowing that the ring will

encapsulate the secondary ammonium group to leave the pyridine moiety free to bind to further metal sites. To illustrate the potential of such an approach, we treated **4** with the dinuclear metal complexes, [Cu₂(O₂CCMe₃)₄(HO₂CCMe₃)₂] and [M₂(H₂O)(O₂CCMe₃)₄(HO₂CCMe₃)₄] (M = Ni or Co). This gave the structures [{M₂(O₂CCMe₃)₄}{[EtNH₂CH₂py][Cr₇NiF₈(O₂CCMe₃)₁₆]}₂] (**5**: M = Cu; **6**: M = Ni; **7**: M = Co),[8] as depicted in Figure 2.
Figure 2. Crystal structure of **5** (see Figure 1 legend for color scheme; Cu orange). Selected bond-length ranges: M–F 1.909–1.967, M–O 1.914–1.997, Cu–O 1.953–1.960 Å. Av esd: 0.008 Å.

The pyridine group from **4** binds to the axial sites of the metal dimer. The M···M distance is fairly similar, at 2.63 Å in **5** and 2.61 Å in **6**. The Cu···Cu distance is similar to that reported for a previously reported copper dimer bridged by pivalate.[10] In related Ni dimers,[11] the Ni···Ni distance depends on the terminal ligands: approximately 2.60 Å for pyridine and longer (ca. 2.72 Å) for lutidines. Complex **4** therefore appears to be similar to pyridine in its donating properties. While these dimers are not switchable, we believe that we can prepare equivalent supramolecules in which M is a 4d or 5d metal and where we could vary the interaction between the [Cr₇MF₈(O₂CCMe₃)₁₆] complexes by redox chemistry or photoexcitation of the multiply bonded dimer.[12]

Magnetic and specific heat studies of **1**–**3** and **5**–**7** were performed. The ac susceptibility was measured over the temperature range 2–100 K (Figure 3a). Each linked ring
Figure 3. a) The χT product of {Cr₇Ni} rings (black ○) and the molecular dimers **1** (brown □), **2** (blue ○), **3** (red △), **5** (green ×), and **6** (yellow +); for **5** and **6**, χ was normalized to half a mole) over the temperature range 2–100 K. Note that χT values saturate to the Curie value expected for an $S = 1/2$ system for all of the derivatives. b) Temperature dependence of the ac susceptibility χ (the susceptibility of dimer **7** is reported in the Supporting Information).

shows essentially the same χT versus T behavior for this temperature range, and after normalization to half a mole the $\chi T(T)$ curves overlap that of a single {Cr$_7$Ni} ring. The anomalies in the χ versus T plot (Figure 3b) are related to the pattern of the lowest lying states in a single {Cr$_7$Ni} ring[5,6] that comprises an $S = 1/2$ ground state and an $S = 3/2$ first excited multiplet. The field dependencies of the magnetization as collected at $T = 0.4$ K for each linked ring almost overlap one another, and as only the ground state is significantly populated at this temperature no deviation from the Brillouin curve calculated for $S = 1/2$ is observed (see Supporting Information).

The temperature dependencies of the specific heat c, normalized to the gas constant R, were recorded over the temperature range 0.4–10 K. Figure 4 shows that after normalization to half a mole for the dimers the data overlap one

Figure 5. Specific heat c, normalized to the gas constant R, of **7** measured as a function of temperature at different magnetic fields: zero field ($\bigcirc$); 1 T ($\triangle$); 3 T ($\square$); 5 T ($\times$); 7 T ($+$). It is evident that the evolution of the Schottky anomaly is essentially due to the Zeeman effect on the lowest lying levels with $S = 1/2$ and $S = 3/2$ of the single {Cr$_7$Ni} wheels. Lines are fitting curves obtained by diagonalizing the spin Hamiltonian of single {Cr$_7$Ni} wheels, as described in the text.

Figure 4. Specific heat c, normalized to the gas constant R, of {Cr$_7$Ni} rings ($\bigcirc$) and of the molecular dimers **1** ($\square$), **2** ($\bigcirc$), **3** ($\triangle$), **5** ($\times$), **6** ($+$), and **7** (square with cross); for **5**–**7**, c was normalized to half a mole for comparison with {Cr$_7$Ni} rings measured as a function of temperature at zero field. Continuous (——) and dotted (-----) lines represent the estimated lattice and magnetic contribution, respectively.

another and with those of {Cr$_7$Ni}. The hump in the $c(T)$ curves at 3–5 K confirms the Schottky anomaly related to the main energy gap, approximately 9 cm^{-1}, between the ground state $S = 1/2$ doublet and the $S = 3/2$ quartet. As a magnetic field is applied, these multiplets are split and the Schottky anomaly evolves for all derivatives similarly to that observed for the {Cr$_7$Ni} ring (Figure 5). This behavior is well-accounted for by the spin Hamiltonian of a single wheel [Eq. (1)].

$$H = \sum_i J \mathbf{S}_i \cdot \mathbf{S}_{i+1} + \sum_i d_i \left[S_{z,i}^2 - S_i(S_i + 1)/3 \right] \\ + \sum_{i<j} \mathbf{S}_i \cdot \mathbf{D}_{ij} \cdot \mathbf{S}_j + \mu_B \sum_i g_i \mathbf{S}_i \cdot \mathbf{B} \quad (1)$$

The first term corresponds to the dominant antiferromagnetic Heisenberg exchange between nearest-neighboring

spins; the second and third anisotropic terms account for the coupling due to the crystal field and for the intracluster dipole–dipole interaction, respectively; the fourth term accounts for the Zeeman coupling to the external field. The microscopic parameters can be determined by fitting the magnetic-field-dependent specific heat data, and within the experimental accuracy for all derivatives the best set of parameters was $J_{Cr-Cr} = 1.46$ meV, $J_{Cr-Ni} = 1.69$ meV, $d_{Cr} = -0.03$ meV, $d_{Ni} = -0.35$ meV, $g_{Cr} = 1.98$, and $g_{Ni} = 2.2 \pm 0.2$. The addition of a coupling term between two wheels does not improve the quality of the fit for $T > 0.4$ K.

These results show that for all these linked complexes, the pattern of the lowest lying states of a single wheel is very close to that of the isolated {Cr$_7$Ni} ring. We estimate an upper limit for a possible coupling interaction between two wheels to be less than about 0.1 cm^{-1}. To check this, we examined the magnetization of microcrystallites of **5** between 40 mK and 400 mK by using a micro-SQUID array and found no evidence for an interaction between the {Cr$_7$Ni} rings even at this temperature (see Supporting Information).

At one level, the lack of a sizeable magnetic coupling may seem disappointing, however this work demonstrates that [Cr$_7$MF$_8$(O$_2$CCMe$_3$)$_{16}$] complexes are relatively stable and that they can be attached to one another by different linkers. At another level, implementation of quantum computing will require one state where the single qubits in the gate do not communicate. These results show that the rings can be brought into close proximity without changing magnetic behavior due to through-space exchange. In the future we hope to switch on the interaction by using photo- or redox chemistry.

Experimental Section

All reagents were used as received from Aldrich. [Cu₂(O₂CCMe₃)₄(HO₂CCMe₃)₂][13] and [M₂(H₂O)(O₂CCMe₃)₄(HO₂CCMe₃)₄][14,15] were prepared according to published methods.

1: Me₃CCO₂H (20.0 g, 195 mmol), H₂N(CH₂)₈NH₂ (0.16 g, 1.11 mmol), and CrF₃·4H₂O (3.0 g, 16 mmol) were heated at 140°C with stirring in a teflon flask for 0.5 h, then 2NiCO₃·3Ni(OH)₂·4H₂O (0.35 g, 0.6 mmol) was added. After 1 h the temperature of the reaction was increased to 160°C for 8 h. The flask was cooled to room temperature, then acetone (35 mL) was added while stirring. The green microcrystalline product was collected by filtration, washed with a large quantity of acetone, dried in air, and then dissolved in hexane (100 mL). The solution was filtered, and the filtrate was evaporated to dryness. The product was recrystallized twice from toluene. Yield: 1.9 g (35%; all yields based on Cr unless otherwise stated). Elemental analysis (%) calcd for C₁₆₈H₃₁₀Cr₁₄F₁₆N₂Ni₂O₆₄: Cr 16.06, Ni 2.59, C 44.53, H 6.90, N 0.62; found: Cr 16.62, Ni 2.51, C 45.48, H 7.06, N 0.50.

Compounds **2–4** were obtained by similar procedures to that for **1**, except that 1,8-diaminooctane was replaced with the amines listed below and the period of heating at 160°C and the crystallization solvents were also varied.

2: 1,9-diaminononane; heated at 160°C for 9 h; extracted and crystallized from 1:2 hexane/ethyl acetate. Yield: 1.5 g (28%). Elemental analysis (%) calcd for C₁₆₉H₃₁₂Cr₁₄F₁₆N₂Ni₂O₆₄: Cr 16.01, Ni 2.58, C 44.65, H 6.92, N 0.62, F 6.69; found: Cr 15.81, Ni 2.64, C 44.37, H 6.96, N 0.54, F 6.68.

3: 1,3-bis(4-piperidinyl)propane monohydrate; heated at 160°C for 11 h; extracted and crystallized from 5:1 pentane/acetone. Yield: 1.0 g (18%). Elemental analysis (%) calcd for C₁₇₃H₃₁₆Cr₁₄F₁₆N₂Ni₂O₆₄: Cr 15.83, Ni 2.55, C 45.19, H 6.93, N 0.61; found: Cr 15.47, Ni 2.54, C 44.81, H 6.90, N 0.54.

4: Me₃CCO₂H (20.0 g, 196 mmol), 4-(ethylaminomethyl)pyridine (0.32 g, 2.4 mmol), CrF₃·4H₂O (3.0 g, 17 mmol), and 2NiCO₃·3Ni(OH)₂·4H₂O (0.3 g, 0.5 mmol) were heated while stirring at 140°C for 2.0 h and then at 160°C for 24 h. The teflon flask was cooled to room temperature, then acetone (35 mL) was added, and the mixture was stirred for 3 h. The precipitated product was collected by filtration and washed with acetone (3 × 15 mL). The solid was dissolved in pentane (40 mL), the solution was filtered, then the filtrate was diluted with acetone (60 mL). Evaporation of this solution at room temperature produced green crystals. Yield: 2.3 g (42%). Elemental analysis (%) calcd for C₈₈H₁₅₇Cr₇F₈N₂NiO₃₂: Cr 15.62, Ni 2.52, C 45.37, H 6.79, N 1.20; found: Cr 15.58, Ni 2.65, C 45.33, H 6.84, N 1.18. Crystals suitable for X-ray studies were obtained by recrystallization from THF/MeCN.

5: [Cu₂(O₂CCMe₃)₄(HO₂CCMe₃)₂][12] (0.077 g, 0.105 mmol) was added to a solution of **4** (0.5 g, 0.2 mmol) in toluene (7 mL), and the mixture was stirred until the copper complex dissolved. Green microcrystalline product began to form during this time and was collected after 2 days, washed with toluene and acetone, and dried in air. Yield: 0.44 g (81.0% based on Cu). Elemental analysis (%) calcd for C₁₉₆H₃₅₀Cr₁₄F₁₆N₄Ni₂Cu₂O₇₂: Cr 14.02, Ni 2.26, Cu 2.45, C 45.35, H 6.80, N 1.08; found: Cr 13.91, Ni 2.23, Cu 2.29, C 45.77, H 6.86, N 0.97. Crystals suitable for X-ray studies were obtained by slow evaporation of a solution of **5** in THF/toluene at room temperature.

6: [Ni₂(H₂O)(O₂CCMe₃)₄(HO₂CCMe₃)₄][14] (0.1 g, 0.1 mmol) was added to a solution of **4** (0.5 g, 0.2 mmol) in Et₂O (7 mL) and briefly stirred. The solution was filtered and diluted with toluene (ca. 5 mL). Green crystals (including some that were suitable for X-ray studies) were formed by slow concentration of this solution at room temperature over 2 days. Crystals were washed with toluene and dried in air. Yield: 0.4 g (71% based on Ni). Elemental analysis (%) calcd for C₁₉₆H₃₅₀Cr₁₄F₁₆N₄Ni₄O₇₂: Cr 14.05, Ni 4.53, C 45.43, H 6.81, N 1.08; found: Cr 13.77, Ni 4.45, C 45.55, H 6.90, N 1.03.

7: All manipulations were carried out under a N₂ atmosphere. [Co₂(H₂O)(O₂CCMe₃)₄(HO₂CCMe₃)₄][14] (0.1 g, 0.1 mmol) was dis-

solved in Et₂O (5 mL), and the solution was added to a solution of **4** (0.5 g, 0.2 mmol) in toluene (10 mL). Green crystals (including some that were suitable for X-ray studies) were formed by slow concentration of this solution at room temperature over 2 days. Crystals were collected by filtration, washed with toluene, and dried under N₂. Yield: 0.31 g (57% based on Co). Elemental analysis (%) calcd for C₁₉₆H₃₅₀Co₂Cr₁₄F₁₆N₄Ni₂O₇₂: Cr 14.05, Co 2.27, Ni 2.27, C 45.43, H 6.81, N 1.08; found: Cr 13.88, Co 2.29, Ni 2.21, C 45.09, H 6.71, N 0.99.

Magnetic and thermal measurements: The magnetic properties and the heat capacity of polycrystalline samples of **1–3** and **5–7** were investigated using a Quantum Design PPMS-7T system provided with an ac susceptometer and a microcalorimeter, respectively. Homemade Hall magnetometer and micro-SQUIDs were used for magnetization measurements below 1 K.

Control of the Coil-to-Globule Transition and Ultrahigh Mechanical Properties of PNIPA in Nanocomposite Hydrogels**

Kazutoshi Haraguchi* and Huan-Jun Li

The coil-to-globule transition of polymer chains caused by external stimuli, such as temperature, pH, pressure, solute, or solvent, is one of the most interesting properties in polymer science, and a polymer that undergoes this transition is referred to as a stimuli-responsive polymer. For example, poly(*N*-isopropylacrylamide) (PNIPA) is the most typical stimuli-responsive polymer and exhibits a well-defined coil-to-globule transition in aqueous media at its lower critical solution temperature (LCST $\approx 32\,°$C).[1] To utilize the coil-to-globule transition effectively, PNIPA is mainly used in the form of polymeric hydrogels, which consist of three-dimensional polymer networks highly swollen with large quantities of water. As PNIPA hydrogels can exhibit many characteristic changes in their properties owing to the coil-to-globule transition, such as swelling/deswelling, absorption/desorption, transparency (transparent/opaque), and surface hydrophilicity (hydrophilic/hydrophobic),[2–5] they have increased importance as advanced soft materials, such as smart gels (e.g. photoresponsive gels),[6] enzyme carriers,[7] colloid crystals,[8] separation devices,[9] drug-delivery systems (e.g. glucose-responsive insulin-releasing gels),[10] and biocompatible materials in tissue engineering (e.g. cell-cultivation substrates, scaffolds).[11] So far, it has been desired to control the stimuli-sensitivity of PNIPA hydrogels over a wide range. However, substantial control of the coil-to-globule transition of PNIPA has not been reported.

In previous studies, the inherent mechanical weakness of polymeric, including PNIPA, hydrogels was an unavoidable problem and there were constant efforts to overcome this.[12] Recently, we proposed a new type of hydrogel, nanocomposite hydrogels (NC gels), which consist of poly(*N*-alkylacrylamides) and inorganic clay.[13] As a result of their unique organic–inorganic network structure, which consists of exfoliated clay platelets uniformly dispersed in an aqueous medium with a number of flexible polymer chains linking them together, NC gels simultaneously solved all of the problems concerning the optical, mechanical, and swelling/deswelling properties associated with conventional, chemi-

cally cross-linked PNIPA hydrogels (OR gels).[14–17] NC gels are anticipated to be promising hydrogels with possibly the most extensive control over both mechanical properties and stimuli-sensitivity. By using NC gels, reversible force generation as a result of the coil-to-globule transition of PNIPA chains was observed for the first time in response to alternating the temperature across the LCST.[18] Additionally, NC gels exhibit many interesting functions such as the formation of unique porous morphologies with a three-layered structure in the freeze-dried state,[19] characteristic sliding frictional behavior with remarkable changes in the coefficient of friction at the surface of the NC gel,[20] and biocompatibility (including implantation, antithrombogenicity, etc).[21] Herein, we report the first observation of total control over the coil-to-globule transition of PNIPA chains by inorganic (clay) nanoparticles and the achievement of strikingly ultrahigh mechanical properties such as the strength, elongation, and fracture energies of NC gels.

Synthetic hectorite ($[Mg_{5.34}Li_{0.66}Si_8O_{20}(OH)_4]Na_{0.66}$; layer size ≈ 30 nm $\oslash \times 1$ nm, cation-exchange capacity: 104 meq/100 g) was used as the inorganic clay after washing and freeze-drying. Sample codes for NC gels (NCc)are defined by the concentration of clay (c_{clay}) on a molar basis in their as-prepared states: for example, NC5 gel indicates 5×10^{-2} moles of clay (38.1 g) in 1 L of H_2O. Here, c_{clay} was varied over a wide range from 1×10^{-2} mole (NC1) to 20×10^{-2} mole (NC20), while the concentration of the monomer, NIPA, was fixed at 1 mol L^{-1} in H_2O. The synthetic procedure for formation of the NC gels is almost the same as that reported previously,[17] except for the mixing process used to prepare the reaction solution. In the present study, mixing by combined rotation and revolution was used to overcome difficulties in forming uniform dispersions of clay, initiator, and catalyst at high contents of clay. Thus, throughout the range of c_{clay} used, uniform dispersion was achieved by controlling the mixing conditions, including the temperature (1–35°C). Next, free-radical polymerization in situ was performed at 20°C for 20 h. As yields for polymerization were almost 100% for all NC gels, the composition of the NC gel was virtually the same as that of the corresponding initial solution.

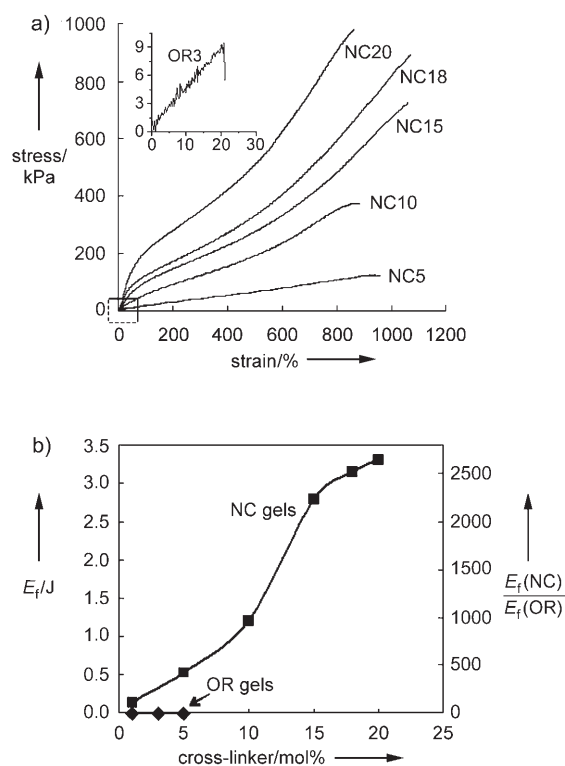
The resulting NC gels were all uniform and mostly transparent regardless of the concentration of clay (Figure 1a), although conventional OR gels became totally opaque when the concentration of organic cross-linker (N,N′-methylenebis(acrylamide); BIS) exceeded 5 mol% relative to NIPA (Figure 1b). All NC gels were mechanically very tough, although they differed greatly in softness depending on the content of clay. Figure 1a shows a soft NC5 hydrogel which was readily deformed on compression, while the NC20 gel could hardly be deformed by hand. Here, the deformation of NC5 gel was almost totally reversible, and all NC gels including NC5 and NC20 gels did not break during the compression tests. Figure 2a shows tensile stress versus strain curves for NC5, NC10, NC15, NC18, and NC20 gels. It is seen that both the initial modulus of elasticity (E_i) and the tensile strength (σ) increase monotonically with increasing values of c_{clay}. NC20 gel exhibits a tensile strength of nearly 1000 kPa, an E_i value of 400 kPa, and approximately 1000%
Figure 1. a) NC5 and NC20 gels with high transparencies exhibit differing degrees of softness. Both NC gels did not rupture under repeated compressions by hand. b) OR gels with different transparencies, transparent OR1 and opaque OR5, are both very brittle under compression.


Figure 2. a) Tensile stress versus strain curves for NC gels with different contents of clay (NC5–NC20). The inset shows a magnified view of the dotted box at the origin, with the curve for OR3 gel. b) Fracture energies (E_f) for the gels and ratios of E_f for NC/OR gels as functions of the amount of cross-linker.

elongation at break—these are the highest tensile properties by far ever reported for polymeric hydrogels and are comparable to those of pristine styrene–butadiene rubber.[22]

If the high water content (ca. 80–90 wt%) of NC gels is taken into account, this is quite a striking result. Also, in most solid polymers, whether they are linear or cross-linked, it is a common feature that the fracture strain ε_f decreases inversely in proportion to E_i.[23] However, in the case of NC gels, ε_f was maintained at a high value (ca. 1000%) despite large increases in the initial modulus of elasticity, E_i. Contrary to this, as shown in Figure 1b (under compression) and Figure 2a (under elongation), OR gels show a very brittle mechanical nature and the brittleness changes little with a varying content of cross-linker. Note that OR gels have the same composition (water and PNIPA) as NC gels except for the difference in cross-linker. The fracture energy for each NC and OR gel was calculated from the areas under the stress–strain curves. The fracture energies (E_f) of NC gels and their dependence on c_{clay} are shown in Figure 2b relative to those of OR gels. The fracture energies of OR gels are almost the same, regardless of the content of BIS cross-linker (the average value for OR1, OR3, and OR5 gels is used in Figure 2b). It is also striking that the fracture energy of NC20 gel could be as much as 2650-times higher than that of the OR gel. All these advantageous results may be ascribed to the unique organic–inorganic network structure[13–15] of NC gels in which the density of cross-links was controlled without sacrificing the large extensional capability of its constituent polymer chains.

We previously reported that NC gels show a distinct change in transparency across the LCST as a result of the coil-to-globule transition.[13, 14] In the present study, we found that decreases in transparency at the LCST varied dramatically with the concentration of clay, as shown in Figure 3a; that is, the loss in transparency gradually decreased as c_{clay} increased until, finally, at c_{clay} values greater than $15 \times 10^{-2}\,\text{mol}\,\text{L}^{-1}$, there was no loss in transparency and gels remained transparent regardless of the temperature. Figure 3b shows NC5 and NC15 gels that exhibit different transparency behaviors at ambient temperature (upper, 20°C) and in hot water (lower, 50°C). The NC15 gel did not change its transparency but retained a high transmittance regardless of the surrounding temperature. In contrast, NC5 gel showed an abrupt change, as previously reported, between transparent and opaque by alternating the temperature across the LCST. The results shown in Figure 3a,b indicate that the thermal molecular motion of PNIPA chains was completely restricted in NC gels with c_{clay} greater than $15 \times 10^{-2}\,\text{mol}\,\text{L}^{-1}$, and, consequently, the thermosensitivity was totally depressed in NC gels with such high concentrations of clay. The molecular restriction of PNIPA chains in NC gels was attributed to restriction by exfoliated clay platelets incorporated in NC gels. As the clay platelets (hectorite) are strongly hydrophilic, the conformational change from coil (hydrophilic) to globular (hydrophobic) form may be hindered in PNIPA chains attached to clay surfaces or lying close to them. This is the first observation of complete control over the coil-to-globule transition of PNIPA chains by inorganic nanoparticles. Note that through interactions with clay platelets, the thermal molecular motions (associated with the transition between random-coil and globular forms) of PNIPA chains towards the globular form are hindered despite the increasing temper-
Figure 3. a) Temperature dependence of the optical transmittance for a linear polymer (LR) and NC gels with different c_{clay}. b) Transparency of NC5 and NC15 gels below (in air: upper) and above the LCST (in water: lower). The observed change in transparency for NC5 gel was not observed for NC15 gel (its transparency was maintained upon heating).

ature. At the same time, PNIPA chains adopt random conformations amongst the clay platelets so that large reversible deformations are possible on applying external stresses as shown in Figure 2a.

Concerning the swelling in water, all NC gels swell to equilibrium at 20°C (< LCST) and their swelling markedly decreases with increasing concentrations of clay. These results clearly indicate that clay platelets act as an effective cross-linking agent in NC gels over the whole range of c_{clay}. At temperatures above the LCST, we previously found that NC gels exhibit very rapid deswelling (volume contraction) compared with OR gels; for example, an NC1 gel took less than 10 minutes to reach equilibrium, although an OR1 gel took more than 1 month.[14] This result was attributed to the rapid dehydration of flexible PNIPA chains, including grafts, in organic–inorganic networks of NC gels. For NC gels with high concentrations of clay, as the conformational change of PNIPA chains was substantially restricted as described above, it is expected that the deswelling behavior may also be depressed. As shown in Figure 4a, deswelling was decreased markedly with increasing c_{clay} values, and for NC gels with c_{clay} values greater than that for NC12 no contraction of volume
Figure 4. a) Deswelling kinetics (at 50 °C) for NC gels with different c_{clay} values. W_o is the weight of each initial (as-prepared) gel; W_{gel} is the weight of the swollen hydrogel. b) Heats for the coil-to-globule transition measured by DSC for NC gels with different contents of clay. The transition peak disappeared for NC gels with a concentration of clay greater than that for NC15.

was observed. Instead, NC gels simply swelled, even at 50 °C (> LCST). Here, PNIPA behaves like a hydrophilic polymer without exhibiting a thermosensitive transition. Thus, the volume changes (due to either swelling or deswelling) of NC gels can be controlled greatly by altering c_{clay} over a wide range. From the variations in both swelling and deswelling, it is expected that certain NC gels with high concentrations of clay will maintain a stable volume in water regardless of the temperature.

All the results herein, particularly the superior mechanical properties and good transparencies, indicate that the unique organic–inorganic network structure is retained even for NC gels with high concentrations of clay. However, from the results of suppressed thermosensitivities of transparency and swelling/deswelling it was concluded that PNIPA chains are subject to steric hindrance by clay platelets and that finally the coil-to-globule transition is prohibited at sufficiently high c_{clay} values. This conclusion was confirmed by differential scanning calorimetric (DSC) measurements for NC gels with various concentrations of clay (Figure 4b). The heat change associated with the coil-to-globule transition in the gel state decreased with increasing c_{clay} and disappeared at c_{clay} values greater than that for NC15. Also, from measurements on dried NC gels it was found that the change in heat capacity at the glass transition temperature (≈ 142 °C) decreased with

increasing c_{clay} values, and by analogy with the coil-to-globule transition in the gel state the glass transition in the dried state due to the micro Brownian motion of PNIPA disappeared at c_{clay} values greater than that for NC15. These phenomena are specific to NC gels and are totally different from those of OR gels, which become opaque at high contents of BIS as a result of the formation of inhomogeneous networks.

In conclusion, we have presented the extraordinarily high strength and high fracture energy of polymeric hydrogels (NC gels) as well as complete control over the coil-to-globule transition in PNIPA chains, in terms of transparency and swelling/deswelling, by inorganic clay nanoparticles. In comparison with conventional rubbers (e.g. styrene–butadiene rubber) that consist of 100% organic polymers, NC gels comprise mostly water (80—90 wt%) and are also essentially nonflammable without the need for any harmful halogen or phosphorus additives. Thus, NC gels can be referred to as truly environmentally friendly soft materials, from both production and disposal viewpoints. By recognizing the control over mechanical and functional properties as reported here, NC gels may lead to new horizons in the fields of advanced research and technologies.

Experimental Section

Synthesis of NC gels with high clay contents: The inorganic clay "Laponite XLG" (Rockwood Ltd., UK) and NIPA monomer were used after purification. The synthetic procedure for NC gels with low concentrations of clay ($c_{clay} \leq 5 \times 10^{-2}$ mol L^{-1}) is the same as that reported previously.[17] For NC gels with high concentrations of clay ($c_{clay} \geq 10 \times 10^{-2}$ mol L^{-1}), the experimental procedure differed in the preparation of the initial reaction solution: For example, for NC20 gel only a part of the clay was used at first and a transparent aqueous solution consisting of water (19 mL), NIPA (2.26 g), and inorganic clay (0.76 g) was prepared by normal magnetic stirring. Next, the remainder of clay (2.29 g) was added to the aqueous solution while stirring at 1 °C and subsequently heating to 35 °C and then cooling again to 1 °C, to avoid flocculation and to accelerate dispersion. Then, to achieve the exfoliation of clay and the good dispersion of all components, the solution was further mixed at 1–5 °C for 30 minutes by utilizing two combinations of rotation and revolution (800/2000 rpm and 60/2200 rpm). The mixtures were subsequently mixed for further periods of 1 minute each after the addition of initiator and catalyst. The amount of clay was varied from 0.152 g to 3.05 g. The concentration of monomer (NIPA) was fixed at 1 mol L^{-1} in H$_2$O, and the molar ratios of monomer, initiator (potassium persulfate), and catalyst (N,N,N',N'-tetramethylethylenediamine) were fixed at 100:0.426:0.735, respectively. Then, free-radical polymerization in situ was allowed to proceed in a water bath at 20 °C for 20 h. Throughout all experiments, oxygen was excluded from the system. Meanwhile, OR1 and OR5 gels were prepared using NIPA (2.26 g, 1 mol L^{-1} in H$_2$O) and the organic cross-linker N,N'-methylenebis(acrylamide) (BIS; 0.028 g, 1 mol%, or 0.140 g, 5 mol%, respectively) instead of clay.

Measurements: Swelling and deswelling experiments were performed by immersing as-prepared gels (initial size: 5.5 mm diameter × 30 mm long) in a large excess of water for approximately 200 h at 20 and 50 °C, respectively, and changing the water several times. Swelling and deswelling ratios are represented as the ratios of weights of the swollen hydrogel (W_{gel}) to the corresponding dried gel (W_{dry}). Tensile mechanical measurements were performed on as-prepared NC and OR gels of the same size (5.5 mm diameter × 70 mm long) using a Shimadzu Autograph AGS-H under the following conditions: 25 °C; gauge length: 30 mm; cross-head speed: 100 mm min^{-1}. The initial

Communications

cross section (23.75 mm^2) and loads detected between elongations of 10% and 50% were used to calculate the tensile strengths (σ) and the initial modulus of elasticity (E_i). Thermogravimetric analyses were conducted using a TG/DTA 220 (Seiko Denshi Ind. Inc.) instrument, by heating samples from 30°C to 1000°C at a heating rate of 10°C min^{-1} in an air flow. DSC measurements were performed using a Perkin–Elmer DSC-7 apparatus in a nitrogen atmosphere for NC gels and milled dried gels, with heating from −50 to 60°C and from 30 to 250°C, respectively, at a heating rate of 10°C min^{-1}.

Synthetic Macrocyclic Peptidomimetics as Tunable pH Probes for the Fluorescence Imaging of Acidic Organelles in Live Cells**

Francisco Galindo,* M. Isabel Burguete, Laura Vigara, Santiago V. Luis,* Nurul Kabir, Jelena Gavrilovic, and David A. Russell*

Synthetic fluorescent probes have found widespread applications in cell biology for the intracellular measurement of several species, from the zinc(II) cation[1] and citrate anion[2] to singlet oxygen[3] and nitric oxide.[4] In recent years, several reviews have appeared that deal with synthetic fluorescent chemosensors.[5,6] Protons are one of the most important targets among the intracellular species of interest, as it is well-known that pH plays a central role in many cellular events.[7] In general terms, two broad ranges of pH values are found in cells. Consequently, two types of synthetic probes have been developed,[8] namely, probes for cytosol that work at a pH of about 6.8–7.4, and probes for the so-called acidic organelles (for example, lysosomes) that function over the pH range of about 4.5–6.0. It is possible to find a large array of commercial probes for the former pH range; however, this is not the case for acidic organelles. Many reports have appeared that connect some cellular dysfunction with abnormal pH values in acidic organelles. For instance, defective pH regulation of acidic compartments has been observed in human breast cancer cells.[9] Another illustrative example is the finding of elevated lysosomal pH in neural ceroid lipofuscinoses, a common inherited neurodegenerative disorder that affects

children.[10] It would, therefore, be extremely desirable to have access to a broad variety of "acidic" probes to study these and other conditions. Unfortunately, as a consequence of the current unavailability of probes for the acidic pH range, there is a research bottleneck as regards progress in some areas of cell biology or medicine. Additionally, in the light of the above discussion, a further fundamental criterion emerges for the design of new probes. This criterion is the possibility of chemical control of the pH reporter probe under extracellular conditions, that is, the potential for precise control (and prediction) of the pK_a value of the probe by adjusting the appropriate elements in the molecular architecture.

Herein, we present a new family of fluorescent macrocyclic probes (FG-H series)[11] that consist of a 9,10-anthracene subunit linked by a C_2-symmetric peptidomimetic chain (Scheme 1). The probes differ only in the size of the chain

($n = 3,4,6,8$), but this structural variation produces a smooth shift in the pK_a values, which is an essential feature that enables a range of pH "windows". The synthesis of the FG-H family members is facile, and the compounds exhibit good photostability and present excellent cellular uptake without the need for derivatization to improve crossing of the cellular membrane. Moreover, the series extends the range of pH utility by about 0.5 pH units (toward a lower pH) over that of currently available probes.

Compounds FG-H503, FG-H504, FG-H506, and FG-H508 were synthesized according to a procedure developed for the preparation of peptidomimetic macrocycles in high yields.[12,13] It has been previously demonstrated that the β-turn conformation adopted by the synthetic intermediates (arising from the presence of two α-amino acids as building blocks) allows the synthesis of the peptidomimetic macro-

cycles in moderate to high yields without the need for high-dilution conditions. In the case of the FG-H series shown in Scheme 1, two units of L-valine were selected because of their reported ability to induce the formation of β sheets.[14] However, it should be possible to introduce virtually any α-amino acid with an appropriate protecting group into the general synthetic procedure (Scheme 2) to obtain a new

Scheme 2. a) Acid activation; b) coupling with 1,*n*-diaminoalkane; c) deprotection; d) ring-closing with 9,10-bis(bromomethyl)anthracene. Cbz = carbobenzyloxy.

family of peptidomimetics with different properties as pH probes. The 9,10-dimethylanthracene moiety was chosen as a fluorophore as it is known to be photostable and also to allow comparison with the widely used pH probe for acidic organelles, LysoSensor Blue DND-167 (Scheme 1). DND-167, which was originally studied by de Silva et al.,[15] is also an anthracene derivative that shares with the compounds in the FG-H series the presence of two amine groups decoupled electronically from the fluorophore by both methylene spacers. However, in the case of DND-167, there is the possibility that more flexible configurations could be adopted. For comparison a second commercial probe, LysoSensor Green DND-189, which has a different photochemical nature, was also selected. LysoTracker Green DND-26 (see Scheme 1)[16] was also used for fluorescence imaging experiments in vivo. This latter compound was employed to certify the acidic nature of the organelles, as it is known to accumulate in lysosomes. (Note, however, that LysoTracker Green DND-26 is not a pH "reporter", as its fluorescence emission does not vary with changing pH.[8a])

Standard fluorescence pH titrations were performed for all the compounds in Scheme 1 in buffered aqueous media (containing 0.2% DMSO from the initial stock solution) at a probe concentration of 2 μM, with measurement at pH intervals narrow enough to allow a precise determination of the apparent pK_a value. Figure 1 shows the absorption spectrum of FG-H503 (Figure 1a) along with the fluorescence emission spectra at different pH values (Figure 1b–g). The fluorescence changes in systems composed of fluorophore–CH$_2$–amine moieties, such as the FG-H series, can be rationalized according to the photoinduced electron-transfer (PET) scheme developed by the research groups of de Silva and Czarnik:[6] Under basic conditions the amino groups are not protonated, and hence the PET process takes place (if thermodynamically allowed by the Rehm–Weller formalism[17]) which leads to fluorescence quenching. In acidic media the electron pair in each amine is protonated, thus preventing
Figure 1. FG-H503 (2 μM) in aqueous solution (0.2% DMSO). a) Normalized absorption spectrum at pH 1.02, and fluorescence spectra ($\lambda_{ex} = 377$ nm) at b) pH 2.55, c) 4.70, d) 5.10, e) 5.41, f) 5.83, and g) 6.90.

[a] Probe concentration: 2 μM in aqueous solution (0.2% DMSO); metal concentration: 200 μM.

PET from occurring, and hence emission from the fluorophore takes place.

In the case of the FG-H series, a minimal variation in the chemical structure of the probe causes an appreciable change in the titration curve (see Figure 2 for some of the titration
Figure 2. Fluorescence versus pH titration curves for the probes under study. Data are normalized at the maximum emission (I_{rel}). Probe concentration: 2 μM in aqueous solution (0.2% DMSO); excitation wavelengths as indicated in Table 1. FG-H503 (▲), FG-H504 (△), FG-H508 (●), DND-167 (□), DND-189 (■).

curves; complete spectra and titration results can be found in the Supporting Information).[18,19] The pK_a values are derived from the nonlinear curve-fitting of the data and are shown in Table 1 along with the excitation and emission wavelengths.

It can be seen in Figure 2 that the DND-189 probe exhibits a fluorescence intensity versus pH profile that is not the same as the other profiles, which reflects its different chemical nature with respect to the anthracene framework. Additionally, a sharp decrease in the fluorescence intensity is measured with DND-189 at acidic pH values.

To examine the useful pH range for each probe, the pH interval for which the tested compound changes from 20 to 80% of its maximum fluorescence was determined (Figure 3; the maximum is measured at pH 2 for the FG-H series and

DND-167, and at pH 4 for DND-189). Thus, it can be seen that the peptidomimetic macrocycles are complementary to the DND probes, as they extend the pH range of measurement toward the acidic side.

On account of the complexity of the intracellular environment, an additional examination of the probes was performed to determine whether other ions were potential interferents. For example, it is well-known that amines can bind many metal cations in solution.[6] In fact, many chemosensors for metal ions use the ability of amines to coordinate the vacant orbitals of such analytes. Among them, zinc(II) and copper(II) are the types of species likely to be targeted by free amines in solution. Consequently, control experiments with FG-H503, DND-167, and DND-189 in the presence of an excess of Zn^{II} and Cu^{II} ions were performed to assess such possible coordination. As can be seen in Table 1, the effect of such metals on the peptidomimetic macrocycle is negligible, particularly when considering that the concentrations used for the experiment were significantly higher than those present in the intracellular environment.

FG-H503 was investigated as a fluorescent probe in cultured cells and was compared to DND-189. The probe

DND-167 did not produce images with sufficient resolution; therefore, the additional probe LysoTracker Green DND-26[16] was also used which is known to be retained specifically in acidic organelles. Two series of experiments were performed: Raw 264.7, a mouse macrophage cell line, was loaded with FG-H503 and with either DND-189 or DND-26. As shown in Figure 4b, g, FG-H503 exhibited a vesicular distri-

Figure 4. Distribution and co-localization of FG-H503 with lysosomal probes DND-189 (a–e) and DND-26 (f–j) in Raw 264.7 cells. Differential interference contrast (DIC; a, f) and fluorescence images of FG-H503 (b, g) and DND-189 (c) or DND-26 (h) were collected with a confocal laser scanning microscope in the DIC, DAPI, and FITC modes. d), i) Merged images of red and green channels; e), j) composite images of red, green, and DIC channels. DND-189 (a–e) and DND-26 (f–j) are from a different set of experiments.

bution. The probe predominantly co-localized with both DND-189 and DND-26, which indicates that the probe is taken up by the cells and that it localizes within acidic organelles. Note that the different excitation and emission wavelengths of FG-H503, as compared to those of the commercial probes, allow simultaneous visualization of both probes (FG-H503 and either DND-189 or DND-26) from the same intracellular compartment. Interestingly, the fluorescence intensity of FG-H503 appears to match that of DND-189: areas of low and high fluorescence (light and dark blue arrows, respectively, in Figure 4b–d) of the probe match those of DND-189, which indicates that the FG-H probe can distinguish between different pH values in the cell in a manner similar to the commercial probe. Analogous results are obtained from the joint use of FG-H503 and DND-26. Composite images of the fluorescence and differential interference contrast (Figure 4e, j) confirm that FG-H503 is located within acidic compartments of this macrophage cell line.

In summary, a new family of fluorescent macrocyclic peptidomimetic compounds has been synthesized, and their abilities as pH probes have been tested both in solution and in live cells with positive results. The synthetic modular scheme is an excellent approach for the development of new tailor-made probes with targeted pH "windows" ideal for measurement of the changing acidic environment of intracellular organelles. Current efforts involve the expansion of the FG-H family with other α-amino acids, spacers, and fluorophores, and determination of the extent by which the peptidomimetic nature of the new probes favors their performance in biological media.

Experimental Section

Synthesis of the peptidomimetic macrocycles: The appropriate 1,n-diaminoalkane was reacted with N-protected (Cbz) L-valine through the formation of an N-hydroxysuccinimide ester.[12] Yields of these intermediate peptidomimetic compounds were about 70%. The cyclization step was performed by treating 9,10-bis-bromomethylanthracene with the diamine formed by N-deprotection of the intermediates with HBr/AcOH (deprotection yields over 90%). The products of the cyclization step (at reflux in acetonitrile as the solvent, and anhydrous K_2CO_3 as the base) were purified by column chromatography to afford the final products in about 30% yield (see Supporting Information for chemical characterization).

Fluorescence measurements: The probes were dissolved in dimethyl sulfoxide (DMSO) to obtain 1 mM stock solutions, and then aliquots were diluted to 2 μM with water containing a mixture of several buffers to facilitate titrations between pH 9 and 2 (40 mM of each sodium salt: acetate, phosphate, borate, and carbonate). All the measurements were performed in the presence of 100 mM NaCl to maintain a constant ionic strength. Slight variations in the pH of the solutions were achieved by adding the minimum volumes (typically 10 μL added to 10 mL) of 0.1–1.0 M NaOH or 0.1–1.0 M HCl, in such a way that dilution effects were negligible. Fluorescence spectra were recorded (Spex Fluorolog Max-2) with excitation at the wavelengths indicated in Table 1. Plots of the fluorescence intensity versus pH were fitted by using a nonlinear curve-fitting technique (Microcal Origin 6.0). All the measurements were carried out at ambient temperature and in air-equilibrated solutions. Copper(II) and zinc(II) were added as the chloride and nitrate salts, respectively (200 μM).

Confocal fluorescence imaging: Raw 264.7, a mouse macrophage cell line, was cultured on 42-mm-diameter round glass coverslips in Dulbecco's modified Eagle's medium (MEM) containing fetal bovine serum (10%), L-glutamine (2 mg mL^{-1}), and antibiotics (penicillin/streptomycin). The cells were stimulated with interferon-γ (IFN-γ) and lipopolysaccharide (LPS) for 16 h, loaded with the dyes for 15 min in serum-free media, and then mounted on a stage at 37°C after changing to phenol-red-free L15 medium containing the above supplements. The cells were observed with a confocal laser scanning microscope (Carl Zeiss, LSM 510 meta) with 350- and 488-nm laser excitation for the 4,6-diamidino-2-phenylindole (DAPI) and fluorescein isothiocyanate (FITC) channels, respectively. An appropriate emission band was selected for the two fluorescent channels. A 63×, 1.4-NA objective was used to ensure high-resolution images. DIC images were collected simultaneously with transmitted light by excitation at 488 nm. Sequential rather than simultaneous acquisition was used to avoid bleed-through between the two fluorescent channels. Images were processed, and double- and composite-merged images were made with Adobe Photoshop.

[18] Such a different protonation behavior must occur for a combination of reasons. To partially explain the phenomenon, the observation made years ago for related systems (ref. [15b]) is relevant: The protonation of the second amine in a 9,10-bis(aminomethyl)anthracene derivative is negatively influenced by the first protonated amine, as a result of the repulsion existing between its ammonium group and the second incoming proton. In this way, larger macrocycles like those presented here would protonate the second amine (and hence lead to restoration of the fluorescence) at a lower concentration of protons (higher pK_a) than the smaller macrocycles, as the former macrocycles would accommodate the second positive charge more easily than the latter. However, other contributions should not be disregarded, in particular solvation effects in protonated species. A more extensive study of a larger family of peptidomimetic molecules is in progress.

Dielectric Properties of Porous Molecular Crystals That Contain Polar Molecules

Heng-Bo Cui, Kazuyuki Takahashi, Yoshinori Okano, Hayao Kobayashi,* Zheming Wang, and Akiko Kobayashi

Molecular materials with porous coordination frameworks have recently drawn considerable interest because of attractive properties arising from the synergy of the host lattice and the guest molecules. These properties include guest-switched spin-crossover transitions,[1] gas sorption,[2] molecular storage,[3] and magnetic solvent sensing.[4] However, to our knowledge, reports on the dielectric properties of porous molecular materials are rare, although the ferroelectric properties of molecular materials have been studied.[5] As large charges can be induced in the highly polarizable materials upon application of a relatively low electric field, it may be useful to construct novel electronic devices such as

ferroelectric field-effect transistors.[6] Except for ferroelectric (or antiferroelectric) materials, heavy-metal compounds such as $PbCl_2$ ($\varepsilon_r = 33.5$ at 20°C), PbO ($\varepsilon_r = 25.9$ at 20°C), and TlBr ($\varepsilon_r = 30.3$ at 25°C) are typical materials with large dielectric constants, ε_r. It would be desirable to develop highly polarizable materials without pernicious heavy metal atoms, in particular, molecular materials with dielectric properties that switch between high and low dielectric states.

As most molecules do not have positional freedom in the crystalline state, the dielectric constants of molecular crystals are usually very small and almost independent of temperature. On the other hand, there exist polar molecules with fairly large polarizabilities in the liquid state. Considering that the guest molecules in the porous materials will have a large degree of positional freedom, molecular solids with large dielectric constants could be designed by the suitable combination of porous molecular materials and polar guest molecules. If the positions of the guest molecules are fixed at low temperature, the material will transform into a low dielectric system, thus allowing the desired variability between high and low dielectric states.

Water and methanol are typical solvents with high polarizabilities. The dielectric constants ε_r of H_2O, CH_3OH, and C_6H_6 measured down to 4.2 K are shown in Figure 1. In
Figure 1. a) Plot of the dielectric constants ε_r of H_2O and CH_3OH as a function of temperature. The closed and open circles correspond to ε_r values of the cooling and heating processes, respectively. The dielectric constant of C_6H_6 is also presented for comparison.

contrast to nonpolar benzene, which displays a very small and constant dielectric constant, the ε_r value of liquid H_2O was as high as 10^2 just above the freezing point and then dropped very sharply. At low temperature, H_2O became a nonpolarizable material like benzene ($\varepsilon_r \approx 2$ at 5 K). Similar behavior was observed for CH_3OH.

We then measured the dielectric constants for $[Mn_3(HCOO)_6]$ and $[Mn_3(HCOO)_6](H_2O)(CH_3OH)$ in the temperature range 4.2–300 K. As reported before, $[Mn_3(HCOO)_6]$(guest) (guest = vacant; H_2O and CH_3OH;, acetic acid; N,N-dimethylformamide, furan; or benzene and iodine) is a porous ferrimagnet ($T_c = 5$–10 K).[7] Most guest molecules were removed below 100°C and the open framework was thermally stable up to about 260°C. The number of guest molecules was determined by elemental and thermogravimetric (TGA) analyses.[8] We reexamined the TGA results and confirmed a 10% weight loss around 100°C, which

exactly corresponds to the weight percent of guest molecules in $[Mn_3(HCOO)_6](H_2O)(CH_3OH)$. The dielectric constants of $[Mn_3(HCOO)_6]$ and $[Mn_3(HCOO)_6](H_2O)(CH_3OH)$ were measured for electric fields applied approximately parallel to the a, b, and c directions ($E = 1$ V, 10 kHz; Figure 2).
Figure 2. Plot of the dielectric constants ε_r of $[Mn_3(HCOO)_6](H_2O)$-(CH_3OH) as a function of temperature (red) upon application of an electric field approximately parallel to the a (E//a), b (E//b), and c directions (E//c). The dielectric constants of $[Mn_3(HCOO)_6]$ without guest molecules are also presented (black).

The porous crystal $[Mn_3(HCOO)_6]$ without guest molecules showed a small dielectric constant that was basically independent of temperature. The difference between the maximum and minimum ε_r values in the temperature range 4.2–300 K was less than one for E//a, and about two for E//b and E//c. Although relatively large changes were observed for E//b and E//c, accurate measurements were difficult for these directions due to problems in cutting suitable rectangular parallelepipeds from small single crystals. The ε_r values of the guest-containing system $[Mn_3(HCOO)_6](H_2O)(CH_3OH)$ increased with lowering temperature to a maximum of $\varepsilon_r \approx 20$ around 150 K for E//a, and then decreased sharply to $\varepsilon_r = 7$. This sharp decrease resembles the large drop of ε_r associated with liquid↔solid phase transitions of H_2O and CH_3OH shown in Figure 1. Thus, the guest molecules seem to be free to some extent at high temperature and then almost fixed at low temperature, as indicated by the large decrease in ε_r; the movement of guest molecules is frozen fairly collectively around 120 K.

As expected, by insertion of polar molecules the porous molecular crystal could be changed into a novel system with high-temperature polarizable and low-temperature nonpolarizable states. Unlike the temperature dependencies of ε_r for H_2O and CH_3OH, no distinct hysteresis was observed. However, if it is considered that the guest molecules in the one-dimensional channel can contact with only a few other

guest molecules arranged along the channel (parallel to the *b* direction; see Figure 3), the sharp drop in ε_r is surprising.
Figure 3. a) Perspective view of the crystal structure of [Mn$_3$(HCOO)$_6$]. The edge-sharing MnO$_6$ octahedrons (pale blue) form an infinite chain along the *b* axis, which are connected by apex-sharing MnO$_6$ octahedrons (purple) to produce the channel structure along *b*. The red spheres in the channel are non-hydrogen atoms (C, O) of water and methanol molecules. The gray triangles are HCOO ligands. b) The array of the edge-sharing MnO$_6$ octahedrons and the arrangement of water and methanol molecules along the *b* axis (at 155 K). The positions of the non-hydrogen atoms of the guest molecules (X$_1$, X$_2$, and X$_3$) were obtained from the structure refinements based on the main peaks in the difference Fourier maps. The distance (*d*) from X$_2$ to X$_3$ is about 1.5 Å, and the distances from X$_1$ to X$_2$ and X$_2$′ are about 3.2 (*d$_1$*) and 3.5 Å (*d$_2$*) at 155 K, suggesting the alternating arrangement of water (X$_1$ or O) and methanol (X$_2$, X$_3$) molecules along the *b* axis. The short contact of 3.2 Å (*d$_3$*) between the O atom of ligand HCOO and X$_1$ is consistent with the expected compact molecular packing along the *c* axis.

The temperature dependence of ε_r for *E//b* showed two characteristic peaks around 200 K and 150 K followed by a sharp drop around 120 K; the latter peak seems to correspond to that observed for *E//a* (Figure 2). For *E//c*, ε_r exhibited only small changes. The difference between the maximum and minimum values of ε_r was only about three. If we take into account the difficulty associated with accurate shaping of the crystal, the small changes in ε_r for *E//c* around 120 K is insignificant. For *E//c*, there seems to be only a negligible contribution from the guest molecules. As the dielectric

properties of a liquid cannot be anisotropic, the anisotropic behavior of the dielectric properties of [Mn$_3$(HCOO)$_6$](H$_2$O)-(CH$_3$OH) cannot be explained by a simple liquid model of the guest molecules.

Similar measurements were made for [Mn$_3$(HCOO)$_6$]-(CH$_3$OH) and [Mn$_3$(HCOO)$_6$](C$_2$H$_5$OH) (Figure 4).[9] As CH$_3$OH (Figure 1) and [Mn$_3$(HCOO)$_6$](CH$_3$OH) display a
Figure 4. Plot of the dielectric constants of a) [Mn$_3$(HCOO)$_6$](C$_2$H$_5$OH) and b) [Mn$_3$(HCOO)$_6$](CH$_3$OH) for *E//a* as a function of temperature. The dielectric constants of both systems exhibited negligible temperature dependencies for *E//b* and *E//c*.

prominent peak around 150 K, the peak at 150 K for [Mn$_3$-(HCOO)$_6$](H$_2$O)(CH$_3$OH) (Figure 2) might be related to a change in the polarizability of the CH$_3$OH molecules. It seems surprising that CH$_3$OH molecules in very different environments exhibit dielectric anomalies around the temperature of the bulk liquid↔solid transition. As H$_2$O shows a peak around 250 K (Figure 1), this solvent may be responsible for the peak observed at 200 K for *E//b* (Figure 2). As shown in Figures 2 and 4, the polarizabilities of [Mn$_3$(HCOO)$_6$](H$_2$O)-(CH$_3$OH), [Mn$_3$(HCOO)$_6$](CH$_3$OH), and [Mn$_3$(HCOO)$_6$]-(C$_2$H$_5$OH) display a characteristic peak for *E//a*. Thus, guest molecules in [Mn$_3$(HCOO)$_6$] seem to have a considerable amount of freedom along the *a* direction at high temperature. However, for *E//b*, only [Mn$_3$(HCOO)$_6$](H$_2$O)(CH$_3$OH) gave the characteristic temperature dependence of ε_r. [Mn$_3$-(HCOO)$_6$](CH$_3$OH) and [Mn$_3$(HCOO)$_6$](C$_2$H$_5$OH) showed small and featureless behaviors upon application of an electric field parallel to this direction. For *E//c*, every system demonstrated characterless dielectric behavior similar to that of [Mn$_3$(HCOO)$_6$].

To obtain information on the thermal motion of guest molecules in the low and high polarizability states, we reexamined the crystal structures at 90, 155, and 230 K,[10] and calculated the channel spaces of [Mn$_3$(HCOO)$_6$](H$_2$O)-(CH$_3$OH). The unit cell volume (V_{cell}), the volume of the space occupied by the atoms of the host lattice (V_{host}, determined from the van der Waals radii), and the channel space ($V_{por} = V_{cell} - V_{host}$) were calculated to be $V_{cell} = 1769$, $V_{host} = 893$, and $V_{por} = 876$ Å^3 at 230 K (for all calculations, similar values were obtained at 90 and 155 K).[11] That is, about half of the volume of the unit cell is vacant. As the "van

der Waals volumes" (the volume occupied by the atoms based on the van der Waals radii) of CH_3OH and H_2O are 35.0 and 17.5 $Å^3$, respectively, V_{guest} is 210 $Å^3$ ($= (35.0 + 17.5) \times 4$) for the unit cell containing four CH_3OH and four H_2O molecules. Therefore, the guest molecules occupy only 24% of the vacant space (V_{por}) and have a large degree of positional freedom in the channel.

We first imagined the possibility of a "1D liquidlike state" for the guest molecules along the channel at high temperature, but the results of the dielectric measurements suggest that the packing of the guest molecules in the channel tends to be loose along the *a* direction (and not the *b* direction). Due to the heavy disorder of the guest molecules, it was very difficult to determine accurately their atomic positions, although the reliability factor of the structure refinement could be reduced significantly by including solvent molecules. The difference Fourier syntheses based on the host lattice atoms gave similar peak distributions at 230, 155, and 90 K. The peaks become relatively large at lower temperatures. The carbon and oxygen atoms of the CH_3OH molecules could not be located uniquely. However, the distribution of the large peaks suggested that the water and methanol molecules are arranged alternately along the channel (parallel to *b*; Figure 3b). The structure refinements gave extremely large temperature factors for the guest molecules (the average B_{eq} value of the non-hydrogen atoms was about 15 at 155 K); the temperature factors reflect not only the large thermal motion but also the broad distribution of the guest molecules in the channel. Examination of the distribution of the main peaks in the difference Fourier maps and the results of the subsequent structure refinements did not provide information on the distribution of the guest molecules. As for the roughly refined positions of the non-hydrogen atoms, there are no contacts shorter than 3.3 Å between guest molecules and the host lattice. The positions of the non-hydrogen atoms X_1, X_2, and X_3 (Figure 3) showed only slight changes between 230 and 155 K. However, the positions of X_2 and X_3 changed significantly between 155 and 90 K, suggesting an alteration in the molecular orientation of CH_3OH. Thus, the change in the orientation polarization due to the CH_3OH molecules is expected below 155 K, which is consistent with the assumption that the peak at 150 K is related to the change of polarizability of the CH_3OH molecules. It is suggested that the non-hydrogen atoms of the guest molecules are arranged along the *b* axis with very short contacts (3.2, 3.5 Å at 155 K; broken lines in Figure 3b). Therefore, the guest molecules do not appear to be as free along this direction. It is possible that the peak at 200 K for *E//b* (Figure 2b) is related to the formation of weak O(methanol)···O(water) hydrogen bonds. However, due to the absence of information on the hydrogen atoms, clear structural evidence for the expected role of H_2O in the appearance of a peak at 200 K for *E//b* was not obtainable. As seen from Figures 3a and b, the distribution of the guest molecules is fairly compact along the *c* direction (transverse direction of the channel). In contrast, the guest molecule seems to have a large open space along the *a* direction. These structural features then cause the anisotropic dielectric behavior of $[Mn_3(HCOO)_6](H_2O)(CH_3OH)$.

Although the desired dielectric properties could be realized by the combination of porous molecular crystals and polar guest molecules, these properties do not originate from the simple 1D liquidlike behavior of the guest molecules. It is nonetheless interesting that molecules confined in the narrow 1D channel show sharp "transition-like behavior", because systems with strong a 1D nature generally do not exhibit this phase transition. As shown in Figure 4, $[Mn_3(HCOO)_6](C_2H_5OH)$ demonstrates a surprisingly steep increase in the dielectric constant around 175 K. Such a strong temperature dependence of ε_r was quite unexpected. This behavior indicates the possibility of a collective freezing of guest molecules, which will be studied in the future. Other than porous molecular crystals with 1D channel structures, there are many interesting capsule-type molecular complexes.[12] Can guest molecules confined in zero-dimensional nanocapsules exhibit characteristic dielectric behaviors? The dielectric properties of such cluster complexes that contain water molecules will be examined in the near future.

Experimental Section

The samples were synthesized according to a reported method.[7] Freshly distilled water, methanol, ethanol, and benzene were used. The guest-containing crystals were obtained by soaking $[Mn_3(HCOO)_6]$ crystals in these solvents. The temperature dependencies of the dielectric constants of H_2O, CH_3OH, C_6H_6, and $[Mn_3(HCOO)_6](guest)$ (guest = vacant, CH_3OH, H_2O, CH_3OH, C_2H_5OH) were measured in the temperature range 4.2–300 K with an LCR meter (Precision Component Analyzer 6440B of Wayne Kerr Electronics). The liquid samples were measured by using a small cylindrical platinum cell with a cell volume of about 0.25 cm^3 (the liquid samples were frozen at low temperatures). The single-crystal measurements were made with crystals cut into rectangular parallelepipeds (ca. $2.2 \times 1.5 \times 0.5$ mm^3). Silver conduction paste painted on the crystal surfaces was used as the electrodes. A 10-kHz electric field of 0.1 V (for the liquid sample) or 1 V (for the single crystal) was applied. Owing to the difficulties in shaping the small crystal, the accuracy of the dielectric constant obtained was not so high (especially for *E//b* and *E//c* because of the small size of the crystal along the *a* direction). However, the temperature dependencies were determined fairly precisely.

[8] As reported in the supplementary data of reference [7a], the composition of $[Mn(HCOO)_3](H_2O)(CH_3OH)$ was determined by elemental analysis and TGA measurements. We reexamined the TGA and confirmed the previous results. The chemical compositions of $[Mn_3(HCOO)_6](CH_3OH)_x$ and $[Mn_3(HCOO)_6]$-$(C_2H_5OH)_y$ were also determined by elemental analyses and TGA experiments. Although the content of CH_3OH could be larger than 1.0, these experiments indicated that both x and y were approximately equal to 1.0.

[9] As the crystals of $[Mn_3(HCOO)_6]$ were destroyed upon placement in water, the susceptibility of $[Mn_3(HCOO)_6](H_2O)_x$ could not be examined.

[10] Although the details of the structural data of $[Mn_3(HCOO)_6]$-$(H_2O)(CH_3OH)$ were reported in reference [7], we reexamined the crystal structures at 230, 155, and 90 K. We previously reported that the crystal has the space group $P2_1/c$, with $\beta \approx 127°$. However, here we adopted the space group $P2_1/n$ in order for β to be approximately 90° so that it was easier to adjust the direction of the electric field E to each crystal axis: $[Mn_3(HCOO)_6](H_2O)(CH_3OH)$, monoclinic, $P2_1/n$, $a = 11.683(1)$ Å, $b = 10.166(1)$, $c = 14.904(2)$, $\beta = 91.674(3)°$, $V = 1769$ Å^3, $Z = 4$, $R = 0.030$, $R_w = 0.033$ at 230 K ($R = 0.032$, $R_w = 0.036$ at 155 K and $R = 0.039$, $R_w = 0.047$ at 90 K).

[11] Pauling's van der Waals radii were used.

Quantitative Spatial Mapping of Mixing in Microfluidic Systems**

*Steven W. Magennis, Emmelyn M. Graham, and Anita C. Jones**

Microfluidics promises to revolutionize chemical analysis,[1,2] synthesis,[3–5] and biotechnology[6] by combining processes such as mixing, separation, reaction, and detection in a single device. These systems function as "labs-on-a-chip",[7] creating a technology that is low-cost, high-throughput, miniaturized, and automated. Their decreased size imparts microfluidics with many benefits, but miniaturization results in a fundamental change in flow characteristics. Turbulent flow predominates at the macroscale, whereas fluids flow in a laminar fashion at the microscale, without the random mixing that is characteristic of turbulence.[8] These laminar flow conditions mean that multiple fluid streams tend to flow in parallel through microchannels, mixing only by diffusion across their interfaces.[9] Whereas laminar flow behavior has been exploited to good effect in microanalytical systems, many emerging applications of microfluidic devices require rapid and efficient mixing.

Miniaturizing the mixing process has been identified as a major hurdle in the performance and development of microfluidic devices.[10] In labs-on-a-chip, the purpose of mixing is generally to bring together solute species from two (or more) flows. In the laminar flow regime, mixing occurs slowly by diffusion of solute (and solvent) molecules across the flow boundary. For rapid mixing, laminar flow must be disrupted to give chaotic mixing, in which there is bulk transfer of fluid (solvent carrying solute) between the flows.

Micromixers can be either passive (static) or active devices. Passive micromixing strategies frequently rely on diffusion-controlled mixing, with multilamination or flow-splitting techniques to minimize the mixing equilibration time.[11] To increase the mixing rate beyond that limited by diffusion, passive mixers that induce lateral transport of fluid between streams have been devised.[12,13] Active micromixers use miniature stirrers or external fields to chaotically

intersperse fluid flows. In spite of the increasing attention paid to the mixing problem, devices are still designed by trial-and-error methods.[14] It is therefore essential that techniques that permit the visualization of fluid composition with high quantitative and spatial resolution are found. This will allow testing of prototype devices and will provide essential experimental data to guide the development of theoretical models and to validate computational simulations. Computational fluid dynamics models have proven useful in preliminary mixer designs, but a rigorous understanding of the fundamental principles of microfluidics would lead to the development of better models for complex mixing devices.[15]

The most common methods for visualizing flow and mixing efficiency are fluorescence intensity imaging[9,10,13,16] and transmitted light microscopy with colored dyes, pH indicators, and colored reaction products.[8,15,17] These techniques are relatively cheap, easy to set up, and, in the case of fluorescence imaging, provide excellent contrast. Unfortunately, the ability of these intensity-based techniques to provide a quantitative picture of fluid composition in microfluidic systems is severely limited by their sensitivity to variations in the optical path, instability of the light source, scattering, uncertainty in the dye concentration, and photobleaching effects.[18]

Herein, we describe a superior approach to the imaging of microfluidic systems by using fluorescence lifetime imaging microscopy (FLIM). This technique involves spatially resolving the fluorescence lifetime of a fluorescent dye, rather than the intensity. It overcomes all of the aforementioned problems of intensity-based methods, because the lifetime is independent of the number of fluorescing molecules. To date, the use of FLIM has been restricted to the imaging of biological systems.[19–21] Herein, we demonstrate that FLIM enables spatially resolved quantitation of fluid mixing in microfluidic devices.

Solutions of the fluorescent dye 1,8-anilinonaphthalene sulfonate (ANS) in pure methanol and a water/methanol mixture (1:1 molar ratio, which corresponds to water at 30.8 % v/v) were pumped into a microchannel flow cell to meet head-on at a T-junction, as illustrated in Figure 1a. The flow channels had a depth of 200 µm and a width of 400 µm. The flow rates were varied from 10–75 µLmin⁻¹. These dimensions and flow rates correspond to Reynolds numbers of less than 10 so that the fluids are in the laminar flow regime.[17]

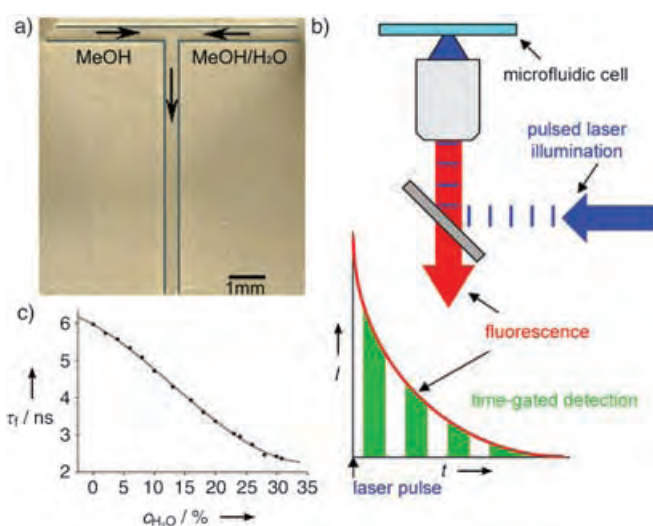
Fluorescence lifetime images were obtained by using wide-field illumination of the microfluidic cell with an ultrafast pulsed laser. A gated intensified CCD camera was used to collect the resultant fluorescence within a short time window after a defined delay following the laser pulse. A series of images was acquired by varying the delay time between the detection window and the laser pulse, thereby sampling the entire fluorescence decay of the ANS probe (Figure 1b); the data from each pixel was then fitted to a single exponential decay. ANS was chosen as the dye because its fluorescence lifetime is extremely sensitive to the composition of water/methanol mixtures, showing a near-linear variation from 250 ps in pure water to 6 ns in pure methanol.[22] The calibration curve in Figure 1c, which correlates


Figure 1. a) Photograph of the microfluidic flow cell, in which arrows indicate the direction of flow; the channel edges have been highlighted for clarity. b) Schematic of fluorescence lifetime imaging microscopy (FLIM). c) Calibration curve showing ANS fluorescence lifetime (τ_f) as a function of the methanol/water ratio in the solution. The following equation gave a good fit to the data:
$y = 5.97258 - (0.09267x) - (0.00382x^2) + (9.82168\times10^{-5}x^3)$, in which y is the lifetime in ns and x is the concentration of water (% v/v) in the water/methanol mixture. The concentration of ANS was 1 mM. Lifetimes were measured by TCSPC. The decays and fitted data are given in the Supporting Information.

the fluorescence decay rate of ANS with the percentage of water in solution, was determined by time-correlated single-photon counting (TCSPC, Supporting Information). ANS displays a single exponential decay at all water/methanol ratios, making it an ideal and unambiguous probe of solvent composition.

The effectiveness of the time-resolved technique is demonstrated in Figure 2, which compares intensity and lifetime images for two regions of the flow cell during a typical experiment. The intensity and FLIM images, which are displayed with the same pseudocolor scale, are noticeably different. The intensity images (Figure 2a) show large, irregular variations in intensity across the field of view, with the regions of highest intensity located near the input of the solution of ANS in methanol. The FLIM images give a clear and unambiguous picture of the liquid composition (Figure 2b). These images show smooth transitions from long to short lifetime (left to right), across a clearly defined mixing region. By using the calibration curve in Figure 1c, the solution composition at each point in the FLIM image can be directly determined. In principle, there should be a clear correlation between the intensity images and the lifetime images; the longer the fluorescence lifetime, the higher the quantum yield and hence the higher the fluorescence intensity (given that the ANS concentration is constant). In practice, however, no such correlation is apparent, and it is clear that the intensity-based images are strongly distorted by variation of the illuminating field, the collection efficiency, and the other variables mentioned above. The microfluidic flow cell
Figure 2. Comparison of a) fluorescence intensity images with b) FLIM images for the mixing of solutions of ANS in pure methanol and ANS in a water/methanol mixture (30:70 *v/v*) by using the arrangement shown in Figure 1 a. The concentration of ANS in both input solutions was 1 mM, and the flow rate was 50 μL min^{-1}. For FLIM, the gate width was 600 ps, and 46 images were recorded at intervals of 500 ps. Every image represents the average of five separate exposures, each with an integration time of 0.1 s and a readout time of 50 ms to give a total acquisition time of about 35 s. The lifetimes of ANS in pure methanol and the equimolar water/methanol solution at the input to the flow cell are the same as those measured by the TCSPC method. The intensity image was constructed by summing the lifetime images, which allows a direct comparison between the time-resolved and intensity-based methods. By using the calibration curve in Figure 1 c, the composition of the fluid can be read directly from the FLIM map.

Figure 3. FLIM images for the mixing of solutions of ANS in pure methanol and ANS in a water/methanol mixture (30:70 *v/v*), showing the spatial dependence of fluorescence lifetime (τ_f) on the flow rate and the position within the flow cell. Images were acquired at three positions in the flow cell and for three flow rates, as indicated. Other experimental parameters are as described for Figure 2 b.

down the channel. In contrast, the two fluids have completely mixed at this distance downstream at the lowest flow rate (10 μL min^{-1}).

FLIM allows mixing to be monitored with high spatial resolution (Figure 4 a,b); it is possible to accurately measure small changes in the fluid composition in sub-picoliter interrogation volumes. The technique is sensitive enough to reliably detect a change in the volume fraction of approximately 2 % (Figure 4 c); this is equivalent to a lifetime change of about 250 ps, which is a measurement limit set by the

used in this study is of a simple design, and it is likely that intensity-based imaging will be even more prone to optical artifacts in complex devices. FLIM, on the other hand, faithfully reports the fluid composition, as the lifetime is governed solely by the solvent environment of the ANS probe, and is immune to other undesirable effects.

The FLIM technique has been used to monitor mixing as a function of flow rate and flow distance (Figure 3). The compositional variation observed in Figure 3 is indicative of two fluids under laminar flow, as expected. One striking feature of the resultant images is how little mixing occurs in the region where the two input streams meet. Despite being forced together, there is no sign of turbulent mixing. The input streams are well-behaved, with no fluctuations in the position of the boundary between them (Supporting Information). Instead, the two streams stay completely separate, except for a narrow mixing region that results from diffusion. The overall trend is for the mixing region to broaden as the flow rate decreases and as the fluids move further downstream, as expected for diffusion-controlled mixing. For the highest flow rate (75 μL min^{-1}), regions that are identical in composition to the input streams persist, even after traveling 1 cm

Figure 4. Quantitation of mixing by using FLIM: a) FLIM image of the mixing of methanol and water/methanol with a 20× objective. The arrangement shown in Figure 1 a was used, and the flow rate was 75 μL min^{-1}. b) Expanded image of the same mixing region from a 100× objective. c) Composition profile along the cross section indicated in Figure 4 b. d) Representation of the fluorescence lifetime data in Figure 4 a as a composition surface; composition values were calculated with the calibration curve in Figure 1 c.

temporal width of the detection windows. The compositional resolution could be improved by increasing the time-resolution of fluorescence detection, using photon counting methods. This method is equally applicable to diffusion-controlled mixing (the fluorescence lifetime responds to the net diffusion of water molecules across the flow boundary) and mixing by mass transport of fluid. Therefore, it is generally applicable to the evaluation of all types of micromixers. The quantitative spatial profiles of fluid composition that can be generated by FLIM (Figure 4c,d) will be particularly valuable for supporting and guiding theoretical models of fluid flow in microfluidic systems.

The present results demonstrate that wide-field FLIM can directly measure the 2D mixing of fluids in microfluidic systems with a level of quantitation that is not available from other methods. It has been shown that intensity-based techniques such as confocal microscopy[13] and optical coherence tomography[23] can provide 3D imaging of microfluidic flows. This is important for cases in which the variations in fluid composition are aligned with the optical axis, as these cannot be resolved by intensity-based wide-field methods.[23] Our wide-field FLIM technique would, however, detect nonuniform mixing along the optical axis, that is, the depth axis of the microchannel, as the superposition of a number of layers of varying composition along this axis would result in the observation of a multiexponential fluorescence decay, rather than the single exponential decay characteristic of uniform mixing throughout the depth of field. The FLIM approach can be extended to full 3D imaging with confocal or multiphoton excitation without loss of the attendant benefits of time-resolved detection that have been established herein. In this version of the technique, the tightly focused excitation laser beam is raster-scanned across the sample, and the fluorescence decay is acquired point-by-point, using TCSPC. The use of multiphoton excitation would also enhance imaging penetration through strongly absorbing or scattering fluids and structures.

The mixed solvent system reported herein, in conjunction with the ANS probe, was devised purely as a measurement tool for the generic study of micromixing, and was not intended to relate to any specific applications of lab-on-a-chip systems. Our approach is, however, generally applicable to any solvent system, as long as there is a change in molecular environment upon mixing that results in variation in the fluorescence lifetime of an appropriate probe. For example, the mixing of aqueous solutions could be studied by using streams of different pH that incorporate a pH-sensitive dye, such as a seminaphthorhodafluor (SNARF) probe. Alternatively, streams containing different concentrations of a collisional quencher, such as iodide, could be used. In view of the flexibility of this approach, we anticipate that FLIM will become an essential tool in the design, modeling, and evaluation of microfluidic systems.

Experimental Section

All measurements were made with the ammonium salt of ANS (Fluka, used as received). The methanol and water used in this study were HPLC grade (Fisher Scientific) and were used as received. Solutions of ANS (≈ 1 mM) were stored in the dark, and the lifetime of ANS fluorescence at room temperature was used as a routine check of sample purity after storage. No emission could be detected from the solvents under the instrumental conditions employed. Time-resolved fluorescence spectroscopy was performed by using the technique of TCSPC as described previously.[22]

The microfluidic cell was fabricated from Perspex with the T-shaped channel milled out to a depth of 0.2 mm using an end mill of diameter 0.4 mm (Drill Service Ltd.). The three inlet/outlet holes were drilled 1.6 mm in diameter and fitted with polypropylene tubing. The cell was sealed by gluing (Norland Optical Adhesive No. 61) a cover-glass over the channels, and was attached to syringes with silicone tubing. The flow of fluids from the syringes was controlled by a syringe pump (Univentor 802, Univentor Ltd.).

For FLIM, frequency-doubled light from a mode-locked Ti sapphire laser ($\lambda = 400$ nm, repetition rate = 4.75 MHz) was expanded, collimated, and directed into a Nikon TE300 inverted microscope operating in an epifluorescence configuration. This excitation light was reflected from a dichroic filter (DM430, Nikon) and focused onto the microfluidic flow cell with either $20 \times$ (PA, NA = 0.75, Nikon) or $100 \times$ (Ph3, NA = 1.3, oil immersion, Nikon) objectives. The laser power incident on the flow cell was typically ≈ 100 μW. The resultant fluorescence was collected through the same objective, passed through a barrier filter (515–555 nm, Nikon) and imaged onto a Picostar HR-12QE gated intensified CCD camera system (LaVision GMBH, Berlin). The excitation beam was split, and one portion was used to trigger a fast photodiode. The photodiode output was passed through a constant fraction discriminator (CF4000, Ortec), and used as the trigger signal for the Picostar system. The experiments described herein were recorded with a gate width of 600 ps, which was measured by detecting laser light reflected from a mirror (the minimum gate width for this camera is 200 ps). The intensifier gate was delayed relative to the laser trigger signal by using a DEL150 picosecond delay module (Becker and Hickl). The 12-bit CCD camera is a progressive scan interline sensor ($1370(H) \times 1040(V)$ pixels; pixel size = 6.45×6.45 μm^2). Images were the average of five separate exposures, were recorded in steps of 500 ps over a range of 23 ns, and employed 4×4 hardware binning. The integration time for each image was 100 ms, with a readout time of 50 ms to give a total acquisition time of approximately 35 s. The excitation intensity was adjusted to give a peak intensity of 3000–4000 counts in the brightest image, which corresponds to the start of the fluorescence decay. The background signal of ≈ 50 counts was subtracted from each image. DaVis 6.2 software running the Picostar DaVis module was used to control the Picostar system and delay card, and to analyze the data. The peak of the fluorescence intensity was found in the fourth image of the image series. To ensure that the instrument response did not interfere with the fitting, the first five images were not used for analysis. The sixth image (which was 1 ns after the peak) and subsequent images were analyzed to allow a decay curve to be constructed for each pixel. Pixels with low counts in the first analyzed image (typically 700 counts) were removed at this stage. Each of these curves was then fitted to a single exponential decay. A lifetime map was produced by assigning a color on a 16-bit pseudocolor scale to each of the fitted lifetimes, and these were displayed over a range of 2.0–6.8 ns.

Communications

The Internal Structure of Helical Pores Self-Assembled from Dendritic Dipeptides is Stereochemically Programmed and Allosterically Regulated**

Virgil Percec,* Andrés E. Dulcey, Mihai Peterca, Monica Ilies, Janine Ladislaw, Brad M. Rosen, Ulrica Edlund, and Paul A. Heiney

Pore-forming proteins, peptides, and their remodeled structures perform diverse biological and biologically inspired functions. These include the formation of viral helical coats[1a] and transmembrane channels,[1b,c] mediation of protein folding,[1d] reversible encapsulation,[1e] stochastic sensing,[1f] as well as pathogenic[1g] and antibacterial[1h] activity. Synthetic strategies to obtain porous or tubular supramolecular assemblies have been elaborated.[2] However, only several synthetic supramolecular pore structures are stable in solution and in solid state.[3] Recently, we reported a class of amphiphilic dendritic dipeptides (amphiphilic dendrons functionalized at their apex with a dipeptide) that self-assemble both in solution and in bulk into supramolecular helical pores.[4a] A *trans* conformation of the dendron is required to mediate self-assembly and to provide a new hydrogen-bonding mechanism of a parallel and partially interdigitated array of dipeptides. This conformation is selected by a solvophobic solvent[4a] or in solid state by the microsegregation of the aliphatic and aromatic parts of the dendron. It has also been suggested that the stereochemistry of the peptide determines the sense of the helical pore.[4]

Herein, we report that the structure of the helical porous structure self-assembled from dendritic dipeptides is programmed by the stereochemistry encoded in the dipeptide. A combination of solution and solid-state analysis techniques together with molecular modeling has been used to provide the sequential pathway to this self-assembly process that

seems to operate by allosteric[5] control. The dendritic dipeptide used in these investigations is (4-3,4-3,5)12G$_2$-CH$_2$-X, in which X = Boc–L-Tyr–L-Ala–OMe, Boc–D-Tyr–D-Ala–OMe, Boc–L-Tyr–D-Ala–OMe and Boc–D-Tyr–L-Ala–OMe, and Boc = *tert*-butoxycarbonyl.
In a previous communication,[4a] we reported the self-assembly of an L-L dendritic dipeptide in solvophobic solvents[2f,6a,6b] such as cyclohexane and deuterated cyclohexane by a combination of ^{1}H NMR spectroscopy, UV/Vis and circular dichroism (CD) techniques. Small- and wide-angle X-ray diffraction (XRD) experiments were carried out on powder and oriented fibers obtained from the porous structures assembled from L-L, D-D, L-D, D-L, and from the racemic dendritic dipeptides. The pore diameter (d_{pore}) was computed for all samples from XRD data[4a,b] at temperatures between 71 and 75.4°C in their 2D hexagonal columnar liquid-crystal phase. XRD experiments on oriented fibers concluded that the amphiphilic dendron mediates the self-assembly into a helical structure, the helical sense of which is endowed by the stereochemistry of the Tyr residue. This mechanism is related to other examples in which a stereocenter determines the twist sense of racemic helical structures,[6a–e] as suggested by the groundbreaking work of Green et al.[6e] However, the assembly of our system differs from published examples in

which a stereocenter induces helicity in an achiral tubular assembly[2g] and in other supramolecular structures.[6f] It is also the dipeptide part of the dendron apex that directs the self-assembly into porous[4a] rather than closed supramolecular columnar structures.[7] However, the role of the stereochemistry of Ala, the potential cooperativity between the stereochemistry of Ala and Tyr, the structure of the dendron in the supramolecular assembly, and the stability of the porous structure at various temperatures are important mechanistic questions that were not previously addressed.[4a]

The CD data of L-L, D-D, L-D, and D-L dendritic dipeptides obtained at different temperatures during their self-assembly in cyclohexane are compared in Figure 1. In all cases, only the weak positive or negative Cotton effect associated with the molecular solution of a dendritic dipeptide[4a] is observed above 30°C (inset in Figure 1). Below 30°C the dendritic dipeptides self-assemble into helical porous columns, and their CD data are associated with the aromatic part of the helical supramolecular dendrimer as demonstrated by wide-angle XRD on oriented fibers[4a] (Figure 2), and by CD and
Figure 1. CD spectra (1.6×10^{-4} M in cyclohexane) of a) (4-3,4-3,5)12G$_2$–CH$_2$–Boc–L-Tyr–L-Ala–OMe; b) (4-3,4-3,5)12G$_2$–CH$_2$–Boc–D-Tyr–D-Ala–OMe; c) (4-3,4-3,5)12G$_2$–CH$_2$–Boc–L-Tyr–D-Ala–OMe; d) (4-3,4-3,5)12G$_2$–CH$_2$–Boc–D-Tyr–L-Ala–OMe. The arrows indicate temperature increases. Insets: 30–60°C.
Figure 2. X-ray diffraction patterns of aligned fibers collected at 23°C from the dendritic dipeptides L-L, D-D, L-D, and D-L. i = short-range helical feature of dendron at ≈ 4.5 Å, j = dendron tilt $\approx 60°$, k = 5-Å registry along the column axis feature.

Figure 3. Influence of dipeptide stereochemistry and temperature on a) column diameter and b) pore diameter.

UV/Vis spectra of model dendrons with and without dipeptide stereocenters (Supporting Information). The CD data of L-L with D-D, and of L-D with D-L dendritic dipeptide assemblies show respective mirror-image Cotton effects. However, the CD results of L-L and D-D are different from those of L-D and D-L. This structural difference observed by CD is supported by the XRD patterns obtained from aligned samples (Figure 2). The XRD of L-L is similar with that of D-D while that of L-D to that of D-L derived porous structures. The k diffraction of L-D and D-L is sharper than that of L-L and D-D. In L-L and D-D, k is most likely overlapped with the i diffraction (Figure 2).

The difference between the CD of the L-L/D-D pair and those of the L-D/D-L pair indicates that the stereochemistry of Ala also plays an important role in the programming of the supramolecular pore structure. These different CD data are generated by various modes of intramolecular and intermolecular dendron arrangements in the helical porous structure that are induced by dipeptide stereochemistry.

To quantify the role of the stereochemistry of Tyr and Ala we used both small- and wide-angle XRD to investigate the structure of the supramolecular pore. The temperature-dependence of the column (d_{col}) and pore (d_{pore}) diameters[4a,b] is shown in Figure 3 for all combinations of dipeptide stereochemistry (XRD data provided in the Supporting Information). Regardless of the dipeptide stereochemistry, the supramolecular assemblies exhibit a glass transition (T_g) at 57 to 60°C, followed by the 2D columnar hexagonal phase that becomes an isotropic liquid at 94°C for L-D and D-L, and at 96°C for L-L and D-D.[4a] Within experimental error, both

d_{col} and d_{pore} are temperature-dependent above T_g and temperature-independent below T_g (Supporting Information). There are two messages provided in Figure 3. The large slopes of d_{col} and d_{pore} temperature-dependence above T_g and below the isotropic state introduce large errors in the estimation of the role of stereochemistry on pore structure in this temperature range. However, the constant values of d_{pore} and d_{col} below T_g provide access to a quantitative structure analysis in the temperature range of interest for practical applications. As can be observed in Figure 3b, the stereochemistry of the dipeptide influences d_{pore}. Within experimental error of the XRD method[4a,b] and of the enantiomeric purity of the Tyr and Ala used (Supporting Information), d_{col} and d_{pore} of L-L are equal to D-D and the respective values for L-D are equal to D-L. A combination of small- and wide-angle XRD results, molecular modeling, and simulation experiments together with density data[4a] was used to create the structure of the porous columns below T_g. Figure 4 indicates that the helical sense of each column is determined by the stereochemistry of Tyr. The cross-section of the porous columns is illustrated in Figure 5. These cross-sections show that within experimental error, the internal structure obtained from L-L is identical to that obtained from
Figure 4. Molecular models of the helical porous columns constructed from XRD, molecular modeling, and density data showing the influence of dipeptide stereochemistry on the helical sense of the column. For simplicity, the alkoxy groups of the dendrons were replaced with methoxy groups.

the D-D dendritic dipeptide, whereas that of L-D is similar to D-L. In all cases, the internal structure of the pore is hydrophobic.

The mechanism responsible for the construction of the pore can be envisioned by inspecting the dendritic dipeptide conformations from the supramolecular structures presented in Figure 4 and 5. Fragments of these dendritic dipeptide conformations containing only the benzyl ether dendritic unit attached to Tyr are compared in Figure 6 (the complete dendritic dipeptide conformations are in the Supporting Information). In all stereoisomers, the hydroxyphenyl group of Tyr is in an *anti* conformation with respect to the Boc group, whereas the dendron is *syn*. The orientation of the tetrahedral carbon atom of the Tyr stereocenter determines the dendron sense and therefore the handedness of the helix. To create a larger pore size with the stereochemistry of L-Tyr–D-Ala and D-Tyr–L-Ala, the methyl group of Ala must be located in the inner part of the pore, whereas in the case of L-Tyr–L-Ala and D-Tyr–D-Ala the methyl ester group of Ala is in the inner part of the pore. This model suggests that the stereochemistry of the dipeptide influences the conformation of the dendron, which in turn determines the conformation of the Ala part of the dipeptide. This cooperative process[4a] resembles a primitive allosteric control mechanism.[5]

The cooperativity between the stereochemistry of Tyr and Ala seems to be required to switch the overall conformation of the dendritic dipeptide and therefore, to determine the internal hydrophobic structure of the pore below T_g. The parallel and partially interdigitated arrangement of peptides in the pore[4a] facilitates the formation of the hydrogen-bonding network structure shown in Figure 7. This structure
Figure 5. Influence of dipeptide stereochemistry on the cross-section structure of the hydrophobic pore and d_{pore} below T_g: L-L, $d_{pore} = 13.4 \pm 1.2$ Å; D-D, $d_{pore} = 14.0 \pm 1.2$ Å; L-D, $d_{pore} = 14.6 \pm 1.4$ Å; D-L, $d_{pore} = 15.6 \pm 1.4$ Å (white = methyl groups of Ala, blue = methyl groups of Boc, red = oxygen atoms, green = N−H of dipeptides, gray = other carbon atoms). These structures were obtained as cross-sections of the columns from Figure 4. For simplicity, the dendrons are not shown.

can be divided in two main types of hydrogen-bonding networks. The first is the bonding network inside one layer indicated by *j–k* or *l–m*. This is the most important for the stability and order of the supramolecular assembly. These directional in-layer hydrogen bonds are responsible for the translation along the column axis from one unit to the proximal neighbors. This translation step is controlled both by the dipeptide and by the dendron size. The in-layer network is independent on dipeptide stereochemistry and creates a *j–k–j–k–j–k…* or *l–m–l–m–l–m…* helical pattern (Supporting Information). The second hydrogen-bonding network is programmed by dipeptide stereochemistry containing the hydrogen bonds between n^{th} to $n \pm 12^{th}$ units. For L-Tyr–L-Ala and D-Tyr–D-Ala, the oxygen atoms of Ala do not participate in any hydrogen bond, whereas for L-Tyr–D-Ala and D-Tyr–L-Ala, the Ala oxygen atoms create the second cross-layer network of hydrogen bonds.

L-Tyr–L-Ala and D-Tyr–D-Ala supramolecular structures have a smaller pore size than L-Tyr–D-Ala and D-Tyr–L-Ala, which indicates that the Ala stereochemistry affects the pore
Figure 6. Influence of dipeptide stereochemistry on dipeptide conformation in the assembled supramolecular porous columns from Figure 4: *i* indicates that orientation of the L-Tyr or D-Tyr tetrahedral stereocenter determines the rotation sense, whereas the strong directional in-layer hydrogen-bonding networks *j–k–j–k–j–k...* or *l–m–l–m–l–m...* require a translation along the column axis in the supramolecular assembly. The proposed mechanism explains the cause of the helical supramolecular columnar assembly in which the stereochemistry of Tyr determines the helical sense. For simplicity, only the first benzyl ether of the dendron is shown (dotted circle).

Figure 7. Hydrogen-bonding network determined by a combination of ^{1}H NMR spectroscopy, XRD analysis, and molecular modeling[4a] for a) L-L, b) D-D, c) L-D, and d) D-L dendritic dipeptides during the formation of the supramolecular pore structure (all distances in Å). The strongest in-layer directional hydrogen bonds are labeled by the same convention as in Figure 6 (*j–k* and *l–m*). The column axis is vertical; for simplicity only the N-bound hydrogen atoms are shown (white).

size. At the same time, there is a slightly larger distance between layers for the latter two (see the 5-Å registry feature in Figure 2). These two results are reflected in dipeptide conformation (Figure 7), with the Ala upper region oriented perpendicular to the column axis for the L-Tyr–L-Ala or D-Tyr–D-Ala, and parallel to the column axis for L-Tyr–D-Ala or D-Tyr–L-Ala. The supramolecular helical hydrogen-bonded structure between *k–j* and *l–m* is shown in Supporting Information together with the inner and outer regions of the pore (the other cross-layer hydrogen bonds have been omitted for simplicity).

   In conclusion, we report herein the first synthetic example of a helical porous supramolecular structure self-assembled from a hybrid dendritic dipeptide in which the internal structure is programmed by the stereochemistry of the dipeptide. The amphiphilic dendron is responsible for the assembly of the dipeptide into a parallel and partially interdigitated porous structure.[4a] The stereochemistry of Tyr selects the sense of the helical porous structure. However, the stereochemistry of the entire dipeptide determines the overall arrangement of the dendron in the supramolecular structure, which in turn determines the conformation of the dipeptide and the structure and diameter of the pore in a cooperative process. This supramolecular porous structure is stable over a broad range of temperatures, has a constant d_{pore} below T_g and represents the first example of a supramolecular dendronized tubular polymer[7,8] exhibiting a 3D structure[9] that is stereochemically programmed. Allosteric regulation[5] seems to be operating in this process. This self-assembly

concept expands the synthetic capabilities of dendrimers and dendrons.[10]

Synthetic Methods

Straightforward Access to a Structurally Diverse Set of Oxacyclic Scaffolds through a Four-Component Reaction**

*Oscar Jiménez, Guillermo de la Rosa, and Rodolfo Lavilla**

Multicomponent reactions (MCRs) constitute an important group of transformations that combine many elements of an ideal synthesis, such as operational simplicity, atom economy, bond-forming efficiency, the access to molecular complexity from simple starting materials, and so on. The modular character of this approach is extremely suitable for drug discovery, and therefore it is widely used for the fast generation of bioactive compounds.[1] Recently, the concept of chemical genomics has sparked the development of diversity-oriented synthesis (DOS)[2] to reach the structural flexibility needed in the small-molecule range, thus demanding new and versatile synthetic methodology. We report herein new processes leading to diversely functionalized oxacycles (privileged structures including carbohydrate-related compounds)[3] based on an MCR that allows access to a variety of scaffolds using commercially available reagents.

The Povarov reaction (the condensation of an aniline, an aldehyde, and an activated olefin), has been useful in the formation of tetrahydroquinoline adducts, including aza- and oxacyclic fused derivatives.[4] Previous reports[5] suggested that the formal [4+2] cycloaddition was nonconcerted and, consequently, opened the possibility to trap the final oxocarbonium intermediate with an external nucleophile (terminator), thus leading to a four-component reaction.[6] Herein, we describe a Lewis acid catalyzed four-component reaction of an amine, an aldehyde, a cyclic enol ether, and an alcohol, which acts as the terminator of the process[7] (Scheme 1).

The first experiment was carried out using equimolar amounts of 3,4-dihydro-2*H*-pyran (**1a**), 3-nitroaniline (**2a**),

Scheme 1. General four-component reaction and proposed mechanism. LA = Lewis acid.

ethyl glyoxylate (**3a**),[8] and an excess of ethanol (**4a**). Under Sc(OTf)$_3$ catalysis,[9] the reaction was successful, and the desired product **5a** (81%) was obtained as a mixture of two isomers in a ratio of 70:30.[10] Similarly, by using glyoxylic acid (**3b**) we obtained the compound **5b** in high yield (83%, isomer ratio 70:30). Purification of this mixture afforded the major component and allowed the stereochemical elucidation of the process[11] by conversion of **5b** into the major isomer of **5a** with EtOH and Sc(OTf)$_3$ and subsequent esterification using Mukaiyama's reagent.[12] As expected, the approach of the imine to the enol ether was similar in both cases whereas the trapping of the oxocarbonium ion took place with opposite stereoselectivity (Scheme 2).
Scheme 2. Three- and four-component reactions leading to **5a** and **5b**. MS = molecular sieves.

All the components were systematically varied in order to investigate the scope of the reaction, starting with the amine **2** (Table 1). The process seemed to be general to anilines with electron-donating or electron-withdrawing groups, as well as alkyl amines. Therefore, there is no need for deactivated anilines to avoid the formal [4+2] cycloaddition (see Scheme 1). Under these conditions, the reaction progresses through a four-component reaction pathway to yield the corresponding adduct with no evidence of the Povarov compound. *n*-Butylamine (entry 2) was less reactive and the reaction required heating (40°C for 48 h). The diastereoselectivity in these series seems to depend on the amine used,

Table 1: Range of amines **2**.

Entry	2	Yield [%]	5		Isomer ratio[a]

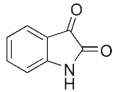
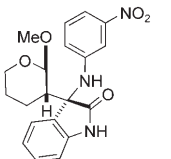
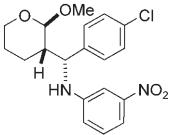
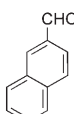
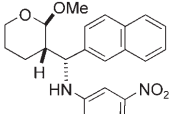
2	*n*BuNH$_2$ **2b**	55	**5d**		2.3:1
3	**2c**	82	**5e**		2.3:1
4	**2d**	93	**5f**		9:1

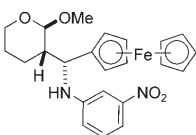
[a] Determined by ^{1}H NMR spectroscopic or HPLC methods; see Reference [11].












ranging from 2.3:1 with anilines and linear amines (entries 1–3) to 9:1 with more bulky amines (entry 4).

The range of carbonyl compounds was also investigated (Table 2). Besides glyoxylic acid and ethyl glyoxylate, aromatic aldehydes showed convenient reactivity and isatin and 2-ferrocenecarboxaldehyde also yielded the expected adducts.[13]

The range of alcohols (terminators) was studied next (Table 3). Primary alcohols such as MeOH, EtOH (Table 1, entries 1–4), and *n*BuOH (Table 3, entry 1) worked very well. Even secondary and long-chain primary alcohols yielded the desired products (entries 2 and 3), although in low yields. The use of water was more problematic, probably because of the reduced stability of the hemiacetal **5n**. Interestingly, ethanethiol could be efficiently used to afford adduct **5o** (entry 5). As expected, the alcohols do not play a significant role in the stereocontrol of the reaction. We have preliminarily explored the possibility of using quenchers with higher structural and biological relevance, such as terpenes (entry 6) and carbohydrate derivatives.[14] Other oxygen-based species with reduced nucleophilicity (AcOH, CF$_3$CH$_2$OH, *p*-nitrophenol) did not afford the expected four-component reaction adducts. With these species, the process furnished the Povarov compound (e.g. **6a**) in a regio- and stereoselective manner (Figure 1).

The study of the fourth component (the cyclic enol ether) opened the possibility to further increase the molecular diversity as well as to better control the stereochemical outcome of the reaction (Table 4).

[a] The isomer ratio in all cases was around 2.5:1; see Reference [11].

A hydroxymethyl substituent at position 2 of the dihydropyran ring (**1c**) efficiently traps the oxocarbonium intermediate to yield adduct **5q** (entry 1), a compound which is structurally related to the sexual attractant insect pheromone brevicomin.[15] An acetoxymethyl at position 6 did not exert relevant streodirecting effects on the MCR, and mixtures of stereoisomers were isolated as shown in entry 2. In sharp contrast, glycals bearing a substituent at position 4 displayed excellent facial stereoselectivity and enabled access to enantiopure compounds. For instance, compound **5s** (36%) was obtained from tri-*O*-acetyl-D-galactal in a process carried out at 40°C during 14 days.[16] Extension of this methodology to the D-glucal derivative afforded **5t** (20%). Microwave irradiation efficiently promoted faster and cleaner reactions, and **5s** and **5t** were obtained in 71% and 45% yield, respectively, in only 2 minutes (entries 3 and 4). Remarkably, we did not observe Ferrier-type or ring-opening transformations, which are common in acid-promoted reactions involving glycals and other enol ethers.[17] Additionally, the Povarov reaction proceeds with improved stereoselectivity to yield compound **6b** as a single stereoisomer (Figure 1).[18]

Tailored enol ethers also worked in this MCR. For example, substrates **1g** and **1h**, respectively prepared by Heck[19] and hetero-Diels–Alder reactions,[20] afforded the desired adducts stereoselectively with diastereomeric ratios of 4:1 for **5u** (the minor isomer is the epimer at the *p*-methoxyphenyl center) and 2.5:1 for **5v**[11] (Scheme 3).

One interesting application of this methodology is the ready access to new α-amino acid derivatives that bear an oxacycle substituent. This was done in just one additional step by hydrogenolysis of the benzhydryl derivative **5f** to afford the corresponding α-amino ester **7a** (78%). Interestingly, the oxidation of the *p*-methoxyaniline derivative **5e** with CAN

Figure 1. Povarov-type compounds **6a** and **6b**.

afforded the quinoline **8a** (55%). An improved protocol (71%) for this transformation involved treatment of **5e** with TFA in open atmosphere (O_2 as the oxidant). Analogously, oxidative treatment of **6b** produced the quinoline derivative **8b** (58%) bearing a stereodefined polyoxygenated chain at position 3 (Scheme 4).

The structural flexibility of this protocol is remarkable and allows the formation of four different scaffolds (Scheme 5) by applying post-condensation reactions to the MCR. Thus, it is possible to obtain compounds such as **5e** by a four-component reaction, **6c** by the Povarov three-compo-

Communications

nent reaction, **8a** by treatment of either **5e** or **6c** with acid, and **6d** by oxidation of **6c** with DDQ.[21]

In conclusion, we have developed a four-component reaction based on the nucleophilic interference of the Povarov reaction. The process is general and allows a broad range of variations in every component. The stereoselectivity of the reaction strongly depends on the substrates and ranges from low to moderate to excellent. Good stereocontrol is observed when sterically demanding amines and enol ethers are used.[22] The modular character of this approach, the simplicity and availability of most building blocks used, and the remarkable level of structural diversity attained make this

Enhanced Metabolic Stability and Protein-Binding Properties of Artificial α Helices Derived from a Hydrogen-Bond Surrogate: Application to Bcl-xL**

Deyun Wang, Wei Liao, and Paramjit S. Arora*

*Dedicated to Professor Peter B. Dervan
on the occasion of his 60th birthday*

The α helix plays a fundamental role in imparting specificity to protein–protein and protein–nucleic acid interactions. Molecules that can predictably and selectively disrupt these interactions would be invaluable as tools in molecular biology and, potentially, as leads in drug discovery.[1] We recently described a new strategy for the synthesis of artificial α helices in which one main-chain i to $i+4$ hydrogen bond in the target α helix is replaced with a carbon–carbon bond derived from a ring-closing metathesis reaction (Figure 1).[2] A key feature of this hydrogen-bond surrogate (HBS) approach is that the internal placement of the cross-link affords short helices with minimal perturbations to their molecular recognition surfaces. This method differs significantly from the commonly employed side-chain cross-linking method for helix stabilization. A limitation of the latter approach is that side-chain functionality must be sacrificed to nucleate stable helical conformations. The modified side chains are unavailable for molecular recognition; moreover, the resulting tether blocks at least one face of the putative helix. The HBS approach uniquely allows the synthesis of artificial helices with all side chains available for molecular recognition, and does not place any steric encumbrances on the helix surface. We believe that our artificial α helices have the potential to target protein receptors and regulate protein–protein interactions more successfully than helices with cross-linked side chains.

Our initial studies demonstrated that the HBS approach affords highly stable α helices from alanine-rich peptide sequences. Herein, we show that this metathesis-based

method can effectively stabilize α-helical conformations in
biologically relevant sequences, that the resulting molecules
resist proteolytic degradation as compared with the uncon-
strained analogues, and that the HBS helices can bind a
protein target with high affinity. For these proof-of-principle
protein-binding studies with our artificial helices, we chose to
target the extensively studied α helix binding protein, Bcl-
xL.[3] Bcl-xL is an antiapoptotic protein that regulates cell
death by binding the α-helical BH3 domain of a family of
proapoptotic proteins (including Bak, Bad, Bid, and Bax).[4–6]
NMR spectroscopic studies by Fesik and co-workers have
shown that the 16-mer peptide **1** derived from the Bak BH3
domain adopts an α-helical conformation upon binding to
Bcl-xL (Figure 1 b).[3] Circular dichroism (CD) studies dem-
onstrated that this peptide is unstructured under physiological
conditions in the absence of the protein partner and only
slightly helical in trifluoroethanol (TFE), a helix-promoting
solvent.[7]

Several methods that afford stabilized α helices or helix
mimetics have already been used to target Bcl-xL, thus

allowing us to directly compare the performance of our
internally constrained artificial α helices.[8–10] Significantly,
Huang and co-workers recently reported that Bak BH3
α helices stabilized by a lactam-based side-chain cross-linking
strategy were unable to bind Bcl-xl.[11] The authors speculated
that the lack of binding might be a result of steric clashes
between the cross-link and the narrow binding pocket of Bcl-
xL. However, Verdine and co-workers found that side-chain-
bridged α helices corresponding to the BH3 domain of a
different proapoptotic protein, Bid, can target Bcl-xL and
suppress the growth of leukemia cells in mice.[1] Judicious
placement of the side-chain constraints requires prior knowl-
edge of the protein–ligand complex; otherwise, multiple
randomly constrained helices must be prepared and tested.
Nevertheless, their report highlights the potential of con-
strained α helices as tools for the control of protein–protein
interactions in vivo. Taken together, these two protein-bind-
ing studies from the Huang and Verdine research groups
illustrate potential problems with the side-chain bridging
strategy. The fundamental advantage of the HBS approach
over this strategy for stabilizing helices is that the helix
surfaces are not encumbered by the constraining element.
The HBS approach should therefore greatly simplify the helix
design process. The key question we ask herein is whether the
HBS-derived Bak α helix can bind Bcl-xL when the side-
chain-constrained (lactam bridge) Bak helix is unable to
target this same protein receptor.

The artificial Bak BH3 α helix **2a** was synthesized on
Rink amide resin by the ring-closing metathesis reaction
shown in Scheme 1.[12] HBS α helices can be synthesized from
commercially available amino acids or simple amino acid
derivatives and do not require preparation of enantiomeri-
cally pure amino acid analogues. In the present case, standard
solid-phase peptide synthesis using appropriate Fmoc-modi-
fied amino acids, dipeptide **4**, and pentenoic acid afforded the
fully protected resin-bound bis-olefin peptide **3**, which was
subjected to the Hoveyda–Grubbs ring-closing metathesis
catalyst to afford the peptide macrocycles. The metathesized
peptide was cleaved from the resin with trifluoroacetic acid to
give the constrained peptide **2a** as a mixture of the *cis*- and
trans-alkene isomers. We were unable to separate these
isomers by HPLC.

The helical conformation of constrained peptide **2a** was
investigated by CD. CD studies on **2a** and the control peptide
1 were performed in TFE/phosphate-buffered saline (PBS,
1:4) to obtain a quantitative measure of their helical content
(Figure 2). The CD results of the artificial α helix **2a** display
double minima at 206 and 222 nm and a maximum at 189 nm,
consistent with those observed for canonical α helices. The
HBS α helix **2a** is roughly 46% helical as measured by Yang's
method (Supporting Information).[13] In agreement with
previous studies,[7] we found that the unconstrained Bak
peptide **1** is only weakly helical ($\approx 20\%$). We hypothesized
that the GDD tripeptide residue (residues 82–84 in the
Bak BH3 domain) in the middle of the Bak peptide sequence
may limit the propagation of the helix and lower the overall
helical content of **2a**, as glycine is known to be a potent "helix
breaker", and aspartic acid has been implicated as a helix stop
signal.[14–16] Fesik and co-workers have previously shown that

the residues Gly82 and Asp83 cannot be substituted with alanine without sacrificing binding affinity for the protein; however, Asp84 may be replaced without any deleterious effects.[3] To test the effect of replacing Asp84 on the helicity of Bak peptide, we prepared HBS α helix **2b** in which Asp84 is substituted with a side-chain-acetylated lysine (Lys^Ac) (Figure 1). We made this particular substitution because the Bak BH3 peptide with a capped lysine residue was previously shown to bind Bcl-xL with high affinity.[17] We were gratified to find that this single substitution provided a significant boost in α helicity (Figure 2). HBS helix **2b** is roughly 65% helical: an increase in helicity of 140% over that of **2a**. As expected, this substitution provided a similar increase in helicity for the unconstrained Bak BH3 (Supporting Information). Importantly, this set of experiments shows that the HBS approach can successfully stabilize α-helical conformations in biologically relevant sequences.

The binding affinities of the unconstrained Bak peptide **1** and artificial Bak α helices **2a** and **2b** for Bcl-xL were assessed by using a previously described fluorescence polar-

ization assay with a fluorescein-labeled 16-mer Bak peptide (fl-Bak, **5**; see Supporting Information). The affinity of fl-Bak for Bcl-xL was determined to be 264 ± 18 nM, which is in agreement with the previously reported values. Competitive inhibition of the fl-Bak–Bcl-xL complex by the Bak peptides (**1**, **2a**, and **2b**) is detected by a decrease in fluorescence polarization as the immobilized probe dissociates from the protein. Regression analysis[18] provided a K_d value of 154 ± 23 nM for the unconstrained Bak peptide **1**, within range of the previously reported values (Figure 3). Under the same
Figure 3. Fluorescence polarization studies indicate that HBS α helices **2a** and **2b** target Bcl-xL with high affinity. The K_d value for each peptide was determined by competitive inhibition of fluorescein-labeled Bak peptide (15 nM) and Bcl-xL (500 nM) complex. Bak BH3 **1** ($K_d = 154 \pm 23$ nM, -----◇-----), HBS helix **2a** ($K_d = 325 \pm 51$ nM, – – –□– – –), and HBS helix **2b** ($K_d = 69 \pm 16$ nM, ——■——).

assay conditions, HBS helices **2a** and **2b** bound Bcl-xL with K_d values of 325 ± 51 and 69 ± 16 nM, respectively. These binding results point to a potential transition-state problem involved in forcing a preformed helix into this pocket, as the unconstrained Bak BH3 peptide **1** targets this protein with twofold higher affinity than the constrained peptide **2a**. Nevertheless, the data validate our helix design principle as we find that our internally constrained Bak α helices do indeed access this deep hydrophobic cleft, whereas Bak α helices prepared by the side-chain-bridging method show no affinity for the same target. Moreover, we show that a very high-affinity binder, **2b**, for the Bcl-xL can be developed by increasing the helicity of the constrained peptide through rational substitutions. On the basis of these preliminary results, we are now preparing a second generation of HBS Bak α helices designed to be more helical and to bind Bcl-xL with higher affinity than **2b**. It remains to be determined if these HBS α helices show selectivity for Bcl-xL over other closely related members of the Bcl-2 family (and over other helix-binding proteins).[8,19,20]

Proteolytic cleavage is one of the principal reasons limiting the in vivo efficacy of peptides as reagents. Proteases are known to bind their substrates in linear or beta-strand conformations,[21] and peptides locked into helical conformations have been shown to resist proteolytic degradation.[22,23] Accordingly, we determined the proteolytic stability of HBS Bak helices **2a** and **2b** relative to Bak peptide **1** in the presence of trypsin, which is expected to cleave the peptide at

the arginine residue (Arg76) positioned two residues away from the macrocycle in helices **2a** and **2b**. We questioned how this residue that lies outside the constraint, yet is close enough to be in a highly helical conformation, responds to the protease. Comparison of the initial velocities of cleavage by trypsin indicated that the HBS α helix **2a** is proteolyzed roughly 30-fold slower than the unconstrained Bak peptide analogue **1** (Figure 4). As expected, an increase in the helicity of the constrained peptide results in a further decrease in the initial velocity of cleavage by trypsin. Thus, the HBS helix **2b** is roughly twofold more stable than **2a** and 60-fold more stable than **1** against proteolysis by trypsin. The proteolytic
Figure 4. Metabolic stability of HBS α helices. HPLC assay shows rapid proteolysis of a) the unconstrained peptide **1** in the presence of trypsin, whereas b) the HBS α helix **2a** degrades at a much slower rate. Tryptophan (500 μM) was used as an internal control for the HPLC studies. c) Comparison of the initial velocities for the proteolysis of Bak BH3 **1** ($k = 18.0$ μM min^{-1}, -----◇-----), HBS helix **2a** ($k = 0.60$ μM min^{-1}, – – –□– – –), and HBS helix **2b** ($k = 0.30$ μM min^{-1}, ——■——).

stability observed for **2a** and **2b** is similar to that reported for a side-chain cross-linked α helix.[22]

In summary, we have demonstrated that artificial α helices prepared by the replacement of a hydrogen bond between the i and $i+4$ residues at the N terminus of a short peptide with a carbon–carbon bond can stabilize biologically relevant peptides in helical conformations. These HBS α helices can bind their expected protein receptor with high affinity and resist trypsin-mediated proteolysis. The results are an important step in our efforts to develop rationally designed modulators of protein–protein interactions. These molecules encompass larger surface areas than those displayed by typical small molecules, and may ultimately prove to be more effective in targeting large protein interfaces.

Biomaterials

Saccharide–Peptide Hybrid Copolymers as Biomaterials**

*Mark Metzke, Naphtali O'Connor, Soumen Maiti,
Edward Nelson, and Zhibin Guan**

Biomaterials are important for many biomedical applications such as implants and prosthetics, pharmaceutical formulations, drug and gene-delivery agents, DNA and protein microarrays, and tissue engineering.[1] Synthetic polymers remain the most versatile class of biomaterials because of the ease in controlling their compositions, structures, and properties.[2,3] There is currently a great demand for novel polymeric biomaterials with tailored structures and more-defined functions. Ideally, desired biomaterials can be chemically synthesized in a ground-up approach to exhibit precisely the needed chemical, biological, and engineering properties for the targeted medical application.

An important strategy for designing new biomaterials is to construct synthetic polymers from natural building blocks. The premise is to combine the advantages of both bio- and synthetic polymers, thereby gaining the biocompatibility and biodegradability of natural materials and the versatility of synthetic structural design. Examples of biomaterials made

Communications

from natural building blocks include poly(lactic acid),[4] poly(glycolic acid),[5] poly(anhydride)s,[6] poly(amino acid)s,[7] pseudo-poly(amino acid)s,[8] carbohydrate-derived polyesters,[9] and artificial proteins.[10] Whereas these polymers generally exhibit good biocompability, and some are used in important clinical applications, their structural diversity and functional properties are relatively limited, warranting further development of more versatile biomaterials.

Herein we describe a new class of biomaterials derived from natural saccharide and amino acid building blocks (Figure 1). Our design is based on the following considerations;
Figure 1. Formation of the saccharide–peptide hybrid copolymer.

1) saccharides and amino acids are abundant and readily available natural monomers, 2) these natural building blocks are likely to yield polymers with inherent biocompatibility that then degrade into natural, nontoxic, and biosorbable species, 3) their rich functionalities allow convenient modification/tailoring of materials for desired applications, and 4) the modular synthesis offers advantages in combining structural precision with design flexibility.

The combination of various modules gives rise to numerous polymers suitable for combinatorial screening of the chemical, biological, and mechanical properties of these polymers. Although much effort has been devoted to making oligomeric glycopeptides that can mimic the structure and function of natural glycoproteins,[11,12] little has been reported on the synthesis of high-molecular-weight saccharide–peptide polymers.[13,14] In our novel design, both the saccharide and peptide building blocks are incorporated into the main chain of the polymer. Herein we report our general design concept, synthesis, and the initial testing of a new class of biomaterials. We also discuss our studies of these saccharide-peptide hybrid copolymers in one specific biomedical application, gene delivery.

We chose oligolysines and a galactose-derived monomer **1** for copolymerization. Three hybrid polymers (poly-**1**, poly-**2**, and poly-**3**) were synthesized by interfacial polymerization with various peptide monomers **2**–**4** (Scheme 1). ^{1}H and ^{13}C NMR spectroscopic analyses were used to confirm the structure of each polymer. The number-averaged molecular weights (M_n) of the three prepolymers for poly-**1**, poly-**2**, and poly-**3** were measured by gel-permeation chromatography with polystyrene calibration standards to be 15 000, 9085, and 13 200 $g\,mol^{-1}$ respectively. Global cleavage of the acetonide and *tert*-butoxycarbonyl (Boc) protecting groups afforded the final carbohydrate–peptide hybrid copolymers, poly-**1**, poly-**2**, and poly-**3** (details of the synthesis and characterization can be found in the Supporting Information).

After the successful synthesis of the hybrid copolymers, we investigated their general properties as biomaterials including the biodegradability, cytotoxicity, and immunological properties. Enzymatic-degradation studies with serine proteases (subtilisin A and trypsin) showed that the polymers are indeed biodegradable. MALDI-TOF mass spectra were measured periodically to monitor qualitatively the decrease
Scheme 1. Synthesis of galactaro–oligolysine hybrid copolymers (poly-**1**, poly-**2**, poly-**3**). a) Interfacial polymerization, H_2O/CCl_4; b) 30% trifluoroacetic acid in THF/water.

in the molecular weight of the polymer over time. The resultant profile indicated that the polymers were nearly completely degraded after 5–7 days of exposure to an enzyme (see Supporting Information).

The cytotoxicity of the polymers was then assayed at various concentrations by means of a standard MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide) test. The hybrid copolymers exhibited minimal cytotoxicity to Cos 7 cells at a range of concentrations (Figure 2). Poly-L-lysine (PLL) with $M_n = 8500 \, \text{g mol}^{-1}$ was used as a control
Figure 2. Cytotoxicity data acquired through MTT testing at various polymer concentrations with PLL as the control. Comparison was made with cationic amino groups at equivalent molar concentrations, consistent with those used in gene transfection studies. Standard deviations are shown with error bars ($n = 4$). The symbol *** indicates statistical significance at levels of $p < 0.001$ for the experimental polymers versus each concentration of PLL (indicated by brackets). The p values were obtained by using Student–Newman–Keuls multiple comparisons testing.

because our polymers are derived partially from L-lysine and are of comparable molecular weight, which affects both cytotoxicity and transfection levels.[15] Comparisons between the polymers and the control were made at equivalent molar concentrations of cationic amino groups (the same as those used in later gene-transfection studies). The contrast is striking: whereas the PLL homopolymer exhibits high cytotoxicity at relatively low concentrations (5–100 μg mL^{-1}), our hybrid copolymers show lower cytotoxicity even at higher concentrations (82–330 μg mL^{-1} for poly-**1**; 56–226 μg mL^{-1} for poly-**2**; and 46–183 μg mL^{-1} for poly-**3**). The placement of saccharide spacers on the main chain of the polymers lowered their cytotoxicity to levels approaching the blank controls in the absence of polymer. Although the exact mechanism for this decrease in toxicity remains to be investigated, we believe that the breakage of the cationic polypeptide into short segments with saccharide spacers lowers continuous charge density while the hydrophilic saccharide fragments shield the surface charge of the polyplexes. Both effects are hypothesized to alleviate disruptive coulombic interactions of the polyplexes with the cell

membrane. Other studies have shown that the introduction of carbohydrate units into other polymers also results in a lower cytotoxicity.[16]

As our carbohydrate–peptide copolymers are new compounds, it is important to test whether they generate immune responses in vivo. As a representative example, the immunogenicity of poly-**3** was evaluated by ELISA with Fisher 344 rats as models. Based on a standard protocol, 100 μg of poly-**3** was administered in the first, third, and sixth weeks by either subcutaneous (SC) injections in the footpad or by intravenous (IV) injections into tail veins. The animals underwent a phlebotomy 21 days after each administration of the polymer. The serum for ELISA testing was obtained at three-week intervals. If a positive immunogenic response is elicited by the polymer, then antibodies generated in the rat serum would bind to the polymer-coated wells. An anti-rat immunoglobulin (IgG) conjugated HRP (horseradish peroxidase) then binds to the adsorbed polymer antibodies, catalyzing oxidation of a substrate that can be detected by UV/Vis spectrometry (see Supporting Information for experimental details). Figure 3 summarizes the ELISA data, which show no evidence of antibody response. All rats were healthy (no weight loss, normal activity, good hygiene/quality fur), which suggests that there is no adverse immune response or toxicity.

After the assays to test their biodegradability, cytotoxicity, and immunogenicity, the hybrid copolymers were evaluated for a specific biomedical application. Synthetic cationic
Figure 3. Anti-polymer ELISA data, which include the results for background (Bkgd), pre-immune serum, subcutaneous (SC), intravenous (IV), and normal rat serum (positive control: the wells were coated with rat serum enriched in antibodies, hence resulting in an expected positive signal). The y axis is the optical density (OD) at $\lambda = 490$ nm for the oxidation product of ELISA substrate, tetramethylbenzidine (TMB), which represents the level of immunogenic response of the polymer. The first, second, and third sera were taken at the third, sixth, and ninth week, respectively ($n = 3$). All experimental details are included in the Supporting Information.

polymers are currently being actively pursued as gene delivery vectors because they can neutralize and condense DNA into particles capable of undergoing endocytosis.[17] A critical issue in developing effective synthetic polymeric vectors is that competent gene carriers, such as PLL and polyethyleneimine (PEI), are often cytotoxic.[17,18] As our hybrid copolymers carry cationic charges at physiological pH values, and have minimal cytotoxicity, they were evaluated as vectors for gene delivery. Electrophoretic mobility-shift assays (EMSAs) indicated that poly-**1**, poly-**2**, and poly-**3** efficiently complex pSV-β-gal plasmid DNA under physiological conditions. For poly-**1** and poly-**3**, an N/P (ammonium positive charge on polymer/phosphate negative charge on DNA) ratio of 1.5 completely retarded the DNA; for poly-**2** this ratio was 2 (see Supporting Information). The difference in DNA/polymer binding efficiency is presumably due to the difference in the molecular weight of the polymer as poly-**2** has a slightly shorter chain length than poly-**1** and poly-**3**. Complex formation occurs largely because of entropic gains owing to the liberation of smaller counterions along the macromolecular chains.[19] Thus, as the chain is shortened (as for poly-**2**), there is less entropic gain during DNA complexation, which results in slightly weaker binding. The physical characteristics of the polymer/DNA complexes were then investigated by using AFM. Each polymer condensed DNA into spherical nanoparticles with typical diameters of 50–200 nm (Supporting Information), which is within the normal size range for cellular internalization.[20]

The transfection efficiency of the three hybrid polymers was tested and compared with PLL by using a luciferase-assay kit under serum-free conditions. As PLL and poly-**1**, poly-**2**, and poly-**3** have only primary amines and lack other amino residues to afford proton sponge effects, chloroquin (which is known to disrupt the membrane of the endosome) was used in all gene-transfection studies to enhance the endosomal release after entrance into the cell. Figure 4 summarizes the gene-transfection efficiency (normalized to the total cellular protein). Poly-**2** and poly-**3** showed a significantly higher transfection ability than PLL at similar N/P ratios. This is due primarily to the high toxicity of PLL at those concentrations. The lower transfection efficiency of poly-**1** compared to poly-**2** or poly-**3** is presumably due to lower local charge density on poly-**1** and the varied nature of the amino groups on the polymer chain. Poly-**2** and poly-**3** have both α-amino and more-flexible ε-amino functionalities, whereas poly-**1** has only α-amine groups. It has been reported that very subtle changes in polymer structure can result in significant changes in gene–transfection efficiency.[16a] Further structure–property correlation will be investigated in the future, which will provide information for structural optimization to improve the transfection efficiency.

In summary, we have described our concept for the design of saccharide–peptide hybrid copolymers as a new class of biomaterials. As examples, galactaro–dilysine (poly-**1**), trilysine (poly-**2**), and tetralysine(poly-**3**) hybrid copolymers were synthesized through interfacial polymerization of a galactose-derived monomer and corresponding L-lysine-derived peptide monomers. Enzymatic degradation, MTT tests, and immunological assays show that the hybrid copoly-
Figure 4. Luciferase gene-transfection data for the hybrid copolymers with PLL as control. Standard deviations are shown by the error bars ($n = 3$). Relative light units (RLU) were normalized by using the total cellular protein in each well. The symbols * and *** indicate statistical significance at levels of $p < 0.05$ and $p < 0.001$, respectively, for the experimental polymers and PLL at corresponding N/P ratios. The p values were obtained by using Student—Newman–Keuls multiple comparisons testing.

mers are biodegradable, nontoxic, and nonimmunogenic. The hybrid copolymers were tested as vectors for possible application in gene delivery. EMSA, AFM, and luciferase-transfection studies demonstrate that the hybrid copolymers can efficiently compact plasmid DNA into soluble nanoparticles and be used as safe gene carriers. Given the natural abundance and functional diversity of saccharides and amino acids, their biodegradability, low cytotoxicity, and nonimmunogenicity, a diverse family of saccharide–peptide hybrid polymers are currently under development in our laboratory for various biomedical applications including gene/drug delivery and tissue engineering.

Natural Product Synthesis

A Diels–Alder Macrocyclization Enables an Efficient Asymmetric Synthesis of the Antibacterial Natural Product Abyssomicin C**

Christoph W. Zapf, Bryce A. Harrison, Carmen Drahl, and Erik J. Sorensen*

In memory of Murray Goodman

In their pioneering report on the diene synthesis, or the Diels–Alder reaction, Otto Diels and Kurt Alder recognized the profound impact that this pericyclic reaction would have in

the syntheses of "complex compounds related to or identical with natural products" and speculated that this process may also be involved in the biosyntheses of natural products.[1] As the premier method for the construction of functionalized and stereochemically complex six-membered-ring systems,[2] the Diels–Alder reaction is the foundation of some of the most important achievements in chemical synthesis, and the question concerning its relevance in biosynthesis is the subject of much active research.[3] There is a wealth of natural products that could conceivably arise from biosyntheses that feature the Diels–Alder reaction.[4] We reasoned that much of the architectural complexity of the polycyclic marine natural product abyssomicin C (**1**) could arise from a Diels–Alder macrocyclization step and were intrigued by the possibility that such a transformation may also occur in the biogenesis of this natural product.

Süssmuth and co-workers recently described the isolation of abyssomicin C and two related compounds from a sediment sample collected 289 m beneath the surface of the Sea of Japan.[5] These natural products are produced by the rare actinomycete *Verrucosispora* and possess complex polyketide-like structures that were elucidated through extensive NMR spectroscopic studies and an X-ray crystallographic analysis. Abyssomicin C is unique within this new class of marine natural product in its ability to inhibit Gram-positive bacteria, including pathogenic methicillin-resistant and vancomycin-resistant *Staphylococcus aureus* strains.[5,6] Although its biomolecular target in bacteria is not yet known, abyssomicin C blocks the conversion of chorismate to *para*-aminobenzoic acid (*p*ABA) and is thus an early-stage inhibitor of the biosynthesis of tetrahydrofolate (Scheme 1).

Inhibitors of the biosynthesis of *p*ABA are highly attractive as potential antibacterial drugs because *p*ABA is produced in many microorganisms but not in humans. As the first bacterial metabolite that inhibits the biosynthesis of *p*ABA, abyssomicin C is an attractive lead structure for the development of new inhibitors of pathogenic bacteria and a compelling objective for research in chemical synthesis.[7] Herein, we describe a remarkably diastereoselective Diels–Alder macrocyclization in the context of a convergent asymmetric synthesis of (−)-abyssomicin C (**1**). Our preferred design reduced the complexity of the target structure to three fragments and called for two carbonyl addition reactions to achieve key bond formations (Scheme 2).

In this scenario, an intermolecular aldol reaction between the hypothetical ketone enolate **2** and commercially available *trans,trans*-2,4-hexadienal (**3**) would be followed by the addition of a lithiated tetronate **4** to an aldehyde carbonyl group. A simple adjustment of the oxidation state would then furnish the needed γ-methylene-β-tetronate derivative **5** for the crucial intramolecular Diels–Alder step.[8] Some impressive large-ring formations that were achieved by the Diels–Alder method[9] bolstered our confidence in the idea that **5** might cycloisomerize to tricycle **6**. If successful, this transformation would establish a substantial portion of the architecture of abyssomicin C and afford a valuable cyclohexenyl double bond for a late-stage epoxidation reaction. Provided that such an oxidation reaction could be achieved in a site- and diastereoselective fashion, we hoped to form the

Scheme 1. The marine natural product abyssomicin C (**1**) inhibits the conversion of chorismate into *para*-aminobenzoic acid (*p*ABA). ADC = aminodeoxychorismate.[6]
Scheme 2. Design for a synthesis of abyssomicin C which features a Diels–Alder macrocyclization.

rigid oxabicyclo[2.2.2]octane substructure of **1** by a *trans*-diaxial opening of the epoxide by a tetronic acid function that would be exposed by demethylation. The successful execution of this general plan is described below.

Because of the symmetrical nature of the hypothetical species **2**, *meso*-2,4-dimethylglutaric anhydride (**7**) was considered to be an ideal starting material for our synthesis (Scheme 3). This substance was prepared on a 100-gram scale by a combination of the procedures developed by Paquette and Boulet[10] and Lautens and co-workers[11] and was subsequently advanced to the known prochiral dimethyl ester **8** in the straightforward fashion shown. The enzymatic desymmetrization procedure of Lautens and co-workers, which had previously been applied to the acyclic *meso*-diester **8**,[11] provided a smooth high-yielding route to the optically active monocarboxylic acid **9**. A chemoselective reduction of the ester function with lithium borohydride was followed by

an acid-catalyzed lactonization to **10**, a known substance[12] that was judged to have an optical purity of 93% *ee* by HPLC analysis. The action of methyllithium on lactone **10** gave the corresponding lactol, after which a simple alcohol silylation step caused ring-opening and afforded methyl ketone **11**.

Our aim was to utilize **11** in an intermolecular aldol addition reaction with **3**. The commercially obtained dienal **3** is admixed with as much as 10 mol% of the 4-*cis* geometrical isomer, so we opted to produce this compound from all-*trans* 2,4-hexadien-1-ol through a Swern oxidation.[13] Aldehyde **3**, prepared in this manner, was taken forward into the key aldol step in crude form. Under the reaction conditions shown, **3** joined efficiently with the kinetic lithium enolate derived from **11**, thus resulting in the formation of a 1:1 mixture of secondary alcohol epimers. A straightforward alcohol silylation step then gave a diastereoisomeric mixture of silyl ethers, shown as **12**. Our intent was to unveil the sensitive triene array of the targeted Diels–Alder substrate immediately before (or perhaps during) the key cycloaddition event through a simple β elimination. Therefore, the production of epimers in the aldol construction of **12** was ultimately inconsequential.

It was pleasing to discover that the triethylsilyl ether in **12** could be directly transformed to keto aldehyde **13** by a Swern oxidation.[14] Our expectation that this electrophilic compound would react chemoselectively with organolithium reagent **4**, the conjugate base derived from the known methyl tetronate **14**,[15] was justified by the construction of intermediate **15** under the conditions shown. This reaction, which established a key carbon–carbon bond and afforded material that contains all of the carbon atoms of abyssomicin C, can be performed on gram scales, although its yield is typically modest and variable (e.g., 35–55%).[16] This aldehyde addition process also yielded a mixture of alcohol diastereoisomers that could be resolved by chromatography on silica gel. However, it was our custom to convert this mixture of four diastereoisomers into two through an alcohol oxidation with the Dess–Martin periodinane reagent.[17] This oxidation proceeded efficiently and yielded the desired acyl tetronate **16**.
Scheme 3. a) MeOH, reflux, 24 h; b) MeOH, H$_2$SO$_4$ (cat.), benzene, reflux, 18 h (87%, 2 steps); c) α-chymotrypsin, phosphate buffer pH 7.8, 23°C, 4 days (96%); d) LiBH$_4$ (2 equiv), THF, 50°C, 5 h; then HCl, H$_2$O, 23°C, 15 h (60%, 93% ee); e) MeLi (1.3 equiv), THF, −78°C, 1.5 h; f) TESCl (1.1 equiv), imidazole (2 equiv), DMF, 0°C, 1.5 h (79%, 2 steps); g) LDA, THF, −78°C, 2.5 h; then *trans,trans*-2,4-hexadienal (1.1 equiv), 1.5 h (94%, d.r.=1:1); h) TBSOTf (1 equiv), 2,6-lutidine (2 equiv), CH$_2$Cl$_2$, 0°C, 0.5 h (85%); i) (COCl)$_2$ (5 equiv), DMSO (10 equiv), Et$_3$N (10 equiv), CH$_2$Cl$_2$, −40→−78°C, 5 h (60–70%); j) LDA, toluene, −78°C, 6 min; then aldehyde **13**, 1.5 h (35–55%, d.r.=1:1); k) DMP (1.5 equiv), CH$_2$Cl$_2$, 0→23°C, 1.5 h (84%). TES=triethylsilyl, TBS=*tert*-butyldimethylsilyl, Tf=trifluoromethanesulfonyl, DMF=*N,N*-dimethylformamide, DMSO=dimethyl sulfoxide, LDA=lithium diisopropylamide, DMP=Dess–Martin periodinane.

The decision to utilize a β-*tert*-butyldimethylsilyloxy keto function as a progenitor to the required trienone array proved to be well founded. Preliminary observations indicated that trienone **5** is a rather unstable substance. Fortunately, we could generate this compound upon exposure of a solution of intermediate **16** in dichloromethane to 5 mol% of the Lewis acid scandium(III) triflate (Scheme 4). Much to our delight, the crude trienone **5** underwent a remarkably efficient and highly diastereoselective cycloisomerization to tricycle **6** when heated to 100°C in toluene. To avoid handling the sensitive trienone **5**, we searched for reaction conditions that would permit the β-elimination/ Diels–Alder sequence to be conducted in a one-pot process. We hoped to find a Lewis acid catalyst that would effect the required elimination of *tert*-butyldimethylsilanol on heating and that this event would trigger the desired Diels–Alder cyclization of the intermediate trienone **5** to **6**. Among the metal triflates that were examined, lanthanum(III) triflate was capable of inducing the direct conversion of **16** into tricycle **6** under the conditions shown. This transformation was also highly diastereoselective; **6** formed cleanly, and we did not observe any other regioisomeric or diastereoisomeric cyclo-adducts. In an effort to gain some insight into this interesting and fortunate selectivity, we located the transition states for all of the possible intramolecular Diels–

Communications

Alder reactions at the HF/3-21G level of theory.[18] The lowest-energy transition-state conformation clearly resembled **17**, and the next lowest transition-state conformation was 5.7 kcal mol^{-1} higher in energy. This analysis predicts that **5** should cycloisomerize through conformer **17**, an asynchronous transition state that has an *anti* relationship between the two carbonyl groups that are part of the acyl tetronate moiety.

From the vantage of **6**, only three seemingly straightforward transformations were needed to reach the target structure. Fortunately, dimethyldioxirane was well suited to the oxidation of the newly formed cyclohexenyl double bond.[19] This site- and diastereoselective oxidation produced the desired epoxide and was followed by a quantitative nucleophilic demethylation of the acyl methyl tetronate substructure. This two-step reaction sequence afforded **18**, a compound that appeared to be an ideal precursor to abyssomicin C (**1**). Because of its carboxylic acid like nature, the hydroxy group in **18** is a weak nucleophile. Compound **18** is essentially impervious to basic reagents; all efforts to achieve base-induced heterocyclizations to abyssomicin C were unsuccessful. After much experimentation, we found that warming a solution of **18**, *para*-toluenesulfonic acid monohydrate, and lithium chloride in acetonitrile to 50°C for 2 h resulted in the formation of abyssomicin C (**1**) and a regioisomeric substance that we named "iso-abyssomicin C". Under these conditions, the ratio of these two compounds is 1:1, but they are readily separated by chromatography on silica gel. Optical rotation studies of our sample of synthetic abyssomicin C (**1**) showed an $[\alpha]_D^{20}$ value of −40 (c = 0.1, MeOH), and spectroscopic studies (^{1}H and ^{13}C NMR, UV, and IR) resulted in data that matched those reported by Süssmuth and co-workers.[5]

In summary, a concise enantioselective synthesis of (−)-abyssomicin C was achieved in 15 steps from the known *meso*-2,4-glutaric anhydride (**7**) by a reaction sequence that features a highly diastereoselective Diels–Alder macrocyclization. We can procure significant amounts of the natural product by this route, which should facilitate an investigation of the intriguing biological properties of abyssomicin C. It was proposed that the rigid oxabicyclo[2.2.2]octane substructure of abyssomicin C (**1**) may serve as a structural surrogate for the conformation of chorismate in solution and that its electrophilic enone system may inactivate one of the enzymes involved in the biosynthesis of *p*ABA in bacteria (Scheme 1) through covalent alkylation.[5] By adapting the chemistry described herein, we anticipate that it will be possible to synthesize affinity-tagged variants of abyssomicin C for studies of its potential chemical reactivity and binding properties in human-tissue proteomes.[20, 21] This information would be part of a comprehensive analysis of the potential of abyssomicin C as an antibacterial drug candidate. Further studies of this fascinating early-stage inhibitor of the biosynthesis of tetrahydrofolate in bacteria are clearly warranted.

on the use of the Group 8 metals (the metals of the iron, cobalt, and nickel triads), in which the metal ions are d^6 or d^8. We are interested in incorporating metal–metal quadruple bonds with a $\sigma^2\pi^4\delta^2$ configuration into organic conjugated polymers because the dinuclear center is redox-active and its ease of oxidation can be tuned over a considerable range by the selection of the metal (M = Cr, Mo, W) and the ancillary ligands,[5] even to the point that the M_2 center is more easily oxidized than cesium.[6] The M_2 center may also be brought into conjugation with the π system of the organic polymer through the agency of a carboxylate link.[7] The carboxylate π system couples with both the π system of the polymer backbone and the M_2 δ orbitals. We recently illustrated this by the preparation of some discrete model complexes of the type $[M_2(O_2CR)_4]$, in which R = mono-, bi-, and terthienyl (α,α') groups.[8]

Herein, we describe our synthesis of oligomeric/polymeric thienyl-based materials incorporating metal–metal quadruple bonds. The general reaction is shown in Equation (1),

$$[M_2(O_2CR)_4] + HOOC\text{-}(Thp)_n\text{-}COOH \xrightarrow[\text{toluene}]{22^{\circ}C}$$
$$[M_2(O_2CR)_2(O_2\text{-}C(Thp)_n\text{-}CO_2)]_m + 2\,RCOOH \quad (1)$$
although, as noted below, there are important restrictions (Thp = thiophene = 2,5-C_4H_2S). Full experimental details are given in the Supporting Information.

To prepare soluble oligomers/polymers of the desired empirical formula, we found it necessary to introduce chain-branching alkyl substituents on both the spectator carboxylate and the thienyl dicarboxylate. Thus far, we have enjoyed most success with 2,4,6-triisopropylbenzoate (2,4,6-iPr$_3$C$_6$H$_2$CO$_2$ = TiPB) as the ancillary ligand. This group has the added advantage that the *trans*-disubstituted product appears to be the preferred thermodynamic product. This is also evident from the preparations of the discrete compounds for molybdenum [Eq. (2)] and for tungsten [Eq. (3)]. For

$$[Mo_2(TiPB)_4] + 2\,HOOC\text{-}(Thp)_n\text{-}R \xrightarrow[\text{toluene}]{22^{\circ}C}$$
$$\textit{trans}\text{-}[Mo_2(TiPB)_2(O_2C\text{-}(Thp)_n\text{-}R)_2] + 2\,TiPB\text{-}H \quad (2)$$

$$[W_2(TiPB)_2(tBuCO_2)_2] + 2\,HOOC\text{-}(Thp)_n\text{-}R \xrightarrow[\text{toluene}]{22^{\circ}C}$$
$$\textit{trans}\text{-}[W_2(TiPB)_2(O_2C\text{-}(Thp)_n\text{-}R)_2] + 2\,tBuCOOH \quad (3)$$
molybdenum, we used the corresponding homoleptic carboxylate $[Mo_2(TiPB)_4]$[9] and for tungsten, the mixed compound $[W_2(TiPB)_2(tBuCO_2)_2]$ as starting materials. Even with the use of only 1 equivalent of the thienyl carboxylic acid, the bis,bis-substituted product $[M_2(TiPB)_{4-x}(O_2C\text{-}(Thp)_n\text{-}R)_x]$ (Thp = 2,4-C_4H_2S; $n = 1,2$: R = H; $n = 3$: R = Me) is formed in preference to other combinations.

Only one isomer is observed in solution for these M_2 complexes and, as is shown in Figure 1, steric factors favor the *trans* substitution about the M_2 paddle-wheel core. The twisting of the phenyl rings out of the plane of their attendant carboxylate groups removes $M_2(\delta)$-to-$C_6(\pi)$ conjugation. In the UV/Vis spectrum, the $M_2(\delta)$-to-(aryl carboxylate) transition is very weak in comparison with the $M_2(\delta)$-to-(thienyl carboxylate) transition. As is shown in Figure 2, the $M_2(\delta)$-to-thienyl(π^*) transition moves to lower energy as n increases

Oligothiophenes Incorporating Metal–Metal Quadruple Bonds**

Malcolm H. Chisholm,* Arthur J. Epstein,*
Judith C. Gallucci, Florian Feil, and Wesley Pirkle

There is considerable interest at this time in inorganic–organic hybrid materials, and metal-containing polymers constitute an important section within this general field. The work of Manners and co-workers[1] with metallocene-derived polymers, Friend, Raithby, and co-workers[2] with metallated polyynes and poly(phenylenvinylene)s, Wolf and co-workers[3] with metallated polythiophenes, and Thompson, Forrest, and co-workers[4] with iridium and platinum complex doped conjugated polymers, represent four prime areas of recent research interest. The majority of efforts thus far have focused

Figure 1. Molecular structure of the centrosymmetric [Mo$_2$(TiPB)$_2$(O$_2$C-Thp-H)$_2$] molecule found in the solid state with two axially coordinating DMSO molecules and one noncoordinating DMSO molecule. The Mo—Mo, Mo—O(TiPB carboxylate), and Mo—O(thiophene carboxylate) interatomic distances are 2.113, 2.111 (av), and 2.110 Å (av), respectively. The dihedral angle between the thienyl ring and its carboxylate group is 0.35° (av).

from 1 to 2 to 3 and is markedly red-shifted and more intense on going from M = Mo to W. The latter is a result of the higher orbital energy of the W$_2$ d electrons and the greater degree of W$_2$(δ)-to-thienyl(π*) overlap.

In reactions of Equation (1), we employed the *n*-hexyl-substituted thienyl dicarboxylic acids (DHTT)H$_2$ (3′,4′-dihexyl-2,2′:5′,2″-terthiophene-5,5″-dicarboxylic acid)[10] and (DHQT)H$_2$ (3″,4″-dihexyl-2,2′:5′,2″:5″,2‴:5‴,2⁗-quinque-thiophene-5,5⁗-dicarboxylic acid)[11] shown below. Further-more, an excess of [Mo$_2$(TiPB)$_4$] or [W$_2$(TiPB)$_4$] was used to ensure the total conversion of the dicarboxylic acids. The polymeric materials [M$_2$(TiPB)$_2$(O$_2$C-(Thp)$_n$-CO$_2$)] are formed as flocculent precipitates that are difficult to filter. They are best isolated by centrifugation followed by repeated washings, first with toluene and then hexanes, to remove the

(DHTT)H$_2$

(DHQT)H$_2$
acid TiPB-H and any unreacted monomeric M$_2$ tetracarboxylates. The resulting dried red (M = Mo) or bluish-green (M = W) powders are somewhat soluble in THF and swell to form gels by absorbing approximately 20 times their mass of THF. The ^{1}H NMR spectra of the samples in [D$_8$]THF only show evidence for one type of TiPB and O$_2$C-(Thp)$_n$-CO$_2$ groups. However, the MALDI MS data show molecular ions that correspond to [M$_2$(TiPB)$_2$(O$_2$C-(Thp)$_n$-CO$_2$)]$_2^+$ loops, [M$_2$-(TiPB)$_2$(O$_2$C-(Thp)$_n$-CO$_2$)]$_3^+$ triangles, and even higher oligomers. These can only arise from a *cis*-substitution pattern at the M$_2^{4+}$ center. We propose that this substitution pattern is less common than that of *trans* substitution, but that it is this property, together with some tersubstitution at the Mo$_2^{4+}$ center, that facilitates the gel-forming capability of the entangled chains. The system can be described as a dynamic equilibrium of chains, cycles, and cross-linked oligomers/polymers[12] as a result of facile carboxylate-exchange reactions, which are well-documented to be catalyzed by both acid and base (H$^+$, carboxylate).[13] A reasonable estimate of the molecular weight is over 10000 Daltons, or more than 10 repeating units.

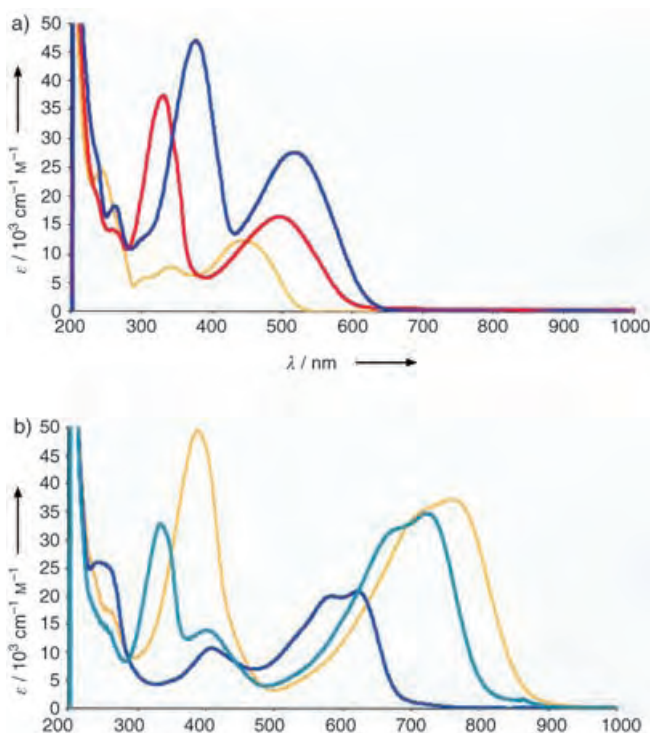
The electronic absorption spectra of these oligomers closely resemble those of the model compounds (Figure 2) in that they have well-defined, although broad, absorptions assignable to M$_2$(δ)-to-thienyl(bridge)(π*) and thienyl(π)-to-thienyl(π*) (bridge-to-bridge) transitions. The emission spectra show only the thienyl(π*)-to-M$_2$(δ) transition, as shown in


Figure 2. a) Electronic absorption spectra of [Mo$_2$(TiPB)$_2$(O$_2$C-(Thp)-H)$_2$] (yellow), [Mo$_2$(TiPB)$_2$(O$_2$C-(Thp)$_2$-H)$_2$] (red), and [Mo$_2$(TiPB)$_2$(O$_2$C-(Thp)$_3$-Me)$_2$] (blue) in THF at room temperature. b) Electronic absorption spectra of [W$_2$(TiPB)$_2$(O$_2$C-(Thp)-H)$_2$] (blue), [W$_2$(TiPB)$_2$(O$_2$C-(Thp)$_2$-H)$_2$] (green), and [W$_2$(TiPB)$_2$(O$_2$C-(Thp)$_3$-Me)$_2$] (yellow) in THF at room temperature.

Figure 3 for the terthienyl-bridged polymer. These photophysical properties can be described in terms of the Jablonski diagram shown in Figure 4.
Figure 3. Absorption spectrum (red) of "$Mo_2(TiPB)_2(DHTT)$" in THF at room temperature, and photoluminescence spectrum (green) with excitation at 531 nm. Higher-energy excitation (360 nm) results in a similar spectral profile. The excitation spectrum is shown in blue.
Figure 4. Proposed Jablonski scheme of the absorptions and emission of [$M_2(TiPB)_2(O_2C\text{-}(Thp)_n\text{-}CO_2)$] oligomers. Absorptions to S_1 and S_2 are observed; emission occurs from S_1 while a nonemissive T_1 state is also observed. IC = internal conversion; ISC = intersystem crossing.

The gels dry to form thin films, and THF solutions can be used to deposit thin films of these metallated oligomers by spin-coating in a dry-box under argon. Deposition on an indium–tin oxide (ITO)-coated glass plate followed by vapor deposition of aluminum or calcium was carried out to make conductivity measurements. As shown in Figure 5, the thin

films of the molybdenum terthienyl-bridged material display diode properties, with current being drawn nearly equally in both the forward and reverse bias, reminiscent of interface-controlled symmetrically configured ac-light-emitting (SCALE) devices.[14] Whereas the terthienylmolybdenum-containing films do not show electroluminescence with aluminum, the pentathienyl analogue (derived from (DHQT)H_2) does, and both the ter- and pentathienyl-derived thin films show electroluminescence when lower-work-function calcium was used as the cathode (Figure 6). The emission from these films is red-shifted relative to that of the parent
Figure 6. Absorption spectra of an "$Mo_2(TiPB)_2(DHTT)$" thin film (red) and an "$Mo_2(TiPB)_2(DHQT)$" thin film (purple), and electroemission of a Ca-"$Mo_2(TiPB)_2(DHTT)$"-ITO device (blue) and a Ca-"$Mo_2(TiPB)_2(DHQT)$"-ITO device (green).

Communications

acids (DHTT)H_2 and (DHQT)H_2.[15] Furthermore, the electroluminescence spectra display an unusual blue shift relative to the photoluminescence spectra, which suggests the important role of charge trapping in these materials.

In conclusion, we believe that the preliminary findings reported herein indicate that polythiophenes incorporating metal–metal quadruple bonds should have interesting and tunable electronic properties. The M_2 δ electrons lie within the band-gap of the polymer, but are strongly coupled by $M_2(\delta)$-to-$CO_2(\pi)$ conjugation. We anticipate that the electroluminescence for tungsten can be moved into the near-IR region. Further work in this area is in progress.

Linking Centered Manganese Triangles into Larger Clusters: A {Mn$_{32}$} Truncated Cube**

Richard T. W. Scott, Simon Parsons, Muralee Murugesu, Wolfgang Wernsdorfer, George Christou, and Euan K. Brechin*

Single-molecule magnets (SMMs) have many potential applications including high-density information storage, in which each bit of information is stored as the magnetization orientation of an individual molecule, and as qubits for quantum computation, in which the required arbitrary superposition of quantum states with opposite projections of spin can be produced by either quantum tunneling of the magnetization, intermolecular exchange, or multifrequency EPR pulses.[1–4] The fundamental requirements for a molecule to behave as an SMM are a) a relatively large spin ground state (S) and b) a large and negative zero-field splitting (zfs) of that ground state (as measured by the zfs parameter D). The upper limit of the barrier to the reorientation of the magnetization is given by $S^2|D|$ for integer spins and $(S^2-1/4)|D|$ for half-integer spins.

To make large molecular clusters, two successful, but somewhat opposing, synthetic strategies have generally been employed. The first is the use of rigid bridging ligands, for example, cyanide, that impose the geometry on the resultant cluster,[5] and the second is the use of flexible ligands, for example, carboxylates, that impose little or no geometry.[6] Both approaches have produced molecules with extremely

large spin ground states: $S = 39/2$ for the former[7] and $S \geq 23$ and $S = 51/2 \pm 1$ for the latter.[8]

We have been exploring the reactivity of tripodal alcohol ligands (Scheme 1) in the synthesis of 3d transition metal
Scheme 1. The tripodal ligands (from left to right) 1,1,1- tris(hydroxy-methyl)ethane (H_3thme), 1,1,1-tris(hydroxymethyl)propane (H_3tmp), pentaerythritol (H_4peol), *cis,cis*-1,3,5-cyclohexanetriol (H_3cht), and 1′,1′,1′-tris(hydroxymethyl)toluene (H_3thmt).

SMMs. The basic principle here is that paramagnetic metal ions linked together in triangular arrays may lead to molecules with large spin ground states. If these arrays consist of simple {M_3} equilateral triangles then the resultant competing exchange interactions or spin frustration may stabilize a nonzero spin ground state. If the arrays consist of {M_4} centered triangles or "metal stars", in which the three peripheral ions are connected only to the central ion and not to each other, then the antiferromagnetic interaction between these ions may stabilize a large spin state. If these high-spin triangular units can then be linked together by using bridging ligands that promote ferromagnetic exchange then the resultant complexes could well be characterized by extremely large spin ground states.

The cation $[Mn_{32}(thme)_{16}(bpy)_{24}(N_3)_{12}(OAc)_{12}]^{8+}$ (Figure 1; bpy = bipyridine) consists of eight such {M_4} centered triangles linked together to form a truncated cube. Each $[Mn_4(thme)_2]^{4+}$ corner unit consists of a central Mn^{4+} ion and three peripheral Mn^{2+} ions. The Mn^{2+} ions are linked to the Mn^{4+} ion through the μ_2-oxygen arms of two $thme^{3-}$ ligands, which sit directly above and below the $[Mn^{IV}Mn^{II}_3]$ plane. The coordination of the peripheral Mn^{2+} ions is completed by one chelating bpy ligand, one acetate group and one azide function. The $CH_3CO_2^-$ and N_3^- ligands bridge the Mn^{2+} ions in neighboring corner units along each edge of the cube (Figure 2). The charge balance of the complex is completed by the presence of eleven ClO_4^- ions and one and a half $[Mn(bpy)_3]^{2+}$ molecules, thus giving the complex the overall formula $\{Mn(bpy)_3\}_{1.5}[Mn_{32}(thme)_{16}(bpy)_{24}(N_3)_{12}$-$(OAc)_{12}](ClO_4)_{11}$ (**1**). The oxidation states of the Mn ions were confirmed by BVS (bond-valence-sum) calculations and bond-length considerations.

To probe the magnetic properties of **1**, susceptibility measurements were performed on powdered crystalline samples in the ranges 1.8–300 K and 0–7 T, and on single crystals at temperatures down to 40 mK. Direct current (dc) susceptibility measurements were carried out in a 0.1-T dc field in the temperature range 1.8–300 K, with the sample restrained in eicosane to prevent torquing. The calculated ($g = 2$) contribution from the 1.5 $[Mn(bpy)_3]^{2+}$ cations per {Mn_{32}} was subtracted from the measured data. The room temperature $\chi_M T$ value of approximately 78.8 $cm^3 K mol^{-1}$
Figure 1. The structure of the $[Mn_{32}]^{8+}$ cation (top) and its core (bottom). In the lower picture the eight corner Mn^{4+} ions of an ideal cube are highlighted in black.

slowly increases upon cooling to a maximum of approximately 86.2 $cm^3 K mol^{-1}$ at 90 K, and then decreases rapidly to a value of approximately 37.8 $cm^3 K mol^{-1}$ at 2 K. This behavior is indicative of dominant antiferromagnetic exchange between the metal centers with the value at 2 K in the region expected for an $S = 9$ ground state (spin-only ($g = 2$) value of 45 $cm^3 K mol^{-1}$).

In alternating current (ac) susceptibility experiments, a weak field (typically 1–5 G) oscillating at a particular frequency (ν) is applied to a sample to probe the dynamics of the magnetization (magnetic-moment) relaxation. The ac susceptibility measurements, which avoid Zeeman and other effects of an applied dc field, are an excellent complementary
Figure 2. The building blocks of complex **1**: the [Mn^{IV}Mn$^{II}_3$] "corner" unit (left) and the [Mn$^{II}_2$] "edge" (right).

tool for the estimation of S as the presence of a temperature-independent (in-phase) $\chi_M'T$ versus T signal would indicate a well-isolated ground state, whereas a sloping $\chi_M'T$ vs T signal would indicate the population of a number of low-lying excited states.[9] In-phase ac susceptibility measurements for complex **1** taken in the temperature range 1.8–10 K are shown in Figure 3. The steeply sloping lines observed show a rapid decrease in $\chi_M'T$ with decreasing temperature and therefore suggest the population of many excited states with larger S values. This is a common feature in many Mn clusters that are either a) of high nuclearity and thus exhibit a large density of spin states or b) contain multiple Mn^{2+} ions that typically promote weak exchange. Extrapolation of the $\chi_M'T$ signal from values above about 3 K (to avoid decreases due to effects such as intermolecular interactions at lower temperatures) to 0 K gives a value of 42–43 cm^{3}K mol^{-1}, which suggests a spin ground state of $S = 9$ (or 10), consistent with the dc data.

Magnetization measurements also confirm the presence of many excited states. Studies on a single crystal of complex **1** at temperatures down to 40 mK and in fields of up to 1.4 T performed on a micro-SQUID setup show curves that do not reach saturation (Figure 3). At all temperatures studied, the magnetization continues to rise sharply with increasing field strength. This is as expected for field-induced stabilization of M_S levels of excited states with S values greater than that of the ground state; approach to and crossing of excited-state M_S levels with those of the ground state lead to increases in the measured magnetization. Thus, for example, the magnitude of the magnetization at 40 mK in an applied field of 1 T is suggestive of $S \geq 25$. Similarly, magnetization measurements (Figure 3) carried out on a powdered crystalline sample at temperatures below 10 K in fields of up to 7 T saturate at a value of $M/N\mu_B \approx 85$, a value consistent with the stabilization of an $S \geq 43$ spin state (with $g = 2.0$). However, when smaller applied fields are used, the magnitude of $M/N\mu_B$ decreases and does not saturate. Again this is indicative of a field-induced stabilization of excited states with larger S values than that of the ground state.

If we were to assume the interaction between the central Mn^{4+} ion and the three peripheral Mn^{2+} ions within an
Figure 3. Top: Magnetization data for **1** plotted as reduced magnetization ($M/N\mu_B$) versus H/T in the temperature range 1.8–10 K and in fields of 0.1 T (▲), 0.5 T (△), 1 T (■), 2 T (□), 3 T (▼), 4 T (▽), 5 T (●), 6 T (○), and 7 T (◆). isolated [Mn^{IV}Mn$^{II}_3$] unit to be antiferromagnetic, then we would expect a spin ground state of $S = 6$ for this unit. Between each of these corner units, the *syn, syn* μ-CH$_3$CO$_2^-$ ligands are likely to promote antiferromagnetic exchange, but the end-on N$_3^-$ ligands are likely to promote ferromagnetic exchange. If the antiferromagnetic interactions were to dominate, then we might expect to observe an overall spin ground state of $S = 0$, but if the ferromagnetic interactions were to dominate then a ground state with $S = 48$ could result. However, there are a total of 24 Mn^{2+} ions present in the {Mn$_{32}$}$^{8+}$ cation and these are known to promote weak exchange between the metal centers, the result of which is likely to be a large number of S states with comparable energies to the ground state. This "problem" is then further compounded by the fact the [Mn^{IV}Mn$^{II}_3$] units are linked

together by two different ligands—one azide and one carboxylate—and this countercomplementarity will likely lead to an interaction that is either weakly ferro- or weakly antiferromagnetic, but in either case near $0\,cm^{-1}$. Weak intermolecular interactions—if comparable in magnitude to the intracluster exchange—will also complicate the analysis. Essentially all of the above means that an accurate quantitative analysis is impossible.

In conclusion, the use of the tripodal ligand H_3thme has again been shown to stabilize elaborate triangular arrays of Mn ions. In the studies described herein, these "high-spin" building blocks have self-assembled in the presence of end-on-bridging azide ligands to form a {Mn$_{32}$} truncated cube. This is the second largest Mn cluster reported to date.[10] Initial magnetic studies revealed that the complex has a spin ground state of $S = 9$ (or 10), but the presence of multiple Mn^{2+} ions, ligand countercomplementarity, and possible weak intermolecular interactions precludes a more accurate analysis. Application of strong magnetic fields effectively overcomes weak antiferromagnetic exchange, thus stabilizing spin states with larger values of S.

However, the combination of tripodal alcohol ligands and end-on bridging azides may be an excellent, yet simple, route to clusters with potentially extremely large spin ground states and promises many more exciting compounds.

Experimental Section

1: NaOAc (1 equiv) and NaN$_3$ (1 equiv) were added with stirring to a solution of [Mn$_2$(Hthme)$_2$(bpy)$_4$](ClO$_4$)$_2$[11] (1 equiv) in MeCN. After 30 min the solution was filtered and layered with diethyl ether. Black crystals grew during one week. Highly Enantioselective Pd-Catalyzed Allylic Alkylations of Acyclic Ketones**

Xiao-Xia Yan, Chun-Gen Liang, Yan Zhang, Wei Hong, Bo-Xun Cao, Li-Xin Dai, and Xue-Long Hou

Since the first example of Pd-catalyzed asymmetric allylic alkylation (AAA) was reported by Trost and Strege,[1] great achievements in this area of chemistry have been made. Today, AAA is not only a well-studied transition-metal-catalyzed asymmetric reaction but also one of the most important asymmetric carbon–carbon bond-forming reactions.[2] As a diversity of bond types can be formed and many chiral elements can be installed at the nucleophile, the electrophile, or both, transition-metal-catalyzed AAAs have become a powerful tool in organic synthesis.[2c] Although a variety of substrates and reagents are suitable in AAA reactions, the use of carbon nucleophiles is mainly limited to the stabilized "soft" carbanions such as β-keto ester and malonate derivatives.[2] Simple ketone enolates are an important class of nucleophiles, but AAA had been ineffective with these nucleophiles because they are nonstabilized and hard. The breakthrough came in 1999, when Trost and Schroeder obtained high enantioselectivity in Pd-catalyzed AAAs with tetralone and cyclohexanone derivatives by using a "chiral pocket" ligand.[3] Since then, several examples were reported and excellent enantioselectivities were obtained.[4,5] Cyclic ketones have been used as substrates in these reactions. Recently, Braun et al. reported the Pd-catalyzed allylic alkylation of 1,3-diphenylallyl acetate with high diastereoselectivity by using mesityl ethyl ketone.[4c] However, the reaction was not asymmetric. Thus, an asymmetric version of Pd-catalyzed AAAs with acyclic ketones remains a challenge. Recently, we designed some ferrocene-derived

chiral P,N ligands and employed them successfully in Pd-catalyzed AAAs.[5,6] High regio- and enantioselectivities were provided by using monosubstituted allyl derivatives as substrates and by using cyclic ketones as nucleophiles. For Pd-catalyzed AAAs with acyclic ketones to be enantioselective, we have modified the ligands. Herein, we report our preliminary results in the synthesis of a novel chiral ligand and its application to a Pd-catalyzed asymmetric allylic reaction that uses acyclic ketones as nucleophiles.

Initially, we examined the reaction of 1-phenyl-propan-1-one (**1a**) with allyl acetate (**2**) in the presence of [{Pd-(C$_3$H$_5$)Cl}$_2$] and a variety of ligands,[6a] but we obtained no encouraging results (Scheme 1). All reactions gave almost no
Scheme 1. a) [{Pd(C$_3$H$_5$)Cl}$_2$] (2.5 mol%), ligand (5 mol%), lithium 1,1,3,3-hexamethyldisilazane (LiHMDS), THF, 0°C.

desired product **3a** under these conditions. According to the reports by Trost et al.[3,4a] as well as our own previous work,[5] chiral pocket ligands have emerged as ligands of choice for the highly enantioselective allylic alkylation of simple cyclic ketone enolates. Thus the modified chiral pocket imine and amine derivatives **L1**–**L4**[8] were synthesized from ferrocene **4**[7] (Scheme 2).

In the presence of **L3**, the reaction of **1a** with **2** gave the allyl product **3a** in 69% yield and with 31% *ee*, whereas in the presence of **L4**, the reaction gave **3a** in 23% yield and with 2.5% *ee*. The lower yield and enantioselectivity is attributed to the mismatched chiralities in **L4**.[9] A further increase in the enantioselectivity (from 31% to 48% *ee*) was observed when **L1** was used in place of **L3**. The choice of base is important: the use of sodium hydride or potassium *tert*-butoxide in conjunction with ligand **L1** led to very low yields. The use of a

Scheme 2. Synthesis of ligands **L1**–**L4**. Reagents and conditions: a) (*S,S*)- or (*R,R*)-cyclohexane-1,2-diamine, *p*-TsOH, 4-Å MS, toluene; b) NaBH$_4$, EtOH.

bulkier base such as LiHMDS led to a slight increase in both yield (77%) and enantioselectivity (57% *ee*), and the use of lithium tetramethylpiperidine gave the product in 48% yield with 56% *ee*. The metal ion of the base has a great effect on the yield and enantioselectivity of the reaction. For example, the reaction with LiHMDS gave the product in 77% yield and with 57% *ee*, but the corresponding reactions with NaHMDS and KHMDS provided products with 2% *ee* and 9% *ee*, respectively, although the yields were higher. A study of the effect of solvent on the reaction showed that among the solvents tested (Et₂O, 1,4-dioxane, 1,2-dimethoxyethane, toluene), THF gave the best results.

On the basis of these results, we envisioned that the lithium enolate derived from an α-alkoxy-substituted ketone would provide a general approach to the control of enantio-selectivity in the AAA of acyclic ketones due to the propensity of this ketone to form the *Z*-chelated enolate. Our results demonstrate that the alkoxy group exhibits a remarkable effect on the level of enantioselectivity. When 1-phenyl-3-methoxypropan-1-one (**1b**) was used with LiHMDS as base, the enantioselectivitiy significantly increased to 68% *ee* and the yield was 72%. Takemoto and co-workers as well as Wang reported that chiral ammonium salts have a dramatic effect on the enantioselectivity of Pd-catalyzed AAA reactions.[10] In our case, the ammonium salts, both chiral and achiral, also showed an ability to improve the enantioselectivity of the reaction (see Table 1). We inferred that this

increase in enantioselectivity in the presence of ammonium salts is caused to some extent by their Lewis acid character. Thus, several Lewis acids were tested (see Table 1).[11]

Lewis acids have a greater effect on the reaction than ammonium salts. Among the Lewis acids tested, silver bromide gave the best result both in terms of enantioselec-tivity and yield. When the reaction proceeded at −20°C in the presence of a catalytic amount of AgBr, the product was obtained in 98% yield with 93% *ee*. The effect of the amount

of catalyst on the reaction was also studied. Reducing the catalyst amount to 1 mol% gave rise to a slight decrease in both yield (93%) and enantioselectivity (90% *ee*). When the amount of catalyst was decreased to 0.5 mol%, the reaction still proceeded smoothly to give the product in 83% yield with 90% *ee*. Under these optimized conditions, a variety of acyclic ketones were tested (see Scheme 1) and the results are given in Table 2.

[a] All reactions were performed at −20°C; [{Pd(C₃H₅)Cl}₂] (2 mol%); **L1** (4 mol%); **1** (100 mol%); LiHMDS (120 mol%); **2** (130 mol%); AgBr (10 mol%). [b] Yield of isolated product. [c] Determined by chiral HPLC.

All acyclic nonstabilized hard ketones gave products in good to excellent yields and enantioselectivities. However, the stabilized soft ketone **1l** gave a racemic product (entry 12, Table 2). The nature of the alkoxy substituent has a great effect on the enantioselectivity. Substrates **1b** and **1c** with less sterically hindered MeO and EtO groups gave the corre-sponding allylated products with *ee* values of 93% and 92%, respectively (entries 2 and 3, Table 2). However, the sub-strates with the bulky *i*PrO, **1d**, and PhO, **1k**, furnished products with *ee* values of 79% and 71%, respectively, although the yields were good to excellent (entries 4 and 11, Table 2). It was unexpected that the reactivity of ketone **1j** with the ester substituent would be so low, although the enantioselectivity was good (50% yield and 86% *ee*; entry 10, Table 2). The electronic property of the substituent on the phenyl ring of the substrate has little effect on the reaction. Thus, the methoxy-substituted aryl ketone **1e** and the chloro-substituted aryl ketone **1f** gave allylated products with 94% and 91% *ee*, respectively. Importantly, the aliphatic cyclo-hexyl methoxymethyl ketone (**1h**) afforded the correspond-ing product in 76% yield with 87% *ee* (entry 8, Table 2). The heteroaryl-substituted simple ketone **1i** gave rise to the corresponding product in 50% yield with 80% *ee*.

Under different conditions, *Z* or *E* forms of an enolate are favored,[12] which may influence the enantioselectivity of the alkylation. Xie et al. reported that the *Z* form of an enolate was formed exclusively by using Ph₂NLi at −78°C, while *Z* and *E* forms of an enolate were provided in a ratio of 48:52 with Me₃CN(TMS)Li (TMS = trimethylsilyl) as base at room temperature.[12] In the reactions reported here, we found that different forms of an enolate dramatically affected the

enantioselectivity of a reaction. In the presence of Ph$_2$NLi at −78°C, the reaction of ketone **1a** gave the product **3a** with 88% *ee*. Even phenyl propyl ketone (**1m**) gave the product **3m** with 87% *ee*, but only enantioselectivities of 34% and 76% *ee* were obtained with Me$_3$CN(TMS)Li (Scheme 3).
Scheme 3. The reactions of **1a** and **1m** to form **3a** and **3m**, respectively.

These results may explain why substrates with an alkoxy group at the α-position of the carbonyl group led to products with high enantioselectivities. The presence of AgBr did not influence the ratio of *Z* and *E* isomers of an enolate: the reaction of **1a** with **2** in the presence of NaHMDS and AgBr gave **3a** with 9% *ee*.

In conclusion, we have synthesized a novel chiral imino ferrocene ligand and used this ligand to carry out highly enantioselective Pd-catalyzed allylic alkylations of simple acyclic ketones. The dramatic effect of AgBr as well as the dependency of the enantioselectivity on the different forms of the enolate have been demonstrated. Further investigations on the role of AgBr and the applications of the ligand **L1** in other types of acyclic ketones are in progress.

Domino Pericyclic Processes

Unexpected Participation of an Unconjugated Olefin during Nazarov Cyclization of Bridged Bicyclic Dienones**

Sören Giese, Robert D. Mazzola, Jr., Clare M. Amann, Atta M. Arif, and F. G. West

The Nazarov reaction is a well-established method for the generation of new cyclopentenone rings from simple dienone precursors.[1] This reaction has enjoyed considerable recent attention with regard to its use in tandem or domino processes,[2] as well as in approaches for controlling the absolute configuration of the stereocenters generated during or after the electrocyclization process.[3] We have recently

found that a variety of bridged bicyclic dienones undergo silyl-directed Nazarov cyclization with high or complete diastereoselectivity.[4] Whereas most dienones furnished the *exo*-disposed cyclopentenone, substrate **1a** provided the *endo* isomer **2a** in high yield, along with minor amounts of by-product **3a** (Scheme 1). The formation of this rearranged

Scheme 1. Unexpected formation of by-product **3a** in the Nazarov cyclization of dienone **1a**.

silyl-containing product was intriguing, and we set out to explore its formation in greater detail. Herein, we report two additional examples in which analogous products are formed exclusively, with the apparent involvement of the remote unconjugated alkene in the rearrangement process.

Substrates **1b–d** were prepared by the carbonylative Stille coupling using cocatalytic amounts of copper(I) iodide, followed by near-quantitative protection of the alcohols in the case of **1c** and **1d** to form **1e** and **1f**, respectively (Scheme 2).[5] These examples were chosen for their relevance to an approach to the taxane skeleton, but were also of interest because of the absence of β-silyl substituents in the case of **1b** and **1e**. Without a facile termination through desilylative elimination,[6] the Nazarov cyclopentenyl cation intermediate might be expected to undergo the alternative pathway to a significantly greater extent.

Initial experiments with **1b** entailed low-temperature treatment with BF$_3$·OEt$_2$, in analogy to the conditions applied

Scheme 2. Preparation of substrates **1b–f** by carbonylative Stille cross-coupling. DMAP = dimethylaminopyridine, TBDPS = *tert*-butyldiphenylsilyl.

to **1a**. Careful monitoring showed no consumption of **1b** until the reaction was warmed to 0°C, at which point a new product was rapidly produced in 60% yield (Scheme 3). Improved yields could be obtained by carrying out the reaction at 0°C for 5 min rather than gradually warming from a lower temperature. The newly formed product displayed several surprising spectral features. The ^{1}H NMR spectrum contained no signals for olefinic protons, and all three methyl groups appeared as singlets at high field (approximately $\delta = 1$ ppm). The ^{13}C NMR spectrum revealed the presence of a conjugated ketone carbonyl functionality and a highly polarized tetrasubstituted alkene. Clearly, neither the "normal" Nazarov product **2b** nor the anticipated anomalous product **3b** had been formed. Moreover,

Scheme 3. Unexpected formation of cyclopropyl ketone **4b**.

the unconjugated alkene had been consumed while leaving the former allylic methyl group intact and apparently next to a quaternary center. These data suggested cyclopropyl ketone **4b** as a likely structure.

As this material was a solid, it was recrystallized from Et$_2$O/pentane and subjected to single-crystal X-ray diffraction studies.[7] Much to our surprise, the structure generated from X-ray analysis was that of **3b**. Spectroscopic analysis of the recrystallized material showed that it had undergone a rearrangement and now possessed only two methyl groups and an exocyclic methylene functionality, as in the case of **3a**. Subsequent studies indicated that the initially formed **4b** undergoes facile conversion into **3b** at slightly elevated temperatures. Given the thermal lability of this compound, direct conversion of **1b** into **3b** was examined (Scheme 4). In the event, a convenient procedure was developed in which the crude product obtained from the Nazarov cyclization of **1b** was heated at 75°C in EtOH to provide **3b** in 85% yield. A similar procedure with **1e** furnished **3c** in 74% yield. For

Scheme 4. Direct conversion of **1b** and **1e** into **3b** and **3c**, and formation of **2c** by the silyl-directed Nazarov cyclization of **1f**.

comparison, reaction of **1f** under standard silyl-directed Nazarov cyclization conditions was performed. In this case, authentic **2c** was produced in good yield and, interestingly, none of the silyl-containing product **3d**, analogous to **3a**, was isolated.

Formation of **4b** presumably involves an initial Nazarov electrocyclization to give the 2-oxidocyclopentenyl cation **5b** (Scheme 5). Conversion into the cyclopropyl ketone could involve a homoallyl/cyclopropylcarbinyl rearrangement to give **6b** (path a), with subsequent intramolecular hydride transfer of H$_\beta$ to the secondary cyclopropylcarbinyl center.[8] Alternatively, direct conversion of **5b** into **4b** is possible through a concerted ene-like rearrangement (path b).[9] In either mechanism, delivery of H$_\beta$ should be facile because of its proximity to C13, which results from the complete selectivity of the Nazarov electrocyclization in which the new cyclopentenyl ring is appended in an *endo* disposition. This stereoselectivity is in accord with that seen in the silyl-directed Nazarov reactions of **1a**[4] and **1f**. The thermal conversion of **4b** into **3b** most likely occurs by the precedented homo-1,5-hydrogen shift or "enolene" rearrangement of alkyl-substituted cyclopropyl ketones,[10] followed by enol→keto tautomerization; notably, this thermal conversion typically occurs at much higher temperatures. The ease with which **4b** undergoes rearrangement is likely to be a result of the additional ring strain that resides in its polycyclic skeleton, as compared with simpler cyclopropyl ketones. Given the
Scheme 5. Proposed mechanisms for the formation **4b** and **3b**.

exclusive formation of **3c**, dienone **1e** is presumed to follow an analogous mechanistic pathway.

In summary, a new class of novel and mechanistically fascinating "interrupted" Nazarov reactions has been observed. In these systems, a nonconjugated alkene held near the dienone nucleus undergoes intramolecular trapping of the Nazarov 2-oxidocyclopentenyl intermediate to yield a strained polycyclic cyclopropyl ketone intermediate. This process may occur by stepwise cation–olefin cyclization/hydride transfer or by a direct ene-like mechanism. Involvement of the alkene is possible because of the high diastereoselectivity of the initial conrotatory electrocyclization. The resulting cyclopropyl ketones undergo thermal opening to provide the anomalous products **3**. In systems that lack a low-energy desilylative termination option, this transformation occurs in high yield, thus providing convenient access to elaborate polycyclic products of potential use in the construction of naturally occurring taxane natural products and their structural analogues. Further studies along these lines will be reported in due course.

Experimental Section

4b: Trienone **1b** (912 mg, 2.90 mmol) was dissolved in CH_2Cl_2 (290 mL) in a 500-mL round-bottom flask under N_2 and cooled to 0°C. $BF_3 \cdot OEt_2$ (0.71 mL, 5.8 mmol) was added by syringe, and the resulting yellow reaction mixture was stirred at 0°C for 10 min. Water (100 mL) was added, the phases were separated, and the aqueous layer was extracted with CH_2Cl_2 (100 mL). The combined organic layers were dried ($MgSO_4$) and concentrated to furnish a solid residue, which was purified by flash chromatography (silica gel, gradient increasing from $15 \rightarrow 20 \rightarrow 25 \rightarrow 30 \rightarrow 35\%$ EtOAc in hexanes) to provide **4b** as a tan solid (775 mg, 85%). M.p.: 98–101°C; $R_f = 0.31$ (20% acetone/hexanes); IR (thin film): $\tilde{\nu} = 1690\ cm^{-1}$; ^1H NMR (500 MHz, $CDCl_3$): $\delta = 4.02$–3.99 (m, 4H), 3.34 (br s, 1H), 2.66 (dd, $J = 18.6$, 1.9 Hz, 1H), 2.54 (dd, $J = 18.8$, 1.8 Hz, 1H), 2.42–2.29 (m, 2H), 1.98 (s, 1H), 1.81 (dd, $J = 6.5$, 6.5 Hz, 1H), 1.78 (ddd, $J = 14.8$, 11.9, 4.6 Hz, 1H), 1.66–1.59 (m, 2H), 1.53 (ddd, $J = 14.9$, 12.0, 4.4 Hz, 1H), 1.45 (ddd, $J = 8.3$, 2.9, 2.9 Hz, 1H), 1.40–1.33 (m, 1H), 1.13 (s, 3H), 1.05 ppm (s, 3H), 0.90 (s, 3H); ^{13}C NMR (125 MHz, $CDCl_3$): $\delta = 197.7$, 163.7, 142.6, 108.4, 64.9, 64.8, 50.3, 49.8, 45.4, 45.1, 38.4, 37.8, 33.2, 30.9, 26.9, 23.6, 21.4 (2 overlapping C nuclei), 19.7, 18.6 ppm; elemental analysis (%) calcd for $C_{20}H_{26}O_3$: C 76.40, H 8.33; found: C 76.47, H 8.37.

3b: Trienone **1b** was treated with $BF_3 \cdot OEt_2$ as described above (on the same scale). The solid residue obtained after aqueous work up was dissolved under N_2 in absolute EtOH (70 mL), and the resulting solution was heated to 75°C for 3 h. The reaction mixture was cooled and carefully concentrated under reduced pressure to leave a solid residue, which was purified by flash chromatography (silica gel, gradient increasing from $10 \rightarrow 15 \rightarrow 20 \rightarrow 25 \rightarrow 30 \rightarrow 35\%$ EtOAc in hexanes) to furnish **3b** as a white solid (775 mg, 85%). M.p.: 119–120°C; $R_f = 0.24$ (20% acetone/hexanes); IR (thin film): $\tilde{\nu} = 1695$, 1646 cm^{-1}; ^1H NMR (500 MHz, $CDCl_3$): $\delta = 4.66$ (dd, $J = 2.3$, 2.3 Hz, 1H), 4.64 (dd, $J = 2.1$, 2.1 Hz, 1H), 4.01–4.00 (m, 4H), 3.40–3.37 (m, 1H), 3.21 (dd, $J = 7.6$, 7.6 Hz, 1H), 2.64 (d, $J = 18.1$ Hz, 1H), 2.53 (d, $J = 7.9$ Hz, 1H), 2.51 (s, 1H), 2.37–2.30 (m, 1H), 2.28–2.21 (m, 1H), 2.03–1.96 (m, 1H), 1.85–1.68 (m, 5H), 1.46–1.39 (m, 1H), 1.09 (s, 3H), 0.93 ppm (s, 3H); ^{13}C NMR (125 MHz, $CDCl_3$): $\delta = 207.8$, 168.5, 147.1, 140.0, 110.2, 108.5, 64.9, 64.8, 54.4, 54.0, 50.0, 48.1, 43.3, 38.9, 30.8, 26.9, 26.7, 23.6, 23.2, 19.2 ppm; elemental analysis (%) calcd for $C_{20}H_{26}O_3$: C 76.40, H 8.33; found: C 76.11, H 8.35.

Communications

Synthesis of Nanowire and Mesoporous Low-Temperature LiCoO₂ by a Post-Templating Reaction**

*Feng Jiao, Kuthanapillil Mani Shaju, and Peter G. Bruce**

The synthesis of transition-metal oxides with controlled nanostructures, such as mesoporous solids, nanotubes, or nanowires, is an important task because such nanostructuring may have a profound influence on the properties of these materials.[1–3] This includes nanostructured materials for energy conversion and storage.[4] Soft templating routes have been used to synthesize mesoporous transition-metal compounds, for example, Nb_2O_5, TiO_2, MnO_x, and Fe_2O_3; however, the materials often have poorly crystallized walls and are thermally unstable, which limits their applications.[3,5]

The introduction of hard templating methods represents a significant step forward in the synthesis of mesoporous solids.[6,7] Solution-based precursors of the desired phase may be loaded within the pores of a mesoporous silica, and, after firing, the hard silica template may be removed to yield a mesoporous compound with highly crystalline walls and good thermal stability. Such nanocasting approaches have been used to form several transition-metal oxides, for example, Cr_2O_3, Fe_2O_3, MnO_x, CeO_2, Co_3O_4, and WO_3.[8–11] The nanocasting method is, however, limited to the use of precursors that do not react with the hard template and to compounds that may be prepared within the temperature range over which the silica template is stable. The former problem renders it difficult to synthesize mesoporous oxides that contain alkali metals. However, the synthesis of nanostructured oxides containing lithium is essential if such materials are to be used as positive electrodes in rechargeable lithium batteries, as the positive electrode is the only source of Li in the cells (the negative electrode is graphite). Mesoporous materials are attractive for electrodes because the controlled and regular porosity permits intimate flooding of the electrolyte within the particles. Hard-templated materials permit the formation of crystalline walls, which can be important in promoting Li intercalation.

Herein, we describe the synthesis of nanowire and mesoporous low-temperature LiCoO₂ (LT-LiCoO₂), a Li

intercalation compound, by the hard template route. The synthesis involves, first, preparation of mesoporous or nanowire Co₃O₄, then, after template removal, reaction of Co₃O₄ with a lithium source whilst retaining the nanostructured morphology. Hence, the lithium-containing compounds may be prepared by avoiding reaction between the lithium precursor and the silica template, which would occur if the compounds were prepared directly. The formation of large (≈100 nm) nanowire arrays of high-temperature LiCoO₂ within an anodic aluminum oxide membrane has been reported, however, the template was only partially removed.[12]

Two mesoporous silica compounds, SBA-15 and KIT-6, were used as hard templates.[7,13] The former contains parallel cylindrical pores arranged with hexagonal symmetry (space group *P6mm*). The latter has a three-dimensional cubic arrangement of pores (space group *Ia3d*). Such pore structures yield nanowire and mesoporous morphologies, respectively. The hard templates were impregnated with a solution of cobalt nitrate in ethanol, calcined at 300 °C, impregnated again to maximize pore filling, and heated at 500 °C, then the silica templates were removed with aqueous HF. Analysis by energy dispersive X-ray spectroscopy (EDX) and inductively coupled plasma demonstrated that all the silica had been removed. Flame emission and atomic absorption spectrometry confirmed that the Li-to-Co mole ratios for nanowire and mesoporous LT-LiCoO₂ samples were 0.95:1.

The nanowire structure of Co₃O₄ arising from SBA-15 is shown in Figure 1A and B. SBA-15 comprises short bridges between the cylindrical pores and these serve to organize the wires into parallel bundles.[9] Co₃O₄ formed from KIT-6 has a cubic nanostructure replicating the pore structure of the template (Figure 1C and D). Mesoporous Co₃O₄, with *Ia3d* symmetry, was prepared for the first time very recently.[11] It

Figure 1. TEM images of Co₃O₄ nanowires A) perpendicular and B) parallel to the wire axis. TEM images of mesoporous Co₃O₄ along the C) [111] and D) [100] directions.

was found necessary to functionalize the pores by attaching vinyl groups to provide superior coordination of Co ions and hence high loadings. As demonstrated here, this is not essential.[10]

Nanowire and mesoporous LT-LiCoO$_2$ samples were prepared by reacting the respective nanostructured Co$_3$O$_4$ materials with LiOH at 400 °C for 1 h. LiCoO$_2$ synthesized at around 800 °C exhibits a layered α-NaFeO$_2$ structure, whereas synthesis at lower temperatures yields LT-LiCoO$_2$ composed predominantly of a spinel structure that contains additional lithium, Li$_2$Co$_2$O$_4$.[14,15] LT-LiCoO$_2$ was anticipated from the temperature at which the synthesis was performed, and this was verified by wide-angle powder X-ray diffraction (PXRD, Figure 2 A). Although the diffraction data for high-temper-

ature and low-temperature materials are similar, it is evident, especially on examining the insets in Figure 2 A, that the material synthesized here is LT-LiCoO$_2$. The use of temperatures that are sufficiently high to promote the formation of HT-LiCoO$_2$ resulted in a loss of the nanostructure.

The nanowire morphology of LT-LiCoO$_2$ prepared from SBA-15 is shown in Figure 3 A–C. This morphology dominates throughout the material. Although the wires are continuous, close inspection of high-resolution transmission electron microscopy (HR-TEM) data (Figure 3 C) indicate
Figure 3. TEM images of LT-LiCoO$_2$ nanowires A) perpendicular and B) parallel to the wire axis, and C) high-resolution image of LT-LiCoO$_2$ nanowires. TEM images of mesoporous LT-LiCoO$_2$ along the E) [111] and F) [531] directions, and G) high-resolution image of mesoporous LT-LiCoO$_2$.

that they are composed of domains that are not structurally coherent. This is different from the single-crystal-like nature of the Co$_3$O$_4$ nanowires. However, importantly, the nanowire morphology of the Co$_3$O$_4$ material has been maintained. By TEM analysis, the diameter of LT-LiCoO$_2$ wires is measured as approximately 10 nm, only slightly larger than the value of 9.5 nm for Co$_3$O$_4$. Turning to mesoporous LT-LiCoO$_2$ formed from KIT-6, TEM data for this material are shown in Figure 3 D–F. It is clear that the cubic mesoporous morphology of Co$_3$O$_4$ is maintained; the morphology extends throughout the sample. The wall thickness of mesoporous LT-LiCoO$_2$ observed in the [111] direction is estimated from the TEM data (Figure 3 F) to be approximately 8.0 nm, which is consistent with that for Co$_3$O$_4$ (7.8 nm). In contrast to nanowire LT-LiCoO$_2$, it is interesting that mesoporous LT-LiCoO$_2$ maintains a single-crystal-like structure; the HR-TEM image (Figure 3 F) indicates that the lattice fringes for LT-LiCoO$_2$ run in the same direction throughout the particle. Further studies will be required to understand the mechanism by which the single-crystal structure is maintained during reaction with LiOH.

A comparison of Figures 1 and 3 reveals that the LT-$LiCoO_2$ nanowires are less ordered than the corresponding Co_3O_4 nanowires. The loss of order between the wires in LT-$LiCoO_2$ may be a result of the breaking up of narrow bridges on reaction with LiOH. Despite this, a lattice parameter a_0 of 108 Å may be estimated for the hexagonal (*P6mm*) meso-structure. This is in reasonable agreement with the value of 117 Å calculated from the low-angle PXRD pattern of the Co_3O_4 nanowires. The low-angle PXRD pattern of nanowire LT-$LiCoO_2$ (Figure 2B, line a) does not show a well-defined peak in the range 0.6–1.0 degrees because the nanowire bundles are insufficiently well ordered (Figure 3A). In the case of LT-$LiCoO_2$ formed from KIT-6, a lattice parameter, a_0 of 226 Å may be extracted for the cubic structure from the TEM data. This value is similar to the lattice parameter of 235 Å calculated from the first peak in the low-angle PXRD pattern of mesoporous LT-$LiCoO_2$ (Figure 2B, line c). This value is a little smaller than the parameter a_0 for mesoporous Co_3O_4 (241 Å) calculated from Figure 2B, line d, and is due to pore shrinkage accompanying the solid-state reaction.

N_2 adsorption/desorption isotherms (Figure 4A, B) for both forms of nanostructured LT-$LiCoO_2$ show type IV
Figure 4. Nitrogen adsorption/desorption isotherms for A) nanowire and B) mesoporous LT-$LiCoO_2$. The inset shows the pore size distributions for C) nanowire and D) mesoporous LT-$LiCoO_2$.

isotherms with an H_1 hysteresis loop, which confirms the mesoporosity. The specific surface areas of nanowire and mesoporous LT-$LiCoO_2$ estimated from the Brunauer–Emmett–Teller (BET) method are 70 m^2g^{-1} and 92 m^2g^{-1}, respectively. In the case of the LT-$LiCoO_2$ nanowires, the size of the pores between the wires exhibits a wide distribution (Figure 4C), indicating a disordered pore structure, which is consistent with the absence of a low-angle PXRD peak (Figure 2B, line a) and with the TEM images (Figure 3A, B); the more-ordered Co_3O_4 nanowires show a narrow distribution around 3.8 nm (see Supporting Information). In the case of mesoporous LT-$LiCoO_2$, the pore size distribution (Figure 4D) is narrow with a peak at 3.67 nm, which is close to the value for mesoporous Co_3O_4 (3.8 nm; see Supporting Information).

The present communication concentrates on the synthesis of LT-$LiCoO_2$ with different nanoarchitectures. The electro-

chemical behavior of these Li intercalation materials and their comparison with normal LT-$LiCoO_2$ will be described in a subsequent paper; however, some preliminary data are presented here. The surface area of the normal LT-$LiCoO_2$, prepared by a solid-state reaction between $CoCO_3$ and Li_2CO_3 at 400°C, was 42 m^2g^{-1}. The cells were first charged to remove lithium from the electrodes. Figure 5 reports the
Figure 5. Discharge capacities for A) normal (▲), B) nanowire (*), and C) mesoporous (⊙) forms of LT-$LiCoO_2$.

discharge capacity for the first and subsequent cycles, for which cycling was carried out at a constant rate of 30 mAg^{-1} between potential limits of 3.0 V and 4.2 V. The first discharge capacity for mesoporous LT-$LiCoO_2$ is some 20 $mAhg^{-1}$ higher than that for the equivalent nanowire material. The initial discharge capacity of normal LT-$LiCoO_2$ lies between the two nanostructured materials. The fade of discharge capacity on cycling is the same for both nanostructured forms of LT-$LiCoO_2$, however, the fade is markedly less than that of normal LT-$LiCoO_2$. The capacity of the nanostructured materials decreases by around 45% after 50 cycles whereas this decrease is 75% for normal LT-$LiCoO_2$.

In conclusion, it has been shown that lithium-containing nanostructured materials may be prepared by a hard templat-ing route, by first forming the transition-metal oxide and then treating this with a lithium source, with preservation of the nanostructure. Both one-dimensional nanowire LT-$LiCoO_2$ (based on SBA-15) and three-dimensional mesoporous LT-$LiCoO_2$ (based on KIT-6) have been synthesized with highly crystalline structures. Preliminary electrochemical data dem-onstrate that the nanostructured materials exhibit superior capacity retention on cycling compared with normal LT-$LiCoO_2$.

Experimental Section

The preparation of the mesoporous silicas, SBA-15 and KIT-6, has been described previously.[7, 10, 13] A typical synthesis of nanostructured LT-$LiCoO_2$ was as follows: $Co(NO_3)_2 \cdot 6H_2O$ (98%, Aldrich; 1 g) was dissolved in ethanol (20 mL) then mesoporous silica (2 g) was added. After stirring at room temperature until all the solution had been absorbed, the sample was heated slowly to 300°C and calcined at that temperature for 3 h. The impregnation procedure was repeated, and the sample was then calcined at 500°C for 3 h. The resulting sample

was treated twice with a 10% solution of HF in water to remove the silica template, then washed with water and ethanol several times, and then dried at 60°C. 0.2 g of the as-prepared nanostructured Co_3O_4 was mixed with excess $LiOH \cdot H_2O$ (0.6 g) in ethanol (20 mL). The solvent was removed by stirring overnight at room temperature, and the mixture was calcined at 400°C for 1 h. The final product was washed with water and ethanol several times to remove the unreacted lithium salt and then dried at 60°C for 2 h. The materials were characterized by TEM (Jeol JEM-2011), PXRD (Stoe STADI/P diffractometer operating in transmission mode with $Fe_{K\alpha_1}$ radiation, $\lambda = 1.936$ Å), low-angle XRD (Rigaku/MSC, D/max-rB with $Cu_{K\alpha_1}$ radiation, $\lambda = 1.541$ Å), and N_2 adsorption (Hiden IGA porosimeter).

Electrochemical cells were constructed by mixing the active material, Kynar 2801 (a copolymer based on polyvinylidene fluoride), and Super P carbon in the weight ratio 80:10:10. The mixture was cast onto Al foil from THF using a Doctor–Blade technique. After evaporation of the solvent at 45°C, the electrodes were assembled into cells with a Li electrode and LP 30 electrolyte (Merck; 1M $LiPF_6$ in 1:1 v/v EC:DMC, EC = ethylene carbonate, DMC = dimethyl carbonate). The cells were constructed and handled in an Ar-filled MBraun glovebox. Electrochemical measurements were carried out using a Biologic MacPile II system.

The Aromaticity of the Stannole Dianion**

Masaichi Saito,* Ryuta Haga, Michikazu Yoshioka,
Kazuya Ishimura, and Shigeru Nagase

In the last decade, much attention has been focused on the anions and dianions of siloles[1] and germoles,[1f,2] which are heavier congeners of the cyclopentadienyl anion.[3] The degree of aromaticity of silolyl anions depends on the substituent,[1b,f] while the germolyl anions do not show aromaticity because the negative charge is localized on the germanium atom.[1f,2a,2c] In contrast, the negative charges in the dianions of siloles and germoles are significantly delocalized in the C_4M (M = Si, Ge) ring and they were concluded to be aromatic.[1d–f,2b,2d,2e,4] The aromatic delocalization in these dianions was evidenced by NMR studies, calculations, and X-ray crystal structural analyses, which showed no alternation of the C−C bonds within the ring. In contrast to the well-investigated mono- and dianions of siloles and germoles, neither mono- nor dianions of stannoles had been reported before we undertook a study of such species a few years ago.

In the course of our studies on the synthesis of tin-containing aromatic compounds,[5] mono- and dianions of stannoles were revealed as fascinating synthetic targets because these species are potential intermediates for the synthesis of tin-containing aromatic compounds. Recently, we reported the synthesis of compound **1** by the reduction of bi(1,1′-pentaphenylstannole)[6] or hexaphenylstannole with the concomitant formation of phenyllithium.[7] The dianion in **1** was characterized by ^{1}H, ^{13}C, and ^{119}Sn NMR spectroscopy and chemical trapping with methyl iodide. However, the formation of phenyllithium prevented the isolation of **1** in a pure form as well as the estimation of its aromaticity by using ^{7}Li chemical shifts[4b,8] because of the intermolecular exchange of lithium cations. Herein, we report the isolation of compound **1** and the crystallographic and theoretical studies of its aromaticity.

The reduction of hexaphenylstannole **2**[9] with excess lithium in ether at room temperature gave **1** and phenyllithium. Refluxing the reaction mixture for 14 h completely decomposed phenyllithium,[10] and **1** was obtained as deep-red crystals in 98% yield (Scheme 1).
Scheme 1. Synthesis of stannole dianion **1** by the reduction of hexaphenylstannole **2**.

The structure of **1** was determined by X-ray analysis. As shown in Figure 1, two lithium atoms lie above and below the stannole ring. Each lithium atom is coordinated to the stannole ring in an η^5 fashion and is also coordinated to an ether molecule. Each unit molecule of **1** contains a benzene molecule in a unit cell. η^5-Bonded lithium atoms were also found in the lithium salts of the dianions of tetraphenylger-

mole[2d] and tetramethylsilole.[1e,f] The C2−C3 bond significantly shortens to 1.442(5) Å from 1.511(6) Å in **2**.[9b] On the contrary, the C1−C2 and C3−C4 bonds significantly lengthen to 1.422(6) and 1.446(6) Å, respectively, from 1.352 Å in **2**.[9b] The stannole ring is almost planar and the C−C distances within the ring are nearly equal, ranging from 1.422(6) to 1.446(6) Å, which suggests a considerable aromatic character of dianion in **1**.
To aid in understanding the structure of **1**, the geometry of unsolvated **1** was optimized with the hybrid density functional theory at the B3LYP[11] level by using Huzinaga's (433321/43321/421; DZP) basis set and a polarization d function ($\xi = 0.183$) for Sn[12] and 6-31G(d) for C,[13,14] H,[15] and Li.[14,16,17] Two different dilithio complexes were found to be minima (Figure 2). One of these (**1a**), which corresponds closely to
Figure 2. Geometry optimization and relative energies of **1a** and **b**.

the X-ray crystal structure, is of C_2 symmetry with both lithium atoms η^5-coordinated to the aromatic ring. The other structure (**1b**) is of C_1 symmetry with one lithium atom bonded to the tin atom and the other bonded in an η^5 fashion to the ring. The structure **1a** was calculated to be more stable than **1b** by 20 kcal mol^{-1}. The calculated C−C distances within the ring of **1a** are nearly equal (1.436 and 1.471 Å), which suggests a considerable aromatic delocalization of the negative charges in **1a**. The calculated structure of **1a** is in good agreement with the X-ray crystal structure of **1** (Figure 1). According to the natural population analysis, the α carbon atoms are considerably negatively charged (−0.713) in **1a**. This finding suggests the large contribution of a resonance form with stannylene character, as indicated in dianions of siloles and germoles, although the natural population analyses of these dianions were not reported. The β carbon atoms are also negatively charged (−0.273) in **1a**, whereas the α (−0.415) and β (−0.030) carbon atoms of **2** are less negatively charged than those of **1a**, which suggests a considerable delocalization of negative charges into the stannole ring.

The NMR spectroscopic analysis of **1** was also carried out. The ^{119}Sn signal for **1** ($\delta = 163.3$) appeared at a lower field than that for **2** ($\delta = -88$ ppm in CDCl$_3$), which reflects the strong contribution of a resonance form with stannylene character in **1** consistent with the natural population analysis of **1a**. The central tin atom of the isolobal diaminostannylene **3** (Scheme 2) is known to resonate at about $\delta = 240$ ppm.[18] However, the ^{13}C NMR signal assignable to the α carbon atom in the five-membered ring ($\delta = 187$ ppm) was observed at a lower field than that for **2** ($\delta = 143$ ppm in CDCl$_3$). This result is contrary to the low-frequency resonance predicted by the natural population analysis and the major resonance contribution. The signal arising from the β carbon atom in the

Figure 1. ORTEP drawing of **1** with thermal ellipsoid plots (40% probability for non-hydrogen atoms). All hydrogen atoms and a benzene molecule are omitted for clarity. Selected bond lengths [Å] and angles [°]: Sn1-C1 2.179(4), C1-C2 1.422(6), C2-C3 1.442(5), C3-C4 1.446(6), C4-Sn1 2.133(4), Sn1-Li1 2.758(8), Sn1-Li2 2.769(8); C1-Sn1-C4 77.43(15).

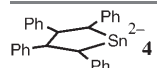
Scheme 2. Mesomeric forms of diaminostannylene **3**.

five-membered ring appeared at a higher field than that for **2** ($\delta = 133$ vs. 155 ppm).

The observed values of **1** are in good agreement with the calculated values of $\delta = 207$ and 138 ppm, respectively (Table 1).[19] The high-frequency resonance of the α carbon


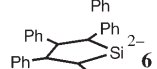


Table 1: Calculated and measured chemical shifts for **1**.

	C_α	C_β	Li
Calculated	206.69	138.15	−6.30
Experimental	187.68	133.46	−4.36

atom could be explained by the paramagnetic contribution of a tin–carbon bond.[20] The ^{7}Li NMR signal attributable to **1** was observed at $\delta = -4.36$ ppm; the calculation predicted $\delta = -6.30$ ppm (Table 1). This appreciable low-frequency resonance is evidently caused by the strong shielding effect of the diatropic ring current resulting from the 6π-electron system, and hence the stannole dianion in **1** is concluded to have considerable aromatic character.[4b, 8]

The nucleus-independent chemical shift (NICS) value of $\delta = -5.96$ ppm[19] calculated at 1.0 Å above the ring (non-weighted mean of the heavy-atom coordinate) of non-lithium-coordinated **4** also suggests that the stannole dianion in **1** should be aromatic (Table 2).[21] The origin of the aromaticity

Table 2: NICS(1) calculation for **4–6**.

Compound	NICS(1)/ppm
4	−5.96
5	−6.26
6	−6.30

of **1** could be reasonably interpreted in terms of the delocalization of negative charges of the tin out-of-plane p orbital into the LUMO of the butadiene moiety (Figure 3).[22] However, the degree of aromaticity of **1** is smaller than those of the germanium and silicon analogues, judging from the NICS(1) values of non-lithium-coordinated dianions **4–6** (Table 2).

In summary, the lithium salt **1** of a stannole dianion was isolated and characterized by NMR and X-ray crystal structural studies, and the related calculations were carried out. The stannole dianion has a planar structure with almost equal C−C distances within the ring, and hence the negative
Figure 3. Orbital correlation between butadiene and tin dianion moieties.

charges considerably are delocalized in the ring. The strong low-frequency resonance arising from the diatropic ring current from the 6π-electron system was observed by ^{7}Li NMR spectroscopy. Compound **1** is concluded to be the first tin-containing carbocyclic aromatic compound.

Experimental Section

Synthesis of **1**: Ether (10 mL) was added to a mixture of **2** (971 mg, 1.54 mmol) and lithium (103 mg, 14.8 mmol), and the resulting suspension was refluxed for 17 h. Insoluble materials were removed by filtration, and the filtrate was concentrated in a glove box. The residue was washed with hexane to give **1** (741 mg, 98%); ^{1}H NMR (400 MHz, Et$_2$O/C$_6$D$_6$): $\delta = 6.61$–6.68 (m, 4H), 6.75–6.82 (m, 12H), 6.88–6.93 ppm (m, 4H); ^{13}C NMR (101 MHz, Et$_2$O/C$_6$D$_6$): $\delta = 121.90$ (d), 124.09 (d), 127.17 (d), 127.21 (d), 128.43 (d), 132.64 (d), 133.46 (s, J(Sn,C) = 29 Hz), 144.18 (s, J(Sn,C) = 14 Hz), 150.57 (s, J(Sn,C) = 34 Hz), 187.68 ppm (s, J(Sn,C) = 375, 393 Hz); ^{119}Sn NMR (149 MHz, Et$_2$O/C$_6$D$_6$): $\delta = 163.3$ ppm; ^{7}Li NMR (156 MHz, Et$_2$O/ C$_6$D$_6$): $\delta = -4.36$ ppm. An elemental analysis and the measurement of the melting point of **1** could not be carried out because of its extremely high reactivity toward water.

Crystal data for **1**: Crystals suitable for X-ray diffraction were obtained by slow evaporation of the solvent from a solution of **1** in ether performed in a glove box. The crystal was mounted in a glass capillary. Data for the X-ray crystallographic analysis were collected on Mac Science DIP3000 diffractometers with Mo$_{K\alpha}$ radiation ($\lambda = 0.71073$ Å) at 298 K. The structure was solved by direct methods by using SIR[23] and refined with full-matrix least-squares procedures on F^2 (SHELXL-97).[24] The non-hydrogen atoms were refined anisotropically except for the disordered carbon atoms (see below), and all the hydrogen atoms were placed at calculated positions (d(C-H) = 0.96 Å). Disorder around one of the ether molecules was found. The occupancies of the disordered ether carbon atoms were fixed as 0.50:0.50 and the corresponding hydrogen atoms were not placed. Formula C$_{36}$H$_{35}$Li$_2$O$_2$Sn, C$_6$H$_6$, $M_r = 710.34$, crystal dimension 0.40 × 0.40 × 0.20 mm^3, triclinic, space group P$\bar{1}$, $Z = 2$, $a = 10.8280(6)$, $b = 13.3290(7)$, $c = 15.2920(10)$ Å, $\alpha = 104.449(3)$, $\beta = 94.865(3)$, $\gamma = 113.249(3)°$, $V = 1921.6(2)$ Å^3, $\rho_{calcd} = 1.228$ g cm^{-3}, $R1 = 0.057$ ($I > 2\sigma(I)$, 5247 reflections), $wR2 = 0.169$ (for all reflections) for 6519 reflections and 423 parameters, GOF = 1.146. CCDC-271622 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

[10] A new singlet was observed in the ^{1}H NMR spectrum in ether/C_6D_6 at $\delta = 5.23$ ppm. In a separate experiment, a solution of phenyllithium was refluxed in ether/C_6D_6 for 14 h. The ^{1}H NMR spectrum of the resulting mixture showed a singlet at $\delta = 5.23$ ppm with the complete disappearance of the signals for phenyllithium. The ^{13}C NMR spectrum showed signals at $\delta = 122.79$ and 128.53 ppm, the latter being assignable to benzene. The signals at $\delta = 5.23$ ppm in the ^{1}H NMR spectrum and $\delta = 122.79$ ppm in the ^{13}C NMR spectrum probably arise from ethylene.

Heterogeneous Catalysis

Tungsten Carbide Microspheres as a Noble-Metal-Economic Electrocatalyst for Methanol Oxidation**

Raman Ganesan and Jae Sung Lee*

Among various fuel cells, the direct methanol fuel cell (DMFC) is suited for portable devices or transportation applications owing to its high energy density at low operating temperatures and the ease of handling a liquid fuel.[1] However, the DMFC has some critical technical drawbacks including the slow oxidation kinetics of methanol relative to hydrogen in the polymer-electrolyte membrane fuel cell (PEMFC). The reaction occurring at the anode of the DMFC is the oxidation of methanol in the presence of water to produce CO_2, electrons, and protons [Eq. (1)].

$$CH_3OH + H_2O \rightarrow CO_2 + 6H^+ + 6e^- \qquad (1)$$
Currently the most promising anode materials for the DMFC are Pt–Ru bimetallic catalysts dispersed on carbon. This catalyst is favored because of its high activity for methanol oxidation and for water activation, which is critical for the removal of strongly adsorbed CO formed during the decomposition of methanol. However, it still requires high loadings of these expensive noble metals, which makes the cost of DMFC prohibitively high. Further, this catalyst system is susceptible to CO poisoning.[2] Thus, in recent years there has been considerable interest in replacing noble metals in DMFC electrodes.[3]

Tungsten carbides have been studied extensively because of their interesting chemical and physical properties.[4] The carbides of Groups 4–6 (Ti–Cr groups) show catalytic properties similar to those of platinum group metals.[5, 6] There have been several attempts to utilize tungsten carbide as an electrocatalyst because of its platinum-like catalytic behavior, its stability in acid solutions at anodic potentials, and its resistance to CO poisoning.[7] But when used for an anodic material under DMFC conditions, tungsten carbide alone showed low electrocatalytic activity although it showed resistance to CO poisoning.[8] Recent surface-science studies have demonstrated that the activity of tungsten carbide film

or carbon-modified W(111) or W(110) single-crystal surfaces could be promoted by adding submonolayer coverages of platinum.[9] Herein we report for the first time the synthesis of W_2C microspheres with high surface areas and chemisorption capacity. The material when combined with platinum showed very high activity for the electrooxidation of methanol exceeding that of a commercial Pt–Ru catalyst with a higher metal loading. Thus Pt/W_2C microspheres could be a promising alternative anodic material for DMFC replacing ruthenium entirely and saving substantial amount of platinum from the current Pt–Ru electrodes. In addition, inorganic spheres have tailored properties, low densities, higher surface areas, and unique optical and surface properties, which are desired for applications as catalysts, sensors, and fillers.[10]

We synthesized W_2C microspheres by heating mixtures of resorcinol–formaldehyde polymer (a carbon precursor) and ammonium metatungstate salt (AMT) (a tungsten precursor). In a typical synthesis, a mixture containing AMT, resorcinol, formaldehyde, and water was mixed in a molar ratio of $8.1 \times 10^{-4}:1.1 \times 10^{-2}:2.2 \times 10^{-2}:1.1$ and heated under reflux at 367 K for 24 h. The resulting gel was dried at room temperature then heated at 1173 K for 1 h in an argon flow and 2 h in a hydrogen flow (100 mL min^{-1}). The H_2 treatment was to remove the free carbon deposited on the W_2C surface.[11] The carbon microsphere was prepared in the same way without AMT salt.

The typical X-ray diffraction (XRD) pattern of the resulting W_2C microspheres is shown in Figure 1. The
Figure 1. XRD patterns of a) W_2C microsphere, b) Pt–Ru/C- microsphere, and c) Pt/W_2C-microsphere. $*$ W_2C, △ WC, □ WC$_{1-x}$, O Pt.

reflections of the microsphere correspond to W_2C (hexagonal-close packed (hcp)) as the major phase and to WC (hcp) and WC$_{1-x}$ (face-centered cubic (fcc)) as minor phases. The formation of tungsten–carbide phases depends on heating rate, temperature, and especially, the amount of carbon present in the sample.[11–13] To study this phase variation, the amount of AMT was varied from 4.1×10^{-4} mol to 16×10^{-4} mol in the polymer while keeping all others factors constant. A phase transition was observed from W_2C (with minor amount of WC$_{1-x}$) to pure WC (no other phases were present) as the amount of AMT increased. But at higher amounts of AMT, the surface area decreased and the spherical structure

Supporting information for this article is available on the WWW under http://www.angewandte.org or from the author.

collapsed into bulk particles. The optimized molar ratio for the spherical structure with a high surface area was the composition specified above. Under these optimized conditions, we observed W_2C as the major phase with WC_{1-x} and WC as minor phases. There were no XRD peaks corresponding to tungsten trioxide, metallic tungsten, and carbon materials. Tungsten trioxide should be present as an amorphous phase because we observed the phase by X-ray photoelectron spectroscopy (XPS). The XRD pattern of carbon microspheres prepared without the tungsten salt AMT indicated an amorphous nature and showed no peaks.

The BET surface area of the W_2C microspheres was about $176 \ m^2g^{-1}$ (compared to $635 \ m^2g^{-1}$ for carbon microspheres). The CO uptake was calculated from temperature-programmed desorption (TPD) (see Supporting Information) by referring the area under the CO mass signal (28) to the known quantity of CO used. The CO uptake value ($956 \ \mu mol \ g^{-1}$) indicates that the number of CO molecules taken up corresponds to 18.7% of the total number of tungsten atoms in the sample. To our knowledge, these surface area and CO uptake values are the highest reported for tungsten carbide.[12,13] Carbon microspheres prepared without the tungsten salt AMT, and the commercial WC (Alfa-JM) did not chemisorb CO molecules. XPS of the W_{4f} doublet ($4f_{5/2}$ and $4f_{7/2}$) showed peaks at 31.6 eV and 32.5 eV, arising from the presence of tungsten carbide (see Supporting Information).[14] Peaks observed at higher binding energies indicate that a part of the tungsten is present as an oxide, which probably arises from surface oxidation of W_2C in air after preparation.[15]

The microscopic images of carbon and W_2C microspheres are shown in Figure 2. Both microspheres showed uniform morphology with diameters of 2–4 μm. The carbon microspheres appear to act as a template for the formation of W_2C microspheres. The W_2C microspheres were also observed under a high-resolution transmission electron microscope (HRTEM). As shown in Figure 2c, the microsphere appears to be a collection of W_2C nanoparticles wrapped with a carbon-rich skin. The surface was fairly rough (Figure 2d). The microspheres must be porous to give the high BET surface area of $176 \ m^2g^{-1}$. Furthermore, application of the Debye–Scherrer equation to the XRD peaks shown in Figure 1 gives a W_2C crystal size of approximately 12 nm. Energy dispersive X-ray spectroscopy (EDX) analysis of the W_2C microspheres showed that the surface was composed of tungsten, carbon, and oxygen and gave a composition of $WCO_{0.06}$ (see Supporting Information). There is a 100% excess of carbon over the stoichiometry of the observed main phase of W_2C. Thus, it appears that the microsphere is a composite material made of W_2C particles and carbon.

Platinum particles were supported on these W_2C and Pt–Ru particles on carbon microspheres by the conventional borohydride reduction method.[16] The HRTEM images (Figure 2e,f) show that the platinum particles are finely dispersed on W_2C microspheres but Ru–Pt alloy particles form large aggregates on carbon microspheres. The average platinum particle size is around 6 nm on W_2C, which is in good agreement with the value calculated from XRD (Figure 1) using the Debye–Scherrer equation (6 nm for 7.5 wt% Pt on
Figure 2. a) SEM image of carbon microspheres, b) SEM image of W_2C microspheres, c) HRTEM image of a W_2C microsphere, d) HRTEM image of the surface of a W_2C microsphere, e) HRTEM image of a Pt–Ru/carbon microsphere, f) HRTEM image of a Pt(7.5 wt%)/W_2C microsphere.

W_2C, 14 nm for 15 wt% Pt on W_2C, and 14 nm for 20 wt% Pt–Ru on carbon microspheres).

By using hydrogen adsorption–desorption methods in conjunction with cyclic voltammetry the electrochemical surface area (ESA) of platinum supported on various catalysts was measured. As shown in Table 1, the ESA of platinum supported on W_2C is several-times higher than those of Pt–Ru supported on carbon microspheres and commercial (E-Teck) 20% Pt–Ru(1:1 atomic ratio)/Vulcan XC-72R carbon. This result indicates that the platinum particles were better dispersed on the W_2C spheres than on the other

Table 1: Electrocatalytic activity of various catalysts for methanol oxidation.

Catalyst	ESA[a] [m^2g^{-1} Pt]	Specific activity[b]	Mass activity[c]
W_2C	0.0	0.0	0.0
7.5 wt% Pt/W_2C	327	156	728
15 wt% Pt/W_2C	189	224	560
11 wt%Pt–9 wt%Ru/Carbon microsphere	58	87	280
13 wt%Pt–7 wt%Ru/VulcanXC-72R[d]	71	114	307

[a] Electrochemical surface area. [b] At 0.75 V [$mA cm^{-2}$]. [c] At 0.75 V [$mA mg^{-1}$ Pt]. [d] Commercial E-Teck catalyst

supports. This dispersion is reflected in the electrochemical activity towards the oxidation of methanol (Table 1 and Figure S4 in Supporting Information). The W_2C microspheres alone without platinum showed no activity. In contrast, both 7.5 wt % and 15 wt % Pt supported on W_2C microspheres show higher current density (taken at 0.75 V, after the cycle was stabilized) than Pt–Ru supported on carbon microspheres and a commercial 20 % Pt–Ru E-Teck catalyst. The mass activity of platinum ($mA mg^{-1}$ of Pt taken at 0.75 V) supported on W_2C microspheres (7.5 wt % Pt) is higher by factors of 2.6 and 2.4 than those of Pt–Ru/carbon microspheres and the commercial E-Teck catalyst, respectively (that is, a lower amount of platinum is required to generate the same current. The mass activity of Pt/W_2C was greater for the lower platinum-loading electrocatalyst (7.5 wt % Pt versus 15 wt % Pt). These results clearly shows that platinum dispersed on W_2C microspheres provides much better utilization of platinum than in the Pt–Ru/carbon catalysts and that ruthenium could be entirely replaced.

There are several reasons why Pt/W_2C-microsphere catalyst performs better than the commercial catalyst even with the smaller platinum loadings and in the absence of ruthenium. The first is the ability of W_2C to stabilize the high dispersion of platinum relative to carbon supports as discussed above. Second, in the presence of platinum, W_2C is active in the electrochemical methanol oxidation and water decomposition as discussed by Chen and co-workers.[9] The formation of hydroxy groups from water activation is essential for the removal of metal-poisoning CO from the surface. This converion is the main role played by ruthenium in conventional Pt–Ru catalysts and this role can be played by W_2C. Finally, W_2C shows high CO resistance. The CO desorption temperature for pure platinum is 460 K.[17] It decreases to 420 K (Figure S1 in Supporting Information), when the platinum is supported on W_2C. This feature would decrease the poisoning of the catalyst surface by CO and increase the activity for electrooxidation of methanol.

The stability of the Pt/W_2C-microsphere catalyst was tested by repeating electrochemical reaction cycles in a 1M $H_2SO_4/1M$ CH_3OH solution. As shown in Figure 3, the specific activity as represented by the area of cyclovoltammogram increased initially, but stabilized after around 30 cycles. We believe that surface oxygen species formed on the catalyst are removed during this transient period. Once a steady state is established, there was no sign of deactivation during 100 consecutive reaction cycles.
In summary we have for the first time synthesized and characterized W_2C microspheres by a polymer method. A new ruthenium-free electrocatalyst composed of platinum supported on these microspheres shows higher activity for electrochemical oxidation of methanol than a commercial Pt–Ru/C catalyst by a factor of 2.4 (per mass of Pt). This activity could be further increased with optimization of the platinum-loading technique to deposit platinum particles smaller than 6 nm. Since the catalyst is also stable in electrochemical environment, it could become a noble-metal-economic electrocatalyst for DMFC and has the potential to replace current Pt–Ru catalysts.

Experimental Section

Before TPD experiments, the catalysts were activated at 473 K in hydrogen for 1 h. After cooling to room temperature the CO chemisorption was carried out at room temperature for 1 h. Finally CO was desorbed by heating from room temperature to 573 K in He flow.

The working electrodes for the electrochemical measurements were fabricated by dispersing the platinum supported catalysts in 1 mL of distilled water and 5 wt % Nafion (10μL). The dispersion was ultrasonicated for 15 min. A known amount of suspension was added on to the glassy carbon and the solvent was slowly evaporated. 5 wt % Nafion (10μL) was added onto the coatings and the solvent was slowly evaporated. Pt foil and Ag/AgCl/3M NaCl were used as counter and reference electrodes, respectively. A solution of 1M $H_2SO_4/1M$ CH_3OH was used for electrochemical studies using Princeton Applied Research (PAR) voltammetry.

Figure 3. Cyclic voltammogram of 7.5 % Pt/W_2C-microsphere in a 1 M $H_2SO_4/1$ M CH_3OH solution at a scan rate of 50 mVs^{-1} at 298 K, arrows indicate changes with increasing numbers of scans.

Rapid Synthesis in Ionic Liquids of Room-Temperature-Conducting Solid Microsilica Spheres**

*David S. Jacob, Augustine Joseph, Somashekarappa P. Mallenahalli, Sangaraju Shanmugam, Shirly Makhluf, Jose Calderon-Moreno, Yuri Koltypin, and Aharon Gedanken**

Herein, we report the rapid synthesis of monodispersed conducting solid microsilica spheres by hydrolyzing tetramethylorthosilicate (TMOS) and tetraethylorthosilicate (TEOS) in an ionic liquid, 1-butyl-3-methylimidazolium hexafluorophosphate, at room temperature. We also report the effect of varying experimental conditions such as the temperature and pH of the solutions on the synthesis and morphology of the silica spheres.

Metal oxide spheres have attracted much attention in fields such as optical materials and catalysts, as well as other nanotechnologies.[1–5] The sol–gel method is one of the most useful means to prepare metal oxide spheres and small particles with high densities.[6] Stöber et al. developed an excellent method to prepare monodispersed silica spheres from silicon alkoxides in alcoholic solutions.[7] This process was extended to the preparation of various metal oxides such as Al_2O_3, TiO_2, and ZrO_2.[8–10] While the original Stöber technique yields silica spheres with sizes in the range of 200–700 nm, a modified Stöber method yields larger spheres of 1–2 μm.[11] However, it is difficult to prepare monodispersed silica spheres larger than 2 μm in alcoholic basic media at room temperature,[7, 11] while the synthesis of silica spheres in acidic media has been reported to produce spheres as well as irregularly shaped particles of 10–60 μm in size.[12] Controlling the size, shape, monodispersity, and yield of the desired product has become a challenge for material chemists.

Room-temperature ionic liquids (RTILs) have received much attention as solvents, and significant progress has been made in their applications to biphasic reactions, chemical synthesis, electrochemistry, catalysis, polymerization, biocatalysis, liquid–liquid separations, extractions, dissolution, biopolymer, molecular self-assembly, and interfacial synthesis.[13,14] Recently, an ionic liquid was used as both a solvent and a template in the synthesis of zeolites.[15] Supermicroporous lamellar and well-defined inverse opal microstructured silicas have been prepared in ionic liquids, which serve as templates.[16,17] Hollow TiO_2 microspheres have been prepared in ionic liquids, and it was reported that their size was influenced by the rate of stirring and the reaction temperature.[14] Elsewhere, mesoporous silica nanoparticles of various morphologies that contained an ionic liquid were used as a controlled-release delivery nanodevice to discharge antibacterial ionic liquids against *Escherichia coli K12*.[18]

Moreover, owing to their diverse electrochemical properties, ionic liquids have been used as electrolytes for electrochemical devices such as lithium secondary batteries, electric double-layer capacitors, dye-sensitized solar cells, fuel cells, and actuators.[19] Several important properties of ionic liquids make them attractive substitutes for volatile organic solvents.[20] The properties of RTILs can be controlled over a wide range through variation of both the anion and cation as well as the chain lengths of the substituent groups. An increasing chain length in the cation alters the melting point of the ionic liquids and increases their viscosity and hydrophobicity.[21] Varying the anion also affects the property of ionic liquids; for example, salts based on the tetrachloroaluminate(III) anion are extremely water sensitive, whereas those based on the hexafluorophosphate anion are neutral and extremely hydrophobic.[22] Through careful consideration of the conducting properties and hydrophobicity of the ionic liquid, we chose 1-butyl-3-methylimidazolium hexafluorophosphate, $BMI^+PF_6^-$, as the solvent for the preparation of the silica spheres.

The hydrolysis of TMOS and TEOS in a fixed amount of ionic liquid under different reaction conditions (temperature, pH) were studied. The products were characterized by small-angle X-ray diffraction (SAXRD), energy-dispersive X-ray (EDX) spectroscopy, mass spectrometry, and Raman spectroscopy. An in-depth morphological study of the silica spheres prepared under different conditions was carried out by scanning electron microscopy (SEM), and the solid-state nature of the silica spheres was confirmed from the microtomed cross-section of the sample by transmission electron microscopy (TEM).

SAXRD results revealed a lack of organization of the pores for the as-prepared silica spheres, whereas some extent of order could be observed in a sample that was calcined at 1000 °C. EDX spectroscopy showed the presence of phosphorus and chlorine from the encapsulation of the ionic liquid, $BMI^+PF_6^-$, and aqueous HCl solution within the silica spheres in the as-prepared sample, whereas their absence was noted in the sample calcined at 1000 °C. Desorption chemical ionization mass spectrometry indicated the presence of 1-butyl-3-methylimidazole (BIM-H) in the sample, while the Raman spectrum of the as-prepared silica spheres revealed

C−H stretching and ring-stretching vibration bands that confirmed the presence of the entrapped ionic liquid as well as O−H stretching bands from water molecules. The entrapped ionic liquid remained intact in the silica spheres even after several washings with acetone. The D and G bands in the Raman spectrum indicate the carbon content of the sample annealed at about 1000 °C.

The size distribution of the microspheres was confirmed by SEM, which revealed diameters in the range of 50–85 μm. The surface area measured for the as-prepared sample was 3.17 $m^2 g^{-1}$, while that for the calcined sample ranged from 8–12 $m^2 g^{-1}$, which is much higher than reported values.[12] The increase in surface area is a result of the evaporation or decomposition of the entrapped molecules of water and ionic liquid inside the silica spheres; upon removal of the entrapped species, empty pores are left behind. Thermogravimetric analysis of the silica spheres showed a weight loss of about 9.6 % at 150 °C due to the removal of water, whereas a weight loss of 17 % at 550 °C was attributed to the decomposition and removal of the entrapped ionic liquid, as confirmed by Raman spectroscopy.

The proposed mechanism for the formation of the different morphologies of the spheres is shown in Figure 1. As a
Figure 1. Schematic representation for the formation of different morphologies of silica spheres under different experimental conditions.

result of the hydrophobicity of the ionic liquid, microsized droplets of aqueous HCl solution are formed under vigorous stirring. Molecules of the silica precursor (TMOS, TEOS) enter these aqueous acidic microdroplets and are hydrolyzed, leading to the formation of microspheres. Aggregated and overgrown dimeric silica spheres also result from the above mechanism, as hydrolysis of the silica precursor takes place inside two attached microdroplets of water.

The formation of silica spheres with rough surfaces (Figure 1a) depends on the reaction time and the temperature. With a longer reaction time, microdroplets of water adhere to the fully grown silica spheres and the silica

precursor is hydrolyzed in those microdroplets to yield a rough surface, as depicted in Figure 2. Changes in the reaction time, the pH of the aqueous solution, the temperature, and the hydrophobicity of the ionic liquid (all under stirring) have
Figure 2. Silica spheres with rough surfaces as synthesized from TMOS at 50°C for 1 h in aqueous HCl solution (0.25 M).

an important effect on the preparation and the peripheral morphology of the silica microspheres. By decreasing the reaction time (Figure 1b,c), silica spheres with smoother surfaces were obtained as shown in Figures 3 and 4.
Figure 3. Silica spheres with a dotted morphology as synthesized from TMOS at 50°C for 1 h in aqueous HCl solution (0.1 M).
Figure 4. Silica spheres with smooth morphology as synthesized from TMOS at 50°C for 5 min in aqueous HCl solution (0.25 M).

It was observed that the pH of the acidic solutions as well the temperature affect the rate of hydrolysis. Reactions were carried out at pH 1–2 (0.25–0.01 M HCl) at room temperature and at 50°C under vigorous stirring. Under similar reaction conditions (room temperature, 0.1 M HCl, 30 minutes), a clear solution was observed for the TEOS precursor whereas silica spheres formed in the case of TMOS which suggests that the rate of hydrolysis of TMOS is faster than that of TEOS. This difference in rate was also confirmed upon hydrolysis of TMOS at room temperature with 0.01 M HCl for 30 minutes by which smooth silica spheres were obtained; under the same reaction conditions with TEOS, a clear solution was obtained. Thus, variation of the reaction conditions leads to the formation of different morphologies of silica.

To determine whether the silica spheres were hollow or solid we microtomed the products, and studied the cross-section of a sample (Figure 5). The TEM image shows a smooth outer layer and small particles arranged inside to form a solid microsilica sphere.
Figure 5. TEM image of the cross-section of single silica spheres.

Control hydrolysis reactions (1 h) in the absence of ionic liquids were also carried out to study the morphology of the hydrolyzed products of TMOS (0.5 mL) and TEOS (0.5 mL) with aqueous HCl solution (0.25 M) under vigorous stirring at room temperature as well as at 50°C. Clear solutions were observed for the reactions performed at room temperature, but silica gels were observed at 50°C, which suggests that the ionic liquid accelerates the rate of reaction at room temperature and plays an essential role in the formation of the spheres. A second control reaction (1 h) in the presence of the ionic liquid but in the absence of aqueous HCl solution was performed to study the morphology of the hydrolysis products of TMOS (0.5 mL) and TEOS (0.5 mL) under vigorous stirring at 50°C. In both cases, dustlike particles (1-micron particles as well as aggregates) were observed. These results demonstrate that in the presence of aqueous HCl solutions, the dustlike particles play a significant role by functioning as seeds for the formation of fully grown silica spheres. These dustlike silica particles tested positive for antibacterial activity (*E. coli*, Gram-negative). Reactions carried out for shorter periods of time and in the absence of aqueous HCl solution resulted in clear mixtures, which substantiate the roles of the acidic solution and the reaction time. The above findings demonstrate the necessity of the ionic liquid and the aqueous HCl solution under vigorous stirring in order to develop silica microspheres.

Angewandte
Chemie

It is known that silica acts as an insulator and that the conducting properties of silica can be improved through doping with electrolytes.[23] Interestingly, with our synthetic route to the silica microspheres, the entrapped molecules of the ionic liquid induce their conducting properties at room temperature.[24] The bulk conductivity as determined by impedance measurements for pristine 1-butyl-3-methylimidazolium hexafluorophosphate BIM$^+$PF$_6^-$ is reported as 3.8×10^{-2} S cm^2 mol^{-1}.[19] The conductivity of the silica spheres was also measured by the impedance method over the frequency range 5–50 kHz at room temperature and 60°C. The conductivities observed at 5 kHz at different time intervals are 7.87×10^{-6}, 8.50×10^{-6} (72 h), and 9.83×10^{-6} S cm^{-2} (144 h) at room temperature. The conductivity decreased after 192 h to 6.77×10^{-6} S cm^{-2}. Thus, the presence of entrapped ionic liquid and water were needed to improve the conductive properties of our synthesized silica spheres. The observed increase in the conductivity with increasing time was due to adsorption of water molecules on the silica.[25] The conductivity was found to increase with an increase in temperature, with values of 8.14×10^{-6} (194 h) and 9.76×10^{-6} S cm^{-2} (216 h) measured at 60°C. These results are interpreted as a result of the increased mobility of entrapped molecules of the ionic liquid.[24]

The conductivity of the silica spheres will hopefully gain importance for their applicability in electrochemistry and sensors.[26a–c] The conductivity is most probably due to a special oriented alignment of the molecules of ionic liquid along the surface. A detailed study of the conductivity of an individual silica sphere is in progress and will be reported soon. The current process for the synthesis of silica spheres in an ionic liquid has opened new directions and opportunities to explore their application in several fields, however more research has to be carried out to address the challenges that remain and to explore the importance of ionic liquids in other fields.

Experimental Section

In a typical synthesis, TMOS (0.5 mL, 0.516 g, 3.38 mmol; Aldrich Chemical Co, 99%) and BMI$^+$PF$_6^-$ (3 g, 0.01 mol; Aldrich Chemical Co., 96%; density = 1.37 g cm^{-3}) were stirred in a 15-mL teflon vessel for 1 min at room temperature to form a homogeneous transparent solution. Then, 0.01 M aq. HCl (0.25 mL) was added under stirring. (Milli-Q water was used to prepare the acid solution and a 0.2-μm Whatman Anotop 25 filter was used for filtration). The reaction mixture was stirred vigorously at room temperature for 30 min and then quenched by the addition of acetone. The white spheres were separated by centrifuging at 9000 rpm for 10 min, and the product was washed with acetone several times to remove excess ionic liquid, then centrifuged at 9000 rpm for 10 min, and dried under vacuum for 24 h. The size of the silica spheres obtained ranged from 50 to 85 μm.

Synthesis, Intermolecular Interaction, and Semiconductive Behavior of a Delocalized Singlet Biradical Hydrocarbon**

Takashi Kubo,* Akihiro Shimizu, Maki Sakamoto, Mikio Uruichi, Kyuya Yakushi, Masayoshi Nakano, Daisuke Shiomi, Kazunobu Sato, Takeji Takui, Yasushi Morita, and Kazuhiro Nakasuji*

Most Kekulé hydrocarbons, which are characterized by a closed-shell electron configuration, accommodate their π electrons only in bonding orbitals and consequently are quite stable. In general, such stable Kekulé compounds have wide HOMO–LUMO gaps, and their electronic structures in the ground state can be well described by a single electron configuration $^1\Phi_0$. In contrast, some Kekulé compounds, such as quinoid hydrocarbons, have a relatively small HOMO–LUMO gap, which leads to an admixture of a doubly excited configuration $^1\Phi_{H,H\rightarrow L,L}$ into the ground configuration $^1\Phi_0$ in the description of the ground state.[1a] As a result of this configuration mixing, the repulsion between the two electrons is taken into consideration and the two electrons with antiparallel spins are permitted to correlate in separate spaces. This electron correlation diminishes the bond covalency and increases the biradical character of the system.

The quinoidal Kekulé hydrocarbons are highly reactive and easily dimerize or polymerize at normal temperature.[2] Such behavior is strongly reminiscent of radical reactivity. Related interesting reactivity has been observed for pleiadene, which dimerizes readily even at 110 K through a two-step cycloaddition or a symmetry-forbidden [4s + 4s] concerted process.[1] The latter process is predicted to be related to the $^1\Phi_{H,H\rightarrow L,L}$ configuration. The biradical-like reactivity implies strong intermolecular interactions in the ground state, which would be a most remarkable feature for singlet biradical compounds. However, great difficulties are encountered in estimating the intermolecular interaction due to the instability. Although kinetically stabilized singlet biradicals such as Chichibabin's hydrocarbon have been isolated and characterized, sterically crowded structures mask the effective intermolecular π–π interactions.[3] To estimate the intermolecular interactions, thermodynamic stabilization of the singlet biradicals would be required instead of kinetic stabilization. One of the most effective means of thermodynamic stabilization is delocalization of unpaired electrons. Herein, we focus on phenalenyl radical as a highly spin-delocalized molecule (Scheme 1). The radical is known to be
Scheme 1. Spin delocalization of phenalenyl radical.

persistent, and many related compounds have been isolated.[4] We report the synthesis and isolation of a singlet biradical utilizing the highly spin delocalizing property of the phenalenyl radical. Furthermore, we present the intermolecular interaction and solid-state properties of a delocalized singlet biradical.[5]

For the purpose of estimating the intermolecular interaction, we focused on a closed-shell conjugated system that contains the phenalenyl radical structure.[6] Hydrocarbon **1a** consists of *p*-quinodimethane and two phenalenyl moieties.[7] The quinoid Kekulé compound **1a** would resonate well with biradical structure **1a′** as a result of gaining the aromatization energy of the central six-membered ring (Scheme 2). The unpaired electrons emerging on the terminal carbon atoms of the *p*-quinodimethane moiety can delocalize on the phenalenyl rings (structure **1a″**). This consideration of resonance

Scheme 2. Resonance structures of **1**.

structures leads to the conclusion that **1a** would be a thermodynamically stabilized singlet biradical. Quantum chemical calculations on **1a** strongly support the biradical character. A CASSCF(2,2)/6-31G//RB3LYP/6-31G** calculation gave an admixture of 15% of the doubly excited configuration $^1\Phi_{H,H\rightarrow L,L}$ into the singlet ground state. A broken-symmetry UB3LYP/6-31G** calculation also gave a similar biradical character; the natural orbital occupation number (NOON)[8] of the LUMO was 0.37, and the spin contamination $\langle S^2 \rangle = 0.65$ (see Supporting Information). Thus, the singlet biradical character of **1a** is estimated to be 30–37%.

The synthetic procedure for the diphenyl derivative **1b** is shown in Scheme 3. The key intermediates **4** were obtained as a mixture of 3,10- and 3,11-dimethyl isomers by Diels–Alder reaction between **2** and **3** followed by decarbonylation and dehydration with *p*-chloranil. Individual isomers were not isolated for further transformations because the two isomers can lead to a single compound **1b**. Bis(propionic acid) derivatives **7** were obtained in three steps. Intramolecular Friedel–Crafts cyclization of the acyl chloride of **7** with AlCl₃ gave diketone **8**, which was reduced and subsequently

dehydrated to afford dihydro compound **10**. Dehydrogenation of **10** with *p*-chloranil provided the target compound **1b** as dark green plates. Compound **1b** was found to be stable in the solid state at room temperature, even in air.

As mentioned above, a small HOMO–LUMO gap is an essential factor for a singlet biradical electronic structure. The small HOMO–LUMO gap of **1b** was confirmed by electrochemical and optical methods. The cyclic voltammogram of **1b** gave an irreversible oxidation wave ($E_{pa}^{ox} = +0.08$ V vs ferrocene/ferrocenyl couple (Fc/Fc⁺)) and a quasi-reversible reduction wave ($E_{1/2}^{red} = -1.07$ V vs Fc/Fc⁺), which led to an electrochemical energy gap (HOMO–LUMO gap) of approximately 1.1 eV. The electronic absorption spectrum of **1b** in CH₂Cl₂ showed an intense low-energy band at 746 nm ($\varepsilon = 178\,000$, $f = 0.649$). An INDO/S configuration interaction (CI) calculation suggested that the low-energy band could be assigned to a symmetry-allowed B₃ᵤ HOMO–LUMO transition. These findings indicate an optical energy gap of 1.66 eV for **1b**. The small HOMO–LUMO gap is ascribable to the nonbonding character of the frontier orbitals, as shown in Figure 1. The frontier orbitals of **1a** retain the nonbonding

Figure 1. The HOMO and LUMO of **1a**, and the SOMO of the phenalenyl radical.

character of the singly occupied molecular orbital (SOMO) of the phenalenyl radical. The most important feature is a quite large spatial overlap between HOMO and LUMO. The large spatial overlap and small energy gap are responsible for the admixture of a doubly excited configuration into the ground state, that is, a singlet biradical character.[9]

Recrystallization of **1b** from a solution in chlorobenzene gave relatively large single crystals (1 × 0.3 × 0.2 mm³), including chlorobenzene molecules of solvation, which were analyzed by X-ray diffraction. As shown in Figure 2, **1b** forms one-dimensional (1D) chains with a slipped stacking arrangement and an average π–π distance of 3.137 Å,[10] which is substantially shorter than the van der Waals contact of carbon atoms (3.4 Å). The π–π overlap was found only on phenalenyl moieties in the same arrangement as that of the phenalenyl radical dimer.[4a] The staggered stacking of the radical dimer maximizes the SOMO–SOMO interaction between radicals, and the overlap of SOMOs is one of the crucial attractive bonding interactions.[11] The dominant attractive force for **1b** would originate from the bonding interaction between the unpaired electrons that appear in the singlet biradical canonical structure **1b″**, in addition to a general attractive dispersion force. In the valence bond description, the interaction of the two unpaired electrons could be repre-

sented by the resonance between intra- and intermolecular interaction, as shown schematically in Scheme 4. Thus, a strong intermolecular covalent character is a characteristic
Scheme 4. Resonance structures of intra- and intermolecular interactions of two unpaired electrons in the 1D chain. Wavy lines denote electron–electron interactions. In parentheses: best descriptions of the electronic structure in each resonance state.

feature of singlet biradicals. A restricted Hartree–Fock (RHF) plus CI method is useful for understanding the intermolecular covalency. For simplicity, the following discussion focuses on a dimer of **1b**, which is the smallest unit of the 1D chain. As described above, **1b** has a biradicaloid ground state with 15% of the doubly excited configuration as a result of the configuration interaction between HOMO and LUMO. The interaction between the partially occupied HOMOs would lead to the partially occupied "HOMO" of the dimer (1.4 e), as shown in Figure 3. The partial occupancy suppresses a four-electron repulsion generally arising from

the interaction between fully occupied orbitals. The LUMO–LUMO interaction would also contribute to stabilization of the system, because a newly formed "LUMO" of the dimer, which is more strongly stabilized than the original LUMO, can accommodate 0.6 electrons.[12] The presence of the well-stabilized intermolecular orbitals would indicate intermolecular covalency.

The electrical conductivity of a compressed pellet of doubly recrystallized **1b** was measured by a two-probe method. The room-temperature conductivity was $1.0 \times 10^{-5}\,\mathrm{S\,cm^{-1}}$ with an activation energy of 0.3 eV at 200–300 K (see Supporting Information). The conductivity of a single crystal along the stacking direction (*b* axis) was slightly larger ($5.0 \times 10^{-5}\,\mathrm{S\,cm^{-1}}$ at room temperature) than that of the powdered sample. To the best of our knowledge, **1b** shows the best single-component conductivity among structurally well-defined hydrocarbon molecules in a neutral state.[13] To estimate the electronic structure in the solid state, we performed band-structure calculations using extended Hückel theory (EHT) on the crystal structure of **1b**.[14] The dispersions of valence and conduction bands were found to be substantial (0.54 and 0.51 eV, respectively) along the π–π stacking direction (*Y*), whereas only slight dispersions were seen along *X* (Figure 4).[15] The dispersion along *Z* (0,0,1/2) should be very small as a result of the presence of chlorobenzene of solvation and bulky phenyl groups of **1b**. Thus, the single crystal of **1b** has an ideal 1D electronic structure with large bandwidths in both HOMO and LUMO, which might lead to ambipolar field-effect transistor (FET) properties.[16] The large bandwidths are ascribed to the short π–π distance (due to the singlet biradical electronic structure) and efficient HOMO–HOMO and LUMO–LUMO overlap (due to a π-overlap arrangement similar to the SOMO–SOMO overlap of the phenalenyl radical dimer).

Solid **1b** gave an extraordinary lower energy shift in the optical spectrum compared to the solution spectrum (Figure 5). The optical conductivity spectra were obtained by Kramers–Kronig transformation of the reflection spectra. Polarization of light along the stacking direction (*b* axis) on the (001) face gave an intense peak at 6804 cm^{-1} ($f = 1.9$), whereas no distinct conductivity was recognized below 13 000 cm^{-1} along the *a* axis. The oscillator strength along the *b* axis is almost three times larger than that of the intense

Figure 4. Band structure of **1b** near the Fermi level along X (1/2,0,0) and Y (0,1/2,0). The dotted line represents the Fermi level.

electrons leads to a decreased singlet–triplet energy gap (ΔE_{S-T}). The ^{1}H NMR spectrum of **1b** exhibited severe line broadening of ring protons except for those of phenyl groups at room temperature. On cooling, progressive line sharpening was observed (see Supporting Information). Similar results have been obtained for a tetra-*tert*-butyl derivative of **1a**, which had a ΔE_{S-T} value of 20.4 kJ mol^{-1} based on solid-state ESR measurements.[18] Equilibrium with the thermally accessible triplet state would cause line broadening of the NMR signals for **1b**. Magnetic measurements on **1b** showed a gradual increase of χT values above 200 K (see Supporting Information). Using the Bleaney–Bowers equation[19] in the singlet–triplet model gave an estimated ΔE_{S-T} value of 2200 K (18 kJ mol^{-1}), which is in good agreement with the result of the ESR measurement.

In conclusion, we have successfully isolated and characterized a biradicaloid hydrocarbon with moderate singlet biradical character. In contrast to most closed-shell compounds, the singlet biradical compound shows strong inter- and intramolecular interactions between two unpaired electrons. Such intermolecular covalency causes substantially close π–π contact, and consequently wide valence and conduction bands are established. Thus, phenalenyl-based singlet biradicals will open up a new avenue for highly delocalized 1D electronic structures.

Experimental Section

The detailed synthetic procedure for **1b** is described in the Supporting Information.

Crystal data for **1b**: $C_{56}H_{34}Cl_2$, $M_r = 777.73$, monoclinic, space group $P2_1/a$ (no. 14), $a = 16.382(14)$, $b = 9.869(8)$, $c = 24.09(2)$ Å, $\beta = 97.065(2)°$, $V = 3865(5)$ Å^3, $Z = 4$, $\mu(Mo_{K\alpha}) = 0.209$ cm^{-1}, $\rho_{calcd} = 1.337$ g cm^{-3}, $R1(wR2) = 0.0691$ (0.1868) for 523 parameters and 6604 unique reflections with $I > 2\sigma(I)$, GOF = 1.135. Data were collected on Rigaku/MSC Mercury CCD diffractometer ($Mo_{K\alpha}$ radiation, $\lambda = 0.71069$ Å) at 200 K. The structure was solved by direct methods and refined with full-matrix least-squares techniques (teXsan). CCDC 275077 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

absorption at 746 nm (13 400 cm^{-1}) in solution; that is, the intense band at 6804 cm^{-1} is derived from the lower energy shift of the HOMO–LUMO transition of the monomer due to the intermolecular interactions. The *J*-type stacking of the 1D chain of **1b** seems to imply that the traditional transition dipole–dipole interaction (exciton resonance) is responsible for the lower energy shift. At short intermolecular distances, however, an electron-exchange interaction (charge resonance, i.e., intermolecular HOMO–LUMO transition) becomes important for intermolecular interactions.[17] Of course, the exchange mechanism requires adequate orbital overlap. The orbital overlap between the HOMO and LUMO of solid **1b** is almost identical to the SOMO–SOMO overlap of the phenalenyl radical dimer, and consequently a large overlap integral is expected. Thus, the origin of the lower energy shift should be the configuration interaction between the exciton resonance and the charge resonance states.

Finally, we describe thermal excitation to a triplet state of **1b**. The weak intramolecular coupling between two unpaired

Rev.* **2004**, *104*, 4891–4945.

[14] The RHF calculation without CI cannot describe the accurate solid-state electronic structure of singlet biradicals; however, we could not obtain a solution maintaining the singlet biradical character using ab initio programs.

[15] Extended Hückel molecular orbital (EHMO) calculation is known to underestimate HOMO–LUMO energy gaps of molecules, and consequently band structure calculations based on EHT tend to give band gaps smaller than experimental gaps of semiconductors or insulators. In the case of **1b**, the EHMO calculation afforded a HOMO–LUMO gap of 0.511 eV and a band gap of 0.047 eV, which were substantially smaller than the experimentally estimated values.

Borane Mimics of Classic Organometallic Compounds: [(Cp*Ru)B$_8$H$_{14}$(RuCp*)]$^{0,+}$, Isoelectronic Analogues of Dinuclear Pentalene Complexes**

Sundargopal Ghosh,* Bruce C. Noll, and Thomas P. Fehlner*

Like carbon, the element boron in combination with hydrogen displays rich catenation chemistry.[1] In contrast to carbon, its structural chemistry must reflect a more complex electronic structure which is associated with having to satisfy the same number of valence functions as carbon with one less electron per atom.[2] Hence, one fascinating aspect of metal-

laborane chemistry is that several classic organometallic complexes that defined fundamental structural and bonding paradigms for the field are mimicked by isoelectronic metal-laborane analogues.[3] In most cases, the geometric structures can be generated by simply replacing C with B plus B-H-B bridging hydrogen atoms and/or net charge to match the valence electron count. Thus, for analogues of polyhapto π complexes[4] there are: $[(CO)_4Fe(\eta^2-C_2H_4)]$ versus $[\{(CO)_4Fe\}B_2H_5]^-$;[5] $[(PR_3)ClPd(\eta^3-C_3H_5)]$ versus $[\{(PR_3)_2Pd\}B_3H_7]$;[6] $[(\eta^5-C_5H_5)Co(\eta^4-C_4H_4)]$ versus $[\{(\eta^5-C_5H_5)Co\}B_4H_8]$;[7] and $[(\eta^5-C_5H_5)Fe(\eta^5-C_5H_5)]$ versus $[\{(\eta^5-C_5H_5)Fe\}B_5H_{10}]$[8] (Scheme 1).
Scheme 1. A selection of metallaboranes with borane fragments that are analogous to π ligands in organometallic complexes. $Cp = \eta^5-C_5H_5$.

Related are polyhapto organic ligands capable of binding two metal centers. In these complexes the metal–metal interactions are of significant interest particularly when mixed-valence organometallic complexes may be formed.[9] In particular, the chemistry of dinuclear metal complexes of pentalene, C_8H_6, (Scheme 2) has been developed extensively
Scheme 2. Schematic drawings of the structures of polyhedral $[(Cp^*Ru)_2B_8H_{12}]$, pentalene analogue **2**, and $[Cp^*Ru(pentalene)RuCp^*]$.

because the strength of the electronic coupling between the two metal centers can be larger than that found in cationic Werner complexes such as the Creutz–Taube ion.[10–12] Herein, we present the synthesis and characterization of borane analogues of $[Cp^*Ru(pentalene)RuCp^*]^{0,+}$ ($Cp^* = \eta^5-C_5Me_5$) where the monocation is a mixed-valence complex.

Recently we have shown that the reaction of $[(Cp^*Ru)_2B_3H_9]$ with $BH_3 \cdot THF$ leads to metallaboranes containing six, eight, and ten boron atoms.[13,14] The ten boron atom cluster has two colorless isomeric forms, one with an exo-cluster borane atom on a Ru_2B_9 cluster framework. This species was shown to be an intermediate on the path to

the second isomer which has a Ru_2B_{10} cluster framework. Given the importance of this isomer pair in defining the broad mechanistic outlines of the cluster-building process, we have investigated this system more extensively for the presence of additional colorless products that may be intermediates in the cluster-building process. This approach has led to the isolation of $[(1-Cp^*Ru)B_5H_{10}]$ (**1**; in which the Cp*Ru fragment occupies the 1-position of the BH cage) and $[(Cp^*Ru)B_8H_{14}(RuCp^*)]$ (**2**). Metallabarane **2** converts into the isomer pair $[(Cp^*Ru)_2B_{10}H_{16}]$[14] on heating in the presence of $BH_3 \cdot THF$ showing that it is indeed another intermediate in the cluster-building process.

Although separated initially from the other reaction products as a mixture, both **1** and **2** are insensitive to air and moisture and can be separated by careful thin-layer chromatography on the laboratory bench by using UV light for detection. Mass spectrometric data for **1** yield the composition $C_{10}H_{25}RuB_5$ which suggests a molecular formulation of $Cp^*RuB_5H_{10}$. In addition to 15 Cp* protons, the ^{1}H NMR spectrum of **1** shows one resonance at $\delta = 2.71$ ppm arising from five terminal hydrogen atoms and one resonance at $\delta = -4.05$ ppm for five bridging hydrogen atoms. In the ^{11}B NMR spectrum of **1**, the high symmetry is confirmed by the observation of a single doublet at $\delta = -0.6$ ppm which collapses to a sharp singlet upon proton decoupling. No suitable crystals for structure determination were obtained but, given the similarity of the spectroscopic data to those of $[(CpFe)B_5H_{10}]$ (Scheme 1),[8] **1** is proposed to be 1-ruthena-hexaborane, a borane analogue of ruthenacene.

The mass spectroscopic data for **2** showed a molecular formula two mass units higher than that of red $[(Cp^*Ru)_2B_8H_{12}]$, a compound which has structure based on a $B_{10}H_{14}$ skeleton which has undergone one diamond-square-diamond (dsd) rearrangement associated with its low formal skeletal electron pair (sep) count of 12 (Scheme 2).[13] With 13 sep does **2** have the structure of $[(Cp^*Ru)_2B_8H_{14}]$ but without the dsd rearrangement? In fact, the three resonances in the intensity ratio 2:2:4 found in the ^{11}B NMR spectrum would be consistent with such a structure if the metals occupied the 2,4-positions. However, the six terminal and eight B-H-B bridging hydrogen atoms suggested by the ^{1}H NMR spectrum are not consistent with this cluster shape and heating **2** in the absence of $BH_3 \cdot THF$ did not produce $[(Cp^*Ru)_2B_8H_{14}]$.

A solid-state structure determination of **2** (Scheme 2 and Figure 1)[15] revealed an unexpected geometry. It could be viewed as two ruthenaborane cages of **1**, fused in a transoid fashion with two common boron atoms, to give a planar B_8 fragment, and eight B-H-B bridges on the eight available edges. It is, in fact, a structure analogous to those of isoelectronic dinuclear pentalene complexes $[Cp^*M(C_8H_6)MCp^*]$, M = Fe, Ru (Scheme 2).[10,16] In **2** the ruthenium atoms are bonded symmetrically to the Cp* ligands (Ru–C 2.04 Å av) but the binding to the five-membered boron rings is not quite symmetric (Ru–B 2.15 Å av versus Ru–BH 2.10 Å av). This asymmetry is also found in structures of dinuclear pentalene complexes.[10]

Communications
Figure 1. X-ray structure of **2**. Selected interatomic distances [Å] and angles [°]: Ru1-B1 2.1115(10), Ru1-B2 2.1076(10), Ru1-B3 2.1067(10), Ru1-B4 2.1491(9), B1-B2 1.8204(15), B2-B3 1.8233(15), B3-B4 1.8274(14), B1a-B4 1.8232(14), B1-B4a 1.8232(14), B4-B4a 1.8198(18); B2-Ru1-B1 51.12(4), B2-Ru1-B4 85.39(4), B3-Ru1-B4a 88.55(4), B2-B1-B4a 104.84(7), Ru1-B4-Ru1a 129.94(4), B3-B4-Ru1a 136.54(6), B4a-B4-B3 109.22(8), B1a-B4-B3 141.75(7).

There is another known ruthenaborane related to both **1** and **2**. It has the formula $Cp^*_2Ru_3B_8H_{20}$ and a structure corresponding to *commo*-[{1-$(Cp^*Ru)(\mu$-H)B_4H_9}$_2Ru$] as shown in Scheme 3.[17] Viewed as a pair of fused pentagonal pyramidal clusters with one common atom, it is a structural variation on **2**. But a relationship to **1** follows from the retro isolobal synthesis shown in Scheme 3 based on the following connections: {Cp^*Ru}+H is equivalent to BH; {1-$(Cp^*Ru)B_5H_{10}$} is an analogue of ruthenacene; and {2-
Scheme 3. A retro-isolobal analysis showing the relationship between ruthenacene analogue **1**, and the *commo*-cluster [$Cp^*_2Ru_3B_8H_{20}$].

$(Cp^*Ru)B_5H_{10}$} is an accessible isomer of {1-$(Cp^*Ru)B_5H_{10}$}. Hence, although the production of the pentalene analogue **2** from a ruthenaborane cluster and its conversion into a larger ruthenaborane cluster may seem bizarre, the analysis in Scheme 3 is a reminder that forms analogous to organometallic complexes are just one structural guise available to chameleonic metallaboranes.

In addition to conceptual connections to pentalene dinuclear complexes, there are real chemical connections to **2**. In its cyclic voltammogram, [$Cp^*Ru(C_8H_6)RuCp^*$] exhibits one reversible oxidation wave and an irreversible wave at 0.29 V higher potential.[10] The irreversible behavior is attributed to the oxidation reaction of the Cp* ligand and is analogous to the behavior of [Cp^*_2Ru] on oxidation.[18] Likewise **2** exhibits two successive one-electron oxidations separated by approximately 0.8 V. The first redox event **2**^{0}/**2**$^+$ is quasireversible, but the second oxidation **2**$^+$/**2**$^{2+}$ is not reversible as shown by the lack of a return wave. The larger ΔE observed for **2** compared to the pentalene analogue may result from a stronger interaction between the metal centers as well as more extensive delocalization in the mixed-valence **2**$^+$ form.[19] If so, the greater delocalization found for the borane analogue of [$Cp^*Ru(C_8H_6)RuCp^*$]$^+$ is consistent with a better match of frontier-orbital energies of the borane and ruthenium fragment energies than of the pentalene and ruthenium fragment energies.

The B_8H_{14} fragment of **2** is a true analogue of the η^5-η^5-pentalene ligand. However, comparison with two related ruthenaboranes both containing eight boron atoms, [$(Cp^*Ru)_2B_8H_{14}$] and *commo*-[{1-$(Cp^*Ru)(\mu$-H)B_4H_9}$_2Ru$], reveals once more the versatility of the boron/hydrogen element combination in accommodating the electronic requirements of a set of metal fragments.

The cyclic voltammetry of **2** was carried out in CH_2Cl_2/toluene (8.5:1.5 v/v) as scan rates of 50–100 $mV\,s^{-1}$ using a Pt working electrode, Pt plate counter electrode, and Pt wire pseudo reference electrode, and 0.1 M Bu_4NPF_6 as supporting electrolyte. Under these conditions the ferrocene/ferrocenium ion couple appears at 0.46 V. For a scan from −0.8 to 0.6 V at 50 $mV\,s^{-1}$, the $\mathbf{2^0/2^+}$ couple is found at 0.17 V ($E_{1/2} = 0.258$, 0.085 V) and in a scan from −0.2 to 1.2 V at 50 $mV\,s^{-1}$, the difference in the half wave potentials for $\mathbf{2^0 \rightarrow 2^+}$ and $\mathbf{2^+ \rightarrow 2^{2+}}$ is 0.76 V.

Bioinorganic Chemistry

The Hierarchical Architecture of Nacre and Its Mimetic Material**

*Yuya Oaki and Hiroaki Imai**

Biominerals fascinate many researchers because of their seemingly well-designed morphologies and hierarchical structures, which provide versatile properties.[1–4] The architecture emerging from self-organization under ambient conditions provides a sophisticated model for materials science. The design of nanostructured materials with tailored morphologies, such as particles, rods, wires, tubes, and sheets, has attracted much interest because of their potential as functional materials. Controlled assembly into a three-dimensional architecture is an important challenge in the broad application of these materials.

Living organisms make up hierarchically organized materials through self-organization from precursors in aqueous solution, and scientists have developed various biomimetic techniques to prepare and organize building blocks.[5,6] It is believed that an exquisite association of organic and inorganic compounds is required for the construction of bioinorganic superstructures; therefore, understanding the roles of macromolecules in the biomineralization process is a significant challenge in biomimetic materials chemistry. Recent findings, for example, the discovery of calcitic microlenses in brittle-stars,[2] chiral morphologies with stereochemical recognition,[3] and the handedness of a snail's shell,[4] bring out hidden elaborate structures and properties of biominerals.

The nacreous layer (mother-of-pearl) has attracted the interest of researchers in a broad range of chemistry disciplines,[7–25] especially in terms of its detailed structure,[10,13,14] defects in different scales,[10] incorporated macromolecules,[15,16] mechanical strength,[17,18] formation mechanisms,[19,20] and mimetics.[21–25] The macroscopic assembly and orientation of aragonite plates, 200–600-nm thick, has been well investigated.[7–11] Although the presence of nanoscopic surface roughness and nanograins was implied in microscopic units reported previously,[13,14,18] morphology and orientation

of the subunits were not clearly demonstrated. The emergent function resulting from an aragonite–biopolymer nanohybrid has never been investigated. An understanding of the real hierarchically organized structure in biominerals is required to advance to the next stage of chemistry, biology, and materials science.

In this study, we show that the nacreous layer is a three-level hierarchical architecture associated with two forms of oriented assembly (Figure 1). Electron microscope analysis determined the morphology of the nanobuilding blocks and their oriented assembly into platy units. Storage, an additional nanoscopic function leading to the incorporation of versatile organic dye molecules, is attributed to the aragonite–biopolymer nanohybrid. Our results are beneficial to the understanding of the overall architecture in the nacreous layer from the nanoscopic to the macroscopic scale. In addition, we demonstrate herein that an organized architecture similar to a real nacreous layer emerged from potassium sulfate (K_2SO_4) in the presence of poly(acrylic acid) (PAA; Figure 2).

Although the formation of mother-of-pearl requires several macromolecules, the two roles of PAA make up the mimetic architecture through oriented assembly. The K_2SO_4–PAA composite also generates nanostorage for the inclusion of organic dye molecules, as is the case with the nacreous layer. To gain a more comprehensive understanding of the superstructures, we show the detailed structures of two hierarchical architectures that have "nanostorage" properties and discuss the mutual growth process associated with the two respective roles of each polymer. The results imply that the manipulation of crystals and polymers could lead to a novel type of excellent inorganic–organic hybrid composites under ambient conditions.

We investigated the nacreous layer (Japanese pearl oyster: *Pinctada fucata* and its artificially induced pearl) by using field-emission scanning electron microscopy (FESEM), field-emission transmission electron microscopy (FETEM) with selected-area electron diffraction (SAED), and powder X-ray diffraction (XRD). In previous studies,[13,14] special techniques were used for FESEM and FETEM. In this study, fractured samples were used for the investigation of the actual nanoscopic structures and morphologies.[26]

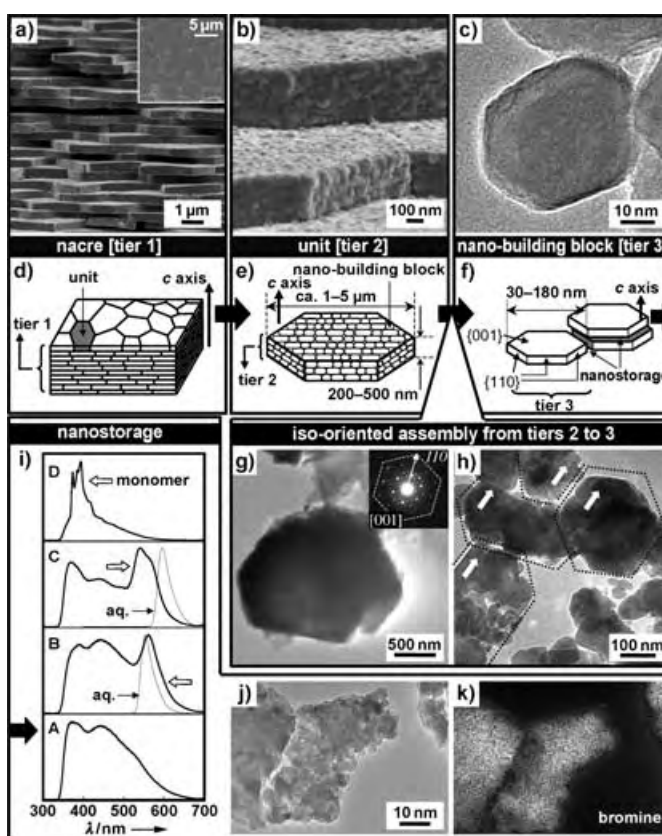
As shown in Figure 1 a–h, mother-of-pearl has a hierarchical structure, with tiers 1–3 mediating the oriented assembly in two ways. As previously reported,[7–12] the layered structure (tier 1, Figure 1 a,d) consists of aragonite plates (tier 2, Figure 1 b,e) that are about 1–5-μm wide and 200–700-nm thick. The magnified FESEM image (Figure 1 b) clearly indicates the presence of smaller components in each aragonite plate. We took an FETEM image of such a nanobuilding block, which had the pseudohexagonal habit of aragonite (tier 3, Figure 1 c,f). The appearance of the nanobuilding blocks was neither attributable to the sample preparation process nor to radiation damage arising from FETEM as preceding FESEM clearly showed the presence of nanobuilding blocks in a plate (see Supporting Information). The high-resolution image on the fringe of the nanobuilding block shows a lattice spacing of 0.423 nm, which corresponds to the (110) plane of aragonite (see Supporting Information). The lengths of the nanobuilding blocks were in the range of


Figure 1. Hierarchically organized structure of the nacreous layer. a,b) FESEM and c) FETEM images of tiers 1–3; d–f) schematic representations of tiers 1–3; g,h) FETEM images with an SAED pattern indicating that the oriented assembly of the nanobuilding blocks make up a unit; i) photoluminescence spectra of comminuted powder of the nacreous layer (A) and with incorporation of EY (B), RB (C), and PY (D) with excitation at 290 nm; j,k) FETEM and corresponding EFTEM mapping image of the aragonite–biopolymer composite with the incorporation of EY. The bromine substituent in the EY molecule was mapped by using an energy-filtering technique.

20–180 nm, whereas the nanobuilding blocks in the mother-of-pearl shell of the oyster were smaller (see Supporting Information).

Oriented assembly mediated the formation of the hierarchical architecture. We consider the layered structure of mother-of-pearl (tier 1) to be an oriented assembly of the aragonite units (tier 2) along the *c* axis (Figure 1 d), although the orientation of the *a* and *b* axes in a layer remains unclear. The mineral-bridges model of Schäffer et al. implies that the *a* and *b* axes should be perfectly oriented in all the layers in tier 1.[19,20] However, DaiMasi and Sarikaya recently reported dark-field TEM images showing that the *a* and *b* axes were not perfectly aligned in all the layers.[11] Our XRD analysis indicates that the layers are perpendicular to the *c* axis (Supporting Information). Consequently, the oriented assembly of the plates (tier 2) in the *c* axis make up the layered structure (tier 1). A single unit (tier 2) is also an oriented assembly of nanobuilding blocks (tier 3). The SAED pattern of the fragment of a unit is spotted, which indicates that the inside of a unit is a highly aligned assembly of nanobuilding blocks (Figure 1 g). Aggregations of the nanobuilding blocks

that exhibit a hexagonal habit are commonly observed and are roughly arranged in the same direction (Figure 1 h). The peak broadening due to the crystallite-size effect is not recognizable in the XRD profiles of the powdered sample (Supporting Information). These results support the idea that the nanobuilding blocks (tier 3) generate a unit (tier 2) with oriented assembly. This concept has been implied in previous reports,[13, 14] but the presence of nanobuilding blocks and their assembly were unclear.

Powdered samples of the nacreous layer were immersed in ethanol solutions of organic dyes for one day. Anionic dyes, eosin Y (EY) and rhodamine B (RB), and a hydrophobic dye, pyrene (PY), were introduced into samples of the aragonite–biopolymer composite (see Supporting Information). The resulting powders were washed with acetone and dried at room temperature. Photoluminescence spectroscopy revealed an emission from each of the included dye molecules upon excitation with UV light (Figure 1 i, white arrows); these spectra show that the aragonite–biopolymer composite incorporated not only hydrophilic but also hydrophobic dyes, such as PY. The luminescence of the aragonite–biopolymer composite was blue, as previously reported (spectrum A, Figure 1 i).[25] The aragonite–biopolymers with EY, RB, and PY incorporated gave strong orange, yellow, and blue luminescence, respectively (spectra B–D, Figure 1 i), which suggests that the EY molecules formed a J aggregate[27] and the PY molecules were included as a monomer,[28] whereas the inclusion of the RB molecules is unclear.

The incorporation of dye molecules suggests that an additional nanoscopic function resides in the aragonite–biopolymer composite. To investigate the dispersion and inclusion behavior of the EY molecules, we next performed FETEM with energy-filtered mapping (EFTEM) and electron energy-loss spectroscopy (EELS). The bromine substituents in the EY molecules were apparent in the EELS spectra (see Supporting Information) and EFTEM images (Figure 1 j,k). The images suggest that the EY molecules were homogeneously dispersed and incorporated into the aragonite–biopolymer composite on a nanoscopic scale. In the case of RB and PY, similar homogeneous incorporation leads to a strong emission. These results indicate that the aragonite–biopolymer composite behaves as a host for organic molecules. We have called this property "nanostorage".

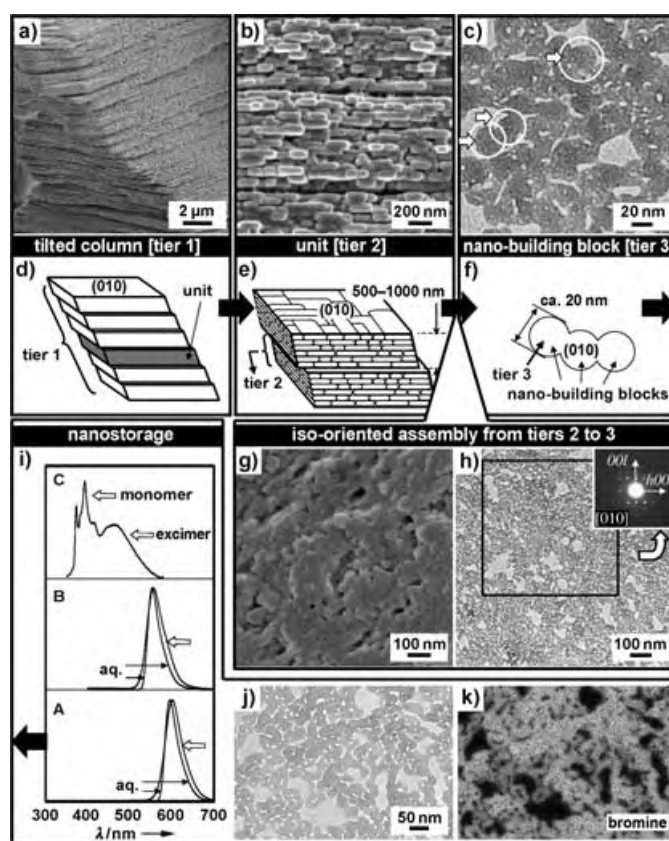
We found that a nacre-mimetic architecture with hierarchy and nanostorage was formed spontaneously from a precursor solution containing K_2SO_4 and PAA under ambient conditions (Figure 2). Herein, we clarify the structural analogy between the K_2SO_4–PAA composite and natural mother-of-pearl. The layered morphology of the prepared material is composed of platy units (tier 1, Figure 2 a,d) that are about 0.5–1.0-μm thick (tier 2, Figure 2 b,e). The layered architecture (tier 1) is an oriented assembly of smaller units (tier 2) along the *b* axis (Figure 2 d,e); the top face of the layered structure and the unit were inferred to be the (010) face through XRD and SAED analyses. The *a* and *c* axes also align in the layered structure in tier 1, as was the case in our previous study.[29] Further FETEM observation shows that nanobuilding blocks 20 nm in diameter (tier 3, Figure 2 c,f) made up a unit (tier 2, Figure 2 b,e). FESEM and FETEM


Figure 2. Hierarchically organized structure on a K_2SO_4–PAA composite. a,b) FESEM and c) FETEM images of tiers 1–3; d–f) schematic representations of tiers 1–3; g,h) FESEM and EFTEM images with an SAED pattern indicating that the oriented assembly of the nanobuilding blocks make up a unit; i) photoluminescence spectra of the nacreous layer with the inclusion of RB (A), EY (B), and PY (C) with excitation at 290 nm; j, k) FETEM and corresponding EFTEM mapping image of the K_2SO_4–PAA composite with the incorporation of EY, similar to those of the nacreous layer shown in Figure 1.

images show that the inside of a unit is an aggregate of nanobuilding blocks (Figure 2 g,h). The corresponding SAED pattern is spotted, which results from the oriented assembly of nanobuilding blocks (inset of Figure 2 h). Because peak broadening was not recognizable in the XRD profile of the powdered sample (Supporting Information), we concluded that the unit, like the nacreous layer, is an oriented assembly of nanobuilding blocks.

Dye molecules were homogeneously introduced by two methods. In the first method, EY and RB molecules were dissolved in the precursor solution and incorporated into a sample of the K_2SO_4–PAA composite as the crystals grew. In the second method, the resultant K_2SO_4–PAA composite was immersed in an ethanol solution of EY, RB, or PY. Photoluminescence spectra of samples with PY incorporated by the second method, EY incorporated by the first method, and RB also incorporated by the first method are given in Figure 2 i. On the basis of a comparison of these spectra with previously reported ones,[27, 30] we surmise that EY and RB molecules organize into a J aggregate within the K_2SO_4–PAA compo-

Communications

sites (spectra A and B, Figure 2i). The incorporated PY molecules exhibit monomer and excimer emissions around 392 and 466 nm, respectively (spectrum C, Figure 2i).[28] Results obtained by FETEM, EFTEM, and EELS also suggest the homogeneous incorporation of EY molecules on a nanoscopic scale (Figure 2j,k and Supporting Information). Therefore, we concluded that, as in the case of the nacreous layer, the K_2SO_4–PAA composite has nanostorage properties.

The mutual growth process associated with the organic polymers lies in the hierarchical structures. Two types of polymers (types I and II) are required for the construction of these architectures (Figure 3a). Soluble and insoluble organic
Figure 3. Schematic illustration of the mutual formation process for both the nacreous layer and the K_2SO_4–PAA composite. a) Overview of the architectures associated with polymers I and II; b) the role of polymer I: growth inhibition and subsequent promotion through the formation of a mineral bridge by polymer II; c) the role of polymer II: the control of polymorphism, crystal size, and incorporation of organic molecules (nanostorage).

molecules that are incorporated into the nacreous layer play the two respective roles in the mineralization process.[8–12,15,16] Since chitin and hydrophobic proteins (type I) form the layered sheets,[19,20] a unit eventually forms that inhibits further growth. The next layer is induced by the formation of a mineral bridge through a small pore in the sheets (Figure 3b).[19,20] The soluble acid proteins (type II) that consist of amino acids with carboxy and hydroxy groups strongly interact with carbonate crystals and produce miniaturized nanobuilding blocks, which have controlled polymorphism and orientation (Figure 3a,c). The nacre-mimetic K_2SO_4–PAA architecture is similarly caused by the two respective roles of the PAA molecules.[29] The strongly interacting PAA molecules (type II) form the nanobuilding blocks and direct the oriented assembly in tiers 2 and 3. The excess PAA molecules (type I) concurrently limit the diffusion of K^+ and SO_4^{2-} ions and inhibit further growth, so a platy unit is eventually formed (Figure 3b). However, growth is not perfectly inhibited by the PAA molecules. After the concentrations of K^+ and SO_4^{2-} ions recover around the surface of a platy unit, the next layer is mediated through the

formation of a mineral bridge. The mineral bridge can be seen in the magnified FESEM image.[31]

In this way, the macroscopic periodic architecture is ascribed to the repetition of growth inhibition and subsequent restarting of the growth process. Switching between the two growth modes results in the generation of platy units and their layered assembly in tiers 1 and 2. An increase in the initial PAA concentration strongly affects the assembly of the units (tier 1),[29] whereas the morphologies in the nanoscopic architectures in tiers 2 and 3 are not much influenced. These results support the two roles played by the PAA molecules in the mineralization process. Nanostorage for organic molecules is generated by electrostatic interactions between the crystals and type II polymer because the carbon main chains not related to any interaction with crystals provide an appropriate nanoscopic environment (Figure 3c). The emergence of a hierarchical architecture associated with the respective roles of polymers can be summarized as follows: type I polymer generates the miniaturized nanobuilding blocks, which strongly interact with the crystals, and subsequently mediates the oriented assembly in a platy unit. Since the consecutive growth is inhibited by type II polymer, a layered assembly is eventually produced through the formation of a mineral bridge. These two types of polymers are combined in the crystal-growth process of real mother-of-pearl and its mimetic material. Moreover, the hierarchy in a bioinorganic superstructure emerges from the two types of polymers that fulfill the respective roles in the mineralization process.

In summary, we have elucidated the hierarchical architecture in nacre and identified its ability to host organic molecules, which we have termed "nanostorage". A nacre-mimetic architecture in terms of hierarchy, oriented assembly, and nanostorage has been generated through biomimetic crystallization of K_2SO_4 and PAA. This model case suggests that a hierarchy similar to that of nacre can be induced through an appropriate combination of inorganic crystals and organic polymers. The specific interaction of the two components generates the nanoscopic architecture, and the switching between the modes of growth leads to the formation of macroscopic structure. Furthermore, an improved understanding of real and mimetic biominerals holds promise for the further development of chemical, biological, and materials sciences.

Experimental Section

Nacreous layer: Samples of nacre comminuted by mortar were used without further washing. For the incorporation of organic dyes, nacreous powder (0.03 g) was immersed in an ethanolic solution of RB (0.2 mM), EY (0.2 mM), or PY (10 mM). The reaction mixture was subjected to ultrasound for 30 min, then left at 25°C for 24 h. The resulting powder was isolated by centrifugation and washed with acetone.

K_2SO_4–PAA composite: A stock solution (100 g dm^{-3}) of K_2SO_4 (Kanto Chemical, 99.0%) was prepared with purified water (0.01 dm^3) at room temperature. An aqueous solution of PAA (Aldrich Chemicals, 35 wt% aqueous solution, $\bar{M}_w = 250000$) was added to the stock solution and the PAA concentration was adjusted to 10 g dm^{-3}.[29] After these materials had completely dissolved, the

sample bottle of the precursor solution was maintained at 25 °C for several days without sealing. Crystal growth proceeded as water evaporated from the solution. The soluble dye molecules EY and RB were preliminarily dissolved in the stock solution and the concentration was adjusted to 0.2 mM. Introduction of PY was carried out by the same method as that described for the nacreous layer.

Characterization: The morphologies were observed by FESEM (FEI Sirion, operating at 2.0 kV) and FETEM (FEI Tecnai F20, equipped with an energy filter (Gatan Imaging Filter), operating at 200 kV). The samples for FESEM were coated by ultrathin osmium films (plasma osmium coater, HPC-1S, Vacuum Device). For FETEM, the powder samples were added in dehydrated ethanol or purified water and subjected to ultrasound for 30 min to ensure a good dispersion. The dispersion liquid was dropped on a cupper grid. XRD was performed by using an X-ray powder diffractometer with $Cu_{K\alpha}$ radiation (XRD, Rigaku RAD-C, $2\theta/\theta$ scanning). The photoluminescence spectra were measured at room temperature by using a Shimadzu RF-5300PC spectrofluorophotometer with a xenon lamp (150 W) as the light source.

Catalytic Enantioselective Friedel–Crafts Alkylation of Indoles with Nitroalkenes by Using a Simple Thiourea Organocatalyst**

*Raquel P. Herrera, Valentina Sgarzani, Luca Bernardi, and Alfredo Ricci**

The addition of aromatic substrates to electron-deficient alkenes, which in many respects may be considered a Friedel–Crafts type alkylation, is a key reaction in synthetic organic chemistry for the formation of new C−C bonds.[1] Catalytic, enantioselective versions of this fundamental transformation have been reported,[2] which use metal-based chiral complex catalysts[3] or an imidazolidinone organocatalyst.[4] Both catalysts are capable of activating α,β-unsaturated carbonyl compounds, through a Lewis acid/Lewis base interaction with the carbonyl moiety in the former case, or through the formation of an iminium ion intermediate in the latter case. In sharp contrast with these remarkable achievements in the enantioselective Friedel–Crafts alkylation of aromatic substrates with α,β-unsaturated carbonyl compounds, to the best of our knowledge there are no reports in which nitroalkenes are employed. Nevertheless nitroalkenes are very attractive Michael acceptors,[5] since the nitro moiety is a strong electron-withdrawing group[6] that can be readily transformed into a range of different functionalities.[7]

The double hydrogen-bonding motif is becoming a powerful tool in organocatalysis for the activation of carbonyl groups and related compounds through weak hydrogen-bond interactions.[8] Considering the various molecular scaffolds that have proved effective as bidentate hydrogen-bond donors, urea- and thiourea-derived catalysts are certainly amongst the most competent structures,[9] and these are useful

for many enantioselective transformations.[10] Accordingly, we have recently reported[11] the Friedel–Crafts alkylation of aromatic and heteroaromatic compounds with nitroalkenes, which are activated by the bidentate hydrogen-bonding motif present in the bis[3,5-bis(trifluoromethyl)phenyl]thiourea first developed by Schreiner for the Diels–Alder reaction.[9b,c]

Herein we present our results on the use of simply obtainable thiourea organocatalysts for the first catalytic enantioselective Friedel–Crafts alkylation of indoles 2 with nitroalkenes 3 (Scheme 1). The indole skeleton is considered
Scheme 1. Addition of indole 2 to *trans*-β-nitrostyrene 3 to give access to optically active 2-indolyl-1-nitro derivatives 4.

to be one of the "privileged" structures in pharmaceutical chemistry,[4b, 12] and the present method provides an easy and practical access to optically active 2-indolyl-1-nitro derivatives 4. Taking into consideration the synthetic versatility of the nitro group, these compounds are useful intermediates for the synthesis of molecules of biological interest, such as tryptamines[13] and 1,2,3,4-tetrahydro-β-carbolines,[14] containing the indole framework in their structures.

The addition of indole 2a to *trans*-β-nitrostyrene 3a was used as the test reaction to explore the feasibility of the enantioselective Friedel–Crafts alkylation of indoles with nitroalkenes catalyzed by chiral thiourea- and urea-based derivatives. Besides the known C_2-symmetric bis-thiourea 1a,[10c] we prepared and screened catalysts 1b–e, which were easily obtained in one step and in nearly quantitative yields from the coupling reaction between 3,5-bis(trifluoromethyl)-phenyl isothiocyanate or isocyanate and the corresponding amino alcohols, both of which are commercially available. All

four thiourea-based organocatalysts 1a–d were able to increase the reactivity of *trans*-β-nitrostyrene 3a in the Friedel–Crafts alkylation reaction with indole 2a, performed at room temperature in toluene (Table 1, entries 2–5), with

Table 1: Catalytic enantioselective Friedel–Cracks reaction of indole **2a** with *trans*-β-nitrostyrene **3a** in the presence of catalysts **1a–e** under different reaction conditions.[a]

Entry	Catalyst	Solvent	T [°C]	t [h]	Conversion [%][b]	ee [%][c]
1	–	toluene	20	65	17	–
2	**1a**	toluene	20	64	40	7
3	**1b**	toluene	20	64	63	13
4	**1c**	toluene	20	45	41	13
5	**1d**	toluene	20	60	>95	35
6	**1e**	toluene	20	118	23	25
7	**1d**	THF	20	110	74	27
8	**1d**	CH2Cl2	20	66	>95	48
9	**1d**	CH2Cl2	−24	72	92	85

[a] Experimental conditions: to a solution of *trans*-β-nitrostyrene **3a** (0.1 mmol) and catalyst **1** (0.02 mmol) in a solvent (100 μL), indole **2a** (0.15 mmol) was added. After the stated reaction time, the product was purified by preparative TLC. [b] Determined by ^{1}H NMR spectroscopy of the crude reaction mixture. [c] Determined by chiral stationary phase HPLC (See Supporting Information).

respect to the noncatalyzed reaction (Table 1, entry 1). However, only catalyst **1d**, obtained from 3,5-bis(trifluoromethyl)-phenyl isothiocyanate and (1*R*,2*S*)-*cis*-1-amino-2-indanol, showed a moderate yet promising asymmetric induction, as the product **4a** was produced in 35% *ee* (Table 1, entry 5). Catalyst **1d** was also the most active in terms of conversion, the reaction being complete in less than 60 h; as predicted,[9c] the corresponding urea derivative **1e** gave much poorer conversion and lower enantioselectivity (Table 1, entry 6). We found that ethereal solvents such as THF had a negative influence on the activity of the catalyst **1d** (Table 1, entry 7), whereas the use of CH2Cl2 led to a slight improvement in the enantioselectivity, giving **4a** in 48% *ee* (Table 1, entry 8). Finally, we were pleased to find that cooling the reaction mixture to −24°C had a remarkable positive effect on the enantioselectivity; the product **4a** was obtained in 85% *ee* while good levels of conversion were maintained (Table 1, entry 9).

We next explored the scope of this new enantioselective Friedel–Crafts alkylation of indoles with nitroalkenes, under the optimized reaction conditions (Table 2). We first tested a few indoles **2a–d** bearing different substituents in the reaction with *trans*-β-nitrostyrene **3a** catalyzed by **1d**.[15] Whereas the reaction of indole **2a** afforded the corresponding product **4a** in good yield and optical purity (Table 2, entry 1), when performed at −24°C, the Friedel–Crafts alkylation of electron-rich 2-methylindole **2b** and 5-methoxyindole **2c** proceeded at a reasonable reaction rate even at lower temper-

atures, furnishing the corresponding derivatives **4b** and **4c** in satisfactory yields and enantioselectivities at −45°C (Table 2, entries 2 and 3). Unfortunately, an electron-withdrawing substituent such as chlorine in the 5-position of the indole ring in **3d** caused a considerable decrease in the yield of **4d**, though the enantioselectivity was only moderately lowered (Table 2, entry 4). The generality of the reaction was further demonstrated by variation of the nitroalkene partner. Nitro-alkenes **3b** and **3c**, bearing heteroaromatic groups, reacted smoothly with indole **2a** affording the corresponding products **4e** and **4f** in good yields and moderate enantioselectivities (Table 2, entries 5 and 6). Finally we tested nitroalkenes bearing aliphatic side chains such as **3d** and **3e**, and both gave good results in terms of enantioselectivity as the expected 2-indolyl-1-nitro derivatives **4g** and **4h** were produced in 83% and 81% *ee*, respectively (Table 2, entries 7 and 8), although the yield of the reaction turned out to be rather poor in the case of the more hindered isopropyl-substituted nitroalkene **3e**.[16]

The high synthetic potential of the present asymmetric transformation was then demonstrated by the straightforward conversion of the optically active product **4a** into highly valuable compounds such as tryptamine **5** and 1,2,3,4-tetrahydro-β-carboline **7**. As shown in Scheme 2, reduction

[a] Experimental conditions: Indole **2** (0.15 mmol) was added to a solution of nitroalkene **3** (0.1 mmol) and catalyst **1d** (0.02 mmol) in CH2Cl2 (100 μL), cooled to −24°C. After 72 h, the product was isolated by flash chromatography. [b] Yield of isolated product. [c] Determined by chiral stationary phase HPLC (see Supporting Information). [d] Reaction performed at −45°C. [e] Reaction time: 142 h. [f] Reaction time: 96 h.

of the nitro group of **4a** proceeded under mild reaction conditions[17] giving tryptamine **5**, which could be isolated in good yield as the corresponding sulfonamide derivative **6**. Alternatively, crude **5** could be directly subjected to Pictet–Spengler cyclization[18] with benzaldehyde to furnish a previously unreported 1,4-diphenyl-substituted 1,2,3,4-tetrahy-dro-β-carboline as a 91:9 mixture of diastereoisomers. The highly prevailing 1,4-*trans* isomer **7** was isolated in good yield and in diastereomerically pure form after chromatography on silica gel (Scheme 2). All reactions occurred without any loss in the enantiomeric enrichment of the products, and the relative stereochemistry of **7** was tentatively assigned as 1,4-

Scheme 2. Conversion of the optically active product **4a** into valuable products such as tryptamine **5** and 1,2,3,4,-tetrahydro-β-carboline **7**. Ts = toluene-4-sulfonyl, TFA = trifluoro-acetic acid.

trans by means of NOE experiments. Furthermore, the formation of the sulfonamide derivative **6** allowed the assignment of the absolute configuration of the catalytic product **4a** as 2*R*, from the comparison of its optical rotation and HPLC retention time with those of an authentic sample of *ent*-**6** (in 94% *ee*), which was synthesized by the ring-opening at the benzylic position of (2*S*)-2-phenyl-1-*p*-toluenesulfonyl aziridine[19] with indole **2a** promoted by LiClO$_4$.[20]

The ability of thiourea **1d** to promote the Friedel–Crafts additions of indoles **2** to nitroalkenes **3** may be interpreted on the basis of the reversible formation of a complex involving a double hydrogen bond between the thiourea hydrogen atoms and the two oxygen atoms of the nitroalkene. The recognition of the nitro group by urea moieties in solution as well as in the solid phase, leads to crystal structures that clearly present this type of interaction.[21] To gain some insight into the substrate–catalyst interactions that lead to the observed stereoselectivity, we prepared catalyst **1f**, in which the hydroxy group was protected by a sterically hindering trimethylsilyl group, and thiourea **1g**, which lacks the alcoholic function. Surprisingly, both catalysts showed poor performances in the reaction between indole **2a** and *trans*-β-nitrostyrene **3a**, not only with regard to the enantioselectivity but also in terms of the catalyst activity (Scheme 3).

On these grounds, but considering also the poor asymmetric induction observed in the reaction of *N*-methyl indole,[15] we envisioned that catalyst **1d** would act in a bifunctional fashion. Therefore, whereas the two thiourea

hydrogen atoms activate the nitroalkene, the free alcoholic function will interact with the indolic proton through a weak hydrogen bond, directing the attack of the incoming nucleophile on the *Si* face of the nitroolefin as depicted in Scheme 4.
Scheme 4. Possible bifunctional mode of action of the catalyst **1d**.

In conclusion, we have developed the first catalytic, enantioselective Friedel–Crafts alkylation of indoles **2** with nitroalkenes **3**, which provides optically active 2-indolyl-1-nitro derivatives **4** in fairly good yields and enantioselectivities. The reaction is efficiently catalyzed by the simple thiourea-based organocatalyst **1d**, which can be easily accessed in both enantiomeric forms from commercially available materials. The extremely simple operational procedure and the high synthetic versatility of the products render this new approach highly appealing for the synthesis of optically active target compounds such as tryptamines and 1,2,3,4-tetrahydro-β-carbolines.

Scheme 3. The hydroxy-protected catalyst **1f** and the thiourea **1g** lacking the alcoholic function and their performance in the Friedel–Crafts alkylation of **2a** with **3a** to give **4a**.

	Yield **4a**	*ee*

[15] An alkyl substituent on the indolic nitrogen atom is not tolerated in this catalytic enantioselective reaction, as the addition of *N*-methylindole to **3a** catalyzed by **1d** gave the product in good yield (75%) but in a nearly racemic form (6% *ee*) under the optimized reaction conditions.

[16] The yield of the Friedel–Crafts alkylation of **2a** with **3e** could be considerably increased by simply performing the reaction at higher temperatures, and only a moderate loss of enantioselectivity in the product **4h** occurs (0°C, 76% yield, 72% *ee*).

Bicyclobutanes

Valence Isomerization of 2-Phosphabicyclo-[1.1.0]butanes**

J. Chris Slootweg, Steffen Krill, Frans J. J. de Kanter, Marius Schakel, Andreas W. Ehlers, Martin Lutz, Anthony L. Spek, and Koop Lammertsma*

The unique electronic properties of the strained bicyclo-[1.1.0]butanes[1] are enhanced by the heteroatoms in the molecular frame. Illustrative is the bond-stretch isomerization of the P_2C_2 and P_2B_2 bicycles.[2] However, very few systems are known with a single heteroatom,[3] probably because of their high reactivity, which is only moderated when the heteroatom occupies a bridgehead position as in the 1-aza derivatives.[4] The increased reactivity of the hetero systems is due to the valence isomerization to which the bicyclo[1.1.0]butanes are prone. We now report on the first 2-phospha derivatives.

The carbene-like phosphinidene $Ph-P=W(CO)_5$[5] was generated in situ by cheletropic elimination from **1** at 110°C in toluene and then allowed to react with cyclopropene **2a**[6] (Scheme 1). This led to the desired $W(CO)_5$-complexed 2-phosphabicyclo[1.1.0]butanes *exo*-**3a** ($\delta^{31}P = -85.1$ ppm) and *endo*-**3a** ($\delta^{31}P = -36.7$ ppm)[7] in a 10:9 ratio, which were isolated in 69% yield as colorless solids. The remarkably
Scheme 1. Synthesis of the 2-phosphabicyclo[1.1.0]butanes **3**. $M = W(CO)_5$.

endo structure with the longer C1−C2 bond is the least stable of the two and decomposes at about 130°C. At this temperature, the *exo* isomer undergoes valence isomerization to give 3-phosphacyclobutene complexes *cis*-**5a** ($\delta^{31}P = 46.3$ ppm) and *trans*-**5a** ($\delta^{31}P = 55.2$ ppm, $^2J(H,P) = 9.5$ Hz)[8] in a 4:1 ratio (35%) besides the phospholene complex **6** as the major product (41%, $\delta^{31}P = 37.9$ ppm; Scheme 2). Formation of the phospholene was confirmed by crystal structure analysis.
Scheme 2. Valence isomerization of **3** to form **5** and, for R = Me, **6**. M = W(CO)₅.

The BP86/6-31G*(LANL2DZ) calculations[9] on models (labeled with an apostrophe (′), no C substituents) did not demonstrate a direct path from **3** to **5**,[10] but instead the involvement of 1-phosphabutadiene **4** was established (see Scheme 2). Isomerization of *exo*-**3′** to give *trans*-**4′** proceeds by a concerted, asynchronous conrotatory ring opening ($\Delta E = -18.4$, $\Delta E^{\ddagger} = 32.8$ kcal mol⁻¹; Figure 2). With subsequent conrotatory electrocyclic ring closure, via the *gauche* form of **4′** ($\Delta E = 3.7$, $\Delta E^{\ddagger} = 7.9$ kcal mol⁻¹), the more stable phosphacyclobutene **5′** is formed ($\Delta E = -4.4$, $\Delta E^{\ddagger} = 19.2$ kcal mol⁻¹). This route implies that 1-phosphabutadiene **4** is a reaction intermediate. The small energy difference between **4′** and 3-phosphacyclobutene **5′** is reflected in Tran Huy and Mathey's[11] use of derivatives of **5** as masked 1-phosphabutadienes.[12] These results highlight that the stability order **3′** ≪ **4′** < **5′** of the three valence isomers differs from the established values for the hydrocarbons (**3″** ≪ **5″** ≪ **4″**).[13]

To gain more insight into the formation of phospholene **6**, we resorted to the more gentle CuCl-catalyzed reaction of **1**[5,14] with **2a** (55°C, 15 h; Scheme 3). This reaction gave, with the exception of **6**, the same products as the noncatalyzed
Figure 2. The relative BP86/6-31G* (LANL2DZ for W) energies (ZPE corrected, in kcal mol⁻¹) for the rearrangement of *exo*-**3′** into **5′**. reaction, that is, *exo-* and *endo-***3a** (4:1 ratio, 16%) and *cis-* and *trans-***5a** (7:8 ratio, 30%). Additionally, the vinyl-phosphirane complexes *anti-***9** (δ ³¹P = −157.1 ppm) and *syn-***9** (δ ³¹P = −150.2 ppm) were also produced in a 3:1 ratio (6%). The vinyl-phosphiranes formed in this milder process (55°C vs. 110°C) corroborates the role of phosphabutadienes as reaction intermediates. Heating of isolated *anti-***9** at 110°C effected epimerization of the phosphorus center to give the *syn-***9** isomer, which underwent the established [1,3]-sigmatropic shift[15] to phospholene complex **6**. The presumed reagent, the [PhP(Cl)W(CO)₅]-Cu-alkene complex,[14] is more sensitive than Ph-P=W(CO)₅ to steric congestion in the 1,2-cycloaddition, which is reflected in the lower yield of the 2-phosphabicyclobutanes **3a**. The competitive reaction is, in our opinion, the formation of zwitterion **7**, for which there is computational support on related systems.[16] Compound **7** can also rearrange to phosphabutadiene **4a** in analogy to the addition of dichlorocarbene to cyclopropenes.[17] Ring closure then gives **5a**,[8] while two known hydride shifts[18] lead, via the secondary vinylphosphane complex **8**, to vinyl-phosphirane **9** (Scheme 3). The **4′→9′** process is exothermic by −1.8 kcal·mol⁻¹ for the parent system (no phenyl substituent on the diene).[9]

Valence isomerization is sensitive to the nature of the bridgehead substituents, and this also applies to **3→4→5**. Reaction of cyclopropene **2b**, which has phenyl instead of methyl substituents, with the phosphinidene precursor **1** at 110°C gave as sole products the 3-phosphacyclobutene complexes *cis-***5b** (δ ³¹P = 43.8 ppm, ²*J*(H,P) = 6.2 Hz) and *trans-***5b** (δ ³¹P = 53.4 ppm, ²*J*(H,P) = 9.6 Hz)[8] (5:1 ratio, 95%); *cis-***5b** was characterized by X-ray crystallography. Apparently, **3b** isomerizes faster than **3a**. In this case, phospholene **6** cannot be formed because the phenyl substituents render a hydride shift (to give **8**) impossible.

2-Phosphabicyclo[1.1.0]butanes *exo-***3b** (δ ³¹P = −70.5 ppm) and *endo-***3b** (δ ³¹P = 3.8 ppm)[7] could be obtained (4:1 ratio, 33%) by the milder CuCl-catalyzed reaction (2 equiv of **1**, 55°C, 0.5 h). The X-ray crystal structure of the *exo* isomer revealed two different triclinic polymorphs with Z = 2 and Z = 6, respectively, and very similar molecular structures. Polymorph I shows a folding angle (113.27(10)°) and a transannular bond length (1.510(2) Å) that are similar to those of *exo-***3a**. Heating of isolated **3b** (*exo + endo*, 4:1) in toluene at 50°C for 60 h gave the favored phosphacyclobutene *cis-***5b**, indicating that

valence isomerization of the novel 2-phosphabicyclo[1.1.0]butanes is indeed directed by the bridgehead substituents (**3b** 50°C; **3a** 130°C). This behavior parallels that observed for the all-carbon analogue 2,2-dimethyl-bicyclo[1.1.0]butane, where the 1,3-diphenyl derivative isomerizes at 130°C and the 1,3-dimethyl derivative at temperatures above 280°C.[19]

In conclusion, W(CO)₅-complexed 2-phosphabicyclo[1.1.0]butanes are remarkably stable compounds that valence-isomerize to 3-phosphacyclobutenes via 1-phosphabutadienes at elevated temperatures. In contrast to the hydrocarbon analogues, the diene can be trapped as a phospholene due to rearrangements that are specific for the phosphorus compounds.

Uncatalyzed Mukaiyama–Michael Reaction: Rapid Access to Simple and Complex Enantiopure γ-Butenolides**

José Barluenga,* Ana de Prado, Javier Santamaría, and Miguel Tomás

Access to enantiopure γ-butenolides currently represents a research area of great interest because of their presence as a subunit in many natural products and, particularly, in compounds with biological activity.[1] Elaboration of the commercial 2-trimethylsilyloxyfuran (TMSOF) reagent by means of an asymmetric Mukaiyama–aldol reaction has been, thus far, the most efficient method for the formation of substituted chiral γ-butenolides.[2] The Mukaiyama–Michael reaction is much less common and can be brought about through the use of either chiral metal catalysts and alkenoyl oxazolidinones[3] or chiral organocatalysts and enals, as was elegantly demonstrated by MacMillan and co-workers.[4] In looking for novel acceptor substrates, we focused on the suitability of enantiopure Fischer carbene complexes **1** as they are strongly electrophilic in nature,[5,6] and are readily accessible by condensation of methylcarbene complexes and chiral aldehydes.[7] Furthermore, the presence of both the acetal/ketal moiety and especially the metal carbene functionality in the Michael adduct permits further elaboration.[8]

We found that enantiopure tungsten carbene complexes **1** are reactive toward 2-trimethylsilyloxyfuran at low temperatures (Scheme 1). Thus, the treatment of carbene **1a** with TMSOF in toluene (−60 °C, 42 h) resulted in the formation of the carbene complex **3a** almost exclusively (92% yield). The high *anti/syn* ratio (11:1) and face selectivity (97:3 d.r.) is notable and allowed the isolation of pure **3a** in 81% yield after a single purification step by flash chromatography. Under similar reaction conditions (toluene, −70 °C, 48 h), the conjugate addition of TMSOF to the carbene complex **1b** afforded the adduct **3b** with high selectivity (*anti/syn* = 8:1,

and > 98:2 d.r.) and yield (88% yield; 76% of pure **3b** after chromatographic purification). Both chiral subunits are reactive and complement each other in terms of stereoselective induction as the configuration of the stereogenic centers created in **3a** and **3b** each subunit are opposite.[9]

The stereoselectivity can be rationalized by assuming the model calculated for the [4+2] cycloaddition of the corresponding isolobal esters.[10] Thus, the less hindered approach of TMSOF to the C=C bond of **1a** from the minimum energy conformation **A** would lead to the major isomer **3a**. In the same way, the adduct **3b** would arise by the attack of TMSOF at **1b** through the conformation **B** (Figure 1).[11]

Z = -C(OMe)=W(CO)$_5$
Figure 1. Proposed TMSOF–carbene complex approach.

The potential of this facile approach to γ-butenolides can be stressed by taking advantage of the broad chemistry of the metal carbene functionality. First, oxidative removal of the metal from **3a** through the action of pyridinium oxide yielded the corresponding ester derivative **4** in 93% yield ($[\alpha]_D^{20} = +74.7$ ($c = 0.17$, CH$_2$Cl$_2$); Scheme 2). In turn, methylenation of **3a** with diazomethane afforded the enol ether **5**, which was transformed into the methyl ketone **6** in situ by hydrolysis over silica gel (77% yield from **3a**; $[\alpha]_D^{20} = +70.2$ ($c = 0.55$, CH$_2$Cl$_2$)). These simple processes constitute efficient alternatives to the unknown Mukaiyama–Michael addition of TMSOF to both esters and ketones (75% and 62% overall yields of **4** and **6**, respectively, from carbene **1a**).[12,13]

The ease of synthesis of some complex enantiopure architectures containing the butenolide nucleus is exemplified in Scheme 3, which illustrates the transformation of **3a** into the fused lactone **8** (a process that formally involves an

Communications

Scheme 3. Transformation of complex **3 a** into **7** and **8**: cyclopropanation and ring-opening reactions.

umpolung Michael addition reaction and therefore requires a metal catalyst). The intramolecular cyclopropanation of **3 a** is carried out in acetonitrile (110 °C, 5 h, sealed tube) to furnish **7** as the sole stereoisomer (93% yield; $[\alpha]_D^{20} = -58.8$ ($c = 0.34$, CH$_2$Cl$_2$)). The subsequent Lewis acid promoted cyclopropane ring opening of **7** gave the *cis*-fused γ-lactone **8** (82% yield; $[\alpha]_D^{20} = -21.5$ ($c = 0.55$, CH$_2$Cl$_2$)).

The ketal chiral subunit is also useful for the formation of further complex enantiopure molecules (Scheme 4). As a result of the advantageous location of the protected diol functionality of **3 a**, it might be possible, among other transformations, to assemble both γ-lactone and tetrahydropyran cores which would therefore give access to linearly fused furan–pyran–furan structures.[14] Simple deprotection of
Scheme 4. Diol deprotection of complex **3 a**: Formation of bislactone **9** and enantiopure fused furan–pyran–furan compounds **10–11**. Py = pyridine.

the ketal functionality of **3 a** with acid and subsequent intramolecular displacement of the methoxy group resulted in the regioselective formation of the cyclic metal carbene **9** (69% yield). The carbene **9** was subsequently treated with base (Et$_3$N/CH$_2$Cl$_2$, 25 °C) to yield the enantiopure metal complex **10** (81% yield) through a diastereoselective intramolecular Michael-type addition.[15,16] Notably, the metal carbene functionality does survive under acidic and basic conditions, thus allowing its reactivity to be exploited at any stage. The oxidative demetalation of **10** gave rise to the enantiopure bislactone **11** in 92% yield ($[\alpha]_D^{20} = -94.2$ ($c = 0.48$, CH$_2$Cl$_2$), which features, two γ-lactone rings as well as a highly functionalized central pyran ring with four stereogenic carbon centers.

In conclusion, we reported herein the first uncatalyzed, diastereoselective Mukaiyama–Michael addition reaction and showed efficient access to a number of enantiopure butenolide-based structures. This sequence is a successful combination of two major features: 1) Fischer alkenyl carbenes that incorporate a chiral fragment at the β-carbon—readily available from the chiral pool—undergo very rapid diastereoselective Mukaiyama–Michael reaction with TMSOF, 2) these adducts can be transformed into valuable enantiopure molecules owing to the diverse reactivity of the metal carbene function, as well as to the conventional functional group transformations of the protected diol. Moreover, the synthetic utility of this strategy could be enhanced as a number of chiral pool derived aldehydes could provide structurally diverse alkenyl carbene complexes.

[16] The configuration of the new stereogenic center was determined by NMR COSY and NOESY experiments. Moreover, this stereochemical reaction pathway is in agreement with molecular modeling studies. The two possible cyclization approaches were analyzed with ab initio calculations by using the anionic Michael-type cyclization to the lactone **11** (replacing W(CO)$_5$ in **10** by O) as the model. At the MP2/6-31G*//HF/6-31G* level of theory, the transition state that gives rise to the isomer observed, is 17.4 kcal mol^{-1} more stable than the alternative transition state.

Finding Adiabatically Bound Anions of Guanine through a Combinatorial Computational Approach**

*Maciej Harańczyk and Maciej Gutowski**

Anions of nucleic acid bases may be formed by trapping low-energy electrons produced in living cells by high-energy radiation. Recent experiments suggested that single- and double-strand breaks develop in DNA exposed to low-energy electrons.[1] Furthermore, charged nucleobases play a critical role in electron and hole transfer in DNA.[2–4] Anionic states of nucleic acid bases have been intensively studied both experimentally and theoretically. On the basis of calculations, guanine is believed to have the lowest electron affinity among the nucleobases.[5–7] This is consistent with the results of electron spin resonance experiments on γ-irradiated DNA, in which the anion is divided between the pyrimidine but not the purine bases.[8]

Gas-phase experiments on guanine are scarce because this nucleic acid base easily decomposes at elevated temperatures. Burrow and co-workers reported a vertical electron affinity of −0.49 eV for guanine and assigned it to a hydroxy (enol) tautomer.[9] We have recently determined—at the coupled cluster level of theory with single, double, and perturbative triple excitations (CCSD(T))[10]—a negative adiabatic electron affinity (AEA) of −0.49 eV for the canonical tautomer.[11] In contrast to earlier experimental and computational predictions, we demonstrate here that guanine supports anionic tautomers that are adiabatically bound with respect to the neutral canonical tautomer by as much as 8 kcal mol^{-1},[12] as calculated at the CCSD(T) level of theory. These

tautomers do not result from proton transfer between the electronegative atoms N or O, which were studied in the past for the neutral and anionic species. Instead they result from enamine–imine transformations, that is, a proton is transferred between the N and C atoms. Some of these anionic tautomers do not require a proton transfer from the N9 position (see Figure 1). Thus, they might exist in DNA or RNA, in which N9 is connected to a sugar unit. The new anionic tautomers might affect the structure of DNA and RNA, and might initiate chemical transformations leading to lesions in nucleic acids.[13,14]

The unexpected positive values of AEA for the new imine tautomers were initially counterintuitive, and their discovery was facilitated by two factors. First, we recently demonstrated that the most stable valence anions of pyrimidine bases, such as 1-methylcytosine[13] and uracil,[14] also result from enamine–imine transformations, though a biologically relevant adiabatically bound anion has not been identified so far. Second, a combinatorial computational approach was invoked in the current study to identify the most stable anionic tautomers, without a bias dictated by stereotypes developed from studies on neutral tautomers of nucleic acid bases, that is, a proton being transferred between N or O atoms.[15]

The computational screening of the anionic tautomers of guanine was started from a buckled molecular framework of heavy atoms among which five hydrogen atoms were distributed. We imposed the following constraints: zero or one hydrogen atom on N1, C2, N3, C4, C5, C6, N7, and N9; one or two hydrogen atoms on N2 or C8; zero, one, or two hydrogen atoms on O4 (Figure 1). With these constraints we generated 499 initial structures including the E and Z tautomers as well as rotamers of imino and hydroxy groups. These structures were divided into three groups: 2N2 (amino tautomers), N2c, and N2t (imino tautomers with a hydrogen atom at N2 arranged cis or trans with respect to N1). Additionally, each group was divided into two subgroups C8 and 2C8, depending on the number of hydrogen atoms attached to C8. We use the notation G_a^b, where "a" is the group and subgroup and "b" is a string of heavy atoms to which the remaining hydrogen atoms are connected. The anionic species bear a prefix a_{val}.

We found that 2.81% of all screened structures are adiabatically stable at the B3LYP/6-31++G** level of theory, with the range of stability at 0.4–12.2 kcal mol^{-1}. For
Figure 1. The heavy atoms of guanine; the cis and trans positions for N2 and O4 are shown.

further studies we selected the following: 1) the most stable valence anion $a_{val}G_{2N2,C8}^{C2,N3}$, which has no hydrogen atom attached to N9; 2) three valence anions that might be biologically relevant because a hydrogen atom is attached to N9 ($a_{val}G_{2N2,2C8}^{N9}$, $a_{val}G_{N2c,C8}^{N3,N9}$, and $a_{val}G_{N2t,2C8}^{N3,N9}$); and 3) the valence anions $a_{val}G_{2N2,C8}^{N3,N9}$ and $a_{val}G_{2N2,C8}^{N3,N7}$, which are based on the two most stable tautomers of neutral guanine (Figure 2).
Figure 2. The relative electronic energies of the various tautomers studied, corrected for energies of zero-point vibrations ($\Delta E + ZPVE$), as well as the electron vertical detachment energies (VDEs). The adiabatically bound anions are on the left and right sides. In the middle, the two most stable tautomers of the neutral and their accompanying valence anions are shown.

These anionic structures were further optimized, and harmonic frequencies were calculated at the second-order Møller–Plesset level (MP2), and the final energies were then calculated at the CCSD(T) level. The aug-cc-pVDZ basis set[16] was used in the MP2 and CCSD(T) calculations. The effects of hydration were included within the IEF-PCM method with the cavity built up using the United Atom model (UA0).[17] The calculations were performed using Gaussian03[18] NWChem,[19] and Molpro software packages,[20] and the molecular structures and orbitals were drawn with the Molden program.[21]

We found that the four anionic tautomers that result from enamine–imine transformations were adiabatically bound with respect to both the neutral $G_{2N2,C8}^{N3,N9}$ canonical tautomer and the most stable neutral tautomer $G_{2N2,C8}^{N3,N7}$. These gas-phase results, presented in Figure 2, are based on the CCSD(T) electronic energies and MP2 geometries and harmonic vibrational frequencies. The most stable anion $a_{val}G_{2N2,C8}^{C2,N3}$ is bound with respect to $G_{2N2,C8}^{N3,N9}$ by 8.50 kcal mol^{-1}. This anion is characterized by a large vertical detachment energy (VDE) of 2.426 eV. Among the three anionic tautomers that have a hydrogen atom on N9, the anion $a_{val}G_{N2c,2C8}^{N3,N9}$ is 8.42 kcal mol^{-1} more stable than $G_{2N2,C8}^{N3,N9}$. This value is much larger than our estimation of uncertainties of the AEAs determined at the CCSD(T)/aug-cc-pVDZ level, which is about 1 kcal mol^{-1}. The two other anions $a_{val}G_{2N2,2C8}^{N9}$ and $a_{val}G_{N2t,2C8}^{N3,N9}$ are more stable than $G_{2N2,C8}^{N3,N9}$ by 7.00 and 3.81 kcal mol^{-1}, respectively. The values of VDE for the last three anionic tautomers are similar, about 1.6 eV, and still much larger than the VDE values of anions based on the most stable neutral tautomers. We predict that there are many anionic enamine–imine

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

tautomers that are adiabatically bound with respect to neutral guanine.

The effect of an aqueous environment on the stability of the new anionic tautomers was tested within the PCM model (Table 1). The new imine tautomers are again more stable

Table 1: Adiabatic electron affinities (AEAs) and electron vertical detachment energies (VDEs) for the tautomers of hydrated guanine characterized within the PCM model.

Tautomer	AEA [eV][a]	VDE [eV][b]
$G_{2N2,C8}^{N3,N9}$	1.329	3.381
$G_{2N2,C8}^{N3,N7}$	1.496	2.643
$G_{2N2,2C8}^{N9}$	2.211	4.625
$G_{N2c,2C8}^{N3,N9}$	2.026	4.424
$G_{N2t,C8}^{N3,N9}$	1.953	4.566
$G_{2N2,C8}^{C2,N3}$	1.861	5.350

[a] $\varepsilon = 78$. [b] $\varepsilon = 78$ and 2 for the initial and final states, respectively.

than anions based on the two most stable tautomers of the neutral molecule. Additionally, the three imine tautomers with a hydrogen atom attached to N9 are more stable than $a_{val}G_{2N2,C8}^{C2,N3}$. Thus the tautomers with a hydrogen atom attached to N9 might dominate in aqueous solution. These tautomers might be susceptible to further transformations, and lesions in the DNA might develop. For instance, the $a_{val}G_{2N2,2C8}^{N9}$ and $a_{val}G_{N2c,2C8}^{N3,N9}$ tautomers cannot maintain Watson–Crick-type hydrogen bonding with cytosine.

We suggest two formation pathways for the new anionic tautomers. First, they might be formed through intermolecular proton transfer, with acidic and basic sites interacting with $a_{val}G_{2N2,C8}^{N3,N9}$. Second, dissociative electron attachment[22,23] to $G_{2N2,C8}^{N3,N9}$ [Eq. (1)]—where $(G_{2N2,C8}^{N3,N9})^{*-}$ denotes a scattering

$$G_{2N2,C8}^{N3,N9} + e \rightarrow (G_{2N2,C8}^{N3,N9})^{*-} \rightarrow (G_{N2c,C8}^{N3,N9})^- + H^{\cdot} \qquad (1)$$
state for an excess electron and $(G_{N2c,C8}^{N3,N9})^-$ denotes a deprotonated guanine in the ground electronic state—can be followed by attachment of a hydrogen atom to C8 [Eq. (2)].

$$(G_{N2c,C8}^{N3,N9})^- + H^{\cdot} \rightarrow (G_{N2c,2C8}^{N3,N9})^- \qquad (2)$$

We have found that this step is barrier-free.

In summary, guanine supports many adiabatically bound valence anions, which result from enamine–imine transformations of the most stable neutral tautomers. These stable anionic tautomers were found using combinatorial computational prescreening at the B3LYP level of theory followed by CCSD(T)/aug-cc-pVDZ calculations. The new anionic tautomers might be formed by dissociative electron attachment followed by attachment of a hydrogen atom to a carbon atom. These tautomers may affect the structure and properties of DNA and RNA exposed to low-energy electrons. Chemical transformations of DNA triggered by the new anionic tautomers will be explored in our future studies.

Chemical Primer Extension: Efficiently Determining Single Nucleotides in DNA**

Patrizia Hagenbuch, Eric Kervio, Annette Hochgesand, Ulrich Plutowski, and Clemens Richert

The replication and transcription of genetic information requires the stepwise extension of DNA or RNA primers in sequence-specific, template-directed reactions (Scheme 1). Template-directed primer extension also underlies PCR,[1] dideoxy sequencing,[2] and attempts to recreate life from inanimate materials.[3] Primer extension presents a formidable chemical challenge. Four different, richly functionalized monomers (the mononucleotides) have to be converted into good electrophiles that react in sequence-selective oligomerization reactions in aqueous solution without polymerizing or hydrolyzing rapidly. Nature employs pyrophosphates as leaving groups and

enzymes with proofreading capabilities (polymerases) to meet this challenge. Entirely chemical, non-enzymatic systems employing imidazolides as leaving groups show a certain level of spontaneous primer extension, but successful replication has remained elusive.[3]

Known non-enzymatic replication reactions with monomers are slow. For ribonucleotides and 2-methylimidazolides as activated monomers, reaction times of days are required, even if the monomers are employed near their solubility limit (≥ 50 mm)[4] under extreme salt conditions (up to 1m Mg^{2+}).[5] Weakly base pairing nucleotides (A or U/T as nucleobase) are incorporated more slowly than those that form stable base pairs (C or G as nucleobase).[6] Even the ligation of oligonucleotides requires the templating of G and C residues.[7] This makes non-enzymatic primer extension seemingly unattractive for practical applications, such as the genotyping of single-nucleotide polymorphisms (SNPs) by mass spectrometry.[8] Herein we demonstrate how these reactions can be accelerated, so that the determination of nucleotides at selected sites of DNA within hours becomes feasible, starting from subpicomole quantities of analytes.

We first used 2-methylimidazolides[9] (LG = MeIm) of 2′-deoxynucleosides **1a–t** as activated monomers **2a–t** (Scheme 2), which were treated with 3′-amino-terminal primers. Amines are known to react faster than alcohols with activated nucleotides,[10,11] so that singly extended primers rather than the product mixtures typical for chemical replication reactions are formed. Assays were monitored by

Scheme 1. Primer extension.

quantitative MALDI-TOF mass spectrometry,[12] thus allowing competitive reactions with all four activated nucleotides in the same solution and selective detection of products in mass spectra.[13] Second-order rate constants were derived from fits to the kinetic data.[13] We tested whether non-enzymatic primer extension was detectable with any of the four possible bases (A, C, G, T) at the templating position of 40-mer templates **4a–t** (Scheme 3).

Sequence-selective extension was observed for each of the four reactions (Table 1). Although this established that chemical primer extension was sufficiently selective to
Scheme 2. Activated monomers **2a–t**.

Table 1: Results from primer extension reactions with a mixture of the four 2-methylimidazolides **2a–t**/MeIm.[a]

Primer/ template	k' [$h^{-1} M^{-1}$][b]	Product ratio (primer+C/T/A/G)
3/4a	46	3:**84**:5:8
3/4c	84	4:5:8:**83**
3/4g	38	**84**:5:10:1
3/4t	43	6:9:**74**:11

[a] [**2a–t**] = 19.3 mM; primer/template: 360 μM; pH 7.9; buffer: HEPES (200 mM), NaCl (400 mM), MgCl$_2$ (80 mM). [b] k' = second-order rate constant for the formation of desired product; oligonucleotide complexes treated as one reactant, activated nucleotide as the other.

identify a templating nucleotide in DNA, the assay was not attractive for genotyping or analyzing epigenomic methylation patterns,[14,15] as it requires 1.8 nmol of template for a 5-μL assay, that is, more template than is available in typical clinical samples after PCR. We therefore decreased the concentration of template and primer tenfold and reduced the concentration of the activated monomers from 19.3 mM to 3.6 mM. Dilution favors hydrolysis of the activated nucleotides, an unavoidable competing reaction, and disfavors the

association of monomers and template. Under these conditions, even a strongly base pairing nucleotide at the templating position, when offered the matched monomer alone, gave a second-order rate constant that was almost an order of magnitude lower than that measured at higher concentration (compare Table 1, entry 3 with Table 2, entry 1). In the absence of competing reactions and/or changes in binding equilibria, second-order rate constants should, of course, be independent of concentration.

We then focused on identifying alternative leaving groups for the activated deoxynucleotides. Ferris and co-workers had previously shown that oligomerization of ribonucleotides on mineral surfaces can be accelerated through judicious choice of leaving groups,[16] but template-directed reactions have proven to be a challenge to accelerate.[17] With EDC[18] alone, template **4a** gives non-sequence-selective extensions. Attempts to improve extension reactions through activation in situ with EDC in the presence of possible leaving groups or through addition of organic catalysts to methylimidazolides failed (see Supporting Information). Proflavine[19] increased the conversion with **2c**–MeIm minimally from 16 to 21% after 4 h, and this effect was observed only at the highest concentration tested (0.67 mM).

Therefore, we focused on the activation of **1c** in organic solvents and the addition of the activated monomers to **3/4g** in aqueous buffer. The tetrazolide of **2c** gave a slight acceleration over **2c**–MeIm, but the only substantial acceleration was observed after activation with HATU[20] and HOAt, reagents originally developed for peptide coupling. Optimized activation conditions gave an active ester in satisfactory yield after precipitation (see Supporting Information). Azabenzotriazolide **2c**–OAt reacts four times faster than **2c**–MeIm with **3/4g** (Table 2) and does not undergo significant side reactions with the primer. Interestingly, an even more dramatic acceleration of primer extension is observed in an all-RNA system when switching from methylimidazolides to azabenzotriazolides, even though the nucleophile is a hydroxy group in that case.[21]
Scheme 3. Primer-extension system employed.

Table 2: Effect of activation of monomers, helper, and pH shift on the rate of non-enzymatic single-nucleotide-extension reactions.[a]

[a] Template and primer: 36 μM; activated **2**: 3.6 mM; aqueous solution; buffer: HEPES (200 mM), NaCl (400 mM), MgCl₂ (80 mM). [b] LG = leaving group; MeIm = 2-methylimidazolide; OAt = oxyazabenzotriazolide, EDC = excess carbodiimide from one-pot activation/extension assay. [c] k' = second-order rate constant; oligonucleotide complexes treated as one reactant, activated nucleotide as the other. [d] Perfectly matched primer-extension products are highlighted in boldface. [e] Activated monomer purified by HPLC.

Next, we studied whether an additional or helper oligonucleotide **5** that binds immediately downstream from the templating base would create a tighter binding site for the incoming monomer (Scheme 3). The rate was accelerated several fold for both **2c**–MeIm and **2c**–OAt (Table 2). For azabenzotriazole-activated **2c**–OAt, the rate enhancement over the helper-free reaction with **2c**–MeIm is 22-fold. A further twofold acceleration resulted from purification of the azabenzotriazolide **2c**–OAt by HPLC prior to use in our assay, an effort invested only for the kinetic study. The azabenzotriazolide-driven primer-extension reaction benefits further from elevated pH values. At pH 9.5, the acceleration of the helper-assisted reaction over that of the unassisted reaction with **2c**–MeIm is 79-fold (Table 2). A pH value of 8.9 gives a similar effect, but lowers the risk of losing sequence selectivity through deprotonation of dT and dG.

We then established HATU/HOAt activation for monomers **1a**, **1g**, and **1t** (CH₃CN was required as solvent for **1t** as cleaner activations were observed when starting from slurries). Hydrolysis of OAt esters, despite their reactivity towards amino and ribo primers,[21] is sufficiently slow. An exploratory study of the hydrolysis of **2t**–OAt in the assay buffer in D₂O by NMR spectroscopy shows a half-life of 16.2 h (see Supporting Information). Mixtures of all four OAt

esters employed in competitive reactions give rapid primer extension and acceptable sequence selectivities for all four templates **4a–t** (Table 2).

To make the chemical primer extension reactions more attractive for biomedical applications, we investigated one-pot activation/primer-extension protocols. When solutions of **1a–t** (0.4 M) were treated with EDC (5 equiv)[16] and HOAt (3 equiv) at pH 5, the solution contained > 90% of OAt esters after 2 h, as determined by ³¹P NMR. Dilution and adjustment of the pH value to 8.9 followed by addition of DNA strands led to reactions similar to those with HATU-activated OAt esters (Table 2), at least in the presence of **5**. Because the excess of activation reagents allows reactivation of nucleotides, the kinetics of these reactions are more complex, but the one-pot procedure makes assays easier to perform by personnel not trained as synthetic chemists.

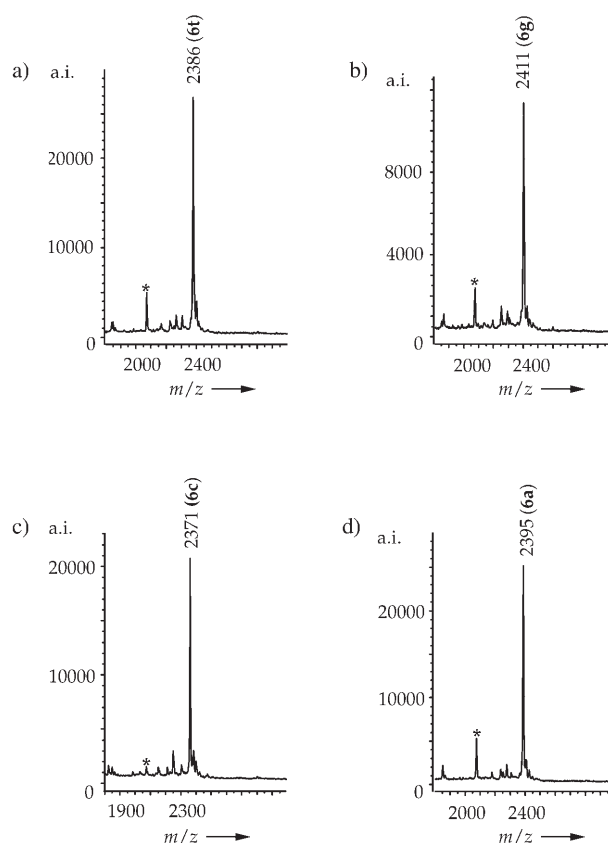
The lower reactivity and selectivity of the reaction templated by adenine was then addressed. We increased the concentration of **2t**–OAt fivefold to compensate for the


Figure 1. MALDI-TOF mass spectra from competitive primer extension reactions with **3/4a–t/5** and a dT-boosted mixture of **2a–t**/OAt at pH 8.9, 8 h. a) Template **4a**, b) template **4c**, c) template **4g**, d) template **4t**. The asterisk denotes the peak for unconverted primer.

lower target affinity. The dT-boosted mixture gives sequence-selective reactions for all four templates **4a–t** in which the correctly extended primer constitutes ≥ 90 % of the elongation products. Furthermore, the half-life of the reactions is ≤ 1.6 h and within a factor of 2 for all four reactions (Table 2). More-refined reactivity-adjusted mixtures may make the rate differences even smaller. Representative MALDI spectra and kinetics are shown in Figures 1 and 2.

Figure 3. System for determining single-nucleotide identity on DNA microarrays for on-chip MALDI-TOF mass spectrometry.[22] DNA strands used: **7** (capture strand): 5′-taaaagataccatcaa-3′; **8** (dA template): 5′-cagcgtgaaattagggtAagaacagaatgattgatggtatcttttaggaacctt-taggtc-3′; **9** (dG template): 5′-cagcgtgaaattagggtGagaacagaatgattgatgg-tatcttttaggaacctttaggtc-3′; **10** (3′-amino-primer): 5′-tcattctgttct-3′; **11** (helper): 5′-accctaatttcacgctg-3′. Lower-case letters denote deoxynucleotides, SNP sites are highlighted as upper-case letters.

Finally, we performed exploratory primer extension reactions with the microarray system shown schematically in Figure 3. It consists of capture oligonucleotide **7**, immobilized on spots of flame-smoothed gold surfaces background-passivated by oligo(ethylene glycol ether) self-assembled monolayers.[22] The spots were exposed to solutions containing one of two different DNA 60-mers **8** or **9** (which contain either nucleotide A (**8**) or G (**9**) at the site of primer extension), primer **10**, and helper **11**. After hybridization, template-directed reactions were induced that employed EDC-activated mononucleotides (3.6 mM each) in the extension buffer at pH 8.9 and 8 °C. After 160 min, the surface was washed, treated with MALDI matrix solution, and subjected to mass-spectrometric analysis. Figure 4 shows spectra obtained in assays starting from solutions containing templates **8** or **9** (500 fmol). Even at 50 fmoles, an SNP call could be made for the A-template (see Supporting Information).

Our optimized activation of nucleotides is a one-step process employing commercial reagents. No significant non-nucleoside extensions of primers have been detected. Given the rate accelerations observed, practical applications of chemical-primer extension, such as SNP genotyping[23] can be envisioned. Chemical-primer extension on a chip does not require purification after the elongation step and avoids sample transfer, as all steps are performed on the same

Figure 4. MALDI-TOF mass spectra from primer extensions performed with the system shown in Figure 3 and 60 mer templates **8/9** featuring the nucleotides A (left) or G (right) at the SNP site after 160 min. Spectra were obtained directly from the surface on which the primer-extension reaction had been performed. Surfaces had been incubated with 500 fmol of template **8** or **9**. See Supporting Information for further details.

surface. This should lower the cost of high-throughput assays. Heavily modified nucleotides, including those that form non-natural base pairs, may be incorporated into primers without the constraints imposed by active sites of polymerases. An extension of this work to assays with fluorophore-labeled monomers that allow optical detection on DNA microarrays

Communications

is being actively pursued in these laboratories. A fluorophore-labeled form of activated **1t** suitable for non-enzymatic primer extension reactions was recently described.[24] Exploratory experiments with 3′-Cy3-labeled **2c**–OAt, and **3/4g/5** gave 42% primer conversion after 1 h and 72% conversion after 3.5 h,[25] demonstrating the feasibility of fluorophore-based genotyping.

Highlights

A challenging strategy for the design of metal-containing polymeric systems with a controlled nanostructure is the introduction of polymerizable groups that are both compatible with the mesomorphic order and reactive in the presence of metals. 1,3-Diene groups have recently been reported to offer such compatibility and reactivity, leading to efficient polymerization (see picture).

No metal–substrate interactions: A transition-metal complex of a primary amine can serve as an efficient bifunctional metal–ligand catalyst that functions without direct interaction of the metal and the substrate. The example shows the transition-state structure of the enantioselective reduction of acetophenone at the molecular surface of a ruthenium hydride complex bearing a diamine with one free NH$_2$ group (O red, Ru green, N blue).

Reviews
Ru complexes emerged from obscurity to become accepted as ideal catalysts for diverse C—C bond-forming reactions beyond the more-well-known redox and metathesis processes. These reactions are highly selective and atom-economic pro- cesses for the synthesis of complex molecules (see scheme). Mechanistic principles provide the basis for the semi- rational design of new reactions, notably for C—C coupling.

Communications

24-Carat bacteria: A bacteria/nanoparticle composite device is operated by applying a bias of 10 V across a bacterial bridge, which is coated with gold nanoparticles and spans two gold electrodes, and measuring the current (see image). A change in humidity from 0 to 20% causes swelling of the bacteria membrane which results in a 40-fold decrease of the current although the interparticle distance increases less than 0.2 nm.
Shrinkage factor: The ligand ppca (4- (pyridin-4-yl)pyridine-2-carboxylic acid) has enabled the synthesis of a new 3D framework material, $[\{[Co_2(ppca)_2(H_2O)-(V_4O_{12})_{0.5}]\cdot 3.62\,H_2O\}_n]$, which exhibits so- called "dynamic structural changes". Temperature changes lead to the reversi- ble removal of guest molecules and/or ligands (e.g. H_2O) bound to the frame- work with a concomitant reversible struc- ture change (see scheme).

Iron aggregates are arranged into a close-packed structure through coordination bonds to give a material that displays a structural and magnetic hierarchy. The tripodal proligand nitrilotripropionic acid (H₃ntp = N(CH₂CH₂COOH)₃) successfully traps {Fe₁₃} aggregates, thus producing a lattice that displays three levels of organization (see picture of its 3D packing arrangement; Fe green; O red; N blue; C black; H white).
Quick on the uptake: A 20-mer DNA oligomer modified with 5-[(6-guanidinio-hexylcarbamoyl)methyl]-2′-deoxyuridine (**Tg**) shows efficient cellular uptake (blue arrow) in HeLa cells without any other reagents. The fluorescence microscopy image reveals FAM-labeled DNA oligomer (green) and stained nuclei (blue). FAM = 6-carboxyfluorescein.

Controlling blood loss: The synthesis of a series of arylamide oligomers **1**, which interact with heparin is described. The heparin–small molecule interaction inhibits the heparin's ability to activate antithrombin. These arylamide oligomers are the first example of low-molecular-weight antagonists that inhibit the anticoagulant function of heparin.
Correlated bond rotations within biconcave molecules that comprise a semirigid C_3-symmetric core and pendant *m*-terphenyl groups (see figure) assist mechanical coupling between the two vertices such that structural changes on one side of the molecule are effectively transmitted to the other side. Self-assembly of one such compound affords a nonporous solid from which entrapped guests can completely escape in the absence of channels that connect interstitial voids.

Contents

What a radical target! Two key hydrogen-atom adducts of 1-methylcytosine have been prepared by the targeted chemical generation of cytosine radicals. Femtosecond collisional transfer of electrons to gas-phase tautomers of protonated 1-methylcytosine using molecular electron donors (dimethyl disulfide and trimethylamine) produces stable radical adducts with the hydrogen atoms positioned at N3 and C5 of the cytosine ring, respectively.

With high quality and in high yield: The synthesis presented here affords CdSe and CdTe semiconductor nanocrystals without the need of a precursor injection. It allows the detailed control of the size and shape of the nanocrystals, as can be seen from the tetrahedral CdSe nanocrystals that have been prepared (TEM image). The method is suitable for industrial-scale preparations.
Antipodal relationship: A convergent synthetic pathway leading to 4-hydroxy-2-pyridinones was involved in the synthesis of apiosporamide (**1**) and YM-215343 (**2**). Both have an antipodal relationship to the natural metabolites, whose relative and absolute configurations have been established. Activated β-alanine enolate equivalents derived from β-lactams were the key to the synthesis.
1 (apiosporamide): X = OH; Y = H
2 (YM-215343): X = Y = O

Between the sheets: The structure of the titanosilicate Ti-YNU-1 reveals a much larger spacing along the *c* axis between the MWW sheets than its lamellar precursor and 3D Ti-MWW (see picture). Formation of twelve-membered rings would explain this cell expansion, which results in increased steric accessibility and may explain the higher catalytic activity of Ti-YNU-1 relative to other titanosilicates.
Contents
Killing by stealth: The highly specific mutual affinity of estrogen receptor and 17β-estradiol (ES) allows apoptotic genes to be targeted at primary human breast adenocarcinoma cells through the use of stealth liposomes. Cells are transfected with a cationic lipoplex containing a targeting lipid (see picture; DPPE = 1,2-dipalmitoyl-Sn-glycero-phosphatidyletha-nolamine, PEG = poly(ethylene glycol)).

200 nm
Double agent: Controlled sulfonation of polystyrene hollow spheres gives hydrophilic layers with sulfonic acid groups that allow the formation of a wide variety of functional composites. In this way, double-shelled hollow spheres have been prepared in one step by using such sulfonated polystyrene hollow spheres as templates (see TEM image of titania sphere).

1   **2**   **3**   **4**   **5**
In the beginning: Mixed carboxylic phosphoric anhydrides **3**, formed from 3′-nucleotides **1** and amino acid N-carboxyanhydrides **2**, undergo competing rearrangement to 2′-aminoacyl esters **4** and cyclization to 2′,3′-cyclic phosphates **5**. The intramolecular aminoacyl transfer is faster than the cyclization despite the ease with which 2′,3′-cyclic phosphates are formed through any other form of phosphate activation.

1   **2**   **3**
Domino-cyclization of two phosphinidene molecules: Methylation of the nucleophilic phosphinidene **1** with MeOTf (OTf = triflate) affords the unusual phosphonium cage **2**, which implies the formation of the novel phosphenium ion **3** as a reactive intermediate.
Even the electropositive element silicon initiates electron-transfer processes in amido-bis(enolate) complexes: This is shown by the reactions of halides RSiX$_3$ with HN[CH$_2$C(O)tBu]$_2$ in the presence of a base. While small substituents (R = H, Cl, Br, Ph) furnish the dinuclear penta-coordinate complexes **1**, the bulkier tBu$_3$Si group favors formation of the dinuclear tetracoordinate complex **2**.
The proteins DesI and DesII are proposed to catalyze a C4 deoxygenation reaction to give the key intermediate **1** in the biosynthesis of D-desosamine. Biochemical characterization of purified DesII showed that it is a member of the *S*-adenosylmethionine (SAM) family of radical enzymes. The involvement of a SAM radical in the reaction with DesII identifies a new strategy for deoxygenation reactions of sugars.

Matrix-isolation IR, electronic-absorption, and Au L$_3$-edge EXAFS (extended X-ray absorption fine structure) data have provided the first experimental evidence that the ground-state structure of AuCl$_3$ is not D_{3h} symmetric (trigonal-planar), but rather has a Jahn–Teller-distorted T-shaped geometry (see picture).
Combining kinetic, structural, and computational studies on complex dynamic feedback systems may lead to the field of "systems chemistry". The approach is exemplified by the analysis of a simple organic self-replicating system that has the potential to express both homochiral autocatalysis and heterochiral cross-catalysis (see picture).
Contents
More active and selective catalysts of alkane metathesis (see scheme) that are based on well-defined tungsten carbyne and hydride complexes supported on alumina have been developed through a structure–activity relationship. The improvement of activity on changing from Ta in **2** to W in **1** and the product selectivity show that olefin metathesis is probably the key process in C−C bond formation in the alkane metathesis reaction.
A dramatic enhancement of the reactivity of the C4- and C8-hydroxy groups of sialic acid has been demonstrated by 1,5-lactam bridging. Sialyl-α(2→4)sialoside and sialyl-α(2→8)sialoside were made available in high yields through direct sialylation (see scheme). Furthermore, the glycan parts of the new gangliosides Hp-s6 and HLG-2 were synthesized for the first time.
Showdown at the OK corrole: The direct borylation of corroles under iridium catalysis through C−H activation proceeds with perfect regioselectivity and excellent yields. 2-Borylated corroles allow an easy access (two steps) to directly linked corrole–porphyrin conjugates and other functionalized corroles (see scheme).

Spinning around: The sensitivity of MRI contrast agents can be increased through multilocus binding. This restricts the internal motion and therefore increases the relaxivity of a bound protein multimer (see picture; A) relative to a single binding group (B), whose flexibility and internal motion limits the relaxivity gain. Protein-targeting groups (TG) can be used to anchor the multimer.
Addition of Bi prevents deactivation of Pd–Sb catalysts in the acetoxylation of toluene. The presence of Bi hinders the formation of an inactive $Pd^{\delta-}$ state and the blockage of the active Pd sites by carbon species from coke deposits (see the photoelectron spectrum). The modified catalyst displays extremely high selectivity for benzyl acetate ($\geq 95\%$) at higher toluene conversions.
Reduction on the spot: Planarly adsorbed thiolated porphyrin molecules (purple) incorporated in an insulating alkanethiol monolayer (blue) function as nanoelectrodes for the local reduction of metals (gray). This approach was applied for the in situ synthesis of nanoparticles of a predetermined size.

Influential neighbors: 1,2-Chirality transfer provides the basis for a novel asymmetric synthesis of cyclopropanes by irradiation of enantiomerically pure alkyl phenyl ketones bearing a leaving group X in the α position. The photochemically excited carbonyl group is able to distinguish between the diastereotopic positions γ and γ' in terms of a desymmetrization. In some cases the configuration is influenced by the temperature.

P. Braunstein Elected

Pierre Braunstein (Université L. Pasteur, Strasbourg, France) was elected to the Deutsche Akademie der Naturforscher Leopoldina (Halle), Germany's oldest science academy (founded in 1652). He is also the first Frenchman to be elected to the Council of the Royal Society of Chemistry in London, whose membership was recently reduced from 50 to a maximum of 18. The research in his group is devoted to polytopic phosphorus ligands, enolate complexes, heteronuclear complexes with silicon ligands, and molecular clusters. Recently, he reported in *Angewandte Chemie* on

P. Braunstein

hydrogen bonds in supramolecular metal carbonyl complexes and on oriented one-dimensional organometallic molecular wires with silver–palladium bonds. He also co-edited a multivolume handbook on metal clusters.[1] Braunstein has been a corresponding member of the French Academy of Science since 1993 and was a recipient of the Grignard–Wittig Award of the French and German Chemical Societies (SFC and GDCh).

Braunstein studied chemistry at the Ecole Supérieure de Chimie in Mulhouse, France, and earned a PhD under the guidance of J. Dehand at the University of Strasbourg in 1971. As a postdoc, he worked with R. S. Nyholm at Imperial College (London). Having received a Doctorat d'Etat in Strasbourg in 1974, he joined E. O. Fischer's group at the Technische Universität München. He is currently a CNRS research director as well as director of the Laboratoire de Chimie de Coordination at the Université L. Pasteur (Strasbourg, France).

J.-M. Basset Elected to the French Academy of Science

Jean-Marie Basset (Ecole Supérieure de Chimie Physique Electronique de Lyon, CPE) was elected member of the Académie des Sciences (Paris) and recently received his member's sword during a colloquium in Lyon. Basset's research group focuses on organometallic chemistry at interfaces. In *Chemistry – A European Journal*, he recently reported on the grafting of [Mn(CH$_2t$Bu)$_2$(tmeda)] (tmeda: *N,N,N′,N′*-tetramethylethylenediamine) on silica and on structure–activity relationships of heterogeneous tungsten catalysts for alkane metathesis.[2]

J.-M. Basset

Basset received his PhD under the guidance of M. Prettre at the Catalysis Research Institute in Lyon, France, in 1969. Subsequently, he worked as a postdoc in the research groups of W. Graydon (University of Toronto, Canada) and G. Wilkinson (Imperial College). When he returned to Lyon, he was appointed assistant professor at the Université C. Bernard, and, later, deputy director of the Catalysis Research Institute. In 1983, he founded the surface organometallic chemistry group at the CPE and has been its scientific director since 1994.

P. Metrangolo Receives Ciamician Medal

Pierangelo Metrangolo (Politecnico di Milano, Italy) was awarded the Società Italiana di Chimica's Giacomo Ciamician Medal, an award for young organic chemists. Metrangolo received his PhD in industrial chemistry in 2001 under the guidance of G. Resnati (University of Milan). In 2001, he was a guest professor at the Université Paul Sabatier in Toulouse, France. In 2002 he was appointed assistant professor and was promoted to associate professor at the Politecnico di Milano in 2005. His research interests include supramolecular chemistry, in particular halogen bonding as a new principle of self-assembly, for which he was cited and that he presented in a Concept article in *Chemistry – A European Journal*. Recently, he reported on halogen bonds between nitrogen and bromine in infinite one-dimensional chains of dibromotetrafluorobenzene and bipyridyl derivatives.[3] In addition, he works on fluorinated reagents for organic synthesis, such as the oxidation properties of perfluorinated heterocycles, and self-assembled thin films for nonlinear optics.

Metal-Containing Nanostructured Materials through In Situ Polymerization of Reactive Metallomesogens

Luis Oriol and José Luis Serrano*

Metallomesogens, or metal-containing liquid crystals, have been widely studied over recent years as a new type of mesomorphic material. Most of the work in this field has involved structural studies as the rich coordination chemistry of metals affords fascinating new geometries for the design of liquid crystals (LCs).[1] Furthermore, the high level of interest in these materials also arises from the potential properties derived from the presence of metal ions within anisotropic phases. Metal ions can be redox active, photosensitive, display magnetic or catalytic properties, and may, in general, extend the properties of organic LCs, which are based on a small range of different atoms. Nevertheless, the stability and processability of metallomesogens is lower than that of similar organic compounds and this drawback has restricted the development of these materials.

One strategy to improve their processability with the aim of fabricating useful devices is the incorporation of metals into liquid-crystalline polymeric assemblies. Metallomesogenic polymers have been studied to a much lesser extent than low-molecular-weight metallomesogens, but such systems combine in a unique material the anisotropy of LCs, the new properties derived from the presence of the metal, and the favorable processing properties of poly-

mers. The design of metallomesogenic polymers generally employs similar approaches to those used for organic liquid-crystalline polymers.[2] In addition, supramolecular polymeric structures can be envisaged by means of metal complexation to give rise to new functional and dynamic liquid-crystalline polymers.[3] Accordingly, both lyotropic (temperature- and concentration-dependent phase transitions) and thermotropic (temperature-dependent phase transitions) metallomesogenic polymers have been reported with main-chain, side-chain, or cross-linked architectures.

Metallomesogenic polymers can be processed into films or other morphologies with controlled macroscopic orientation and a high metal content.[4] Orientation is mainly achieved by means of mechanical forces, as polymers are difficult to orient by other techniques that are successful with low-molecular-weight liquid crystals. In this sense, an excellent method to fix the orientation of liquid-crystal phases into polymeric films is the bulk polymerization of reactive LCs.[5] The polymerization of these materials in situ at the mesophase temperature converts the fragile structure of a self-organized molecular assembly into a polymeric material that displays good mechanical tractability and a structure that corresponds to the organization of the mesophase in which the polymerization takes place.[6] In the design of these reactive mesogens, moieties that undergo radical polymerization (mainly acrylates or methacrylates) have generally been chosen because radical polymerization is more tolerant of organic functional groups than other polymerization techniques.

Furthermore, if the polymerization is photochemically initiated, the processing is decoupled from the temperature — a situation that allows prior macroscopic orientation of the liquid crystal into monodomains and subsequent irradiation to yield highly oriented polymeric nanostructured films that are useful, for example, as optical devices[7] or low-dimensional ion conductors.[8]

In Situ Polymerization of Lyotropic Metallomesogens

The advantageous processability of reactive LCs has also been applied to metallomesogens, mainly in lyotropic systems but also in some thermotropic ones. The templated polymerization of lyotropic mesomorphic materials gives rise to nanostructured materials that have been used as biomembrane models, drug-delivery systems, and templates for nanocomposites.[9] A number of different lyotropic mesomorphic aggregates are known, but the inverted hexagonal (H_{II}) system has probably received most attention in the polymerization of lyotropic reactive metallomesogens. The specific interest in this system is due to the architecture of this H_{II} phase, which is highly reminiscent of zeolites or mesoporous sieves — materials that are investigated in different areas such as nanotechnology or catalysis. As a consequence, it is clear that the combination of tunable organic analogues and functional metal ions in the nanometric channels is a field of increasing interest.[10]

Gin and co-workers have described several examples of reactive lyotropic metallomesogens for different applica-

tions. For example, a series of reactive amphiphiles that contain transition-metal or lanthanide ions, which form strongly bonded chelates with carboxylate moities, was prepared using the organic monomer shown in Figure 1 as the

ever, in these cases the best strategy to prepare the desired materials was not polymerization of the Pd^{II} or Sc^{III} metallomesogenic materials but the photochemical polymerization of the H$_{II}$ mesophase of an ionic Na^I salt of a reactive

In Situ Polymerization of Thermotropic Metallomesogens

The polymerization of thermotropic organic liquid crystals in situ yields anisotropic materials that have applications in different optical technologies.[7] Despite this fact, reactive thermotropic metallomesogens have hardly been studied so far, probably as a consequence of the problems encountered in the polymerization of metal-containing monomers, and those compounds studied have generally been limited to acrylate derivatives.

Figure 1. Structure of the reactive amphiphiles prepared by Gin and co-workers, and schematic representation of the "locking" of the inverted hexagonal (H$_{II}$) mesophase by in situ polymerization of the acrylic groups.

reactive ligand.[11] H$_{II}$ phases were prepared by combining these monomers with water and a solution of a radical photoinitiator in xylene. Subsequent irradiation of the sample at room temperature gave rise to a cross-linked material that retained the H$_{II}$ structure. Selection of an appropriate metal ion enables both the dimensions and the properties of the nanostructured polymer network to be controlled. For example, Eu^{III}-containing anisotropic networks exhibit intense luminescence and were used to prepare nanocomposites by polymerizing 1,4-phenylenevinylene in the nanochannels of the H$_{II}$ phase.[12]

The confinement of metal ions within the nanometric channels of H$_{II}$ polymeric networks also provides the possibility of using these materials as nanoreactors. This strategy has been applied to the preparation of heterogeneous catalysts based on polymeric networks that contain nanoparticles of Pd^{II}[13] or Sc^{III}[14] as catalytic metal entities. How-

amphiphile (e.g. as shown in Figure 1) followed by ion exchange. Gin and co-workers also synthesized a series of metal carboxylates derived from a mixture of regioisomers of *p*-styryloctadecanoic acid (Figure 2), and these com-

Figure 2. Lyotropic metallomesogens based on regioisomers of *p*-styryloctadecanoic acid.

pounds exhibit mesomorphic behavior that is dependent on the nature of the metal ions.[15] An interesting application of these materials is the generation of CdS nanoparticles in nanometric channels by exposing a photopolymerized H$_{II}$ network of the Cd^{II} metallomesogen to H$_2$S vapor.

The first results in this field were reported by Drenth and co-workers, who described the synthesis of a Cu^{II} phthalocyanine that contained eight terminal acrylate groups and attempted the production of low-dimensional conductors through locking a hexagonal columnar organization by polymerization of the acrylates in situ.[16] Attempts at photochemically initiated polymerization were unsuccessful but thermal polymerization using AIBN as initiator gave rise to a thermally stable polymeric network in which the columnar organization was maintained. Later, Maldivi and co-workers pointed out that transition-metal centers that have unpaired valence electrons can inhibit radical polymerization.[17] They described a series of metal complexes based on carboxylates that mainly incorporated closed-shell metal cations (Figure 3). Inhibition of photochemical polymerization was observed in the case of the Cu^{II} complex.

Figure 3. The series of reactive metal complexes described by Maldivi and co-workers.

Nevertheless, the Zn[II] and Mg[II] complexes could be polymerized in a manner similar to that for the organic monomers, whose polymerization kinetics depend on the ordering effect of polymerizable groups, anisotropic mobility, and diffusion in a liquid-crystalline medium. Another remarkable result of this study was the observation of reduced mesomorphic properties of these monomers in comparison with the nonreactive complexes which was attributed to the steric and dipolar effects introduced by the acrylate groups.

Metal complexes of *N*-alkyl[18] or *N*-aryl[19] salicylaldiminates (Figure 4) have also been studied, and conclusions similar to those mentioned above were drawn. The Cu[II] complexes did not polymerize, but the Zn[II] (nonmesogenic) or Pd[II] complexes could be polymerized in situ upon both thermal and photochemical initiation (note, polymerization was more efficient with the Zn[II] complex). As an alternative, the photopolymerization of homologous reactive metallomesogens that contain vinyl ethers was also attempted by a cationic mechanism promoted by free-radical species. However, evidence for

polymerization was not found in these systems. Similar problems were encountered in the photopolymerization in situ of mesogenic acrylates based on dicarbonylrhodium(I) salicylaldiminate complexes, whereby the presence of the metal ions inhibited the polymerization of the acrylates.[20]

1,3-Diene Tails as an Alternative in the Preparation of Reactive Metallomesogens

The drawbacks of thermotropic metallomesogens mentioned above, which are mainly based on acrylates, can be avoided by using different reactive groups. To this end, Attard and Templer proposed the preparation of oriented networks by irradiation with UV light of highly ordered crystalline fibers, processed from an unusual lamellar discotic phase of a Cu[II] carboxylate that bears diacetylene groups in the linear carboxylate chains.[21] The authors suggested this topochemical polymerization as an easy way to obtain macroscopically ordered single crystals of good optical quality with a view to using the materials in nonlinear optics.[21] Nevertheless, this

polymerization took place in the crystalline phase.

As far as the polymerization of mesogens in situ is concerned, reactive 1,3-diene groups located at the end of an aliphatic terminal chain have proved to be an interesting alternative for the preparation of cross-linkable liquid-crystal monomers.[22] This kind of monomer can be polymerized in situ by either using a conventional radical photochemical initiator or thermally. In the case of thermal initiation, 1,3-dienes have a tendency to undergo [4+2] cycloaddition with one another. Furthermore, the replacement of acrylate terminal groups by 1,3-dienes improves the mesomorphic properties of the reactive monomers because these tails more closely resemble the conventional terminal *n*-alkyl or *n*-alkoxy chains generally used in the design of low-molecular-weight LCs. Several series of thermotropic LCs that comprise a bent core[23] or a polycatenar structure,[24] as well as lyotropic monomers,[25] have been described using this kind of polymerizable group.

Very recently, Gin and co-workers described the first examples of reactive metallomesogens that contain these kinds of groups as an alternative to acrylate-containing metallomesogens for the formation of anisotropic networks.[26] The Pd[II] and Ni[II] metallomesogens shown in Figure 5 were synthesized, and the properties of diene- and acrylate-containing and nonreactive metallomesogens were compared. The comparison highlighted several advantages for the diene derivatives: First, reactive diene groups have a less marked destabilizing effect on the mesomorphic state than the acrylate groups do. Second, thermally induced cycloaddition of the diene monomers yielded metallopolymeric networks that re-
Figure 4. Examples of thermotropic reactive metallomesogens based on salicylaldiminates,[19] and schematic representation of their polymerization in situ.
Figure 5. Structures of the reactive and nonreactive thermotropic metallomesogens described by Gin and co-workers.

tained the structure of the mesophase in which polymerization took place. In contrast, attempts to obtain a cross-linked anisotropic network from diene or acrylate derivatives by radical photo-polymerization failed as a consequence of either the reduction of Pd[II] ions or chain transfer to thioester ligands in the case of Ni[II] metallomesogens. Consequently, diene groups seem to be more compatible with redox-active metal ions or functional groups than acrylates are in the design of metallomesogens.

In conclusion, the polymerization of reactive metallomesogens in situ opens up new possibilities for the processing of nanostructured metal-containing materials. Nevertheless, metals may have an adverse effect on the efficiency of the polymerization, especially in the free-radical polymerization of acrylates — the most widely studied polymerizable groups used to design both lyotropic and thermotropic reactive metallomesogens. Recent research has demonstrated that 1,3-dienes offer new possibilities relative to the acrylates: on the one hand, dienes have a higher compatibility with mesomorphic ordering than acrylates, and, on the other hand, they can react by an alternative mechanism to the free-radical route to undergo efficient polymerization and consequently avoid the inhibition or retardation introduced by metal ions and some organic groups.

Bifunctional Metal–Ligand Catalysis: Hydrogenations and New Reactions within the Metal–(Di)amine Scaffold**

*Kilian Muñiz**

*T*he observation of the ligand-associated heterolytic splitting of H_2 dates back to pioneering work by Fryzuk et al. on organometallic amide complexes of rhodium and iridium.[1] The general importance of the reversible storage of dihydrogen within a transition metal/ligand framework was later proposed by Crabtree but remained restricted to the stoichiometric formation of hydrides of iridium–amide complexes.[2] Starting in 1995, Noyori disclosed novel ruthenium diamine complexes that enabled a conceptually new enantioselective hydrogenation process and thereby marked that start of the rational design of chiral catalysts with unprecedented activity in the reduction of prochiral ketones and imines.[3] In principle, the basic task of the catalyst consists of the concerted transfer of dihydrogen within a hydride–ruthenium–diamine assembly. If the diamine or the remaining coordination sphere of the metal center bears defined stereochemical information, an enantio-
Scheme 1. Catalytic enantioselective transfer hydrogenation of ketones.

selective process is possible (e.g., structure **A**, Scheme 1).

For this purpose, two types of reactions were envisioned. Transfer hydrogenation of both ketones and imines used 2-propanol or formic acid/triethylamine as the hydrogen source.[3a,c,d] The overall reaction pathway was determined in a seminal study in which all active metal complexes involved in the catalytic cycle were isolated.[4] Typically the actual catalyst is generated in situ through interaction of base which causes elimination of HCl from precatalyst **1**. The resulting low-coordinate ruthenium–amide complex **2** interacts with 2-propanol (**A**, $R^1 = R^2 = Me$) and within a concerted process takes up hydride and proton to generate the hydride catalyst **3**. Reduction of the carbonyl is then accomplished via transition state **A** ($R^1 \neq R^2$) without metal–carbonyl interaction to yield the chiral alcohol or amine product and **2**. In principle, the

reaction turns endlessly at the Ru–NH surface of the two catalytically active species **2** and **3** (Scheme 1).

For transfer hydrogenation in formic acid/triethylamine azeotrope, the working mode of catalyst formation was addressed recently by Ikariya et al., who published an extensive investigation including the first structural elucidation of a transition-state analogue for this step.[5] Reaction of the isolated ruthenium–amide complex **2**[4] with formic acid at −40°C in THF generated the formate complex **4a** as a single diastereoisomer. This confirms once again that the formation of the actual hydride catalyst proceeds with complete stereoselectivity.[4] As expected for an immediate catalyst precursor of high reactivity, **4a** was found to be rather unstable and no crystal structure could be obtained. Instead, the related acetate **4b** was characterized by X-ray structure analysis. The structure is in accordance

with the expected absolute configuration at the Ru atom, and the distance between the carbonyl group and the NH$_2$ entity is only 2.77 Å. Kinetic NMR studies on the decarboxylation of **4a** revealed a first-order rate dependence in substrate. Activation parameters of $\Delta H^+ = 76$ kJ mol^{-1}, $\Delta S^+ = -38$ J mol^{-1} K^{-1}, and $\Delta G^+ = 87$ kJ mol^{-1} were obtained, and the negative entropy value suggests that the active hydride catalyst **3** is formed from **4a** by an intramolecular process. Within this context, a remarkable study on the transfer hydrogenation of aromatic ketones in water was reported recently, which suggested a dramatic pH dependence of both catalyst performance and regeneration mode.[6]

recently led to an efficient catalyst class for the enantioselective hydrogenation of *tert*-alkyl ketones.[7c,d]

These extremely efficient catalyses have stimulated ongoing mechanistic investigations.[8] The exact working mode of the uniquely enantioselective catalyst derived from **5** was uncovered by Noyori et al. in 2003.[9a] The structurally defined hydride–borohydride–ruthenium precursor **6**[9b] was found to initiate catalysis even without addition of base and therefore served as the molecular basis for the unambiguous determination of the underlying kinetics and the influence of solvent, base, and hydrogen pressure on the overall reaction profile. Two cycles turned out to be of importance. Borohydride dissociation

from **6** gives the cationic complex **10** (Scheme 3). In protic solvents such as 2-propanol this intermediate originates from protonation of the basic imido function in neutral **8**. Complex **10** then accomodates dihydrogen to yield the cationic dihydrogen complex **11**, which represents the resting state of the catalyst and is the immediate catalyst precursor. Dihydride catalyst **7** is formed from **11** by loss of a proton (Scheme 3, cycle II).

In an elegant experiment Bergens et al. showed that **11** can be generated directly from the cationic binap–Ru–hydride complex **12** (with tetrafluoroborate as the counterion) by addition of the diamine ligand under 1 atmosphere of hydrogen.[10] The general structure of **11** was determined by NMR spectroscopy as was the absence of deuterium scrambling between the η^2-bound dihydrogen and the hydride ligand. However, when generated this way **11** is not an active catalyst precursor in the absence of base. This shows that 2-propanol itself is not sufficiently basic to deprotonate the dihydrogen ligand in **11** and that the nature of the formal counterion is of high importance. For reactions in aprotic solvents, **6** generates the dihydride catalyst **7**, which reduces the ketone substrate to give amide complex **8**. This complex splits dihydro-
Scheme 2. Enantioselective hydrogenation of ketones. R = phenyl, 4-tolyl, xylyl.

In contrast to transfer hydrogenation, the direct enantioselective hydrogenation of ketones requires the use of ternary ruthenium complexes made up of a bisphosphine, a diamine, and a ruthenium(II) center, which are usually provided as preformed dichlorides such as **5** (Scheme 2). In view of catalyst efficiency, these compounds are unparalleled. Peak turnover rates reach 62 per second, while enantioselectivities of up to 99% *ee* can generally be obtained.[3b,c] Since the ternary composition allows for selective replacement of the individual ligands, the catalyst can be fine-tuned.[3b] For example, a binap–Ru^{II} complex with a 1,4-diamine ligand acts as a precatalyst for the enantioselective hydrogenation of tetralones,[7a,b] a substrate class which proves problematic for the conventional 1,2-diamine-chelated catalysts such as **5**. Application of pyridinyl amines has
Scheme 3. Catalytic cycles for ketone hydrogenation and the transition-state structure.

gen in a heterolytic manner (→**9**) to regenerate catalyst **7** (Scheme 3, cycle I).

Thus, the mechanistic scenario for the occurrence of peak turnover frequencies in bifunctional metal–ligand hydrogenation is based on a well-balanced overall neutral environment with only a local appearance of acidic and basic species as provided by **6**. Complexes **6** and **12** are the only direct catalyst precursors isolated to date, since the exact formation of **7** either from **6** under nonprotic conditions or from the dichloride **5** or related monohydrides through base interaction remains to be determined. Significant contributions by Morris et al. include the isolation of various ruthenium dihydrides related to **7**, hydride chlorides, and amide complexes which all show the expected catalytic activity in ketone and imine hydrogenation.[11] An extensive comparative study on some dihydrides from monophosphine complexes aimed to clarify the preferential geometrical arrangement of these catalysts.[12] In the predominant catalysts the two hydrides were found to adopt a *trans* arrangement, a result that in agreement with the suggested geometry for **7**.[9a]

The enantiofacial differentiation of the substrate is accomplished kinetically on the molecular surface of the chirally modified RuH$_2$ catalyst. The final hydrogen transfer proceeds through a six-membered transition state and involves simultaneous transfer of a proton from an amino moiety of the chiral diamine ligand to the carbonyl oxygen atom and hydride transfer from ruthenium to the carbonyl group. A molecular model of the active *trans*-RuH$_2$ species from the hydrogenation is depicted in Scheme 3; it shows how the hydride and the amine proton (H-Ru-N-H$_{ax}$) are involved in the transition state. The prerequisite diamine ligand plays a dual role: it contributes to the chiral environment of the catalyst and takes part actively in hydrogen transfer.

Although the two catalytic systems with hydride and dihydride catalysts (**3** and **7**, respectively) apparently share the mode of hydrogen transfer, they differ from each other in catalyst regeneration. The decisive step of the hydrogen transfer from the polarized donor molecules 2-propanol or formic acid consists of a

concerted addition across the polar Ru–amide bond. The ionic character of the hydrogen-transfer reagent is necessary, since direct activation of Ru–amide **2** with hydrogen requires a pressure of 80 bar.[4] In contrast, cationic ruthenium complexes such as **10** can activate dihydrogen heterolytically by η^2 coordination. The subsequent deprotonation of this dihydrogen ligand is rapid and results in the high productivity of the overall reaction, that is, the kinetic preference of cycle II over cycle I.

In what represents a significant structural alternative in this area of hydrogenation catalysts, Grützmacher et al. introduced a novel rhodium–amide system for the heterolytic activation of hydrogen activation.[13] Starting from the bistropylidenylamine **13**, a two-step sequence led to the formation of a defined rhodium complex in which the bistropylidenylamine acts as a tridentate ligand. The amino hydrogen displays the expected acidity (p$K_{a,\text{DMSO}}$ = 15–20) and can be removed upon addition of base (Scheme 4). The resulting rhodium–

splitting at −78 °C under 1 atm of hydrogen and are transformed into the corresponding rhodium hydrides **15 a,b**. Compound **15 b** was again characterized by X-ray structure analysis, and its structure was very similar to that of **14 b**. This result indicates that the accommodation of hydrogen in this systm is readily reversible; this was confirmed by the observation of selective and reversible deuterium incorporation under D$_2$.

The structure and reactivity of the resulting rhodium hydrides thus match that required for bifunctional metal–ligand hydrogenation catalysts. Comparative DFT calculations confirm a high preference for the heterolytic dihydrogen cleavage, which yields the amino rhodium hydride by an exothermic pathway ($\Delta H_R = -67$ kJ mol^{-1}), while the conventional homolytic splitting to yield a rhodium dihydride would proceed by an endothermic pathway ($\Delta H_R = 71$ kJ mol^{-1}) and via an higher energy transition state ($\Delta H^{\ddagger} = 61$ kJ mol^{-1} for heterolytic vs $\Delta H^{\ddagger} = 75$ kJ mol^{-1} for homolytic cleavage). Under 100 bar of
Scheme 4. A structually novel rhodium amide complex for the heterolytic cleavage of dihydrogen. cod = cyclooctadiene.

amide complexes **14 a,b** are sufficiently stable. Complex **14 b** was characterized by its solid-state structure, which revealed a Rh−N bond length of 2.0 Å. In addition, the observed sawhorse structure of the four-coordinate **14 b** is unique among this type of complexes and appears to be a geometrical prerequisite for dihydrogen splitting. Compounds **14 a,b** readily induce heterolytic H$_2$

hydrogen, both the crystalline amide and the isolated hydride catalyze hydrogenation of ketones and imines with TONs of up to 650. No further additives are required; that is, the reaction proceeds under neutral conditions. Aside from the borohydride complexes of type **6**, this is a rare example of a base-free bifunctional metal–ligand hydrogenation catalyst.[14]

Apart from their unmatched efficiency in the enantioselective hydrogenation and transfer hydrogenation of carbonyl compounds, bifunctional metal–ligand complexes have been employed recently for other processes as well. Sadler et al. described a structurally closely related cationic (η^6-arene)-Ru(en) unit for the recognition of nucleoside and nucleotide binding sites.[15] In the area of transition-metal catalysis, Ikariya et al. reported the catalytic hydrogenolysis of epoxides in 2-propanol in the presence of an aminophosphine ligand and a pentamethylcyclopentadienyl (Cp*) ruthenium precursor.[16] The catalyst formed in situ was suggested to be the ruthenium hydride **17**, which at S/C = 100 gave yields from 79 to 99 % and a 99:1 ratio in favor of the branched alcohol over the linear (Scheme 5).

Scheme 6. Enantioselective Michael additions employing bifunctional ligand–metal catalysts.

Scheme 5. Ruthenium catalysts for the hydrogenolysis of epoxides and for the conversion of diols to lactones.

Hartwig et al. employed catalysts of ternary composition for lactone formation from the dehydrogenative cyclization of 1,4-butanediol. Among various catalysts screened for this purpose, **18** performed best and converted the diol quantitatively. The reaction could be performed on a large scale; 22 g of diol was converted into the lactone in 100 % yield with as little as 5.4 mg of catalyst, which corresponds to an overall TON of 17 000.[17]

The successful ruthenium diamine motif was used to develop an enantioselective Michael addition.[18] Here, the addition of dimethyl malonate across prochiral cyclic enones such as cyclopentenone and cyclohexenone was catalyzed by **2** with selectivities of up to 99 % ee.[18a–c] The reaction is believed to

start from an α-metalated structure **19** and to proceed through a highly organized transition state **20** with hydrogen bonding toward the carbonyl oxygen and olefin-face selection through the imposing stereochemical environment of the catalyst surface (Scheme 6).

The identical transformation was accomplished by Morris et al. using ternary catalysts of the binap–ruthenium–aminophosphine composition.[18d] Here, the borohydride complex **21** proved to be the most efficient catalyst precursor, leading to the Michael addition with 96 % ee at S/C = 100. Since complexes derived from binap, ruthenium, and aminophosphines have proven to be versatile hydrogenation catalysts as well,[19] **21** can be used for a domino catalysis.[18d] Thus, when the Michael

addition was complete, application of 28 bar of hydrogen pressure led to concomitant reduction of the ketone to the corresponding alcohol with 30:1 selectivity in favor of the *trans*-configured cyclohexenanol. An identical sequence with slightly lower selectivities (90 % ee for the Michael addition and 10:1 selectivity at 99 % yield) was observed for related ruthenium complexes based on binol-derived bisphosphinites.[18e]

A ruthenium–amine moiety proved successful for the isomerization of allylic alcohols to ketones.[20] Again, the established Cp* ruthenium catalyst **17** from epoxide hydrogenolysis was employed and was generated in situ with KOtBu. Various allylic alcohols could be isomerized to give the corresponding ketones (Scheme 7).

Isotopic labeling provided the first information about the mechanism. Apparently the reaction is initiated by alcohol dehydration to give the unsaturated ketone together with a ruthenium hydride or deuteride. Regioselective conjugate addition of this complex furnishes the simple ketone product with the observed deuterium incorporation in the 3-position. This observation matches the chemoselectivity observed in related Michael addition processes (Scheme 6). The fact that the reaction proceeds with complete chemoselectivity for substrates containing further C=C bonds led to the development of an enantioselective allylic isomerization
Scheme 7. Bifunctional metal–ligand catalysts for the isomerization of allylic alcohols and the reduction of polarized C=C bonds.

with a proline-derived ligand. At 5 mol% loading, catalyst **22** selectively converted the shown triene into the corresponding enantioenriched ketone, which within two subsequent steps gave the natural product (*S*)-muscone.

While the original Noyori transfer-hydrogenation catalyst displayed high chemoselectivity for the preferential reduction of C=O over C=C bonds, Deng et al. have now found that this preference can be reversed for strongly polarized olefinic substrates.[21] In addition, application of the triethylamine/formic acid protocol led to an efficient saturation of the C=C bonds for a variety of unsaturated nitriles when a slightly modified diamine ligand was employed (precatalyst **23**). Enantiomeric excesses of up to 89% could be obtained, and experiments with deuterated formic acid suggest that the reaction involving the polarized amine–ruthenium hydride catalyst follows a conjugate reduction pathway related to the Michael additions from Scheme 6.

Bifunctional metal–ligand catalysis had originally been conceived as a synthetic methodology for the enantioselective hydrogenation of ketones and imines. The first transition metal employed, ruthenium, is still the most broadly applicable, but similar reactivity has been shown for other metals as well.

Certainly future interest in this area will focus on the elucidation of the few remaining mechanistic questions, for example, the exact mode of catalyst formation, and the development of structurally new systems such as the rhodium catalyst **15**. Apart from this, bifunctional metal–ligand catalysis may develop into a more general concept for enantioselective catalysis. In view of the first examples of enantioselective Michael additions and the isomerization of allylic alcohols, and considering the yet unexplored hydrometalation[22] and the recent detection of highly reactive ruthenium and iridium alkoxides,[23] one expects further exciting reactions to emerge in due course.

Ruthenium Catalysis

Ruthenium-Catalyzed Reactions—A Treasure Trove of Atom-Economic Transformations

Barry M. Trost,* Mathias U. Frederiksen, and Michael T. Rudd
The demand for new chemicals spanning the fields of health care to materials science combined with the pressure to produce these substances in an environmentally benign fashion pose great challenges to the synthetic chemical community. The maximization of synthetic efficiency by the conversion of simple building blocks into complex targets remains a fundamental goal. In this context, ruthenium complexes catalyze a number of non-metathesis conversions and allow the rapid assembly of complex molecules with high selectivity and atom economy. These complexes often exhibit unusual reactivity. Careful consideration of the mechanistic underpinnings of the transformations can lead to the design of new reactions and the discovery of new reactivity.

From the Contents

1. Introduction

The synthetic chemical community has been put under increased pressure to produce, in an environmentally benign fashion, the myriad of substances required by society. Thus, green chemistry has emerged as a discipline that permeates all aspects of synthetic chemistry. A major goal of this endeavor must be to maximize the efficient use of raw materials and simultaneously to minimize waste. Thus, synthetic efficiency has to address not only selectivity (i.e. chemo-, regio-, diastereo-, and enenatioselectivity) but also atom economy.[1,2] That is, in chemical transformations of the general form A + B → C + D, if the desired product is C, then the by-product D must be as small and innocuous as possible if no use for it can be found. In an ideal scenario D would vanish all together, and the general scheme would simplify to A + B → C, with anything else needed only catalytically. In other words, the use of simple addition reactions must be emphasized if we are to make chemical manufacturing more efficient.

Several reactions of this type have been developed, with the Diels–Alder reaction perhaps representing the ideal reaction in that C–C bonds may be formed, not only with a high degree of chemo-, regio-, diastereo-, and enantioselectivity, but also atom economically. Few industrial processes make use of the exquisite power of the Diels–Alder transformation, even though it is an invaluable tool in the synthesis of complex molecules.[3] Hydroformylation, on the other hand, is an atom economic reaction that enjoys widespread industrial use, but sees only limited use in typical research laboratories.[4,5] Finally, catalytic hydrogenation represents an almost ideal reaction that is extensively used both industrially and academically. Unfortunately, few reactions in multistep synthetic sequences are simple addition reactions, and as a result few types of molecular transformations are possible in an atom-economic fashion. Expanding the synthetic toolbox to include more addition reactions will certainly change this picture. In this context transition-metal catalysts have occupied and continue to occupy a central role, both in improving existing processes and, more importantly, in discovering new ones. In this regard our research program directed at the development of non-metathesis ruthenium-catalyzed reactions has been a particularly fruitful avenue of investigation.

A comprehensive treatment of this area goes well beyond the scope of this Review.[6] Rather, we illustrate that by approaching the development of reactions in a semirational way, one can discover, indeed invent, new reactions guided by the mechanistic underpinnings of these transformations. An understanding of the mechanisms of these reactions continues to provide the basis and impetus for the discovery of new reactions, even if the proposed hypothesis does not always turn out to be the actual mechanism! This Review is roughly divided into sections along the lines of the proposed operating mechanisms, with special care being taken to guide the reader through the reasoning behind the design of the reactions.

2. Additions via Vinylidene Complexes

A number of reactions have been reported in which alkynes were reported to be converted either thermally into carbenes,[7,8] or in the presence of a metal into the corresponding metal complexed carbenes.[9] There were, however, several issues with the generation of these carbenes. First, the thermal route [Eq. (1), path A], required extremely high
temperatures, which made the synthetic usefulness of this method doubtful. The formation of metal vinylidenes [Eq. (1), path B], on the other hand, proceeds under extremely mild conditions, but unfortunately these complexes were generally too stable to be synthetically useful.[10–16]

The work disclosed by Bruce and co-workers in which various ruthenium vinylidene complexes (e.g. **2**) were reportedly synthesized from [CpRu(PPh$_3$)$_2$Cl] (**1**) [Eq. (2); Cp =

Barry M. Trost was born in Philadelphia, PA in 1941 and studied at the University of Pennsylvania (BA, 1962). He obtained his PhD in 1965 at MIT. He moved to the University of Wisconsin where he was made Professor in 1969 and subsequently Vilas Research Professor in 1982. He moved to Stanford University in 1987 and became Tamaki Professor of Humanities and Sciences in 1990. In addition to holding Visiting Professorships at several universities worldwide, he has been awarded numerous prizes. His interests span the entire field of organic synthesis, particularly in the development of novel methodology.

Michael T. Rudd was born in 1976 and studied chemistry at Purdue University. After obtaining his BS in 1999, he joined the research group of Professor Barry M. Trost at Stanford University, where he obtained his PhD in 2004. He is currently a medicinal chemist at Merck Research Laboratories in West Point, PA.

Mathias U. Frederiksen was born in 1975 in Luxemburg. He studied chemistry at Mount Allison University, Canada. After the completion of his undergraduate studies, he joined the research group of Professor Tony Barrett at Imperial College in London, UK, where he obtained his PhD in 2002. After postdoctoral studies in the group of Professor Barry M. Trost, he is now a medicinal chemist at the Novartis Institutes for Biomedical Research in Basel, Switzerland.

cyclopentadienyl],[17–21] stimulated a search for how such complexes may function as reactive intermediates in a catalytic cycle. These complexes are remarkably stable towards nucleophiles, for example, complex **2** must be heated at reflux in methanol to obtain the addition product. Moreover, higher alcohols do not react with this complex at all.[19]

To overcome the inherent low reactivity of **2** towards alcohols, the possibility of precoordinating the nucleophile may offer a viable option. In such a scenario the double bond of an allylic alcohol would coordinate to the metal, and hence deliver the hydroxy group in an intramolecular fashion (Scheme 1). Thus, the reaction of a coordinatively unsatu-

Scheme 1. Mechanistic rationale for the reconstitutive addition of alkynes and allylic alcohols.

rated Ru complex such as **3** with a terminal alkyne was expected to generate the corresponding vinylidene complex **4**. Ligand exchange would form the complex **5** in which the nucleophilic hydroxy group is proximal to the vinylidene carbon atom. Nucleophilic attack then generates ruthenadiene **6**, which may undergo sigmatropic rearrangement followed by reductive elimination to give the β,γ-unsaturated ketone **8** via allyl complex **7**.

Initial studies in this program focused on the reaction between complex **1** and various terminal alkynes. These

revealed that in contrast to other aliphatic alcohols, various allylic alcohols reacted cleanly with terminal acetylenes in the presence of catalytic amounts of complex **1** and ammonium hexafluorophosphate to form the desired β,γ-unsaturated ketones in good yield [Eq. (3)].[22] The reaction tolerates
branching at the allylic position, but not substituents on the double bond, presumably due to steric factors. Mechanistic studies lent strong support for the proposed mechanism.[23] First, the coordination of the allylic alcohol is proposed to take place by ligand exchange with triphenylphosphane in the second step of the catalytic cycle. Several results support this rationale. For example, the rate of reaction between **9** and allyl alcohol is significantly retarded in the presence of excess triphenylphosphane (> 1 equiv/Ru). Moreover, the use of a bidentate ligand such as dppe (1,2-bis(diphenylphosphanyl)-ethane) instead of triphenylphosphane completely shuts down the reaction, presumably due to the reluctance of the dppe ligand to dissociate from the ruthenium center, which in turn precludes coordination of the olefin.

Labeling experiments cast light on other aspects of the proposed mechanism [Eq. (4) and Eq. (5)]. Treatment of 1-

internal alkynes, as well as alcohols to be present in the acetylenic coupling partner.[24] Moreover, it lends itself well to synthesis. For example rosefuran (**22**), the essence of rose oil, was synthesized in 23% overall yield in a concise six-step sequence starting with acetylene **19** and allylic alcohol **20**. In this case, the Ru-catalyzed reaction generates the 1:1 adduct **21**, which is readily converted into the target furan **22** (Scheme 2).[25]

Scheme 2. Reconstitutive condensation in the total synthesis of rosefuran (**22**).

Later, a second-generation catalyst system with In(OTf)$_3$ as a halophilic cocatalyst allowed a decrease in the amounts of allylic alcohol required for complete conversion into a nearly equimolar ratio with respect to the alkyne coupling partner.[24,26] The role of the cocatalyst is probably to remove chloride ion, thus generating a coordinatively more unsaturated Ru cation.

ethynylnaphthalene (**12**) with deuterated allylic alcohol **13** led to addition products **14** and **15** ($\approx$ 7:1). The carbon atom that bears the allylic hydroxy group preferentially formed the new C–C bond with the terminal alkyne carbon atom [Eq. (4)]. Similarly, treatment of **12** with *trans*-dideuterated allylic alcohol **16** gave the with a 11.5:1 ratio [Eq. (5)]. The retention of the geometry of the alkene demonstrates the intervention of a π-allyl species (e.g. **7**) in the catalytic cycle, in which isomerization is slower than reductive elimination. More-hindered allylic alcohols show complete scrambling of the olefin geometry, thus indicating that η^{3-}·η^{1-}·η^3 isomerization now competes with reductive elimination.

This reaction exhibits excellent chemoselectivity and allows the presence of acetals, esters, conjugated ketones,

The potential susceptibility of vinylidene complexes towards nucleophilic attack by precoordinated nucleophiles prompted an examination of the possibility of intercepting such species by a tethered nucleophile [Eq. (6)]. In this
scenario a homopropargylic (**23**, $n = 1$) or higher alcohol (**24**, $n = 2$) was expected to attack the vinylidene complex **25** to form the oxacarbene species **26**. An oxygen heterocycle may then be released upon oxidative decomplexation, for example, in the form of a lactone **27**.

The synthesis of Fischer oxacarbene species such as **26** has been known since the early 1970s, and systems containing five-,[27] six-,[28] and seven-membered rings[29] have been prepared. The development of preparatively useful methods that make use of the Fischer oxacarbene complexes has been hampered by the perceived difficulty of the decomplexation step.[30] Many useful transition-metal-mediated methods for alkynol cycloisomerization have nevertheless been developed.[31]

The logical extension of this work has been the development of viable catalytic methods for alkynyl cycloisomerization-type reactions. In this regard McDonald and co-workers developed elegant catalytic versions of their tungsten-mediated *endo* cycloisomerization, which provides access to structurally diverse dihydropyrans in a highly efficient manner [Eq. (7)].[32–36] This methodology has been extensively

(7)
utilized in the synthesis of biologically significant glycosides.[37–40]

The key to using the ability of Ru vinylidene complexes to be trapped by a homopropargylic alcohol is the design of a decomplexation pathway of Ru–oxacarbene complexes. One approach considers a subsequent oxidative decomplexation step, which would lead to γ-butyrolactones (see **27**, $n = 1$ [Eq. (6)]). Literature precedent indicated that the latter step had been effected by strong oxidants such as cerium ammonium nitrate[41,42] and dimethyl dioxirane.[43] The critical issue seemed to be the discovery of an oxidant that would be chemoselective and would maintain the catalytic cycle. The choice of oxidant (*N*-hydroxysuccinimide) and a small

electron-poor phosphine (trifurylphosphane) was critical for achieving the catalytic reaction as shown in the transformation of substrate **30** into product **32** catalyzed by Ru complex **31** [Eq. (8)].[44]

(8)
This methodology was applied in a short asymmetric synthesis of (−)-muricatacin, a natural product with antitumor properties (Scheme 3).[45,46] The chemoselectivity of this oxidative cyclization of **35** for the formation of a five-preferentially to a six-membered ring is noteworthy.

This synthetic methodology can be extended to 5-hydroxy-1-alkynes. Initial forays in this direction met with limited success owing to significant competitive *exo* cyclization, rather than cyclization in the desired *endo* mode. Considerable experimentation revealed a most intriguing divergence. When a 5-hydroxy-1-alkyne (e.g. **37**) was exposed to catalytic [CpRu(Ar₃P)₂Cl] with electron-donating phosphine ligands (e.g. tris(*para*-methoxyphenyl)phosphane) the lactone **39** formed exclusively [Eq. (9)]. In contrast, the catalyst bearing electron-withdrawing phosphine ligands (e.g. tris(*para*-fluorophenyl)phosphane) led to clean conversion into the dihydropyran **41** [Eq. (10)].[47] Slightly higher catalyst loadings are necessary to reach complete conversion in the former case.

This interesting dichotomy can be explained by considering the proposed mechanism (Scheme 4). The initial stages of the catalytic cycle are common for both pathways. Thus, vinylidene **43** is formed, and nucleophilic attack of the hydroxy group at the vinylidene carbon atom leads to the pivotal intermediate **44**. In the case of the cycloisomerization (Scheme 4, cycle A), the electron-deficient ligand favors ligand exchange to form anionic intermediate **45**, which upon protonation liberates the dihydropyran **46** and Ru-complex **47**. Simple ligand exchange liberates *N*-hydroxysuccinimidate and regenerates the catalyst **42**. An electron-rich

phosphine is used in the oxidative cyclization (Scheme 4, cycle B), in which protonation of the ruthenadihydropyran **44** is preferred and affords the cationic complex **48**. Attack at the anomeric center by the nucleophilic oxidant gives complex **49**, followed by protonation to liberate the lactone **50** and regenerate the catalyst **42**. The formation of the dihydropyran is particularly interesting as some groups have reported the attempted formation of dihydropyrans from the ruthenium intermediates and noncoordinating bases.[48] In the case at hand the choice of a coordinating base, specifically *N*-hydroxysuccinimide, is critical for turnover, as other bases failed entirely to give the hydropyrans.[49]

The divergent reaction lends itself well to synthetic applications. For example, iterative cycloisomerization, akin to the elegant application of tungsten-catalyzed cycloisomerization by McDonald and Wu,[39] opened up an approach to narbosine A (**51**), an antiviral bistetrahydropyran natural product isolated from *Streptomyces* (Scheme 5).[50] Thus, alcohol **52** was converted into the dihydropyran **53** under the standard conditions. Stereoselective formation of the anomeric ether **54** preceded the second cycloisomerization, which afforded the glycal **55** in very good yield. Finally, acid-catalyzed addition of methanol followed by deprotection gave narbosine A (**51**).

Likewise, the oxidative cyclization is also useful for the synthesis of natural products, for example, in the concise formal synthesis of the mosquito pheromone **56** (Scheme 6).[51,52] In this case, oxidative cyclization of **57** under the standard conditions revealed the hydroxylactone **58** (64% yield), an intermediate in the synthesis by Kotsuki et al.[53]

The marine ladder toxins represent a structurally fascinating class of natural products.[54] With the efficient Ru-catalyzed cycloisomerization in hand, an iterative approach to the *trans*-fused tetrahydropyran ring systems found in the BCD ring fragment of yessotoxin,[55] a polyether toxin implicated in diarrhetic shellfish poisoning, was envisaged (Scheme 7). Readily available alcohol **59** was subjected to the standard cycloisomerization conditions to afford glycal **60** in

excellent yield. This was readily converted into the alkynyl alcohol **61** in two steps, thus setting the stage for a second cycloisomerization reaction, which proceeded uneventfully to give bicycle **62**. Straightforward manipulations again delivered the requisite 5-hydroxy-1-alkyne **63**. A third cycloisomerization then gave tricyclic glycal **64** in excellent yield.

Alternative methods for the interception of ruthenium vinylidene complexes by nucleophiles have also led to

catalytic cycles. For example, Liu and co-workers recently described an efficient Ru-catalyzed synthesis of functionalized furans (e.g. **65**) from propargylic epoxides (e.g. **66**) in very good yield [Eq. (11); Tp = tris(pyrazolyl)borate].[56]

(11)
Ruthenium vinylidene **67** is proposed to be the key intermediate in this reaction, and evidence for this mechanism was supported by deuterium-labeling experiments. Similarly, carbon nucleophiles have also been used to trap ruthenium vinylidenes. Merlic and co-workers demonstrated that dienyl
Scheme 7. Iterative Ru-catalyzed cycloisomerization in the synthesis of *trans*-fused tetrahydropyrans.

alkynes (e.g. **68**) could be cyclized to the corresponding furan (e.g. **69**) in high yield in the presence of [RuCl$_2$(*p*-cymene)PPh$_3$] and NaPF6 [Eq. (12)].[57]

(12)

68   **69** (89%)
A ruthenium vinylidene species is also invoked as an intermediate in the cyclization of 1-alkyne-6-allyl silanes **70** to produce 1,4-dienes **71**. Echavarren demonstrated that enyne **70** cyclized smoothly to diene **71** in the presence of the [CpRu(PPh$_3$)$_2$Cl] precatalyst and NaPF$_6$. The silane is proposed to stabilize the positive charge that develops during ring closure [Eq. (13)].[58] Ruthenium catalysis was also used

(13)

70   **71** (92%)
to mediate the alkenylation of pyridine to give 2-alkenyl pyridines **72**–**74** in high yield. The pyridine species is thought to undergo ligand exchange with one phosphine ligand, thereby placing the heterocycle proximal to the vinylidene moiety and thus enabling regioselective alkenylation [Eq. (14)]. Evidence for this mechanism was found by switching to a bidentate phosphine, dppe, which led to no alkenylation.[59]

(14)

73: R = *p*-MeC$_6$H$_4$ (92%)
74: R = 1-cyclohexenyl (75%)
Ruthenium vinylidenes can also participate in carbametalation reactions, and a number of these have emerged in the literature.[60] A particularly interesting example was revealed by Yi and co-workers: vinylidene complex **75** was found to catalyze the cross-coupling of *tert*-butyl acetylene (**76**) with a variety of alkynes (e.g. **77**) to give the addition products (e.g. **78** and **79**) in excellent yield [Eq. (15)].[61] Notably both

(15)

76   **77**   **78**: R = CO$_2$Me (76%)
79: R = Me (87%)
electron-poor and electron-rich alkynes functioned equally well in this cross-coupling reaction.

3. Additions via Allenylidene Complexes

Transition-metal–allenylidene complexes have attracted a great deal of attention in recent years owing to their interesting structural features as well the multitude of transformations they undergo.[62,63] Most syntheses are based on the spontaneous dehydration of propargylic alcohols first reported by Selegue, or on variations thereof.[64] Several stoichiometric metal–allenylidene complexes have been described, and their chemistry has been well documented.[13] Their use in non-metathesis catalytic applications, however, are less developed.

It was the potential for the activation of three carbon atoms that primarily evoked our interest in the use of Ru–allenylidene complexes in catalytic processes. At the outset, complexes had been utilized in stoichiometric amounts in several interesting settings, but no catalytic applications had been developed. The use of ruthenium–vinylidene complexes in the reconstitutive condensation (see Section 2) encouraged exploratory studies with allenylidene complexes. Specifically, the use of tethered nucleophiles could potentially trap the allenylidene complex, thereby generating a vinylidene complex that could undergo the standard reconstitutive addition, thus giving rise to a tandem cyclization–reconstitutive addition process (Scheme 8). The allenylidene complex **80** is expected to form readily from Ru complex **3** and the propargylic alcohol. The tethered hydroxy group would lead to concomitant formation of the tetrahydrofuran **81** as well as the vinylidene complex, which would undergo a standard reconstitutive addition (via **82**–**85**) as described previously.

ω-Hydroxypropargylic alcohols participated well to form both five- and six-membered cyclized products in good yield when exposed to catalytic [CpRu(Ph$_3$P)$_2$Cl] and NH$_4$PF$_6$ [Eq. (16)]. For example, diol **86** cyclized smoothly to give

(16)

86   **20**   **87** (57%)
bicycle **87** in very good yield (57%).[65] Similarly, the spiroketal subunit of calyculin A was accessed readily by subjecting propargylic alcohol **88** to the tandem cyclization–reconstitutive addition protocol [Eq. (17); Piv = pivaloyl][66] to give ketone **89**, a precursor for **90**.

More recently, Ru–allenylidene intermediates have been invoked in several fascinating reactions. For example, Hidai, Uemura, and co-workers have published extensively on the use of thiolate-bridged bimetallic ruthenium complex **91** in several Nicholas-type addition reactions to terminal propargylic alcohols.[67] They isolated the allenylidene complex **92**

(17)
Scheme 8. Tandem cyclization/reconstitutive addition of propargyl alcohols with allyl alcohols.

dicarbonyl compounds [Eq. (22)],[70] as well as amides, amines, phosphine oxides,[67] phenols,[71] and olefins.[72] Hidai, Uemura, and co-workers expanded the scope of this reaction to include thiols as nucleophiles as well as internal propargylic alcohols as electrophiles. In this case, a different mechanism to that proceeding through allenylidene complex (such as **92**) has been invoked.[73,74]

Another notable application by this group of researchers is the one-pot sequential Ru- and Pt-catalyzed formation of furans and pyrroles. Propargylic alcohols undergo Ru-catalyzed propargylic substitution by a ketone followed by Pt-catalyzed hydration/cyclization to give the desired heterocycle (e.g. **99**) in good yield [Eq. (23)].[74] This methodology is also amenable to the synthesis of pyrroles (e.g. **100**) by the addition of 1 equivalent of aniline [Eq. (24)]. In the latter case, a higher catalyst loading is required for complete conversions.

Notably, the synthetic chemist is not limited to Ru catalysis, as several groups have reported metal-catalyzed propargylic substitutions. For example, Mahrwald and co-workers developed a

in 84% yield by treating **91** with 1,1-ditolylpropargylic alcohol. Complex **92**, in turn, underwent substitution at the C_γ position when heated in ethanol to afford ether **93** in 89% [Eq. (18); Cp* = pentamethylcyclopentyl, Tol = tolyl].

(18)
The precatalyst **91** was screened in a number of different propargylic substitution reactions and found to be a very efficient and general catalyst system for the addition of a number of nucleophiles, including alcohols [Eq. (19)], ketones [Eq. (20)],[68] aromatic groups [Eq. (21)],[69] 1,3-

titanium-catalyzed propargylic substitution.[75] Toste and co-workers described the rhenium-catalyzed addition of alcohols,[76] allyl silanes,[77] and electron-rich aryl groups[78] to terminal and internal alkynes in excellent yields. Finally, Matsuda and co-workers reported the iridium-catalyzed alkylation of propargylic esters with enoxysilanes.[79]

4. Redox Isomerization

The adjustments of oxidation levels are transformations of fundamental importance in organic synthesis. These processes often suffer from poor atom economy, as they frequently require multiple steps and stoichiometric amounts of reagents. Thus, much effort has been expended on developing more-atom-economical ways to effect this transformation. The transformation of unsaturated alcohols (e.g. allylic alcohols) into their corresponding ketones or aldehydes represents an attractive one-step alternative to traditional reduction–oxidation procedures. Many catalyst systems based on transition metals have been developed.[80, 81] Among these, Ru-catalysis has occupied a central role ever since early work by Strohmeier and Weigelt[82] and later Pascal and Dedieu[83] demonstrated the utility of RuCl₃·3H₂O as a catalyst for the isomerization of allylic alcohols (e.g. **101**) into the corresponding aldehydes (e.g. **102**) [Eq. (25); TFE = trifluoroethanol].

$$(25)$$

101 → **102** (82%)

RuCl₃·3H₂O (0.6 mol%)
TFE, 70°C
The studies on the reconstitutive addition reaction revealed that some allylic alcohols were isomerized to saturated ketones by certain Ru complexes. This interesting observation warranted further examination, especially as the complexes in question had exhibited high chemoselectivity, which might overcome the inherent problems of chemoselectivity usually observed in transition-metal-catalyzed isomerization reactions. Indeed, compounds that contain isolated olefins (such as **103**) [Eq. (26)] undergo clean isomerization to yield the corresponding ketones **104** in excellent yield simply by exposing the allylic alcohols to
catalytic [CpRu(Ph₃P)₂Cl] (**1**) and triethylammonium hexafluorophosphate in hot dioxane; the isolated double bond is not affected.[84] Chemoselectivity was also demonstrated by the compatibility with free alcohols, esters, carbonyl groups, alkynes, and terminal alkenes.

Cyclic substrates along with sterically encumbered allylic alcohols reacted sluggishly with the cyclopentadienyl complex. The lower rates were attributed to the slower coordination of a sterically demanding olefin to the catalyst as well as the to the requirement that a coordination site must be liberated for β-hydrogen elimination. The dissociation of a phosphine group to free such a coordination site would be disfavored in this case as phosphine–Ru bond is stronger than the olefin–Ru bond. A decrease in the hapticity of the cyclopentadienyl ligand from η⁵ to η³ would also achieve the same result [Eq. (27)]. Thus, changing to a ligand that would

$$(27)$$

105 ⇌ **106**
more readily undergo a switch of hapticity was expected to enhance the reactivity in the isomerization of more-difficult substrates.[85] Indeed, the indenyl complex **105**[86–88] proved to be much more reactive and afforded the isomerized product **108** in excellent yield in only 2 h [Eq. (28)]. However, the increased reactivity is offset by some loss in chemoselectivity.

108: 83% for **105**
Scheme 9 outlines the mechanism for the redox isomerization of allylic alcohols. Initial coordination of the olefin and the allylic hydroxy group would give rise to a complex such as **109**. Subsequent β-hydride elimination leads to the ruthenium hydride **110**. Migratory insertion gives the ruthenaenolate **111**, which is readily protonated to give the aldehyde **112** with regeneration of the catalyst **3**. Deuterium-labeling experiments support this mechanism.[89]

Ru complexes that give the critical 14-electron species **3** more readily would probably serve as more-reactive isomerization catalysts. Indeed, complexes that bear more-labile ligands (e.g. [RuCp(PR₃)(MeCN)₂][PF₆]) have been examined and found to be more reactive; they allow the reaction to
Scheme 9. Postulated mechanism for the redox isomerization of allylic alcohols.

be carried out at lower temperatures.[90] Concomitant with increased reactivity, however, is lower chemoselectivity. Finally, other Ru complexes, including several Ru hydride species,[80] tetrapropylammonium perruthenate (TPAP),[91] and the Grubbs vinylidene-metathesis catalyst[92] have been found to catalyze the redox isomerization of allylic alcohols effectively.

The Ru-catalyzed isomerization distinguishes itself from other isomerization reactions as it is not limited to allylic alcohols. In fact, propargylic alcohols function equally well in the redox isomerization to form α,β-unsaturated carbonyl compounds. This transformation is normally effected by the Meyer–Schuster rearrangement, in which a propargylic hydroxy group is transposed.[93] Transition-metal-catalyzed isomerizations based on Pd,[94–96] Rh,[97] Ir,[98] and Ru[99] have been described. The latter employs tris(triphenylphosphane)-ruthenium dichloride precatalyst in combination with a trialkyl phosphine. This reaction did not show good reproducibility in our hands. Inspired by this and our success in the isomerization of allylic alcohols catalyzed by [CpRu-(Ph₃P)₂Cl] and triethylammonium hexafluorophosphate, we applied this methodology to the isomerization of propargylic alcohols. In the event, the indenyl catalyst **105** effected the redox isomerization of propargylic alcohols (e.g. **113**), cocatalyzed by indium(III) chloride and sodium hexafluorophosphate. Enals **114** [Eq. (29)], and enones **116** [Eq. (30)] are readily available by using this methodology.[100] The reaction is highly chemoselective and allows the presence of carbonyl, hydroxy, alkyne, and alkene groups.
The apparent analogy of the isomerization of propargyl alcohols into enones with that of allyl alcohols into saturated ketones is completely misleading. Mechanistic work indicates that an intramolecular 1,2-hydride migration is the critical step (Scheme 10) that gives rise to the presumed vinyl–

(30)
Scheme 10. Redox isomerization of propargylic alcohols.

ruthenium species **118** from **117**, in stark contrast to the mechanism of the redox isomerization of allyl alcohols. The exact role of the indium(III) salt is not entirely clear; most likely it functions as a halophile, and enables the formation of the coordinatively unsaturated ruthenium cation. The mechanistic proposal has been supported by deuterium-labeling experiments.[100]

5. The Ruthenium-Catalyzed Alkene–Alkyne Coupling Reaction

5.1. Background

The Alder-ene reaction[101,102] is a prime example of an atom-economic reaction that only involves a simple addition of an alkene **119** with allylic protons to an enophile acceptor, which is typically another unsaturated compound such as an alkyne **120**, to give the corresponding 1,4-diene **121** [Eq. (31)].

(29)

(31)
In a classical sense, this reaction is promoted by heat and is believed to take place through a supra-suprafacial *endo* or *exo* six-electron electrocyclization.[103] Electron-withdrawing groups on the enophile accelerate the coupling, and strong Lewis acids accentuate this effect.[104] Conversely, electron-rich alkenes can also greatly accelerate this reaction.[105–107] Although the thermal ene reaction has found some use in synthesis,[105,106] the generally harsh conditions required have limited its synthetic utility.

The expansion of the synthetic utility of this reaction requires the development of a catalyst that could selectivity carry out this type of transformation. It has long been known that palladium can mediate[108] and even catalyze[109] sigma-tropic reactions, and similar ene-type reactions were known with dienes catalyzed by rhodium[110–113] and palladium.[114] A major advance arose from discovery of the palladium-catalyzed formal Alder-ene-type reaction of enynes [Eq. (32)],[115,116] the alkene–alkyne addition.

$$\text{(32)}$$
For example, enyne **122** is readily cyclized to 1,4-diene **123** in 71% yield in the presence of [(Ph$_3$P)$_2$Pd(OAc)$_2$] (5 mol%). Previous to this work, several references to the oligimerization of alkynes and alkenes had appeared,[117–119] along with one case of allyl halide–alkyne coupling, which results in a 1,4-diene.[120] Related palladium-catalyzed alkene–alkyne coupling to yield 1,3-dienes have been noted,[121] as well as ruthenium-catalyzed alkyne–diene coupling to yield 1,3-enynes.[122] The mechanism of the palladium-catalyzed alkene–alkyne coupling reaction is clearly different from that of the thermal Alder-ene reaction, and thus selectivity can often be different.[123] The conditions of the catalytic reaction are generally mild, and its utility has been demonstrated in synthesis.[116] Palladium can be quite effective for the catalytic cycloisomerization of enynes, but, importantly, the intermolecular alkene–alkyne coupling reaction is not feasible under these conditions. Furthermore, 1,4- versus 1,3-diene formation is often substrate-controlled.[124] For example, a 1,3-diene is generally the major product if an allylic oxygen functionality or a tertiary carbon atom is present at the allylic position [Eq. (33)]. Catalytic palladium rapidly converts enyne **124** into the diene **125** as a single geometrical

$$\text{(33)}$$
isomer in 91% yield. In a related reaction, 1,3-dienes can also be obtained by using ruthenium catalysis in an intermolecular fashion from alkynes and α,β-unsaturated olefins [Eq. (34)].[125]

$$\text{(34)}$$
Given the factors listed above, the development of a general catalytic system that carries out the inter- and intramolecular alkene–alkyne coupling reaction with control of olefin geometry and regiochemistry would constitute an important synthetic development.

5.2. Intermolecular Alkene–Alkyne Coupling Reactions To Form 1,4-Dienes

Inspired by our successful development of the Ru-catalyzed reconstitutive addition reaction (see Section 2) in which a coordinatively unsaturated Ru complex derived from [CpRu(PPh$_3$)$_2$Cl] catalyzes the addition of an alkyne and an allylic alcohol,[22] we were interested to examine the effect of replacing the phosphine ligands with more-labile ligands, thereby generating a coordinatively more-unsaturated {CpRu} cationic complex that can catalyze alkene–alkyne coupling reactions.[126] This reaction could give rise to two regioisomeric products, a "branched" (**131**) and a "linear" 1,4-diene (**132**) [Eq. (35)].

$$\text{(35)}$$
Mechanistically, two scenarios may account for the addition reaction. First, an insertion of an alkyne into a π-allyl ruthenium hydride species generated through C–H activation could lead to the coupled products **131** and **132**. Alternatively, a mechanism that involves a ruthenacyclopentene intermediate, analogously to the well-known Pauson–Khand reaction[127] and the [2+2] addition of strained olefins and alkynes,[128] could be involved. Both mechanisms appear reasonable. Although the C–H activation mechanism was originally proposed,[129] it has since been found that the ruthenacycle mechanism explains many key features of this reaction more accurately (Scheme 11).

As alkynes are better ligands than alkenes, coordination of two molecules of alkyne and formation of ruthenacyclopentadiene is both possible and likely. However, no product
Scheme 11. Mechanistic rationale for the alkene–alkyne coupling reaction. L = solvent.

There are several factors that explain the observed isomeric products (i.e. **144** and **145**), of which the simplest is based on steric arguments (Scheme 12). Thus, in the path to branched products, steric interactions occur during the C–C bond-forming event, **146**, whereas in the pathway to linear products, steric interactions occur between the {CpRu}$^+$ moiety and the R group on a monosubstituted alkyne in the intermediate **138** following β-hydride elimination, rather than in the transition state **147**. Thus, the kinetically formed ruthenacycle is **136**, whereas **137** can lead to the major product under thermodynamically controlled conditions (i.e. when β-hydride elimination is slow). The inherent selectivity for branched products with simple alkenes and alkynes can be explained by assuming that the ruthenacyclopentene formation is fast and reversible when both isomers **137** and **136** (Scheme 12) are accessible (as should be the case with simple alkenes and alkynes).

Transition state **146** contains significant steric interaction in the formation of the ruthenacyclopentene **137**. The product formation, however, is not determined until

formation is seen though this pathway, presumably due to the reversible nature of the oxidative cyclization and the lack of productive pathways leading from the ruthenacyclopentadiene. Following coordination and cyclization to either of two ruthenium(IV) species, **136** and **137**, *syn* β-hydride elimination yields two different regioisomeric vinyl ruthenium species **138** and **139**, which undergo reductive elimination to yield the observed products **140** and **141** along with regeneration of the catalyst **133**. The coordination and subsequent cyclization of the alkyne can proceed in two distinct ways: 1) Coordination such that the R group on the alkyne is adjacent to ruthenium (i.e. **134**) leads to ruthenacyclopentene intermediate **136**, which thus results in "linear" product **140**. 2) Coordination and cyclization in the opposite regioisomeric sense (i.e. **135**) leads to "branched" product **141**. Presumably the olefin may coordinate in two different orientations, but the product derived from ruthenacyclopentene **A** is not observed. The principal reason for this is that the geometrical constraints of the endocyclic *syn* β-hydride elimination step are difficult to achieve in such a cyclic species.

To render this reaction truly synthetically useful, control of the two regioisomeric products is necessary. Indeed, when simple unfunctionalized monosubstituted alkenes and alkynes are subjected to a catalytic amount of {CpRu}, the "branched" isomer is typically favored, with ratios ranging from 5:1 to 10:1.[129] 1-Octyne (**142**) is coupled to 1-octene (**143**) to give "branched" 1,4-diene **144** selectively in a 5:1 ratio with "linear" 1,4-diene **145** [Eq. (36)]. Remarkably, no homocoupling products from either alkyne **142** or alkene **143** partner are isolated.

(36)

the β-hydride-elimination step, which is slower than the ruthenacyclopentene formation. As β-hydride elimination is disfavored in the path towards linear products owing to the accumulating steric strain resulting from β-elimination (i.e. **138**), the branched product is favored with simple unbranched alkenes and alkynes (Curtin–Hammet situation). However, this inherent selectivity can be modified through various pathways. Most simply, if the rate of β-hydride elimination is increased relative to ruthenacycle formation, then the kinetically formed ruthenacyclopentene **136** leads to the formation of predominantly "linear" products. Other factors that influence the inherent selectivity are discussed in this section.

The original catalyst discovered for this reaction was [CpRu(cod)Cl], which is a precatalyst for the presumed active species (CpRuL$_2$Cl or [CpRuL$_3$]Cl; L = solvent). The typical reaction conditions for this catalyst system involve the ruthenium catalyst (5 mol%) in a mixture of DMF (*N,N*-dimethylformamide) and water at 100 °C. Before any alkene–alkyne coupling takes place, cyclooctadiene reacts with one molecule of alkyne in an unusual ruthenium-catalyzed

Angew. Chem. Int. Ed. **2005**, *44*, 6630–6666
Scheme 12. Steric interactions in alkene–alkyne coupling.

[2+2+2] cycloaddition reaction.[130] This reaction results in a coordinatively more-unsaturated and thus more reactive ruthenium catalyst. The second-generation catalyst [CpRu(CH$_3$CN)$_3$]PF$_6$[131,132] is generally much more active, and under typical conditions the reaction is carried out at room temperature in acetone or DMF. Presumably the enhanced reactivity is due to the greater coordinative unsaturation provided by the absence of a chloride ion in the precatalyst and the rate of ligand exchange of the bound acetonitrile molecules.

The power of this methodology to assemble complex building blocks rapidly from simple alkenes and alkynes was demonstrated in the formal synthesis of alternaric acid (**148**)[133] (Scheme 13). In this example, the coupling of the unbranched alkyne **149** and the highly functionalized alkene **150** under standard conditions leads to predominantly branched product **151** (4.9:1 ratio). Interestingly, this ratio increased to 8.9:1 when the reaction was conducted under higher pressure.

The introduction of propargyl substituents leads to lower amounts of branched products. For example, propargylic oxygen substituents effectively reverse the observed regiochemistry such that linear products are favored. This result can be rationalized by assuming that both ruthenacyclopentanes must be readily accessible in order to produce branched products. If the rate of ruthenacyclopentene formation is retarded significantly owing to the presence of extreme steric interactions during C−C bond formation (i.e. **146**), then the β-hydride elimination is no longer the rate-limiting step, and the major product is determined by the kinetic ratio of ruthenacyclopentene intermediates **136** and **137**. An illustration of this effect is presented in Equation (37) (Bn = benzyl, TIPS = triisopropylsilyl) in the coupling of differentially protected alcohols **152** and **153** with alkene **154**.

In this case, changing the steric bulk of the propargylic protecting group from benzyl (i.e. **152**) to TIPS (i.e. **153**) alters the ratio of branched to linear products from 1:2 to 1:4. While the explanation for the propargylic oxygen effect could be
Scheme 13. Formal synthesis of alternaric acid (**148**). Fmoc = 9-fluorenylmethoxycarbonyl.

R	Yield (%)	155/156
Bn	82%	1 : 2
TIPS	68%	1 : 4
thought of as a coordination effect, the fact that a non-coordinating propargylic oxygen functionality (OTIPS) also promotes the formation of the linear product reinforces the notion of a primarily steric effect.[129]

Nearly exclusive formation of the linear product is possible when a tetrasubstituted center is adjacent to the alkyne. For example, 2-methyl-3-butyn-2-ol (**157**) reacts with monosubstituted olefin **158** in the presence of the second-generation catalyst to give the linear product **159** in excellent yield (91%) in a 32:1 ratio with respect to the corresponding branched isomer [Eq. (38)].[134]

(38)

159 (91%, 32:1)

(40)

165 (76%, 20:1)
Not surprisingly, the choice of solvent also plays a major role in determining the product ratios. For example, DMF generally favors production of the branched isomer, whereas acetone tends to produce a large fraction of linear product. This disparate behavior is due to the greater ligating ability of DMF relative to acetone. First, this would make the effective size of the ruthenium center larger, thus enhancing the steric effect present in **138** (Scheme 12). Furthermore, a more fully ligated ruthenium center decreases the rate of β-hydride elimination, as the latter requires an open coordination site. Essentially, the use of DMF as solvent decreases the rate of β-hydride elimination to the extent that the thermodynamic pathway (Scheme 12) becomes the major route. This effect is further enhanced in the presence of the chloride-free catalyst [CpRu(CH₃CN)₃]PF₆. For example, the reaction between 5-hexynenitrile (**160**) and alkene **161** in acetone with this catalyst leads to branched and linear products in a 1:1 ratio. However, switching the solvent to DMF resulted in a much improved ratio of 8:1 [Eq. (39)].[132]

(39)

Solvent	Yield (%)	**162/163**
acetone	78%	1 : 1.1
DMF	65%	8 : 1
The possibility of using disubstituted alkynes would dramatically expand the power and scope of this method.[135] The selectivity issue becomes even more complicated with unsymmetrical alkynes, as the regiodifferentiation with respect to the alkyne is greatly diminished. As was seen with monosubstituted alkynes, the selectivity is dominated by the presence of propargylic substituents. In the case at hand, the determining factor in product formation is not the propargylic alcohol moiety but rather the *tert*-butyl group of the alkyne **164**; the linear product **165** is formed almost exclusively [Eq. (40)].[135] This example demonstrates that a *tert*-butyl group is a more powerful director than an unhindered propargylic alcohol.[135] This is plausible due to the
greater steric bulk of the *tert*-butyl group and again reiterates that coordination is not a major factor in determining the regiochemistry.

The propargylic alcohol may still be a significant directing group in simple disubstituted alkynes. For example, when but-2-yn-1-ol (**166**) is coupled to a monosubstituted olefin **161**, there is seemingly little steric difference between the two propargylic positions. Still the propargylic hydroxy group directs the C–C bond formation at the alkyne carbon atom distal to the hydroxy group and results in a 6:1 ratio in favor of the isomer **167** [Eq. (41)].

(41)

167 (71%, 6:1)
Clearly, the steric difference between a methyl group and a primary propargylic alcohol is minimal, and thus the selectivity arises from the differing electronic properties. The electron-withdrawing nature of the hydroxy group preferentially promotes the formation of linear products. This effect has been exploited successfully in a key step in the total synthesis of callipeltoside A (**168**) (Scheme 14).[136,137] The functionalized propargylic ether **169** was treated with protected alcohol **170** to give the 1,4-diene **171** as a single regioisomer in 85% yield, as a result of carbon–carbon bond formation distal to the propargylic oxygen atom.

The carbon–carbon bond formation can also be directed to the distal carbon atom to a lesser degree by homopropargylic alcohols. The ratio for simple homopropargylic alcohols is generally approximately 4:1 in favor of linear products. If some steric bias is included (secondary or tertiary alcohol), then this selectivity can be raised to excellent levels [Eq. (42)].[135] For example, cyclohexanol **172** gave almost exclusively linear product **174** when coupled to alkene **173**.

In general, the effect of simple steric and electronic factors can be summarized as follows: In the absence of propargylic substituents, branched isomers are favored. However, when propargylic substituents are present, then the steric demand at the forming C–C bond leads to larger

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
Scheme 14. Total synthesis of callipeltoside A (**168**). Troc = trichloro-ethoxycarbonyl.
proportions of linear products. When proximal polar functional groups are present on the alkyne, linear products are favored.
Yet another way that the selectivity rules can be modified is with a change to the more sterically demanding catalyst $[Cp*Ru(CH_3CN)_3]PF_6$, in which the cyclopentadienyl ligand has been replaced with the sterically encumbered pentamethylcyclopentadienyl (Cp*) ligand. This was elegantly illustrated in the synthesis of the proposed structure of amphidinolide A (**175**).[138, 139] The target molecule was rapidly assembled through an intermolecular followed by an intramolecular alkene–alkyne coupling reaction (Scheme 15).[140]

As one would anticipate from the above discussion, with either of the standard catalysts, the selectivity in the first alkene–alkyne coupling between **176** and **177** tends towards the linear product because of the propargylic oxygen substituent. The branched product **178** can be favored, however, if a bulky catalyst is used, which disfavors alkyne substituents near the ruthenium center (see **136**). The steric interaction of the {Cp*Ru} moiety is more severe in the potential intermediate **136**; thus the pathway towards branched products predominates. The $[Cp*Ru(CH_3CN)_3]PF_6$ catalyst resulted in a 3.5:1 ratio of branched to linear isomers (46% yield of isolated product, 76% based on recovered **178**). Although it is unclear that the same factors that govern intermolecular reaction would also be applicable to a macrocyclization, the second alkene–alkyne coupling reaction of **179** proceeds to favor the branched product **180** in 58% yield; this result was anticipated given that neither alkyne nor alkene partner has severe bulk or functionality that could readily coordinate. The efficiency of this macrocyclization is noteworthy, as it is significantly more effective than either Stille cross-coupling[141] or olefin metathesis[142] in the formation of the same ring system. More recently, the robust nature of the ruthenium-catalyzed alkene–alkyne coupling reaction as well as the extraordinary chemoselectivity was demonstrated in the determination of the correct structure of amphidinolide A.[143] Nine different amphidinolide diastereomers were synthesized by using this chemistry, finally resulting in the identification of the natural isomer.

Scheme 15. Total synthesis of amphidinolide A (**175**). Fm = fluorenylmethyl; brsm = based on recovered starting material.

Another member of the amphidinolide family of natural products, namely amphidinolide P (**181**), was recently synthesized by using an alkene–alkyne coupling reaction (Scheme 16). In the key step, monosubstituted olefin **182** was coupled with enyne **183** with complete selectivity for
Scheme 16. Synthesis of amphidinolide P (**181**).

formation of the branched product **184**, which was isolated in 75% yield. Apparently, conjugation increases the rate of the equilibration of the ruthenacycles and thus results in a greater selectivity for the branched product. The synthesis of amphidinolide P (**181**) highlights several features of the Ru-catalyzed alkene–alkyne coupling: 1) the remarkable chemo-selectivity of the Ru catalyst—four double bonds are present in the two partners, but only the monosubstituted alkene function reacts; 2) the sensitive β-lactone is also tolerated under the reaction conditions; 3) an enyne may participate in the coupling reaction.

The propargylic steric effects alluded to earlier can be utilized to an even greater extent through the use of alkynyl silanes. The bulky silyl group on the alkyne **185** acts in a similar fashion to the *tert*-butyl group, but the vinyl silane products have further synthetic utility owing to the variety of subsequent transformations possible, including cross-coupling,[144] *ipso* substitution with halides,[145] and oxidation.[146] A wide variety of silyl groups can be used to give exclusively products resulting from carbon–carbon bond formation distal to the silyl group **187** [Eq. (43)].[147] This effect can be thought of in purely steric terms, but an electronic factor could also be contributing: Silicon is well known to stabilize positive charge in the β position, and in this case one could visualize attack of the olefin at this partially positive alkyne terminus (i.e. **188**), which would lead to the branched regioisomer **189**.

The ability of alkynyl silanes to give exclusively branched products opens up a wide range of potential synthetic applications, exemplified by the formal synthesis of (−)-mycalamide A (**190**) (Scheme 17).[148] In the key step for the construction of the pyran moiety **191**, the functionalized alkyne **192** was coupled to β,γ-unsaturated alkene **193** to afford the 1,4-diene **194** in 63% yield as a single regioisomer. The coupling is noteworthy as the β,γ-unsaturation is isomerized into conjugation with the ester as a result of the reaction. In the case at hand, the trimethylsilyl group was

simply protodesilylated, thereby unmasking the delicate exo methylene functionality present in the target molecule **190**. However, the trimethylsilyl group served two important roles in this synthesis. First, the TMS group controlled the regioselectivity of the coupling reaction, and secondly it also stabilized the olefin in the desired exo position until this sensitive functionality could be revealed later in the synthesis.

The highly selective coupling reaction with alkynyl silanes may be combined with other metal-catalyzed processes, such as the palladium-catalyzed cyclization of nitrogen and oxygen nucleophiles onto π-allyl species. This tandem process could give access to a wide variety of heterocycles in an expeditious manner.[145] For example, the *N*-protected alkynylsilane **195** is readily coupled to *para*-nitrophenyl-protected homoallyl alcohol **196** to give **197** as a single regioisomer [Eq. (44); Ns = 4-nitrophenylsulfonyl, PNP = 2,6-bis(diphenylphospha-nylmethyl)pyridine, DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene]. The diene **197** may be added without isolation to an asymmetric palladium catalyst (derived from ligand **198** under basic conditions) to afford the pyrrolidine **199** in 90% yield with 91% *ee*. This process also gave access to six-membered nitrogen heterocycles as well as five- and six-membered oxygen heterocycles.[145] In this case, the alkyne–

(44)

(45)
alkene coupling isomerizes the homoallyl ether **196** to the allylic ether **197**, thereby setting the stage for Pd-catalyzed π-allyl formation and subsequent trapping with the tethered nucleophile.

If a chiral homopropargylic alcohol (**200**, Scheme 18) is utilized as the coupling partner, either diastereomer **201** and **202** of the target heterocycles may be accessed, by simply switching the chirality of the ligand, **198** or *ent*-**198**, used in the second Pd-catalyzed step (Scheme 18). The ruthenium-catalyzed alkene–alkyne coupling reaction has also been coupled by means of Prins and Friedel–Crafts cyclizations to form various medium-sized rings in an expeditious fashion.[149] For example, silylpropargyl alcohol **203** was coupled to allyl ether **204** with complete regioselectivity to yield acetal **205** in good yield. Subsequently, a Sn-mediated Friedel–Crafts-type cyclization gave tricycle **206** in excellent yield [Eq. (45)].

The convergence of steric and electronic effects observed with alkynyl silanes can also be seen when alkynoates are used in the alkene–alkyne coupling reaction. Normally, addition of these Michael acceptors occurs at the β-carbon atom. This is also true for Lewis acid catalyzed ene reactions. In contrast, the major products in the presence of a ruthenium catalyst result from addition to the α-carbon atom. Moreover, in the case of γ-hydroxybutynoates such as **207** or **208**, the product reacts further under the conditions of the reaction to give the unsaturated lactone **209** [Eq. (46)].[150]
Both the ester and the hydroxy group contribute to the observed selectivity. The ester group potentially stabilizes a partial negative charge β to the ruthenium center in the initially formed ruthenacyclopentene **137** (Scheme 12). Whereas a simple unhindered substrate **207** leads to moderate levels of selectivity (2.9:1) in favor of addition α to the ester when coupled to olefin **161**, an increase in steric bulk at the propargylic position with two geminal methyl groups (i.e. **208**) results in excellent levels of selectivity (12.2:1).

This strategy was used in the synthesis and assignment of configuration of (+)-ancepsenolide (**211**; Scheme 19).[150,151] Its expedient assembly utilized a bidirectional coupling of propargylic alcohol **212** and diene **213** to afford the bislactone **214** in excellent yield. The latter, in turn, was transformed into the target molecule **211** by hydrogenation. A similar alkynoate–alkene coupling was also used in the synthesis of the squamocins, exemplified by squamocin E (**215**; Scheme 20).[152,153] Alkene **216** was coupled with alkynoate **212** regioselectively to produce **217**, which was readily
Scheme 19. Total synthesis of (+)-ancepsenolide (**211**).

converted into the target molecule **215** in only four steps. Similarly, squamocin K was produced in a single step from **217** by simple hydrogenation of the disubstituted double bond. Another related butenolide natural product, (+)-solamin, was also synthesized by using this methodology.[154]

Pyrrolinones such as **218** [Eq. (47)] are also readily accessible in a two-step protocol by this method.[155] In this case, propargylic amine **219** was coupled to triene **220**, which gave the unsaturated amine **221** in good yield. Lactamization of **221** upon treatment with a suitable Lewis acid gave lactam **218**. This example demonstrates the regioselectivity (4.2:1 ratio of α:β regioisomers) obtained with alkynoates, as well as

the remarkable chemoselectivity for monosubstituted olefins. No reaction was seen at the 1,3-diene portion of **220**, even though 1,3-dienes are generally more reactive than isolated olefins [Eq. (47)].

When the seemingly related α,β-unsaturated ynone **222** is used in this reaction, no 1,4-diene product is isolated. Interestingly, the half-open ruthenocene compound **223** is the only isolable product [Eq. (48)].[156] It is unclear why there
is such a marked difference between alkynoates and alkynones. Not only is catalytic turnover not seen, but the regiochemistry of the coupling is reversed as well.

With the first-generation catalyst, disubstituted olefins are unreactive; however, the cationic catalyst [CpRu-(CH$_3$CN)$_3$]PF$_6$ enables these substrates to react well. In a similar fashion for the propargyl alcohols for which steric bulk at the propargylic position is key for high regioselectivity, the more sterically hindered 1,1-disubstituted alkenes lead predominately to linear products. The steric bulk that directs the reactivity towards the linear product in this case comes from the olefin partner and not from the alkyne [Eq. (49)].[157]
Unhindered alkynoate **224** is cleanly coupled with 1,1-disubstituted olefin **225** to furnish the 1,4-diene **226** in 79% yield as a mixture of regioisomers (4.4:1 ratio).

The 1,4-diene products of alkene–alkyne coupling reaction can also be obtained in related, but less-atom-economic reactions, for example, indium-mediated allyl halide addition

Scheme 20. Total synthesis of (+)-squamocin E (**215**).

to alkynes,[158–161] Lewis acid catalyzed addition of allyl silanes/stannanes,[162–164] or palladium-catalyzed addition of allyl halides to alkynes.[165]

5.3. Ruthenium-Catalyzed Alkene–Alkyne Coupling Reactions That Do Not Result in Simple 1,4-dienes

Besides all the above-mentioned reactions and applications, the principles of alkene–alkyne coupling can be applied to several more specialized systems that give rise to products other than 1,4-dienes. Exposure of allyl alcohols to a phosphine-free {CpRu} catalyst system results in an alkene–alkyne coupling reaction to give γ,δ-unsaturated ketones or aldehydes.[126] When this coupling reaction is attempted with simple alkynes, mixtures of branched and linear products are obtained; however, the same principles discussed above can be used to tune the reaction to give largely a single product. An explanation for the increased production of linear isomer when allyl alcohols and ethers are used may lie in the weaker allylic C–H bond in these substrates which should increase the rate of β-hydride elimination, thus resulting in the formation of more linear/kinetic product (see Section 5.2). A combination of this effect with the tendency of tertiary propargylic alcohols **227** to promote linear product as well, leads to the generation of a single product **228** [Eq. (50)].[126] In this case, both electronic and steric factors lead primarily to the linear product. Dixneuf and co-workers also developed such a reaction.[166]

As detailed in Section 5.2, this inherent selectivity for linear product in the case of propargyl alcohols can be overcome with the more sterically bulky [Cp*Ru(cod)Cl] catalyst.[167] For example, the propargyl alcohol **229** can be coupled with excess allyl alcohol to yield tetrahydropyran **230** in excellent yield [Eq. (51)]. In contrast, when the less sterically encumbered [CpRu(MeCN₃)₃]PF₆ catalyst system is utilized in combination with a silyl-protected allyl alcohol

tionalized propargyl ether **233** reacts with Boc-protected allyl amine **234** to yield carbamate **235** in 65% yield as a mixture of regioisomers (2.5:1). In the presence of the standard {CpRu} catalyst used in these cases, the propargylic heteroatom functions as the directing element for the generation of primarily linear products. The ratio is lower mainly because the alkyne substrate is a secondary propargylic ether.

5.4. Multicomponent Alkene–alkyne Coupling Reactions

The indication that ruthenacyclopentenes are key intermediates in alkene–alkyne coupling reactions led to the investigation of whether nucleophiles could participate in addition reactions when no protons were available for β-hydride elimination. These reactions were designed to differ from the previously mentioned examples in that the proposed ruthenacyclopentene would be trapped by the addition of an external nucleophile (Scheme 21, path A) analogously to the alkyne/carboxylate addition chemistry to form vinyl esters developed by Dixneuf and co-workers.[170] Either water or HX could attack the ruthenacyclopentene **236** formed from an alkyne and a vinyl ketone to give ruthenacyclopentane intermediate **237**; β-hydride elimination and reductive elimination would then give ketone **238** or vinyl halide **239** (Scheme 21, path A).

The same products could also be produced through a *cis* or *trans* Wacker-type addition to the alkyne **240**, either by water to produce intermediate **241** or by halides to give intermediates **242** or **243**. Subsequent 1,4-addition to an acceptor alkene (Scheme 21, path B) would then yield **238** or **239**. The first of these processes explored was a three-component addition of a vinyl ketone, an alkyne, and water to form 1,5-diketones [Eq. (54)].[171] 4-Pentyn-1-ol (**245**) is coupled with methyl vinyl ketone (MVK) to yield 1,5-diketone **246** as the sole

identifiable product. This reaction works with a variety of terminal alkynes and vinyl ketones to serve as a versatile synthesis of 1,5-diketones. A related addition reaction with enones and propargylic alcohols (e.g. **247**) was developed to provide α,β-unsaturated 1,5-diketone products **248** [Eq. (55)].

The absence of any branched product, which would be anticipated at least in minor amounts, may lead one to propose a tandem Wacker/Michael non-ruthenacycle mechanism.

During the course of the development of the intermolecular hydrative alkyne/alkene coupling, side products containing vinyl chlorides were isolated. It was postulated that these products arose from competitive addition of chloride, which originates from the precatalyst, to the alkyne. This observation was explored, and the process was optimized (Scheme 22).[172,173] This reaction works well for a variety of mono- and disubstituted alkynes and monosubstituted vinyl ketones to give *E* vinyl chlorides and *Z* vinyl bromides in generally good yields. [CpRu(cod)Cl] was used as the catalyst for optimization of the chloride addition, but [CpRu-(CH₃CN)₃]PF₆ can also be used and leads to similar yields and *E/Z* selectivities.

For the chloride addition reaction, the observed isomeric mixtures can be rationalized by assuming that both *cis*- and

trans-chlororuthenation are possible in a Wacker-type mechanism. A less-polar solvent such as acetone leads predominantly to *Z* products—presumably due to the lower polarization of the Ru–Cl bond, thus leading to more internal attack and therefore the observed *Z* products. Even though the Ru–Cl bond is stronger than the Ru–Br bond,[174] increased amounts of *Z* products during bromide addition can be explained by the weaker nucleophilicity of bromide relative to that of chloride in aprotic solvents.[175] As a consequence, excellent *Z/E* ratios can be attained with bromide addition in acetone (Scheme 22).[176] The potential utility of this methodology has been demonstrated in an expeditious synthesis of various cyclopentanoids, for example, that of tetrahydrodicranenone (**252**) from the vinyl ketone **253** and alkyne **254** via vinyl bromide **255** (Scheme 23).[177,178]

We were drawn towards the possibility of expanding the scope of the three-component coupling to include a fourth component. Indeed, if the proposed tandem Wacker/Michael mechanism (Scheme 21, path B) is at play, then the addition of a vinyl ketone to the vinyl ruthenium species **256** should lead to a ruthenium enolate **257** [Eq. (56)]. Support for this mechanism could be gained if the enolate could be trapped with any species other than a proton, for example, an aldehyde. In fact, when alkyne **142**, halide source (Me₄NCl), vinyl ketone, and aldehyde **158** were combined under the standard reaction conditions the corresponding keto alcohol **259** was obtained [Eq. (57)].[179] The diastereoselectivity in the aldol addition step is generally quite high. The main limitation is that the inability to suppress completely the proton-quenched three-component coupling

leads to slightly lower yields. The resulting *syn* relationship following the aldol reaction indicates the preferential formation of the *Z* enolate.

More recently, it was shown that terminal alkynes can be added to vinyl ketones in a 1,4-fashion, thus showing the mechanistic diversity that can be obtained through the use of various ruthenium catalysts.[180,181] Furthermore, recent work demonstrated that treatment of strained olefins (such as **260**) with propargyl alcohol in the presence of a ruthenium catalyst give the corresponding cyclopropanes **261** in excellent yield [Eq. (58)].[182] The mechanism of this reaction is proposed to proceed via a ruthenacyclopentene, and diverges from the known [2+2][128] and [4+2] reactions[130] because of the presence of the propargyl alcohol moiety.
5.5. Cycloisomerization of Enynes To Form 1,4-Dienes

In a test of the synthetic versatility of the alkene–alkyne coupling reaction, the possibility of an intramolecular coupling reaction was also examined. Ruthenium has been shown to mediate a large variety of ring-closing reactions, including the widely used metathesis reactions,[183–185] many of which

have been thoroughly reviewed.[6] Furthermore, many metals have been shown to promote ene-type cyclizations or the related isomerizations to 1,3-dienes: palladium,[115] rhodium,[186,187] iridium,[188] titanium,[189] and other ruthenium systems.[190,191]

In fact, the ruthenium catalyzed alkene–alkyne coupling reactions to form 1,4-dienes can be applied very successfully in an intramolecular sense,[192] and a wide range of substrates function extremely well, including trisubstituted olefins **262** as well as electron-poor alkynes, to give the corresponding cycloisomerized product **263** in good yield [Eq. (59)]. This
method is complementary to the palladium-catalyzed reaction as selectivities are often different, and 1,4-dienes are almost always obtained with the {CpRu} catalysts. One of the biggest differences between the palladium- and the ruthenium-catalyzed systems is that allylic silyloxy functionality (i.e. **264**) leads to geometrically defined 1,4-dienol silyl ethers **265** [Eq. (60)],[193] in a similar manner to the intermolecular version (see [Eq. (52)]).
When unsymmetrical trisubstituted olefins are used, two possible β-hydride abstractions are possible which lead to two different products. However, in this system, one pathway is preferred to a large degree based on the original geometry of the olefin. As illustrated in Scheme 24, *E*-olefin **266** undergoes cycloisomerization to 1,4-diene **267** in moderate yield and good selectivity for formation of the trisubstituted double bond.[192] On the other hand, *Z* olefin **269** produces 1,1-disubstituted olefin **270** selectively.

This selectivity can be explained through analysis of intermediates **268** and **271**. In both cases, the pseudoequatorial substituent, which is determined by the starting geometry of the olefin, has a β-hydrogen atom adjacent to the metal such that the required overlap is easily obtained. These results are in contrast to the thermal ene reaction in which the olefin geometry has little effect on the allylic proton abstracted.[102] Generally, this cycloisomerization to 1,4-dienes is effective for the formation of five- and six-membered rings. Although the asymmetric version of the enyne cycloisomerization is not yet feasible with ruthenium catalysis, Zhang and co-workers have demonstrated that rhodium in combination with chiral phosphines can be quite effective for this task with a limited range of substrates.[194,195] The groups of Trost,[196] Ito,[197] and
Scheme 24. Regioselectivity control in the cycloisomerization of enynes.

Mikami[198–200] have also developed palladium-catalyzed systems for asymmetric enyne cyclo-isomerization.[201]

When the Ru-catalyzed enyne cycloisomerization is attempted with alkynoate substrates **272** that contain a tetrasubstituted propargylic center, an alternate reaction takes place to yield a seven-membered ring **273** [Eq. (61)].[202,203] In general, this reaction functions well for 1,6-enynoates with a *cis* methyl group and a tetrasubstituted propargylic carbon atom. 1,7-Enynoates give "normal" enyne cycloisomerization products (six-membered-ring 1,4-dienes), whereas 1,6-enynoates that lack a *cis* methyl group do not react well or result in "normal" five-membered-ring 1,4-dienes (if a *trans*-1,2-olefin is used).

rium-labeling experiments, which indicated that only protons from the *cis* methyl group are incorporated in the product.[203]

The hydrative alkyne vinyl ketone reaction (see Section 5.4) can also be carried out in an intramolecular fashion to form five- and six-membered rings. Various alkynes and vinyl ketones can be used, and it is noteworthy that, again, the use of the more active catalyst [CpRu-(MeCN₃)]PF₆ allows disubstituted alkenes to be used as is required in this intramolecular cyclization (Scheme 26).[204] In the first case, ynenone **278** undergoes the hydrative reac-

Scheme 25. Postulated mechanism for the formation of seven-membered rings.

The proposed mechanism of this reaction involves π-allyl formation through C–H activation (Scheme 25). Enynoate **272** coordinates to the ruthenium catalyst to form intermediate **274**. Subsequent C–H activation of the *cis* allylic hydrogen atoms gives intermediate **275**, which can undergo conjugate addition to the alkynoate to produce intermediates **276** and **277** as an equilibrium mixture. To produce a *cis* double bond in the seven-membered-ring product, **275** must be present as the *anti* π-allyl species. The addition could also form a five-membered ring from the opposite end of the π-allyl system; however, this addition is only seen in the formation of six-membered rings. The product **273** is then released following β-hydride elimination from **276**. No product is seen from **277** owing to the severe allylic strain that would occur after β-hydride elimination. This mechanism is supported by deute-

tion just as in the intermolecular case to yield 1,5-diketone **279** in good yield. However, when the reaction is carried out under anhydrous conditions, [4+2] cycloaddition takes place to yield the pyran **280**. The production of the pyran products supports the ruthenacyle mechanism. The formation of ruthenacyclopentene **281** followed by isomerization to the
Scheme 26. Hydrative cyclization and [4+2] cycloaddition of ynenones.

oxygen-bound enolate (**282**) and reductive elimination account for the observed product **280** (Scheme 27).

Such pyran products can sometimes also be isolated through intermolecular hydrative cyclization. This observation suggests that all the products result from this type of mechanism, with diketones simply arising by hydrolysis of the initially formed pyrans. However, a different mechanism cannot be excluded for reactions carried out under anhydrous conditions.
Scheme 27. Postulated mechanism for the [4+2] cycloaddition ynenones.

5.6. Related Ruthenium-Catalyzed Cycloisomerizations of Enynes

Ruthenium can also catalyze many other reactions of enynes through ruthenacyclopentene intermediates, and several comprehensive reviews are available.[6, 205] Some of the more recent applications are detailed in this section. If no β-hydride elimination pathway is available to an enyne, 1,3-dienes can be formed by utilizing ruthenium hydride catalysts,[190, 206] in analogy to palladium-catalyzed chemistry.[116]

Monosubstituted enyne **283** [Eq. (62)] undergoes cycloisomerization to 1,3-diene **284** in the presence of [Cp*Ru-
(cod)Cl] in acetic acid, whereas highly functionalized ynenoate **285** is cyclized to 1,3-diene **286** when treated with a ruthenium hydride catalyst [Eq. (63)]. Besides this modifica-

tion of the substrate and catalyst to control the direction of the reaction, different ruthenium catalysts can be used to alter the reaction pathway.
Under an atmosphere of CO and in the presence of a dimeric ruthenium carbonyl catalyst, an enyne (e.g. **287**) that bears a terminal alkyne and an appropriately substituted alkene undergoes an enyne-metathesis reaction to give rearranged 1,3-dienes **288** [Eq. (64)].[207] The mechanism of
this reaction is unknown, but, analogously to the alkene–alkyne coupling reaction, is presumed to go through a ruthenacycle intermediate. In another related reaction, an appropriately substituted dienyne **289** can be transformed into a complex tetracyclic product **290**, which contains two cyclopropane units [Eq. (65)].[208]
The proposed ruthenacyclopentane may be intercepted by small, coordinating molecules such as CO; in this case, the reaction is a ruthenium-catalyzed version of the venerable Pauson–Khand reaction [Eq. (66); *N,N*-dimethylacetamide]
and affords a variety of ketones (e.g. **292**).[209] Similarly, catalytic ruthenium complexes can also promote hetero-Pauson–Khand reactions in which a tethered aldehyde (e.g. **293**) acts as one unsaturated component to produce, after carbonylation, unsaturated lactones **294** [Eq. (67)].[210]

5.7. Ruthenium-Catalyzed Alkyne–Alkyne and Diyne-Coupling Reactions

Whereas Section 5.6 dealt with the coupling of an alkene and an alkyne, Section 5.7 describes various ruthenium-catalyzed alkyne–alkyne coupling reactions. Ruthenacyclopentenes are

(67)

293 → **294 (74%)**
believed to be key intermediates in the former case, whereas the corresponding ruthenacyclopentadienes are frequently invoked in the latter processes. The simplest example of an alkyne–alkyne addition reaction is the metal-catalyzed dimerization of terminal alkynes **295** to produce enynes[211–213] or 1,3-dienol esters **296** when carried out in the presence of a carboxylic acid (e.g. acetic acid) [Eq. (68)].[214,215]

(68)

295
2 equiv.

296 (90%)
Two alkynes can also be coupled by the addition of a third unsaturated component through a [2+2+2] cycloaddition. Reactions of this type can be catalyzed by many different metals.[216–219] The use of ruthenium in a wide range of intramolecular [2+2+2] cycloadditions is also well established. The mechanism proposed for these reactions involves the formation of a ruthenacyclopentadiene **298** from a diyne **297** [Eq. (69)], followed by cycloaddition or insertion of

(69)

297 → **298** → **299**
another unsaturated molecule to yield, after expulsion of ruthenium, cyclized products **299**.

When all three components are alkynes, benzenoid compounds are formed.[220] A particularly intriguing application of this concept was recently described by Yamamoto and co-workers [Eq. (70); Cy = cyclohexyl, dba = *trans,trans*-dibenzylideneacetone]:[221] To achieve complete regioselectivity in the cycloaddition, a boronic acid **300** was used. It is thought that a borononate ester is initially formed in situ from **300** and **301**. The boronate tethered
diyne then participates in a cycloaddition with 1-hexyne (**302**) to yield bicycle **303**, which was used directly in a Suzuki–Miyaura coupling with 4-iodoacetophenone to give **304** in 63% yield over two steps. In this example, the known[222] *meta* selectivity of the {Cp*Ru} catalyst was used to yield **304** as a single regioisomer.

The ruthenacyclopentadiene can also be trapped with various other unsaturated molecules. If an olefin[223] or a

(71)

305 + **306** → **307 (65%)**
diene[224] is substituted for the third alkyne moiety, cyclic dienes and trienes can be formed [Eq. (71)]. The use of diyne **305** and diene **306** is key to the isolation of cyclooctatriene **307** in good yields. Less-substituted 1,3-dienes give significant amounts of vinyl cyclohexadiene products as well. The mechanism of this reaction is proposed to involve insertion of one double bond of the diene into ruthenacyclopentadiene **298** [Eq. (69)], β-hydride elimination, reductive elimination, and conrotatory 8π-electrocyclization. A variety of heterocycles can also be accessed through this general concept. For example, activated nitriles **308** undergo cycloaddition with diyne **305** to yield substituted pyridines **309** [Eq. (72)].[225–228]

Simple nitriles generally do not function well in this reaction, and require activation by an electron-withdrawing group or adjacent coordinating nitrile. It has been proposed that reactions with electron-deficient nitriles proceed via an azaruthenacyclopentadiene instead of the all-carbon analogue. Heterocumulenes also participate readily to produce pyridones **310** from diynes **311** and isocyanates **312** [Eq. (73)].[229] 2*H*-Thiopyran-2-imines are formed from isothiocyanates,[230] and dithiopyrones from carbon disulfide.[230]

(72)

305 + **308** → **309 (72%)**

(70)

300 + **301** → **302** (4 equiv.) → **303** → **304 (63%)**

(73)

(76)
Other quite different ruthenium-catalyzed alkyne–alkyne cycloaddition reactions are also known. For example, a versatile synthesis of bicyclic catechol derivatives proceeds in the presence of a ruthenium carbonyl complex [Eq. (74)].[231] In this transformation, two molecules of

(74)
carbon monoxide are incorporated to form catechol derivative **315**, reportedly through the formation of a hydrido ruthenium carbyne in situ. Along with the well-known alkene and enyne metathesis reactions, ruthenium complexes can also promote metathesis-type processes with diynes.

A recent example employs a tandem diyne cycloisomerization/cross-olefin metathesis to yield 1,3,5-trienes [Eq. (75)].[232] Various diynes (e.g. **311**) and olefins (e.g. **231**)

(75)
may be utilized. The *E/Z* selectivity, however, is low unless the olefin bears a bulky group (e.g. TBSO).

Activated carbonyl compounds participate in a cycloaddition-type reaction to form highly unsaturated carbonyl compounds [Eq. (76)]:[233] The unsymmetrical diyne **317** undergoes coupling with diethyl ketomalonate (**318**) to yield unsaturated ketone **320**. Although the mechanism is unknown, a cycloaddition is proposed that presumably would give 2*H*-pyran **319**; an electrocyclic opening would then yield the product **320**.

Analogously, a range of propargylic alcohols (e.g. **321**) dimerize in the presence of a {CpRu} catalyst to produce α,β,γ,δ-unsaturated ketones **322** in good to excellent yields [Eq. (77)].[234] The conditions of the reaction have been optimized to yield exclusively the
α,β-*Z* olefin isomer, as well as a single γ,δ geometrical isomer if there is branching in the alkyl substituent.

A mechanistic rationale for this unusual dimerization is represented in Scheme 28. Initial coordination of two alkyne molecules to the coordinatively unsaturated Ru catalyst forms the complex **323**. After cyclization to ruthenacyclopentadiene **324**, a molecule of water is expelled to give carbene intermediate **326**. Water then presumably adds again to the carbene carbon atom, thus resulting in an overall 1,4-shift of the hydroxy group to give intermediate **327**, which upon β-hydride elimination and reductive elimination releases product **329** (via vinyl ruthenium species **328**). The expulsion of a molecule of water is depicted as a simple elimination, but could also be viewed as a series of 1,2-shifts. The degree of reactivity of the propargyl alcohols in this reaction is linked to the leaving-group ability of the alcohol, with tertiary or

(77)
Scheme 28. Mechanistic rationale for the dimerization of propargyl alcohols.

secondary benzylic being the best. This mechanism is supported by the formation of the thermodynamically less stable Z-olefin isomer, as well as by the isolation, under different reaction conditions, of other products that should result from alternate ruthenacyclopentadiene isomer **325**. Additionally, a vinylidene-based mechanism is unlikely given the fact that internal alkynes also react, albeit with a lower efficiency. The more-electron-rich and sterically encumbered complex [Cp*Ru(CH$_3$CN)$_3$]PF$_6$ may also be used in this reaction to form unsaturated aldehyde hemiacetal products from ruthenacyclopentadiene **325** [Eq. (78)].

(78)
When this type of reaction is carried out in DMF with the 1-ethynylcyclobutanol **333**, then a different reaction manifold is accessed to produce the 1,3-diene **334** [Eq. (79)].[235] The

(79)
mechanism of this ring expansion/dimerization is proposed to proceed via a ruthenacyclopentadiene similar to **325** (Scheme 25), but prior to elimination, a 1,2-alkyl shift occurs to expand the four-membered ring into a five-membered ring (Scheme 29).

The reason for this type of reaction occurring and not the previously mentioned elimination-type reaction (see [Eq. (77)]) is likely related to the change in solvent as well as the presence of the cyclobutane ring. Attempts to perform the same transformation with alkyne **330** in DMF led to a very sluggish reaction, which indicates that the elimination is disfavored in this solvent. Thus, with a slow elimination, the ring expansion can occur. Notably, higher temperatures are required for the ring expansion/dimerization to proceed.

A completely different, but related, dimerization of similar tertiary propargylic alcohol substrates is possible in the presence of [CpRu(cod)Cl] catalyst in isoprene [Eq. (80)].[236] Tertiary propargylic alcohols (e.g. **340**) dimerize

(80)
Scheme 29. Mechanistic rationale for the ring-expansion/dimerization of acetylenylcyclobutanols.

upon addition of a carboxylic acid to form alkylidene cyclobutenes (e.g. **341**) in moderate to good yields. The mechanism of this reaction is proposed to proceed through ruthenium cyclobutadiene complexes, one of which (**344**, Scheme 30) was isolated and characterized by X-ray crystallography. The reason for the observed difference in reactivity is likely to be related to the use of a {Cp*Ru} complex in combination with the very nonpolar solvent.

A similar dimerization of allenyl alcohols in the presence of the same ruthenium catalyst to produce 1,4-dienol esters was recently reported by Ihara and co-workers.[237] Based on these mechanisms, we believed that only a single propargylic alcohol should be required for a reaction to take place, and a cross-coupling between an unfunctionalized alkyne and a propargylic alcohol should therefore be possible. Indeed, an intramolecular version works well to form a wide range of five- and six-membered rings [Eq. (81)].[238] In this case, a

(81)
bicyclic product **348** is formed in very high yield in the presence of only 1 mol% of catalyst. In contrast to the intermolecular dimerization, even secondary and primary propargyl alcohols function well in this cycloisomerization reaction.

The utility of this method was demonstrated in the total synthesis of (+)-α-kainic acid (**350**; Scheme 31).[239] In this

Scheme 30. Postulated mechanism for the dimerization of propargyl alcohols upon addition of carboxylic acids.

Scheme 31. Synthesis of (+)-α-kainic acid (**350**).

which resulted from the addition of a molecule of water to the starting diyne **353** [Eq. (82)]. This result led us to believe that a hydrative diyne cyclization could be possible, thus enabling the transformation of diynes into enones. We envisioned a mechanism for the reaction based on the addition of water to a ruthenacyclopentadiene/ruthenacyclopenta-triene intermediate in analogy to the mechanism proposed by Kirchner and co-workers[240] and by Dixneuf and co-workers[214,215] (Scheme 32).

Attack of a molecule of water on ruthenacyclopentadiene **356**, or its tautomer **357**, would give carbene **358**, which could, in turn, rearrange to vinyl ruthenium species **359**. Protonation would yield dienol **360**, which would readily tautomerize to the observed product **361**. This process works for a variety of diynes. For example, simple, symmetrical diynes **362** are converted into unsaturated ketones **363** in high yield and selectivity in the presence of only 5 mol% of catalyst [Eq. (83)].[241]

This hydrative cyclization works well for the formation of a broad array of five- and six-membered ring enones and is tolerant of most functionalities, including epoxides. Even more dramatic is the chemoselective addition of water to unsymmetrical diynes (e.g. **364** and **366**) [Eq. (84) and Eq. (85)], almost exclusively at the least sterically hindered alkyne. Thus, regioselective addition is possible if the steric differentiation (i.e. the branch site) is α to the alkyne (e.g. **364**) [Eq. (85)]. Excellent selectivity (~20:1) is realized if the steric element is β to the alkyne (e.g. **366**) [Eq. (85)]; even a hydroxy group may act as a branch site. The fact that the methanol-addition product was isolated when water was replaced with methanol lends further support to the proposed mechanism [Eq. (86)].

case, protected aminodiyne **351** underwent regioselective cycloisomerization to unsaturated ketone **352** in high yield and with no loss of enantiopurity at the propargylic center. This intermediate could be elaborated into the neuroexcitatory natural product (+)-α-kainic acid in several steps. The ability of the catalyst to cleave unhindered TBS ethers is exploited to cyclize the protected propargyl alcohol directly.

During the ruthenium-catalyzed reaction in the aforementioned synthesis of (+)-kainic acid (Scheme 31), we isolated a side product **354**,

Scheme 32. Mechanistic rationale for the hydrative diyne cyclization.

$$(82)$$

$$(83)$$

$$(84)$$

$$(85)$$

$$(86)$$

Remarkably, effects other than steric differentiation may be utilized to direct attack of water to either alkyne function in the diyne. For example, in the case of diyne **370**, which contain an alkene function conjugated to one of the alkyne groups, water adds to the sterically most encumbered alkyne to give ketone **372** (Scheme 33). If, on the other hand, the olefin is replaced with a methyl group (e.g. **371**), water is added, as expected, to the sterically least hindered alkyne to afford ketone **373**. The potential utility of the chemoselective hydrative diyne was demonstrated in the total synthesis of several cyclindricine alkaloid natural products, for example, cylindricine C (**376**; Scheme 33).[242]

6. The Allene–Alkene Addition via Ruthenacyclopentene Intermediates

Allenes constitute important building blocks in organic synthesis.[243] Recent developments have been extensively investigated in a wide array of transition-metal-catalyzed reactions of allenes in intra-[244] or intermolecular fashion.[245,246] In the latter case, several elegant Pd^{II}-catalyzed studies, in which allenes that contain several tethered nucleophiles were coupled with other unsaturated groups to give interesting heterocycles, were described by Ma and co-workers.[247–250]

After our successful application of alkynes in the alkene–alkyne coupling reactions it was tempting to pose the question as to whether other sp-hybridized species, such as allenes, may enter into similar mechanistic manifolds under Ru catalysis. Such a coupling reaction would give rise to 1,3-dienes, an important structural motif in organic synthesis.[251,252] The mechanistic proposal based on the alkene–alkyne reaction is detailed in Scheme 34. The active catalyst is envisioned to be the coordinatively unsaturated cationic ruthenium complex, which facilitates the coordination of the two reaction partners. Thus, initial bonding to the allenic C(sp) atom in **377** and the double bond of the enone **378** leads to the ruthenacyclopentane **380** via **379**. The stage is now set for β-hydride elimination, which generates a 1,3-diene **381**, with concomitant formation of a ruthenium hydride species. The steric constraints of the vinyl substituent and the exo methylene group would presumably favor the depicted conformation, which leads to the *E* isomer. Reductive elimination completes the catalytic cycle and regenerates the Ru^{II} catalyst. Importantly, a second runthenacyclopentane **383** may emanate from the initial coordination (step 1), but only **380** is capable of further reaction. Thus the formation of **383** is probably reversible, which enables equilibration to **380** and leads to a productive reaction.

The initial studies examined the reaction between allene **384** and MVK in the presence of [CpRu(cod)Cl] (10 mol %) and hydrated cerium(III) chloride in DMF. MVK was chosen to avoid β-elimination. In any event, the reaction gave the desired 1,3-diene **385** in satisfactory yield (66 %). We had discovered earlier that the activation of the [CpRu(cod)Cl] complex stemmed from a [2+2+2]-type cycloaddition of cod and the alkyne substrate. We reasoned that the allene moiety might be a poorer activator of ruthenium, and added a catalytic amount of an alkyne "activator" **386**, which gratifyingly increased the yield of the desired product **385** to 81 % (Scheme 35).[253] The 1,3-dienes obtained in this manner are useful intermediates; for example, treatment with maleic anhydride and acidic methanol gave bicyclic lactone **387** with excellent chemo- and diasteroselectivity as well as atom economy.

The reaction is not limited to monosubstituted allenes; in fact, polysubstituted systems may also be used in the two-component coupling. In these cases, regioselectivity issues may occur, but synthetically useful ratios are attained with suitable directing functionality, that is, either electronic or steric factors may control the regiochemical outcome of the
Scheme 33. Chemoselective hydrative diyne cyclization and application in the total synthesis of cyclindricine C (**376**).
reaction.[254] The use of a 1,1-disubstituted allene, for example, raises the question of regioselectivity in the β-hydrogen elimination, which may be influenced by placing an "activating" functional group proximally to the hydrogen atom. When a 1,1-disubstituted allene such as **388** is exposed to MVK and the cationic catalyst system, only the depicted regioisomer **389** is obtained. In this case, β-hydride elimination of **390** is greatly aided by the conjugated ester functionality, thus leading to exclusive elimination of H_B over H_A. When this functionality is reduced to the corresponding alcohol, no selectivity is observed, leading to a 1:1 ratio of regioisomers [Eq. (87)].

Steric strain is a useful way to induce regiocontrol in trisubstituted allenes. For example, allene **391** undergoes smooth reaction to afford regioisomer **392** in a 8.3:1 ratio with the other regioisomer in 70% combined yield (Scheme 36). The origins of the regioselectivity become apparent when considering the possible ruthenacyclopentanes emerging in the mechanism of this reaction: Two metallacycles **393** and **394**, which are formed reversibly, can be envisioned. The fact that the apparently more hindered ruthenacyclopentane **393** leads to the observed major product should not be surprising seeing that the reaction is under Curtin–Hammett control. As β-hydride elimination, not ruthenacyclopentane formation, is the product-determining step, the formation of **392** should be favored as β-hydride elimination relieves strain in the spirometallacycle **394**. The latter, on the other hand, develops considerable strain in the β-elimination step in which a tetrasubstituted exo double bond is formed. The synthetic utility of this substrate is evident when exposed to *N*-phenylmaleimide to generate the highly functionalized polycyclic system **396** in

Scheme 34. Proposed mechanism for allene–alkene coupling.

Scheme 36. Coupling of trisubstituted allenes with vinyl ketones.

excellent yield. The potential for this reaction to generate complexity rapidly should render it useful for diversity-oriented synthesis.[255,256]

The postulated mechanism for the formation of 1,3-dienes from the two-component coupling between allenes and vinyl ketones suggests the intermediacy of a ruthenacyclopentane. This ruthenacycle undergoes β-hydride elimination on the route towards the 1,3-diene (Scheme 31, step 2). The suggested presence of the allyl ruthenium moiety enticed us to

question whether this could serve in chemical transformations typical of other allyl metal complexes. The known susceptibility of such complexes towards nucleophilic attack suggested that a suitably tethered nucleophile might trap the incipient Ru allyl species faster than it underwent the β-hydride elimination.[257] At the time, relatively little was known about ruthenium-catalyzed allylic substitutions.[258] The scant precedence, nevertheless, encouraged us to explore the feasibility of this reaction. We were pleased to discover that tethered hydroxy groups and amines work well for the formation of bicyclic ethers (e.g. **398**) [Eq. (88)] and amines (e.g. **400**), respectively [Eq. (89)]. These reactions were run in the presence of the cationic catalyst and a Lewis acidic cocatalyst and enabled access to a wide range of five- and six-membered fused heterocycles with good diastereoselectivity. Carboxylates **401** are also competent nucleophiles in this reaction and generate structurally diverse lactones **402** in very good yields [Eq. (90)].[259]

Our working hypothesis for the mechanism is detailed in Scheme 37. The ruthenacyclopentane **405** intermediate can exist in an equilibrium with the π-allyl species **406**. In the absence of the tethered nucleophile, the intermediate **405** undergoes β-hydride elimination to reveal the 1,3-diene as described earlier (see Scheme 34). In the presence of a
Scheme 37. Postulated mechanism for Ru-catalyzed alkylative cyclization.

tethered nucleophile, however, the π-allyl **406** is trapped, resulting in the ring-closed neutral species **407**. Subsequent protonation releases the cyclized product **408** and regenerates the coordinatively unsaturated complex. Thus, product formation is critically dependent on the relative rates of β-hydride elimination and nucleophilic attack. In accord with this hypothesis, the formation of small rings should be favored, whereas medium-sized rings should be disfavored owing to the slower rates of cyclization. Similarly, when β-hydride elimination is favored, for example, by conjugation of the resulting double bond to an ester, no nucleophilic trapping is observed.

Ihara and co-workers reported an interesting alkylative ring expansion catalyzed by ruthenium that also intercepts the proposed π-allyl intermediate.[260] In this reaction, allenocyclobutanes such as **409** undergo alkylation with an activated olefin **410**, which in turn expands presumably via **412** to form the α-substituted cyclopentanone **411** in good to excellent yield [Eq. (91)].

Fujiwhara et al. recently disclosed a related cross-dimerization.[261] Although an allene is not involved as a coupling partner, it is nevertheless proposed to proceed via a ruthenacyclopentane intermediate. In the event, Fujiwhara et al. found that when isoprene and vinyl acetate was warmed in methanol in the presence of [CpRu(cod)Cl], the coupled products **413** and **414** were formed in 95% overall yield (96:4 ratio) [Eq. (92)].

(91)

(92)
7. Ruthenium-Catalyzed [5+2] Cycloaddition

A common theme for many of the reactions described herein invokes various ruthenacycles (e.g. **136**) as intermediates in our working mechanisms, the fate of which has been β-

hydride elimination to give the desired products. Spurred by our desire to extend our understanding of these intermediates, we pondered the possibility of placing a small, strained ring proximal to the double bond (e.g. **415**), analogous to the highly successful rhodium-catalyzed system pioneered by Wender and co-workers.[262–281] The key question in this mechanistic scenario would be whether the presence of a small, strained ring would lead to cleavage of the cyclopropyl moiety rather than to β-hydride elimination. If the latter could be suppressed, intermediates such as **415** should prove to be useful in higher-order cycloaddition reactions, and as such would provide an attractive alternative to the aforementioned Rh-catalyzed cycloadditions championed by Wender and co-workers.
Thus, inspired by the mechanistic underpinnings of the Ru-catalyzed alkyne–alkene coupling reaction and the Rh-catalyzed [5+2] cycloaddition, we proposed the mechanism illustrated below (Scheme 38). Initial complexation (see **417**) of the cationic ruthenium complex **416** and the vinyl cyclopropane leads to the ruthenacyclopentene **418**. This cyclopropylcarbinyl intermediate was expected to undergo a cyclopropylcarbinyl-to-homoallyl rearrangement to **419**, driven by the release of ring strain. Competitive β-elimination is suppressed in **418**, as it would necessarily lead to a highly strained alkylidenecyclopropane species. Finally, reductive
Scheme 38. Proposed mechanism for Ru-catalyzed [5+2] cycloaddition.

elimination would complete the catalytic cycle by formation of the cycloheptadiene **420** and regeneration of the Ru catalyst **416**.

Initial experiments in this program revealed that the Ru-catalyzed [5+2] cycloaddition proceeds with extraordinary efficiency. For example, catalyzed by [CpRu(MeCN)₃]PF₆ (10 mol%) in acetone at ambient temperature, the cyclopropylenyne **421** underwent cyclization to give the hexahydroazulene **422** in excellent yield after only 2 h [Eq. (93)].[282]

(93)
The investigation of substrates that contain more highly substituted backbones revealed that the 1,1-disubstituted cyclopropane **423** cyclized smoothly to give the corresponding bicycle **424** in excellent yield as a single diastereomer [Eq. (94)]. The reaction strongly favors the hydrogen atom at the newly formed bridgehead stereocenter to be *anti* with respect to the homoallylic hydroxy group.[283] This apparently general trend is in agreement with the Stork–Houk–Jäger "inside-alkoxy" model.[284–286]

The examination of substrates that contain 1,2-disubstituted cyclopropanes revealed several interesting trends. For

(94)
example, treatment of the 1,2-*cis*-disubstituted cyclopropane **425** with the Ru catalyst under standard conditions produced exclusively the diastereomer **426** [Eq. (95)]. Changing the group at C2 to an electron-withdrawing group (e.g. CHO; **427**) reveals a complete switch in regioselectivity [Eq. (96)] to give **428** as a single diastereomer.[287]

These observations show that the regioselectivity of the reaction of *cis*-disubstituted cyclopropanes may be controlled by simply switching the electronic nature of the substituent at C2; electron-withdrawing substituents show a total preference for cleaving the more-substituted cyclopropyl bond. In the case of electron-neutral or -donating substituents a preference for the less-substituted cyclopropyl bond is observed. For 1,2-*trans*-disubstituted cyclopropanes poorer selectivities are generally observed. In these cases, the best strategy for obtaining regioselective cyclopropyl cleavage is to alter the steric

(95)

(96)
demands of the substituents at C2. Notably, the reaction is completely diastereoselective in all the aforementioned cases.

The observed regio- and diastereoselectivities provide circumstantial evidence for the proposed mechanism and act as a guiding principle for applications of this chemistry. Thus, when considering the possible ruthenacyclopentenes **429** and
430, it appears evident that the *cis* substituent is better accommodated in structure **429** than in **430**, in which severe steric interactions lead to exclusive cleavage of the least-hindered cyclopropane bond. In the case of electron-withdrawing groups, the steric effect is offset by the strong preference for the cleavage of the more-substituted (i.e. weakest) bond. In the case of *trans*-cyclopropanes, it is clear that the R_{trans} substituent is easily accommodated in both conformers.

The extraordinarily mild conditions of the Ru-catalyzed [5+2] cycloaddition, combined with the regio- and diaster-

eocontrol that can be readily invoked, render this methodology highly suitable for applications to the total synthesis of bioactive natural products that contain the polyhydroazulene motif concealed in more-complex architectures. Indeed, complex polycyclic frameworks have been accessed by fusing the cyclopropane to various carbocyles (e.g. **431–433**) to give the desired tricycles (e.g. **434–436**) in excellent yields; these ring systems are present in many bioactive natural products [Eq. (97)].[288]

8. Summary and Outlook

Transition-metal catalysis provides a rich avenue of research opportunities that address key questions of selectivity and atom economy. In this regard, the extraordinary potential of Ru complexes to catalyze highly unusual and powerful transformations has added valuable processes to the synthetic toolbox. Yet one can only have a feeling that we have barely begun to scratch the surface of the immense possibilities afforded by Ru catalysis, particularly when considering the vast number of ruthenium complexes that may be synthesized combined with the incredible array of possible oxidation states possible for ruthenium. Indeed, only a handful of ruthenium species have been described herein, yet an impressive number of unusual and powerful transformations have been discovered. Thus, by careful design of novel catalysts combined with a semirational approach to reaction design, we should be able to tap into the virtually boundless opportunities for research provided by Ru catalysis in particular and transition metals in general. It is therefore with a great degree of confidence that we can assure that new reactions and processes will be discovered that address the goals of simultaneously decreasing the depletion of raw materials as well as the generation of waste, while satisfying the ever-expanding demand for sophisticated molecular targets.

Lysine-capped gold nanoparticles can be electrostatically assembled on the surface of *Bacillus cerius*, a Gram-Positive bacterium. The conductivity of the "gold-plated" bacteria assembly immobilized between electrodes is a function of the humidity experienced by the nanoparticles. For more details on this bioelectronic device, see the Communication by R. F. Saraf and V. Berry on the following pages.

Nanodevices

Self-Assembly of Nanoparticles on Live Bacterium: An Avenue to Fabricate Electronic Devices**

*Vikas Berry and Ravi F. Saraf**

Recently, hybrid structures of microorganisms with inorganic nanoscale moieties have received great interest owing to their potential in fabricating electronic systems. The electronic properties of metal nanoparticles, as a result of the single-electron transport of current,[1] make them ideal materials for nanodevices. Concomitantly, the nanostructure of micro-organisms such as bacteria,[2] viruses,[3,4] and yeast[5] are attractive scaffolds for the templating of metal nanoparticles through the interactions of the former with surface charges and the affinity of certain metals for specific biological molecules.[2–7] However, the key challenges in building hybrid devices are 1) to pattern nanostructures without destroying the biological construct of the microorganism and 2) to achieve active integration of a biological response to the electrical transport in a nanoparticle device.

Herein, we present a simple method to build hybrid devices that use the biological response of a microorganism to control the electrical properties of the system. In our design, a monolayer of gold nanoparticles is deposited on the peptido-glycan membrane of a live Gram-positive bacterium. The hydrophilic peptidoglycan membrane is then actuated by humidity to modulate the width of the electron-tunneling barrier between the metal nanoparticles. A decrease in interparticle separation by less than 0.2 nm (decrease in humidity from 20 to $\approx 0\%$) causes more than a 40-fold increase in tunneling current. Vapor sensors based on the increase in resistance due to separation of Au nanoparticles have been reported in three-dimensional (3D) clusters of Au nanoparticle/organic composite films.[8–10] In the present study, the coupling between the large expansion of an underlying hygroscopic bacterium membrane and the mono-layer of Au particles is key to achieving a larger change in current, by an order of magnitude, relative to the above-mentioned 3D nanocomposite devices, for which the change in current results from the swelling of an interparticle organic

phase. The method shown herein could be used to pattern various nanoscale inorganic materials, whose optical, electrical, and magnetic properties could be biologically controlled, and thereby lead to an important advance in the present technology.

Electrically percolating clusters of metal nanoparticles, in contrast to their microparticle cousins, are fundamentally different in terms of electrical properties as a result of the nature of interparticle electron transport.[1] On the nanoscale, the energy cost to insert a single electron in a nanoparticle is over 1–10 times greater than the thermal energy, and the flow of the interparticle current takes place through the transport of single electrons, as explicitly shown by transport studies on single nanoparticles,[11,12] their 2D and 3D assemblies,[13–16] and single-nanoparticle devices (such as single-electron transistors[17,18]). The above studies demonstrate that a percolating cluster of metal nanoparticles is a viable unit to fabricate single-electron devices, whereby micron-scale clusters allow an easy-to-fabricate, robust interconnection network for the nanodevice system. Because metal nanoparticles such as gold are stabilized in solution by electrostatic repulsion, the formation of a percolating cluster on physical substrates requires either an organic cross-linker to bind the particles[13,19] or a polyelectrolyte to shield the charge of the particles.[16,20] For biological substrates, the highly selective deposition of nanoparticles relies on either highly specific binding (such as DNA hybridization[21–23] or biotin–streptavi-din interactions[24]) or strong specific intermolecular inter-action (such as electrostatic interactions[25–27]).

Bacillus cereus, a Gram-positive bacterium, was deposited by using a previously described technique on a silicon substrate with a layer of 500 nm of thermally grown silica and gold electrode lines spaced 7 ± 0.2 microns apart and coated with poly(L-lysine) (average molecular weight 164 kDa).[2] In a typical deposition process, the bacteria were cultured in nutrient broth (Difco) in a shake flask for approximately 14 h at 30°C. The bacteria were subsequently filtered and centrifuged to extract similar sized cells that were around 4–6 μm in length and 0.8–1.0 μm in diameter. The bacteria were suspended again in sterile water and were deposited on the poly(L-lysine)-coated substrate. On the substrate, there are 20 sets of electrodes. The deposition time of the bacteria was approximately 10–15 min to form bridges spanning the Au electrodes. Usually, about 10 bridges were formed along the 10-mm-long Au electrode pair. The extracellular polymeric substances (EPS) on the bacteria (and around the bacterium) were removed by washing with 2N NaOH for 1 min. The bacteria-deposited chip was then immediately immersed in a solution of poly(L-lysine)-coated gold nanoparticles (of diameter $d = 30$ nm).[2] Highly controlled deposition of nanoparticles was achieved by regulating the deposition time in the solution of gold nanoparticles (see Figure 1 a–e). As the Au nanoparticles and the substrate are both positively charged, the deposition is highly selective with formation of the monolayer only on the negatively charged bacteria surface. However, a simple negative surface charge is not sufficient to obtain electrically percolating deposition. Figure 1 f shows the result of deposition of Au nanoparticles on a negatively charged physical surface prepared by

Figure 1. Scanning electron microscopy (SEM) images reveal the highly controlled and selective deposition on bacteria of poly(L-lysine)-coated 30-nm Au nanoparticles from a solution at pH 7 over a) 30 min, b) 1 h, c) 2 h, d) 4 h, and e) 8 h. f) Positively charged Au nanoparticles are deposited on a negatively charged PSS-coated lysine/SiO$_2$/Si substrate over 16 h. The Au nanoparticles percolate after deposition during 4 h on the bacteria, while no conduction is observed for the physical surface in (f). The small amount of multilayer formation with a long deposition time is due to contraction of the membrane through loss of water in the scanning electron microscope. Scale bar: 300 nm.

ment with concanavalin, the role of the acid in high-density deposition is justified.

A standard assay of PI/SYTO 9 dye was used to confirm the fate of the bacteria.[31] The green fluorescence in Figure 2 confirms that the bacteria survived the complete fabrication process of the device. As the integrity of the peptidoglycan surface membrane in which the teichoic acid molecular brush is imbedded is critical for the deposition of Au nanoparticles, the survival of the bacteria for the fabrication of the device is important: Any lysis of the bacteria (or release of EPS and/or internal bacterial fluids) will lead to ill-formed, nonfunctional devices.

The insets of Figure 3 show a typical bacterial bridge, coated with a monolayer of gold nanoparticles, con-

adsorbing a monolayer of poly-(sulfonated styrene) (PSS; 70 kDa with < 90% sulfonation) on the poly(L-lysine)-coated SiO$_2$/Si substrate. For maximal deposition, poly(L-lysine) and PSS were introduced at pH values of around 4 and 8.5, respectively, and 1 mM NaCl was added to the suspension of the nanoparticles at pH 7. However, the 2D packing density was found to be low and nonpercolating. X-ray reflectivity measurements showed that in the multilayer films of polyelectrolytes (in our case, PSS on poly(L-lysine)) the polymers are layered and their conformations are flat with no significant loops caused by multiple-point binding.[28] As a result, the mobility of the polymer is highly restricted. On the other hand, the polyelectrolyte on the bacterium surface, that is, teichoic acid (-OCH$_2$CH(OCH$_3$)CH$_2$OPO$_2$-), is a flexible "brush" that is tethered to the peptidoglycan surface at one end which leaves the remainder of the chain in high thermal motion (i.e. high mobility). Furthermore, because the brush contour length is typically around 18 nm,[29] it is reasonable to expect that the negatively charged teichoic acid molecule with its high mobility and chain flexibility may wrap over the positively charged Au nanoparticle up to a maximum possible subtended angle of 135° from the point of contact to minimize the free energy. A similar screening of charge by PSS would be difficult in the case of the PSS–poly(L-lysine) structure owing to restricted mobility. Specific attachment of a con-canavalin–fluorescein isothiocyanate dye conjugate to teichoic acid[30] followed by confocal microscopy confirmed the uniform distribution of the acid molecules on the bacterium. As no deposition of nanoparticles on the bacterium occurs subsequent to the neutralization of teichoic acid after attach-

Figure 2. The standard PI/SYTO 9 assay in combination with confocal microscopy is used to probe the survival of the bacteria at various stages of the fabrication process: a) immediately after immobilization from the nutrient broth on the substrate; b) after deposition of the gold nanoparticles over 4 h; and c) after subjecting to 10^{-5} Torr vacuum for 2 h. The green and red fluorescence indicate that the bacteria are alive and dead, respectively.
Figure 3. Typical device current (I, normalized per bridge) as a function of relative humidity (H_{rel}) for "up" (i.e. decreasing humidity; △) and "down" cycles (i.e. increasing humidity; □) at a bias voltage of 10 V. The inset shows SEM images of two typical bacteria bridges which span the electrodes. The peripheral strip is a (percolating) monolayer of deposited gold nanoparticles.

nected to the gold electrodes. One bridge constitutes a device. All the currents reported subsequently were measured at 22°C and were normalized according to the number of bridges between the electrodes. Figure 3 depicts the normalized current, I, between the bridges as a function of the relative humidity, H_{rel}. The deposition of the Au nanoparticles was optimized for 4 h (see Figure 1) to obtain the largest change in current due to humidity. Figure 3 indicates that the device behavior is reversible and stable over a slow run, measured over approximately 40 min per cycle. Because of the complete reversibility of the device, it is unlikely that the water inside the bacteria plays any significant role. In contrast to most impedance-based microelectronic humidity probes,[32] the resistance of this device decreases as humidity increases. The largest change in current, and hence the highest sensitivity, was observed for the low humidity region of $H_{rel} < 20\%$.

The simple model shown in Figure 4 explains the observation in Figure 3. As the humidity increases, the peptidoglycan membrane absorbs water. If it is assumed that there is no
Figure 4. Schematic showing two poly(L-lysine)-coated Au nanoparticles clutched by negatively charged teichoic acid molecules. The distance between the surfaces of the Au nanoparticles is given by a. The electron transport from left to right takes place across a mixture of organics (lysine, teichoic acid) and air. The role of the electric-field-inducing electron transport is discussed in Figures 3 and 5.

excess volume of absorbed water, the volume fraction of water absorbed is fH_{rel}, in which f is Henry's constant. If it is also assumed that there is affine swelling of the peptidoglycan membrane, the linear extension of the membrane due to absorption is $(1-fH_{rel})^{-1/3}$. As the nanoparticles are fixed on the membrane, the interparticle separation is given by $a/a_0 = (1-fH_{rel})^{-1/3}$, where a_0 is the separation at $H_{rel} = 0$. Also, as electron tunneling is the primary transport mechanism, the current is given by the Fowler–Nordheim equation [Eq. (1)],[33] where $K = (32\pi^2 m_e \varphi/h^2)^{0.5}$ (h is Planck's constant, m_e is the mass of an electron at rest, and φ is the barrier height at the nanoparticle/organic interface), R_B is the resistance to the leakage current from the peripheral as shown in Figure 3, R_0 is a normalization constant proportional to the resistance of the device at $H_{rel} = 0$, and V is the bias across the device (i.e. the bacteria bridge).

$$I = \left\{ \frac{V}{R_0} \exp\left[-\frac{K a_0}{\sqrt[3]{(1-f H_{rel})}} \right] + \frac{V}{R_B} \right\} \tag{1}$$

We assume that the peripheral strip that leads to finite R_B is due to deposition of proteinaceous substances secreted by the bacterium (probably for adhesion to the substrate). To study the effect of water absorption by poly(L-lysine) on the performance of the device after the fabrication of the device, we capped the amine groups of poly(L-lysine) with glutaraldehyde to decrease the water uptake by lysine. No significant change in the performance of the device was observed which indicates that the role of moisture absorption by poly(L-lysine) on the performance is negligible.

Figure 5a shows the fit of the experimental results to Equation (1) for the same device at different bias V. Each exposure to humidity lasted approximately 40 min, and the lapse between consecutive runs was about 1 h on average. Although Equation (1) requires four fitting parameters, the validity of the model is justified because they are reasonably constant over all the biasing voltages (see Figure 5b). The constant R_B implies ohmic behavior (independent of H_{rel}) for leakage current given by $I_B = V/R_B$. This is reasonable because on the peripheral region, the nanoparticles are not located on the peptidoglycan membrane but adsorbed onto proteinaceous corona of the bacteria that do not change significantly in the lateral dimension with humidity. As the contact resistance is not expected to be large[2] and is a strong function of humidity, it is included in R_B. We also note that because the current through a bacteria bridge that lacks deposited gold nanoparticles is insignificant, ionic currents can be neglected.

Figure 5c shows the corrected current, $I-I_B$, which flows through the nanoparticle monolayer as a function of the change in the interparticle separation (estimated from f). Interestingly, for a humidity change from 20 to 0%, which corresponds to a calculated decrease of only 7% in the interparticle distance, the corrected current increases over 40-fold. As the corresponding increase in the total current I is only about sevenfold (see Figure 5a), a decrease in peripheral deposition will improve the device sensitivity significantly. The high sensitivity to subtle changes in the interparticle distance is attributed to transport by single-electron tunneling through the percolation network because the charging energy $e^2/(2\pi\varepsilon\varepsilon_0 d)$ (ε is the dielectric constant of the organic coating and is approximately 3; e is the electron charge) approximates to $1.5 kT$. Using the model parameters and a tunneling barrier of 5.1 eV (i.e. a is much larger than the thickness of the coating of poly(L-lysine) shown in Figure 4 at the metal–poly(L-lysine)/air/metal–poly(L-lysine) junction), the nanoparticle separation at 0% humidity was determined as about 2.3 nm, which implies an absolute change (for the 0–20% humidity range) of less than 0.2 nm. We note that the sensitivity is significantly lower for devices fabricated with deposition times of greater than 8 h and that ohmic I–V behavior is observed[2] in contrast to the non-ohmic behavior observed for devices prepared with deposition times of 4 h (see Figure 5d). At the other extreme, for a deposition time of 2 h the interparticle distance in the contiguous clusters is too large for a significant tunneling current to be observed. Thus, a combination of the exponential dependence on a and that $a \approx 2.3$ nm explains the high sensitivity of the system. Furthermore, in contrast to the earlier reports on gold nanoparticle/

organic composite thin-film sensors[8–10] in which electron transport takes place by thermionic emission or activated tunneling, electron transport in our device takes place through tunneling because the activation energy for tunneling is approximately 1.7 meV (see Figure 6), which is much lower than the thermal energy of a free electron ($kT \approx 25$ meV) at room temperature.

In summary, we have illustrated an approach to fabricate an active hybrid bioelectronic device using physical nano-materials and a live microorganism. The electrical properties of a monolayer of gold nanoparticles is controlled by actuating the peptidoglycan layer of the bacterium. An actuation of less than 8% in the peptidoglycan membrane, induced by a change in humidity from 20 to 0%, leads to more than a 40-fold increase in the tunneling current. These results open up an avenue to obtain active coupling between microorganisms and electrical, optical, and/or magnetic nano-devices. We believe that such hybrids will be the key to conceptually new electronic devices that can be integrated with microorganisms on flexible plasticlike substrates by using simple chemistry.

Framework Materials

$[Co_2(ppca)_2(H_2O)(V_4O_{12})_{0.5}]$: A Framework Material Exhibiting Reversible Shrinkage and Expansion through a Single-Crystal-to-Single-Crystal Transformation Involving a Change in the Cobalt Coordination Environment**

*Chun-Long Chen, Andrea M. Goforth, Mark D. Smith, Cheng-Yong Su, and Hans-Conrad zur Loye**

It is well known that many materials undergo structural phase transitions as a function of temperature, and that different atomic arrangements are stable in different temperature ranges. Although some of these phase transitions are irreversible, the original structure generally re-forms readily upon returning to the initial temperature. This process is fundamentally different from that observed for a small and rather unique category of organic–inorganic framework materials that exhibit so-called "dynamic structural changes".[1] In these materials, temperature changes lead to the reversible removal of guest molecules which is often accompanied by large atomic motion and significant changes in the framework structures.[1b,c] Importantly, the original framework structure is not restored by a temperature change, but rather by the reabsorption of the guest molecules.[2] As structural changes upon loss of guest-molecules are typically induced by heating of a porous three-dimensional framework, significant thermal stability, both in the presence and absence of guest molecules, is a necessity.

Dynamic structural changes induced by the removal/reabsorption of guest molecules are rare, and even less common are those structural changes that are caused by the removal/addition of ligands from the framework itself. Such changes in metal coordination environment can lead to changes in physical properties, for example, color, and could potentially lead to their use in sensing devices.[1,2]

Herein, we describe the synthesis and structural characterization of a new, mixed-metal 3D porous coordination polymer: $[\{[Co_2(ppca)_2(H_2O)(V_4O_{12})_{0.5}]\cdot 3.62 H_2O\}_n]$ (**1**, ppca = 4-(pyridin-4-yl)pyridine-2-carboxylic acid; Scheme 1),

Scheme 1. Structure of 2-pyrazinecarboxylate (left) and the much longer 4-(pyridin-4-yl)pyridine-2-carboxylic acid (ppca) (right).

which undergoes two distinct, reversible single-crystal-to-single-crystal transformations (Scheme 2). The first involves a volume change owing to the reversible removal of guest solvent molecules from the pores of the framework, where shrinkage occurs upon dehydration and reexpansion occurs upon reintroduction of the guests. The second process involves an unusual change in the coordination number of the cobalt center, from 6 (octahedral) to 5 (trigonal bipyramidal), with a concomitant color change.

Our group has previously explored heterometallic coordination polymers with the pyrazinecarboxylate ligand,[3] (Scheme 1) as the simultaneous presence of two different metals can give rise to increased structural diversity and, potentially, to unusual physical properties resulting from the synergistic interaction of two different metal centers.[4] The pyrazinecarboxylate ligand and its substituted derivatives have proven to be extremely versatile for the construction of mixed-metal framework structures because of their ability to engage in several different coordination modes.[3,5] In framework structures synthesized from pyrazinecarboxylate-based ligands, however, the cavity dimensions are limited by the length of the pyrazine ring. Consequently, to increase the cavity dimensions, we recently synthesized a new ligand, 4-(pyridin-4-yl)pyridine-2-carboxylic acid (Hppca) (Scheme 1),[6] which is significantly longer than the pyrazine-

carboxylate ligand, but maintains the same number, type, and arrangement of Lewis basic sites. Molecular modeling showed that the terminal N–N separation is about 7.10 Å in Hppca in contrast to 2.75 Å in pyrazinecarboxylate-based ligands. This extension of pyrazinecarboxylate chemistry allows the synthesis of frameworks with larger cavities than those observed in the pyrazinecarboxylate-based framework structures. Consequently, we are exploring the use of this ligand in the preparation of new mixed-metal systems, and herein we report an interesting new framework structure in which cobalt atoms are linked into a 2D array by ppca and cross-linked into a 3D array by vanadium-oxo units. It is well known that vanadium oxide groups are often engaged in the cross-linking of structural components and that they can promote the formation of unique structural geometries.[7] Whereas the coordination modes of the cobalt and the vanadium in this structure are fairly typical for these elements, surprising is the observation of dynamic structural changes that take place upon the thermal removal of both noncoordinated and coordinated water molecules, the process of which is highlighted herein.

The hydrothermal reaction of Hppca, $Co(NO_3)_2 \cdot 6H_2O$, and NH_4VO_3 in a 1:1:1 ratio at 160°C for 48 h yielded small, red, block-shaped crystals of the title compound. Structural analysis of **1** by single-crystal X-ray diffraction revealed that the vanadium centers are part of 1D mixed-metal chains, in which $\{V_4O_{12}\}$ cyclic units bridge neighboring 2D Co/ppca metal–organic layers to form a 3D open framework. The structure contains two crystallographically independent cobalt atoms, Co1 and Co2, which are both found in pseudooctahedral coordination environments. Co1 is coordinated to two oxygen atoms from two different $\{V_4O_{12}\}$ units and to three different ppca ligands; Co2 is likewise coordi-
Scheme 2. The reversible single-crystal-to-single-crystal transformations between **1**, **2**, and **3**; noncoordinated and coordinated H_2O molecules are shown as large opaque and large solid, red spheres, respectively. Hydrogen bonds are indicated by dotted red lines.

nated to three different ppca ligands, but to only one oxygen from one {V_4O_{12}} unit, leaving the sixth coordination site occupied by a water molecule (Figure 1).
Figure 1. View of the coordination environments of the two crystallo-graphically independent cobalt centers and the ligand coordination mode of **1**. Co: green; V: cyan; O: red; C: black; N: blue; H: white.

As shown in Figure 1, each ppca ligand is coordinated to one cobalt atom in a bidentate fashion through one carboxylate oxygen atom and the adjacent nitrogen atom of the ring. The second nitrogen atom of the ligand is coordinated to a second cobalt atom, and the remaining carboxylate oxygen atom further coordinates to a third cobalt atom in a monodentate fashion in the *syn,anti* carboxy mode. Thus, each ppca ligand functions in a μ_3-bridging mode that leads to 2D layers with the composition [{$Co_2(ppca)_2(H_2O)$}$_\infty$] (Figure 2a).

The VO_3^- anion of the ammonium vanadate reagent is the source of the tetrahedral vanadium in the present structure. Vanadium is found in complex **1** as {V_4O_{12}} units, which bridge the 2D metal–organic layers described above, and in doing so, become an integral part of 1D inorganic [{$Co_4(V_4O_{12})$}$_\infty$] chains (Figure 2b). When one considers the connectivity between the 2D metal–organic layers and the 1D mixed-metal chains, the overall structure is best described as a 3D porous organic–inorganic framework containing rectangular channels of approximate dimensions 5.2×22.3 Å^2 (atom-to-atom) running parallel to the *c* axis (Figure 3) and 5.6×11.3 Å^2 along the *a* axis (see Supporting Information). These channels constitute 15% of the crystal volume[8] and are much larger than those found in similar complexes constructed from the simple pyrazinecarboxylate ligand.[6b,c] The channels are filled by guest water molecules that participate in a collective, well-ordered hydrogen-bonded network involving water molecules, carboxylate oxygen atoms, and the vanadium oxide units of the framework (see Supporting Information).

It is a well-known phenomenon that guest solvent molecules located in cavities or channels can often be removed from the framework structure without causing framework collapse and, furthermore, that they can sometimes also be reinserted. To explore this possibility, single crystals of the present cobalt–vanadium framework were heated to different temperatures. These crystals were then analyzed by single-crystal X-ray diffraction. Heating the single crystals to 150°C for 1 day yielded [{[Co$_2$(ppca)$_2$(H$_2$O)-
Figure 2. a) 2D metal–organic layer of composition [{$Co_2(ppca)_2$-(H_2O)}$_\infty$]; b) 1D inorganic chains of composition [{$Co_4(V_4O_{12})$}$_\infty$]. Co: green; V: cyan; C: black; O: red.
Figure 3. View of the 3D porous organic–inorganic framework with rectangular channels filled with guest water molecules. The guest water molecules are shown as large green spheres; Co octahedra: orange; V tetrahedra: pink.

$(V_4O_{12})_{0.5}]\cdot 0.55 H_2O\}_n]$ (**2**) (see Supporting Information). The structure determination of **2** revealed that the crystal system and space group remain the same as those of **1**, but that approximately three water molecules had been removed from the pores per formula unit. The remaining water molecules are located near Co2, where they form hydrogen bonds to the coordinated water ligand (see Supporting Information). These hydrogen bonds appear to impart the noncoordinated water molecules with enhanced thermal stability. The removal of the three water molecules of hydration is accompanied by a slight decrease in cell volume (from 1411 to 1336 Å^3) and in

the volumes of the channels (from 15 to 12% of the total crystal volume).[8]

Immersion of crystals of **2** in water results in complete rehydration and re-formation of the original structure, including the hydrogen-bonding network observed in the original structure of **1** (see Supporting Information). The unit-cell volume of the rehydrated framework material was determined to be 1409.5(1) Å^3, and the channels again constitute 15% of the total crystal volume.[8] The reintroduction of guest water molecules also occurs spontaneously when crystals of **2** are exposed to air; they take less than 1 week to become fully saturated, and the process demonstrates that the removal and reinsertion of the guest water molecules is completely reversible.

Next, to investigate the removal of all noncoordinated and coordinated water molecules, single crystals of **1** were heated to 300°C for 2 h. The effects of heating were again analyzed by single-crystal X-ray diffraction. The structure determination of $[\{Co_2(ppca)_2(V_4O_{12})_{0.5}\}_n]$ (**3**) confirmed the complete removal of the guest water molecules as well as the removal of the water molecule coordinated to Co2 (see Supporting

Information). Although the crystal system and space group remain unchanged, the 3D framework is significantly changed from that of **1** or **2** in that the Co2 center in **3** is now only five-coordinate and has changed from an octahedral (as in **1** or **2**) to a trigonal bipyramidal coordination environment (Figure 4). Accompanying this change in the cobalt coordination environment is a color change from red to brown (Figure 5). Whereas **3** remains almost isostructural with **1** or **2**, the 2D metal–organic layer in **3** has the composition $[\{Co_2(ppca)_2\}_\infty]$, rather than $[\{Co_2(ppca)_2(H_2O)\}_\infty]$. More importantly, however, the unit-cell volume is decreased further and the channels only retain one-third of their original volume, now constituting only 5.8% of the total crystal volume.[8]

Brief immersion of **3** into water or exposure to air for several days completely reverses the structural change, and the original material, **1**, including the coordinated water molecule, is reconstituted (see Supporting Information). Thus the rehydration process is accompanied by return of the original color (Figure 5). A crystallographic investigation determined that the structure of the reconstituted **3** is the same as that of **1** (see Supporting Information).
Figure 4. a) View of the $[\{Co_2(ppca)_2(H_2O)(V_4O_{12})_{0.5}\}_n]$ framework containing hydrated Co2 in an octahedral coordination environment; b) view of the dehydrated $[\{Co_2(ppca)_2(V_4O_{12})_{0.5}\}_n]$ framework containing Co2 in a trigonal-bipyramidal coordination environment.
Figure 5. Pictorial representation of the dehydration and rehydration processes. The red crystal turns brown upon dehydration and change of the cobalt coordination environment from octahedral to trigonal bipyramidal. The crystal changes back to the original red color upon rehydration and returns to the original octahedral cobalt coordination environment.

A closer analysis of the structure of **3** suggests a possible cause for such a large decrease in volume upon complete dehydration. The removal of the coordinated water molecule from Co2 removes a quasi-pillaring between the channel walls (Figure 4), hence allowing a shear motion to bring the channel walls closer together. Thus, whereas the removal of the guest water molecules leads to a small decrease in volume, similar to what has been observed in other framework materials,[9] it is the removal of the coordinated water molecules that initiates the more substantial channel "collapse".

In summary, we have successfully synthesized a vanadium oxide bridged, mixed-metal 3D porous framework by using the new ligand ppca. The framework undergoes a dynamic structural change initiated by the removal of both non-coordinated and coordinated water molecules. The most significant structural change involves an unusual transformation of the local Co2 coordination environment, permitting unusual shrinkage and expansion in a single-crystal-to-single-crystal dehydration/rehydration process. Clearly, the existence of the five-coordinate cobalt center suggests a series of follow-up experiments to determine if the religation is possible with, for example, ammonia, rather than water. Such experiments will be performed in the near future.

Experimental Section

1: Hppca (0.2 mmol), $Co(NO_3)_2 \cdot 6H_2O$ (0.2 mmol), and NH_4VO_3 (0.2 mmol) were mixed in an aqueous solution (12 mL). The mixture was stirred at room temperature for about 1 h, and then placed in a 45-mL teflon-lined autoclave and heated at 160°C for 2 days. Red crystals of **1** formed and were manually isolated, washed with water, and dried in air (9.4 mg, 12%). The structural consistency and phase purity of the product was checked by comparison of the observed X-ray diffraction pattern with that calculated from the single-crystal structural data (see Supporting Information). Single-crystal X-ray crystallography was carried out on a Bruker SMART APEX CCD diffractometer system.[10]

Hierarchical Assembly of {Fe₁₃} Oxygen-Bridged Clusters into a Close-Packed Superstructure**

*Muralee Murugesu, Rodolphe Clérac,
Wolfgang Wernsdorfer, Christopher E. Anson, and
Annie K. Powell**

*Dedicated to Professor Heinrich Vahrenkamp
on the occasion of his 65th birthday*

Hierarchical materials can be regarded as systems in which small units are incorporated into larger superstructures, thereby investing the resulting construct with a hierarchy of properties that operate on different scales. Such systems become of particular interest when nanometer scales are involved, as these represent a situation in which nanoparticles are organized into a specific array. The organization of nanoparticles is important in terms of creating devices but poses significant difficulties if the particles have to be physically arranged, for example, by using electron-beam lithography. Therefore, the idea of the combination of such particles along chemical principles is attractive as it leaves the chemical-bonding interactions to do the work. Herein, we describe the realization of this idea in a material obtained from aqueous solution and composed of a close-packed superstructure of connected iron(III) nanomagnets, which themselves display close-packed core architectures.

Our conceptual hierarchy begins at the atomic level with Fe^{III} ions in water in the form of the hexaaqua ion [Fe-$(H_2O)_6]^{3+}$. Under normal conditions, a variety of hydrolysis reactions would lead to the precipitation of an amorphous hydroxide, which would then age into well-defined mineral phases, such as the oxyhydroxide and goethite phases, and finally transform into the most thermodynamically stable oxide haematite.[1] We have observed that supply of tripodal chelating ligands of the general form $N(RCOOH)_2R'$ (in

which R′ can be any organic residue) to such solutions can halt this process through the stabilization of captured intermediate phases composed of close-packed cores, which are portions of the brucite structure (exemplified by $Mg(OH)_2$) encased in a shell of the ligand units.[2,3] It is worth looking at this hydrolysis process in more detail: The brucite structure is an AB_2 lattice composed of close-packed hydroxide (B) layers that are arranged as double strips and M^{II} ions (A) that sit in the octahedral holes between these strips so that each hydroxide unit bridges three metal ions (Figure 1). In the hydrolysis process, we can imagine the
Figure 1. The AB_2 lattice as seen in the brucite $Mg(OH)_2$ structure. Green: metal atoms; red: oxygen atoms.

starting point (first generation) to be a hexaaqua metal ion which will link to six further metal ions (second generation) on production of the hexahydroxo metal ion, and the process will continue through production of the hydroxide ions and coordination to a further six metal centers (third generation), then twelve (fourth generation), and so on, as can be seen in Figure 1.

Aggregates that contain portions of such core structures have been structurally characterized for a variety of metal ions.[2–15] Clearly, an infinite brucite structure is not possible for the examples of M^{III} ions on the basis of charge imbalance, which could be stabilized by the shell of ligands coordinated to the outermost metal ions of the hydroxide lattice in the observed aggregates. A further pertinent point is that removal of half the protons from the double strips of hydroxide moieties in brucite leads to a layer of the α-oxyhydroxide structure, which is exemplified for the Fe^{III} center by goethite, α-FeO(OH), itself the precursor to the most thermodynamically stable phase haematite. Thus, we can think of such aggregates as metastable intermediates that are trapped through the process of crystallization. These aggregates prove to be magnetically interesting for the Fe^{III} center because, although the overall coupling is antiferromagnetic, the pairwise interactions are unequal in magnitude over the whole molecule, thus leading to residual ground-state spins of up to 33/2 and a display of hysteresis of the magnetization.[3,16–18] Thus, a secondary level of organization both in terms of the structure and properties of the compound is demonstrated. In the specific case we describe herein, the tripodal proligand nitrilotripropionic acid (H_3ntp = $N(CH_2CH_2COOH)_3$) has been used to successfully trap {Fe₁₃} aggregates (Figure 2), in which the production of the

Figure 2. Fe green; O red; N blue; C black; H white.

brucite lattice has effectively been arrested at the third generation.

The iron–oxygen framework is shown in Figure 2b, which shows that the central core of the [Fe$_7$(OH)$_6$]$^{15+}$ ion clearly corresponds to the first two generations of the brucite lattice and that the final six Fe^{III} centers of the third generation are connected to this core by six triply bridging oxide rather than hydroxide ions. These oxides provide an important structural element as they link three metal ions in a trigonal rather than pyramidal fashion. This coordination mode has the result that the final six iron centers are disposed above and below the core, thus alternating with the hydroxide units to give a "diabolo" arrangement, and means that the iron centers form

a trigonal-antiprismatic arrangement, which becomes important in the quaternary structure.

The proligand H$_3$ntp did not coordinate to the aggregate in the tripodal chelation mode as expected and as seen in the {Cu$_{44}$} compound we recently reported[19] because the central nitrogen atom carries a proton and, therefore, does not form bonds with the peripheral iron centers. This coordination mode has, however, been observed by us in some different Cu^{II} compounds.[20] Consequently, the carboxylate groups are not constrained to form chelate rings, and so the carboxylate functionalities from six ligands display extensive bridging interactions around the periphery of the molecule. Two further ligands complete the encapsulation of the iron core by

capping above and below, with coordination to the peripheral iron centers from the carboxylate groups and hydrogen-bonding interactions between the non-coordinated carboxylate oxygen atoms and the hydroxide functionalities in the core. The proton on the central nitrogen atom of each ligand also forms hydrogen-bonding interactions with the carboxylate oxygen atoms in a trifurcated fashion. The resulting structure is nearly spherical, with a diameter of about 1.5 nm. The positive charge of $5+$ on the aggregate (the ligand is dinegative in this zwitterionic form) is balanced in the crystal structure by nitrate counterions. In fact, there are two almost identical aggregates, $[Fe_{13}(\mu_3\text{-}OH)_6(\mu_3\text{-}O)_6(Hntp)_8(H_2O)_6]^{5+}$ (cluster **A**; Hntp = $HN(CH_2CH_2COO)_3$) and $[Fe_{13}(\mu_3\text{-}OH)_6(\mu_3\text{-}O)_6(Hntp)_8]^{5+}$ (cluster **B**), in a 1:2 ratio in the three-dimensional structure. The subtle difference between these clusters becomes clear when the structure is examined in detail: In the third level of organization, the **A**-type clusters are linked to the **B**-type clusters by a *syn–anti* carboxylate bridge from a ligand located on **A** which connects a peripheral Fe^{III} center in **A** to a peripheral Fe^{III} center in **B**. In addition, the **B**-type clusters are linked to each other through double *syn–anti* carboxylate bridges (Figure 2c).

The molecules are arranged in layers that correspond to an ABBABBABBA ordering. A closer examination of the packing reveals the consequences of the arrangement of the peripheral Fe^{III} centers in the trigonal antiprismatic geometry and the fourth level of organization. As a result of the links between the aggregates that arise from ligands coordinated to these iron centers, each aggregate is octahedrally surrounded by six further aggregates (Figure 2c); therefore, for a given **A** aggregate there are six **B** aggregates, whereas for a **B** aggregate there are three **A** and three further **B** aggregates that assume three facial positions of the octahedral "coordination" geometry in each case. The overall result for the organization of the aggregates can be visualized as the interpenetration of *pseudo*-cubic lattices, which is exemplified by the sodium chloride structure. The fact that this organization is actually an AB_2 structure complicates the description slightly, but if we refer back to the brucite structure shown in Figure 1, in which the green and red spheres now represent the **A** and **B** clusters, respectively, the hierarchical nature of this material becomes clear. The unit cell marked in Figure 1 corresponds to the unit cell for our compound (also marked in Figure 2c). In this way, nanoscale aggregates with cores of close-packed atoms with an AB_2 structure have been organized into a close-packed AB_2 superstructure. It is of particular note that within the cores of the aggregates we see Fe^{III} centers that occupy octahedral holes between two layers of close-packed hydroxide moieties and in the superstructure we have **A** clusters that occupy octahedral sites between two layers of **B** clusters.

The question now arises as to whether this hierarchical structure is reflected in the magnetic properties of the material. The plot of χT versus T decreases continuously over the whole temperature range studied from 16.5 emu K mol^{-1} at 300 K to 4.11 emu K mol^{-1} at 30 K (Figure 3). Below this temperature, the χT product decreases faster to reach 1.37 emu K mol^{-1} at 1.8 K. The χT value at room temperature is well below the expected value (56.9 emu K mol^{-1}, if $g = 2$)
Figure 3. Temperature dependence of the χT product (per Fe^{III} aggregate) at 1000 Oe. Inset: Topology of the magnetic interactions in the iron aggregates.

for 13 high-spin Fe^{III} centers ($S = 5/2$), thus indicating strong antiferromagnetic interactions between the centers.

A simplified scheme of the magnetic-interaction topology based on the coordination modes between the Fe^{III} centers can be proposed (inset Figure 3) with three types of pathway: J_1 coupling through the μ_3-O and μ_3-OH double bridges, J_2 coupling through the μ_3-OH double bridges, and J_3 coupling through the single μ_3-O bridges. All of these exchange couplings are known to lead to antiferromagnetic interactions. Therefore, the topology and the symmetry of the $\{Fe_{13}\}$ aggregates (inset Figure 3) reveal the presence of a triangular assembly, with a competing set of antiferromagnetic interactions. Modeling the magnetic susceptibility is not possible as 1) there is no analytical model available for 13 coupled Fe^{III} centers in such a configuration and 2) numerical methods would require the diagonalization of too large a matrix. However, numerical density functional theory calculations on $[Fe_{19}(metheidi)_{10}(\mu_3\text{-}OH)_6(\mu\text{-}OH)_8(\mu_3\text{-}O)_6(H_2O)_{12}]NO_3$ (H_3metheidi = $N(CH_2COOH)_2(CH(Me)CH_2CH_2OH)$), a molecule with the same brucite-core structure as seen in the $\{Fe_{13}\}$ aggregate,[21] were recently used to evaluate Fe^{III}–Fe^{III} magnetic coupling through different types of oxygen bridges. Herein, we suggest that the J_3 coupling through the μ_3-O bridge will be the strongest and will occur at around -100 K and that the J_2 coupling should be almost half of the J_1 coupling (namely, around -10 K compared with -20 K). Therefore, a simple view of the ground state can be proposed based on this coupling scheme in which all the outermost spins are parallel to each other and antiparallel to the spins on their neighbors that make up the middle ring. Finally, the J_2 coupling results in the spin on the central Fe center being antiparallel to these neighboring spins and, thus, parallel to the outermost spins, which would result in a spin ground state for the $\{Fe_{13}\}$ aggregates of 5/2.

Low-temperature measurements give further insight into the ground state and the anisotropy of the $\{Fe_{13}\}$ units. The fact that the χT product does not go directly to zero at low temperature indicates that it is not a singlet ground state, as to be expected for an odd number of antiferromagnetically coupled spin carriers. The value reached at 30 K is 4.1 emu K

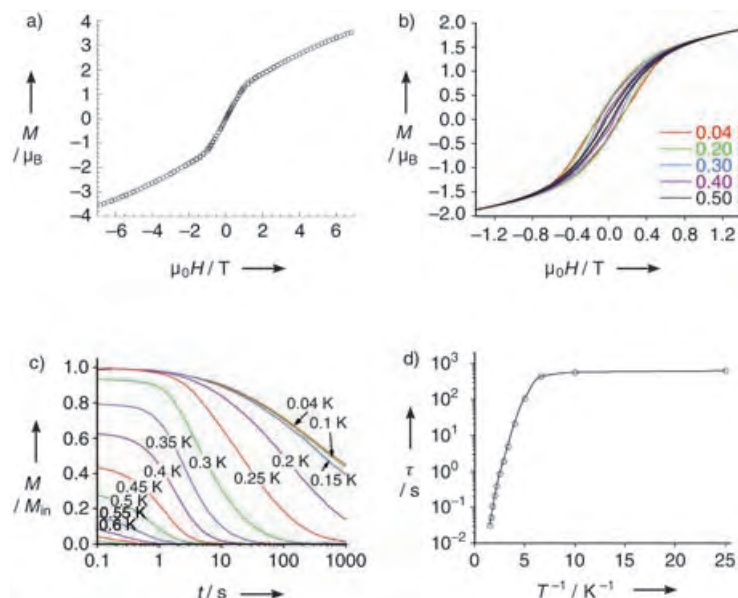
mol^{-1}, which is compatible with a ground state of $S = 5/2$. The further decrease of the χT product at lower temperature is probably because of the intercluster interactions mediated by the *syn–anti* carboxylate bridges, a zero-field-splitting contribution, or both of these. This interpretation is confirmed by the field dependence of the magnetization at 1.8 K (Figure 4a). Two regimes are observed: 1) at low field below 1 T,


Figure 4. a) Bulk-field dependence of the magnetization (per Fe^{III} aggregate) at 1.83 K and b) field dependence of the magnetization on a single crystal from 0.04 to 0.5 K by the micro-SQUID technique with the magnetic field applied along the *c* axis. c) Relaxation of the magnetization below 0.7 K normalized to the initial magnetization at 0.04 K by the micro-SQUID technique with the magnetic field applied along the *c* axis. d) Plot of relaxation time τ versus $1/T$.

where the magnetization increases rapidly and linearly, and 2) above 1 T, where the increase is slower. Although saturation is not achieved at 7 T, the nonlinear behavior indicates that the saturation should be achievable at higher fields and have a value probably close to 5 μ_B, which is to be expected for a ground state of $S = 5/2$. The presence of these two regimes may be the result of the anisotropy and/or the interactions between the aggregates; therefore, micro-SQUID measurements were performed on a single crystal at temperatures lowered to 0.04 K for yet further insight into the magnetic behavior. This technique and rotation of the applied field around the single crystal shows that the measured magnetization becomes clearly uniaxially anisotropic below 2 K, thus implying a negative value of D. Furthermore, below 1 K and when the applied field does not coincide with the *c* direction, the curves for M versus H exhibit a characteristic S shape that is typical for antiferromagnetically coupled systems with an inflexion point at around 0.6 T at 40 mK. Therefore, these two simple observations demonstrate that both anisotropy and interaggregate interactions are relevant in the low-temperature regime. Hysteresis loops are observed below 1 K with the largest effect seen when the field coincides with the *c* axis, thus suggesting that this effect corresponds to the easy axis (Figure 4b). Although the loops do not show a large temper-

ature dependence, we can rule out the possibility that they result from a spin-glass behavior from the temperature dependence of the magnetization relaxation time. In a classical spin-glass system, the relaxation time follows what looks like an Arrhénius behavior but with nonphysical values for the energy barrier and the pre-exponential factor,[22] which is, in fact, not the case, as seen in Figure 4d.

As the curves for M/M_{in} versus t (M/M_{in} is the magnetization normalized to its initial value at 0.04 K) obtained below 0.7 K have the same shape (Figure 4c), the data were scaled to a single master curve and the relaxation time τ was extracted by simply taking the time when M/M_{in} reaches the value $1/e$ (Figure 4d). The relaxation time for the high-temperature section of the plot of τ versus $1/T$ does not follow the simple Arrhénius behavior expected for single-molecule magnets (SMM) in the thermally activated regime. This nonexponential behavior is probably a result of the magnetic interactions between the {Fe$_{13}$} aggregates and suggests that these units when isolated from each other would behave as SMMs. Below 0.1 K, saturation of τ is reached, thus indicating that the dominant process of relaxation becomes time independent. This feature is reminiscent of SMM behavior when quantum tunneling of the magnetization is the main pathway for the relaxation. In our case, the slow relaxation of the magnetization is induced necessarily not only by the spin ground state and the anisotropy of the {Fe$_{13}$} aggregates but also by the significant three-dimensional antiferromagnetic coupling between them. This result illustrates the influence of the hierarchical structure of this compound and the role of the chemical and magnetic coupling between the {Fe$_{13}$} aggregates that give rise to a hierarchy of magnetic properties.

Although further work needs to be carried out on the physics of this complicated system, it is clear that by physically connecting the spins of the aggregates with chemical bonds, cooperative interaction at low temperature has been enabled, thus giving rise to the exotic effects observed. Overall, we feel that this system is fascinating both in terms of the aesthetic appeal of the structural concepts and its potential to provide detailed insight into magnetic interactions between nanoscale particles.

CCDC-260817 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

Magnetic susceptibility measurements on **1** were obtained on a finely ground polycrystalline sample (5.9 mg) using a Quantum Design SQUID magnetometer MPMS-XL. The dc measurements were collected from 1.8 to 300 K and from -70 to 70 kOe. Experimental data were also corrected for the sample holder and for the diamagnetic contribution calculated from Pascal constants.[24] Field and time dependences of the magnetization on single crystals were measured with an array of micro-SQUIDs.[25]

ribozymes (catalytic RNAs) are typically used for the regulation of gene expression.[1–4] The recent discovery of RNA interference promises an efficient gene regulation method for both basic and therapeutic research.[5–7] However, the cell membrane is a formidable barrier against the delivery of nucleic acids,[8–10] and therefore effective implementation of oligonucleotide technology depends on the efficient transfection of oligonucleotides. Thus, the enhancement of oligonucleotide uptake for targeted delivery is still a topic of great interest.

Cationic peptides are efficient tools for the transfection of oligonucleotides and cationic liposomes,[11,12] polycationic dendrimers,[13] and polyethyleneimine,[14,15] but if antisense oligonucleotide–cationic peptide conjugates are used in cellular delivery, the conjugates are often insoluble.[16] Furthermore, the conjugation is still not chemically straightforward and needs improvement,[17] and the peptide inhibits the function of the nucleic acid to which it is conjugated.[18] In the development of oligonucleotide technology, direct chemical modification of DNA or RNA is one method of improving function or adding a novel function, because the oligonucleotide-based structure and synthesis allow easy conjugation to DNA and RNA molecules for biochemical and biophysical applications. For example, a base-pair-mimic nucleoside induces site-selective RNA cleavage,[19] and the creation of modified DNA analogues with fluorescent aromatic compounds allows the rapid combinatorial screening and discovery of color-changing sensors of light exposure from a library.[20] Therefore, a modified nucleic acid analogue with efficient cellular uptake would be a useful tool for biochemical applications.

Herein, we report the initial synthesis of 5-[(6-guanidiniohexylcarbamoyl)methyl]-2′-deoxyuridine (**Tg**), which has a guanidinium group at the C5 position of deoxyuridine (Figure 1a). The guanidinium group is a side chain of arginine (Arg). Previous studies revealed that basic peptides such as
human immunodeficiency virus type 1 (HIV-1) Tat-(48-60) have membrane permeability and carrier function for intracellular protein delivery.[21] Moreover, many Arg-rich peptides such as HIV-1 Rev-(34-50) and octaarginine (Arg$_8$) can translocate efficiently through cell membranes.[22,23] Therefore, it is expected that **Tg** is likely to perform as an excellent transmembrane carrier for oligonucleotides. Herein, the guanidinium-modified DNA clearly shows cellular uptake in HeLa cells without any reagents.

A 20-mer DNA oligomer labeled with 6-carboxyfluorescein (FAM) at the 5′ end was prepared as the core strand: 5′-FAM-dTGTGAAGTGTCCCAGCCTGT. Then, four **Tg** moieties were added to the core at the 3′ end by a primer-extension reaction. After optimization of the reaction conditions (Supporting Information), the primer-extension reaction was performed with DNA polymerase. The primer extension used in this study might be useful for further applications because its products are easily purified. Next, the effect of the modified DNA (core-**Tg**$_4$) on duplex stability was measured, because modified DNA base analogues often destabilize duplex formation. The melting temperatures (T_m) of the 20-mer core duplex (5′-FAM-dTGTGAAGTGTCC-CAGCCTGT-3′/5′-ACAGGCTGGACACTTCACA-3′), a duplex in which the core strand has four dangling T nucleotides at the 3′ end (core-T$_4$ duplex: 5′-FAM-dTGTGAAGTGTCCCAGCCTGT(T)$_4$-3′/5′-ACAGGCTG-GACACTTCACA-3′), and a core duplex with **Tg**$_4$ at the 3′ end (core-**Tg**$_4$ duplex: 5′-FAM-dTGTGAAGTGTCC-CAGCCTGT(**Tg**)$_4$-3′/5′-ACAGGCTGGACACTTCACA-3′) were measured by UV/Vis spectroscopy in a buffer containing NaCl (100 mM), in close approximation to typical physiological conditions (Figure 1b). The T_m values of the core, core-T$_4$, and core-**Tg**$_4$ duplexes (3 μM each) were 71, 72, and 71 °C, respectively. The data indicate that **Tg**$_4$ as a dangling end does not noticeably inhibit duplex stability; these data are in agreement with previously observed trends. The 3′ dangling ends in B-form DNA are not energetically favored as a result of fewer geometric intrastrand stacking events.[24]

Next, the uptake of single-stranded core-**Tg**$_4$ by HeLa cells was studied with both fluorescence-activated cell sorting (FACS) and microscopy. In typical experiments, HeLa cells were cultured in Eagle's minimum essential medium containing single-stranded core-**Tg**$_4$ (4 μM) for 48 hours, washed with phosphate-buffered saline, and quantified by fluorescence measurement. The uptake of core-**Tg**$_4$ was monitored by FACS analysis of FAM (Supporting Information). After 48 hours, cells incubated with core-**Tg**$_4$ had higher fluorescence than a population of cells incubated in the absence of core-**Tg**$_4$. To confirm the role of the guanidinium group, we synthesized 5-[(6-aminohexylcarbamoyl)methyl]-2′-deoxyuridine (**Ta**),[25] which has a Lys side chain (Supporting Information); it is known that Arg peptides undergo cellular uptake more readily than Lys peptides.[26,27] If the cellular uptake does not depend on the guanidinium group, then one would expect the cellular uptake efficiency of **Tg**- and **Ta**-modified DNA to be the same. Quantitation of FAM by FACS analysis showed that the uptake of core-**Ta**$_4$ was 1.8 % of that of core-**Tg**$_4$, which suggests that the guanidinium group works efficiently as a carrier.

result of fluorescence of the FAM-labeled DNA oligomer and stained nuclei, respectively. As the cells incubated with the core (FAM-labeled DNA without Tg_4) did not exhibit this green color (Supporting Information), the images clearly show that the chemical modification induces the cellular uptake activity. Moreover, the green areas do not seem to overlap the blue, which suggests that the cellular localization of these compounds is in the cytoplasm. Confocal microscopy studies were carried out to determine whether the guanidinium-modified DNA is internalized or simply attached to the cell surface. Fixed cells are usually used for confocal microscopy to obtain clear images, but recent studies indicate that cell fixation leads to the artifactual redistribution of cationic peptides into the nucleus.[28] Therefore, images of fixed cells and living cells were obtained (Figure 2b,c). Interestingly, these images showed that the distribution of the green color observed in the cytoplasm was similar to that observed with the fluorescence microscope. This suggests that the cellular localization of these compounds is mainly cytoplasmic. Recent studies on cationic peptides, such as the Tat peptide, support the notion that uptake occurs through an endocytosis pathway and that most cationic peptides reside in cytosol.[29–32] Our result for modified DNA is consistent with this behavior

of cationic peptides. Although detailed future investigations are necessary, the intracellular redistribution of the modified DNA might occur through endocytosis.

Finally, the effect of modified DNA length on the cellular uptake efficiency was investigated (Figure 3). The amount of cellular uptake with core-Tg_3 was 70% of that of core-Tg_4. Interestingly, the amount of cellular uptake with core-Tg_6 was
Figure 3. a) DNA sequence studied to investigate the effect of modified DNA length on cellular uptake. b) Uptake efficiency relative to core-Tg_4 quantified by FACS analysis of FAM.

only 30% of that of core-Tg_4. Even at DNA concentrations that were twice as high (8 μM), the order of the amount of cellular uptake was still core-Tg_4 > core-Tg_3 > core-Tg_6. In the case of Arg peptides, the efficiency of cellular uptake decreased with increasing polypeptide length because of aggregation. The length range showing more efficient uptake was between eight and ten Arg residues.[23] Our data are in agreement with an increase in length being unfavorable for cellular uptake. However, the most favorable length (four Tg nucleotides) is shorter than an eight- to ten-residue poly-Arg peptide. Although the reaction conditions of core-Tg_4 were not optimized, the degree of cellular uptake for core-Tg_4 at 8 μM with incubation for 48 hours was about 75% that of the uptake for the core through a commercial liposome transfection agent (LipofectAMINE 2000 reagent (Invitrogen)) under optimized conditions. This indicates that the cellular uptake of core-Tg_4 is not so inefficient.

In summary, we have found that 5-[(6-guanidiniohexyl-carbamoyl)methyl]-2′-deoxyuridine (Tg) plays the important role of carrier for cellular uptake. In the case of the Arg-rich peptide, HeLa cells are a typical example of a cell type that is difficult for intracellular peptide delivery.[23] Therefore, the cellular uptake of Tg in HeLa cells indicates that Tg could be applied as a carrier agent for a wide range of cell types. The activity of Tg as the carrier was observed not only for HeLa

cells but also for RAW 264.7 cells, which are known to allow uptake readily (Supporting Information).[23] Interestingly, the optimal number of **Tg**-modified bases as a carrier for a 20-nucleotide DNA oligomer was only four. Oligonucleotide-based functional molecules allow easy conjugation to DNA and RNA for biochemical and biophysical applications. Thus, **Tg** could be used as a new tool in future applications for intracellular oligonucleotide delivery.

Communications

variety of protein–protein[3] and protein–membrane interactions.[4] Their semirigid structures and their adjustable lengths mean that they provide excellent starting points for the elaboration of protein mimics that might be difficult to design based on small-molecule scaffolds. Here we describe the design of aryl amide oligomers that compete for heparin–protein interactions. Heparin, a linear and highly sulfated polysaccharide, is a crucial component in a variety of biological processes mediated by specific heparin–protein interactions including blood coagulation, viral infection, and cell growth. Heparin has become a commonly used clinical anticoagulant to prevent and treat thrombotic diseases.[5,6] However, bleeding complications including hemorrhage and heparin-induced thrombocytopenia (HIT), which is a common immune-mediated disorder, are major adverse effects associated with heparin therapy.[7] Therefore, frequent coagulation monitoring may be necessary to minimize the risk of life-threatening hemorrhages resulting from an overdose, while at the same time maximizing the anticoagulant efficacy.

Low-molecular-weight (LMW) heparins, like unfractionated (UF) heparin, consist of repeating units of L-iduronic acid and D-glucosamine (Scheme 1a). LMW heparins have
Scheme 1. a) The major repeating unit and b) the antithrombin III binding pentasaccharide of heparin.

resolved some of the problems associated with UF-heparin use, in that they have a more predictable dose response, an improved bioavailability, and a longer half-life.[8] Protamine is used extensively as a clinical heparin antidote to neutralize the anticoagulation function of heparin following cardiovascular surgery[9] but it is not prescribed for use with LMW-heparin therapy. Protamine treatment can also cause several side effects mediated by nonimmunologic and immunoglobulin-mediated pathways.[10] Thus, much safer and more effective agents for neutralizing the anticoagulant function of heparin are currently of great interest.

The interaction between heparin and antithrombin, a plasma serine proteinase inhibitor that is the major inhibitor of the coagulation cascade, facilitates a conformational change in antithrombin. This conformational change accelerates inhibition of coagulation factors such as thrombin and factor Xa.[11,12] Through X-ray crystallographic analysis of the antithrombin–pentasaccharide complex[13,14] and several studies of site-directed mutagenesis of antithrombin,[15,16] it has been shown that the negatively charged pentasaccharide binds to the basic amino acids (lysine and arginine) of antithrombin.

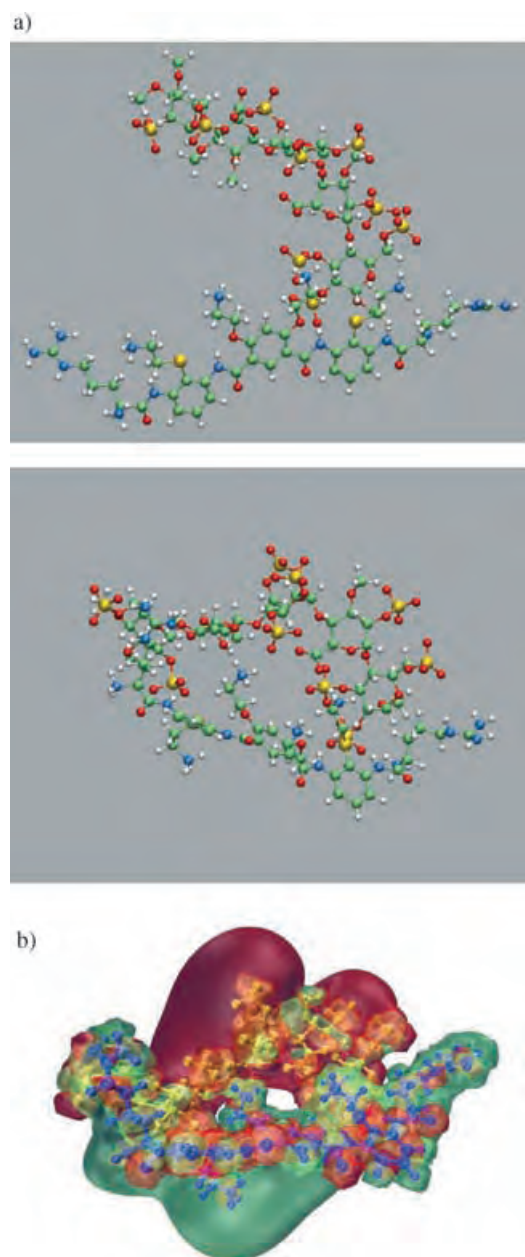
Furthermore, by comparing various heparin-binding proteins, Cardin and Weintraub classified two consensus sequences responsible for binding, XBBXBX and XBBBXXBX, where B is a basic residue and X is any other amino acid. It was suggested that these sequence motifs fold along one face of an α helix or β sheet.[17] Most heparin-binding sites have a bipolar structure, in which the basic amino acids are facing one side; neutral or lipophilic amino acids generally face the opposite side, regardless of the secondary structure.[18]

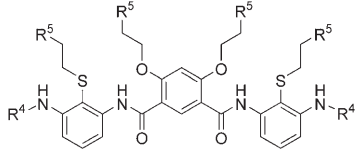
A few medium-sized peptides such as protamine analogues,[10,19] antithrombin-derived peptides,[20] and polyarginine peptides,[21] have been reported as potent heparin antidotes. Small-molecule inhibitors of heparin may alleviate complications associated with peptide-based heparin antidotes, such as proteolytic stability, distribution, and difficulty of scale-up. We have previously reported the synthesis of amphiphilic arylamide oligomers that mimic the biological properties of antimicrobial peptides and proteins.[4] Herein, we expand this strategy towards the design of small molecules that strongly interact with highly sulfated heparin.

Our design is based on a 1,3-substituted arylamide oligomer with additional hydrogen-bonding substituents included to increase solubility and conformational rigidity and to provide appropriately spaced cationic groups to interact with heparin. The thioether and ether groups of the generic oligomer **1** provide internal hydrogen-bond acceptors, while simultaneously providing points of attachment for additional functional groups.

1
Initially, a molecular dynamics study on binding of one of the arylamide analogues (shown in Figure 1, compound **8c**) to heparin in aqueous solution was undertaken. Analysis of the obtained trajectory suggests that these compounds might interact strongly with the pentasaccharide sequence of heparin (PDB code: 1E03). Owing to the extensive charge complementarity between the inhibitor and the heparin analogue, the binding is dominated by electrostatic interactions. At early stages in the trajectory, the two guanidium cations of the terminal side chains (R^4, Table 1) anchor compound **8c** to the pentasaccharide in a nearly parallel mode, by closely interacting with $CH_2-OSO_3^-$ groups of the two terminal pentasaccharide sugars (Figure 1a). The other positively (NH_3^+) and negatively (COO^-, OSO_3^-) charged groups of compound **8c** and the pentasaccharide, respectively, are then aligned. The limited flexibility of the pentasaccharide (Figure 1a) allows these groups to assume optimal positions, thereby maximizing the attractive interactions (Figure 1b) and hydrogen bonding without incurring an overly large loss in conformational entropy, which might occur with more flexible small peptides. All the side chains of compound **8c** are involved in the binding, with the terminal ones playing an

a)

b)




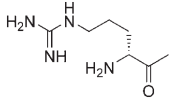


Figure 1. a) The initial (top) and final (after 7 ns, bottom) conformations of the aryl amide oligomer–pentasaccharide heparin system. In the initial stage of the simulation, the aryl amide backbone undergoes an internal twist, which facilitates the anchoring of the terminal aryl amide groups to pentasaccharide. Color code: S: yellow; C: cyan; N: blue; O: red. Water molecules and hydrogen atoms are not shown for clarity. b) The final aryl amide oligomer–pentasaccharide conformation, with electrostatic potential surfaces[29] shown in red (aryl amide oligomer) and green (pentasaccharide).

additional role of initial anchoring and aligning. However, some of the pentasaccharide charged groups are pointing away from the complex, toward the solution.

Based on these observations, we synthesized a series of aryl amide oligomers, as described in Scheme 2.

We examined the interaction between compounds **8a–d** and LMW heparin (Lovenox, $M_W = 4500$ Daltons) and UF heparin, respectively, both of which contain an antithrombin-

Table 1: Biological activity of small molecules **8a–d**.

Compound	R[4]	R[5]	IC$_{50}$ [µM]	K_B [µM][a]	HC$_{50}$ [µM][b]
8a	H	NH$_2$	256	6.7	>1540
8b	H	(guanidine group)	77.9	3.2	>1363
8c	(ornithine-type group)	NH$_2$	22.5	1.8	>1087
8d	(guanidine group)	NH$_2$	28.1	2.0	927

[a] The dissociation constant (K_B) was measured by Schild plot analysis by using the anti-Factor Xa assay. [b] The HC$_{50}$ value (measurement of hemolytic activity) was obtained by measuring 50% lysis of human erythrocytes.

Boc = tert-butoxycarbonyl, DEAD = diethylazodicarboxylate, DIEA = N,N-diisopropylethylamine, DMAP = 4-dimethylaminopyridine, DMF = N,N-dimethylformamide, Fmoc = 9-fluorenylmethoxycarbonyl, PIP = piperidine, TFA = trifluoroacetic acid, THF = tetrahydrofuran, Ts = toluene-4-sulfonyl.

binding domain (pentasaccharide, Scheme 1b). The ability of the compounds to compete with antithrombin for binding to Lovenox at physiological salt concentration (0.15 M NaCl) was assessed by a standard *anti*-factor Xa chromogenic assay (Figure 2).

Figure 2. Dose-dependent neutralization of a) LMW heparin and b) UF heparin by compounds **8a–d**. a) Factor Xa assay. b) aPTT clotting assay in the presence of UF heparin (2.42 μg mL^{-1}).

a dose-dependent manner. The Schild plot of inhibition for compounds **8a–d** establishes that they are competitive inhibitors for heparin–antithrombin formation with dissociation constants (K_B) of 6.7, 3.2, 1.8, and 2.0 μM, respectively. These data also show that **8c** was the most potent inhibitor among compounds **8a–d**.

To further address the specificity and affinity of these foldamers in a stringent biological medium, we examined their abilities to inhibit clotting in human plasma by measuring the neutralization of UF heparin by **8a–d** and protamine in an activated partial thromboplastin time (aPTT) clotting assay. The study was conducted with UF heparin because conventional aPTT clotting assays are a relatively insensitive method for measuring the activity of LMW heparin. As shown in Figure 2b, **8a–d** and protamine efficiently reversed heparin-induced aPTT clotting. Also, similar patterns of neutralization of heparin by **8a–d** were observed, which were consistent with those from the factor Xa assay. The most active compounds **8c** and **8d** were only two- to threefold less potent than protamine (average $M_W = 5100$ Daltons), despite the fact that these are small molecules.

Finally, as an initial test of toxicity, we measured hemolytic activities of the compounds against human erythrocytes. None of these small molecules lysed human red cells at concentrations as high as 1000 μM.

In summary, we have described the synthesis of a series of arylamide oligomers, which interact with LMW heparin and UF heparin. This interaction inhibits the ability of LMW heparin to activate antithrombin and, in this way, affects the biological function of LMW heparin. These arylamide oligomers are the first example of low-molecular-weight antagonists that inhibit the anticoagulant function of heparin.

Compound **8a** served as an initial lead compound to inhibit the function of Lovenox. Although it exhibited a low in vitro inhibition (IC$_{50}$ = 256 μM, Table 1) against Lovenox, we were inspired to investigate the possible role of the basic side chain of the compound in its interaction with polysulfated heparin. The conversion of the side chains of **8a** to give the polyguanidinylated derivative **8b** resulted in a threefold increase in potency. This result is consistent with observations reported by Linhardt and co-workers. They suggested that arginine binds about 2.5 times more tightly than lysine to the sulfate groups of heparin due to distinct hydrogen bonding.[22] Therefore, we reasoned that the increased activity of compound **8b** arose from differences in hydrogen bonding between ammonium or guanidinium cations and the sulfate groups of LMW heparin.

To obtain more potent heparin inhibitors, further chemical modification was necessary. The introduction of extra positively charged substituents at the terminal amines gave compounds **8c** and **8d**, which exhibited a greater than tenfold increase in potency compared to that of **8a**. Additionally, **8d** was found to have a similar in vitro efficacy to **8c**, in that both compounds provide significant improvement and have similar inhibition constants (IC$_{50}$ = 28.1 and 22.5 μM, respectively, Table 1). The introduction of additional positive charges enhanced the potency of the compounds, as expected from the molecular dynamics study.

To estimate the binding affinities of compounds **8a–d**, Schild plot analysis, which measures agonist dose–response curve shifts by a competitive antagonist, was used to evaluate their capacity to interact with LMW heparin. Table 1 lists the dissociation constants (K_B) of these four compounds. These compounds prevent the binding of heparin to antithrombin in

Experimental Section

The synthesis of all compounds is described in the Supporting Information. The factor Xa assay in the presence of Lovenox and inhibitor was measured in a chromogenic assay by using reagents purchased from DiaPharma. In brief, the reagents were reconstituted in a 0.02 M tris(hydroxymethyl)aminomethane (Tris) buffer at pH 8.4. Antithrombin was prepared with 0.336 M NaCl for a physiological salt concentration (0.15 M) in the final reaction. Antithrombin (0.08 IU mL^{-1}; 50 μL) was mixed with Lovenox (11.2 μg mL^{-1}; 1 μL). After the incubation for 5 min, different concentrations of inhibitor (1 μL) were added to each row of wells; the wells were then gently shaken and incubated for 20 min. Factor Xa (2.8 nkat mL^{-1}; 50 μL) was then added and the reaction mixture was shaken and incubated for an additional 10 min. Substrate (S-2765; 10 μL) was added and the 96-well plate was then shaken and read every 30 s for 7 min at 405 nm on a ThermoLabsystems Multiskan Spectrum. In the assay for Schild plot analysis, we followed the same protocol as for the anti-factor Xa assay except the concentrations of Lovenox and inhibitors were varied.

aPTT activity was resolved by using a BBL Fibrometer (Becton Dickinson, San Jose, CA) and a commercial kit containing Citrex I Control Plasma and Cephalinex-Activated PTT Reagent (Bio/Data Corporation, Horsham, PA). In brief, heparin (5 μL) and antagonist (5 μL) were preincubated (37 °C on a Fibrometer's heating block) for 10 s prior to addition of control plasma (0.1 mL) into the test cuvette. This mixture was allowed to incubate for 2 min at 37 °C. Meanwhile, 25 mM CaCl$_2$ (0.2 mL) was set to preincubate in a separate cuvette. Cephalinex (0.1 mL) was pipetted into the test cuvette containing the

plasma and incubated for exactly 5 min. The preincubated CaCl$_2$ (0.1 mL) was added with simultaneously starting of the Fibrometer's timer. Once a clot formed, the timer stopped and the clotting time was recorded. Biochemicals not provided with the kit were heparin sodium salt from bovine intestinal mucosa (Sigma, H-0777, 150 Units mg^{-1}) and protamine sulfate from salmon (Sigma, p4020).

The details of the interaction between heparin and compound **8c** were investigated by using molecular dynamics simulations. A pentasaccharide heparin sequence (charge −11) was placed in a box (55.69 × 53.09 × 60.04 Å) with compound **8c** (+8 charges, Table 1) and three Na$^+$ ions to balance the charge. The system was solvated by TIP3P water,[23] thereby resulting in a size of ≈17 500 atoms. Parameters for compound **8c** were derived from the newly developed force field for aryl amide oligomers,[24] to ensure proper description of the backbone conformational dynamics, in combination with semi-empirical (MOPAC) charges.[25] Heparin parameters were developed partly by analogy with the existing Amber parameters,[26] augmented by parameters for the SO$_4^-$ groups,[27] partly from semiempirical calculations.[25] The system was equilibrated for 1 ns and the analysis was performed based on a subsequent 6 ns production run. The simulations were carried out by using the NAMD2 software[28] with full electrostatics by use of the Particle Mesh Ewald method and a time step of 1.5 fs.

Escape from a Nonporous Solid: Mechanically Coupled Biconcave Molecules**

Justin A. Riddle, John C. Bollinger, and Dongwhan Lee*

Molecular motions play a central role in many biologically important processes.[1] The correlated movement of a finite number of symmetrically disposed building blocks in naturally occurring constructs can amplify a local distortion into a global structural change.[2,3] This process is well illustrated by the unidirectional rotation of C_3-symmetric transmembrane protein complexes[4] and the pH-induced conformational changes of viral fusion proteins,[5] which continue to inspire synthetic mimics of their structural as well as functional properties.[6–9] Relaying mechanical signals to remote sites within such functional aggregates requires structurally rigid units, and the noncovalent interactions between these units can be maximized by positioning them in a symmetric fashion. In an effort to implement such an architectural motif in a small-molecule setting, we have devised a general synthetic

route to a new class of C_3-symmetric biconcave molecules. The solid-state structures of these molecules reveal effective mechanical communication between two vertices, by which structural changes on one side of the molecule are effectively transmitted to the other side (Scheme 1). Remarkably, the
Scheme 1. Schematic representation of conformational transmission by correlated opening and closing of the two concave sides of a molecule.

flexible solid-state structure of one such compound allows the complete release of clathrated guest molecules from a nonporous solid under ambient conditions. This dynamic crystal-to-crystal transformation has been confirmed by single-crystal X-ray crystallography.

We developed a convergent synthetic route in order to realize the mechanical coupling illustrated in Scheme 1. Our molecular design positions three *m*-terphenyl "wings" at the periphery of a C_3-symmetric core. The six wing-tips of these elongated aromatic groups converge to define the two vertices of a biconcave molecule. As each pseudo-C_2-symmetric terphenyl unit is disposed nearly perpendicular to the disc-shaped core, expansion of one cavity was expected to nicely correlate with contraction of the other (Scheme 1). Preliminary molecular modeling suggested that a triphenylene-type core **2** (Scheme 2) should be able to support three symmetrically disposed *m*-terphenyl fragments without severe steric constraints. As a structural surrogate of this planar polyaromatic platform, tris(salicylideneamine) **1**[10,11]

(Scheme 2) was chosen in our synthesis. In addition to assisting the facile construction of three-dimensional structures from modularly accessible building blocks, the semirigid six-membered rings afforded by the resonance-assisted hydrogen bonds (RAHBs)[12] were expected to better accommodate the structural changes depicted in Scheme 1.

The reaction between 1,3,5-triformylphloroglucinol (**3**)[10] and five equivalents of 2,6-di(*p*-methoxyphenyl)aniline[13] in EtOH at reflux cleanly afforded the desired Schiff base product **4** in over 85% yield (Scheme 2). The ^{1}H and ^{1}H–^{1}H COSY NMR spectra of this compound in CD$_2$Cl$_2$ at 25°C display a doublet ($\delta = 12.43$ ppm, 3H, $=$CNH) coupled ($J = 13$ Hz) to another doublet ($\delta = 7.53$ ppm, 3H, $=$CHN).[14] Upon treatment with D$_2$O, the resonance at lower field completely disappears and the upper-field signal merges into a sharp singlet. This observation is consistent with the keto-enamine tautomer of the C_3-symmetric tris(salicylideneamine) core rather than the enol-imine.[10,11] The six methyl groups in **4** could be removed by treatment with BBr$_3$ at -78°C to furnish **5** in a yield of 70%. A more sterically hindered homologue **6** could be obtained (65% yield) by triple Schiff base condensation of **3** with 2,6-dimesitylaniline.[13]

This high-yielding and operationally simple route afforded **4–6** in four to five steps from readily available materials without the need for chromatographic separation of synthetic intermediates. Notably, the selective formation of C_3-symmetric **4–6** stands in stark contrast to the previous synthesis of less hindered tris(salicylideneamine) derivatives,[15] in which mixtures of C_s and C_3 isomers were generally obtained (Scheme 2).[10,11] By defining symmetric spaces above and below the molecular core, the *m*-terphenyl fragments apparently suppress the formation of the undesired C_s isomer. The reaction between **3** and 2-(4-hydroxyphenyl)aniline still furnished a mixture of C_s and C_3 isomers ($\approx 3:1$ ratio).

The nine aromatic rings in each of **4–6** are all connected by single C–C bonds rather than by direct ring fusion, thus allowing a balance between structural rigidity and flexibility. As shown in Scheme 3,[16,17] the three *m*-terphenyl wings can undergo concerted tilting with respect to the threefold axis.[18] Intramolecular steric considerations demand that this molecular motion proceeds in a merry-go-round fashion to establish a pair of C_3-symmetric enantiomers, similar to the Δ and Λ isomers of an octahedral tris(chelate)–metal complex. The pseudo-Δ and pseudo-Λ enantiomers are present in equal amounts in solids **4–6**.

As part of this iris-like opening and closing motion, **5** displays conformational communication between two vertices in that the opening of one concave side closes the other side of the molecule (Figure 1).[19] The pronounced asymmetry of the cavity topology is reflected by the distances between adjacent *m*-terphenyl wing-tips on each side
Scheme 2. Synthetic routes to C_3-symmetric biconcave hosts **4–6**.
Scheme 3. Iris-like opening and closing motion: concerted tilting affords an enantiomeric pair of open conformers (right); reversing one rotation imposes steric constraints between adjacent *m*-terphenyl groups (left). Shown next to the schematic diagram is a capped-stick (core) and space-filling (mesityl groups) representation of the crystal structure of **6** (only the *Λ* isomer is shown).
Figure 1. Crystal structure of **5**·6.5 DMF: a) space-filling and capped-stick representations viewed from the top (left) and bottom (right) of the molecule (DMF molecules are omitted); b) ORTEP diagram with thermal ellipsoids at the 50% probability level (hydrogen atoms and DMF guests have been omitted for clarity); c) three DMF molecules (in space-filling model) occupy the open concave side of **5** (capped-stick representation).

guest interaction is yet to be elucidated, this adaptive structural change convincingly demonstrates the conformational transmission proposed in Scheme 1.

The immediate functional relevance of structural semi-rigidity was highlighted by a single-crystal-to-single-crystal transformation of **4**, in which clathrated $CHCl_3$ molecules completely escape the crystal lattice without disrupting it. Compound **4** crystallizes in the trigonal system (space group *P*31*c*). Two chemically identical, but crystallographically unique, molecules **4a** and **4b** were identified in the lattice, each having a crystallographic threefold axis passing through the molecular core (Figure 2a). In the solid state, facing pairs
Figure 2. Molecular packing of **4a** (blue) and **4b** (red) in solvent-free solid **4**: a) capped-stick representation of two unique molecules interpenetrating each other; b) interaction between **4a** and a trigonal array of **4b**; c) schematic representation of a portion of the interdigitated bilayer comprising **4a** (six molecules, top) and **4b** (six molecules, bottom).

of the molecule: the "open" side $C_{para}\cdots C_{para}$ distances range from 10.470 to 10.988 Å (mean value: 10.697 Å), whereas the "closed" side distances range from 5.183 to 5.491 Å (mean value: 5.339 Å). In the solid state, three molecules of DMF (*N*,*N*-dimethylformamide) are located on one concave side of **5**. Although the detailed nature of this van der Waals host–

of **4a** and **4b** interpenetrate each other to open one side of the molecule and close up the other side. The *m*-terphenyl wings on the open side of **4a** function as a tripod when it docks with a triangular array of molecules of **4b** underneath (Figure 2b). In turn, each molecule of **4b** is associated with three **4a** molecules stacked on top of it, thus defining repeating interdigitated bilayers of **4a**·**4b** perpendicular to the crystallographic *c* axis (Figure 2c). The overall shape complementarity of the C_3-symmetric **4** reinforces intermolecular van der Waals contacts and assists in efficient molecular packing. As a result, only 3.9% of the crystal volume is available to guests.

Evenly spaced interstitial spaces were identified within the two-dimensional closest packed layer of **4** (Figure 3). Each of these C_3-symmetric crevices, with a volume of around
Figure 3. a) Crystal structure of a portion of **4**·1/2 CHCl$_3$, shown as a space-filling representation of six **4a** molecules (blue) stacked on top of six **4b** molecules (red) viewed along the crystallographic *c* axis. Every interstitial void space is surrounded by a triangular array of **4a** and fully occupied by one molecule of CHCl$_3$ (green), which is disordered over two positions (not illustrated). b) Crystal structure of **4** redetermined after the complete release of CHCl$_3$.

112 Å^3, is centered over a triangular array of **4a** and is fully occupied by one molecule of CHCl$_3$ when **4** is recrystallized from CHCl$_3$/Et$_2$O.[20] After standing at room temperature for 10 weeks, the co-crystal of **4** and CHCl$_3$ perfectly retained its crystallinity despite the complete loss of CHCl$_3$ from the interstitial space. This was confirmed by a redetermination of the X-ray crystal structure of the same crystal, which also revealed a substantial ($\approx 4.3\%$) decrease in the volume of the

Figure 4. a) Overlaid structures of **4a** in capped-stick representations viewed along the crystallographic threefold axis. b) Perpendicular view. For each conformer, all three *m*-terphenyl groups are related by crystallographic C_3 symmetry. Structures ■ and ▲, which are related by positional disorder of 0.13 and 0.87 site occupancy, respectively, were obtained before the release of CHCl$_3$, whereas ● is from the desolvated crystal. c) Cavities in the crystal structures of **4** corresponding to different conformations ■, ▲, and ● viewed along the crystallographic *c* axis. The surface of the cavities was constructed by tracing the center of a van der Waals sphere of 4.5 Å diameter as it rolls over the surface of **4** within a 2×2×1 array of unit cells. Dark gray surfaces correspond to voids in the upper layer and light gray surfaces correspond to those in the lower layer when viewed along the crystallographic *c* axis. The van der Waals volume of CHCl$_3$, calculated to be about 75 Å^3, corresponds to that of a spherical object with a diameter of about 5 Å. Therefore, the actual space explored by the center of CHCl$_3$ should reside within the cavity surfaces depicted in this figure.

unit cell.[21,22] Except for C$_{aryl}$–C$_{aryl}$ rotations involving three *p*-methoxylphenyl groups of **4a** close to CHCl$_3$ (Figure 4), no significant structural changes were observed before and after solvent loss. The rigid tris(salicylideneamine) cores perfectly fit each other with a maximum deviation of less than 0.05 Å, and the aryl groups on the closed side of **4a** show a maximum deviation of 0.270 Å. The structure of **4b** revealed deviations of less than 0.250 Å for all atoms.[14]

Unlike conventional microporous materials developed for the uptake and release of small-molecule substrates,[23] no unobstructed channels could be found that connect individual cavities within **4** (Figure 4).[24] Escape of CHCl$_3$ therefore requires a cooperative movement within the crystal lattice, which could provide a transient passage for CHCl$_3$ in its hopping between adjacent interstitial voids.[25,26] We suggest that C$_{aryl}$–C$_{aryl}$ rotations of **4a** accompany this process because its overlaid X-ray crystal structures reveal a concerted movement of three *m*-terphenyl groups in response to the departure of adjacent CHCl$_3$ molecules.[14] As shown in Figure 4, the contours of the accessible surface also exhibit drastic morphological changes following this motion.

We note that structural distortions might seem insignificant at the single-molecule level, but their collective effects could be amplified by interlocking arrangements within higher-order assemblies (Figure 2). Harnessing the flexibility of a loosely held aromatic-rich scaffold could be a viable approach to amplifying adaptive molecular motions. This is currently being investigated in our laboratory.

Sequence Symmetry as a Tool for Designing DNA Nanostructures**

Yu He, Ye Tian, Yi Chen, Zhaoxiang Deng, Alexander E. Ribbe, and Chengde Mao*

DNA sequence symmetry brings at least three advantages to any given DNA structure: 1) minimization of the required sequence space and simplification of sequence design; 2) reduction of the number of different DNA strands; and 3) cancellation of some unpredictable distortions in DNA nanostructures, thus allowing DNA two-dimensional (2D) arrays to grow to large sizes. Herein, DNA sequence symmetry is introduced into the design of DNA nanostructures, to give DNA 2D arrays that reach a width of 1 mm.

DNA is an excellent system for studying self-assembly and constructing nanoscale patterns[1,2] because of its extraordinary capability of molecular recognition, well-predictable double-helix structures, huge diversity of unique sequences, and various preexisting toolkits. It is generally believed that DNA sequence symmetry should be eliminated when designing a DNA motif. Each DNA segment has to be unique and can only base pair with its sole, complementary segment, which promotes the formation of designed structures. This rule has been established for 20 years[3] and strictly followed in the field of DNA nanotechnology.[1,4,5] The success of DNA nanotechnology proves the effectiveness of this rule. As DNA nanotechnology has matured, more knowledge and experience have accumulated. We would like to ask: can sequence symmetry provide any advantage? Herein, we will address this question and show a successful application of sequence symmetry.

We studied sequence symmetry with a cross motif (Figure 1)[4d] in which nine different strands (**1–9**) associate with each other and fold into a nearly planar structure (Figure 1a). There is a pseudo-fourfold rotational symmetry of the DNA backbones, but no symmetry when taking the bases into account. If a true fourfold symmetry exists, strands **2–5** will be related to each other by the symmetry and be identical, strands **6–9** will be identical, and strand **1** will become a circular repetitive tetramer. The symmetric cross structure still consists of nine strands, but only three different sequences (Figure 1b). The unique DNA sequences are

Figure 1. Introduction of sequence symmetry. a) An asymmetric cross motif consisting of nine unique strands. The arrows indicate the 3′ ends of the DNA strands b) A symmetric cross motif containing only three unique strands. c) Corrugated self-assembly in two dimensions. Any two neighboring units face in opposite directions; yellow and turquoise squares indicate units facing up and down, respectively. The dimensions of a unit cell of the 2D array are 4.5×4.5 turns.

reduced by four times as all four arms of the cross become identical to each other. Note that sequence symmetry is still avoided when designing each individual DNA strand. Symmetry is only applied to the construction of the cross motif out of the three different strands.

Sequence symmetry substantially influences the self-assembly behavior of the cross motif. The cross structures with sticky ends can be programmed to self-assemble into 2D arrays. Some unpredictable curvatures are associated with the cross motif, because of our limited understanding of branched DNA structures and oversimplification by the DNA duplex model. If the curvatures accumulate, small aggregates will be generated instead of large 2D arrays. A corrugation strategy has been used[4d] to prevent curvature from accumulating during 2D assembly. Adjacent building blocks face up and down alternately in each growing direction, such that the curvatures cancel each other out (Figure 1 c). This strategy has been proved to be effective.

However, each arm of the asymmetric cross motif has a different base composition and a curvature of different direction and extent. The corrugation strategy is not enough to cancel all curvatures. To further remove any curvature and promote growth of planar 2D arrays, new strategies are needed. The introduction of sequence symmetry is promising for this purpose. If a true fourfold symmetry exists, the four arms are symmetrically related and have exactly the same curvatures no matter what they are. When blocks of the symmetric cross assemble in two dimensions, all curvatures are cancelled, and large 2D arrays would be expected. In previous reports, DNA 2D arrays often showed anisotropic shapes,[4] presumably resulting from unequal cohesion strengths between DNA blocks in different directions or from curvature accumulation, or both. Sequence symmetry will remove this problem. The block containing the symmetric cross has exactly the same pair of sticky ends in each direction. Thus, the cohesion strength between the blocks in any direction is exactly the same, which allows equal growth of the 2D arrays in each direction.

The strategy of sequence symmetry has been experimentally proved to be very successful. We followed previously reported experimental protocols (see the Supporting Information).[4] First, the symmetric cross motif was characterized

by native polyacrylamide gel electrophoresis (PAGE). The symmetric cross complex migrated as a single sharp band with an expected mobility in the gel (Figure 2, the second lane from the right), which indicates that the cross complex is
Figure 2. Native PAGE (6%) analysis of the symmetric cross motif. The DNA content of each lane is indicated at the top of the gel image and the identity of each band is indicated on the left. The molar ratios of the strands are given in parentheses. The lane on the far right (50 bp ladder) contains a series of DNA duplex size markers.

stable. Then we modified strand **3** to get complementary sticky ends, and used atomic force microscopy (AFM) to examine whether the cross motif could self-assemble into 2D arrays (Figure 1c and Figure 3). In previous reports[4] and in our own studies,[6] DNA 2D arrays with asymmetric motifs were normally less than 1 µm wide. In sharp contrast, DNA 2D arrays assembled from the symmetric motif are normally in a size range of 20 to 40 µm. The arrays are well-ordered, as judged by direct observation of the images and by Fourier-transform analysis. The observed repeating distance is (18.9 ± 0.3) nm, in good agreement with the value calculated from the
Figure 3. AFM analysis of DNA 2D arrays self-assembled from a symmetric cross motif. Image scanning areas decrease from left to right, thus showing the entire 2D array and the detailed structure. A Fourier-transform pattern (inset, center) shows the regularity of the DNA array.

model $((46 \times 0.33) + (2 \times 2) = 19.2 \text{ nm})$ by assuming that the pitch of the DNA duplex is 0.33 nm per base pair and the diameter of a DNA duplex is 2 nm.

The DNA arrays were often larger than the AFM imaging fields. AFM imaging is well-suited to the study of nanoscale structures. Its drawbacks are that the imaging area is small (practically limited to less than 50 µm for our DNA samples), and that the imaging process is very slow, which prevented us from surveying the overall situation of the DNA samples. To overcome these limitations, we used fluorescence microscopy, which allows the imaging of arrays with areas up to the millimeter scale. This technique provides complementary information to that from the AFM images.

Figure 4 shows fluorescence images of DNA arrays stained with YOYO-1 immediately before imaging. Sample preparation for fluorescence imaging is much simpler than for
Figure 4. a) and b) Fluorescence images (taken from different areas within the same sample) of DNA 2D arrays self-assembled from the symmetric cross motif with a) the largest DNA array found with width 1 mm.

AFM imaging and avoids destroying the DNA arrays. DNA arrays can be easily found under a fluorescence microscope. The overall morphologies of the arrays are very similar to each other when observed by both fluorescence and AFM imaging. The largest array that we have found reaches a size of 1 mm width (Figure 4a), which is hundreds of times larger than previously reported DNA 2D arrays self-assembled from asymmetric motifs.[4]

The DNA arrays can be used as templates to fabricate nanostructures of other materials. We have previously reported a strategy to transfer DNA nanostructures to gold structures by vapor deposition of gold against flat substrate-supported DNA structures.[6] One major concern of this strategy is that the areas of the gold structures are too small to be useful for technological applications. With the new DNA arrays developed here, we can easily address this concern. The gold structures extend up to 40 µm² (Figure 5).

In conclusion, we have demonstrated that sequence symmetry is a powerful tool for designing DNA nanostructures. We are currently testing the symmetry strategy in various DNA nanostructures and hope to determine how general sequence symmetry can be applied. Sequence symmetry dramatically reduces the size of unique sequences and decreases the number of DNA strands. This reduction is important for the fabrication of complicated structures because they need large pools of unique sequences, which, in turn, dramatically increase the difficulty of sequence design. We believe that sequence symmetry will be appreci-

ated as a new tool for the design in these complicated cases. Sequence symmetry is also a useful tool for fine-tuning the structures of DNA motifs, as in the example herein. It is a common concern for molecular self-assembly as to whether self-assembled 2D arrays can be grown to sizes large enough to satisfy the requirements of many technological applications. Herein, we have clearly demonstrated that large 2D arrays are feasible.

Experimental Section

Oligonucleotides: DNA sequences were designed by the computer program SEQUIN.[3b] All oligonucleotides were purchased from IDT, Inc. and purified by 20% denaturing PAGE. Strand **1**: 5′-AggCAC-CATCgTAggTTTTCTTgCCAggCACCATCg-TAggTTTTCTTgCCAggCACCATCgTAggTTTTCTTgCCAgg-CACCATCgTAggTTTTCTTgCC-3′ (circularized); strand **2**: 5′-ACTATgCAACCTgCCTggCAAgCCTACgATggACACgg-TAACg-3′; strand **3**: 5′-CgTTACCgTgTggTTgCATAgT-3′; strand **3′**: 5′-CgCgCgTTACCgTgTggTTgCATAgTCATg-3′.

Formation of DNA complexes and 2D arrays: Strands **1** (0.6 μM), **2** (2.4 μM), and **3** or **3′** (2.4 μM) were combined in Tris/acetate/EDTA/Mg^{2+} (TAE-Mg^{2+}) buffer, which consisted of Tris (40 mM, pH 8.0), acetic acid (20 mM), EDTA (2 mM), and Mg($CH_3COO)_2$ (12.5 mM). Individual DNA complexes for native PAGE analysis were formed by cooling solutions of the mixture as follows: 95 K/1 min, 65 K/30 min, 50 K/30 min, 37 K/30 min, and 22 K/30 min. DNA 2D arrays were formed by slowly cooling the DNA solution from 95°C to room temperature over 48 h. For individual cross molecules, we used strands **1**, **2**, and **3**; for 2D arrays, we used strands **1**, **2**, and **3′**.

Denaturing PAGE: Gels contained 20% polyacrylamide (19:1 acrylamide/bisacrylamide) and 8.3 M urea. The running buffer was Tris/borate/EDTA (TBE), which consisted of Tris buffer (89 mM, pH 8.0), boric acid (89 mM), and EDTA (2 mM). Electrophoresis runs were performed on a Hoefer SE 600 unit at 55°C and 600 V (constant voltage). After electrophoresis, the gels were stained with Stains-All dye (Sigma) and scanned.

Native PAGE: Gels contained 6% polyacrylamide (19:1 acrylamide/bisacrylamide), and electrophoresis runs were performed on an FB-VE10-1 electrophoresis unit (FisherBiotech) at 4°C and 100 V (constant voltage). The running buffer was TAE-Mg^{2+}. After electrophoresis, the gels were stained with Stains-All dye (Sigma) and scanned.

Replication of DNA patterns: All the metal evaporations were carried out with a thermal evaporator (Turbo Vacuum Evaporator EFFA). The evaporation speed was adjusted to 0.2 nm s^{-1}. After metal evaporation (to a thickness of about 20 nm), a drop of premixed epoxy adhesive was placed on the gold film and immediately covered by a glass slide. The epoxy was allowed to solidify completely (normally left overnight), and the metal replicas were mechanically lifted off the mica surfaces.

AFM imaging: A drop of DNA sample solution (2 μL) was spotted onto a freshly cleaved mica surface and left there for 10 s to allow for strong adsorption. The sample drop was then washed off with Mg($CH_3COO)_2$ solution (10 mM, 30 μL) and the surface was dried by compressed air. DNA samples and their metal replicas were imaged by tapping-mode AFM on a Nanoscope IIIa microscope (Digital Instruments) with NSC15 tips (silicon cantilever, Mikro-Masch). The tip–surface interaction was minimized by optimizing the scan set-point.

Fluorescence microscopy imaging: A drop of DNA sample solution (3 μL, in TAE-Mg^{2+} buffer) was spotted onto a clean glass slide and left for 5 min to allow DNA arrays to adsorb onto the glass surface. Then a YOYO-1 (Molecular Probes) solution (1.7 μM in TAE-Mg^{2+} buffer, 1 μL) was spotted onto the DNA sample, which was immediately protected with a coverslip and imaged with a fluorescence microscope.

Lipid Bilayers

Hydrogel Stamping of Arrays of Supported Lipid Bilayers with Various Lipid Compositions for the Screening of Drug–Membrane and Protein–Membrane Interactions**

*Sheereen Majd and Michael Mayer**

Herein we describe a rapid, reproducible, and straightforward method to form copies of functional membrane arrays with various lipid compositions and the application of these arrays for the screening of drug–membrane and protein–membrane interactions. We employed topographically patterned agarose gels to stamp spatially addressable arrays of supported bilayers on glass and confirmed the fluidity of these membranes by fluorescence recovery experiments. We took advantage of the storage capability of hydrogels and demonstrated that inking posts on an agarose stamp, with extremely small volumes (≤ 1 μL) of a solution that contains liposomes, was sufficient to transfer at least 100 copies of a membrane array without the need for reinking. We used stamped membrane arrays for screening the interactions of a protein (annexin V) and an anti-inflammatory drug (nimesulide) with bilayers of various lipid compositions and discovered that the interaction of the prescription drug nimesulide with membranes depends on the membrane cholesterol content.

Interest in supported bilayers[1–3] includes studies of the dynamic structure of membranes,[4,5] their self-assembly,[5] lipid–protein interactions,[5] ligand–receptor interactions,[5–8] development of membrane-based biosensors,[5,9–15] and drug discovery.[16] Furthermore, many pharmaceuticals are known to interact with biological membranes and, as such, assays for testing drug–membrane interactions are important for a better understanding of drug activity, targeting, and toxicity.[17] To use supported bilayers efficiently for the study of the aforementioned processes, the membranes must be fluid[1,16,18,19] and mechanically stable.[19] Techniques that are currently employed to form arrays of supported membranes exploit a) the deposition of droplets of a liposome solution onto surfaces,[6,18] b) vesicle fusion from a bulk solution onto patterned substrates,[20,21] c) delivery of liposomes by microfluidic channels,[22,23] and d) microcontact printing with poly(dimethylsiloxane) (PDMS).[24]

An ideal fabrication method for the application of membrane arrays for screening protein–membrane or drug–membrane interactions would consist of the rapid creation of many functional copies of an array of different bilayers with minimal consumption of the amount of lipid. Among the existing methods, microcontact printing allows the creation of many spots of membranes in parallel. To prepare arrays with various compositions, however, posts of the stamp used for microcontact printing must be inked individually. Such an inking procedure can be time consuming and can introduce heterogeneity into the stamped arrays. It would therefore be advantageous if a biocompatible stamp, once inked, could store the inking solution and allow multiple transfers without the need for reinking.

Herein, we demonstrate that stamping with hydrogel stamps allows multiple stamping while using minute amounts of material. We fabricated stamps from agarose gel (4%) with a pore size sufficiently large to allow the diffusion of macromolecules and small liposomes (the pore size of 2% agarose gel is ≈ 470 nm[25]). This capability makes it possible to store inking solution within the stamp while replenishing molecules at the surface and, thus, to perform multiple stamping of biomolecules.[25] Recently, agarose stamps[26,27] were applied to pattern arrays of proteins,[28,29] bacteria,[30] and mammalian cells.[31] Herein we present the first attempt to use hydrogel stamps to create functional arrays of fluid lipid membranes.

To form arrays of lipid bilayers, we inked each post on the agarose stamp with a sub-microliter volume of liposome suspension. After the posts had absorbed the solution, we placed the inked stamp in contact with glass slides for 5–10 s (see Supporting Information for details and stamp dimensions). Immediately after removal of the stamp, we immersed the patterned substrates in either deionized water or PBS buffer solution. We hypothesize that during stamping, supported membranes form by diffusion of small liposomes (diameter 20–80 nm)[32] through the pores of the agarose stamp and the subsequent spread of liposomes onto the regions in contact with the glass. As the agarose stamps used in this method consist mostly ($\geq 96\%$ *w/w*) of water, we suggest that the mechanism of bilayer formation is similar to the mechanism of the established method of vesicle fusion from solution.[16]

We examined the structure of the stamped lipid bilayer spots on the glass substrate by atomic force microscopy (AFM) experiments (see Supporting Information). The AFM results revealed a smooth surface of bilayer with scattered defects. The area of the defect sites was $\leq 23\%$ of the total imaged bilayer area. Cross-section analysis of the defects revealed a thickness of 4.3 ± 0.8 nm, which corresponds to the height of a single lipid bilayer.[6]

To investigate the capability of agarose stamps to store small liposomes, we used a stamp that was inked once and stamped 100 times without intermediate reinking. This stamp was inked with a solution of liposomes composed of L-α-

phosphatidylcholine derived from chicken egg (egg PC) and 1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(lissamine-rhodamine B sulfonyl) (rh-PE; 1% *w/w*). We found no significant loss in the fluorescence intensity of the spots over 100 stamping events (Figure 1a). Figures 1b and c show
Figure 1. Fluorescence intensity after stamping of 100 arrays of membranes by using a hydrogel stamp (without intermediate inking), and test of bilayer fluidity. The bilayers composed of egg PC and rh-PE (1% *w/w*) were stamped on glass slides. a) Mean fluorescence intensity of supported bilayers as a function of the number of stamping events. The error bars represent the standard deviation of the intensity of all spots in each array. The dashed line represents the mean fluorescence intensity of the background. b) Micrograph of spots of supported bilayers after the 6th and c) 100th stamping event. d) Fluorescence images from a FRAP experiment performed on the array from the last (100th) stamping event after photobleaching for 8 min.

fluorescent micrographs of membrane arrays on glass that were obtained after 6 and 100 stamping events, respectively. To test the fluidity of the stamped bilayers, we performed fluorescence recovery after photobleaching (FRAP) experiments (see Supporting Information for details). Figure 1d shows the recovery of a photobleached spot in a bilayer of the last (100th) array. Fluorescence recovery of the bilayers in this array was similar to that in the 6th array (difference in diffusion constant ≤ 5%) which therefore indicates that the quality of the stamped arrays remained constant over ≈ 100 stamping events. The fluorescence intensity in the photobleached spot recovered to ≈ 90% of its original intensity, a value typical for supported membranes of high quality.[6]

We used a stamp with 200-μm-diameter posts to explore the potential of this method for the production of membrane arrays with a high density. Figure 2a shows such a resultant array with a density of 600 membrane spots per cm². If such a stamp were inked by using robotics, it should, in principle, be possible to stamp multiple copies of high-density arrays with various membrane compositions.[29]

To demonstrate the ability of this method to create, in parallel, bilayers with different lipid compositions, we transferred arrays of supported membranes by using liposomes that contained 0–50% negatively charged lipids and 0–50% cholesterol. Remarkably, hydrogel stamping resulted in high-quality membrane arrays on glass substrates even when the bilayers contained 50% negatively charged lipids (Figure 3a). Figure 2b shows an array of bilayers with two different fluorescently labeled lipids. These spots were transferred in parallel from the same stamp.
Figure 2. Stamped high-density array of supported bilayers and membrane arrays with various compositions. a) Fluorescent micrograph of a patterned array of bilayers composed of egg PC with rh-PE (1% *w/w*) by using an agarose stamp with a post size of 200 μm. b) Fluorescent micrograph of an array of bilayers that contains egg PC and rh-PE (1% *w/w*; red) and NBD-PE (3% *w/w*; green).
Figure 3. The protein annexin V binds to bilayers with different DOPS content. a) Micrographs of fluorescently labeled annexin V bound to bilayers that contain 0, 20, and 50% (*w/w*) DOPS. b) Increase in fluorescence intensity due to the binding of annexin V to an array of bilayers with a gradient in DOPS. The binding of annexin V is calcium-dependent; these data were obtained in (■) 1 mM and (●) 8 mM Ca²⁺. The error bars represent the standard deviations in fluorescence intensity.

To determine if liposomes with different lipid compositions are transferred differentially from the agarose stamp to the glass slide, we inked the posts of a stamp with mixtures of two different liposome populations (the first population was composed of egg PC (99% *w/w*) and rh-PE (1% *w/w*) and the second was composed of egg PC (50% *w/w*) and 1,2-dioleoyl-*sn*-glycero-3-[phospho-L-serine] (DOPS; 50% *w/w*)). We used this stamp to create a membrane array and subsequently studied the compositions of the resultant bilayers (see Supporting Information for details). Epifluorescence microscopy images showed that the fluorescence of the transferred bilayers was proportional to the ratio of the two liposome populations in the inking solution. This result suggests that there is no significant preference in transfer between the neutral and negatively charged liposomes.

To explore the possible applications of membrane arrays with various compositions for the screening of protein–

membrane interactions, we formed arrays from egg PC with a gradient in the negatively charged lipid, DOPS, and measured the binding of annexin V to these bilayers. Annexin V is a calcium-dependent binding protein that interacts with negatively charged lipids.[33] Figure 3a shows micrographs of the binding of fluorescently labeled annexin V to supported bilayers with three different concentrations of DOPS. Figure 3b illustrates that the binding of annexin V to supported membranes increases with an increasing concentration of both DOPS in the bilayer and calcium ions in solution. These results show that stamped arrays of supported membranes can be used effectively to quantify protein–membrane interactions.

Further to the investigation of protein–membrane binding, membrane arrays may be useful for screening drug–membrane interactions. These interactions can depend on the composition of the lipid membrane[17] (e.g. the content of cholesterol) and can induce a change in the fluidity of the bilayer.[34] The therapeutic and toxic effects of many drugs are affected by their interactions with lipid membranes.[17,34] To demonstrate the influence of the lipid composition on drug–membrane interactions, we studied the fluidity changes that are introduced by the non-steroidal anti-inflammatory drug (NSAID), nimesulide, in bilayers with various cholesterol content. NSAIDs, (e.g. aspirin or ibuprofen) are the most-important drugs in the treatment of inflammation, pain, and fever.[34]

Lucio et al. reported that nimesulide increases the fluidity of membranes composed of egg PC.[34] In the studies described herein, we incubated stamped membrane arrays of egg PC with various cholesterol content in solutions that contain 0, 50, and 100 µM nimesulide for 2 h, and monitored the changes in fluidity by FRAP experiments.[35],[36] Figure 4 shows the fluorescence recovery of bleached spots in the presence of nimesulide. In agreement with Lucio et al.,[34] we found that nimesulide (50 µM) increased the fluidity in egg PC membranes. We discovered the same effect in bilayers with a moderate cholesterol content ($\leq 20\%$). Surprisingly, however, nimesulide had the opposite effect, namely a decrease in fluidity, on bilayers with a high cholesterol content ($\geq 50\%$). Furthermore, nimesulide decreased the fluidity of all the examined bilayers when it was added at a concentration of 100 µM (Figure 4c). The diffusion coefficients of fluorescently labeled lipids in these bilayers are summarized in Table 1.

Figure 4. Influence of nimesulide on the fluidity of stamped lipid bilayers with various cholesterol content. Recovery curves of supported lipid bilayers of egg PC and rh-PE (1 % *w/w*) which contain (■) 0 % cholesterol, (●) 20 % cholesterol, and (▲) 50 % cholesterol in the presence of a) 0, b) 50, and c) 100 µM nimesulide.

In conclusion, we present a strikingly simple and reproducible method to obtain copies of functional membrane arrays from a range of lipids (including up to 50 % negatively charged lipids). This method allows the fabrication of at least 100 copies of a bilayer array while using only picomolar amounts of lipids per spot—a characteristic that may be particularly beneficial for stamping precious membrane preparations that can often only be obtained in limited quantities, such as cellular membrane fragments. Binding assays with these arrays elucidated an unknown effect of cholesterol on the interaction of a prescription drug with bilayers, and as such, we expect liposome stamping to be useful for the rapidly growing interest in drug–membrane interactions,[17,34] protein–membrane interactions,[5] and arrays of membrane proteins.[6]

Table 1: Diffusion coefficients, *D* of rh-PE in supported membranes composed of egg PC and rh-PE (1 % *w/w*) with various cholesterol content in the presence of nimesulide.

| Cholesterol content [%] | *D* [cm²s⁻¹][a] | | |
	0 µM nimesulide	50 µM nimesulide	100 µM nimesulide
0	2.0×10^{-9}	2.7×10^{-9}	1.4×10^{-9}
20	1.8×10^{-9}	2.4×10^{-9}	1.2×10^{-9}
50	1.5×10^{-9}	0.7×10^{-9}	0.4×10^{-9}

[a] The errors of the diffusion coefficients are $\leq \pm 7\%$ and were obtained through measurement of the differences between diffusion coefficients of fluorescently labeled lipids in bilayers made from the same lipid composition, but stamped on different days.

Enantioselective Thiourea-Catalyzed Acyl-Mannich Reactions of Isoquinolines**

*Mark S. Taylor, Norihito Tokunaga, and Eric N. Jacobsen**

Aromatic molecules represent an attractive class of feedstock compounds for organic synthesis because of their ready availability, their stability, and the wealth of classical and modern chemistry available for their preparation and manipulation. The development of enantioselective, catalytic methodologies that engage aromatic π systems as substrates offers particular promise for synthetic applications. Despite this potential, it is only recently that aromatic frameworks have been employed successfully as electrophiles[1] or nucleophiles[2] in asymmetric, catalytic reactions, and many important challenges in this area remain unmet. The addition of carbon-centered nucleophiles to nitrogen-containing heteroaromatic compounds is a particularly interesting problem, in light of the potential impact of such a methodology on alkaloid synthesis. Diastereoselective reactions controlled by chiral auxiliaries currently constitute the state-of-the-art methods for the majority of stereocontrolled transformations of this type.[3] The elegant alkaloid syntheses of Comins et al. based on diastereoselective nucleophilic additions to chiral (4-methoxy)acylpyridinium derivatives illustrate the utility of such approaches.[4] Only one enantioselective, catalytic method for the addition of carbon-centered nucleophiles to aromatic nitrogen heterocycles has been developed to date: the aluminum-catalyzed acylcyanation of quinolines, isoquinolines, and pyridines (the Reissert reaction) developed by Shibasaki and co-workers.[1a–d] Herein, we report the first example of an asymmetric, catalytic addition of enolate equivalents to heteroaromatic electrophiles. This acyl-Mannich reaction,[5] catalyzed by a chiral thiourea derivative, provides access to useful enantioenriched dihydroisoquinoline building blocks.[6]

N-Alkylations or *N*-acylations of nitrogen-containing heteroaromatic compounds give rise to highly electrophilic

iminium or acyliminium ions that are susceptible to a variety of addition reactions. There are very few examples of the asymmetric catalysis of such additions,[1a–e] a fact that may reflect, to some extent, the difficulty in the development of catalysts capable of the activation of such intermediates. In that context, we were highly encouraged by the discovery that chiral thiourea **1** catalyzes an enantioselective acylative variant of the Pictet–Spengler reaction (Scheme 1). The
Scheme 1. Enantioselective acyl-Pictet–Spengler reaction catalyzed by **1**.

possibility that **1** can activate a putative intermediate acyliminium ion towards enantioselective cyclization by hydrogen-bond donation[7,8] prompted us to study its application to the reactions of acyliminium ions derived from nitrogen heterocycles.

In light of the prevalence of the 1-substituted tetrahydroisoquinoline motif in alkaloid architecture,[9] we selected isoquinoline as a model substrate (Table 1). The enantioselectivity of acyl-Mannich-type reactions catalyzed by **1** was found to depend strongly on the nature and structure of the acylating agent and nucleophile. A screen of acylating agents was performed using the *O-tert*-butyldimethylsilyl (TBS) ketene acetal derived from methyl acetate as the nucleophile.[10] Acetyl chloride, the optimal reagent for enantiose-

lective Pictet–Spengler reactions, furnished the acyl-Mannich product in poor enantiomeric excess (28% *ee*; entry 1). More encouraging results were obtained using chloroformates (entries 2–5), with which tuning of the alkoxy substituent had a pronounced effect upon enantioselectivity. The dihydroisoquinoline product was obtained in a promising 82% *ee* by using 2,2,2-trichloroethyl chloroformate (TrocCl). Further improvement upon this result was realized by variation of the structure of the nucleophile (entries 5–7), with the best result provided by the silyl ketene acetal derived from isopropyl acetate. The acyl-Mannich reaction of isoquinoline proceeded in 80% yield with 86% *ee* under the optimized conditions.

Despite markedly different dependences of enantiomeric excess upon the structure of the acyl group, the acyl-Mannich and acyl-Pictet–Spengler reactions share several common features. Pronounced solvent effects were observed in both cases, with diethyl ether affording the highest enantioselectivity. In addition, **1** is the optimal catalyst identified to date for both reactions.[11] In particular, the *ee* values of both the acyl-Mannich and acyl-Pictet–Spengler reaction exhibit a dramatic dependence upon the substitution pattern of the pyrrole moiety (Table 2). The crystal structure of **1** may help to explain this behavior (Figure 1).[12] The orientation of the 2-methyl-5-phenylpyrrole structural motif places the phenyl group in position to interact closely with any species that undergoes hydrogen-bonding interactions with the acidic thiourea protons (Figure 1).[13] In the solid state, **1** exists as a dimeric structure through bifurcated hydrogen-

precursors to enantioenriched 1-substituted tetrahydroisoquinolines: hydrogenation of the enamide moiety and reductive cleavage of the trichloroethyl carbamate group occur in good yield without detectable racemization (Scheme 2).[15] Thus, this method represents a straightforward approach to the preparation of enantioenriched heterocycles with potential
Scheme 2. Synthesis of an enantioenriched tetrahydroisoquinoline. TFA = trifluoroacetic acid.

utility for alkaloid synthesis from stable, readily accessible aromatic starting materials. For certain applications, this methodology may prove complementary to the Pictet–Spengler reaction, both in terms of electronic requirements (both electron-rich and electron-poor products may be accessed) and regioselectivity (the substitution pattern of the product is determined only by the choice of the isoquinoline starting material). In addition, this study demonstrates that thiourea catalyst **1** mediates two distinct enantioselective transformations of N-acyliminium ions: intramolecular Friedel–Crafts reactions of acyliminium ions derived from acyclic, aliphatic imines (the acyl-Pictet–Spengler reaction) and intermolecular Mannich reactions of acylisoquinolinium ions. Further extension of this mode of catalysis to encompass other reactions of N-acyliminium intermediates and investigation of the mechanism by which these electron-poor species are activated by a hydrogen-bond donor are the focus of future study.

Experimental Section

General procedure for acyl-Mannich reactions catalyzed by **1**: 1-Isopropoxycarbonylmethyl-1H-isoquinoline-2-carboxylic acid 2,2,2-trichloroethyl ester (Table 3, entry 1): Isoquinoline (61 μL, 0.50 mmol; 97% purity) was dissolved in diethyl ether (5.0 mL) in a flame-dried round-bottomed flask and cooled to 0°C. 2,2,2-Trichloroethyl chloroformate (76 μL, 0.55 mmol, 1.1 equiv; 98% purity) was added dropwise by syringe, and the resulting white suspension was warmed to 23°C, stirred for 30 min, and then cooled to −78°C (dry ice/isopropanol bath). Catalyst **1** (26.9 mg, 0.050 mmol, 10 mol%) in diethyl ether (4.0 mL + 1.0 mL rinse volume) and then 1-(tert-butyldimethylsilyloxy)-1-isopropoxyethene (216 mg, 1.0 mmol, 2.0 equiv) were added. The reaction mixture was warmed to −70°C (isopropanol bath equipped with immersion cooler) and stirred for 14 h. Cooling was stopped and the bath allowed to warm to 23°C over 3 h. After the solvent was removed in vacuo, the residue was purified by chromatography on silica gel (0→5% ethyl acetate/hexanes), thus yielding a colorless oil (161 mg, 0.40 mmol, 80% yield). The enantiomeric excess was determined to be 86% by SFC using a commercial chiral stationary phase (Chiralpak OD-H, 5% methanol/CO₂, 5 mL min⁻¹, 50°C, 285 nm; t_r(minor): 2.23 min, t_r(major): 2.66 min); α_D −240° ($c = 1.1$ g 100 mL⁻¹, CH₂Cl₂); ¹H NMR (500 MHz, CDCl₃): the compound exists as a 1.7:1 mixture of carbamate rotamers; signals corresponding to the major rotamer: δ = 7.26–7.17 (3H, m), 7.10 (1H, d, $J = 7.5$ Hz), 6.90 (1H, d, $J = 7.5$ Hz), 5.99 (1H, d, $J = 8.0$ Hz), 5.84–5.82 (1H, m), 4.97–4.88 (2H, m), 4.78 (1H, d, $J = 12.0$ Hz), 2.67–2.58 (2H, m), 1.20 (3H, d, $J = 6.0$ Hz), 1.16 ppm (3H, d, $J = 6.5$ Hz); representative signals corresponding to the minor rotamer: δ = 6.90 (1H, d, $J = 7.5$ Hz), 6.04 (1H, d, $J = 8.0$ Hz), 4.82 (1H, d, $J = 11.5$ Hz), 2.77 (1H, dd, $J = 14.0$, 9.0 Hz), 1.11 ppm (3H, d, $J = 5.5$ Hz); ¹³C NMR (100 MHz, CDCl₃), signals corresponding to both rotamers: δ = 169.6, 169.5, 151.6, 151.2, 131.4, 131.2, 129.9, 129.8, 128.6, 128.5, 127.7, 127.5, 126.7, 126.6, 125.5, 125.3, 124.5, 123.6, 110.7, 110.6, 95.2, 95.2, 75.7, 75.6, 68.4, 68.4, 53.3, 53.1, 40.8, 40.1, 22.0, 22.0, 21.9, 21.9 ppm; IR (neat): $\tilde{\nu}$ = 3063 (w), 2980 (m), 2936 (w), 1728 (s), 1651 (s), 1452 (m), 1262 (m), 1109 (m), 968 cm⁻¹ (w); HRMS (ES): m/z calcd for [C₁₇H₁₈Cl₃NO₄+H]⁺: 406.0380; found: 406.0380.

[10] A preliminary survey of ketone enolates did not yield satisfactory results; for example, 2-(trimethylsilyloxy)propene underwent addition to isoquinoline in the presence of TrocCl and **1** to yield the corresponding dihydroisoquinoline in 14% ee (unoptimized).

[11] A list of solvents and other catalysts tested may be found in the Supporting Information.

[12] Slow evaporation of a solution of **1** in hexanes/diethyl ether yielded crystals suitable for X-ray analysis; crystal data for **1**: $C_{32}H_{50}N_4OS$, $M_r = 538.82$, colorless prism, $0.20 \times 0.18 \times 0.14$ mm, orthorhombic, $a = 16.590(3)$, $b = 17.202(3)$, $c = 22.411(4)$ Å, $V = 6396(2)$ Å^3, $T = 193(2)$ K, space group $C222_1$, $Z = 8$, $\rho_{calcd} = 1.119$ g cm^{-3}, $\mu = 0.130$ mm^{-1}; a total of 22451 reflections were measured, 7659 independent, final residuals were $R1 = 0.0394$ and $wR2 = 0.0877$ for 7659 observed reflections with $I > 2\sigma(I)$, 543 parameters, GOF = 0.960, maximum residual electron density 0.438 e Å^{-3}; data were collected on a Bruker SMART CCD (charge-coupled device) based diffractometer equipped with an Oxford Cryostream low-temperature apparatus; data were measured by using scans of 0.3° per frame for 45 s, such that a hemisphere was collected; a total of 1271 frames were collected with a maximum resolution of 0.76 Å; the first 50 frames were recollected at the end of data collection to monitor for decay; the structure was solved by the direct method (G. M. Sheldrick, SHELXL-97, Program for the Solution of Crystal Structures, University of Göttingen, Germany, **1997**) followed by refinement by the least-squares method on F^2 (SHELXL-97); all non-hydrogen atoms were refined anisotropically; the positions of hydrogen atoms were found by difference Fourier methods and refined isotropically. CCD-275454 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

[13] A neutral chloroamide structure, rather than an ion pair, may represent a more accurate depiction of the bonding interactions in *N*-acyliminium chlorides in nonpolar organic solvents (for an NMR spectroscopic study that supports this assertion, see: A. K. Bose, G. Spiegelman, M. S. Manhas, *Tetrahedron Lett.* **1971**, 3167–3170). Calculations that use the density-functional theory
(B3LYP/6-31G ++ (d,p)) predict substantial chloroamide character for *N*-acylisoquinolinium chloride (M. S. Taylor, E. N. Jacobsen, unpublished results), and the strong dependence of enantioselectivity upon solvent polarity observed in both acyl-Mannich and acyl-Pictet–Spengler reactions may be a reflection of the importance of the pairing of the *N*-acyliminium ions in these processes. These reactions are also subject to dramatic leaving-group effects upon reactivity and enantioselectivity, a phenomenon that seems difficult to reconcile with a fully ionized *N*-acyliminium ion as the reactive species. The possibility that **1** activates intermediate chloroamides toward substitution reactions by hydrogen-bonding interactions with the carbonyl group represents an intriguing, albeit speculative, mechanistic hypothesis that is consistent with these observations.

A Family of Hierarchically Self-Assembling Linear-Dendritic Hybrid Polymers for Highly Efficient Targeted Gene Delivery**

Kris C. Wood, Steven R. Little, Robert Langer, and Paula T. Hammond**

To fully realize the potential for new medical advances in the postgenomic era, safe and efficient delivery systems for nucleotide-based drugs must be developed.[1] Ideally, such systems will be nontoxic, nonimmunogenic, and made from versatile building blocks that allow optimal delivery to a range of cells or tissues of interest. Herein, for the first time, we present the design, synthesis, and evaluation of a unique family of hierarchically structured linear-dendritic hybrid polymers that self-assemble with DNA to form stable nanoparticles with a series of concentric, functional "shells" that display independently tuneable properties necessary for effective targeted delivery. The resultant ligand-functionalized systems demonstrate receptor-mediated delivery to targeted cells with robust serum stability, transfection efficiencies that exceed the most efficient commercially available polymer poly(ethylenimine) (PEI), and low toxicity at concentrations one to two orders of magnitude higher than those at which PEI is toxic. These systems may find potential utility as targeted in vivo gene delivery systems for DNA- or RNA-based therapies.

The success of gene-based therapies is dependent upon the ability to deliver genes that express key proteins when and where they are needed. As of yet, no such therapies have been approved for clinical use, primarily because of the lack of versatile, safe, and efficient gene delivery systems.[2,3] A suite of electrical, mechanical, and modified viral delivery systems have been investigated with some success, but these systems suffer from significant drawbacks.[4–7] Notably, modified viruses often elicit severe immunogenicity, are prone to insertional mutagenesis, and are refractory to repeated administrations. Chemical delivery systems, such as cationic linear polymers, dendrimers, or lipid-based reagents, while generally safer than their viral counterparts, typically lack the high efficiency or multiple functionalities required for in vivo administration. Moreover, even subtle synthetic modifications to these systems can dramatically influence existing biological properties.[8–10] Herein, we present a new family of multifunctional gene delivery polymers based on dendritic poly(amidoamine) (PAMAM) and linear poly(ethylene glycol) (PEG) with a wide array of properties (namely, blood stability, cellular targeting, DNA binding, and endosomal buffering capacity) that can be independently tuned in a modular fashion to address each of the barriers to effective gene delivery. As a proof of concept, we demonstrate the ability to independently modulate targeting and expression levels by choice of the ligand and dendrimer species, respectively. Furthermore, these systems represent a platform on which additional functionalities may be added to impart properties such as vector unpackaging and nuclear targeting.[11,12]

Linear-dendritic hybrid polymers were designed based on the hypothesis that these unique polymer architectures, which contain functionalities that are both chemically orthogonal and physically separate, could self-assemble with DNA to yield nanoparticles with an outer shell of targeting ligands accessible to cell-surface receptors, a flexible hydrophilic corona designed to prevent protein opsonization, plasma clearance, and nonspecific uptake, and an interior of amine groups to promote DNA binding and escape from endosomal vesicles into the cytoplasm[13,14] (see Scheme 1 and the Supporting Information). Ligand-functionalized linear-dendritic polymers were synthesized as follows: Fmoc-PEG-NHS

($M_n = 3500$, $n = 72$, polydispersity index (PDI) = 1.01; Fmoc = 9-fluorenylmethoxycarbonyl, NHS = N-hydroxysuccinimide) was dissolved in 0.1M NaHCO₃ buffer (37.5 mg mL⁻¹) and adjusted to pH 8.5 with 1M NaOH. Amine-modified mannose and galactose ligands were dissolved separately in 0.1M NaHCO₃ buffer (30 mg mL⁻¹), adjusted to pH 8.5, and added to an aliquot of dissolved polymer in solution at a molar excess of 10:1 (24 h, 25°C, under N₂). The polymers were recovered by filtration and lyophilization, dissolved in dimethylformamide (DMF; 100 mg mL⁻¹), and added dropwise to a solution of 20% piperidine in DMF to remove the Fmoc protecting group (30 min, 25°C, under N₂). Following this step, the polymers were recovered by precipitation with diethyl ether and dried overnight under vacuum. The dendrimer synthesis proceeded by serial Michael addition and amidation steps by the addition of methyl acrylate and ethylene diamine, respectively, as described previously (see Supporting Information).[15] In general, the ligand-functionalization and deprotection steps proceeded at 80–85%, and all the dendrimer synthetic steps proceeded with conversions of 90–100% (see Supporting Information). The physical properties of these polymers are listed in Table 1. The growth of the amide (3200–3400 cm⁻¹) and carbonyl (1600–1800 cm⁻¹) bands

Figure 2. Biophysical characterization of linear-dendritic polyplexes. a) Electrophoresis on 1% agarose gel demonstrates DNA binding at the indicated mass ratios. b) Particle diameter measured with dynamic light scattering (DLS). c) Transmission electron microscopy (TEM) images depict narrowly dispersed, roughly spherical particles.

charge neutralization of DNA by linear-dendritic polymers incubated at mass ratios of > 20:1, 10:1, 5:1, 1:1, and 1:1 for generations 2.0 (G2.0), 3.0 (G3.0), 4.0 (G4.0), 5.0 (G5.0), and 6.0 (G6.0), respectively (an acetate buffer of pH 5.1 was used in all cases to ensure complete protonation of the primary amines on the dendrimer periphery). The nature of this trend is consistent with intuition, as the exponentially increasing number of the amine functionalities with increasing dendrimer generation results in higher charge density with increasing dendrimer size. Dynamic light scattering (DLS) suggests that polyplexes of G3.0, G4.0, and G6.0 are around 150 nm in diameter on average, which is under the reported cut-off point of around 200 nm that is required for efficient cellular uptake (Figure 2b).[16] G5.0 polyplexes form larger particles with DNA, a seemingly anomalous result that was nevertheless highly repeatable. The large size of G2.0 polyplexes reflects the fact that little DNA binding and charge neutralization occurred in these systems. In all cases, mass ratios in the range 0.1:1–200:1 were tested, and polyplex size was shown to be relatively insensitive to mass ratio above the point at which complexation occurs in each system, thus suggesting that in all cases the polyplexes consist of a single DNA plasmid and that excess polymers remain dispersed in solution. Thus, particle diameters given in Figure 2b represent average diameters for an evenly weighted range of mass ratios up to 200:1. Finally, transmission electron micrographs of G6.0 polyplexes show narrowly dispersed, roughly spherical complexes with an outer corona of approximately 6–8 nm, which is consistent with the expected size of PEG–PAMAM G6.0 (Figure 2c).[17]

In all of the above cases, complexes were formed prior to assay by incubation of the dilute solutions of the plasmid-DNA-encoding firefly luciferase (6.2 kb, 2.05×10^6 g mol^{-1}, 0.1 mg mL^{-1}, 25 mM acetate buffer, pH 5.1) with equal volumes of solutions that contain polymers (in 25 mM acetate buffer (pH 5.1) at appropriate concentrations to achieve the indicated mass ratios) for 20 min at room temperature.[18]

To evaluate the ability of polyplexes to transfect target cells by receptor-mediated uptake, we transfected two cell types, P388D1 murine macrophages bearing a mannose receptor and HepG2 human hepatocytes bearing an asialoglycoprotein receptor (for galactosylated ligands).[19–22] The transfections were performed in quadruplicate in a 96-well plate format. The polymers and DNA were combined for 20 min at mass ratios in the range 1:1–200:1 (polymer/DNA) in 25 mM acetate buffer, added to a serum-free or 10% serum-containing medium, and incubated with cells for 4 h (587 ng DNA well^{-1}), after which the polyplex-containing medium was removed and replaced with growth medium. The cells were assayed for expression of the luciferase reporter gene after 72 h.[18] Figure 3a shows the

Figure 3. Transfection of P388D1 macrophages bearing the mannose receptor. a) Transfection by linear-dendritic polyplexes with and without the mannose ligand and in the presence of soluble mannose (0.1 mg well^{-1}); * indicates $p < 0.04$, ** indicates $p < 0.002$ (two-tailed, unpaired Student's T-Test). Results normalized to an optimized formulation of PEI (2:1 PEI/DNA, serum free, no free mannose added). b) Serum stability is demonstrated through transfection in the presence of serum proteins. levels of luciferase-reporter-gene expression in macrophages (in the absence of serum) with optimized formulations of ligand-functionalized polyplexes, control polyplexes bearing no ligand, ligand-functionalized polyplexes in the presence of excess soluble ligand, and PEI. The G6.0 mannose-bearing polyplexes demonstrate transfection 1.6- to 1.8-fold higher than PEI, the most efficient commercially available polymer for in vitro transfections. The G5.0 polyplexes mediate

reporter expression levels approximately 1.3-fold higher than PEI, whereas the G4.0 polyplexes (as well as G3.0 and G2.0, data not shown) transfect at low levels comparable to naked DNA. The highest transfection levels were observed in polymer/DNA ratios under 50:1 in all systems (under 20:1 in G6.0), presumably because of the effects of toxicity at high concentrations. Polyplexes with no mannose ligand exhibited significantly lower transfection efficiencies, and competitive inhibition of mannose receptors by an excess of soluble ligand virtually silenced reporter-gene expression without affecting expression levels in the positive and negative controls (Figure 3a). These data further support the hypothesis of cellular internalization by means of specific receptor-mediated endocytosis. Finally, macrophages were transfected in the presence of a 10% serum-containing medium to probe the serum stability of pegylated polyplexes (Figure 3b). Fourfold transfection enhancements were observed relative to PEI, most likely because of the "stealth" effect imparted by PEG, which is known to lower particle agglomeration by attenuation of opsonization of serum proteins.[23]

Transfection of HepG2 hepatocytes by linear-dendritic polyplexes bearing the galactose ligand is shown in Figure 4. In the absence of serum, optimized formulations of G6.0 and G4.0 ligand-functionalized polyplexes transfect significantly more efficiently ($p < 0.06$) than control polymers with no

yield enhanced targeting relative to the monomeric species.[24,25]

To assess the cellular toxicity of linear-dendritic hybrid-polymer-based systems, a methylthiazolyldiphenyltetrazolium bromide (MTT) assay was performed to measure the relative viability of cells treated with various polymer/DNA mass ratios. Cells were seeded in clear 96-well plates and transfected exactly as previously described. A range of polymer/DNA mass ratios were studied that corresponded to concentrations equal to and above those at which the optimal transfection levels were observed. In P388D1 macrophages (Figure 5a), cells that we have found to be highly

ligand (Figure 4a). Moreover, G6.0-, G5.0-, and G4.0-targeted systems mediate transfection levels within one order of magnitude of PEI in the absence of serum and as much as eightfold more than PEI in the presence of serum (Figure 4a,b). Optimal polymer/DNA mass ratios were in the range 100:1–200:1 for all the systems studied. Taken together, these data suggest that the hepatocyte-targeted polyplexes are serum-stable and demonstrate enhanced transfection because of a cell-specific receptor-mediated process. Interestingly, expression levels were unaffected by the presence of an excess of soluble galactose, a finding that may arise from the multivalent nature of ligand binding by the asialoglycoprotein receptor; thus, it is suggested that multivalent ligand presentation through synthetic multimeric galactose ligands may

sensitive to environmental conditions in culture, no measurable toxicity was observed in the G4.0-based systems over the entire concentration range studied. More significant toxicity was observed at high mass ratios in G5.0 (60–80% viability relative to untreated controls) and the G6.0 systems (50–70%), though these toxicities were primarily observed at concentrations higher than those optimal for transfection. In HepG2 hepatocytes (Figure 5b), no measurable toxicity was observed in the G4.0 and G5.0 systems at polymer/DNA mass ratios up to 200:1; in G6.0, moderate toxicity became apparent at ratios of 150:1 and above. In all cases, linear-dendritic systems failed to display toxicity until concentrations reached one to two orders of magnitude greater than those at which PEI was toxic.

Herein, we have described the design, synthesis, and evaluation of a new family of linear-dendritic hybrid polymers for their ability to deliver DNA to two distinct mammalian cell lines. These hierarchically self-assembling polymers have functionalities that are physically and chemically distinct and can be independently modified. The modular nature of these systems makes them a platform from which further, serial modifications may be added to impart additional desired characteristics without any substantial alteration of the existing properties. As a proof of concept, we have demonstrated the condensation of DNA by linear-dendritic polymers into nanoparticle structures with small size and robust serum stability appropriate for systemic delivery. Moreover, through the presentation of an outer shell of targeting ligands, these particles can transfect cells bearing targeted surface receptors with low toxicities and efficiencies that exceed the best commercially available polymer PEI.

Communications

Taken together, our data suggest that this new family of materials may find use as safe and highly efficient in vivo delivery agents for DNA, siRNA, or other nucleotide-based therapeutics.

Specific Generation of 1-Methylcytosine Radicals in the Gas Phase**

*Chunxiang Yao, Maria L. Cuadrado-Peinado,
Miroslav Polášek, and František Tureček**

Nucleobase-derived radicals are crucial transient intermediates in the radiation damage of nucleic acids (RNA and DNA). Among the recognized mechanisms of radiation damage, capture of a low-energy electron followed by protonation of the transient anion radical results in the formation of hydrogen-atom adducts that can undergo further degradation reactions.[1] Radiation damage has been studied extensively by pulse radiolysis in solution and the solid state, in which characterization of the transient nucleobase radicals relied mainly on the detection of species with unpaired electrons by electron paramagnetic resonance (EPR) spectroscopy. In particular, cytosine and cytosine-containing nucleosides have been the subject of numerous studies that reported the formation of adducts with the hydrogen atom positioned at C5, C6, N3, and N7 in the solid state (Scheme 1).[2] However, the identity of these radicals has

R = H, CH₃, or deoxyribose

Scheme 1. Formation of cytosine radicals by the direct mechanism.

been subject to discussion, and the factors that affect their formation and kinetic and thermodynamic stability have not been established unequivocally by EPR in the complex mixtures produced by pulse radiolysis. EPR analysis can be further complicated by the formation of cation radicals upon

radiolysis.[2f,g] To our knowledge, the chemically specific generation of cytosine radicals has not been attempted.

In contrast to the condensed phase, the rarefied gas phase, which exists in the vacuum system of a mass spectrometer, offers an inert medium for the specific generation and investigation of highly reactive transient molecules, radicals, biradicals, and so forth.[3] We report herein on the targeted generation of two key hydrogen-atom adducts of 1-methylcytosine (**1**), namely, 1-methyl-3,4-dihydrocytosine-4-yl (**2**) and 1-methyl-5,6-dihydrocytosine-6-yl (**3**; Scheme 2). 1-Methylcytosine was selected as a simple model system that

Scheme 2. Generation of 1-methylcytosine radicals **2** and **3** by collisional electron transfer in the gas phase.

exists as a dominant tautomer and, thus, avoids the problems of gas-phase tautomerism that are present in the parent cytosine, which exists as a mixture of three major tautomers in the gas phase.[4] Our approach relies on the specific generation of 1-methylcytosine cations that have the same bond connectivity as the target radicals. The cations are accelerated to a high velocity ($105\,000$ m s^{-1}) and discharged by a glancing collision with a molecular electron donor (dimethyl disulfide or trimethylamine). The nascent radicals are formed with the structure of the precursor cation because of the extremely short duration of the electron transfer (10–12 fs). The radicals are observed for several microseconds, during which time dissociation may occur. The neutral precursors and their dissociation products are then nonselectively ionized, the resulting cations are separated by mass and detected by neutralization–reionization (NR) mass spectrometry. The spectra, thus, provide a more-or-less complete analysis of all

the reaction products that originate from the nucleobase radical.[5]

The synthetic route to **2** utilizes electrospray ionization (ESI) of **1** to generate the pertinent ion **2⁺** and transfer it in the mass spectrometer. Compound **1** is the most stable tautomer in solution[6] and is protonated exclusively at N3, thus specifically yielding **2⁺**.[7] Our concurrent ab initio calculations[8] have established that **2⁺** is more stable (by 31–32 kJ mol^{-1}) than the tautomer protonated at O2 (**4⁺**), which is the second most stable in water and methanol. Tautomer **2⁺** is also the most stable structure in gas-phase clusters with water, thus strongly indicating that **2⁺** is transferred from solution to the gas-phase by electrospray without isomerization. Unimolecular isomerization **2⁺→4⁺** requires a high-energy barrier (153 kJ mol^{-1})[8] that is inaccessible to thermalized ions formed by electrospray ionization.[9]

Tautomer **3⁺** is substantially less stable than **2⁺** ($\Delta H_{g,0}(\mathbf{2^+}\rightarrow\mathbf{3^+}) = 111$ kJ mol^{-1}) and cannot be generated specifically by protonation of **1**.[8] However, electron-ionization-induced α-cleavage dissociation of a stable precursor, 1-methyl-6-ethyl-5,6-dihydrocytosine (**5**),[10] yields **3⁺** as the most abundant ion in the mass spectrum and provides access to the generation of radical **3**.

Ions **2⁺** and **3⁺** were characterized by collisionally activated dissociation (CAD) mass spectra that showed characteristic differences in ion-dissociation patterns (Figure 1). Ion **2⁺** dissociates by loss of NH$_3$ (m/z 109) and HO−C≡N (m/z 83), whereas **3⁺** dissociates by loss of CH$_2$=C=NH (m/z 85) and HN=C=O (m/z 83). The identity of the fragments and the dissociation mechanisms have been established by deuterium labeling and ab initio calculations.[8] The important outcome from the CAD spectra and theoretical calculations is that **2⁺** and **3⁺** are distinct stable isomers that reside in potential-energy minima and do not interconvert under our experimental conditions.

Collisional neutralization of **2⁺** and **3⁺** followed by reionization yielded NR mass spectra that showed peaks of survivor ions at m/z 126 for both **2** and **3** (Figure 2). These signals indicate that a fraction of the cytosine radicals **2** and **3** did not dissociate on the 5.7-μs timescale of the measurement. Thus, **2** and **3** represent intrinsically stable neutral species in the gas phase. The NR mass spectra also show substantially different dissociations of **2** and **3**. In particular, **3** undergoes the facile loss of a hydrogen atom (m/z 125) and C$_2$H$_4$N (m/z 84) and the formation of C$_2$H$_3$N (m/z 41). The elimi-

Figure 1. CAD mass spectra of a) **2⁺** and b) **3⁺** obtained at 5.5-eV center-of-mass collision energy in a radio-frequency-only quadrupole under multiple-collision conditions. The ion intensities are relative (%) to the total ion current.

Figure 2. NR mass spectra. a) Neutralization of 2^+ with CH_3SSCH_3 and reionization with O_2 at 70% ion transmittance. b) Neutralization of 3^+ with $(CH_3)_3N$ and reionization with O_2 at 70% ion transmittance.

nation of C_2H_4N may be because of the combined losses of $(H + C_2H_3N)$ or $(CH_3 + HCN)$, which would require a detailed mechanistic study to be distinguished. In contrast to **3**, **2** shows only minor loss of hydrogen atoms, no fragment ion at m/z 84, and a dominant CO fragment ion at m/z 28. The differences in the spectra confirm that **2** and **3** do not interconvert by unimolecular isomerizations. This deduction was further corroborated by dissociations of deuterium-labeled radicals [3,7,7-D$_3$]-**2**, [6-D]-**3**, and [5,7-D$_2$]-**3**, of which [6-D]-**3** showed a specific loss of a hydrogen atom, thus indicating the absence of hydrogen/deuterium exchange at C5 and C6. A competitive loss of hydrogen and deuterium atoms from the methylene group at C5 was seen in [5,7-D$_2$]-**3**. These dissociations indicate that **1** forms as the stable product from the loss of a hydrogen atom from **3**. This conclusion is corroborated by the NR mass spectrum of $1^{+\cdot}$, which showed a dominant survivor ion at m/z 125 and so confirmed that **1** was stable when formed by collisional electron transfer in the gas phase.

The relative stability and dissociation energetics of **2** and **3** were addressed by combined ab initio and density-functional theory calculations[6] to provide insight into the dissociation mechanisms. Both **2** and **3** are found to reside in potential-energy minima; whereby, **2** is more stable than **3** by 36 kJ mol^{-1}. The minimum-energy reaction pathway of **2** is the dissociation of the N3–H bond (path a) to yield **1** (Scheme 3). Competitive dissociations may involve the loss of a hydrogen atom from the amino group at N7 (path b) to yield the imine–oxo tautomer **6**. We note that it has been postulated that **6** is formed by tautomerization of **1** in the gas phase at 463 K.[11] Loss of the methyl group at N1 (path c) yields a cytosine tautomer **7**. The loss of the CH_3 group is seen to occur competitively with the loss of a hydrogen atom in the NR mass spectrum of **2** (Figure 2a). Ring opening by C2–N1 and C2–N3 bond dissociations (paths d and e) require somewhat higher transition-state (TS) energies (169–170 kJ mol^{-1}) to form **8** and **10**, respectively, as transient intermediates in the loss of CO and HNCO (Scheme 3). However, the ring cleavage of **2** and subsequent dissociations require several steps with high TS energies or product threshold energies (e.g., **9** and **11**) and can be expected to be kinetically disfavored on the potential-energy surface of
Scheme 3. The relative energies in parentheses (kJ mol^{-1}) are from B3-PMP2/6-311++G(3df,2p)+ZPVE calculations. E_{TS} = transition-state energy.

the ground electronic state. The preponderance of small fragments of m/z 26–29 and 38–43 in the NR mass spectrum of **2** (Figure 2a) is probably because of a combination of dissociations that originate from the excited electronic states of 2[12] and post-reionization dissociations of the primary dissociation products. The calculations further indicate that vertical electron transfer in 2^+ results in only a modest vibrational excitation in the ground electronic state of **2** by Franck–Condon effects ($E_{exc} = 39$ kJ mol^{-1}), which is in keeping with the detection of a stable fraction of **2** in the spectrum.

The potential-energy surface for dissociations of **3** (Scheme 4) is substantially different from that of **2**. In particular, **3** shows a low-energy dissociation pathway for the loss of a hydrogen atom from the methylene group at C5 (path a), which is consistent with the prominent loss of a hydrogen atom in the NR mass spectrum (Figure 2b). The loss of the hydrogen atom competes with the loss of the CH_3 group (path b, **12**) and ring opening by cleavage of the weak C2–N1 bond (path c, **14**). The latter leads to expulsion of $CH_3N\equiv C$, which appears as the intense peak at m/z 41 in the NR mass spectrum of **3**. The formation of another major fragment at m/z 84 (Figure 2b) maybe because of combined losses of $(H + C_2H_3N)$ or $(CH_3 + HCN)$, which are currently unresolved and will require further study for satisfactory elucidation. In contrast, a 1,2-hydrogen migration between C5
Scheme 4. The relative energies in parentheses (kJ mol^{-1}) are from B3-PMP2/6-311++G(3df,2p)+ZPVE calculations.

and C6 in **3** that yields isomer **13** requires a high-energy TS to be crossed. This energy barrier explains why **3** does not exchange H5 and H6 atoms prior to the loss of the methylene hydrogen atom at C5.

In conclusion, transient radicals that correspond to adducts with a hydrogen atom positioned at N3 and C5 of the cytosine ring have been specifically generated in the gas phase for the first time. The isomeric radicals **2** and **3** are found to be intrinsically stable, distinct species that show specific unimolecular dissociations by loss of a hydrogen atom or the CH$_3$ group and ring cleavage followed by expulsion of small molecules. It can be expected that substituents at N1 larger than a methyl group (for example, 2′-deoxyribos-1-yl) would increase the propensity for N1−C bond dissociation in cytidine radicals, as the proposed mechanisms for nucleobase loss from radiation damage to DNA suggest.[1] Generation and computational studies of such nucleoside radical systems are underway.

Experimental Section

NR mass spectra were measured on a tandem-quadrupole mass spectrometer equipped with an electrospray ion source, as described previously.[13] Precursor ions **2**$^+$ were produced by the electrospray of 50–100 μM solutions of 1-methylcytosine in methanol/water (70:30), desolvated, cooled to ambient temperature, transferred to high vacuum, accelerated to 7200 eV, and discharged by collisions with dimethyl disulfide under predominantly (83%) single-collision conditions. Radical **2** and its dissociation products were nonselectively ionized after 5.7 μs by collisions with O$_2$, decelerated to 70–75 eV, and analyzed by mass. Another set of NR mass spectra of **3**$^+$ was measured at 8-keV ion kinetic energy on a ZAB2-SEQ double-focusing mass spectrometer that was furnished with an additional collision cell in the first field-free region. The spectra were obtained by a linked scan of the magnet and electrostatic sectors. Ion **3**$^+$ was generated in the ion source by 70-eV electron ionization of 1-methyl-6-ethyl-5,6-dihydro-cytosine. The details of the computational methods were described previously.[6,14]

Synthesis of CdSe and CdTe Nanocrystals without Precursor Injection**

Yongan Andrew Yang, Huimeng Wu,
Kathryn R. Williams, and Y. Charles Cao*

With the growing interest in applications based on nanoscale materials[1] comes a need for an industrial-scale synthesis of colloidal semiconductor nanocrystals with uniform size and shape and well-confined surface passivation. To date, the most successful and widely used nanocrystal synthesis relies on rapid precursor injection.[2,3] However, it is difficult to scale up such a synthesis for making nanocrystals in large quantities (e.g., tens to hundreds of kilograms).[4] Therefore, there is a need to develop nanocrystal synthesis without precursor injection.

Although many publications have described the synthesis of semiconductor nanocrystals without precursor injection,[5] only a few of them have led to nanocrystals with very good monodispersity.[5a–c] However, these nanocrystals exhibit optical properties inferior to those of nanocrystals produced by the injection method. They normally do not show as many multiple exciton absorption peaks, which are critical for nanocrystal applications in advanced optical and electronic devices. Recently, we reported a non-injection-based synthesis of CdS nanocrystals.[4] The sample quality (i.e., size distribution and optical properties) is as good as that of the best CdS nanocrystals synthesized by using precursor injection. Nucleation initiators are important to the CdS synthesis, but unfortunately, such nucleation initiators are not readily available for making nanocrystals with other compositions. Herein, we report how to design a noninjection synthesis for making high-quality CdSe and CdTe nanocrystals without nucleation initiators.

The formation of high-quality nanocrystals is often favored at high temperatures (e.g., > 200 °C). This factor creates a major challenge for making monodispersed nanocrystals through a noninjection synthesis because such a synthesis involves a period of increasing temperature over a broad range (e.g., from room temperature to over 200 °C). If the reactivity of a precursor is too high, this broad change of temperature often leads to concurrent nucleation and growth

of nanocrystals in the synthesis, which results in products with poor monodispersity. However, if the precursors are too stable, a very small number of nuclei may form, which leads to uncontrollable particle growth. (Note that suitable nucleation initiators could lead to a synthesis of monodisperse nanocrystals in this case.) Therefore, when suitable nucleation initiators are not available, only precursors with suitable reactivity can result in monodisperse nanocrystals. In general, the ideal precursors should exhibit no (or very low) reactivity below the desired temperature for growth of the chosen nanocrystals, but they should also exhibit high reactivity when the temperature reaches the desired point.

To test this hypothesis, we first designed a noninjection synthesis for making CdSe nanocrystals. We chose 240 °C as the growth temperature, which was in accordance with the lesson learned from the injection-based synthesis of CdSe nanocrystals.[2,3] At this growth temperature, pure cadmium myristate is a suitable cadmium precursor because it has a decomposition point at about 226 °C.[6] Selenium powder can be an effective selenium precursor for two reasons: 1) it has a melting point at 221 °C;[6] 2) it is insoluble in octadecene (ODE) at room temperature and becomes slightly soluble at temperatures over 190 °C. As selenium has low solubility in ODE, it is unreactive with cadmium myristate up to 200 °C. In a typical synthesis (see Experimental Section for detailed conditions), small particles (i.e., nuclei) suddenly appeared at 210 °C (Figures 1a and b). As the nanocrystals grew, the number of particles quickly increased to a maximum, and then during further growth it continued to decrease. Significantly, about 72 % of the particles formed in the initial stage disappeared after two hours of growth, while the size distribution of the nanocrystals continued to become more narrow throughout the synthesis (Figure 1c–e). Such size

Figure 1. Temporal evolution of a) the fluorescence (*f*) spectrum, b) the absorption spectrum, c) the diameter (*D*) of the nanocrystals, d) (and inset) the concentration (*C*) of the nanocrystals, and e) full width at half-maximum (FWHM) of the fluorescence spectrum during the CdSe synthesis. The size and concentration of the nanocrystals were obtained according to a reported procedure.[2b, 3b]

focusing is not likely to arise from diffusion-limited growth because this growth does not lead to a decreasing number of nanocrystals.[2b] Additional investigation is required to understand the detailed mechanism involved in this phenomenon.

The addition of oleic acid during the synthesis is important to control the quality of the nanocrystals. Without oleic acid, the nanocrystals show absorption spectra with a tail of higher intensity at the low-energy end after their diameter reaches around 3.0 nm and with further growth, they show broad absorption spectra (Figure 2, dotted lines). Such spectral
Figure 2. Absorption spectra of CdSe nanocrystals with (solid lines) and without (dotted lines) oleic acid a) after 16 min of growth and b) after 60 min of growth.

changes are normally attributed to broadening of the particle size distribution due to Ostwald ripening. However, in this synthesis we found that the phenomenon was caused by particle aggregation as it could be reversed by adding a small amount of oleic acid into the growth solution (Figure 2, solid lines). After this addition, nanocrystal growth turned out to be extremely stable. The size distribution of the nanocrystals further narrowed with particle growth (Figure 1), and the narrow size distribution was maintained for at least 16 h at the reaction temperature.

Without size sorting, typical CdSe nanocrystals from this synthesis show sizes with a standard deviation (σ) of less than 5% (see Figure 3d) and a quantum yield of photoluminescence (PL) of about 30 to 40%. Interestingly, these nanocrystals have a zinc-blende (ZB) structure but not a wurtzite (W) structure. Although these two crystal phases produce similar X-ray powder diffraction (XRD) results with nanocrystals, the XRD pattern of 4.0-nm particles shows unambiguous evidence that the particles have a ZB structure (Figure 3a): a) the valley between the the (220) and (311) peaks is deep; b) the (400) peak is at 61.0°; c) the (620) peak is at 106.2°. In the case of wurtzite crystals, there are no peaks in these positions.[2a,4,6] This structural assignment is consistent with the high-resolution transmission electron microscopy (HRTEM) observation (JEOL-JEM 2010 operated at 200 kV): a square cross-fringe pattern represents an ordered distance of 0.22 nm, which corresponds to the lattice spacing of the (220) faces in ZB CdSe (Figure 3a, inset). Such a cross-fringe pattern does not exist in a wurtzite structure. Note that ZB CdSe nanocrystals have been made recently by an injection-based synthesis.[7] However, this synthesis only led to high-quality nanocrystals in very small sizes, and these small nanocrystals show nearly identical XRD patterns to
Figure 3. a) XRD pattern of 4.0-nm-diameter ZB CdSe nanocrystals. The standard diffraction peak positions and relative intensities of bulk ZB CdSe are indicated. The inset shows an HRTEM image (5 nm×5 nm) of the nanocrystal sample. b) Absorption (black) and emission (gray) spectra of the ZB CdSe sample. c) Absorption (black) and emission (gray) spectra of a wurtzite (W) CdSe nanocrystal sample made by chalcogen precursor injection according to a reported procedure.[3a] d, e) TEM images of ZB (d) and W (e) CdSe nanocrystals. Scale bar: 10 nm.

those of small wurtzite nanocrystals made by Bawendi and co-workers.[2a] In contrast, the noninjection method presented in this paper can also result in larger CdSe nanocrystals, which allow us to unambiguously identify ZB nanocrystals.

Indeed, zinc-blende and wurtzite CdSe nanocrystals can be easily distinguished by their optical properties (Figure 3b–e). For both cases, nanocrystals with an identical position of the absorption peak for the first exciton transition band are nearly identical in size. The Stokes shifts of the emission peaks are nearly identical and PL quantum yields of band-gap emissions are similar. However, the fine structures in their absorption spectra are different. The gap between the first ($1S_{3/2}1S_e$) and second ($2S_{3/2}1S_e$) exciton transition peaks for ZB particles is clearly wider than that for W particles. The peak positions for the exciton transitions with higher energies also vary for these two types of CdSe nanocrystals. These differences in the absorption spectra originate from the different electronic band structures at the center of the Brillouin zone for these two types of crystal phases.[8]

To further demonstrate the power of noninjection synthesis, we synthesized nonspherical CdSe nanocrystals. In the case of a ZB structure, nonspherical particles are normally cubes, tetrahedral pyramids, or triangular prisms, and these particles have a higher surface energy than spherical particles.[9] Therefore, making nonspherical particles requires growth conditions with a high chemical potential, which we

thought could be achieved by increasing the per-particle concentration of the precursors.[6] To create such conditions, we chose a method to decrease the number of initial nuclei while leaving the precursor concentration unchanged. Because more reactive precursors can lead to fewer nuclei,[4] we used tributylphosphine selenide (TBPSe) in place of selenium powder for making CdSe nanocrystals. Indeed, the number of nuclei at the initial stage in this synthesis decreased by 75% as compared with the synthesis with selenium powder; after 30 min, tetrahedral particles with edge length of 5.0 nm and σ of 7% were formed. The high uniformity of these nanocrystals allows the formation of ordered, triangular close-packed nanocrystal assemblies on TEM grids (Figure 4).

Figure 5. a) Temporal evolution of the absorption spectrum in CdTe nanocrystal synthesis. b) TEM image of CdTe nanocrystals with a first absorption peak at 625 nm.

Experimental Section

Cadmium myristate was prepared by an ex situ method: a solution of cadmium nitrate in methanol (0.05 M, 40 mL) was added to a solution of sodium myristate in methanol (0.025 M, 240 mL). The resulting white precipitate was washed twice with methanol and dried under vacuum overnight to remove all solvents. Note that the purity of cadmium myristate is important to the following CdSe nanocrystal syntheses.

Synthesis of spherical CdSe nanocrystals: selenium powder (0.05 mmol, 100 mesh from Aldrich) and cadmium myristate (0.1 mmol) were added into a three-neck flask with ODE (5.0 g). The mixture was degassed for 10 min under vacuum ($\approx 3 \times 10^{-2}$ Torr) at room temperature. Under a flow of Ar, the solution was stirred and heated to 240°C at a rate of 25 K min^{-1}. Serial quantitative aliquots (50 μL) were taken for kinetic studies,[6] and the time was counted as zero when the temperature reached 240°C. After the particle diameter had reached about 3.0 nm (i.e., the first absorption peak at 550 nm), a solution of oleic acid in ODE (0.05 M, 1.0 mL) was added dropwise into the reaction solution to stabilize the growth of the nanocrystals.

The synthesis of tetrahedral CdSe nanocrystals followed a similar protocol as above, but TBPSe was used instead of selenium powder (cadmium myristate: 0.1 mmol, and TBPSe in ODE: 0.05 mmol of TBPSe in a mixture of tributylphosphine and ODE, 0.012 g and 0.5 g, respectively[2]).

In the synthesis of CdTe nanocrystals, cadmium octadecylphosphonate was made in situ: a mixture of CdO (0.1 mmol), octadecylphosphonic acid (0.22 mmol), and ODE (5.0 g) was heated to 300°C to give a colorless solution. The solution was cooled to room temperature, and TBPTe (0.20 mmol in 0.19 g of tributylphosphine,[2a]) was added. The mixture was degassed, then stirred and heated to 240°C (25 K min^{-1}) under a flow of Ar. Note that adding oleic acid is not needed during the CdTe synthesis.

Figure 4. TEM image of tetrahedral CdSe nanocrystals.

Moreover, the principle for designing a noninjection synthesis can be applied to the synthesis of CdTe nanocrystals. The key point is to find suitable precursors. The reactivity of cadmium myristate with tellurium powder in ODE is too low, whereas with tributylphosphine telluride (TBPTe) it is too high. Neither case resulted in the formation of uniform nanocrystals. We then decreased the reactivity of the cadmium precursor by replacing cadmium myristate with cadmium octadecylphosphonate. The reaction between cadmium octadecylphosphonate and TBPTe just perfectly fits the need for growth of monodisperse CdTe nanocrystals. A typical synthesis led to CdTe nanocrystals with a size distribution of less than 5%, which exhibit up to five exciton absorption bands (Figure 5). Such particle quality is at least comparable with that of the best particles made by the injection synthesis.[3b]

In summary, we reported the synthesis of high-quality CdSe and CdTe nanocrystals without precursor injection. This noninjection synthesis allows detailed control of nanocrystal size and shape. In addition, because it exhibits easily controllable nanocrystal-growth kinetics, such a synthesis is very important for a large-scale industrial preparation of CdSe and CdTe nanocrystals in which the rates of heating and cooling of reaction solutions are limited.

challenging. Although homonuclear and heteronuclear 2D NMR spectroscopic experiments permitted the assignment of the relative configuration of the decalin ring, the configuration of the epoxydiol system could not be determined unambiguously. The latter moiety was tentatively assumed to have an all-*syn* topology. Unfortunately, the stereochemical features of the *trans* decalin portion present an independent ¹H NMR spectroscopic system relative to the cyclohexanediol moiety owing to the planarity of the central pyridinone linkage. Lastly, the substitution pattern of the pyridinone ring was assumed by comparison with the ¹³C NMR spectroscopic chemical shifts of **1** with ilicicolin H, which was previously described and confirmed by total synthesis as a 5-aryl-4-hydroxy-3-acyl-2-pyridone.[3] Some examples of this family include militarinone A,[4] oxysporidinone,[5] fischerin,[6] and funiculosin.[7] Herein, we report a convergent total synthesis of (+)-apiosporamide (**1**) and its subsequent oxidation to yield YM-215343 (**2**). Our efforts have established the assignments of the relative and absolute configurations, which confirm the antipodal relationship of our synthetic materials with the naturally occurring metabolites.

To address the structural ambiguities of **1**, we chose to explore a convergent plan for stereocontrolled syntheses of the *trans*-decalin and the epoxydiol components. This strategy required appropriate functionalization of each subunit for the late stage formation of the central pyridone. Additionally, we sought to devise general, stereodivergent schemes that would permit the flexibility necessary to examine the substantial stereochemical issues previously outlined.

Studies of the cyclohexanediol portion of **1** began with the synthesis of nonracemic 4-hydroxy-2-cyclohexenones. The multigram preparation of **4** (Scheme 1) utilized (−)-quinic acid as a chiral-pool precursor through formation of the pure acetonide **3** as described by Danishefsky and co-workers.[8] Consideration of the appropriate functionality for direct linkage with the decalin component as well as subsequent pyridone ring formation led us to examine the enolate condensation of *N*-(4-methoxybenzyloxy)azetidin-2-one (**5**) with **4**.

Techniques for the incorporation of intact β-lactams are rare.[9] Although the ring strain of **5** incorporates the desired activation for coupling operations, the limited prospects for addition reactions with unsubstituted β-lactams suggest issues of incompatibility that arise from enolate instability, self-condensation, and acylation of alkoxide intermediates. Thus, we were gratified to find that the hydroxamic acid derivative **5** led to solutions of dependable enolates.[10] The starting β-lactam **5** was readily obtained through procedures described by Reinhoudt and van Elburg.[11] Complete deprotonation was initially recorded through reaction with LiHMDS for 2 h

DBU = 1,8-diazabicyclo[5.4.0]undec-7-ene; TBS = tert-butyldimethylsilyl; HMDS = 1,1,1,3,3,3-hexamethyldisilazane; TBAF = tetrabutylammonium fluoride; MLPBA = meta-chloroperoxybenzoic acid.

at −78°C. Although the enolate decomposed upon warming to −40°C, the addition of simple aldehydes at −78°C immediately led to the formation of addition adducts in 80–95% yields.[12] In the case of cyclohexenone **4**, these experiments gave the two readily separated β-lactam diastereomers **6** and **7** (1.2:1) in high yields, (Scheme 1) without evidence of competing α deprotonation or conjugate addition. The stereochemical features of **6** and **7** are rationalized by arrangements **A** and **B** (Scheme 1), which illustrate nucleophilic addition to either face of the carbonyl group while minimizing nonbonded interactions with the α-methylene of the starting ketone. Coordination with the lithium cation is not essential as reactions in the presence of 12[crown]-4 produced similar product ratios. This conclusion was supported when the reactions were increased to multigram levels, as the

use of KHMDS afforded diastereomers **6** and **7** (1.6:1 d.r.) in 97% yield. Although modest improvements in stereocontrol were recorded,[13] the overall efficiency, scale, and ease of separation for reactions with KHMDS proved most advantageous for these efforts.

The relative stereochemistry within the cyclohexane ring of **1** was investigated through the epoxidation of **6** and **7** with catalytic molybdenum hexacarbonyl and tert-butylhydroperoxide,[14] to yield a single oxirane in each case. Coupling constants derived from ¹H NMR spectroscopic data for these materials failed to provide a clear basis for stereochemical assignments. However, mild hydrolysis of the TBS ethers gave the crystalline diols **8** and **9**, which were unambiguously assigned by X-ray diffraction studies.[15] Internally directed reactions were confirmed, and led to the use of the secondary allylic alcohol derived from **10** for Henbest epoxidation and silyl protection to yield diastereomer **11**. Further studies to prepare sufficient quantities of the remaining fourth diastereomer that corresponds to the C4′ epimer of **11** encountered several problems. Comparisons of ¹H NMR spectroscopic data for various derivatives of **8**, **9**, and **11** with the reported ¹H NMR spectroscopic characteristics of apiosporamide were not feasible. The presence of the pyridone ring of **1** effectively inverts the relative positions of chemical shifts observed for the hydrogen atoms of the neighboring oxirane moiety. Thus, each β-lactam of Scheme 1 was independently advanced in the synthetic pathway.

The decalin portion of **1** was prepared through an intramolecular Diels–Alder reaction that began with (S)-citronellol (**12**; Scheme 2). Oxidation[16] of **12** with TEMPO

THF (1:1); then H₃CC(O)CH₂P(O)(OMe)₂, K₂CO₃, 91% (13:1 E/Z); d) [Cp₂Zr(H)Cl], CH₂Cl₂, RT; then I₂, 77%; e) [Pd(PPh₃)₄] (5 mol%), (E)-BrZnCH=CHCH₃ (2.5 equiv), THF/Et₂O/pentane (4:4:1), −30°C→RT; 74%; f) Dess–Martin periodinane, py, CH₂Cl₂, 90%; g) EtAlCl₂, toluene, −78°C→RT, 72% (>97:3 d.r.); h) LiHMDS, THF, −78°C→0°C; then HMPA at −78°C; then MeOC(O)CN, 62%; i) KOH, aq. MeOH, 0°C, 81%. TEMPO = 2,2,6,6-tetramethyl-1-piperidinyloxy radical, Cp = cyclopentadienyl, HMPA = hexamethylphosphoric triamide.

and treatment with the Ohira–Bestmann reagent **13**[17] provided a volatile alkyne. Selective oxidative cleavage of the trisubstituted olefin followed by treatment with $H_3CC(O)CH_2P(O)(OMe)_2$ led to the conjugated enone in **14** (13:1 *E/Z*). The *syn* hydrozirconation of **14** followed by treatment with iodine yielded the *E* alkenyl iodide **15** with concomitant reduction of the ketone.[18] Facile Negishi coupling[19] with (*E*)-prop-1-enylzinc(II) bromide cleanly delivered a single diene diastereomer without the need for protection strategies to prevent the competing Heck reaction, and subsequent mild oxidation recovered the intact enone of **16**.

The Lewis acid mediated intramolecular Diels–Alder reaction of **16** proceeded in toluene at −78 °C with subsequent warming to 22 °C. Excellent stereoselectivity was observed, and the *trans* decalin **17** was assigned by ¹H NMR spectroscopy. Decalin **17** arises through an *exo* bridging arrangement with *endo* positioning of the ester function; a chairlike conformation of the tether is adopted with a pseudoequatorial disposition of the methyl substituent.[20] The corresponding thermal cycloaddition (toluene, 180 °C) occurred with poorer stereocontrol (d.r. 70:30). Deprotonation of **17** under kinetic conditions and C-acylation according to the Mander protocol[21] gave pure β-ketoester **18**, which was then used to produce the labile carboxylic acid **19** prior to coupling studies.

The synthesis of **1** was pursued from **11** (Scheme 3). Although several pathways were examined, superior results involved the initial nucleophilic opening of **11** to give the *N*-alkoxyamine **20** for quantitative *N*-acylation with the carboxylic acid **19**. Subsequent acyl activation in the presence of DBU resulted in ring closure to form **21**. Reduction with

samarium diiodide yielded the dihydropyridone **22** with selective N−O bond cleavage. Subsequent oxidation with bromotrichloromethane, based upon our previous studies,[22] gave the expected 4-hydroxy-2-pyridinone for final deprotection to afford (+)-apiosporamide (**1**). The spectral data of **1** proved to be identical to that reported for the naturally occurring **1**, but the optical rotation was opposite.[1,23,24] Further confirmation was obtained by the Dess–Martin oxidation[25] of synthetic **1** to yield the antipode of **2**, (+)-YM-215343,, which was validated by comparison with published data for the natural product.[2,26] Although the structural homology of pyridones **1** and **2** suggest evidence of a common biogenesis, we did not assume homochirality. However, the characterization of these natural products provides physical and spectral data that uniquely identify the synthetic **1** and **2** compared to other diastereomers of this series.

In conclusion, we have established the relative and absolute configuration of apiosporamide and have illustrated an efficient strategy for the synthesis of complex pyridinones. The use of unsubstituted β-lactams as β-alanine enolate equivalents has been demonstrated. Finally, the conversion of synthetic (+)-apiosporamide into (+)-YM-215343 has been described and has confirmed the antipodal relationship to the natural products.
Scheme 3. Synthesis of apiosporamide (**1**). a) Allyl alcohol, *n*BuLi (1 equiv); then **11**; −78 °C→RT; 80%; b) BOP, Et₃N, MeCN, RT, 99%; c) [Pd(PPh₃)₄], pyrrolidine, CH₂Cl₂, 85%; d) BOP, CH₂Cl₂, DBU, −20 °C, 56%; e) SmI₂, THF, 98%; f) BrCCl₃, TMG, 65%; then HF·pyr, THF, 75%; g) Dess–Martin periodinane, CH₂Cl₂, 92%. BOP = benzotriazol-1-yloxy-tris(dimethylamino)phosphonium hexafluorophosphate, TMG = 1,1,3,3-tetramethylguanidine.

[23] Optical rotation data for naturally occurring apiosporamide was recorded as $[\alpha]_D = -97.4°$ ($c = 0.0004$ MeOH). Characterization of synthetic **1**: $R_f = 0.12$ (19:1 CH$_2$Cl$_2$/MeOH); $[\alpha]_D^{24} = +108°$ ($c = 0.40$, MeOH); IR (film): $\tilde{\nu} = 3248$ (br), 3072, 3006, 2953, 2925, 1656, 1652, 1602, 1544, 1455, 1214, 1063, 1021, 964 cm^{-1}; ^{1}H NMR (400 MHz, CD$_3$OD): $\delta = 7.45$ (s, 1 H), 5.51 (m, 1 H), 5.31 (d, $J = 9.8$, 1 H), 4.30 (dd, $J = 11.2$, 5.7 Hz, 1 H), 4.04 (ddd, $J = 5.9$, 5.9, 3.1 Hz, 1 H), 3.53 (d, $J = 3.2$ Hz, 1 H), 3.32 (dd, $J = 3.2$, 3.1 Hz, 1 H), 2.73 (m, 1 H), 2.11 (dd, $J = 13.0$, 9.0, 1 H), 1.85 (dd, $J = 12.1$, 2.5 Hz, 1 H), 1.78–1.70 (m, 2 H), 1.70–1.56 (m, 3 H), 1.52–1.37 (m, 2 H), 1.30–1.20 (m, 1 H), 0.94 (ddd, $J = 12.8$, 12.1, 3.3 Hz, 1 H), 0.87–0.76 (m, 1 H), 0.84 (d, $J = 6.5$ Hz, 3 H), 0.74 (d, $J = 7.2$ Hz, 3 H), 0.71 ppm (ddd, $J = 12.4$, 12.4, 12.4 Hz, 1 H); ^{13}C NMR (101 MHz, MeOH): $\delta = 211.7$, 179.5, 164.2, 139.9, 132.7, 131.7, 116.7, 108.8, 70.6, 67.1, 60.5, 57.6, 54.3, 43.3, 43.2,

37.6, 36.7, 34.4, 32.5, 31.6, 31.0, 25.8, 23.0, 18.4 ppm; HRMS: *m/z* calcd for C$_{24}$H$_{32}$NO$_6$ [*M* + H]$^+$ 430.2224; found: 430.2225.

[24] Due to the anticipated similarities of ^{1}H and ^{13}C NMR spectroscopic data, and the discrepancy in the specific optical rotation in **1**, the route was adapted for independent preparation of three diastereomers with the *syn* relationship between the epoxide and tertiary alcohol (as in **8** and **9**). All of these isomers demonstrated great instability and underwent opening of the oxirane, as illustrated in the formation of **24** through directed oxidation of **23**. Interestingly, five-membered-ring products were not observed. Additional information will be provided in a full account.
[25] D. B. Dess, J. C. Martin, *J. Am. Chem. Soc.* **1991**, *113*, 7277.

[26] Synthetic and natural **2** were identical in all respects, except for rotation. Optical rotation for natural YM-215343 was recorded as $[\alpha]_D^{25} = -44°$ ($c = 0.10$ MeOH), and synthetic **2** was $[\alpha]_D^{24} = +47°$ ($c = 0.225$ MeOH). Diastereoisomer **25** proved to be stable and spectroscopically similar to apiosporamide. However, oxidation gave ketone **26** which was clearly diastereomeric to **2**.

Zeolite Structures
Structure Elucidation of the Highly Active Titanosilicate Catalyst Ti-YNU-1**

*Juanfang Ruan, Peng Wu, Ben Slater, and Osamu Terasaki**

A major breakthrough in the field of zeolite catalysis was the development of MFI-type (a zeolite framework type of ZSM-5) titanosilicate (TS-1) as a liquid-phase oxidation catalyst.[1] Nevertheless, TS-1 has a major disadvantage in that its medium-sized pores with 10-membered rings (10-MRs) restrict its application to molecules of relatively small size. To overcome this problem of TS-1, other titanosilicates with larger pores, such as Ti-Beta,[2,3] Ti-MOR,[4] Ti-ITQ-7,[5] and Ti-MCM-41,[6] have been prepared and have partially solved the problems of steric constraints encountered in the oxidation of bulky molecules. However, it seems that none of the above titanosilicates has sufficient intrinsic activity and stability, and this has stimulated researchers to prepare Ti-containing catalysts that are both highly stable and accessible to bulky substrates. In this context, MWW-type zeolite has a promising framework structure consisting of MWW sheets and contains two independent noninterconnected pore systems with 10-MR channels.[7,8] Three-dimentional (3D) Ti-MWW was successfully prepared by hydrothermal synthesis,[9] but on calcination of the layered MWW sheets, access to the supercages is seriously restricted by the openings of the 10-MR pores. Thus, in the case of aluminosilicate, a micro-mesoporous hybrid material MCM-36 was prepared by swelling the MWW sheets of the lamellar precursor with organic surfactant followed by pillaring with a silica precursor.[10] With similar objectives, ITQ-2 was synthesized by swelling the layers of the MWW lamellar precursor and than sonicating the product.[11] Both MCM-36 and ITQ-2 have an extremely high surface area that is highly accessible to bulky molecules, but lack an ordered crystalline structure. From a steric point of view, it is desirable to retain the space between the MWW sheets after calcining the lamellar precursor. In the particular case of the titanosilicate, this not only makes the active sites within the supercages more accessible to bulky molecules, but also promotes activity in oxidation reactions with aqueous H_2O_2 as oxidant, as the silanol groups are less hydrophilic than in pillared and delaminated materials. This could open up new applications for titanosilicates in the synthesis of fine chemicals. Previously, a novel titanosilicate denoted Ti-YNU-1 was prepared from an MWW-type precursor.[12] It has an expanded pore window between the crystalline MWW sheets and shows a far higher intrinsic catalytic activity than 3D Ti-MWW and large-pore Ti-Beta in the epoxidation of bulky alkenes with H_2O_2. Although Ti-YNU-1 was reported to contain MWW sheets, the nature and structure of the linkage between the sheets were not established. We have now investigated the structure of Ti-YNU-1 by focusing on the pore structure and space between the MWW sheets at the atomic scale by high-resolution transmission electron microscopy (HRTEM), powder X-ray diffraction (XRD), scanning electron microscopy (SEM), and NMR spectroscopy. From a combination of computer simulations and experimental observations, we suggest a likely structure of Ti-YNU-1.

The SEM images of the MWW lamellar precursor, 3D Ti-MWW, and Ti-YNU-1 samples are shown in Figure 1. All
Figure 1. SEM images of a) lamellar precursor, b) 3D Ti-MWW, and c) Ti-YNU-1.

samples crystallized as thin platelets with hexagonal morphology, and the unit cell *c* axis lies perpendicular to the plate surface. The thin platelets of all samples were approximately 2 μm in width and 0.1 μm in thickness; no significant differences in morphology between the three samples can be discerned from the images, although some roughening of the crystal edges in the Ti-YNU-1 sample is evident.

The XRD pattern of the lamellar precursor shows reflections at large scattering angles that are much broader than those of 3D Ti-MWW and Ti-YNU-1 (Figure 2). This indicates that the lamellar precursor is composed of MWW sheets, and on acid treatment or calcination the sheets are fully connected to form 3D Ti-MWW or Ti-YNU-1. The powder XRD pattern of Ti-YNU-1 appears to be similar to those of the lamellar precursor and 3D Ti-MWW, but the principal difference is that the diffraction peaks associated

Figure 2. Powder XRD profiles of a) lamellar precursor, b) 3D Ti-MWW, and c) Ti-YNU-1.

FD of Ti-YNU-1 show no significant differences from those of the lamellar precursor and 3D Ti-MWW, which clearly exhibit the characteristic hexagonal framework topology of MWW-type materials in this projection.[7] It is apparent that postprocessing does not alter the structure within the MWW sheet, and there is no evidence for aperiodically or periodically repeating defects. As all three materials show the same projected images of the MWW sheet (and the same FDs), structural study of Ti-YNU-1 perpendicular to the MWW sheet, that is, along [100], is essential to find differences between the lamellar precursor, 3D Ti-MWW, and Ti-YNU-1.

The HRTEM images of the lamellar precursor, 3D Ti-MWW, and Ti-YNU-1 with [100] incidence and the corresponding FDs are shown in Figure 4. The image of the lamellar precursor was taken under overfocus conditions and indicates the presence of 3D order (Figure 4a). The image of

with unit-cell distance c are all shifted to lower 2θ values in comparison to the lamellar precursor and 3D Ti-MWW. For example, the (001) peak of Ti-YNU-1 is found at 3.20°, (002) at 6.41°, and (101) at 7.85°, but for 3D Ti-MWW and the lamellar precursor, (001) is found at 3.52° and 3.29°, (002) at 7.04° and 6.56°, and (101) at 7.97° and 7.94°. In contrast, the diffraction peaks associated with unit-cell distance a remain almost constant: (100) is found at 7.16°, as opposed to 7.15° and 7.23° for 3D Ti-MWW and the lamellar precursor, respectively. These observations suggest that calcination and acid treatment do not affect the basic crystalline structure within the layers, but do influence the space between the MWW sheets. Table 1 lists the powder XRD data of the lamellar precursor, 3D Ti-MWW, and Ti-YNU-1. The unit-cell parameters were calculated to be $a = b = 14.238$ Å and $c = 27.571$ Å for Ti-YNU-1, $a = b = 14.263$ Å and $c = 25.098$ Å for 3D Ti-MWW, and

$a = b = 14.108$ Å and $c = 26.926$ Å for the lamellar precursor. The parameter c of Ti-YNU-1 is enlarged by about 2.5 and 0.6 Å relative to those of 3D Ti-MWW and the lamellar precursor, respectively. The structural expansion also led to an enlarged specific surface area and pore volume for Ti-YNU-1 (654 m^{2}g^{-1} and 0.20 mLg^{-1}) in comparison to 3D Ti-MWW (548 m^{2}g^{-1} and 0.16 mLg^{-1}; see Supporting Information).

The [001] HRTEM images of the lamellar precursor, 3D Ti-MWW, and Ti-YNU-1 are shown in Figure 3 together with corresponding Fourier diffractograms (FDs). The image and

Ti-YNU-1 in Figure 4c was taken under underfocus conditions and reveals that it has a structure similar to that 3D Ti-MWW (Figure 4b) but with a different c distance. Selected-area electron diffraction with the calibration of the camera length was conducted to show the different c distances of Ti-YNU-1 and 3D Ti-MWW (see Supporting Information). To confirm the above observations, HRTEM images for [100] incidence were simulated for both over- and underfocus conditions by the multislice method using the structural parameters of 3D MWW (see Supporting Information). By comparing these simulated images with the observed
Figure 3. HRTEM images of a) lamellar precursor, b) 3D Ti-MWW, and c) Ti-YNU-1 taken with [001] incidence. Corresponding FDs are inset in each image.
Figure 4. HRTEM images of a) lamellar precursor, b) 3D Ti-MWW, and c) Ti-YNU-1 taken with [100] incidence. Corresponding FDs are inset in each image.

HRTEM images of Figure 4, we conclude that Ti-YNU-1 has a 3D-connected framework structure of the MWW type, analogous to that of 3D Ti-MWW. On the other hand, the lamellar precursor also has a 3D ordered structure, which indicates that the structure-directing agent present in the interlayer region causes regular stacking along *c* at a well-defined distance.

To further probe the nature of the interlayer structure in Ti-YNU-1, ^{29}Si MAS (magic-angle spinning) NMR spectroscopy was performed. The spectrum of Ti-YNU-1 (Figure 5) showed a Q^2 band around 89 ppm which was absent for 3D Ti-MWW. This band implies the possible presence of $Si(OH)_2$-$(SiO_2)_2$ or $Si(OH)(OTi)(SiO_2)_2$ linkages between the MWW sheets. Considering that Ti-YNU-1 has a lattice expansion of about 2.5 Å, as confirmed by XRD, wholly intact linkages

between MWW layers according to HRTEM observations, and the potential linking species indicated by NMR spectra, it is proposed that the Ti-YNU-1 structure is simply an expanded form of MWW in which a single T site acts as a pillar connecting the MWW layers (Figure 6).

Atomistic computer simulation techniques were used to model the proposed crystal structure. Initially, we used methods based on interatomic potentials, as described by, for example, Chiu et al.[13] and Jentys and Catlow,[14] to verify the bulk structure of pure Si-MWW, using the GULP code.[15] The computed cell parameters of 14.187, 14.187, and 24.957 Å are within 0.5% of the measured values reported by Corma and co-workers.[16]

To assess potential Ti-YNU-1 structures, we first constructed a model in which two additional T sites are introduced per unit cell, midway between the lamellar layers of MWW, to form layer spacing or $Si(OH)_2$ "pillars". This
Figure 6. Schematic transformation of MWW to YNU.

structure was then relaxed by using the computational approach outlined above to give the structure shown in Figure 7a. Introduction of two additional T sites causes essentially no change in the *a* and *b* lattice parameters but an expansion in the *c* direction of 2.59 Å relative to pure Si-MWW. This increase closely agrees with the magnitude of the structural expansion inferred from XRD and TEM. Critically, the introduction of the additional T sites expands the

Figure 5. ^{29}Si MAS NMR spectra of a) Ti-YNU-1 and b) 3D Ti-MWW.
Figure 7. Three possible configurations for Si-YNU indicating the flexible nature of the 12-MR, viewed along [100].

interlayer ten-membered ring to form a twelve-membered ring, which affords increased transport rates and the potential to filter larger products than the 10-MR. Two other possible configurations were generated, one in which the T sites are placed as close together as possible and an "indented 12-MR" configuration (Figure 7b and c). The relative energies of the configurations shown in Figure 7a–c (0.079, 0.084, and 0.000 eV, respectively) are almost identical and are comparable to kT, and this suggests that at moderate temperature, because the $Si(OH)_2$ group can freely rotate, all three of these configurational states will be occupied on a picosecond timescale. The breathing of the 12-MR will lead to electron scattering and hence weak contrast in the HRTEM image.

Finally, the substitution energetics for Ti in MWW was assessed by the interatomic potential approach. The span of Ti substitution energies measured relative to the most favorable site is 0.70 eV for the potentials reported by Jentys and Catlow.[14] The spread of energies is substantially greater than that in silicalite, for which the range is about 0.22 eV, from which it can be inferred that the selectivity of Ti for particular lattice sites within MWW is rather high. As the typical Ti/Si ratio for MWW is about 1:240, it follows that the sixfold rim site shown in Figure 8, which is identified as the lowest energy site, may be selectively occupied. As the next most favorable site is 0.14 eV higher in energy than the rim site, the rim site is likely to be occupied first. In Figure 8, the location of the most (rim) and least (spiro) favorable sites (shown in white and black, respectively) are displayed. However, it is worth noting that the activation barrier for formation of MWW/YNU is likely to be comparable to the range of substitution energies,

and hence ordering of Ti towards particular lattice sites may be relaxed due to kinetically favored pathways.

To assess the preferred location of framework Ti in Ti-YNU, the proposed Si-YNU structure was first relaxed using the local-orbital-based, periodic density functional code SIESTA.[17] A titanium center was then introduced into the unit cell at the pillar site and at the most and least favorable sites in the MWW sheet, identified by the interatomic potential calculations, to give three distinct configurations that were relaxed at constant pressure. The relative stability of the three sites was rim > pillar > spiro, with relative energies of 0, +0.24, +0.27 eV, respectively, under anhydrous conditions. Although the pillar site appears not to be the most favorable framework site, the position of Ti within the YNU lattice will depend strongly on the water content[18] in the lattice and on the susceptibility to Ti leaching from MWW lamellae under acid conditions. It is possible that under acid/reflux conditions, Ti would leach from the rim site and occupy the pillar site, where it could easily expand its coordination sphere to give a quasi-octahedral configuration. In the pillar site, Ti could easily physisorb one or more water molecules and thus enhance its stability within the lattice while retaining steric accessibility and a flexible coordination number for catalytic activity.

The simulated XRD pattern of the proposed Ti-YNU-1 structure compares well with measured data (see Supporting Information). The HRTEM images simulated for the new structure with 12-MRs match very favorably with the observed images (see Supporting Information). However the differences between the images of MWW 10-MRs and Ti-YNU-1 12-MRs are extremely slight, except for the marked increase in c. The weight of evidence suggests that Ti-YNU-1 has 12-MRs between the MWW sheets from the observed c period in the HRTEM image and the XRD data.

In conclusion, the structure of Ti-YNU-1, which is structurally related to MWW, was studied by TEM in combination with powder XRD, SEM, NMR spectroscopy, and computer simulations. We found that Ti-YNU-1 has a 3D-connected MWW-like framework with much larger spacing along the c axis between the MWW sheets than the lamellar precursor and 3D Ti-MWW. A newly formed 12-MR that is distinct from the 10-MR of the MWW structure would explain this cell expansion. The expanded pore window, which would result in a concomitant increase in steric accessibility, may explain the significant enhancement of catalytic activity measured relative to other titanosilicates. Additionally, simulation results suggest that Ti has high site selectivity relative to materials such as MFI,[18] and we speculate that the Ti centers could occupy the pillar sites, which have a much higher steric accessibility than framework positions in MWW and, for example, TS-1. It is tempting to speculate that Ti in the pillar site of YNU will be conducive to temporary expansion of the Ti coordination sphere, which is thought to be crucial to epoxidation activity in, for example, TS-1.[19] As the silicon or titanium ions that intercalate the sheets must originate from the framework by acid treatment, an intriguing possibility would be to adjust the postsynthesis procedure to include silicate monomers or larger oligomers, and thus to potentially design the pillar height and hence ring size. Such

Figure 8. A [001] view of Ti-YNU indicating favorable substitution at the "rim" site (white) and less favorable incorporation at the "spiro" site (black).

an approach could lead to tailored zeolites with the capability to obtain extremely high selectivity.

Experimental Section

The lamellar precursor of the MWW titanosilicate was synthesized from highly siliceous MWW zeolite, tetrabutyl orthotitanite (TBOT), piperidine (PI), and deionized water following procedures reported elsewhere.[12] Typically, PI (7.24 g) and TBOT (0.29 g) were dissolved in 22.5 g of deionized water, then a highly deboronated MWW (5 g) was added to the solution. The resultant mixture was rotated in an autoclave at 443 K for 5 days. The as-synthesized precursor (Si/Ti = 100, containing 15.4 wt % PI) was directly calcined at 823 K for 10 h to burn off PI and obtain the 3D MWW titanosilicate Ti-MWW (Si/Ti = 100). This was heated at reflux in $2\,\text{M}$ HNO_3 solution and further calcined at 823 K for 10 h to obtain a novel titanosilicate, denoted Ti-YNU-1 (Si/Ti = 240).

Powder X-ray diffraction (XRD) patterns were collected on a MAC Science MX-Labo diffractometer ($Cu_{K\alpha}$ radiation). The crystal size and morphology were monitored by SEM on a Hitachi S-5200 microscope. For TEM measurements, the sample was crushed in an agate mortar, dispersed in ethanol (95 vol %) by ultrasonication, and then dropped onto a carbon microgrid. HRTEM observations were carried out with a 300 kV TEM (JEOL-3010, $C_s = 0.6$ mm, resolution 1.7 Å). Images were recorded with a Kodak electron film SO-163 using low-electron-dose conditions. The HRTEM images were simulated by the multslice method using the MacTempas program as a function of crystal thickness and defocus values under the parameters of an accelerated voltage of 300 kV, $C_s = 0.6$ mm, and semiangle of beam convergence of 0.6 mrad. The ^{29}Si MAS NMR spectra were recorded on a JEOL ECA-400 multinuclear solid-state magnetic resonance spectrometer at 79.6 MHz at a spinning rate of 5 kHz and with a pulse interval of 15 s.

Anticancer Genes

17β-Estradiol-Associated Stealth-Liposomal Delivery of Anticancer Gene to Breast Cancer Cells**

Bathula S. Reddy and Rajkumar Banerjee*

Estrogen receptor (ER), a member of the nuclear hormone receptor superfamily, is classically known to express as intracellular steroid receptor. It shows up predominantly in estrogen-responsive organs, such as ovary, uterus, and mammary cells. ER possesses mainly genomic properties but nongenomic, steroidal functions are also known.[1–5] Interestingly, classical ERs are implicated in several cancer phenotypes in the female population and are expressed in 60–80% of breast cancer samples.[6] These receptors are mostly confined to the primary stage of the tumor, and therefore endocrine-based therapy is generally used in the initial stages of neoplastic transformation.

β-Estradiol or estrogen is the endogenous ligand of ER. Estrogen-induced ER acts as a ligand-dependent transcription factor during its genomic activity, and regulates cell proliferation in cancer cells such as that observed in breast carcinoma, thereby becoming the principal target for breast cancer therapy. There are several ER antagonists, aromatase inhibitors, and selective estrogen receptor modulators (SERMs) that alone, or in combination, provide several clinical options for breast cancer therapy with limited efficacy.[7–11]

Liposomes have long been utilized as viable options for targeting cancers.[12–14] Poly(ethylene glycol)(PEG)-associ-

Communications

ated liposomes offer a stealth property to the payloads encapsulated in liposomal formulations with enhanced circulation half-lives.[14–16] Recently, a PEG- and cyclic RGD-associated (RGD: Arg-Gly-Asp) polymeric micelle has been exploited to deliver encapsulated doxorubicin to integrin-expressing specific tumorigenic cell types.[17] We have also shown that genetic payloads can be efficiently targeted to sigma-receptor-expressing breast cancer cells when haloperidol, a low-molecular-weight sigma-receptor-targeting drug, is covalently grafted to the headgroup region of a stealth cationic liposome.[18] This finding prompted us to investigate whether estrogen, the natural ER ligand, associating with a gene-carrying stealth liposomal system can act as a targeting ligand for delivering genes to breast cancer cells implicated with ER. This option

Scheme 1. Representative synthesis and structure of the lipids. Modified ES, which is produced in five steps, is treated with DPPE-PEG-NH$_2$ to obtain the targeting lipid DPPE-PEG-ES. DSPE-PEG-mal is the control lipid (DSPE = distearoylphosphatidylethanolamine, mal = maleimide).

of targeting genes at breast or estrogen-responsive cancer cells is expected to eliminate the chemotherapeutic drug-induced toxicity to normal cells.

Recently, it was found that estrogen exhibits high affinity to GPR30, an orphan receptor ubiquitously present in most of the cell types. In association with estrogen, GPR30 executes several nongenomic functions.[1,19] We envisaged that an estrogen-associated reporter-gene-carrying liposomal delivery system would uniquely target ER-expressing cells irrespective of existing GPR30.

With such a rationale in mind, we conjugated 17β-estradiol (ES) to the distal end of a phospholipid with a PEG spacer in between. The conjugation was performed without potentially diminishing the estrogenic property of the ligand. 3-Hydroxy-protected estrone was subjected to a Grignard reaction by following a previously reported procedure[20] to obtain the 17α-allyl moiety. This moiety was converted to a primary alcohol which was reacted with succinic anhydride to obtain an estradiol-associated molecule with a carboxylic acid end group. After silyl deprotection, the carboxylic acid group was conveniently conjugated to the amine end group of the 1,2-dipalmitoyl-Sn-glycero-phosphatidylethanolamine (DPPE)-linked PEG moiety to obtain the targeting lipid DPPE-PEG-ES (Scheme 1). NMR peaks at δ = 6.6–7.2 ppm ascertained the conjugation of the estrogen moiety in DPPE-PEG-ES (Figure 1B), whereas no aromatic peaks were obtained in the PEG-suppressed NMR spectrum

of DPPE-PEG-NH$_2$ (Figure 1A). The MALDI mass spectrum of DPPE-PEG-ES showed an inverted U-shaped pattern with an increment of 44 mass units between molecular weights 2756 and 3410. In spite of the two PEG populations in the sample, the peak of the U-shaped spectral pattern was obtained at a molecular weight of 3018.8, which was about 132 (that is, about three CH$_2$CH$_2$O residues) less than the calculated molecular weight of the product of 3151.67 (comparable to the peak at 3151.7 in Figure 1C). The calculated molecular weight was obtained by summing the molecular weights of the contributing estrogen fragment (413.3) and the starting material (DPPE-PEG-NH$_2$; 2739.37), and then subtracting one (the hydrogen lost from the lipid fragment upon conjugation). The mass spectrum of the starting material also revealed two different populations of PEG (the spectrum contains a molecular ion peak at 2739; see the Supporting Information).

This ligand-conjugated PEG-lipid was included at 5 mol% with respect to the known cationic lipid *N,N*-di-*n*-octadecyl-*N,N*-di-hydroxyethylammonium chloride (DODEAC)[18] and the neutral colipid cholesterol (at 1:1 molar ratio), to form long-circulating and targeting cationic liposomes. We used 5 mol% DSPE-PEG-mal (Scheme 1) in association with a DODEAC/cholesterol (1:1) formulation as our control liposome. This nontargeting lipid was included in the study to show the effect of the estradiol moiety in targeting liposomes to ER-expressing MCF-7 cells.
Figure 1. ¹H NMR spectra of A) the starting material, DPPE-PEG-NH₂, and B) the final product, DPPE-PEG-ES. The inset in (B) shows the aromatic proton signals from the lipid-associated estradiol. C) MALDI mass spectrum of DPPE-PEG-ES.

The DNA-binding characteristics of both the targeting and the nontargeting liposomes were confirmed by a simple gel retardation assay, and the DNase I sensitivity of the lipoplex-associated DNA was evaluated by a conventional DNase I protection experiment (see the Supporting Information). The sizes and surface charges of the lipoplexes under transfection conditions were also measured (see the Supporting Information). The targeting and nontargeting lipoplexes showed a comparable stability. Except for lipoplex sizes with a charge ratio of 8:1, the surface charges and sizes of lipoplexes in the presence of serum were comparable.

We measured the β-gal gene expression in ER-expressing breast adenocarcinoma MCF-7 cells pretreated or untreated with 100 μM tamoxifen, an ER antagonist. Cells were transfected with cationic lipoplex containing either the targeting lipid DPPE-PEG-ES or the nontargeting lipid DSPE-PEG-mal. To mimic in vivo conditions, the transfection was carried out in the presence of a serum-containing medium. Figure 2
Figure 2. β-Gal gene expression in MCF-7 cells. MCF-7 cells, with or without pretreatment by tamoxifen (100 μM), were transfected with 0.3 μg of pCMV-β-gal DNA complexed in the estradiol-associated targeting cationic liposome (DPPE-PEG-ES) or in the nontargeting control cationic liposome (DSPE-PEG-mal). All cells were treated in the presence of 7% serum. Transgene expression is represented as β-galactosidase activity. The targeting and nontargeting lipoplexes were treated with the cells in cationic lipid/DNA charge ratios ($+/-$) of 8:1, 4:1, 2:1, and 1:1. The transgene expression obtained for each data point was acquired from triplicate treatments performed in a single day. The difference between the data obtained for DPPE-PEG-ES and DSPE-PEG-mal is statistically significant at all charge ratios (the probability of getting more extreme results than the observed value (p) < 0.0001), whereas that for DPPE-PEG-ES and DPPE-PEG-ES + 100 μM tamoxifen is statistically significant at all charge ratios (p < 0.0001) except for a charge ratio of 4:1, when $p = 0.00029$.

shows that the cells treated with targeting lipoplex express significantly more reporter gene than cells treated with nontargeting lipoplex at all the charge ratios (20- to 100-fold). Moreover, the presence of tamoxifen significantly inhibits targeting-lipoplex-mediated gene expression at all the charge ratios. However, in the case of the nontargeting-lipoplex-mediated transfection, the presence of tamoxifen has almost no effect ($p > 0.1$). This result demonstrates the ability of the DPPE-PEG-ES containing targeting lipoplex to transfect MCF-7 cells in a target-specific manner. The number of ligands is higher at a charge ratio of 8:1, but the highest transfection was obtained at a ratio of 4:1. This is probably because the lipoplex size at a charge ratio of 8:1 is almost three times that at a charge ratio of 4:1 (see the Supporting Information), and also because the larger lipoplex size may not be favorable for efficient cellular uptake, particularly in this system. However, the size and surface charge of lipoplexes with other charge ratios are comparable. Therefore, in comparison to lipoplexes obtained at charge ratios of 2:1 or 1:1, the lipoplex obtained at a charge ratio of 4:1 tends to have a greater targeting ability as a result of the availability of more

ligands on the surface, and hence a higher transfection efficiency.

MDA-MB-231 is an advanced-stage breast cancer cell with drug-resistant properties. This cell does not possess ERs but expresses GPR30 protein[19] and therefore it is a natural, ER-knockout cell line. This cell line was chosen for transfection with targeting lipoplex, and the extent of transgene expression was compared with that obtained from MCF-7 cells. Figure 3 shows that there was almost negligible β-gal
Figure 3. β-Gal transfection in various cell lines. MDA-MB-231 (ER-knockout cell), Hela, CHO, and L-27 cells were transfected with targeting cationic lipoplex containing DPPE-PEG-ES and the results were compared with those for MCF-7 (ER-positive cell) for lipid/DNA charge ratios (+/−) of 8:1, 4:1, 2:1, and 1:1. The transgene expression obtained for each data point was acquired from triplicate experiments performed in a single day. The transgene expressions obtained in MCF-7 cells were all statistically significant ($p < 0.0001$) when compared to those obtained from other cell lines.

expression in MDA-MB-231 cells compared to that obtained in MCF-7 cells ($p < 0.0001$). This result shows that the targeting lipoplex can deliver and hence express genes only in cells possessing ER. GPR30 has a high affinity for estrogen,[19] and perhaps upon interacting with targeting lipoplex it can deliver gene to the cytoplasm. However, the lipoplex is probably unable to mediate delivery of genes to the nucleus because of the absence of ER. It is not clear how ER mediates selective delivery of genes to the MCF-7 nucleus in association with or in the absence of a lipid shell. This interesting observation in itself warrants further investigation, especially in the light of the finding that PEG blocks the intracellular trafficking of DNA associated with the liposomal system.[21]

Next, we evaluated the gene-targeting efficiencies of the DPPE-PEG-ES-associated lipoplex in three more cell lines not known to express ER, namely human cervical carcinoma (Hela), Chinese hamster ovary (CHO), and murine sarcoma cells (L-27, which is genetically modified to overexpress integrin receptors), by using β-gal plasmid. The transgene expression from these cell lines was compared with that obtained from MCF-7 cells. Figure 3 shows that gene expression in Hela, CHO, and L-27 cells is statistically insignificant in comparison to that obtained in MCF-7 cells. In general, the CHO and Hela cell lines are highly transfectable with cationic lipids and the present targeting, stealth,

cationic transfection lipid/DNA complex mediates negligible transfection in these cells, probably because the gene targeting is inefficient in the absence of ER.

Finally, we tested the targeting delivery system and estimated the relative anticancer efficacies of the apoptosis-inducing p53 gene delivered to MCF-7 cells with both the targeting and nontargeting lipoplexes. Figure 4 shows that the
Figure 4. Anticancer-gene-mediated targeted killing of MCF-7 cells. The cells were treated with 0.3 μg of pCMV-p53 DNA complexed with cationic liposomes containing targeting lipid, DPPE-PEG-ES (○), and nontargeting lipid, DSPE-PEG-mal (■), in a cationic lipid/DNA charge ratio (+/−) of 2:1. The treatment was similar to that described for the β-gal transfection experiments. The cells underwent MTT assay on days 2, 4, and 6 after transfection. The *y* axis shows the percentage viability, and each data point was acquired from triplicate treatments; $p < 0.005$ (**), $p = 0.007$ (*).

targeting lipoplex can indeed induce cell death, possibly through apoptosis, in a target-specific manner. From the second day onwards, the cell viability of the group treated with DPPE-PEG-ES-associated targeting lipoplex showed significant toxicity ($p < 0.005$ and $p = 0.007$), which persisted during the subsequent six days. Furthermore, we examined the stability of the targeting lipoplex at various serum concentrations. No perceptible change in the targeting efficiency, even at the biologically relevant in vivo serum concentration of 53%, was observed (see the Supporting Information). This result proves that the targeting gene delivery system will remain undeterred in its targeting efficiency in vivo.

In summary, our findings demonstrate a highly efficient, novel route for targeting anticancer genes at breast cancer cells through the use of 17β-estradiol-associated stealth liposomes. The chemistry involved is simple and inexpensive. Evaluation of the in vivo potential of the technique for eradicating breast cancer is currently in progress.

Template Synthesis

General Synthetic Route toward Functional Hollow Spheres with Double-Shelled Structures**

Mu Yang, Jin Ma, Chengliang Zhang, Zhenzhong Yang, and Yunfeng Lu**

Hollow spheres and capsules have stimulated great interest because of their potential applications in controlled delivery systems, artificial cells, lightweight fillers, catalysis, and as vessels for confined reactions.[1] Hollow spheres, in particular those with complex core–shell structures, have increasingly attracted interest as a result of their superior properties.[2] For example, a unique plasmon hybridization has been reported on hollow spheres with two concentric metallic nanoshells, thus providing a novel method of tuning resonance frequency by nanostructure engineering.[2a] Polymeric hollow spheres with a movable gold nanoparticle core have also been obtained, which allow the optical sensing of chemicals diffused into the cavity.[2b] In addition, polyelectrolyte capsules with a shell-in-shell structure exhibit an enhanced mechanical strength and preserved permeability.[2d] To date, the synthesis of such complex structures is essentially based on a time-consuming layer-by-layer templating technique, in which layers of desired materials (for example, metals, polymers, and polyelectrolytes) and of sacrificial materials (such as silica) are alternately grown on preformed spheres (for example, silica and polystyrene particles).[2,3]

Herein, we report a one-step approach to the synthesis of hollow spheres with a double-shelled complex structure by using commercial polymer hollow spheres as templates. As shown in Figure 1, a polystyrene hollow sphere containing a thin hydrophilic inner layer and transverse channels of poly(methyl methacrylate)–poly(methacrylic acid) (PMMA–PMA)[2e] is treated with sulfuric acid, and sulfonation takes place in three locations: the exterior shell surface, the interior shell surface, and the transverse channels. This procedure

Figure 1. Schematic illustration of the formation of double-shelled hollow spheres.

creates a hollow sphere that contains a hydrophilic inner layer, outer layer, and channels of sulfonated polystyrene gel. Control of the shell thickness of the original polystyrene sphere and the degree of sulfonation allows precise control over the thickness of the hydrophilic sulfonated layers and of the unsulfonated polystyrene middle layer. The sulfonation process produces hydrophilic shells with sulfonic acid ($SO_3^-H^+$) groups that are capable of adsorption or of forming complexes with a large variety of functional components, such as metal ions, metal oxide precursors (for example, titania alkoxides), and basic organic precursors (for example, aniline).[4] Preferential growth of desired materials (such as TiO_2)[4c] within the hydrophilic sulfonated regions followed by removal of the middle polystyrene layer creates various functional composites with a double-shelled structure. This direct approach allows the fabrication of double-shelled functional-composite spheres with controllable shell thickness and shell separation distance.

Figure 2 shows scanning electron micrography (SEM) and transmission electron micrography (TEM) images of unsulfonated spheres, sulfonated spheres, and the resultant double-shelled titania spheres. The unsulfonated hollow spheres (Figure 2a) have an average diameter of 500 nm and a smooth, uniform shell of thickness 80 nm. Sulfonation at 40°C for 0.5, 2, and 4 h results in sulfonated hollow-sphere templates denoted as S1, S2, and S3, respectively. Compared to the unsulfonated spheres, the S1 spheres (Figure 2b) show a significantly thickened shell (from 80 to 125 nm), a decreased cavity diameter (from 340 to 260 nm), and a slightly deformed spherical shape, which indicate the effective sulfonation and gel formation on both exterior and interior shell surfaces. The appearance of the sulfonic and sulfonyl peaks in the FTIR spectrum further confirms the sulfonation (see Supporting Information). Elemental analysis showed that the S1 spheres contain 2.5 wt% of sulfur atoms. An increase in the sulfonation time to 2 h (sample S2) increased the amount of sulfur to 6.1 wt% and resulted in a thinner
Figure 2. unsulfonated polystyrene middle layer, which indicates a higher degree of sulfonation. An excess degree of sulfonation may completely consume the entire polystyrene middle layer, and cause collapse of the structure upon drying. Indeed, the S3 spheres were easily deformed and lost their spherical contour after freeze-drying (see Supporting Information).

We have previously found that tetrabutyl titanate (TBT) can favorably undergo a sol–gel process within sulfonated polystyrene gel to form titania.[4c] The same reactions can be applied to the sulfonated hollow spheres. Figure 2c and d shows the resultant titania spheres produced with S1 as the template. The spheres are approximately 500 nm in diameter (Figure 2c) with a similar morphology to that of the S1 template (Figure 2b). The removal of the polystyrene templates, which was confirmed by the weakening of the characteristic peaks of polystyrene in the FTIR spectrum, creates the double-shelled, concentric titania hollow spheres shown in the TEM image (Figure 2c, inset). The thickness of the shells is around 25 nm and the distance between the shells is around 75 nm, although the contour of the inner shell is somewhat unclearly defined (Figure 2d). The use of sulfonated templates with a higher degree of sulfonation results in

hollow titania spheres with an increased diameter and decreased shell-to-shell distance. For example, the S2-templated titania hollow spheres show an average diameter of 580 nm, a reduced shell-to-shell distance of approximately 30 nm, and a thicker shell of 50 nm (Figure 2e). The use of the S3 template results in 630-nm single-shelled titania hollow spheres (Figure 2f). These results demonstrate the efficiency of controlling the morphology of the double-shelled structure by simply tuning the degree of sulfonation. As a control experiment, titania spheres were prepared by using the unsulfonated hollow spheres as templates. Titania was formed only within the hydrophilic inner layer[2e] and not on the exterior surface, which indicates the key role of sulfonation in the formation of such double-shelled structures.

The synthesized double-shelled titania hollow spheres are strong enough to survive calcination at 450°C in air, which removes the polymer and generates titania crystalline phases. In contrast to the dissolution of polystyrene by *N,N*-dimethylformamide (DMF), calcination leads to a significant volume contraction. For example, the diameter of the S1-templated titania spheres contracts from 500 to 400 nm (see Figure 3a and Supporting Information). The inner shell, in
Figure 3. Morphologies of representative double-shelled crystalline metal oxides and conducting polymer hollow spheres. a, b) TEM images of titania hollow spheres templated by S1 and S2, respectively, followed by template removal by calcination at 450°C in air to form anatase. c) SEM image of double-shelled Fe_3O_4 hollow spheres templated by S2. d) SEM image of double-shelled polyaniline hollow spheres templated by S2. The insets in (c) and (d) show TEM images of the spheres after treatment with DMF.

particular, contracts remarkably and becomes a movable inner hollow sphere. High-resolution TEM analysis indicates that the nanoparticles in both the shell layers have a crystalline order and form almost fully crystallized inorganic frameworks (see Supporting Information). Increasing the amount of titania in the composite helps to stabilize the double-shelled structure. For example, thermogravimetric analysis (TGA) shows that titania/S1 and titania/S2 composite spheres contain 24.3 and 37.1 wt% titania, respectively. As a result, the S2-templated titania spheres maintain the concentric double-shelled structure after calcination (Figure 3b and

Supporting Information). X-ray diffraction (XRD) studies show that the calcined titania is composed of anatase (Figure 4a). The average particle size calculated using Scherrer's formula is about 11.4 nm, consistent with the
Figure 4. X-ray powder diffraction spectra of TiO_2 hollow spheres calcined at a) 450 and b) 600°C for 2 h in air (rutile ▽; anatase ●).

TEM result. A higher calcination temperature (for example, 600°C) results in a dominant rutile phase with a small amount of the anatase phase (see Figure 4b and Supporting Information; the calculated average particle size is 32.0 nm) and also deterioration of the spherical structure (see Supporting Information).

The unique template structure combined with the complexation capability of the sulfonic acid groups within the sulfonated layers allows this synthesis approach to be generalized for the production of a large variety of double-shelled composite spheres. For example, double-shelled composite hollow spheres containing crystalline Fe_3O_4 nanoparticles can be fabricated, based on the complex of iron ions and sulfonic acid groups. Figure 3c shows SEM and TEM (inset) images of the Fe_3O_4 nanoparticle composite spheres prepared with S2 as the template. The composite spheres contain 57 wt% of Fe_3O_4 nanoparticles of diameter 10–15 nm, as deduced from TGA and TEM studies. The positions and relative intensities of all the XRD diffraction peaks (see Supporting Information) are well-matched with those of magnetite (JCPDS card 19-0629). Thus, it can be concluded that magnetite dominates the nanoparticles. The crystallographic form was further verified by its color change from the dark brown of the as-prepared sample to red, which corresponds to maghemite, upon oxidation at 100°C for 4 h. The average particle size calculated from the XRD data is 11.0 nm. Such crystalline nanoparticles show superparamagnetic behavior at room temperature (see Supporting Information). Similarly, by utilizing acid–base interactions, aniline monomer can favorably be adsorbed within the sulfonated layer. Subsequent polymerization leads to the formation of conductive double-shelled polyaniline composite spheres. Figure 3d shows the SEM and TEM (inset) images of the polyaniline composite spheres prepared with S2 as the template; the spheres have a smooth surface with well-retained spherical contour. Compared with the easily deformed single-shelled polyaniline hollow spheres,[4d] the

double-shelled structure effectively enhances the mechanical stability of the hollow spheres, which is similar to the previous reports of double-shelled polyelectrolyte capsules.[2c,d] As revealed by the FTIR spectrum (see Supporting Information), the resultant polyaniline (36.8 wt% of the composite, estimated from elemental analysis) was doped in situ with the sulfonated polystyrene and formed the emeraldine salt,[5] which resulted in an appreciable conductivity of 6×10^{-3} S cm^{-1}. Studies aimed at a detailed understanding and possible applications of such functional spheres are in progress.

In conclusion, we have demonstrated a one-step method for the synthesis of double-shelled composite hollow spheres by using sulfonated hollow spheres as templates. Controlled sulfonation allows the synthesis of templates with tunable thickness of the sulfonated outer layer, sulfonated inner layer, and unsulfonated middle layer. The sulfonation process gives layers with sulfonic acid groups that allow the formation of a wide variety of functional composites. This research provides a novel and efficient approach to the synthesis of various double-shelled functional spheres for many important applications.

Experimental Section

Sulfonated hollow-sphere templates: Freeze-dried polymer hollow spheres[2e] (Rhom & Haas Company) were immersed in concentrated sulfuric acid. Sulfonation at 40°C for 0.5, 2, and 4 h resulted in the sulfonated hollow-sphere templates denoted as S1, S2, and S3, respectively. The sulfonated spheres were thoroughly rinsed with water and ethanol.

Titania hollow spheres: Freeze-dried sulfonated templates (0.1 g) were immersed in tetrabutyl titanate (TBT)/ethanol (1:1 v/v, 5 mL) for 24 h. After centrifugation and rinsing with ethanol, the resultant materials were transferred to a closed vessel containing ethanol (5 mL) at ambient temperature. Water (5 mL) was then added to the dispersion with stirring, and the sol–gel process was allowed to proceed for 4 h. Double-shelled titania hollow spheres were obtained after centrifugation, rinsing with ethanol, and template removal by dissolution in DMF or calcination at 450°C for 2 h in air.

Magnetite hollow spheres: Freeze-dried S2 (0.1 g) was immersed in ammonium hydroxide (10 M, 5 mL) for 12 h before transfer to a solution containing water (10 mL). Aqueous ferrous chloride/ferric chloride (1:2 M, 0.6 mL) was then added dropwise with stirring under a nitrogen atmosphere.[6] Magnetite hollow spheres were obtained after the polymer was dissolved with DMF and collected by a magnet (see Supporting Information). The collected spheres could be readily redispersed by ultrasonication.

Polyaniline hollow spheres: Freeze-dried S2 (0.1 g) was dispersed in water (10 mL) containing monomeric aniline (0.1 g) with stirring. After 2 h, aqueous ferric chloride (1 M, 0.5 mL) was added to initiate oxidative polymerization at room temperature for 24 h. Polyaniline hollow spheres were obtained after centrifugation and treatment with DMF to dissolve the polystyrene.

Characterization: The structure and morphology of the spheres were characterized by TEM (JEOL 100CX instrument operated at 100 kV) and SEM (Hitachi S-4300 instrument operated at an accelerating voltage of 15 kV). TEM samples were prepared by dispersing the spheres from dilute ethanol dispersions onto carbon-coated copper grids or by the ultramicrotoming technique. The ultramicrotomed samples were prepared by embedding the spheres in resin and ultramicrotoming to form 30–50-nm-thick slices with a Leica ultracut UCT ultramicrotome at room temperature. The SEM samples were prepared by vacuum sputtering of Pt onto the dried samples at ambient temperature.

FTIR spectroscopy was performed using a Bruker Equinox 55 spectrometer with the samples pressed into KBr pellets. X-ray powder diffractometry (Rigaku D/max-2500) was used to characterize the crystalline phases of the materials. A Perkin-Elmer TGA 7 apparatus was used to determine the inorganic content of the composite spheres. Elemental analysis was carried out with a Flash EA-1112 apparatus. A vibrating-sample magnetometer (VSM JDM-13) was used to characterize the magnetic properties of the magnetite composite spheres. Conductivity measurements were performed on pieces of compressed dry powder by using a standard four-probe method at room temperature.[4d]

Nucleotides

Expeditious, Potentially Primordial, Aminoacylation of Nucleotides**

*Jean-Philippe Biron, Alastair L. Parkes, Robert Pascal,** and John D. Sutherland**

In contemporary biochemistry, enzymatically synthesized, activated aminoacyl-tRNA esters (aa-tRNA) serve as substrates for coded peptide synthesis by ribosomes,[1] and a major goal is to understand the evolutionary path through which this process arose. As a first step towards this goal, we have been looking to find a prebiotically plausible means for the aminoacylation of ribonucleotide 2′-/3′-hydroxy groups. A number of simple, potentially prebiotic, activated amino acid derivatives have been reported, most notably *N*-carboxyanhydrides (NCAs).[2] The case for NCAs in prebiotic evolution has recently been strengthened by the finding that they can be produced from amino acids through the action of the simple volcanic gas carbonyl sulfide.[3]

We therefore decided to investigate the aminoacylation of nucleotides by NCAs. Initially we were concerned that the nucleobase amino groups of adenine and cytosine would prove more nucleophilic than the 2′-/3′-hydroxy groups; however, recent findings show that NCAs react with inorganic phosphate to give aminoacyl phosphates.[4] This suggests that it might be possible to generate nucleotide aminoacyl esters by initial aminoacylation of the phosphate monoester, followed by intramolecular aminoacyl transfer. Nucleotide aminoacylation by way of intermediate carboxylic phosphoric anhydrides would be analogous to the chemistry of aminoacyl-tRNA synthetase (aa-RS) enzymes. These enzymes

generate 5′-aminoacyladenylates (5′-aa-AMP) **1** (A = adenine) through an initial nucleophilic attack of an amino acid carboxylate on ATP. The aa-RS then catalyzes the intermolecular aminoacyl transfer from **1** to the 2′/3′-terminus of a cognate tRNA to give adenosine-5′-monophosphate (5′-AMP) (**2**) and an equilibrating mixture of 3′- and 2′-aa-tRNAs **3** and **4** (Scheme 1).
Scheme 1. The biochemistry and chemistry of 5′-aa-AMP **1**: biochemically (upper), **1** is used by aa-RS enzymes for the aminoacylation of cognate tRNA. In the absence of enzymes (lower), **1** can undergo intramolecular aminoacyl transfer and hydrolysis reactions.

When separated from the protective environment of an aa-RS, 5′-aa-AMPs are highly unstable and undergo hydrolysis and isomerization in aqueous solution.[5,6] The isomerization involves a slow initial intramolecular aminoacyl transfer from the 5′-phosphate to the 3′-hydroxy group via an eight-membered transition state to give the 3′-aminoacyl ester **5**, followed by rapid equilibration of the latter with a 2′-aminoacyl ester. If it were possible to generate 5′-aa-AMP **1** from 5′-AMP **2** by reaction with an NCA, then this intramolecular transfer would hopefully result in the sought-after formation of aminoacyl esters.

We first investigated whether the aminoacylation of a simple model phosphate monoester with an NCA was possible. We chose methyl phosphate **6** as the model phosphate monoester and the valyl derivative **7** to allow comparison with the previous work on inorganic phosphate[4] and because **7** can be easily prepared and stored (Scheme 2).[7] In a general sense, the reaction of a phosphate monoester with any electrophile is faster at pH values above 7 when the phosphate is in its dianionic state, (pK_a for the monoanionic state ≈ 6–7 (Supporting Information)); however, NCA hydrolysis/polymerization is also favored at high pH values.

Communications
Scheme 2. Aminoacylation of model phosphate monoester by Val-NCA **7**.

To slow such degradative reactions while still allowing reaction of the NCA with the phosphate group of **6**, we conducted our experiments under very slightly acidic conditions. In this case, although **6** was predominantly monoanionic, some of the reactive dianionic form still existed. Using ^{1}H NMR spectroscopy for analysis, we observed a low-level conversion of **6** and **7** into L-valyl methyl phosphate **8** (not isolated, according to ^{1}H NMR integration $\approx 23\%$ based on **7**, see Supporting Information). The conversion was only transient, however, and **8** was gradually converted back into the starting methyl phosphate **6** along with valine and oligovaline.

These observations imply that the reaction of **6** and **7** to give **8** is an equilibrium that is rapidly established and lies in favor of **6** and **7**. The equilibrium is eventually dissipated through the hydrolysis of **7** and **8** to valine, and the subsequent reaction of the valine with further **7** and **8** giving oligovaline. The existence of the proposed equilibrium was proven when we found that **8**, as prepared by conventional synthesis, was almost completely converted into **6** and **7** in the presence of bicarbonate. Once again, hydrolysis/polymerization of the activated valine derivatives subsequently yielded the free amino acid and oligomers.

We next turned our attention to the reaction of nucleotides with Val-NCA **7**. 5'-AMP **2** showed similar behavior to methyl phosphate **6**, and we observed an equilibrium production of 5'-Val-AMP **1** (R = iPr). However, the equilibrium was dissipated by NCA hydrolysis/polymerisation before the rearrangement of **1** into **5** occurred (see Supporting Information).[5,8] We next studied the reaction of other regioisomeric nucleotides with Val-NCA **7**. We recognized that if a nucleoside 3'/2'-valyl phosphate **9/10** could be transiently formed from the corresponding 3'/2'-nucleotide **11/12** and **7**, then intramolecular aminoacyl transfer to the 2'/3'-OH group, via a seven-membered transition state[9] might now be faster than hydrolysis/polymerization of the NCA or the intermediate mixed anhydrides (Scheme 3). We reasoned, therefore, that even an unfavorable equilibrium situation might lead to subsequent intramolecular aminoacyl transfer, and that this transfer should then displace the equilibrium according to Le Chatelier's principle. There was a major concern with the 3'/2'-nucleotides, however, as we foresaw cyclization of the intermediate 3'/2'-aminoacyl phosphates **9/10** to give the 2',3'-cyclic phosphate **15** as a likely competing reaction (Scheme 3). Indeed, 2'/3'-phosphates can be cyclized with great ease, to 2',3'-cyclic phosphates via five-membered transition states, by almost any form of phosphate activation.[10]
Scheme 3. Aminoacylation/cyclization of 3'- and 2'-nucleotides by Val-NCA **7**.

Undeterred by this concern, we initially studied the reaction of cytidine-3'-monophosphate (3'-CMP) **11** (base (B) = cytosine (C)) with Val-NCA **7**, again under very slightly acidic conditions. After 55 min, no new signals consistent with **9** (B = C) were observed in the ^{1}H NMR spectrum. However, new signals were observed which were tentatively assigned to the aminoacyl-transfer product **13** (B = C) (Figure 1 a)). In
Figure 1. ^{1}H NMR spectra (500 MHz, D$_2$O) of the products of the reaction of 3'-CMP **11** (B = C) with Val-NCA **7**. a) Spectrum acquired after 1 h. b) Spectrum acquired after spiking the sample with authentic **15** (B = C) (0.5 mg).

particular, a diagnostic triplet between $\delta = 5.4$ and 5.5 ppm was shown by COSY analysis to correspond to 2'-H of the new species, and the downfield shift of this signal was consistent with a 2'-ester. Although **13** was not isolated,[11] integration of the ^{1}H NMR spectrum of the reaction mixture suggested that it had been formed in $\approx 9\%$ overall yield (Table 1).

Table 1: Yields of the products observed in the reactions of 3′/2′-nucleotides **11/12** with Val-NCA **7**.

Nucleotide	t [min]	Starting material [%]	Valyl ester (13 or 14) [%]	Divalyl ester [%]	15 [%]
11 (B = C)	55	90.6	(**13**) 8.7	trace	0.7
11 (B = A)	30	82.2	(**13**) 13.8	3.9	trace
	90	79.5	(**13**) 13.4	5.6	1.5
12 (B = C)	45	94.9	(**14**) 3.0	0	2.1
12 (B = A)	90	99.0	(**14**) 0.5	0	0.5

As our experiment was initiated at a pD value close to the pKa of the monoanionic form of **11**, the yield of **13**, based upon the reactive dianionic form of **11**, is probably considerably higher. This suggests that isomerization of the intermediate **9** into **13** is highly efficient relative to the fast backwards reaction of **9** with CO_2. After further time had passed (> 1 h), ^{1}H NMR spectroscopic analysis suggested that **13** underwent very slow reversion to **11**, presumably by a combination of hydrolysis and nucleophilic attack by the amino group of valine and valyl derivatives, including **13**. The minor signals in the ^{1}H NMR spectrum (accompanying the signals of **13**) in the reaction of **11** and **7** were shown, by spiking the reaction with an authentic sample, to be due to the 2′,3′-cyclic phosphate **15** (B = C) (Figure 1b)). However, this anticipated by-product was formed in much lower amounts (**13/15** > 10:1), and we have not been able to prove the structure of the second minor product definitively, but MS and HMBC data strongly suggest that it is the 2′-divalyl analogue of **13**.

We next investigated the effect of the nucleobase on this remarkable conversion and examined the reaction of 3′-AMP **11** (B = A) with Val-NCA **7**. Again, we could not detect the intermediate aminoacyl phosphate **9** (B = A) but observed the aminoacyl-transfer product **13** (B = A) in a maximal overall yield of $\approx 14\%$ after 30 min (Table 1). In this experiment the putative 2′-divalyl analogue of **13** was also formed in a greater quantity and, after 90 min, had accumulated to the level of $\approx 6\%$. On the basis of the amount of the reactive dianionic starting material, the combined synthesis efficiency of **13** (B = A) and the divalyl analogue is again, probably considerably higher. Close examination of the ^{1}H NMR spectra revealed the presence of the 2′,3′-cyclic phosphate **15** (B = A) in low yield (**13/15** > 8:1). It thus appeared that the nucleobase had a relatively small effect on the aminoacylation of 3′-nucleotides with Val-NCA, and as such, we switched our attention to the isomeric 2′-nucleotides with the expectation of equally efficient aminoacylation.

Through the use of the same conditions employed for the 3′-isomer, we found that cytidine-2′-monophosphate (2′-CMP) **12** (B = C), in the presence of Val-NCA **7**, gave the 3′-ester **14** (B = C) in only $\approx 3\%$ yield after 45 min (Table 1). Not only was the aminoacyl-transfer product formed in low yield, but it was accompanied by a comparable ($\approx 2\%$) amount of the 2′,3′-cyclic phosphate **15** (B = C) (**14/15** < 2:1). The lower yield of the ester product and the higher yield of **15** suggest that aminoacyl transfer from **10** is less efficient than it is from the 3′-phosphoryl isomer **9**. This conclusion was

supported by experiments with 2′-AMP **12** (B = A) and Val-NCA **7** in which we found that both the 3′-ester **14** (B = A) and the cyclic phosphate **15** (B = A) were formed in only trace amounts. This marked contrast in aminoacylation behavior between 3′- and 2′-nucleotides was not anticipated. It now seems likely that the efficiency of the aminoacylation reaction depends on the pK_a value of the phosphate and 2′/3′-OH groups, and possibly on conformational effects such as the furanose ring pucker. The pK_a value of the phosphate presumably influences the efficiency of the intramolecular aminoacyl-transfer step through a correlation with the leaving-group ability. Although the absolute pK_a values reported in the literature for the individual nucleotides differ (Supporting Information),[12–14] there is a consensus that the 3′-phosphates are more acidic than the 2′-phosphates by approximately 0.2 pK_a units and this is consistent with the more efficient conversion of **11** into **13**. Within the 3′-phosphate series, the greater yield of **13** (B = A) relative to **13** (B = C) is possibly related to the fact that aden-9-yl is a better stabilizer for the 2′-oxyanion than any other aglycons.[15]

The results described herein indicate that uncoded aminoacylation of 3′-nucleotides by NCAs is a prebiotically plausible reaction. The chemical mechanism of this process suggests that it should also be possible for 3′-phosphoryl oligoribonucleotides to undergo aminoacylation by NCAs in the same way, but with potential assistance by the ribonucleic acid chain through stereocomplementary binding. It is therefore possible that ribozymes, capable of coded aminoacylation by NCAs might have evolved and could have been key intermediates in the emergence of translation.[16] The use of 5′-aa-AMPs as intermediates in coded aminoacylation of RNA is most likely a later evolutionary development.

Formation of a Bowl-Shaped, Pentacyclic Phosphonium Cage by Methylation of a Nucleophilic Phosphinidene

Matthias Driess,* Nicoleta Muresan, Klaus Merz, and Michael Päch

Dedicated to Professor Gottfried Huttner on the occasion of his 68th birthday

Phosphinidenes, that is, carbene-analogous compounds of monovalent phosphorus (phosphanylidenes, R–P) represent a simple class of valuable electrophilic building blocks in organophosphorus chemistry, which are usually highly reactive transients and therefore difficult to isolate.[1] However, one simple chemical trick that aids the preparation of a room-temperature stable phosphinidene is the intra- or intermolecular addition of a donor group D to the initially electron-deficient phosphorus atom (D→PR); this affords an electron-rich (nucleophilic) phosphinidene, having eight or more valence electrons at the phosphorus center. Several types of donor-stabilized phosphinidenes have already been isolated and used as versatile precursors for the preparation of "free" phosphinidenes such as phospha-Wittig reagents $(R_3P=PR')$[2] and related phosphinidene metal complexes $(L_nM=PR)$.[3] The intramolecular donor-stabilization of a

P(+1) atom is also the reason for the intriguing stability of the nucleophilic phosphinidene **1** (Scheme 1), which has a planar, T-shaped three-coordinate phosphorus atom with 10 valence electrons (10-P-3 system).[4] Although **1** is a promising versatile building block for the synthesis of novel electronically tunable organophosphorus ligands, its reactivity has only been sparingly investigated.[5] The relatively high nucleophilicity at the P atom prompted us to investigate whether alkylation of phosphorus with classical alkylation reagents RX (R = alkyl; X = anionic leaving group) leads to a nucleophilic phosphenium salt **A**, phosphonium species **B**, or neutral phosphorane **C** as possible valence isomers, depending on the electronic nature and steric demand of R and X, respectively (Scheme 1).

Here we report the surprising formation of the unusual phosphonium cage cation in **2**, which results from a domino cyclization of two molecules of **1** in the presence of methyl trifluoromethylsulfonate (MeOTf). When a solution of MeOTf in CH_2Cl_2 was added to a solution of **1** in CH_2Cl_2 in the molar ratio of 1:1 at 20°C, a rapid reaction occurs (^{31}P NMR monitoring), affording the unexpected phosphoni-
Scheme 1. The possible valence isomers **A**, **B**, and **C** formed by alkylation of **1** with RX (R = alkyl, X = anionic leaving group; ET = electron transfer.

um salt **2** [Eq. (1)]. The latter is insoluble in hydrocarbon solvents and other nonpolar solvents and can be isolated in
the form of a colorless solid in 35% yield. The yield can be increased up to 78% by changing the molar ratio of the starting materials MeOTf and **1** to 1:2. Interestingly, compound **2** results also exclusively even if a solution of **1** in CH_2Cl_2 is slowly added to a very large molar excess or even by using neat MeOTf at room temperature or below ($-10°C$).

The composition and constitution of **2** was established by EI-FAB and ESI (electrospray ionization) mass spectrometry

(*m/z* 497), correct combustion analyses (C,H,N,P), and NMR spectroscopy (^{1}H, ^{13}C, ^{31}P). The ^{31}P NMR spectrum of **2** in CD$_2$Cl$_2$ shows two multiplets at $\delta = 107.4$ and 112.8 ppm without scalar ^{31}P–^{31}P coupling. Since the connectivity of **2** was difficult to interpret based exclusively on the NMR spectra, its structure was unequivocally established by an single-crystal X-ray diffraction analysis (Figure 1).[6] The latter revealed that **2** is an ion pair that consists of a bowl-shaped phosphonium cage with a λ^3-pyramidal and a λ^4-tetrahedral coordinate phosphorus atom, and a "non-coordinating" triflate anion.
Figure 1. a) Molecular structure of the cation in **2**; b) core of the cage in **2**, including the terminal methyl carbon atom (C26) at the *phosphonium* P atom; hydrogen atoms are omitted for clarity. Selected distances [pm] and angles [°]: P1−O1 155.3(4), P1−O2 156.1(4), P1−N2 164.0(5), P1−C26 175.8(6), P2−O3 165.1(5), P2−N1 171.7(5), P2−C1 191.2(5); O2-P1-O1 117.0(2), O2-P1-C26 106.8(3), N2-P1-C26 121.8(3), O3-P2-N1 89.5(2), C20-N1-C12 106.6(4), C20-N1-P2 132.4(4), C12-N1-P2 111.1(3), C13-N2-C6 110.6(4), C13-N2-P1 108.6(3), C6-N2-P1 108.7(3).

The pentacyclic cation consists of a C$_7$O$_3$N$_2$P$_2$ skeleton with "globular-fused" five-membered rings. The core of the cation can be simply described as a cycloadduct of two molecules of **1**. The P−O and P−N distances are shorter than those in **1** but similar to the values for related *phosphane*-P−O and -P−N systems[7] and corresponding *phosphonium*-P−O[8] and -P−N systems,[9] respectively. The terminal P1−C26 distance of the *phosphonium*-P atom (175.8(6) pm) is significantly shorter than the other P−C distances within the cation core and in other phosphonium cations with P−CH$_3$ bonds.[10] This is probably due to the relatively high positive partial charge at the phosphorus center and the resulting σ-bond polarity of the P1−C26 bond. Because of the steric congestion around the N1 atom, it adopts an almost trigonal-planar configuration (sum of bond angles $\Sigma = 350.2°$); this is in

contrast to the coordination geometry around the N2 atom which displays a less distorted pyramidal configuration ($\Sigma = 328°$). The structural parameters have been consistently reproduced by density functional theory (DFT) calculations[11] on the model cation **2′**, in which the *t*Bu groups were replaced by Me groups: The values for the distances and angles differ by less than 3 pm and 2°, respectively. The formation of **2** is in strong contrast to the result of the related protonation of **1** with HOTf, which, surprisingly, leads to the nucleophilic phosphenium ion in **3** as the sole product [Eq. (2)].[12] Since the molecular structure of the cation in **3**
was hitherto unknown, we carried out a single-crystal X-ray diffraction analysis (Figure 2).[6] The phosphenium cation consists of a planar, five-membered C$_2$NOP ring, which has close structural and electronic similarities to other related cyclic phosphenium ions.[13]

The P1−N1 distance of 165.1(3) pm is slightly longer than that in the acyclic phosphenium ion [P(N*i*Pr$_2$)$_2$]$^+$ (161.3(4) pm)[14] but similar to the values in related cyclic phosphenium ions.[13] The relatively long P−O distances of 282
Figure 2. a) Molecular structure of **3**; b) side view of the cation in **3**. Selected distances [pm] and angles [°]: P1−O1 163.1(3), P1−N1 165.1(3), O1−C2 137.7(4), N1−C1 139.2(5), N1−C7 146.5(4), O2−C8 122.4(4), C7−C8 149.0(5), C1−C2 134.3(5), P1−O2 250.1(1); O1-P1-N1 90.65(1), O1-P1-O2 165.2(2), C2-O1-P1 115.0(2), C1-N1-C1 118.9(3, C1-N1-P1 112.4(2), C7-N1-P1 128.6(2).

and 285 pm of two oxygen atoms of neighboring OTf groups reflect the very weak donor–acceptor interactions between the phosphorus atom and the counterion. Thus, it is peculiar that the low-coordinate P atom is only weakly stabilized by intramolecular coordination of the carbonyl oxygen atom as indicated by the relatively long O2–P1 distance of 250.1(1) pm. Surprisingly, the carbonyl oxygen atom approaches the P atom in the ONP plane and not perpendicular to it, as usually observed for other donor adducts of phosphenium ions.[13] This is confirmed by DFT calculations of the respective model compound 3C, which show that instead of the vacant p_z orbital at the phosphorus center, the P1–O1 σ* orbital serves as the acceptor orbital.[11] The respective geometry optimizations of the corresponding isomers 3A–3C clearly confirm the preference for 3C by 10.6 (3A) and 37.5 kcal-mol^{-1} (3B) (Figure 3). The nature of the phosphorus atoms in 3A and 3B should be quite different: While 3A possesses a P(+3) atom with a lone pair of electrons and the atom is coordinated by a monobasic, tridentate ketoimino-enolate, 3B has a P(+5) atom of the "classical" phosphonium type,

coordinated by a tribasic, tridentate bis(enolate)amido ligand. How can one explain the formation of the cation in 2? Apparently, the reaction implies a remarkable domino-cycloaddition reaction between the hitherto unknown P-methylated cationic species 4 and 1, which involves the formation of one new P–C and three additional C–C bonds. However, the structural analogue of 3c, that is, the donor-stabilized phosphenium ion 4c (see Figure 3), can be excluded as the key intermediate for the formation of 2. Since no intermediate could be observed, we performed DFT calculations[11] of the respective model systems 4A, 4B, and 4C
Scheme 2. Proposed domino-cyclization for the formation of **2**.
Figure 3. B3LYP/6-311+G(d)-optimized structures of 3A–3C and 4A–4C.[11] Relative energies in parentheses [kcal mol^{-1}]; distances in Å.

(Me groups instead of tBu groups in 4) to learn whether the phosphenium cation 4A or the symmetric phosphonium valence isomer 4B is the preferred initial product of the oxidative addition of a methyl cation. Interestingly, the geometry optimizations revealed that even in the series 4A–4C, the O→P stabilized phosphenium analogue 4C (O→P distance 237.0 pm) is slightly favored over 4A by 3.5 kcal mol^{-1} but is 19.2 kcal mol^{-1} lower in energy than 4B (ΔE (4B–4A) = 15.7 kcal mol^{-1}). DFT calculations of the possible experimental systems 4 (A-type and C-type with tBu groups) at a lower level of theory (BLYP/6-31G*) revealed that the A-type is now slightly favored over the C-type by about 2 kcal mol^{-1} due to steric hindrance.[11] Accordingly, the formation of the unexpected phosphonium cage cation in 2 as the sole "self-trapping" product during the methylation of 1 clearly suggests the preferred population of the 4A-type compound as the reactive intermediate. Since the latter phosphenium cation possesses a highly electrophilic backbone, it gets easily attacked by the electron-rich phosphinidene 1, which initiates the tandem-cyclization (Scheme 2).

Further investigations in the presence of other competing trapping reagents are currently underway to explore the use of the strong electrophilic phosphenium transient 4 as a novel building block for other polycyclic phosphonium ions.

Experimental Section

2: MeOTf (0.432 g, 2.65 mmol) was added to a stirring solution of **1** (1.27 g, 5.31 mmol) in dichloromethane (50 mL). The resulting clear solution was stirred at room

temperature and then concentrated to 10 mL. The desired product was precipitated by addition of diethyl ether (10 mL), filtered, and dried under vacuo to yield a white solid (1.32 g; 78%). Slow diffusion of diethyl ether in a solution of **2** in dichloromethane afforded crystals suitable for an X-ray structure analysis. M.p.: 205–207 °C (decomp); ^1H NMR (CD$_2$Cl$_2$): δ = 1.27 (s, 9H; tBu), 1.32 (s, 9H; tBu), 1.35 (s, 9H; tBu), 1.49 (s, 9H; tBuCO), 2.62 (d, $^2J(^1H,^{31}P)$ = 17.3 Hz, 3H; MeP), 3.62–3.65 (m, 2H; HC-N), 4.92 ppm (d, $^3J(^1H,^{31}P)$ = 17.0 Hz, 1H; HC-N); $^{31}P\{^1H\}$ NMR (CD$_2$Cl$_2$): δ = 107.4 (s), 112.8 ppm (s); EI-FAB: m/z (%): 497 ([M−OTf]$^+$, 5), 57 (tBu$^+$, 100); ESI-MS (CH$_2$Cl$_2$): m/z: 497 ([M−OTf]$^+$, 100); elemental analysis (%) calcd. for C$_{26}$H$_{46}$F$_3$N$_2$O$_7$P$_2$S (649.67): C 48.06, H 7.13, N 2.15, P 9.54; found: C 47.65, H 7.15, N 2.08, P 9.33.

3: The compound was prepared as reported by Arduengo et al. and the NMR data (^1H, ^{31}P) of the sample were identical with the reported values.[12]

A Novel Type of Pentacoordinate Silicon Complexes and Unusual Ligand Coupling by Intramolecular Electron Transfer

Matthias Driess,* Nicoleta Muresan, and Klaus Merz

Dedicated to Professor Herbert Schumann
on the occasion of his 70th birthday

There are only a few reports on intramolecular electron-transfer (ET) reactions in coordination compounds of the main-group elements.[1] Some years ago, Arduengo et al. reported on the intriguing coordination properties of the electron-rich trianionic amido-bis(enolate) ligand $[\text{N}\{\text{CH}=\text{C}(t\text{Bu})\text{O}\}_2]^{3-}$ (generated in situ from $\text{HN}[\text{CH}_2\text{C}(\text{O})t\text{Bu}]_2$ (**1**) and a base),[2] which can serve both as a tridentate NO_2 ligand and intramolecular two-electron reducing agent toward heavier Group 15 elements (P, As, Sb, Bi) owing to ligand-to-element ET.[3,4] Thus, reaction of PCl_3 with **1** in the presence of a base furnishes solely the corresponding nucleophilic phosphinidene with a planar λ^3, T-shape-coordinated phosphorus atom with 10 valence electrons. Recently, we have shown that trilithiated **1** is a remarkable redox ligand even towards metal dihalides of the Group 14 elements Ge, Sn, and Pb, leading to novel nucleophilic carbene homologues.[5] The fascinating coordination properties of **1** prompted us to explore whether the ligand is also capable of ET to a tetracoordinate Si^{4+} center. Here we describe the unexpected coordination behavior of **1** toward halosilanes, which affords two different types of unprecedented silicon complexes. Reaction of SiX_4 (X = Cl, Br) or RSiCl_3 (R = H, Ph) with **1** in the presence of NEt_3 as an auxiliary base furnishes deeply colored solutions from which the dimeric bis(N→Si) donor complexes **2a–d** can be isolated as the sole products (Scheme 1) in high yields. As expected, there is no reaction or color change if the halosilanes are added to solutions of **1** without the presence of a base. The final products **2a–d** are air-stable, moisture-sensitive, colorless solids that are well soluble in common aprotic organic solvents.

The composition and constitution of **2a–d** was confirmed by EI mass spectrometry, combustion analyses, and multinuclear NMR spectroscopy. The high-field ^{29}Si NMR chem-

ical shifts in solution and in the solid state are diagnostic for λ^5-coordinate silicon, and the similarity of respective solid state and solution values proves that the dimeric structure is retained in solution (see Table 1).[6]

Table 1: ^{29}Si NMR chemical shift values for **2a–d**; CP-MAS solid-state values in parentheses.

Complex	2a	2b	2c	2d
δ [ppm]	−81.8[a]	−85.9	−106.7	−38.3
	(−87)	(−93)	(−112)	(−45)

[a] $^1J_{\text{Si,H}} = 276.6$ Hz.

The shielding of the ^{29}Si nucleus is influenced by the nature of the substituents, thus the least shielding in the case of the phenyl-substituted complex **2d** is in accordance with values for related pentacoordinate silicon complexes with N→Si donor bonds (e.g., intramolecular amine→Si(Ph) donor–acceptor adducts).[7] Remarkably, there was no indication for a dissociation up to 100 °C in toluene solutions, as shown by variable-temperature ^{29}Si NMR experiments. The dimeric structure of **2c** was additionally confirmed by a single-crystal X-ray diffraction analysis.[8] Compound **2c** crystallizes in the triclinic space group $P\bar{1}$, and the molecular structure consists of a planar four-membered Si_2N_2 ring as the central structural motif (Figure 1). The latter results from a head-to-tail dimerization through N→Si donor–acceptor bonds of two hypothetical monomeric amido-bis(enolate) silicon bromide units. This leads to a slightly distorted trigonal-bipyramidal coordination of silicon with the Br1 and N1 atoms in axial and the O1, O2, and N1A atoms in equatorial positions. The axial Si1−N1 distance is about 20 pm longer than the equatorial Si1−N1A value (180.4(14) pm) but similar to N→Si distances observed in related Si_2N_2 dimers and silatranes.[9] The Si1−O1 distance (166.2(13) pm) is slightly longer than the Si1−O2 value (163.8(13 pm) but similar to Si−O distances observed for hypercoordinate silicon in silatranes with a N_2O_3 coordination.[9] Both the

Si—O single and the endocyclic C6—C7 and C11—C14 double-bond lengths of the ligand skeleton confirm that each silicon atom in **2c** is coordinated by a trianionic amido-bis-(enolate) chelate ligand.

Since similarly substituted amido-dialkoxyhalosilanes such as $XSi(OR)_2(NR'_2)$ ($X = Cl$, $R = Me$, $R' = alkyl$, $SiMe_3$)[10] are reluctant to dimerize, the formation of the thermally resistant dimers **2a–d** is amazing. To understand the facile dimerization of the hypothetical monomers **3** (see Scheme 1), we performed DFT calculations (B3LYP/6-311G** level of theory)[11] of the three possible monomeric valence isomers **3A–3C**. The resulting energy profile for **3A–3C** is depicted in Figure 2. The calculations revealed that the amido-bis(enolate)-chloro silicon complex **3A**, which has a puckered, bicyclic C_4O_2NSi skeleton, is most favored, whereas the silylene-like species **3C**, which implies a two-electron transfer from the ligand to silicon, is disfavored by 34.4 kcal mol^{-1} and the least stable one. This is in marked contrast to the Ge and Sn analogues, which clearly prefer the formation of nucleophilic germylenes and stannylenes,[4,5] reflecting that Si^{4+} is more electropositive than Ge^{4+} and Sn^{4+}. Interestingly, the optimized structure of **3B** with a planar-tetracoordinate silicon atom represents the transition state (one imaginary frequency) for the ring inversion of **3A**, being only 12.3 kcal mol^{-1} higher in energy (Figure 2). The latter process is reminiscent of related theoretical results on the hypothetical bis(*o*-catecholate)silicon complex with a much higher inversion barrier of 32.9 kcal mol^{-1}.[12] In accordance to previous predictions,[12] the significant lowering of the barrier in **3** indicates that the tridentate amido-bis(enolate) chelate is a more efficient π-donor–σ-acceptor than the

Figure 2. Top: DFT-(B3LYP/6-311G**)-optimized structures of **3A–3C**;[11] distances are given in Å. Bottom: Energy profile for the isomerization of **3A** to **3B** and **3C**. The valence isomer **3B** is the transition state (one imaginary frequency) for ring-inversion of **3A**.

bidentate *o*-catecholate ligand. What is the driving force for the facile dimerization of **3A**? According to the calculation of the natural atomic charges in **3A**, the Si and the N atoms bear partial charges (Si +2.14, N −0.88) in accordance with the presence of a masked (ylide-like) Si—N π bond, reminiscent of iminosilane adducts with λ^4-coordinate silicon and λ^3-coordinate nitrogen atoms.[13]

In fact, the HOMO exhibits an unsymmetrical π-charge distribution around the nitrogen and silicon atom and two symmetrical C—C π bonds (Figure 3). The calculated energy of the head-to-tail Si=N dimerization of **3A** to the corresponding dimer **2A** is −21 kcal mol^{-1}, and the geometrical

Figure 1. Molecular structure of **2c**; hydrogen atoms are omitted for clarity. Selected distances [pm] and angles [°]: Si1—Br1 227.5(6), Si1—O1 166.2(13), Si1—O2 163.8(13), Si1—N1 200.6(13), Si1—N1A 180.4(14), O1—C14 139(2), O2—C6 143(2), C7—N1 146(2), C11—N1 145(2), C6—C7 129(2), C11—C14 131(2); O1-Si1-O2 124.1(6), O2-Si1-N1A 115.8(6), O1-Si1-N1 85.1(6), N1-Si1-N1A 79.4(6), Br1-Si1-N1 177.4(4).
Figure 3. HOMO of **3A** with an ylidic Si—N π bond.

parameters of the latter are in good agreement with the respective experimental data of **2c**. Thus, the remarkably exothermic process prevents the observation of the monomeric units in **2a–d**. To protect the Si=N moiety against dimerization, we used the highly substituted trifluoro(silyl)-silane *t*Bu₃SiSiF₃ as starting material:[14] The latter readily reacts with trilithiated **1** in THF at −78 °C but leads to the unusual dimer **4** in the form of pale yellow crystals in moderate yield (29 %) as the only isolable product [Eq. (1); LDA = lithium diisopropylamide].

4: R = Si*t*Bu₃
The composition and constitution of **4** was confirmed by NMR spectroscopy, EI mass spectrometry, and an X-ray diffraction analysis (Figure 4).[8] The latter reveals that **4** crystallizes as a racemic mixture in the triclinic space group P1̄.

In contrast to the dimeric complexes **2a–d**, the dinuclear compound **4** possesses only tetracoordinate silicon atoms. Its formation involves a remarkably mild C−C bond coupling of two amido-bis(enolate) frameworks of **1** and the concomitant

Figure 4. Molecular structure of **4**; hydrogen atoms are omitted for clarity. Selected distances [pm] and angles [°]: Si1−Si2 236.8(10), Si2−O1 168.6(5), Si2−O2 164.7(6), Si2−N1 174.9(8), C1−O1 139.8(6), C8−O2 144.7(8), C6−N1 144.6(5), C1−C6 132.2(6), C7−C8 156.3(7), C7−C7A 154.7(6); O1-Si2-O2 122.3(2), O1-Si2-N1 94.2(3), O1-Si2-Si1 104.1(3), N1-Si2-Si1 136.8(2), C1-O1-Si2 110.6(3), C6-N1-C7 115.8(3), C1-C6-N1 115.8(3).

hydrogenation of the C8 and C8A atoms, presumably by a radical mechanism in which THF functions as the hydrogen source, to afford a hexa-basic bis[amido(enolate)-alkoxide] ligand capable of coordination of two formal *t*Bu₃Si−Si³⁺ fragments. The observed distances and angles (Figure 4) are in the range expected for tetravalent silicon compounds (e.g., amido-alkoxysilanes).[10] In summary, the deprotonated (anionic) ligand **1** shows remarkable coordination and electron-donor ability even towards tetravalent silicon, leading to the new types of silicon complexes **2** and **4**. Further investigations aimed at isolating the initial colored intermediates during the conversion of the halosilanes with deprotonated **1** and at synthesizing a stable monomeric silicon complex **3** are underway.

Experimental Section

General procedure for the synthesis of **2a–2d**: To a mixture of **1** (2 g, 9.38 mmol) and the equimolar amount of the corresponding halosilane (HSiCl₃ for **2a**, SiCl₄ for **2b**, SiBr₄ for **2c**, and PhSiCl₃ for **2d**) in dried, Ar-saturated THF (50 mL) at −78 °C was added dropwise three molar equivalents of triethylamine. The reaction mixture was allowed to warm up to room temperature (6 h) and was then stirred for an additional 2 h. All volatiles were removed in vacuo and the solid residue was extracted with hexane (3 × 10 mL). After filtration, the solvent was evaporated off and the residue was recrystallized from CH₂Cl₂ to afford a micro-crystalline sample of **2a** (0.73 g, 1.52 mmmol; 33 %); m.p.: 127–129 °C; ¹H NMR (CDCl₃): δ = 1.18 (s, 36H; *t*Bu), 4.22 (br s, 2H; SiH), 5.67 ppm (br s, 4H; NCH); ¹³C{¹H} NMR (CDCl₃): δ = 27.56 (s, CH₃), 34.87 (s, C(CH₃)₃), 106.01 (s, CN), 164.17 ppm (s, CO); ²⁹Si NMR (CDCl₃): δ = −81.8 ppm (d, $J_{\text{Si,H}}$ = 276.56 Hz); EI-MS: *m/z* (%): 478 ([M]⁺, 20), 463 ([M−Me]⁺, 10), 239 ([M/2]⁺, 15), 224 ([M/2−Me]⁺, 20), 209([M/2−2Me]⁺, 20), 57 (*t*Bu⁺, 100); correct elemental analyses (C,H,N,Si).

2b: (2.5 g, 4.69 mmol; 100 %); m.p.: 120–122 °C; ¹H NMR (CDCl₃): δ = 1.12 (s, 36H; *t*Bu), 5.55 ppm (s, 4H; NCH); ¹³C{¹H} NMR (CDCl₃): δ = 27.19 (s, CH₃), 33.84 (s, C(CH₃)₃), 107.63 (s, CN), 163.83 ppm (s, CO); ²⁹Si NMR (CDCl₃): δ = −85.9 ppm (s); EI-MS: *m/z* (%): 546 ([M]⁺, 90), 431 ([M−Me]⁺, 20), 511 ([M−Cl]⁺, 10), 273 ([M/2]⁺, 95), 258([M/2−Me]⁺, 100), 243 ([M/2−2Me]⁺, 20); correct elemental analyses (C,H,N,Si).

2c: (2.5 g, 3.94 mmol, 84 %); m.p.: 131–133 °C (decomp); ¹H NMR (CDCl₃): δ = 1.07 (s, 36H; *t*Bu), 5.48 ppm (s, 4H; NCH); ¹³C{¹H} NMR (CDCl₃): δ = 27.38 (s, CH₃), 34.47 (s, C(CH₃)₃), 107.63 (s, CN), 163.81 ppm (s, CO); ²⁹Si NMR (CDCl₃): δ = −107.6 ppm (s); EI-MS: *m/z* (%): 636 ([M]⁺, 100), 621 ([M−Me]⁺, 20), 557 ([M−Br]⁺, 17), 318 ([M/2]⁺, 87), 302 ([M/2−Me]⁺, 78), 289 ([M/2−2Me]⁺, 18); correct elemental analyses (C,H,N,Si).

2d: (1.56 g, 2.73 mmol, 58 %); m.p.: 117–119 °C (decomp); ¹H NMR (CDCl₃): δ = 1.17 (s, 36H; *t*Bu), 5.55 (s, 4H; NCH), 7.3–7.9 ppm (m, 10H; Ph); ¹³C{¹H} NMR (CDCl₃): δ = 28.73 (s, CH₃), 34.97 (s, C(CH₃)₃), 112.39 (s, CN), 127.9 (s, Ph), 129.8 (s, Ph), 135.8 (s, Ph), 149.7 ppm (s, CO); ²⁹Si NMR (CDCl₃): δ = −38.3 (s); EI-MS: *m/z* (%): 630 ([M]⁺, 30), 615 ([M−Me]⁺, 10), 315 ([M/2]⁺, 35), 300 ([M/2−Me]⁺, 30), 57 ([*t*Bu⁺, 100); correct elemental analyses (C,H,N,Si).

4: A solution of BuLi in hexane (Aldrich, 0.76 g, 12 mmol) at −78 °C was added to a stirred solution of diisopropylamine (1.21 g, 12 mmol) in THF (10 mL). The solution was allowed to warm up to room temperature and stirred for 0.5 h. To this freshly prepared solution of LDA, a solution of **1** (0.8 g, 3.75 mmol) in THF (10 mL)

was added dropwise at $-20\,^{\circ}$C over 10 min, affording a deep red solution of lithated **1**. The reaction mixture was warmed up to room temperature and stirred overnight. Subsequently, all volatile components were removed in vacuo and the red solid was redissolved in THF. To this solution was added a solution of $(t\text{Bu})_3\text{SiSiF}_3$ (1.06 g, 3.75 mmol) THF (in 10 mL) and the reaction mixture was stirred overnight. The solvent was removed under vacuo and the pale yellow solid was taken up in CH_2Cl_2 (30 mL). The filtrate, a slightly yellow solution, afforded (at $-30\,^{\circ}$C) pale yellow crystals suitable for X-ray diffraction analysis (0.48 g, 0.54 mmol, 29%); ^{1}H NMR (CDCl$_3$): $\delta =$ 0.88 (s, 54H; tBuSi), 1.22 (s, 18H; tBu), 1.14 (s, 18H; tBu), 1.34 (m, 2H; HCN), 1.39 (m, 2H; HCO), 5.21 (s, 2H; NCH); EI-MS: m/z (%): 877 ($[M]^+$, 40), 862 ($[M-\text{Me}]^+$, 30), 438 ($[M/2]^+$, 15), 57 ($[t\text{Bu}^+$, 100); correct elemental analyses (C,H,N,Si).

Biosynthesis of TDP-D-Desosamine: Identification of a Strategy for C4 Deoxygenation**

*Ping-hui Szu, Xuemei He, Lishan Zhao, and Hung-wen Liu**

*Dedicated to Professor Koji Nakanishi
on the occasion of his 80th birthday*

D-Desosamine (**1**), a 3-(dimethylamino)-3,4,6-trideoxyhexose found in a number of macrolide antibiotics including methymycin and pikromycin produced by *Streptomyces venezuelae*, plays an essential role in conferring biological activities to its parent aglycones.[1] Although numerous strategies for the biological C—O bond scission have been elucidated, little is known about the mechanism of deoxygenation at the C4 position in the formation of desosamine.[2] Insight into the mechanism of this key transformation is essential to fully establish the sequence of reactions in the desosamine pathway.

Past studies of the biosynthesis of various deoxyhexoses showed that the deoxygenation mechanism correlates with the position of the scissile C—O bond, either α or β to an activating group such as a keto group.[3] For example, a stepwise dehydration–reduction sequence catalyzed by a pyridoxamine 5′-phosphate (PMP)-dependent [2Fe-2S]-containing enzyme, E_1,[4] and an iron–sulfur flavoprotein reductase, E_3,[5] is the prototypical mechanism for α-deoxygenation of a ketosugar substrate (Scheme 1).[6] Hence, deoxygenation
Scheme 1. A prototypical mechanism for α-deoxygenation of a ketosugar substrate. E_1 and E_3 are iron- and sulfur-containing enzymes. PMP = pyridoxamine 5′-phosphate; NAD(H) = (reduced) nicotinamide adenine dinucleotide.

at C4 in the biosynthesis of D-desosamine could follow the α-deoxygenation path similar to that catalyzed by E_1 and E_3 starting from 3-keto-6-deoxyhexose (**3**) to give 3-keto-4,6-dideoxyhexose (**4**, Scheme 2, path A). This possibility is supported by the fact that the translated sequences of two genes, *desI* and *desII*, which are assigned to encode proteins involved in the C4 deoxygenation in the desosamine biosynthetic gene cluster,[7] are highly similar to B_6-dependent enzymes and those containing an iron–sulfur center, respectively.

However, recent characterization of the purified DesI protein showed that it catalyzes the C4 transamination of **2** to generate TDP-4-amino-4,6-dideoxy-D-glucose (**5**; TDP = thymidine diphosphate) in the presence of pyridoxal 5′-phosphate (PLP) and L-glutamate.[8] Further sequence analysis revealed that DesII, which contains a [4Fe-4S] consensus motif (**CXXXCXXC**), belongs to the recently identified *S*-adenosylmethionine (SAM) superfamily of radical enzymes.[9] These two observations prompted a revision of the proposed biosynthetic pathway for TDP-D-desosamine. As depicted in Scheme 2 (path B), the DesI/DesII reaction may be initiated by the incorporation of a nitrogen-containing functional group from PMP at C4 (such as **6**), followed by a radical-induced 1,2-nitrogen shift (**6**→**7**→**8**→**9**) to yield an aminol intermediate (such as **10**). Subsequent elimination of an ammonium ion would afford the predicted product **4**. The regeneration of PMP may be facilitated by the transamination activity of DesI in the presence of L-glutamate.

The key mechanistic components of this reaction are reminiscent of those used in the reaction catalyzed by lysine 2,3-aminomutase (LAM), which is a [4Fe-4S]-containing enzyme that requires PLP and SAM for activity.[10] Catalysis by LAM is triggered by the abstraction of a hydrogen atom from the lysine–PLP adduct by the 5′-deoxyadenosyl radical (**11**; AdoCH₂·), which is formed by the reductive cleavage of SAM through involvement of the reduced [4Fe-4S] center.[11] A similar abstraction of a hydrogen atom, induced by the 5′-deoxyadenosyl radical, from **6** at C3 to give **7** may also be the key event of the C4 deoxygenation reaction. To test this hypothesis, we purified and studied the catalytic properties of DesII. Herein, we report the biochemical characterization of DesII and the mechanistic implications for the overall C4 deoxygenation reaction.

The *desII* gene was amplified from the genomic DNA of *S. venezuelae*[7b] by the polymerase chain reaction and cloned into the pET24b(+) vector at the *Nde*I and *Xho*I restriction sites.[12] The DesII protein with a His₆ tag at the C terminus was purified to near-homogeneity by using a Ni-NTA column followed by elution from a MonoQ column attached to an FPLC system.[13] A molecular mass of 48.4 kDa for DesII as estimated by gel filtration chromatography suggests that DesII, which has a calculated molecular mass of 54.265 kDa (including the His₆ tag), is a monomer in solution. Although purified DesII exhibits a broad absorption band between 400 and 500 nm ($\varepsilon_{420} = 4000\,\mathrm{M^{-1}\,cm^{-1}}$), which is indicative of an iron–sulfur center,[14] titration showed the presence of only
Scheme 2. a) Organization of the D-desosamine biosynthetic gene cluster. Scale indicates the length of DNA (kb). b) Possible mechanisms of deoxygenation at the C4 position in the biosynthesis of D-desosamine. TDP = thymidine diphosphate; L-Glu = L-glutamate; NAD(P)H = reduced nicotinamide adenine dinucleotide (phosphate).

0.6 equivalents of iron[15] and 0.5 equivalents of sulfur[16] per DesII monomer. Hence, most of the iron–sulfur cluster was depleted and/or decomposed during purification under aerobic conditions. Anaerobic reconstitution, carried out in the presence of a sixfold molar excess of Na$_2$S and Fe(NH$_4$)$_2$-(SO$_4$)$_2$ in 100 mM Tris-HCl buffer, at pH 8 containing 5 mM dithiothreitol (DTT) at 18°C,[17] led to holo-DesII, which contains nearly 4 equivalents of iron and 3.9 equivalents of sulfur atoms per subunit, with a broad absorption band at

420 nm ($\varepsilon_{420} = 9200 \, \text{M}^{-1} \text{cm}^{-1}$). Both features are characteristic of a [4Fe-4S]$^{2+}$ cluster.[14]

To test the proposed mechanism of C4 deoxygenation, the purified and reconstituted DesII was treated with sodium dithionite anaerobically to reduce the [4Fe-4S]$^{2+}$ cluster to the [4Fe-4S]$^+$ state.[18] The reduced DesII was then incubated with DesI and 2[8] in the presence of SAM, PMP (or PLP), and L-glutamate under anaerobic conditions.[19] HPLC analysis of the reaction mixture using a Dionex anion-exchange column

$(4 \times 250 \text{ mm})$[20] revealed a new product with a retention time of 28.2 minutes which was not detected when dithionite or SAM was omitted from the incubation mixture. This new product was identified as **4** on the basis of its retention time, which was identical to that of a standard,[21] as well as high-resolution FAB-MS data (calcd for $[M-\text{H}]^-$: 529.0625, found: 529.0621). These results clearly demonstrate that SAM and the reduced $[4\text{Fe-4S}]^+$ cluster are required for DesII activity and they establish, for the first time, an essential role for DesII in the C4 deoxygenation reaction. The fact that the addition of DesV (in the presence of PLP and L-glutamate) to the above incubation mixture[22] led to the isolation of **12** as the final product[23] provided further evidence for the formation of **4** as a result of reaction with DesI/DesII.

To our surprise, when the reduced DesII was incubated by itself under anaerobic conditions with SAM and **5**, which was generated separately using DesI and **2** in the presence of PLP and L-glutamate,[8] compound **4** was again detected as the sole TDP–sugar product.[24] This finding, obtained in the absence of DesI, strongly suggests that the actual substrate of DesII is **5** and that the conversion of **2** into **4**

Scheme 3. Possible mechanisms of deoxygenation at C4 in the biosynthesis of D-desosamine. Generation of 5'-deoxyadenosyl radical (**11**) is expected to be the first part of the reaction. Met = methionine.

proceeds in two steps, in which DesI catalyzes the C4 transamination of **2** to **5** and DesII carries out the C4 deamination of **5** to give **4**. The failure to establish the formation of a DesI–DesII complex in vivo by the yeast two-hybrid assay[25] is consistent with the observation that DesI and DesII function independently. Taken together, these results clearly demonstrate that DesII is a SAM-dependent deaminase, not a deoxygenase as previously surmised.

To account for these results, two possible mechanisms for the DesII-catalyzed reaction can be envisioned. As depicted in Scheme 3, generation of the 5'-deoxyadenosyl radical (**11**) is expected to be the first part of the reaction facilitated by the reduced $[4\text{Fe-4S}]^+$ center as found in other SAM–radical-dependent enzymes.[26] The actual chemical conversion may be triggered by abstraction of a hydrogen atom at C3 of **5** by **11** to give **13**. The mechanism for the subsequent transformation is less obvious, but may parallel the reaction catalyzed by the coenzyme B_{12} dependent ethanolamine ammonia lyase, which converts ethanolamine into ammonia and acetaldehyde.[27] As shown in Scheme 3 (path A), the key step may be a radical-induced deamination followed by the readdition of ammonia to the resulting cation radical intermediate (**14/15**), which is effectively a 1,2-amino shift (**13**→**14/15**→**16**→**10**), to form an aminol radical **16**.[28] Reclaiming a hydrogen atom from 5'-deoxyadenosine results

in the formation of **10** and the regeneration of **11**, or more likely the reduced $[4\text{Fe-4S}]^+$–SAM complex.[29] Elimination of an ammonium ion from **10** would afford the desired product **4**. The reaction may also involve deprotonation of the 3-hydroxy group of **13** to yield a ketyl radical anion **17**,[30] whose resonance form **18** facilitates the β-elimination of the 4-amino group (Scheme 3, path B). The reaction catalyzed by (R)-2-hydroxyacyl-CoA dehydratase[31] in the fermentation of α-amino acids by anaerobic bacteria provides a precedent. The key step of the latter reaction involves ketyl radical anion induced C_β–O cleavage to expel a hydroxy group. Experiments to distinguish these mechanistic proposals are in progress.

In summary, the data reported herein show that DesII is a SAM-dependent [4Fe-4S]-containing enzyme and is directly responsible for the production of a key intermediate **4** in the biosynthesis of desosamine. In contrast to our previous proposal that DesI/DesII function as a pair to catalyze the α-deoxygenation of a 3-ketosugar substrate **3**, the C4 deoxygenation step is now established to proceed in two stages via an amino sugar intermediate **5**. These results are significant for two reasons: DesII has been identified as a unique deaminase, and the entire desosamine pathway has now been characterized (**2**→**5**→**4**→**12**→**1**). Although the mechanism of DesII catalysis remains elusive, utilization of 5'-

deoxyadenosyl radical (**11**) derived from SAM to abstract a hydrogen atom from **5** is believed to be an integral part of the reaction of DesII. Evidently, the mode of C4 deoxygenation by DesI/DesII is distinctly different from that of the E_1/E_3 paradigm. Currently, only a handful of SAM–radical enzymes have been characterized and all are involved in unusual biotransformations.[32] The fact that DesII is responsible for a radical-induced deamination further illustrates the catalytic versatility of this class of enzymes. Its participation with a transaminase (DesI) in an overall deoxygenation reaction underscores Nature's ingenuity in devising strategies for C–O bond scission.

[12] Two primers were designed to amplify the *desII* gene by the polymerase chain reaction (PCR). The start primer, 5′-CGCG-**CATATG**ACCGCCCCGCCCTTTCC-3′, contained an *Nde*I restriction site (in bold), and the stop primer, 5′-GCGC**CTCGAG**GCGCAGGAAGCC-3′, contained an *Xho*I restriction site (in bold). Amplification was carried out by using an initial incubation step at 95 °C for 3 min, followed by 30 cycles comprising incubation at 95 °C for 30 s, 60 °C for 30 s, and 72 °C for 90 s. The PCR product was purified and ligated into the *Nde*I/*Xho*I sites of the vector pET24b(+). The resulting plasmid was used to transform *E. coli* BL21(DE3).

[13] The elution profile began with a linear gradient of 0 to 50% of buffer B (buffer A with 0.5 M NaCl) in buffer A (20 mM Tris-HCl, pH 7.5) for 25 min, followed by a gradient of 50–70% of buffer B in buffer A for 2 min. The flow rate was 3 mL min^{-1} and the detector was set at 280 nm. The DesII protein eluted at 55% buffer B.

[17] Protein-bound iron was removed by incubating the as-isolated DesII in 100 mM Tris-HCl buffer (pH 8), containing 100 mM EDTA and 2 mM sodium dithionite, for 1 h at 25 °C. The apo-protein was loaded and eluted through a Sephadex G-25 column with the above Tris-HCl buffer and concentrated to 10 mg mL^{-1} by an Amicon concentrator with a YM10 membrane. This apo-DesII was incubated with a sixfold molar excess of Na$_2$S and Fe(NH$_4$)$_2$(SO$_4$)$_2$ in 1 mL of 100 mM Tris-HCl buffer (pH 8) containing 5 mM DTT for 3 h at 18 °C. A deaerated solution of EDTA (2 mM) was then added, and the incubation was continued for another 30 min. The reconstituted DesII was eluted through a Sephadex G-25 column as described above, and the green-gray protein fractions were pooled and concentrated to approximately 10 mg mL^{-1} by an Amicon concentrator with a YM10 membrane. All of the above operations were performed in an anaerobic chamber.

[18] Reduction of the [4Fe-4S] center of reconstituted DesII (0.19 mM) was achieved by using sodium dithionite (sixfold molar excess) prepared in 100 mM Tris-HCl buffer (pH 8) over 40 min. Reduction was conducted in an anaerobic chamber and monitored by the decrease of the absorbance at 420 nm.

[19] The activity assay was carried out anaerobically by mixing **2** (0.6 mM), L-glutamate (0.5 mM), pyridoxal 5′-phosphate (PLP; 0.14 mM), DesI (0.026 mM), reduced DesII (0.1 mM), and SAM (0.1 mM) in 100 mM Tris-HCl buffer (pH 8) in the presence of DTT (2 mM). The final volume was 1 mL. The reaction mixture was incubated at 25 °C for 3 h, and the reaction was quenched by filtering through an Amicon ultrafiltration cell equipped with a YM10 membrane to remove the enzymes. The reaction progress was monitored by HPLC.

[20] A linear gradient from 20 to 35% of eluent B (1 M ammonium acetate, pH 7.0) in eluent A (H$_2$O) over 30 min gave a satisfactory separation. The flow rate was 0.6 mL min^{-1} and the detector was set at $\lambda = 267$ nm. The retention time for the substrate **2** is 13.8 min and that for DesII product **4** is 28.2 min, which is identical to that of the synthesized standard.[21]

[21] Compound **4** was prepared by incubating synthetic **12**[23] with purified DesV in the presence of PLP and α-ketoglutarate.

[22] To the reaction mixture prepared under conditions described in reference [19] (after 3 h incubation) were added L-glutamate (10 mM), PLP (0.8 mM), and DesV enzyme (0.1 mM). The resulting mixture was incubated at 25 °C for 30 min, and then passed through an Amicon ultrafiltration cell equipped with a YM10 membrane to remove the enzymes. The formation of the DesV product **12** was detected by HPLC;[20] the retention time of 3.7 min is identical to that of the synthesized standard.[23]

Experimental Evidence for a Jahn–Teller Distortion in AuCl₃**

*Ian J. Blackmore, Adam J. Bridgeman, Neil Harris, Mark A. Holdaway, John F. Rooms, Emma L. Thompson, and Nigel A. Young**

Gold halides have generated considerable interest amongst both computational and experimental chemists because of their intriguing bonding and structures.[1–4] Advances in gas-phase (mass-spectrometry) experiments[5] and the theoretical importance of relativistic effects in gold chemistry[6] have recently been reviewed. The common oxidation states for gold are Au^{III} and Au^{I}, with Au^{II} being comparatively rare. The Au^{I} monohalides display large structural relativistic effects, and the very short Au···Au distances in their dimers (caused by the so-called "aurophilic attraction") are regarded as classic examples of metallophilic interactions.[6] All of the monohalides have been characterized experimentally.[1,5,7] Monomeric Au^{II} is a rare oxidation state, although multi-nuclear complexes are more common,[8] and some examples such as solid-state $AuCl_2$ are mixed valent.[9] Perhaps the most significant Au^{II} complexes are those containing Au–Xe bonds, such as $[AuXe_4][Sb_2F_{11}]_2$.[10] Schröder et al. have recently identified $AuCl_2$ (as neutral, anionic, and cationic species) in sophisticated mass-spectrometric experiments.[11] The D_{3h} trigonal-planar structure of the d^8 Au^{III} halides are Jahn–Teller distorted to T-, Y-, and L-shaped geometries. This distortion was highlighted computationally by Schwerdtfeger et al. in 1992,[12] and recently elaborated by Hargittai and co-workers[1–3] as well as by Schwerdtfeger and co-workers.[4] Both the stability of the gold trihalides and the Jahn–Teller stabilization energy decrease from the fluoride through to the iodide. The T-shaped structure is the minimum of the Jahn–Teller surface for AuF_3, $AuCl_3$, and $AuBr_3$, and is the global minimum of the ground state for the first two. The Y-shaped geometry is a transition state between the T-shaped geometries. For AuI_3, the Y-shaped structure lies at lower energy than the T-shaped structure, but for both $AuBr_3$ and AuI_3 the potential-energy surface is very flat, and the energy gain arising from a Jahn–Teller distortion is small. Schulz and Hargittai[1] suggest that AuF_3 and $AuCl_3$ are static Jahn–Teller

systems, whereas $AuBr_3$ and AuI_3 are dynamic Jahn–Teller systems. Of the monomeric Au^{III} halides, experimental data is only available for AuF_3, with the T-shaped structure being confirmed by electron diffraction studies.[13] AuI_3 has been reported to be stabilized in a cuprate lattice,[14] but more recent calculations[15] and experiments[16] suggest that the gold is present as Au^I and not Au^{III}, therefore the D_{3h} structure is unsurprising. The solid-state structures of both Au_2Cl_6 and Au_2Br_6 consist of discrete D_{2h}-symmetric halogen-bridged dimers[12] which become the principal gold-containing vapor species. Vaporization is accompanied by extensive decomposition, and in the recent electron-diffraction study, only approximately 6% of the vapor was Au_2Cl_6 (the remainder being Cl_2), and it was noted that it was not possible to obtain any data for monomeric $AuCl_3$.[2] Therefore, the authors proposed that the only way forward was to use detailed computational methods.

We have previously used matrix isolation in combination with IR, UV/Vis and extended X-ray absorption fine structure (EXAFS) spectroscopy to synthesize and characterize monomeric noble-metal chlorides such as PtCl and $PtCl_2$.[17] For the platinum chlorides, hollow-cathode sputtering with chlorine-doped argon was used to generate the atomic Pt, and although this approach was used for $AuCl_3$, thermal evaporation and laser ablation were also employed.

Figure 1a shows the electronic absorption spectrum of Au_2Cl_6 in an argon matrix, and is in good agreement with the vapor-phase spectrum.[18] The intense bands at 40590 and 46060 cm^{-1} were assigned to bridging- and terminal-ligand-to-metal charge-transfer transitions, respectively.[18] The weaker features at 22300 and 32890 cm^{-1} were assigned to d-d transitions.[18] Figure 1b shows the spectrum obtained when thermally evaporated gold atoms were matrix isolated in 1% Cl_2/Ar. The sharp peaks at 39050, 43670, and 44085 cm^{-1} are due to atomic gold.[19] The broad feature at approximately 30500 cm^{-1} and the tail into the UV region are both due to Cl_2. In addition to these, a weaker band at about 16000 cm^{-1} with vibrational fine structure was observed. The spectra obtained when thermally evaporated gold atoms were trapped in a 5% Cl_2/Ar matrix were very similar, except that there was less unreacted gold, and the fine structure on the band at 16000 cm^{-1} was less well resolved. A similar spectrum was obtained when gold was sputtered with Cl_2/Ar mixtures, and the band at 16000 cm^{-1} was also present when HCl was used as the chlorine source in the sputtering experiments. Figure 1c shows the spectrum obtained when thermally evaporated gold atoms were condensed in a 1% Cl_2/Ar mixture that had passed through a microwave discharge just prior to deposition. This process had the effect of increasing the yield of the feature at 16000 cm^{-1} relative to similar experiments with no discharge, as well as reducing the amount of residual Cl_2 present, although there is a substantial amount of unreacted gold. These observations indicate that the band at 16000 cm^{-1} only appears when chlorine atoms or molecules are present, and that there are no high energy features associated with the band at 16000 cm^{-1} that are obscured by the UV tail arising from the presence of Cl_2 (Figure 1b). As the feature at 16000 cm^{-1} was only present in spectra which contained both gold and chlorine and is independent of the source of both gold atoms and chlorine, it can readily be assigned to an $AuCl_x$ species. An expansion of the vibrational fine structure on this band is shown in Figure 1d, and the separation of about 310 cm^{-1} between the sharpest peaks on the low energy side is consistent with a symmetric Au–Cl stretching mode in an excited state. The observation of only one band implies the presence of one $AuCl_x$ species. As this band is much lower in energy than both the charge-transfer and d-d bands in Au_2Cl_6, it is most likely to be a d-d transition, with any charge-transfer bands beyond the effective upper spectral limit of about 50000 cm^{-1}.

IR spectroscopy of the Au–Cl stretching modes (ν_{Au-Cl}) in combination with the natural isotopic abundances of Cl (^{35}Cl, 75.5%; ^{37}Cl, 24.5%) is a very powerful method of identifying molecular shape. For AuCl, a simple 3:1 isotope pattern is expected. For $AuCl_2$, a 9:6:1 pattern would be observed, and if the separation of the outermost components could be identified accurately, the bond angle could be determined. The presence of threefold rotation axes in both D_{3h}- and C_{3v}-symmetric $AuCl_3$ would result in nonbinomial isotope patterns for the degenerate modes. One IR-active E′ ν_{Au-Cl} band with a 81:9:27:11 pattern is expected for D_{3h}-symmetric $AuCl_3$, whereas C_{3v}-symmetric $AuCl_3$ would have two IR-active ν_{Au-Cl} bands, an E mode with a 81:9:27:11 isotope pattern, and an A_1 mode with a 27:27:9:1 pattern. Calculations[1,2] for T-shaped $AuCl_3$ predict three IR-active ν_{Au-Cl} modes ($2A_1 + B_2$), but the two A_1 modes have very low intensity so that only the B_2 mode is expected to be observed.
Figure 1. Matrix-isolation electronic absorption spectra of a) Au_2Cl_6 in Ar, b) thermally evaporated gold atoms in 1% Cl_2/Ar, c) thermally evaporated gold atoms mixed with 1% Cl_2/Ar passed through microwave discharge, d) expansion of (c).

Our calculations indicate that the B_2 mode will display a 9:6:1 chlorine isotope pattern, and the two very low intensity A_1 modes will yield a complex isotope pattern derived from 9:6:1 and 3:1 isotope patterns, but which is dependent on their separation. The Y-shaped transition state is also calculated[1,2] to have three IR-active ν_{Au-Cl} modes ($2A_1 + B_2$) with similar frequency, intensity (intense A_1, very weak $A_1 + B_2$), and isotope patterns to the T-shaped geometry.

The argon-matrix IR spectrum of Au_2Cl_6 is shown in Figure 2a. This spectrum is in very good agreement with the
Figure 2. Matrix-isolation IR spectra of a) Au_2Cl_6 in Ar, b) gold atoms sputtered with 5% Cl_2/Ar, c) thermally evaporated gold atoms in 100% Cl_2.

previous data from both the solid state and the gas phase,[20] and complex chlorine isotopic structure is observed in both bands. The feature at approximately $386\ cm^{-1}$ arises from terminal ν_{Au-Cl} asymmetric stretching modes ($\nu_{12}(B_{2u})$ and $\nu_{16}(B_{3u})$), and the bridging ν_{Au-Cl} asymmetric stretching modes are at about $312\ cm^{-1}$ ($\nu_{13}(B_{2u})$ and $\nu_{17}(B_{3u})$). Figure 2b displays the spectrum of the matrix-isolated products from a gold foil sputtered with 5% Cl_2/Ar. The only significant ν_{Au-Cl} band is at approximately $420\ cm^{-1}$, and it is clear that there is no evidence for the formation of Au_2Cl_6 under these conditions. Although this band shows signs of asymmetry, it did not display isotopic chlorine features at higher spectral resolution, probably because of the considerable Cl_2 concentration in the matrix. Although sputtering, thermal evaporation, and laser ablation were all used with lower Cl_2/Ar concentrations, the spectral quality was not sufficient to provide convincing evidence of the geometry of the gold-containing species. Pure Cl_2 matrices were then used, and thermally evaporated gold atoms were condensed at 50 K and then cooled to about 12 K. The resulting spectrum is shown in Figure 2c. The most intense band at approximately $410\ cm^{-1}$ clearly displays a 9:6:1 isotopic pattern with a splitting that is consistent with a vibrational mode involving two chlorine atoms attached to a heavy element. There is also evidence for a second 9:6:1 pattern with a similar peak separation a few wavenumbers higher. The most reasonable interpretation of this is that there are two 9:6:1 patterns in close proximity that are derived from the same vibrational mode, which is subject to matrix-site effects in the pure Cl_2 matrix. This band is in a very similar position to that obtained for argon matrices with sputtering, laser ablation, and thermal evaporation, thus indicating that it arises from the same species in all cases, which also gives rise to the band at $16000\ cm^{-1}$ in the electronic absorption spectra. In addition to the relatively intense bands around $410\ cm^{-1}$, there is a complex multiplet at $375–350\ cm^{-1}$. Although $TaCl_5$ is known to have spectral features in this region,[21] no such bands were observed when a bare tantalum filament was heated during the deposition of a pure Cl_2 matrix. Therefore, this multiplet is also assigned to an $AuCl_x$ species.

The presence of 9:6:1 isotope patterns in the bands at $410\ cm^{-1}$ rules out AuCl, but they could be assigned to either $AuCl_2$ or $AuCl_3$. Au^{II} is commonly considered to be a rare oxidation state, especially for monomeric compounds.[8] Solid-state $AuCl_2$ is known to be mixed valent[9] and $AuCl_2$ has only been detected in the vapor phase by using sophisticated mass spectrometric experiments starting with mass-selected $AuCl_2^-$.[11] Stace and co-workers have reported that Au^{II} can be stabilized in the gas phase by σ-donor, π-acceptor ligands, especially if the ligands have a large dipole moment and high ionization energy,[22] but this is not the case for chloride. It would be expected that pure Cl_2 matrices would yield stable gold chloride with the highest oxidation state. From all of the various experimental conditions used for the electronic absorption spectra, only one band at $16000\ cm^{-1}$ was associated with both gold and chlorine, and whereas the presence of Cl atoms increased its intensity, no other bands were observed. The presence of weak features in the region between 375 and $350\ cm^{-1}$ is compatible with $AuCl_3$, but not with $AuCl_2$. Despite reporting an extensive set of calculations on monomeric, dimeric, and anionic gold halides, Hargittai and co-workers[1,2] did not appear to consider $AuCl_2$. Schröder et al. have carried out some DFT calculations that indicate that $AuCl_2$ would be stable to disproportionation in the idealized gas phase, but not in the solid state.[11] Our DFT calculations[23] indicate that although the $\Delta_f H$ values for $AuCl_{2(g)}$ and $AuCl_{3(g)}$ from gold atoms and Cl_2 are very similar (-271 and $-273\ kJ\,mol^{-1}$, respectively), the enthalpy of atomization to gold and chlorine atoms is much larger for $AuCl_3$ than for $AuCl_2$ (672 and $537\ kJ\,mol^{-1}$, respectively). The previous MP2 and B3LYP calculations[2] indicate that the IR-active ν_{Au-Cl} mode of "T-shaped" $AuCl_3$ should be about $20\ cm^{-1}$ higher than the terminal ν_{Au-Cl} modes in Au_2Cl_6, with the most intense ν_{Au-Cl} mode of the Y-shaped transition state being a few wavenumbers less than that of the T-shaped ν_{Au-Cl}

mode. The ν_{Au-Cl} mode of AuCl is calculated[2] to be just above midway in terms of energy between the terminal and bridging ν_{Au-Cl} modes in Au_2Cl_6, although our DFT calculations incorporating the high-level relativistic effects within ADF (Amsterdam Density Functional package) indicate that the value should be closer to that of the terminal ν_{Au-Cl} mode in Au_2Cl_6. Our calculations on $AuCl_2$ indicate that its IR-active ν_{Au-Cl} mode should be higher than that of $AuCl_3$ by about $17\ cm^{-1}$.

Therefore, on the basis of both experimental and computational considerations, the most reasonable assignment of the bands at about $420\ cm^{-1}$ in the IR spectrum is to $AuCl_3$. The 9:6:1 chlorine isotope pattern demonstrates that it does not have D_{3h} (or C_{3v}) symmetry but adopts a Jahn–Teller-distorted geometry, which on the basis of the calculations[2] is most likely to be T shaped. These calculations also indicate that the two A_1 modes in the T-shaped $AuCl_3$ species will be separated by about $10\ cm^{-1}$ and be about $30\ cm^{-1}$ lower than the B_2 mode, but will have very low (effectively zero) intensity. The two low-intensity A_1 and B_2 modes in the Y-shaped geometry are also calculated to be separated by $10\ cm^{-1}$, and about 30–$40\ cm^{-1}$ lower than the intense A_1 mode. The complex multiplet at 375–$350\ cm^{-1}$ clearly falls into this region, but the intensity is incompatible with the calculations.[2] It is possible that the Cl_2 matrix exerts sufficient perturbation so that these modes gain some intensity. The isotope pattern is very sensitive to the separation of the two modes, and as a site effect was observed on the intense ν_{Au-Cl} mode, it is likely that this multiplet is also subject to site effects.

The Au L_3-edge EXAFS and FT for the matrix products of gold sputtered with 5% Cl_2/Ar are shown in Figure 3. Sputtering was chosen as it gives the best dilution of metal atoms in the matrix, thus avoiding the problems of aggregation.[17] The FT contains one peak that fits[24] to a single Au–Cl bond length with no evidence for two different bond lengths, thus ruling out the presence of Au_2Cl_6. The Au–Cl bond length of $2.22(2)$ Å is 0.06 Å shorter than that observed for $[AuCl_4]^-$ with the same analysis protocols. Previous B3LYP and MP2 calculations[2] indicate that the T-shaped ground state of $AuCl_3$ will have Au–Cl bond lengths shorter by about 0.07 Å than $[AuCl_4]^-$, and our ADF calculations indicate that the Au–Cl bond length in $AuCl_2$ will be approximately 0.04 Å shorter than that of $AuCl_3$. The chlorine occupation number refined to a value of about 1.7, or an $AuCl_3$ fraction of about 57%. Whereas this could indicate a lower-coordination species, the presence of bands corresponding to unreacted gold in all of the electronic absorption spectra, the IR evidence for $AuCl_3$, as well as the Au–Cl bond lengths, indicate it is much more likely to be caused by the presence of both $AuCl_3$ and Au in the matrix. Although the small peak at around 4.4 Å in the FT might be due to multiple scattering pathways through the central Au atom, indicative of a linear or very near linear ($> 160°$) $AuCl_2$ unit,[25] its intensity is too low to make any firm conclusions, and this is also where Au⋯Ar interactions would be expected.

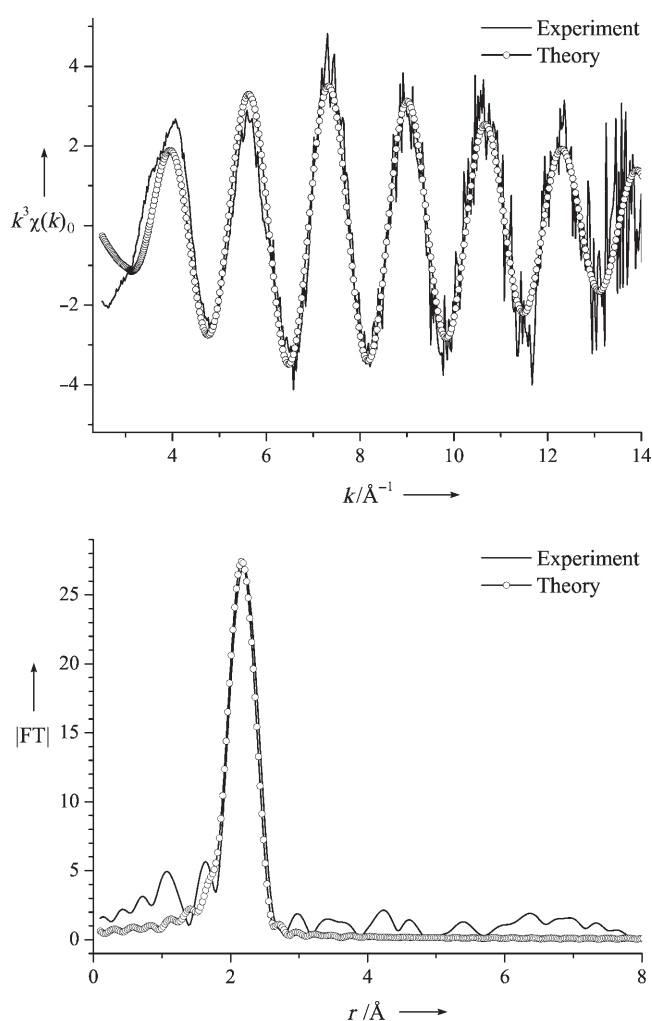
In conclusion a combination of matrix-isolation electronic absorption, IR, and Au L_3-edge EXAFS has provided the first experimental data for $AuCl_3$ and shown conclusively that it


Figure 3. Au L_3-edge EXAFS (top) and FT (bottom) of the matrix-isolated products of gold atoms sputtered with 5% Cl_2/Ar.

does not have D_{3h} symmetry in the matrix, but rather a Jahn–Teller-distorted geometry. The experimental data is consistent with a calculated ground state having a T-shaped geometry.

Systems Chemistry: Kinetic and Computational Analysis of a Nearly Exponential Organic Replicator**

Maik Kindermann, Insa Stahl, Malte Reimold, Wolf Matthias Pankau, and Günter von Kiedrowski*

In 1997, Wang and Sutherland reported a case of self-replication in a Diels–Alder reaction.[1] This system is remarkable for at least two reasons: it constituted the first example of nearly exponential growth and it had the potential to exhibit two kinds of self-replication, homochiral autocatalysis and heterochiral cross-catalysis, because a chiral diene was employed. Unfortunately, the authors could not complete a stereochemical analysis of their system. We report herein mechanistic and stereochemical studies of variants of the Wang–Sutherland replicator. We show that only one of four potential diastereomers is formed within our detection limits and that this diastereomer is involved in both autocatalytic and cross-catalytic channels. A computational study suggests that the system can be classified as an example of a nearby

strong-exponential replicator according to our minimal replicator theory.[2]

Self-replication of chiral information has recently received considerable interest from its relevance to the question of the breaking of chiral symmetry on the early earth[3]. An impressive implementation of Frank's model[4] now exists in the reaction of Soai et al., whose kinetic analysis has recently revealed important insight.[5] Further examples of self-replication with prochiral precursors were successfully designed for cycloaddition reactions.[6] Self-replication experiments with peptides as chiral building blocks constituted the first example of homochiral autocatalysis in the sense that templating requires the same helicity, as in the case of template precursors.[7] The general predictability of homochiral autocatalysis versus heterochiral cross-catalysis is, however, far less pronounced for molecules without a predefined secondary structure (Figure 1).

We therefore became interested in the re-evaluation of the Wang–Sutherland system with respect to its stereochemical features.[1] Our approach is guided by our curiosity as to whether a combination of kinetic, computational, and theoretical methods could lead to a better understanding of structurally simple but dynamically complex systems. The
Figure 1. Principle of a) heterochiral cross-catalysis and b) homochiral autocatalysis.

components and principle reactions of the Wang–Sutherland system are shown in Figure 2a.

We thought that the replacement of the heterocyclic recognition units by amidopyridines and carboxylic acids, independently used by the research groups of Hamilton[8] and Philp,[6] could also expand the solubility range in the Wang–Sutherland system. Our components and reaction products as
Figure 2. Reaction schemes; each arrow indicates a distinguishable reaction channel. a) Self-replicating Diels–Alder reaction as described by Wang and Sutherland.[1] b) Our self-replicating system taking into account both enantiomeric forms. c),d) Control reactions with compounds without recognition properties.

well as model components without recognition properties are depicted in Figure 2b–d.

We synthesized diene **4** in racemic form and as separate enantiomers from the corresponding 2,4-cyclohexadienylacetic acids[9] (Supporting Information). The reactions were monitored by ¹H NMR spectroscopy and evaluated by using our SimFit program.[10] A stack plot of the ¹H NMR spectrum of the reaction of *rac*-**4** with **5a** to give *rac*-**6a** is depicted in Figure 3, which shows the olefinic protons of *rac*-**6a**.

Figure 3. Stack plot of ¹H NMR spectra of the reaction of *rac*-**4** with **5a** to give *rac*-**6a** (CDCl₃, 600 MHz, 293 K).
Figure 5. X-ray crystallographic structure of *rac*-**6b**.

Three phenomena are directly observable: an induction period, an autocatalytic increase of integrals, and a concomitant change of chemical shifts for the development of the product signal. The latter caused by the transition of free templates at low concentrations to template complexes and duplexes at higher product concentrations. Minimal modeling according to A + B + *p*C→(1 + *p*)C for the autocatalytic channel and A + B→C for the non-autocatalytic channel, both for the building blocks **5a** and **5b** as B, leads to the profiles of theoretical concentration over time shown in Figure 4 and yields the kinetic parameters given in Table 1. From this data it is evident that our variants are reasonable approximations of the Wang–Sutherland system, of which the autocatalytic reaction order *p* over similar conversion was 0.8.[1]

Wang and Sutherland assumed an *endo* product but were not sure whether one or two diastereomers that differ in the configuration of the stereocenter carrying the recognition site at the [2.2.2]bicyclo-octene scaffold are formed. We were able to crystallize a single racemic diastereomer of the reaction product, *rac*-**6b**, the X-ray crystallographic structure is shown in Figure 5.[11]

There is no indication for another diastereomer above the detection limits of NMR spectroscopy. Transition-state modeling of simplified model reactions at the B3LYP/6-31G* level of calculation confirmed that the diastereomer with NN orientation is expected (Supporting Information).[12] An interesting detail from these studies is the presence of weak bifurcating hydrogen bonds, which stabilize the transition state of the model reaction between 5′-methyl-1,3-cyclohexadiene and *N*-carboxymethylmaleimide, but these are absent in the product. Weak bifurcating hydrogen bonds were also found to stabilize the transition state of the noncatalyzed template-formation reaction in the NNN conformation.[12] As expected, model reactions with the building blocks **7a** and **9** that are without recognition properties revealed no autocatalysis, but allowed us to determine the second-order rate constants: (*rac*-**4**+**7a**→*rac*-**8a**, *T* = 293 K, *k* = 4.49 × 10⁻⁵ M⁻¹ s⁻¹; **9** + **5a**→**10**, *T* = 293 K, *k* = 5.83 × 10⁻⁵ M⁻¹ s⁻¹).

We studied the individual reactions involving diene (*R*)-**4** and (*S*)-**4** in the presence of the template (*R*)-**6a** at 10%.

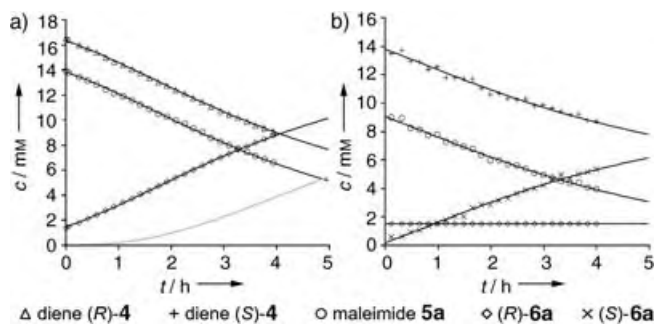
From Figure 6 it is clear that the effect of the template is similar in both cases, which indicates the presence of autocatalytic and cross-catalytic reaction channels. This finding could be confirmed by kinetic modeling and fitting both


Figure 6. Profiles of concentration over time for the reaction of maleimide **5a** with: a) diene (*R*)-**4** to give (*R*)-**6a** (the gray line demonstrates product formation without any template added initially); b) diene (*S*)-**4** to give (*S*)-**6a**, both with 10% of template (*R*)-**6a** added initially (CDCl$_3$, 293 K, 15 mM). The first four hours of the reaction time were analyzed.

data sets simultaneously to the model shown in Figure 7. The ratio of the association constants of the template duplexes ($K_{2\,hetero}/K_{2\,homo} \approx 2$) suggests that homochiral and heterochiral duplexes are nearly equally populated.

The limited structural and dynamic complexity of our replication system led us to the question of whether computational chemistry could help to explain the kinetic data on the base of an energy profile. We took the following approach: a conformational search of the noncomplexed template at the MMFF94 level followed by further refinement at the B3LYP/6-31G* level led to two conformational families, NNN and NNX,[12] which differed in the orientation of the carboxy group relative to the C—C double bond.

Formation of template duplexes requires the units of recognition to be in a specific orientation, coaligned in the same direction. Considering that each of these template conformations can exist in both enantiomeric forms, we systematically constructed the six possible duplexes by manual docking and energy refinement at MMFF94, PM3, and B3LYP/6-31G* levels, successively. As expected, duplexes arising from inner-family combinations were found to be centrosymmetric in the heterochiral case and to have rotational symmetry in the homochiral case. The lowest-energy duplex has the conformation that was found in the crystal structure of **6b**. Transition states were derived from a transition-state search of the model reaction between *N*-methylmaleimide and 5-methyl-1,3-cyclohexadiene; all atoms, except those of the methyl groups, were frozen and the skeleton of frozen atoms were inserted into the respective position of the corresponding duplex. Geometry optimization of the nonfrozen atoms was carried out at the B3LYP/6-61G* level. The termolecular complexes were derived from the transition states by relaxation after unfreezing. Figure 8 shows the result of our computational study. For the case of the nontemplated reactions, we were able to find the true transition states. These are greater than 6 kcal mol^{-1} below

the approximated counterparts in Figure 8. We observed that the energy difference between the respective conformations is similar to their counterparts in the approximated transition states with frozen atoms. Therefore, we trust the approximated transition states.

The largest energy differences between autocatalytic and cross-catalytic pathways were found at the level of transition states and template duplexes. Interestingly, transition-state stabilization by weak bifurcating hydrogen bonds (approximately −1.5 kcal mol^{-1}) leads to the lowest-energy conformations only in the autocatalytic cases. For the cross-catalytic cases the effect is counterbalanced by repulsive and/or dihedral distortion, which leads to a less optimal geometry at the recognition sites. The cross-catalytic pathway shows the lowest enthalpy of activation. There is always a clear enthalpic preference of termolecular complexes over the respective template duplexes. Further work on the temper-

ature dependence of rates and equilibria in a slightly modified self-replicating system has revealed evidence that the above enthalpic preference is not overcompensated by the respective entropy differences.[13]

In summary, our re-evaluation of the Wang–Sutherland replicator with simplified variants reveals that the exponential dynamics arise from conformational constraints. Whereas the termolecular complexes offer enough freedom for an optimal docking of the reactants with the template, template duplexes are conformationally restricted in their finding of an optimal orientation of the recognition units. A similar rationale was reported to explain the nearly exponential growth of a peptide replicator.[14] Our replicator theory predicts that for systems with a negligible background channel, the question of parabolic versus exponential growth is solely answerable by the stabilities of the ground-state and not the transition-state complexes involved.[2] Further cases are needed to prove that exponential growth can be literally designed by taking into account the conformational control of ground states. If this recipe can be generalized, it could open a door to a field that may be termed "systems chemistry", namely, the design of prespecified dynamic behavior.

[12] We use a four-letter notation to describe the configuration and conformation of template molecules. The first letter is either N or X to indicate an *endo* or *exo* Diels–Alder product, respectively. The latter distinction is based on the relative orientation of the C=C double bond to the maleimide ring. We employed the C=C double bond also as a reference to describe the relative orientation of the 5-pyridinylaminocarbonylmethyl substituent (second letter) and of the carboxymethyl substituent (third letter). *R/S* (fourth letter) is determined by the absolute configuration of the precursor diene.

tantalum hydride supported on silica, [(≡SiO)$_2$TaH], catalytically transforms a given alkane into its higher and lower homologues—an alkane metathesis reaction.[4,5] This reaction involves selective cleavage and formation of carbon–carbon bonds; for example, propane metathesis selectively gives ethane (45–50%) and butanes (30–35%) along with methane and minor amounts of higher alkanes. Moreover, it is possible to catalyze the reverse reaction, which allows methane to be incorporated into higher alkanes.[6] Similarly, the cross-metathesis of ethane and toluene is also catalyzed by [(≡SiO)$_2$TaH].[7] With [(≡SiO)Ta(=CH*t*Bu)(CH$_2$*t*Bu)$_2$] as a catalyst precursor,[8] the ratio of cross-metathesis products and the selectivity in higher alkanes led us to propose that the key step in alkane metathesis involves metallocarbenes and metallacyclobutane intermediates as is the case with olefin metathesis.[9,10]

This discovery led us to investigate the use of Group 6 metals, particularly W, which play a central role in olefin metathesis.[11] By using surface organometallic chemistry (SOMC), the goal of which is to enter directly into the catalytic cycle via reaction intermediates,[12] several attempts have been directed at generating well-defined tungsten carbene complexes on oxide surfaces by grafting [W(≡C*t*Bu)(X)$_3$] (X = Cl, O*t*Bu, CH$_2$*t*Bu). It was proposed that metallocarbenes were formed on the basis of their activity in olefin metathesis.[13–15] In fact, we have recently shown that the reaction of [W(≡C*t*Bu)(CH$_2$*t*Bu)$_3$] (**1**) with partially dehydroxylated silica (PDS) at 700°C generates the corresponding supported metallocarbyne [(≡SiO)W(≡C*t*Bu)-(CH$_2$*t*Bu)$_2$]$_{PDS}$ (**2**) instead of a metallocarbene.[16] Although highly active in olefin metathesis and highly electrophilic (formal 12-electron species),[13–15] this complex and the corresponding hydride displayed little to no activity in alkane metathesis.[4,5] Therefore, we decided to generate more electrophilic centers by preparing the corresponding W alkyl and hydride on partially dehydroxylated alumina (PDA).[17–23] Herein, we report the grafting and characterization of **1** on alumina, the preparation of the corresponding hydride, and their respective activity in alkane metathesis.

Grafting of **1** was performed typically by heating a mixture containing an excess of **1** (0.40 mmol per gram of alumina) and Al$_2$O$_{3-(500)}$ at 66°C to provide solid **1**–Al$_2$O$_3$. Excess molecular complex was removed by washing the solid with pentane (3 cycles), and the final solid was dried under vacuum. A yellow solid was obtained, which was fully characterized by IR and NMR spectroscopy as well as elemental and chemical analysis. During grafting, 0.9 equivalents of 2,2-dimethylpropane/W was formed, and the W loading of the resulting solid was 3.8–4.7 wt% (0.20–0.26 mmol W g^{-1}). The reaction with surface hydroxy groups was only partial, as revealed by IR spectroscopy (presence of residual hydroxy groups; see Figure 1b). Carbon elemental analysis data (3.6–4.6 wt%) corresponded to 14.3–14.8 C/W, and the reaction of the solid with excess H$_2$ at 150°C for 15 h gave a mixture of CH$_4$ (13.7–14.7 CH$_4$/W) and C$_2$H$_6$ (0.3–0.4 C$_2$H$_6$/W), corresponding to 14.3–15.5 C/W. Both results are consistent with about 2.9 ± 0.15 neopentyl-like ligands per W atom for **1**-Al$_2$O$_3$. Therefore, the surface complex has the following average structure: [(Al$_s$O)W(≡C*t*Bu)(CH$_2$*t*Bu)$_2$] (**2**,

Scheme 1). The solid-state magic-angle spinning (MAS) ^{1}H NMR spectrum exhibits only one broad signal at $\delta = 1.0$ ppm, whereas the solid-state cross-polarization (CP)/MAS ^{13}C NMR spectrum of the ^{13}C-enriched complex, selectively labeled on the carbon atom bonded to the metal, displays the following features (Supporting Information): a broad and weak signal at $\delta = 318$ ppm, a broad intense signal at $\delta = 85$ ppm with a shoulder at $\delta = 103$ ppm, several signals around $\delta = 52$ ppm, and a signal at $\delta = 32$ ppm with a shoulder at $\delta = 29$ ppm. The signal at $\delta = 318$ ppm is consistent with a neopentylidyne ligand.[16] The two broad signals at $\delta = 85$ and 103 ppm are attributed to different types of methylene carbon atoms (CH_2tBu), probably associated with the heterogeneity of alumina and possibly with the presence of neutral and cationic W surface complexes.[22,23] The signals at $\delta = 52$ and 32 ppm, already observed on silica materials, have been assigned respectively to the quaternary carbon atoms of the neopentylidyne group and to the methyl groups of the various tBu groups.[16] The shoulder at $\delta = 29$ ppm, not observed on other supports, may correspond to the presence of small amounts of [(Al–CH_2tBu)$^-$] fragments. This species would result from the reaction of a neopentyl group with an adjacent Lewis acidic Al site, as already proposed.[22,23] The data are therefore consistent with an average structure formulated as [(Al$_s$O)W($\equiv$CtBu)-(CH_2tBu)$_2$]$_{PDA}$, which corresponds to a mixture of a neutral complex **2a** as the probable major species ($\delta = 85$–95 ppm), along with the possible minor cationic or partially cationic surface complexes **2b** and **2c** ($\delta = 95$–110 ppm).[17–23] Whereas the neutral complex **2a** arises from the reaction of **1** with the hydroxy groups of alumina, the partially and fully cationic surface complexes **2b** and **2c** would have been formed by the interaction/reaction of **2a** with a neighboring Lewis acidic site; the latter complex is consistent with the formation of a small amount of [(Al$_s$–CH_2tBu)$^-$] (as revealed by a shoulder at $\delta = 29$ ppm in the ^{13}C NMR spectrum).[22,23] The structure was further confirmed by extended X-ray absorption fine structure (EXAFS) data (Table 1 and Supporting Information), and is consistent with the following coordina-

the bands associated with ν(C–H) and δ(C–H), as well as consumption of some residual AlOH, while two large bands appear at 1903 and 1804 cm^{-1}. The latter are readily exchanged under D$_2$ to generate the corresponding W–D bands at 1388 and 1293 cm^{-1}. After this D$_2$ treatment, a weak band at 1930 cm^{-1} remains unexchanged and is assigned to ν(Al–H).[30] Solid-state NMR and ESR spectroscopy on this alumina-supported tungsten hydride **3** provided no further information.[31] Moreover, no particles were detected in the transmission electron microscopy (TEM) image, in contrast to what is observed on silica, which shows that the migration of W atoms (sintering) is prevented on alumina. These data are

therefore consistent with the presence of isolated W atoms grafted to the surface through covalent Al_sO-W bonds. The formation of the final species probably involves the reaction of WH with adjacent Al−O−Al bridges or AlOH species (Scheme 2). The former generates AlH, as observed in the
Scheme 2. Proposed structure of **3** on $Al_2O_{3\text{-}(500)}$ ($x=1$–3 ; $y=1$–3).

formation of other hydrides,[32–35] and the latter is consistent with partial consumption of AlOH. As the formation of WH species is accompanied by the formation of AlH and the consumption of AlOH, we propose this WH species to be the bis-aluminoxy tungsten hydride **3**, but further work will be necessary to propose a definitive structure.

The activity of species **2** and **3** is noteworthy. In contrast to the W complex supported on silica, **2** is active in the metathesis of propane under our standard conditions (Supporting Information). The initial rate is 1.8 mol propane $mol_W^{-1}h^{-1}$, which is slightly lower than that of $[(\equiv SiO)Ta(\equiv CHtBu)(CH_2tBu)_2]$ (3.0 mol propane $mol_{Ta}^{-1}h^{-1}$, turnover number (TON) = 35 mol propane mol_{Ta}^{-1} at 120 h), but the TONs after 120 h are similar, which indicates that deactivation of this catalyst is slower (Table 2).[9] Under similar conditions, the initial rate (8–9 mol propane $mol_W^{-1}h^{-1}$) and the TON (120 mol propane mol_W^{-1}) after 120 h for tungsten hydride **3** are higher than those obtained with the best Ta-based catalysts. For example, the initial rate and TON at 120 h

for $[(\equiv SiO)_2TaH]$ are 3–4 mol propane $mol_{Ta}^{-1}h^{-1}$ and 60 mol propane mol_{Ta}^{-1} under the same experimental conditions. To understand the origin of this beneficial effect, alumina-supported tantalum hydride **4** was prepared (Supporting Information). However, its activity is similar to that of $[(\equiv SiO)_2TaH]$ (for **4** : initial rate = 2.5 mol propane $mol_{Ta}^{-1}h^{-1}$ and TON = 60 mol propane mol_{Ta}^{-1}). Thus, W is indeed the key to the improved activity in alkane metathesis.

The product selectivities are also noteworthy (Table 2). As observed for Ta, linear alkanes are favored over branched alkanes, and the selectivities for higher homologues are as follows: $C_{n+1} > C_{n+2} \gg C_{n+3}$. These selectivities are fully consistent with the model proposed earlier (Scheme 3),[9, 10] which

Scheme 3. Model for product selectivities in alkane metathesis. $R^1 = tBu$, $R^2 = H$; $R^1 = Et$, $R^2 = H$; $R^1 = Me$, $R^2 = Me$.

is based on olefin metathesis intermediates and predicts that the favored pathway for the formation of higher homologues involves a 1,3-disubstituted metallacyclobutane rather than a 1,2-disubstituted one, as proposed in olefin metathesis.[36] The higher selectivity of linear over branched compounds is also consistent with this model, as the latter would involve the less-reactive disubstituted carbenes. The major difference between the Ta and the W catalysts is that the selectivity for methane is less than 3% (after 120 h) for the W-based catalysts **2** and **3**, whereas it is about 10% for the corresponding Ta-supported catalysts, which is consistent with the greater hydrogenolysis capability of Ta.

In conclusion, we have shown that organo- and hydrido-tungsten surface complexes (**2** and **3**, respectively) supported on alumina catalyze the metathesis of propane. Tungsten hydride **3** has an overall turnover number of 120 mol propane mol_W^{-1}, which is much higher than that of the best known Ta system, that is, tantalum hydrides supported on silica or alumina. This significant improvement in activity probably reflects the difference between the intrinsic properties of W and those of Ta. Interestingly, in olefin metathesis, the same trend is observed (W-based are much better than Ta-based homogeneous catalysts because of the instability of tantalacyclobutanes).[28,37] These data corroborate what we observed and proposed earlier: alkane meta-

Table 2: Propane metathesis: comparison of the activity (TON) and the product selectivities of tungsten and tantalum perhydrocarbyl species on oxide and their corresponding hydrides after 120 h of reaction in a batch reactor (see Supporting Information).

Experimental Section

Representative procedure for grafting **1** on Al_2O_3: An excess of **1** (311 mg, 0.66 mmol, 1.1 equiv) and $Al_2O_{3-(500)}$ (1.8 g) were stirred at 66°C for 4 h. All volatile compounds were condensed into another reactor (of known volume) to quantify 2,2-dimethylpropane evolved during grafting. GC analysis indicated the formation of 0.21 ± 0.05 mmol of 2,2-dimethylpropane (0.9 ± 0.1 CH_3tBu/W). Pentane (10 mL) was introduced into the reactor by distillation, and the solid was washed three times. After evaporation of the solvent, the resulting light brown powder was dried under vacuum to yield **2**.

Preparation of **3**: Solid **2** was heated at 150°C in the presence of a large excess of anhydrous H_2 (77 kPa). After 15 h, the gaseous products were quantified by GC, and the resulting solids were obtained after evacuating the gas phase for 15 min.

General procedure for propane metathesis: In a glove box, the solid was introduced into a batch reactor (of known volume). After evacuation of Ar, dry propane was added, and the reaction mixture was heated at 150°C. To monitor the reaction, aliquots were expanded in a small volume, brought to atmospheric pressure, and analyzed by GC (see Supporting Information for experimental details).

Sialylation

1,5-Lactamized Sialyl Acceptors for Various Disialoside Syntheses: Novel Method for the Synthesis of Glycan Portions of Hp-s6 and HLG-2 Gangliosides**

Hiromune Ando,* Yusuke Koike, Sachiko Koizumi, Hideharu Ishida, and Makoto Kiso*

The ongoing studies on oligosaccharide synthesis have resulted in the development of precise synthetic methods by which a large portion of the complex natural oligosaccharides can be duplicated.[1] Although the synthesis of the sequence Neu5Acα(2→8)Neu5Ac (α(2→8)disialic acid; Neu5Ac = N-acetylneuraminic acid) has been a major difficulty, the emergence of several exquisite methods[2] that employ indirect coupling by using a C3-functionalized N-acetyl sialyl donor and direct coupling by using an N-trifluoroacetyl (TFAc)-protected sialic acid donor with the help of the nitrile solvent effect have paved the way for the successful synthesis of α(2→8)disialic acid containing oligosaccharides, such as those with GD3[2c] and GQ1b[3] glycan portions. However, it is obvious that the synthesis of new congeners of disialic acid, such as 8-O-sulfo-Neu5Acα(2→8)Neu5Ac in ganglioside Hp-s6[4] and Neu5Gcα(2→4)Neu5Ac in ganglioside HLG-2[5] (Scheme 1), is still difficult because of the diverse modifications possible at the functionality level. On the basis of the predicted biological functions of the disialic acid congener containing oligosaccharides relevant to functions such as neural network formation and fertilization, the establishment of an expedient synthetic method that includes the entire disialic acid family seems essential not only for the progress of glycochemistry but also for studying in detail the molecular

Scheme 1. Structures of novel disialyl gangliosides Hp-s6 and HLG-2.

basis underlying the biological functions of these compounds. In this study, we report a novel synthetic method for the synthesis of disialic acid congener containing glycans that uses highly reactive lactamized sialyl acceptors and an N-2,2,2-trichloroethoxycarbonyl (Troc)-protected sialyl donor.

Recently, we reported an N-Troc-protected sialyl donor (N-Troc donor **1**) that shows elevated reactivity and a high degree of accessibility for various sialic acid congeners such as N-glycolylneuraminic acid (Neu5Gc), 8-O-sulfo-Neu5Ac, and 1,5-lactam-Neu.[6] Initially, we anticipated that use of the N-Troc donor would enable the design of HLG-2 and Hp-s6 glycan sequences in an expedient manner. However, as depicted in Scheme 2, the results of the condensations with 4-OH and 8-OH sialyl acceptors, **2** and **3**, respectively, did not meet expectations with regard to yields and stereoselectivity. Even in the case of **2**, which showed the relatively higher reactivity, α-disialyl glycoside was obtained in less than 5%. We hypothesized that the poor results were mainly due to unfavorable hydrogen bonding with the amide moiety at C5, as proposed previously by Tsvetkov and Schmidt.[7] This hypothesis was the basis of the idea that the conformational transformation from the $^2C_5$ chair form to the fixed boat form with the 1,5-lactam bridge would result in increased reactivity of both the C4- and C8-hydroxy groups.[8]

To form the 1,5-lactam bridge in the sialoside, the previously reported N-TFAc-sialic acid derivative **6**[9] was used as the key precursor (Scheme 3). After the coupling reaction of **6** and tribenzylated glucosyl acceptor **7**, the resulting sialyl-α(2→6)Glc disaccharide, **8**, was subjected to 1,5-lactamization. First, we attempted a carbodiimide-mediated intramolecular amide formation after the complete deacylation and saponification of **8**, but this reaction yielded a complex mixture. The optimum yield was obtained when **8** was treated with methanolic sodium methoxide in the presence of Drierite under reflux to provide the 1,5-lactam-sialyl glucoside **9** in 85% yield; through regioselective benzoylation of the C9-hydroxy group of **9** with benzoyl chloride and pyridine, under kinetic control, triol acceptor **10** was produced. For the synthesis of the 8-hydroxy-1,5-lacta-

Scheme 2. Unsuccessful sialylation to 4-OH and 8-OH sialyl acceptors. Bn = benzyl, MS = molecular sieves, NIS = N-iodosuccinimide, SE = 2-(trimethylsilyl)ethyl, TfOH = trifluoromethanesulfonic acid.

mized sialyl acceptor, 8,9-O-benzylidenation was required prior to the lactamization because 8,9-O-acetalization of the lactamized derivative was unsuccessful. Thus, compound **6** was de-O-acetylated and this was followed by the conventional 8,9-O-bezylidenation with benzaldehyde dimethyl acetal and camphorsulfonic acid to produce **11**, which was then subjected to the one-pot 1,5-lactam formation mentioned earlier to yield bicyclo-sialoside **12** in 89% yield. Next, **12** was completely acetylated with Ac_2O in the presence of pyridine and the product was successively de-N-acetylated with hydrazinium acetate in a chemoselective manner to produce compound **14**. Finally, reductive ring opening of the benzylidene acetal moiety, influenced by $BH_3 \cdot NMe_3$ and $AlCl_3$ in THF,[10] produced the 8-OH lactam acceptor **15**.

Next, we carried out the glycosylation of the lactam acceptors **10** and **15** with N-Troc- and N-TFAc-sialyl donors to evaluate their properties as glycosyl acceptors (Scheme 4). First, the triol acceptor **10** was treated with N-Troc donor **1** in the presence of NIS, TfOH, and a molecular sieve in EtCN[11] at −40 °C to provide the Neuα(2→4)Neuα-(2→6)Glc sequence **17**, along with the corresponding β isomer. The anomeric configuration of the new ketosidic linkage was determined on the basis of previous reports[12] by measuring the long-range $^3J_{C1,H3ax}$ coupling constants. For compound **17** this coupling constant was 5.4 Hz, whereas for the β isomer it was less than 1.0 Hz, a fact indicating that the amomeric configuration of **17** was α. Similarly, the coupling reaction with the N-TFAc donor **6** and the complete acetylation that followed yielded the corresponding Neuα(2→4)Neuα(2→6)Glc sequence **17** in 41% yield, along with the β isomer (10%) and the Neu(2→8){[Neu(2→4)]Neuα}(2→6)Glc sequences as an anomeric mixture (8%).

Next, we attempted to fashion the purest form of Neuα(2→8)Neu sequence (Scheme 4). As initially expected, the glycosylation reactions of the lactam acceptor **15** with N-Troc and N-TFAc donors (**1** and **6**) yielded the corresponding Neuα(2→8)Neu sequences. Thus, N-Troc donor **1** and N-TFAc donor **6** were incorporated, in the presence of NIS, TfOH, and a molecular sieve in EtCN, at −80 °C to yield α(2→8)disialosides **18** and **19** in 49 and 71% yield, respectively; no corresponding β form was generated in either event. To the best of our knowledge, the yield of addition to the C8-hydroxy group of sialic acid (71%) during the sialylation process was the highest value obtained by direct coupling methods[2] In keeping with the results of the previous experiments, the anomeric configuration of the new linkages was determined to be α from $^3J_{C1,H3ax}$ coupling constants that

Scheme 4. a) **1** (2.0 equiv), NIS (3.0 equiv), TfOH (0.3 equiv), EtCN, MS (3 Å), −40 °C, 6 h, 84 % (α/β 66:18); b) 1. **6** (2.0 equiv), NIS, TfOH, EtCN, MS (3 Å), −40 °C, 6 h; 2. Ac₂O, py, DMAP, 40 °C, 17 h, 51 %; c) **1** (3.0 equiv), NIS, TfOH, EtCN, MS (3 Å), −80 °C, 5 h, 49 % (α only); d) **6** (3.0 equiv), NIS, TfOH, EtCN, MS (3 Å), −80 °C, 3 h, 71 % (α only).

ranged from 6.7 to 6.9 Hz. Furthermore, the phenylsulfenyl group at the bridgehead anomeric center of acceptor **15** remained unaffected during the coupling reactions. This result confirmed our initial hypothesis, based on Bredt's rule, suggesting the basis of a novel method for the complete deactivation of a sialyl donor.

On the basis of the results obtained with regard to the performance of 1,5-lactamized sialic acid acceptors **10** and **15** in the sialylation reactions, we focused on the synthesis of the glycan portions of HLG-2 and Hp-s6 gangliosides of **16** and **18**, respectively, in order to demonstrate the practical efficacy of the synergic strategy for synthesizing variant disialosides from the 1,5-lactam-sialyl acceptor and *N*-Troc-sialyl donor.

In the initial stages of the synthesis of the HLG-2 glycan portion (Scheme 5), the trisaccharide **16** was *O*-acetylated to provide **20**, to which the *N*-glycolyl moiety was introduced by our reported method,[6] thereby providing **21** in a relatively high yield (66 % from **16**). Next, we attempted to recover the $^2C_5$ conformation of the inner sialic acid unit. The following reaction sequences supplied HLG-2 glycan frame **23** in a high yield: *N*-benzyloxycarbonylation, basic hydrolysis, and ensuing methylation of the carboxy group. Debenzylation and acetylation to replaced the Cbz group of **23** by the acetyl group and full deprotection of the product **24** yielded the HLG-2 glycan structure **25**.

In the case of the Hp-s6 glycan frame, the "locked-up" phenylsulfenyl group at the bridgehead carbon atom of **18** was converted into an active state in the initial stages (Scheme 6). To be precise, the reaction sequences mentioned earlier yielded $^2C_5$ conformer **27** in 62 % overall yield. For the purpose of 8-*O*-sulfonylation in the final stages of the synthesis, **27** was further transformed into the 8-hydroxy derivative **28** by our regioselective acetyl-transfer method,[6] and the C8 hydroxy group was capped with a levulinoyl group

to produce high yields (89 %) of the suitably protected disialic acid donor **29** in two steps. Compound **29** was then treated with glucosyl acceptor **7**, influenced by the NIS/TfOH activator system in EtCN at −80→−60 °C, to provide Neuα-(2→8)Neuα(2→6)Glc sequence **30** in 66 % yield, predominantly in the α configuration. Next, replacement of the Cbz and benzyl groups of trisaccharide **30** by the acetyl group, followed by chemoselective deblocking of the levulinoyl group with hydrazinium acetate[13] and sulfonylation with SO₃·pyridine resulted in the formation of a completely protected Hp-s6 glycan frame, **33**.[14] The ¹H NMR signal for the C8 proton of the outer sialic acid appeared in compound **33** at lower magnetic field ($\delta = 4.92$ ppm) than in compound **32** ($\delta = 4.22$ ppm), and the heteronuclear multiple-bond coherence (HMBC) spectrum of compound **33** contained cross-coupling signals between carbonyl carbon atoms of acetyl groups at C7 and C9, and H7 ($\delta = 5.40$ ppm) and H9

($\delta = 4.19$ ppm). Thereby, the installation of the sulfonyl group on the C8-hydroxy group was determined.

In conclusion, we have discovered that 1,5-lactam bridging in sialic acid endows high reactivity to the C4- and C8-hydroxy groups, thereby leading to the supply of α(2→4)- and α(2→8)disialic acid sequences in high yields. Furthermore, the practical efficacy of the synergic synthetic approach toward diverse disialic acid containing oligosaccharides,

based on the *N*-Troc donor and the lactamized acceptors as the main units, has been demonstrated by the novel method for the synthesis of the HLG-2 and Hp-s6 glycan chains. On the basis of these results, we are now investigating the synthesis of α(2→8)-linked oligosialic acids.

[14] Furuhata's group first reported the 8-*O*-sulfonylation of neuraminic acid. They also confirmed that no migration or cleavage of the sulfonyl group at the C8-hydroxy group had occurred during the full deacylation and saponification process: M. Tanaka, T. Kai, X.-L. Sun, H. Takayanagi, K. Furuhata, *Chem. Pharm. Bull.* **1995**, *43*, 2095 – 2098.

roles which enables easy functionalization of the corrole structure at the 2-position with perfect regioselectivity. Owing to the rich chemistry of organoboranes, this strategy offers a powerful tool for the construction of corrole-based molecular assemblies.

A solution of 5,10,15-tris(pentafluorophenyl)corrole (**1**)[7] in dioxane was heated at 100°C for 24 h with bis(pinacolato)diborane (1.1 equiv) in the presence of a catalytic amount of [Ir(cod)OMe]$_2$ (1.5 mol%) and 4,4′-di-*tert*-butyl-2,2′-bipyridyl (dtbpy; 3.0 mol%) according to the Miyaura–Hartwig–Smith protocol (Scheme 1).[5,6b] Purification by preparative GPC-HPLC afforded the monoborylated corrole **2** in 91%

Corrole Derivatives

Synthesis of Corrole Derivatives through Regioselective Ir-Catalyzed Direct Borylation**

Satoru Hiroto, Ichiro Hisaki, Hiroshi Shinokubo, and Atsuhiro Osuka**

Corroles are 18-π-aromatic tetrapyrrolic macrocycles that contain a direct pyrrole–pyrrole linkage, that exhibit interesting optical properties and unique metal-coordination chemistry, and serve as excellent ligands for oxidation catalysis.[1] Although covalently linked multiporphyrinic molecules have received much attention from the viewpoint of the development of novel functional materials and molecular devices,[2] the synthesis of molecular assemblies based on corroles has remained rather limited owing to the lack of effective synthetic strategies for their regioselective modification.[3] Thus, considerable efforts have been made to develop selective methods that allow the effective functionalization of corroles. However, electrophilic substitution of corroles can occur at the C3 position, and multisubstitution products are sometimes formed.[4] To the best of our knowledge, the selective derivatization of corroles at the C2 position has not been reported. Very recently, we reported the highly regioselective direct borylation of porphyrins at the β position under iridium catalysis.[5,6] Herein, we disclose the successful application of this strategy to 5,10,15-triarylcor-

Scheme 1. Iridium-catalyzed direct borylation of corrole **1**. PinB–BPin = bis(pinacolato)diborane; cod = cycloocta-1,8-diene.

yield. Introduction of the boryl group was confirmed by the presence of the parent-ion peak at *m/z* 921.1529 (calcd for (C$_{43}$H$_{21}$BF$_{15}$N$_4$O$_2$)$^-$: 921.1531 ([*M*−H]$^-$)) by high-resolution electrospray-ionization time-of-flight mass spectrometry (HRMS). Even with the use of excess diborane reagent for a prolonged period, bisborylated corrole could not be obtained. The ^{1}H NMR spectrum of the product revealed its unsymmetrical nature. One singlet and one doublet peak, which can be assigned to hydrogen atoms H^3 and H^4, respectively, were shifted downfield as a result of the neighboring effect of the boryl group which indicates that the boryl group is introduced at the 2-position. This reaction proceeded with perfect regioselectivity, and none of the other isomers were detected.

The structure of the 2-boryl-substituted corrole **2** was unambiguously confirmed by X-ray diffraction analysis (Figure 1).[8] The most sterically accessible hydrogen atom H^1 in **1** is replaced by boron. The dioxaborolane rings in **2** are only slightly tilted (27.8°) relative to the corrole core, thereby probably maintaining electronic interaction between the vacant orbital of boron and the π orbital of the core. In this conformation, the bulky tetramethyldioxaborolane moiety hampers the access of a second molecule of the reactive metal complex, hence preventing the second borylation at another pyrrolic site (18-position). While electronic factors generally dominate the regioselectivity at the 3-position in the electrophilic substitution of corroles,[4c–e] the regioselectivity in the present protocol is likely to be determined by steric reasons: the peripheral aromatic groups block borylation at sites other than the 2- and 18-positions. This selectivity is consistent with our observations with previous borylation reactions of porphyrins under iridium catalysis.

Figure 2 shows the UV/Vis absorption and emission spectra of **1** and **2**. The Soret bands as well as the Q bands

Organoboron compounds are the most useful substrates for the formation of carbon–carbon bonds by the Suzuki–Miyaura cross-coupling reaction. Indeed, the reaction of **2** with bromoanthracene or bromodimethoxybenzene afforded the desired coupling products **3a** and **3b** in excellent yields (Scheme 2). We also report the synthesis of a directly linked corrole–porphyrin hybrid **3c** through the coupling of **2** with *meso*-bromoporphyrin. In contrast to the recent developments in directly linked porphyrin arrays,[9, 10] there has been no previous report on directly linked corrole–porphyrin molecules. Corrole–porphyrin **3c** may be used to ligate two metal ions in different valence

states (M^{2+} and M$'^{3+}$). Additionally, the 1,4-phenylene-bridged dimer **3d** was also very easily obtained by the Suzuki–Miyaura coupling of **2** with 1,4-dibromobenzene. The present procedure provides the desired compounds in excellent yields in only two steps—borylation and cross-coupling—from the original corroles.

The oxidation of organoboranes is a versatile tool for the synthesis of alcohols and phenols. Thus, we attempted the synthesis of 2-hydroxycorroles by oxidation of **2** with oxone according to Smith's procedure (Scheme 3),[11] and oxidation product **4** was obtained in 62% yield. HRMS revealed a parent-ion peak for **4** at m/z 811.0629 (calcd for (C$_{37}$H$_{10}$F$_{15}$N$_4$O): 811.0621 ([M−H]$^-$). The ^{1}H NMR spectrum
Scheme 3. Synthesis of 2-hydroxycorrole and its tautomerization.

of the product in CDCl$_3$ revealed that the keto form, keto-**4**, had been isolated, with the presence of a peak at $\delta = 4.75$ ppm for the two methylene hydrogen atoms (H^a) at the α position of the ketone group. Additionally, signals for the carbonyl and sp^3-hybridized carbon atoms were detected at $\delta = 197.9$ and 45.6 ppm, respectively, in the ^{13}C NMR spectrum of the product in CDCl$_3$. To the best of our knowledge, this is the first reported isolation of the keto form of a dihydrocorrole.[12]

In contrast, the enol form enol-**4** was predominant in solution in [D$_6$]DMSO, and the hydroxy proton was detected at $\delta = 11.8$ ppm (Figure 3).[13] While the keto form is exclusively observed in solution in CDCl$_3$ and CD$_2$Cl$_2$, both keto and enol structures were detected in varying ratios in [D$_8$]THF, CD$_3$CN, [D$_6$]acetone, and CD$_3$OD. Interestingly, the inner NH protons appear as sharp signals at $\delta = -0.44$, -3.05, and -4.84 ppm for the keto form (in CDCl$_3$, while the corresponding signals were very broad at $\delta \approx -0.59$, -1.02, and -3.51 ppm for the enol form (in [D$_6$]DMSO). This observation is consistent with the presence of fixed NH protons in the keto form keto-**4** versus fast NH tautomerism on the NMR timescale between enol forms **4** and **4'** (Scheme 3), as observed for regular corroles.[14] In the enol form, a signal at $\delta = 7.82$ ppm, which was assigned as H^b on the basis of H–H COSY experiments, appeared at higher field than the other β-pyrrolic signals. This shift is
Figure 4. UV/Vis absorption spectra of a) keto-**4** (——) and **1** (----) in CH$_2$Cl$_2$, and b) enol-**4** (——) and **1** (----) in DMSO. Emission spectra of c) keto-**4** (——) and **1** (----) in CH$_2$Cl$_2$, and d) enol-**4** (——) and **1** (----), intensity scaled down by 1/10 in DMSO.

caused by the electron-donating nature of the neighboring hydroxy substituent. Interestingly, the signal for H^b gradually decreased upon the addition of D$_2$O while that for the hydroxy proton disappeared. This result supports the presence of exchange between the OH proton and hydrogen atom H^b through tautomerization.

The UV/Vis and emission spectra of **4** showed a strong dependence on the solvent, reflecting the structural difference between the keto and enol forms (Figure 4). The absorption spectrum of **4** in DMSO is quite similar in shape to that of the original corrole **1** in the same solvent (Figure 4b). In contrast, four Q bands were observed in CH$_2$Cl$_2$, probably as a result of the dihydrocorrole structure of the keto form, and the same holds for the red shift of the Soret band (Figure 4a). The enol form emits enol-**4** at the same wavelength as **1**, with a similarly shaped but less-intense spectrum in DMSO (Figure 4d), while the spectrum of the keto form keto-**4** in CH$_2$Cl$_2$ was significantly red-shifted relative to that of **1** in the same solvent (Figure 4c). The effect of the hydroxy group in the enol form upon the fluorescence intensity is not clear at this stage.

In conclusion, we have demonstrated the highly regioselective synthesis of a 2-borylated corrole, which is a useful platform for the functionalization of corroles and the construction of molecular assemblies based on corroles. The utility of the present protocol has been demonstrated by the first syntheses of the directly linked corrole–porphyrin hybrid **3c** and the 2-hydroxy-substituted corrole **4**. Further studies involving borylated porphyrins and corroles are currently underway in our laboratory.

Multilocus Binding Increases the Relaxivity of Protein-Bound MRI Contrast Agents

Zhaoda Zhang, Matthew T. Greenfield, Marga Spiller, Thomas J. McMurry, Randall B. Lauffer, and Peter Caravan*

Dedicated to Professor Iwao Ojima on the occasion of his 60th birthday

The utility of clinical magnetic resonance imaging (MRI) has been greatly expanded by the use of contrast agents—gadolinium complexes that serve to increase the longitudinal nuclear relaxation rate $(1/T_1)$ of water protons. Commercial contrast agents are only effective at high concentrations (> 0.1 mM) and, as a result, there has been considerable effort to increase their sensitivity. One approach is to increase the number of gadolinium ions in the molecule by making polymeric or dendrimeric contrast agents.[1] A second approach is to optimize the parameters that influence relaxation enhancement, such as rotational diffusion and water exchange.[2]

An effective mechanism for increasing relaxivity ($r_1 = (\Delta 1/T_1)/[\mathrm{Gd}]$) is the receptor-induced magnetization-enhancement (RIME) effect.[3] An example is the GdDTPA derivative MS-325, which targets serum albumin. When MS-325 binds to albumin, the rotational correlation time (τ_R) increases from that of a small molecule to that of the protein,

and the relaxivity increases ninefold to $51\ \mathrm{mm^{-1}s^{-1}}$ (37°C, 20 MHz).[4] This is shown schematically in Figure 1a and b. Despite this increased relaxivity, there is still a drive to increase relaxivity further to allow imaging of lower concentration targets. One approach for increased molecular relaxivity would be to combine the RIME effect with a multimeric gadolinium agent (Figure 1c). However, polymeric contrast agents such as GdDTPA-monoamide tethered to poly-lysine[5–8] or dextran[9,10] have much lower relaxivities ($r_1 < 13\ \mathrm{mm^{-1}s^{-1}}$ per ion at 37°C) than one might expect based on their molecular weight because of internal motion along the polymer.[11] Furthermore, targeting multimeric contrast agents to a specific protein may also result in lower relaxivity than expected because of internal flexibility within the multimer.

It was hypothesized that a large RIME effect could be maintained if the multimer exhibited a certain rigidity when bound to the protein target. One approach would be to prepare a rigid multimer[12] by limiting the degrees of rotational freedom along the chain and then attaching a targeting vector to the multimer. A second approach in which a second targeting vector is used to anchor the terminus of the chain (multilocus binding) is outlined in Figure 1d. The second vector can be designed to bind nonspecifically to a hydrophobic patch on the target. In the absence of a target, there is rotational flexibility and low relaxivity; however, upon binding of the protein with both binding groups, the bound complex becomes more rigid and the relaxivity increases. In the absence of the second targeting group, the relaxivity of the bound species is lower because of internal flexibility. It is possible that the second targeting group could target a second protein which would also induce rigidity and enhance relaxivity.

To test this hypothesis, three tetrameric GdDTPA-based compounds were prepared (Figure 2) containing zero, one, or
Figure 2. Compounds described in this study: GdDTPA tetramer containing zero (**1**), one (**2**), or two (**3**) HSA-binding groups (BG), and benchmark GdDTPA monomer MS-325.

Figure 1. Strategies for increasing relaxivity: a) Discrete Gd chelate and targeting moiety, for example, the fast tumbling of MS-325 limits the relaxivity. b) Binding to the target slows tumbling, and relaxivity is increased. c) Gd chelate multimer with targeting; relaxivity may be limited by the fast internal motion. d) Gd chelate multimer with multi-locus binding rigidifies the bound complex and increases the relaxivity.

two protein-binding moieties. The DTPA moiety[13] shown in Figure 2 was used instead of the monoamide, because the GdDTPA complex has a more favorable water-exchange rate and the thermodynamically stable GdDTPA core is already present in several clinically approved contrast agents.[14] Human serum albumin (HSA) was chosen as the protein target for proof of principle and MS-325 (Figure 2) was used as a benchmark compound. Although MS-325 does not contain the same biphenyl albumin-binding group, it exhibits both high relaxivity and albumin binding and represents the state of the art.

The binding of each compound **1–3** (0.1 mm) to HSA (4.5% $w/v = 0.67\ \mathrm{mm}$) was assessed by ultrafiltration[4] through a 5-kDa-molecular-weight cut-off membrane at 37°C and at pH 7.4; the gadolinium concentration in both the initial solution (total) and the filtrate was measured by inductively coupled plasma mass spectrometry (ICP-MS). Not surprisingly, compound **3** (with two binding groups) exhibits the highest affinity for HSA (Table 1). The relaxivities of **1–3** (0.1 mm) were measured at 20 MHz, pH 7.4, 37°C in phosphate-buffered saline (PBS), in the presence or absence of HSA (0.67 mm). As a result of their increased molecular size, the relaxivities per Gd of the tetramers in buffer solution are higher than that of MS-325. When the measurement is made in an excess of HSA, the observed relaxivities follow the order **3 > 2 > 1**. To determine if this is simply a result of increasing albumin affinity, the relaxivity of the bound fraction can also be calculated ($r_1^{\mathrm{bd}} = \{r_1^{\mathrm{obs}} - f^{\mathrm{free}} r_1^{\mathrm{free}}\}/f^{\mathrm{bd}}$). Table 1 shows that compound **3** has the highest albumin-

Table 1: Binding of MS-325, **1**, **2**, and **3**.[a]

Compound	Number of Gd	% bound	r_1^{obs} (PBS)	r_1^{obs} + HSA	r_1^{bd} (HSA)

[a] Percentage of 0.1 mм compound bound to 0.67 mм HAS, observed per Gd relaxivities (mM^{-1}s^{-1}) at 20 MHz in the absence and presence of 0.67 mм HSA, and calculated albumin-bound relaxivities. Numbers in parentheses refer to relaxivity per molecule; all measurements were performed at pH 7.4, 37°C, with 0.1 mм compound in PBS.

bound relaxivity of the three multimeric chelates. Although the GdDTPA moieties of **3** have a somewhat flexible linkage to the albumin-binding groups, the relaxivity per Gd of **3** in HSA approaches that of the more compact and rigid MS-325/HSA. On a per molecule basis, the relaxivity of **3** is clearly the highest.

To demonstrate that this result is indeed a rotational phenomenon, nuclear magnetic relaxation dispersion (NMRD) profiles were recorded for each of the three compounds, both with and without excess HSA at 35°C. Figure 3 shows the relaxivity profiles for each compound
Figure 3. ^{1}H NMRD relaxivities expressed per Gd (35°C, pH 7.4) of **1** (triangles), **2** (squares), and **3** (circles) (0.1 mм) in PBS only (open symbols) or bound to 4.5% HSA (filled symbols).

when bound to albumin (solid symbols, r_1^{bd}) or in buffer solution only (open symbols). The NMRD of the three compounds in buffer solution are similar and rather featureless, with an estimated rotational correlation time of about 0.3 ns. In the presence of excess albumin, however, the relaxivities of all three compounds are increased. Notably, the appearance of a high-field peak at about 25 MHz is typical of a slow-motion fraction.

The relaxivity in buffer solution and the HSA-binding data were used to calculate the bound relaxivity NMRD profiles. The high-field region is shown in Figure 3. Despite

the complexity of the system (multiple chelates, complex rotational motion), it is informative to model these curves and this was performed in an approach previously described for the high-field part of the NMRD curve.[15] The NMRD of a $q = 0$ triethylenetetraamine hexaacetic acid (TTHA) derivative reported earlier[4] was used to estimate the second- and outer-sphere contributions to relaxivity. The water residency time at 35°C was fixed for all three compounds at 100 ns based on an analogy with other substituted GdDTPA compounds.[4,14] As the chelate part of the molecule is the same for all three compounds, it was assumed that the water-exchange rate would also be the same. The Gd—H(water) distance was fixed at 3.1 Å.[16] The three bound relaxivity NMRD data sets were fit simultaneously, the two parameters for electronic relaxation (Δ^2, τ_v) were treated as global parameters (owing to the identical chelating portions), and the rotational parameters were treated locally.

These data were fit in two ways: first, an isotropic model of rotation was employed to analyze these data. This model did not fit well—the peak shape was not well reproduced—and the fitted curve gave a much flatter peak that underestimated the relaxivity maximum and overestimated the relaxivity at higher fields. The correlation times from the fitting are in the 1-ns range and do not reflect the physical reality of an albumin tethered complex. The second method was a Lipari–Szabo model-free approach that has been described previously.[15] Equation (1) describes the dipolar

$$\frac{1}{T_{1M}} = \frac{C}{r_{GdH}^6}\left(\frac{3F\tau_{cg}}{1+\omega_H^2\tau_{cg}^2} + \frac{3(1-F)\tau_{cl}}{1+\omega_H^2\tau_{cl}^2}\right);$$
$$\frac{1}{\tau_{cg}} = \frac{1}{\tau_g} + \frac{1}{T_{1e}} + \frac{1}{\tau_m}; \frac{1}{\tau_{cl}} = \frac{1}{\tau_{cg}} + \frac{1}{\tau_l}$$

(1)

relaxation of the coordinated water. In this case, the spectral density function has two terms that are related by a factor F (sometimes called an order parameter and denoted S^2), which describes the degree of spatial restriction. If the motion of the Gd chelate is independent of the protein, then $F = 0$; if the chelate is completely immobilized on the protein, then $F = 1$. There are two correlation times, τ_{cg} and τ_{cl}, which contain contributions from global (τ_g) and local (τ_l) rotational correlation times, as well as from the electronic relaxation time T_{1e}.

A global correlation time based on fluorescence anisotropy decay was fixed at 41 ns,[17] whereas the local correlation time for each compound was allowed to vary along with its order parameter. In this case, the peak shape is much better reproduced, and the resultant fitted parameters are given in Table 2. As may be expected, the order parameter F increases from compound **1** to **2** to **3** as the number of binding groups

Table 2: Fitted NMRD parameters for compounds **1**, **2**, and **3**.[a]

τ_v [ps]	Δ^2 [10^{18} s^{-2}]	**1** F	**1** τ_l [ns]	**2** F	**2** τ_l [ns]	**3** F	**3** τ_l [ns]
13 (1)	7.1 (0.2)	0.05 (0.01)	0.68 (0.03)	0.09 (0.01)	0.92 (0.03)	0.16 (0.02)	1.40 (0.04)

[a] Global (HSA) rotational correlation time fixed at 41 ns. Numbers in parentheses represent one standard deviation.

increase. The local correlation time also increases in the order **1** < **2** < **3**, which suggests that compound **3** is the most rigid when bound to albumin. Although the order parameters are relatively low, it was noted that they correlated with the global correlation time—arbitrarily chosen shorter global correlation times also gave good fits, but the order parameter was increased. Although the Lipari–Szabo approach models the data well, motion within this system is complex and care should be taken in comparing these rotational parameters with other unrelated systems.

There have been gains reported in increasing the relaxivity of single gadolinium complexes through the optimization of water exchange, hydration number, etc. Multilocus binding may prove to be a useful technique for maintaining this high relaxivity when these complexes are incorporated into targeted multimeric MRI contrast agents.

Experimental Section

The compounds **1**, **2**, and **3** were synthesized in an analogous fashion (see Supporting Information for full details). 4-Mesitylbenzoic acid was coupled to zero, one, or two of the primary amine groups of triethylenetetraamine. After reduction of the amide, the resultant tetraamine was coupled to four protected DTPA moieties. Deprotection, chelation, and purification by HPLC yielded the complexes shown in Figure 2. All Gd concentrations were determined by ICP-MS (Agilent 7500). NMRD profiles were recorded on a Koenig-Brown field-cycling relaxometer.

Heterogeneous Catalysis

Deactivation of Pd Acetoxylation Catalysts: Direct Observations by XPS Investigations**

Jörg Radnik,* Abdulhadi Benhmid,
Venkata Narayana Kalevaru, Marga-Martina Pohl,
Andreas Martin, Bernhard Lücke, and
Uwe Dingerdissen

Catalyst deactivation is a problem of great concern in industrial catalytic processes. Hence, prevention of catalyst deactivation poses substantial challenges in the design and operation of large-scale catalytic processes. The usual way to overcome the deactivation problem is to modify the catalyst composition by using different promoters. Although various promoters have been used for different oxidation reactions,[1–4] their precise role is not known. Unfortunately, most of the interpretations on the role of promoters are rather hypothetical probably owing to the lack of information about the exact surface structure. Among the known promoters, bismuth has very attractive properties as a promoting element in numerous heterogenous oxidation catalysts, particularly in association with noble metals.[1–6] However, the origin of the promoting role of Bi is still a matter of discussion.

Acetoxylation is an industrially important reaction for producing esters in a single step. Benzyl acetate (BA), the desired product from acetoxylation of toluene, is widely used in the food, perfumery, and chemical industries. Most of the work reported so far on the acetoxylation of toluene is confined to liquid-phase and batch reactors.[7–9] Vapor-phase processes were previously not successful in terms of obtaining higher yields of BA with acceptable time-on-stream stability of the catalysts.[10,11] However, the recently developed Pd–Sb/TiO$_2$ catalysts[12–13] displayed remarkably higher conversion of toluene (> 90%) and yields of BA (> 75%) with a space–time yield of up to 700 g kg^{-1} h^{-1}. To our knowledge, this is the best result reported so far under gas-phase conditions. However, these catalysts are observed to undergo deactivation readily after several hours of operation as a result of coke deposits, which obviously hampers their application on a commercial scale.

Considering the limited lifetime of these catalysts, we have directed our research efforts to develop stable and novel Pd compounds that have improved catalyst lifetime as well as the higher activity and selectivity of the earlier catalysts. To achieve this objective, we modified the composition of the Pd-Sb/TiO$_2$ catalysts by adding promoters such as Bi, Cu, and Sn.[14–15] Among these promoters, the Bi modification improved both the catalyst life as well as the selectivity for desired product (BA). However, the precise role of Bi remained unclear. In the present study we examine the catalyst deactivation phenomenon of Pd–Sb/TiO$_2$ catalysts and the role of Bi in improving catalyst lifetime and selectivity.

In the earlier investigations on Pd–Sb/TiO$_2$ catalysts[13] we clearly detected differences between the fresh and used catalysts. The used catalysts displayed drastic increase in Pd particle size, coke deposition, loss of both Pd and Sb at the surface etc. In view of this, a TiO$_2$-supported catalyst with 10 wt% Pd and 8 wt% Sb was then chosen as a model catalyst (designated as 10Pd8Sb) and subjected to reaction conditions for a wide range of reaction times. We could thus obtain useful information on the changes that occur during the course of the reaction.

In a similar way, in the present study we chose a sample containing 10 wt% Pd, 8 wt% Sb, and 7 wt% Bi as a model catalyst (designated as 10Pd8Sb7Bi). We subjected it to reaction conditions for a range of reaction times and analyzed the sample by X-ray diffraction (XRD), transmission electron microscopy (TEM), and X-ray photoelectron spectroscopy (XPS). This catalyst was selected because it lies in the middle of the series (i.e. between high and low Pd loading) and displays good performance (55% toluene conversion, 95% selectivity for BA). We intended to discover the changes that take place during the course of reaction, which in turn can give hints to understand the cause of deactivation. The reaction times in these long-term tests were 1, 2, and 4 days.

Interesting effects of the addition of Bi are 1) high selectivity for BA ($\geq$ 95%) and 2) improved catalyst lifetime. Figure 1a and b compare the time-on-stream catalytic performance of 10Pd8Sb/TiO$_2$ in the presence and absence of Bi. It is obvious from Figure 1a that the catalyst displays a very low initial activity (toluene conversion: 3%), which increases until ca. 11 h (> 68%), remains stable for few more hours, and then decreases with extended reaction times (ca. 30% after 34 h). The yield of BA and benzaldehyde (BAL) as a by-product also changes in a similar way. The increase in toluene conversion with time can be attributed to an increase in Pd particle size, while the decrease in catalytic activity can be attributed to the increase in coke deposition with time on stream.[13] TEM studies showed that the size of Pd particles increases to a critical size with time (i.e. during the course of the reaction) and then remains more or less constant even though the catalytic activity decreases. Both the most active and completely deactivated catalysts contained the Pd particles of similar size, indicating that the particle growth during reaction has no effect on deactivation. The only difference between these samples is the considerable amount of coke deposition in the deactivated catalysts, which is the primary cause of catalyst deactivation. Nevertheless, the deactivated samples can be regenerated in air and reused with consistent performance.

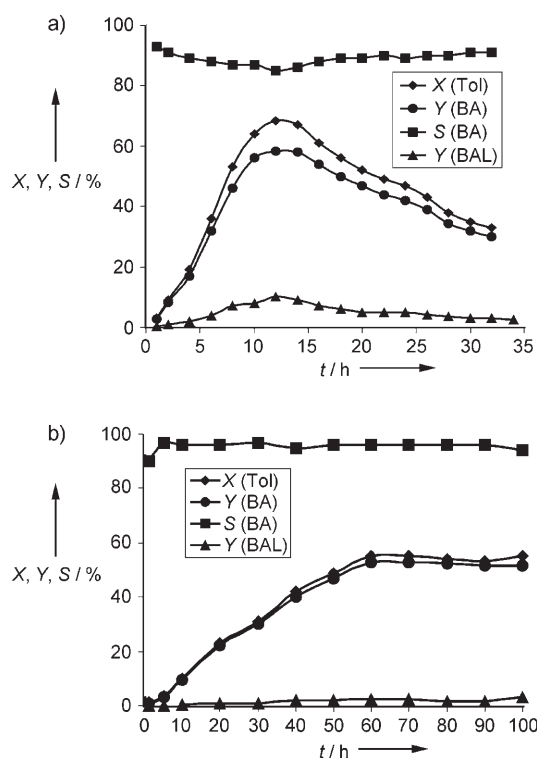

Figure 1. Comparison of the conversion (X), yield (Y), and selectivity (S) of 10Pd8Sb catalysts versus time on stream: a) without Bi; b) with Bi. Molar ratio of toluene/acetic acid/oxygen(air)/argon = 1:4:3(15):16, T = 210°C, gas hourly space velocity (STP) = 2688 h^{-1}, τ = 1.34 s.

Figure 2. Electron micrographs of 10Pd8Sb7Bi catalysts: a) fresh sample showing Bi-containing sheets (left) and Pd (right); b) after 1 day; c) after 2 days; d) after 4 days.

In contrast, the Bi-modified catalyst (Figure 1b) exhibits low initial activity (1%), attains a steady state (maximum activity: ≈55% toluene conversion) after about 55 h, and then displays quite stable performance with almost constant conversion and product selectivity up to 100 h on stream in contrast to the non-Bi-containing Pd–Sb catalyst. However, this phenomenon has no effect on the selectivity for BA, which remains more or less constant (95%) throughout. In other words, selectivity is independent of conversion regardless of the presence of Bi in the catalyst. This result reflects the fact that BA is quite stable and does not undergo any subsequent reactions.

No clues were found from XRD for the formation of any kind of crystalline intermetallic phases between Pd and Bi, which are, however, known from literature.[3,11] XRD results show the presence of Pd and PdO phases only in the catalysts tested for 1 day and 2 days. However, after a reaction time of 4 days the PdO disappeared. This result is in good agreement with XPS results (see Figure 4).

Electron micrographs of 10Pd8Sb7Bi catalyst recorded after different reaction times are shown in Figure 2. In the fresh catalysts Bi exhibits a sheetlike morphology and is located far from the TiO$_2$ support (Figure 2a, left). On the other hand, the Pd particles show a spherical morphology and are clearly present on TiO$_2$ surface. The size of Pd particles ranges from 1 to 2 nm. In other words, Pd and Bi display different morphologies (no free Sb particles can be seen by TEM). Furthermore, the presence of Bi leads to very fine Pd particles (1–2 nm) in these solids compared to those in the

non-Bi-containing Pd–Sb catalysts (1–10 nm). The catalyst tested for 1 day (Figure 2b) contains a mixture of both smaller (below 5 nm) and bigger Pd particles (even up to 45 nm). Interestingly, Bi moves closer to the TiO$_2$ support as the reaction proceeds. This movement is most pronounced during the first 24 h on stream and thereafter no such significant movement is observed.

These results are well supported by XPS. In the catalyst tested for 2 days (Figure 2c), one can still find a mixture of both smaller and bigger particles. Particles up to 70 nm can be found, while the smaller ones are mostly < 5 nm. With regards to the catalyst tested for 4 days (Figure 2d), the smaller Pd particles have almost disappeared and bigger ones up to 100 nm can be seen. This observation supports the view that the size of the Pd particles increases progressively with time under the influence of reactant feed mixture in the same way as the activity of the catalysts. The growth of Pd particles appears to be essential for obtaining better catalyst performance. Pd particles up to 100 nm form in Pd–Sb solids after only 11 h on stream, whereas for the Bi-modified catalysts particles of this size are obtained after 4 days. This result suggests that the growth of Pd particles is a slow process in the presence of Bi. In addition, larger Pd particles often contain some traces of Sb. The deactivated 10Pd8Sb catalyst sample and the stable 10Pd8Sb7Bi catalyst (after 4-day tests) contain large Pd particles of more or less the same size. This indicates that the growth of Pd particles during the course of the reaction has no effect on catalyst deactivation and is in fact favorable for better performance.

Figure 3 depicts the variation of surface Pd/Ti, Sb/Ti, and Bi/Ti ratios in the 10Pd8Sb7Bi catalyst with time on stream. The amounts of Pd, Sb, and Bi in the near-surface region decrease mainly during the first 24 h on stream and then
Figure 3. Change in the surface concentrations c in the 10Pd8Sb7Bi catalyst with time on stream.

remain more or less constant throughout the 4-day test. Interestingly, the decrease in the Bi/Ti ratio (from 0.4 to 0.08) is much more pronounced than the decrease of the Pd/Ti ratio (from 0.17 to 0.1) and that of the Sb/Ti ratio (from 0.24 to 0.1). TEM examination of this particular 10Pd8Sb7Bi catalyst (Figure 2) also support these observations: During the first day of testing the sheetlike morphology of Bi vanishes and Bi moves closer to the TiO_2 support. This movement of Bi is assumed to be the more probable reason for such significant decrease in the Bi/Ti ratio.

To check the influence of Bi on the surface composition and the electronic states of the surface components, the results of XPS investigations on Bi-modified samples were compared with those of recently published results on 10Pd8Sb catalysts.[13] Normalized XP spectra of the Pd 3d state of fresh and used 10Pd8Sb catalysts with and without Bi are shown in Figure 4. The variation of surface Pd/Ti ratios and the presence of different surface Pd species in the presence and absence of Bi at different stages of reaction are also compared in this figure. Bi-containing catalysts (10Pd8Sb7Bi) exhibit only two states, either metallic (Pd^0), or oxidized (PdO_x), or both, at different stages of the reaction (i.e. after 1, 2, and 4 days). It is not possible to distinguish between bi-, tetra-, and hexavalent Pd, because the reference data available ranges from 336 to 338 eV for all these oxidation states. XRD experiments indicate the existence of a PdO phase , in other words, bivalent Pd, but other oxidation states at the surface of the particles cannot be excluded. In contrast, Bi-free catalysts (10Pd8Sb) exhibited three states: metallic (Pd^0), oxidized (PdO_x), and a $Pd^{\delta-}$ state, in which the electron binding energy of the Pd electron is lower than that of metallic Pd (335.1 eV). The formation of this third state is correlated with a strong interaction between the carbon deposits and surface Pd. The most striking feature here is that in the 10Pd8Sb7Bi sample even after 4 days of testing the $Pd^{\delta-}$ species is not observed. In contrast, the deactivated 10Pd8Sb sample contains up to 35% $Pd^{\delta-}$ on its surface, indicating the adverse effect of the $Pd^{\delta-}$
Figure 4. Normalized XP spectra of the Pd 3d state for fresh and used 10Pd8Sb catalysts with and without Bi (after Shirley background subtraction).

species on the life of the catalyst. The addition of Bi apparently prevents the formation of such undesired $Pd^{\delta-}$ species and thereby improves the lifetime of the catalysts.

Another interesting observation is that even after 1 and 2 days of use, oxidized Pd species could still be found in the Bi-modified samples whereas in the Bi-free catalysts the PdO phase disappeared after only 20 h of operation. This result suggests that PdO_x species are more stable in presence of Bi (Figure 4). Nevertheless, after 4 days of reaction the oxidized Pd is completely reduced to metallic Pd, which indicates that the presence of Bi slows the reduction of Pd. XRD studies also show an improved stability of PdO phase in the presence of Bi. However, no significant changes in the electronic states of the other components, Bi and Sb, were observed.

Another notable difference is the surface Pd/Ti ratio of the catalyst. (Figure 4). Bi-containing catalysts exhibit significantly higher Pd/Ti ratios than the Bi-free catalysts. Both systems further show a decrease in the Pd/Ti ratios during the course of the reaction. However, Bi-containing catalysts showed a large decrease in the Pd/Ti ratio (from 0.17 to 0.11) only during the first 24 h on stream (see also Figure 3). This change might be a result of catalyst restructuring as reflected by the movement of Bi closer to TiO_2 during this time. Once the restructuring has occurred, the amount of surface Pd remains more or less constant without any significant loss and hence the catalyst has a longer lifetime. In contrast, Bi-free catalysts display a continuous and significant decrease in the

Pd/Ti ratios of over 40% (from 0.09 (fresh) to 0.05 (deactivated); Figure 4). This ultimately leads to the deactivation of the catalyst, and this finding undeniably supports the proposition of the stronger interaction of surface Pd with the deposited coke.

The experimental observations such as 1) the absence of the $Pd^{\delta-}$ state and 2) the higher Pd/Ti ratios for the Bi-containing catalyst even after longer test times (100 h) undeniably indicate a weaker interaction between carbon atoms from deposited coke and the surface Pd atoms. To check this hypothesis, the C/Pd ratios were also estimated for both 10Pd8Sb and 10Pd8Sb7Bi samples (Figure 5). If we
Figure 5. Changes in the C/Pd ratio of the near-surface region of the 10Pd8Sb7Bi catalyst and the Bi-free catalyst 10Pd8Sb catalyst after 1, 2, and 4 days.

compare the C/Pd ratios between the most active (after ca. 10 h) and deactivated (after ca. 20 h) 10Pd8Sb catalyst, an abrupt increase (from ca. 30 to 122) was found, which might be due to stronger a interaction between C and Pd. This strong interaction not only leads to the high carbon amount but also modifies the electronic state of Pd, as evidenced from the appearance of the $Pd^{\delta-}$ state and the formation of a carbide-like or similar such structures cannot be ruled out. However, in XRD experiments we could not find any such crystalline Pd-C phases in any of these catalysts. In contrast, the presence of Bi weakened the interaction between the deposited coke and the surface Pd atoms, and hence low C/Pd ratios in the range of about 10 to 34 are found even after 100 h on stream. All these findings clearly show that the prevention of such unwanted $Pd^{\delta-}$ species results in a remarkable enhancement of catalyst life.

Mechanistically, catalyst deactivation results the formation of $Pd^{\delta-}$ species by the interaction between the carbon atoms from deposited coke and surface Pd species. Our results show that this interaction between Pd and C can be significantly reduced by the addition of Bi, as evidenced by the low C/Pd ratios in Bi-modified catalysts compared to those of Bi-free catalysts.

In this first report on catalyst deactivation phenomenon in the gas-phase synthesis of benzyl acetate from toluene we have identified the role of Bi in preventing catalyst deactivation and in enhancing the selectivity. The results indicate room for further improvements in the preparation and development of suitable catalysts with novel compositions for the acetoxylation of various alkyl aromatics and hetero-aromatics in the near future.

Experimental Section

The Pd-Sb-Bi/TiO$_2$ catalysts were prepared by impregnation in two steps. In the initial step, first SbCl$_3$ then BiCl$_3$ were deposited on an anatase carrier in an aqueous HCl solution with subsequent removal of excess solvent. The solid was dried and then calcined at 400°C (3 h, air). In the second step, the above solid was impregnated with PdCl$_2$ in the desired amounts followed by drying (120°C, 16 h). The detailed procedures for catalyst preparation,[16] screening of the catalysts, and product analysis have been described elsewhere.[13] The XPS measurements were conducted at a VG ESCALAB220iXL with Al$_{K\alpha}$ radiation. The TEM analyses were carried out with a Philips CM20 (twin) at 200 kV with EDAX PV9900 (energy dispersive X-ray spectroscopy (EDX)).

Nanoparticle Deposition

Size-Controlled Electrochemical Synthesis of Metal Nanoparticles on Monomolecular Templates**

Thomas Hirsch, Michael Zharnikov,
Andrey Shaporenko, Joachim Stahl, Dieter Weiss,
Otto S. Wolfbeis, and Vladimir M. Mirsky*

The introduction of in situ synthesis on the surface of solid substrates has resulted in tremendous progress in different fields of science and technology. Immobilized metallic nanoparticles are of particular interest. Their applications include electrocatalysis, data storage systems, new electronic devices, electrochemical chemo- and biosensors, and refractometric and fluorescent sensors based on plasmon effects.[1–4] The strategies for the preparation of these systems are mostly based on the deposition of presynthesized nanoparticles with[5] or without[6,7] further treatment. So far the particles have been deposited mostly by the electrospray technique[8] or by adsorption,[6,9] and only a few techniques based on the in situ synthesis of nanoparticle have been tested. Such a synthesis is possible by electroless deposition or by electroplating. The electroless deposition of nanoparticles was used for the deposition of gold, silver, nickel, palladium, copper, and cobalt nanoparticles onto different substrates.[1,2,10,11] Deposition by electroplating was used for formation of bulk phases of nanocrystalline metals by the reduction of corresponding salts in ionic liquids.[12,13] Formation of metallic nanoparticles by electrochemical reduction on the tip of a scanning tunneling microscope (STM) followed by transfer to planar metal electrodes was reported[14,15] and then reproduced by other groups.[16] Here, we describe an alternative approach for the preparation of metallic nanoparticles on electrode surfaces that does not require STM. Our approach is based on the reduction of metals on nanoelectrodes formed by the recently developed spreader-bar technique.[17]

We tested the approach for the deposition of platinum and copper nanoparticles but do not see any principal limitations for its extension to other conductive or semiconductive materials such as metals, electrochemically synthesized polymers, and nanocomposites. The size of the nanoparticles can be controlled by the value of the reduction charge. In the present work the nanoparticles are between 20 and 1000 nm, but smaller particles are most likely possible.

The spreader-bar technique[17] is based on the coadsorption of two types of molecules: long-chain matrix molecules and large rigid planar molecules (templates or molecular spreader-bars). This results in the fabrication of heterogeneous monomolecular film in which the spreader-bar moieties are imbedded in the matrix. In contrast to two-dimensional molecular imprinting, the structures formed by this technique are permanently stable, because the spreader-bar molecules remain in the monolayer. This approach was successfully applied to generate stable artificial receptors for different purines and pyrimidines.[18] Also, the formation of enantioselective receptors was reported.[19] In the present work, the spreader-bar approach was used to design a nanostructured self-assembled monolayer (SAM) consisting of insulating matrix (long-chain alkylthiols) with incorporated conductive "islands" (large, planarly adsorbed molecules). Then, metals were deposited onto the heterogeneous film by reduction. Since the density of the electrical current through the spreader-bar molecules was much higher than through the insulationg alkylthiol environment, metallic nanoparticles formed.

The monolayer was formed on the gold substrate by coadsorption of 1-dodecanethiol (C12) and a thiolated derivative of tetraphenylporphyrin (TMPP, Figure 1), a large planar rigid molecule with an extended π-electron system. The ratio of C12 to TMPP in the solution was varied. The deposition time was 72 h, which is far beyond the kinetic limit for surface–solution exchange of thiolated compounds on a gold surface.[20] Therefore one can expect a quasi-equilibrium ratio of the template and matrix molecules in the film.

The structure and the composition of the mixed C12/TMPP monolayers were analyzed by near-edge X-ray absorption fine-structure (NEXAFS) spectroscopy, X-ray photoemission spectroscopy (XPS), and X-ray absorption spectromicroscopy (XAM). The XPS and NEXAFS data (Figure 2a and Figure 3) indicate that the amount of TMPP in the mixed film can be precisely adjusted by the composition of the solution. The monolayer formed from the C12/TMPP (1:10 000) solution contains only TMPP moieties, that from the 1:1000 solution is mostly TMPP with only a few percent of C12, that from the 1:100 solution contains a minor amount of TMPP, and that from the 1:10 solution consists exclusively of C12 moieties. According to the NEXAFS difference curves (Figure 2b), the TMPP molecules in both the one-component and the mixed films have an in-plane (strongly inclined) orientation. XAM data (not shown) demonstrate that these molecules are incorporated individually into the C12 matrix and do not form clusters.

Figure 1. Electrochemical preparation of platinum nanoparticles on a template SAM made up of dodecanethiol (C12) and TMPP.
Figure 2. a) NEXAFS spectra (carbon K-edge, $\theta = 55°$) of SAMs formed from one-component and mixed solutions of TMPP and C12. b) Corresponding difference spectra for X-ray incidence angles of $\theta = 90°$ and 20°. A continuous variation of the spectra and difference curves with the solution composition (C12/TMPP) is observed, which indicates the formation of a mixed monolayer of variable composition. The π_1^* resonance at 285.1 eV (TMPP) and R* resonance at 287.7 eV (C12) are characteristic for these two molecules in the TMPP/C12 film. The one-component TMPP film contains contamination as, for example, evidenced by the $\pi(C^*=O)$ resonance at 288.5 eV.

Figure 3. XPS spectra (sulfur 2p orbital, $h\nu = 400$ eV) of SAMs formed from one-component and mixed solutions of TMPP and C12. In the film formed from pure TMPP, two doublets arising from the thiols (a binding energy of 162.0 eV for S $2p_{3/2}$) and sulfones (a binding energy of 168.5 eV for S $2p_{3/2}$) are observed. The occurrence of the thiol-related doublet implies the chemical anchoring of the TMPP species to the substrate. Because C12 films do not contain sulfones (see the bottom spectrum), the sulfone-related peak can be considered as a fingerprint of TMPP and used to monitor the composition of the TMPP/C12 films.

A similar large planar molecule but without thiol anchor groups (Al-PC) was also tested as a spreader-bar. Because of the 12 conjugated aromatic rings in this molecule and the presumed strong π interaction with the metal substrate, we hoped that it would adsorb in a planar fashion even without gold–thiolate binding. In fact, the immersion of a gold substrate in a one-component Al-PC solution led to a highly oriented film consisting of two to three molecular layers. However, when a two-component Al-PC/C12 solution was used, even with a 100-fold excess of Al-PC, the Al-PC molecules were completely expelled by the C12 species and a one-component C12 SAM formed. This result demonstrates that even large planar molecules with extended π-electron systems but without anchor groups do not form mixed monolayers with alkanethiols on deposition under quasi-equilibrium conditions.

The designed architecture and stability of the C12/TMPP nanostructures were exploited for the selective reduction of platinum into the nanopores formed by the spreader-bar TMPP molecules. Metal nanoparticles were visualized by electron microscopy. Depending on the reduction charge, the size of the nanoparticles could be varied between 20 and 1000 nm (Figure 4): an increase in the reduction charge led to an increase in the mean size of the particles and a decrease in their surface concentration. Presumably, an increase of the reduction charge results in the fusion of smaller particles due to secondary nucleation. This is confirmed by the increased roughness of the particle surface (Figure 4).

The total area of the formed platinum nanoelectrodes was estimated by underpotential deposition of copper; the respective charge density was 920 μC cm^{-2}. If one takes into account the usual surface scaling factor of 420 μC cm^{-2}, the surface area is about 220% of the geometrical electrode area. Such a high increase in the surface area can be obtained only for nanoparticles having high surface roughness. Similar
Figure 4. SEM images of platinum particles formed electrochemically on gold electrodes coated by the nanostructured TMPP/C12 monolayer. The deposition charge was 41 C m^{-2} (left) and 160 C m^{-2} (right). The observed differences in contrast are caused by different detectors and accelerating voltages.

experiments were performed with gold electrodes coated with a pure matrix monolayer (C12). Platinum deposition on such electrodes resulted in widely spaced large metallic islands. For example, the particles generated on C12-coated electrodes by the deposition charge similar to the system presented in the right panels of Figure 4 were as large as 10 μm. We assume that these particles were formed at borders of gold microcrystals or on other defects in the monolayer.

We have described a new nanoelectrochemical approach for the in situ synthesis of metallic nanoparticles. To our knowledge this is the first application of spreader-bar-stabilized nanostructured monomolecular films as templates for electrochemical synthesis. This new bottom-up technology does not require expensive instrumentation and can be easily transferred to industrial applications. Possible application fields include the development of novel (electro)catalysts, (bio)fuel cells, chemo- and biosensors, and nanoelectronic devices. Preliminary experiments have confirmed the high electrocatalytic activity of platinum nanoparticles formed on the spreader-bar-structured electrode in the electrochemical oxidation of ascorbic acid.

Experimental Section

1-Dodecanethiol (C12, Sigma-Aldrich) was used without further purification. TMPP (Porphyrin Systems) was fabricated from a precursor, 5,10,15,20-tetrakis(4-sulfonatophenyl)porphyrin. The sulfonato groups of the latter compound were chemically reduced to thiol groups by triphenylphosphine and iodine;[21] XPS detected two thiol groups per TMPP molecule. The substrates were fabricated by evaporation of gold (200 nm) on Si(100) wafers precoated with a Ti/Pd adhesion layer (5 nm). The SAMs were prepared at room temperature by immersing the substrates for 72 h in an ethanol (Baker) solution of C12 and TMPP. The TMPP concentration in the solution was varied from 15 μmol L^{-1} to 15 mmol L^{-1} while that of C12 was maintained at 1.5 μmol L^{-1}.

The SAMs were characterized by XPS, NEXAFS spectroscopy, and XAM (room temperature, UHV conditions). The XPS and NEXAFS measurements were carried out at the HE-SGM beamline of the synchrotron storage ring BESSY II in Berlin, Germany. The energy resolution was ≈ 0.40 eV, and the binding energy scale was referenced to the Au $4f_{7/2}$ peak at 84.0 eV. The NEXAFS spectra were collected at the carbon K-edge in the partial electron yield mode with a retarding voltage of -150 V. Linearly polarized synchrotron light was used. The X-ray incidence angle was varied to monitor the orientational order within the TMPP/C12 films. The original NEXAFS spectra were normalized to the incident photon flux. The energy scale was referenced to the π_1^* resonance of highly oriented pyrolytic graphite at 285.38 eV. The spectromicroscopic characterization of the SAMs was performed at a microscopy branch (7.3.1.1) of the beamline 7.3.1 at the Advanced Light Source in Berkeley, USA, using an X-ray photoelectron emission microscope, which was operated in the total electron yield acquisition mode and provided a spatial resolution of typically 50–100 nm.

C12/TMPP SAMs for the metal deposition were fabricated at a TMPP concentration of 1.5 mmol L^{-1}. Electrodeposition of platinum on these templates was performed at a constant potential of -25 mV vs SCE from 2.5 mmol L^{-1} H$_2$[PtCl$_6$] in 50 mmol L^{-1} KCl. Electrochemical measurements were conducted with AutoLab-PG-stat-12 Electrochemical Workplace (EcoChemie, The Netherlands). SEM measurements were conducted with a LEO SUPRA35 scanning electron microscopy. Other experimental details are described elsewhere.[17–19, 22–26]

Communications

ously loses this information. A distinguishing feature in the intramolecular transfer of central chirality is the distance between the source and the target of the chiral information. While relatively many examples of 1,3-chirality transfer exist,[2] which are mainly based on the transfer of chirality along an allylic system, there are only a few examples of 1,2-chirality transfer.[3]

Some time ago we developed the concept of spin-center shift,[4,5] which provides a completely new access to cyclopropanes. In contrast to the classical Norrish–Yang reaction,[6] phenyl ketones **1** with a suitable leaving group X in α position are used. At the stage of 1,4-diradicals **2** this results in a shift of the radical center from the carbonyl C atom to the adjacent C atom as a result of HX elimination. The resulting 1,3-diradicals **3** cyclize with often complete diastereoselectivity and good to very good yields to give cyclopropanes **4** (Scheme 1).[4]

1,2-Chirality Transfer in the Synthesis of Cyclopropanes**

Pablo Wessig* and Olaf Mühling

In the last few years organic photochemistry has made remarkable progress in the area of asymmetric synthesis.[1] A range of new strategies has been developed that drastically enhance the diastereo- and enantioselectivity of certain photochemical processes. Here we report on an entirely novel concept concerning the synthesis of enantiomerically enriched cyclopropanes based on a photochemically induced intramolecular 1,2-chirality transfer.

During chirality transfer a prochiral moiety incorporates the chiral information of a chiral moiety, which simultane-

Scheme 1. The principle of spin-center shift in the synthesis of cyclopropanes.[4] ISC = intersystem crossing.

By extensive quantum chemical calculations we could elucidate details of the mechanism and found that the leaving group X already has a significant impact on the first reaction step, the photochemical H-shift (**1**→**2**, Scheme 1).[4] Owing to hyperconjugation between the σ* orbital of the C−X bond and the π system of the excited carbonyl group, X prefers a pseudoaxial arrangement with respect to the approximately chairlike six-membered transition state.[4b] If we consider enantiomerically pure ketones of type **5** with two identical substituents in β position, we can formulate two different transition states for the γ-H abstraction (**TS-5a** and **TS-5b**), which differ in the arrangement of the leaving group X (axial or equatorial, Scheme 2). Based on the quantum chemical calculations,[4b] **TS-5a** with X in the axial position should be favored over **TS-5b**. In **TS-5a** the γ-methylene group is attacked, whereas in **TS-5b** the attack takes place at the γ′-methylene group, which means that the carbonyl oxygen atom must distinguish between the two diastereotopic methylene groups. During the photochemically induced H-transfer and the following elimination of HX, the enantiomeric diradicals **6a** and **6b** are formed, and the chiral information of the α-C atom has been transferred to the adjacent prochiral β-C atom (1,2-chirality transfer). Consequently, after the cyclization the enantiomeric cyclopropyl ketones (R)-**7** and (S)-**7** are obtained, whereby the formation of (R)-**7** should be favored over (S)-**7**. Thus, during such a process desymmetrization relative to the methylene groups (γ and γ′) takes place.

Scheme 2. The concept of 1,2-chirality transfer in ketones **5** (simplified representation). The configuration designations are relative to C-β.

The concept shown in Scheme 2 should in principle be applicable to all ketones of type **5** carrying two identical substituents in β position. It can be expected that bridging between the substituents R, in other words, a conformational constraint in flexibility, creates the best situation for an efficient 1,2-chirality transfer. Therefore, for our investigations we chose systems in which the atoms β, γ, and γ′ (Scheme 2) are part of a saturated six-membered ring.

To verify the concept shown in Scheme 2 we first of all needed an efficient method for the synthesis of enantiomerically pure ketones of type **5**. As sulfonates were found to be suitable leaving groups,[4] the retrosynthetic analysis of **5** led to α-hydroxy ketones. Various methods for the synthesis of enantiomerically pure α-hydroxy ketones are known, whereby oxidative methods starting from the ketones or their enol ethers are the most common.[7] Based on the results of Sharpless et al.[8] and Kirschning et al.,[9] we developed a very efficient sequence for the synthesis of enantiomerically pure α-hydroxy ketones. The sequence starts with aldehydes **8** and **9**, which provide the enantiomerically pure α-hydroxy ketones **10** in only a few very efficient steps. The key step in this synthetic sequence is a Horner–Wadsworth–Emmons olefination (HWE), which is followed by an asymmetric dihydroxylation (AD) of enol ethers **11**. It should be pointed out that this very reliable method delivers α-hydroxy ketones **10** in high enantiomeric excesses and generally unaffected by R (Table 1). Furthermore the configuration of the product can be determined by the choice of the ligand during the AD (AD-mix-α or AD-mix-β).[10] Tosylation of **10** with tosyl anhydride finally yields ketones **12**.

Irradiation of the ketones **12** delivers the cyclopropyl ketones **13** in good yields and in part with considerable enantiomeric excess (Scheme 3, Table 1). It should be pointed out that the stereoselectivity obtained in the formation of **13** exclusively reflects the efficiency of the 1,2-chirality transfer, whereas the asymmetric induction of the chiral center in the β position of diradicals **6** on the two newly formed chiral centers

Table 1: Results of irradiation of **12a–d** to give **13a–d**.[a]

leads to the formation of the *exo* products **13** with complete selectivity (Scheme 2).[4]

To verify the postulated stereochemical course depicted in Scheme 2 it was necessary to determine the absolute configuration of compounds **13**. Particularly predestined for conformationally rigid molecules of type **13** is vibrational circular dichroism (VCD).[11] By this method, which is based on the comparison of experimental and calculated VCD spectra, we succeeded in unambiguously determining the absolute configuration of **13a,b,d**.[12]

Since lowering the reaction temperature, also in photochemical reactions, often leads to an increase in stereoselectivity, we examined the temperature dependence of the stereoselectivity. In Figure 1 the relevant Eyring plots $(\ln([(R)\text{-}\mathbf{13a}]/[(S)\text{-}\mathbf{13a}]) = f(T^{-1}))$ are shown for irradiation in dichloromethane and methanol.

Surprisingly, we found in both solvents increasing stereoselectivity with increasing temperature and decreasing stereoselectivity with decreasing temperature, starting from room temperature. This behaviour, which has already been observed in other thermal and photochemical reactions,[13–15] seems to be contraintuitive at first but can be explained easily. The preferred formation of one enantiomer during an
Figure 1. Eyring plots for the irradiation of **12a**. A = (*R*)-**13a**, B = (*S*)-**13a**. Inset: $\Delta\Delta H^{\neq}$ values in kcal mol^{-1}, $\Delta\Delta S^{\neq}$ values in cal mol^{-1} K^{-1}, $T_0 = \Delta\Delta H^{\neq}/\Delta\Delta S^{\neq}$ in °C.

unimolecular reaction like **12**→**13** is based on a difference in the free enthalpy of activation $\Delta\Delta G^{\neq}$, which in turn is the sum of an enthalpic and an entropic term ($\Delta\Delta G^{\neq} = \Delta\Delta H^{\neq} - T\Delta\Delta S^{\neq}$, Gibbs–Helmholtz equation). Thus, the stereoselectivity of such a reaction is always a function of temperature if the entropies of activation of the two channels of selectivity are different. A special situation occurs if the differences of the enthalpies of activation $\Delta\Delta H^{\neq}$ and the entropies of activation $\Delta\Delta S^{\neq}$ have the same sign. In this case a temperature $T_0 = \Delta\Delta H^{\neq}/\Delta\Delta S^{\neq}$ exists, at which the selectivity is inverted.

We observed exactly this behavior when we irradiated compound **12a** (Figure 1). For the reaction in dichloromethane as well as in methanol, $\Delta\Delta H^{\neq}$ and $\Delta\Delta S^{\neq}$ have the same sign, so that in both cases a temperature T_0 can be calculated, at which **13a** is formed as a racemic mixture and below which the formation of the other enantiomer is favored ((*R*)-**13a**, Scheme 3). While for methanol this temperature lies at an experimentally impractical region (−104°C), for dichloromethane it is −23°C. The selectivity for the formation of **13** at room temperature is determined by the entropies of activation, which compensate the enthalpic influence. Only below T_0 do the differences in the enthalpies of activation determine the selectivity.[16]

In summary, we have described a novel concept for a 1,2-chirality transfer. The mechanistic basis is the preferred colinear arrangement of a leaving group and the π system of a photochemically excited carbonyl group, which can be explained by stereoelectronic effects.[4b] We were able to demonstrate this concept by means of the photochemical cyclization of four ketones **12a–d** to the bicyclic compounds **13a–d**. The configuration of the preferred enantiomer at room temperature has been determined easily for the photolytic products **13a,b,d** by a combination of quantum chemical calculations and VCD spectroscopy. Because both the differences of the entropies of activation and the enthalpies of activation are positive, the stereoselectivity increases at temperatures above T_0. On the other hand, at temperatures below T_0 the ratio of the enantiomers is inverted, and

selectivity increases with decreasing temperature in favor of the other enantiomer. This behavior can be explained by the compensation of entropic and enthalpic influences. At low temperatures, the *R*-configurated reactants **5** always lead to the products with *R* configuration at C-β, which is consistent with our prediction (see Scheme 2).

Cover Picture

Kit T. Rodolfa, Andreas Bruckbauer, Dejian Zhou, Yuri E. Korchev, and David Klenerman*

The persistence of Edgar Degas is illustrated in the formation of highly complex, graded, 'two-color' images on the submicron scale. Two species can be delivered independently from a single pipette through the use of scanning ion-conductance distance control. The cover picture shows biological molecules being delivered in air through a liquid meniscus at the tip of a double-barreled nanopipette (Salvador Dali, not to scale, is shown painting the Degas Dancers with a nanopipette) as described by D. Klenerman et al. in their Communication on page 6854 ff.

Combinatorial Catalysis

In many reactions catalysts with bidentate ligands yield the best results. In his Minireview on p. 6816 ff., B. Breit describes how these chelates can be emulated by two monodentate ligands held together by attractive interactions.
Natural Product Discovery

How are leads for drug development identified? In their Review on page 6828 ff., H. B. Bode and R. Müller describe the identification and manipulation of biosynthetic pathways towards new natural products and derivatives potentially suitable for this task.
Cluster Compounds

In their Communication on page 6848 ff., L. F. Dahl, E. G. Mednikov, and co-workers describe the synthesis and structural characterization of two new large palladium–carbonyl–triethylphosphine clusters that contain Pd_{52} and Pd_{66} cores.

Books

Highlights

Chemical Bonding

1.579 Å

To be or not to be (a bond, that is)? Recent progress in X-ray charge-density analysis is discussed with emphasis on the characterization of unusual bonding situations, such as the recently reported C—C "bonding" interaction in a [1.1.1]propellane (see structure).

Asymmetric Catalysis

1 → **2** 99% yield, 98% ee
Ketene esterification after 100 years: In the latest advance in the esterification of ketenes, Schaefer and Fu described the catalytic asymmetric conversion of 2-tolyl(ethyl)ketene (**1**) and diphenylacetaldehyde to give the enol ester **2** in 99% yield and 98% ee (see scheme).

Minireviews
Ligands scoot together: Noncovalent attractive interactions between ligands in the coordination sphere of a metal center lead to a situation typical for complexes with classical bidentate ligands (see picture). In tests with catalyzed reactions these self-assembled systems gave results comparable to those obtained with complexes having classical bidentate ligands.

Reviews
Increasing genomic information together with new tools in molecular microbiology have led to powerful and rational applications in natural product research (see picture). Today, it is possible to produce novel and altered secondary metabolites with biological activity.

Communications

Room for one more? The structures of nanosized Pd_{52} and Pd_{66} clusters that are based upon a common Pd_{38} vertex-truncated ν-octahedral kernel have been determined. The 45 CO ligands in the Pd_{66} cluster (see core structure), $[Pd_{66}(CO)_{45}(PEt_3)_{16}]$, are described in terms of one extra and 44 normal ligands, two of which undergo rearrangement to accommodate the 45th CO ligand without causing any substantial changes to the architecture of the metal core.

Pretty as a picture: The printing of highly complex graded images with two different species (see picture) has been developed through the use of double-barreled pipettes. This method of submicron deposition of biomolecules eliminates registry problems that are inherent to other deposition techniques.

A combination of techniques (Mössbauer and X-ray absorption spectroscopy, H$_2^{18}$O exchange experiments, and DFT calculations) has shown that the reaction of [Fe(H$_2$O)$_6$]$^{2+}$ with ozone generates [(H$_2$O)$_5$Fe^{IV}=O]$^{2+}$ (see calculated structure). The oxidation of selected substrates with [(H$_2$O)$_5$Fe^{IV}=O]$^{2+}$ yields unique products that are different from those generated in the Fenton reaction or derived from HO• radicals.

H Box: The clusters [Rh$_6$(PR$_3$)$_6$H$_{12}$][BAr$^F_4$]$_2$ (R = cyclohexyl, *i*Pr; see scheme, pink Rh, orange P) reversibly take up two molecules of H$_2$ under ambient conditions (1 atm H$_2$, 298 K) to give discrete octahedral clusters surrounded by 16 hydride ligands.
Crystals with broad robust channels are rare, especially if self-assembled without the aid of metal ions. Three such crystals were prepared based on a common steroid motif. The channels formed are chiral, directional, aligned, and wide enough (> 1 nm) to accept a variety of guests (see picture; red: oxygen, blue: nitrogen, green: fluorine).
Microporous: Chiral metal complexes as templates under solvothermal conditions resulted in two novel germanates Ni@Ge$_{14}$O$_{24}$(OH)$_3$·2 Ni(L)$_3$ (L = ethylenediamine, 1,2-diaminopropane). The chiral Ni@Ge$_{14}$O$_{24}$(OH)$_3$ cluster motifs have an unprecedented trigonal-bipyramidal Ni@Ge$_5$ core with Ni—Ge bonds and are linked to each other to form a 3D germanate framework containing 24-ring channels (see picture).
A homogeneous catalytic complex is tagged with two ferrocenyl groups to control its solubility properties by reversible switching between its neutral and dicationic states (see scheme). This approach is carried out on an olefin- metathesis catalyst and is shown to effectively switch its catalytic activity on and off; furthermore, efficient separation of the catalyst from the reaction products and subsequent recycling of the catalyst is possible.
Getting a grip on the flu: A mechanism-based probe, **1**, for neuraminidase was developed. It is capable of forming a biotinylated adduct with neuraminidase (NA) from *Arthrobacter ureafaciens*. It also displays an inhibitory effect on a number of NA activities. ELISA experiments successfully demonstrated that influenza viruses can be selectively captured with this probe.
An auraoxetane, obtained from the reaction of norbornene with a gold(III) oxo complex, has been isolated and fully characterized (see structure). Action of the olefin leads to elimination of the epoxide from the auraoxetane.

The isolation and intramolecular cyclization of (S)-(1-alkynyl)isothiouronium and (S)-(1-alkynyl)thiobenzimidonium salts suggest the mechanism for the one-pot synthesis of 2,4-disubstituted thiazoles (see scheme; Ms = methanesulfonyl): Michael addition of sulfur nucleophiles to hypervalent iodanes followed by the 1,2-rearrangement of sulfenyl groups in the resulting alkylidene carbenes.

Contents

Interaction over a distance: Long-range antiferromagnetic interactions between distant copper(II) and silver(II) ions are observed only for triply and singly linked diporphyrins with at least one β–β bond, which underscores the critical importance of this direct bond for antiferromagnetic coupling. These results can be qualitatively accounted for in terms of the spin distribution of copper(II) and silver(II) porphyrins (see picture).
A rational building-block approach was employed to construct organometallic/ polyoxometalate (POM) hybrids in which POM clusters and transition-metal complexes are linked by a π-conjugated bridge. The synthetic strategy for molecular and polymeric hybrids—POM functionalization with iodo-bearing groups, attachment of a terpyridine-type ligand, and metal coordination—is shown schematically in the picture.
Mixed-ion and electron-conducting perovskite membranes are used to produce oxygen-enriched air (see picture). These membranes are thermally and mechanically stable at high temperatures ($> 875\,°C$) over a long period of time, thus making them suitable for industrial processes. Oxygen concentrations of the enriched air typically reach 30–50 vol%.
To twist or not to twist? A ditopic ligand, L^1, that contains a potentially tetradentate pyridyl–thiazole ligand chain and a "external" crown ether unit is presented. Reaction of L^1 with Cu^+ or Zn^{2+} ions results in the formation of a dinuclear double helicate $[Cu_2(L^1)_2]^{2+}$ or a mononuclear $[ZnL^1]^{2+}$ species. This ditopic system changes its preference for Cu^+ or Zn^{2+} ions on the inclusion of s-block-metal ions at the crown ether binding site (e.g., Sr^{2+} ions as shown in the scheme).

Synthetic Methods
An air-stable, heterogeneous, and recyclable catalyst composed of palladium nanoparticles entrapped in aluminum hydroxide was applied to a highly selective α alkylation. A wide range of aliphatic and aromatic ketones and primary alcohols were coupled to prepare enones in an O_2 atmosphere and ketones in an argon atmosphere (see scheme).

M. S. Kwon, N. Kim, S. H. Seo, I. S. Park, R. K. Cheedrala, J. Park* —— **6913–6915**

Recyclable Palladium Catalyst for Highly Selective α Alkylation of Ketones with Alcohols

Biomimetic Complexes
A highly specific and catalytic oxidation of water occurs when using a dinuclear Mn complex of a mononegative carboxylate-containing pentadentate ligand (see scheme). Isotope-labeling experiments coupled with membrane inlet mass spectrometry show that one oxygen atom in the evolved O_2 molecule is derived from water and the other from the oxidant.

A. K. Poulsen, A. Rompel, C. J. McKenzie* —————— **6916–6920**

Water Oxidation Catalyzed by a Dinuclear Mn Complex: A Functional Model for the Oxygen-Evolving Center of Photosystem II

Magnetic Resonance Imaging

A europium complex capable of selectively binding zinc (see picture) has been developed as a new paramagnetic chemical exchange saturation transfer (PARACEST) imaging agent for use in magnetic resonance imaging (MRI). A hydroxide group on the bound Zn ion increases the rate of water exchange on the Eu ion.
R. Trokowski, J. Ren, F. K. Kálmán, A. D. Sherry* —————— **6920–6923**

Selective Sensing of Zinc Ions with a PARACEST Contrast Agent

Asymmetric Catalysis
Stereochemical alchemy! Racemic allyl β-ketoesters allow the regiocontrolled formation of enolates, where the same catalyst is intimately involved in both the stereoablative (C–C bond-breaking) and stereoselective (C–C bond-forming) steps. This mechanistic and practical insight led to the formation of multiple quaternary carbon stereocenters in a single cascade reaction (see scheme).

J. T. Mohr, D. C. Behenna, A. M. Harned, B. M. Stoltz* —————— **6924–6927**

Deracemization of Quaternary Stereocenters by Pd-Catalyzed Enantioconvergent Decarboxylative Allylation of Racemic β-Ketoesters

Contents

Structural transition from type I to type II is accompanied by a large increase in lattice constant a in $CH_4 + C_2H_6$ clathrate hydrates (see picture). In contrast, the lattice constants of $CH_4 + CO_2$ clathrate hydrates are independent of composition. Data for a natural gas hydrate from the sediments of Lake Baikal are also consistent with these trends.
Versatile intermediates for the synthesis of N-aryl-α-amino acids and N,N-disubstituted 1,2-diamines can now be synthesized with high efficiency by the ruthenium-catalyzed oxidative cyanation of tertiary amines. The use of hydrogen peroxide as an oxidant in the presence of NaCN/AcOH or HCN provides the corresponding α-aminonitriles (see reaction).
Promising building blocks: High-density radially-oriented amorphous silica nanowires standing on a single-crystal Si nanocore were synthesized by simple thermal evaporation of silicon with tin as catalyst. The growth process (see schematic picture) appears to involve concurrent vapor–liquid–solid and oxide-assisted growth mechanisms. Scanning electron micrographs corresponding to **1** and **2** are also shown.
Two tags are better than one: Sixteen individual stereoisomers of murisolin (see scheme) are synthesized together and isolated in pure form with the aid of a double-separation tagging procedure. A strategy for solution-phase stereoisomer synthesis based on double-separation tagging and double demixing is implemented with fluoroalkyl and oligoethylene glycol (OEG, (OCH$_2$CH$_2$)$_n$OCH$_3$) tags.
When excess charge is deposited on thymine and uracil by resonant attachment of low-energy electrons (0–3 eV), H atoms are cleaved exclusively from the N positions. This bond selectivity can be made site selective (N1 vs. N3 position) by properly tuning the electron energy. This conclusion was drawn from experiments with methylated thymine and uracil (see picture) in crossed beam experiments.

Optical control of the photo- and electro-chemiluminescence of a brightly fluorescent reporter group is possible by switching between the photochromic units of dyads **1a** and **1b**. Irradiation, that is, writing in information, with UV light converts the highly luminescent dihydroazulene **1a** into the weakly emissive vinylheptafulvene **1b**. Readout of the system can be performed by either electrochemically generated or photogenerated luminescence.
Out of thin air, a rhodium complex converts molecular oxygen into hydrogen peroxide, bis(trimethylsilyl) peroxide, and methyl hydroperoxide. Intermediate η^1-hydroperoxo and η^1-silylperoxo, and η^1-methylperoxo complexes have been isolated. Another η^1-methylperoxo (see picture) and an η^1-hydroperoxo complex have been characterized by X-ray crystallography.
In one go: (Hetero)aryl iodides, alkynes, carbon monoxide, and amidines can be assembled in a consecutive four-component reaction to give pyrimidines by a sequence of carbonylative alkynylation and cyclocondensation. Carbonylative alkynylation also is the key step in the two-step syntheses of meridianins and meridianin derivatives.

Contents

Polyhedral Al halides: Four halogen atoms directly coordinated to an Al_{12} icosahedron in two structurally characterized Al_{20} clusters indicate the mechanism of formation of $Al_{22}X_{20}$ subhalides. No Al atom is located in the center of the icosahedron in either of these icosahedral compounds!

Meeting Reviews

### The Diverse World of Silicon Chemistry**

Guido Kickelbick*

Besides carbon, the only other element that reveals a similarly rich chemistry is silicon, spanning classical main-group to organometallic to materials chemistry, biochemistry and biotechnology, as well as theoretical chemistry. Although both elements have many properties in common, silicon often reveals a remarkably different reactivity compared to carbon. The extraordinary properties of silicon and the large variety of products that can be prepared given its similarity to carbon make it not only a prominent element in academic research but also in industry, where its value has been recognized, for example, in polymers and as a semiconductor material.

The particular reactivity of silicon and its highly innovative chemistry are also reflected by the fact that a conference series celebrated its 40 year tradition, namely, the 14th International Symposium on Organosilicon Chemistry. Hundreds of scientists gathered in Würzburg (Germany) to discuss ground-breaking news in the field of silicon chemistry. For the first time, this meeting was held in conjunction with the European Organosilicon Days. The exceptional characteristic of this meeting series was the close contact between scientists from both academia and

[**] 14th International Symposium on Organosilicon Chemistry (ISOS XIV) in conjunction with the 3rd European Organosilicon Day in Würzburg (Germany), 31st July to 5th August, 2005.

industry as well as the variety of research from both areas, as evident from the composition of the lecture program which covered all of the above-mentioned aspects of silicon chemistry. The scientific program included more than 150 talks and over 220 posters.

Silicon chemistry still is mainly driven by the interest to compare the similarities and differences in its reactivity relative to that of carbon. A major challenge is the synthesis of Si—Si multiple bonds. A pioneer in this area is Mitsuo Kira (Tohoku University, Sendai, Japan), who presented an overview of the latest developments in the field of dialkylsilylenes and Si=Si double-bonded compounds, such as spiropentasiladiene and trisilaallene (Scheme 1). Kira and co-workers suc-
Scheme 1. Some extraordinary Si compounds produced by Kira's group.[1]

ceeded in isolating stable disilene in the form of the silicon analogues of cyclopropene and cyclobutene.[1] Further highlights from Kira's laboratory were the first stable compound with a formal sp-hybridized silicon atom, cross-conjugated Si=C compounds, and 1,3-disilabicyclo[1,1,0]butane as the first isomer with an inverted bridged Si—Si bond. In honor of his pioneering work in this field, Kira was awarded the 2005 Wacker Silicon Award in Würzburg.

Research in the field of silicon-containing polymers is currently fuelled by an interest in controlling their composition and morphology as well as the patterning of materials by using macromolecules. Ian Manners (University of

Toronto, Canada) revealed the many possible applications of polyferrocenylsilanes. These metal-containing polymers that are produced by ring-opening polymerization reveal a controllable structure, which facilitates the control over their self-organization. The resultant supramolecular metal-containing structures can be used, for example, as magnetic materials. Application of UV photolithography allows the use of polyferrocenylsilanes for the patterning of thin films, which can be additionally metalated by binding cobalt carbonyl compounds.[2,3] Catalytic cross-dehydrocoupling reactions of silanols and silanes represent a route to novel siloxane-based polymers. Yusuke Kawakami (Japan Advanced Institute of Science and Technology, Nomi, Japan) and co-workers have used tris(pentafluorophenyl)borane as an effective catalyst for the synthesis of such polymers.[4] Patterning of silicon-based materials is regularly carried out by applying the self-organization of amphiphilic macromolecules. Ulrich Wiesner (Cornell University, Ithaca, USA) and his team make use of the organization of amphiphilic block copolymers in complex three-dimensional structures as templates to perform chemistry in the formed domains. By application of this method, it is possible to produce three-dimensional silica-based structures as well as SiCN- and SiC-based systems, which can be viewed as the reproduction of the previously formed structures.[5,6]

Nicola Hüsing (University of Ulm, Germany) demonstrated new possibilities of the structuring of sol–gel-based materials using tetrakis(2-hydroxyethyl)silane as precursor, which releases glycol instead of an alcohol during hydrolysis and condensation.[7] The use of a drying process, which leads to a more-hydrophobic surface, helps to produce highly porous monoliths.[8] Besides pure oxidic materials, organically modified silsesquioxanes have become an important topic of research in recent years. Speculations that were often reasons for scientific discussion about the structure of ladder-type silsesquioxanes produced by the sol–gel process of

trialkoxysilanes were seen in a new light by Masfumui Unno (Gunma University, Kiryu, Japan) and co-workers. They succeeded in the synthesis of oligomeric silsesquioxanes with control over the stereochemistry.[9] Besides ladder-type structures, cage-type silsesquioxane are used as precursors for nanocomposites in materials chemistry. For example, Gion Calzaferri (University of Bern, Switzerland) and his co-workers have used $R-H_7Si_8O_{12}$ to close channels of dye-carrying zeolites and created new photonic devices by this technique.[10] The corners of cagelike silsesquioxanes and spherosilicates can be functionalized through various methods by organic groups. Such molecular building blocks are used by Richard Laine (University of Michigan, Ann Abor, USA) and his group to form three-dimensional nanocomposites.[11]

The controlled formation of nanoparticles is also an important topic in the field of silicon chemistry. Application of novel types of surfactant molecules that contain a citrate head group allowed Michael Brook (McMaster University, Hamilton, Canada) and co-workers to prepare and stabilize silver nanoparticles. Self-organization of the derived systems leads to chains and ellipsoidal rings, as well as structures of higher complexity, such as multilayer bands (Figure 1). Solvent-based methods to produce silicon nanoparticles and functionalize their surfaces in situ were presented by Susan Kauzlarich (University of California, Davis, USA).[12, 13] The particles thus obtained show a photoluminescence that is stable over long periods of time.

Graham Showell (Paradigm Therapeutics Ltd., Cambridge, GB) impressively convinced the audience that organosilicon-based medicinal chemistry can lead to the development of novel drugs. Often this development is based on the selection of proven compounds and the formation of derivatives that contain silicon atoms or silicon-containing groups. Sila substitution (C–Si exchange) in well-known drugs—the formation of so-called bioisosters—is one possibility to search for novel compounds that reveal advantageous biological properties, such as improved pharmacodynamic profiles. Furthermore, this approach can be used to get

Figure 1. Novel surfactant molecules for the production of silver nanoparticles and their supramolecular arrangements, as presented by Brook.

around existing patents and help to minimize costs in pharmaceutical research. Some fundamental differences in the reactivity of silicon compared to that of carbon can also lead to changes in the biological properties of the silicon-containing analogues, and the advantageous differences are exploited in the design of novel pharmaceuticals.[14]

Iain MacKinnon (Dow Corning Ltd., Barry, GB) presented to the predominately academic audience the many industrial applications of functionalized polysiloxanes. He showed industrial solutions for the large-scale production of N-functionalized polysiloxanes, which are used in everyday products such as shampoos, shoe polish, or conditioners. The introduction of organic functional groups to avoid the yellowing of the N-functionalized polysiloxanes was one of the many examples discussed.

The functionalization of silicon surfaces is an important aspect in many

applications as well as being of fundamental chemical interest. Jillian Buriak (University of Alberta, Edmonton, Canada) revealed a selection of chemical reactions at surfaces that differ fundamentally from the molecular chemistry of silicon compounds. One of the methods her group has used is electrografting, which has allowed the covalent attachment of alkynes to H-terminated silicon surfaces by conducting-probe atomic force microscopy (CP-AFM). This method allowed the production of structures with dimensions of less than 30 nm (Figure 2).[15]

Manfred Sumper (University of Regensburg, Germany) introduced the audience to the world of biomineralization, where silicates and the biochemistry of silicon play an important role. The complex and sometimes spectacular shapes of diatoms are an interesting display of Nature. Analysis of the silicate cell walls reveal that they are formed by composites that contain zwitterionic proteins (silaffines) and long-

Figure 2. Application of CP-AFM makes it possible to connect molecules covalently on modified silicon surfaces and to form patterns. Adapted from Reference [15].

chain polyamines together with the inorganic phase. Quaternized ammonium groups seem to play a particular role in these systems.[16] The complex mechanisms of their patterning can be explained by the self-organization processes of polyamines, which act as templates.

ISOS XIV showed how exciting and full of innovation the research into a single element can be, and we look forward again to see how this field develops until the next meeting.

Charge Densities Come of Age

*Philip Coppens**

*I*n 1915, just three years after the discovery of X-ray diffraction by Von Laue, Peter Debye noted that "*the scattering from light atoms should get more attention, since along this way it should be possible to determine the arrangement of electrons in crystals*".[1] Debye's statement preceded the development of quantum mechanics and Born's definition of electron probability distribution, but correctly assumed that the electron distribution was an observable that had become accessible. Interestingly, it took the better part of a century for this vision to be realized and for X-ray charge-density analysis to become a true analytical technique that was capable of providing quantitative insight into controversial issues and sufficiently rapid to be applicable to a series of related problems. In 1990 we wrote, "At present, charge-density analysis is far from a routine technique", pointing out the need for time-consuming collection of large data sets and the limitations in accuracy of the experimental measurements.[2] These limitations have now to a large extent been overcome as a result of the development of more-intense X-ray sources, sensitive area detectors that allow rapid (and redundant) data collection, much improved cryogenic techniques, and last, but not least, the dramatic increase in computing power. As a result, not only has the accuracy improved but the analysis can be fast and precise, as demonstrated by Koritsanszky et al. in 1998 with the determination of accurate

experimental electronic properties of DL-proline monohydrate within 1 day.[3] It illustrates the disappearance of time limitations, making the time required for experimental charge-density analysis comparable with that for theoretical calculations. Of course, the experiment yields the charge density for the molecule in the solid state rather than the isolated molecule or complex, thus incorporating in the case of molecular crystals the small but subtle effects of the molecular environment. It must also be kept in mind that the charge distribution and not the wave function is accessible, a crucial distinction, though recently wave functions derived from experiment have been obtained by constraining Hartree–Fock variational calculations to fit the experimental structure factor amplitudes.[4] However, the theory of "atoms in molecules", as pioneered by Richard Bader, which provides a quantitative link between the total electron density and the all-important physical properties of a molecule, bypasses the wave function in the analysis.[5] Topological analysis of the total density has been exploited to obtain net atomic moments, including charges, and to infer the nature of chemical bonding directly from the electron-density distribution. The chemical bond analysis derives much of its power from the characteristics of the topological bond path between atoms, including the density (ρ) at the bond critical point (BCP) and the Laplacian of the electron density at the BCP and in other regions around the atoms. At the BCP, ρ is a minimum along the bond path but is a maximum along the perpendicular directions.

The results recently reported by Luger and co-workers on the bonding in a [1,1,1]propellane with its inverted

carbon atoms[6] are a culmination of a series of careful studies of charge density on strained hydrocarbons[7] and other small molecules[8] from Luger's laboratory. The work on the propellane addresses the important issue of the nature of this relatively short (< 1.6 Å) C–C interaction, which has been the subject of earlier theoretical[9] and experimental[10] studies. The analysis showed the presence of a bond path between the two inverted carbon atoms with a significant electron density at the BCP, corresponding to a bond order of 0.71, as derived with Bader's empirical relationship, in very good agreement with theory. The agreement is less close for the value of the Laplacian ($\nabla^2\rho(\boldsymbol{r}_{BCP})$) at the BCP, which is much more positive according to the experiment, and indicates a closed-shell rather than a shared interaction. To assess this discrepancy, it must be realized that the experimental Laplacian, being a second derivative, is quite sensitive to the functions used in both the experimental and theoretical analyses. To obtain precise experimental information on a second-derivative function such as the Laplacian, very high order X-ray data would be needed. These are weak or even absent as the X-ray scattering falls off with scattering angle as a result of interference and the effects of thermal motion. The experimental Laplacian may therefore be rather dependent on the functions used in the fitting of the experimental observations.[11] Similarly, the theoretical Laplacian may vary with the nature of the basis set and its completeness. In this context it is relevant that the X-ray refinement on which the static density is based is performed with Slater-type functions, while Gaussian functions are used in the theoretical computation with which comparison is made. So the dis-

agreement between the experimental and theoretical Laplacians in the bridgehead bonds may be less surprising than appears at first glance.

The results from Luger and co-workers may be compared with another unusual C–C interaction. Topological analysis of the experimental electron density of *syn*-1,6:8,13-biscarbonyl[14]annulene (Figure 1),[12] derived from high-resolution data at 19 K, shows a bond path between the two bridgehead carbon atoms across the central ring, as

Figure 1. The *syn*-1,6:8,13-biscarbonyl[14]annulene molecule.[12] The bridgehead carbon atoms between which a bond path was found are indicated by the arrow.

indicated by the arrow in Figure 1, even though the C···C distance is much longer than that for the bridgehead bond in the [1.1.1]propellane (2.593 Å versus 1.579 Å). Also, $\rho(r_{BCP})$ is much smaller for the annulene (0.116(3) versus 1.31(3) e Å^{-3}), whereas the Laplacian $\nabla^2\rho(r_{BCP})$ has a value of 1.53(1) e Å^{-5} for the annulene at the BCP compared to $\nabla^2\rho(r_{BCP}) = 10.3(1)$ e Å^{-5} for the [1.1.1]propellane. In the annulene, no BCPs were found along other transannular lines although the distances are shorter (by about 0.1 Å) than the distance between the bridgehead atoms. Such results demonstrate the need for additional criteria for judging the nature of atomic interactions. Several such criteria have been applied in particular to bonds involving heavier atoms, for which the radial shape of the atomic Laplacian makes this function less useful in characterizing the bonding interaction.[13] In the classification proposed initially by Cremer and Kraka,[14] and extensively applied in later work,[15] covalent interactions are characterized

by local excess of the negative potential-energy density $V(r)$, over the positive kinetic-energy density $G(r)$. Thus the total energy density, $H(r) = G(r) + V(r)$, will be negative at the BCP for covalent bonds. A second, most useful measure is the electron-localization function (ELF),[16] which provides information on the pairing of electrons in the bonding region. This function can be obtained approximately from the experimental density[17] by the use of a functional proposed by Kirshnitz.[18] As the functional is approximate, the experimental ELF is often referred to as the "approximate ELF" (AELF). The AELF contains a number of undesirable artifacts, but its features are in broad agreement with the ELF.[19] A third function that has been successfully used in the analysis of M−M bonding (M = metal) but can only be obtained from the pair density distribution is the delocalization index $\delta(A,B)$ of Bader and Stephens,[20] which corresponds to the number of electron pairs delocalized between atoms A and B. In a combined experimental/theoretical analysis of the M−M bonding in $[FeCo(CO)_8]^-$, Macchi et al. compared the various criteria upon the (hypothetical) fluxional rearrangement of the CO coordination from terminal to bridging.[21] For the Fe−Co bond, $\delta(Fe,Co)$ varies smoothly along the fluxional rearrangement path, even though the topological bond path disappears somewhere along the transition from the terminal to the ligand-supported conformation, which suggests the shortcomings of a sole reliance on the bond path criterion. When the M−M BCP is present, the energy density is small but nevertheless negative.

Clearly, although much progress has been made in recent years, the characterization of the chemical bond is not a closed subject. Experimental studies of unusual bonds, as presented in the recent report by Luger and co-workers, demonstrate how new light can be shed on longstanding issues in chemical bonding.

# Catalytic Asymmetric Esterification of Ketenes**

*Thomas T. Tidwell**

Ester formation by addition of alcohols to ketenes was discovered 100 years ago, when Hermann Staudinger prepared diphenylketene as the first isolated member of this versatile and reactive family, and by reaction with ethanol formed the ethyl ester of diphenylacetic acid.[1a] As soon as unsymmetrical disubstituted ketenes were prepared it became apparent that esterification of these ketenes by alcohols generates a new chiral center, and by 1919 an attempt was made by Weiss to achieve asymmetric synthesis in this reaction, by the addition of the optically active alcohol (−)-menthol to phenyl(4-tolyl)ketene (**1**) [Eq. (1)].[1b] This report at-

tracted considerable attention at the time and was initially accepted, but upon reexamination it was agreed there was no selectivity in the formation of the new stereocenter.[1c–e] This was an un-

suitable substrate and an improbable outcome, as the only difference between the two aryl groups is the 4-methyl substituent in one aryl ring, which would have an imperceptible effect on proton transfer forming the new chiral center. However, the goal of achieving stereoselectivity in ketene esterification has been a major challenge for synthetic chemistry ever since, especially in view of the prominent bioactivity of many 2-arylalkanoic acids that are potentially available by this reaction.

The search for stereoselectivity using this methodology received new impetus with a prominent report of the reaction of phenyl(trifluoromethyl)ketene (**2**) with several chiral alcohols including **3** (Mes = 2,4,6-trimethylphenyl) which formed **4** with significant 53% stereoselectivity, and showed the way to reach the goal envisaged by Weiss [Eq. (2)].[2]
This path for asymmetric synthesis by ketene esterification using chiral alcohols was pursued at the Merck laboratories, where the addition of the chiral alcohol (*R*)-pantolactone (**6**) to ketene **5** was found to give 2-arylpropionate **7** with 99.5% diastereoselectivity [Eq. (3)].[3a] The origins of the selectivity in this reaction have been elucidated by computational means using (*S*) methyl lactate as a model.[3b] Many variations
on this reaction have been reported, including the use of a polymer-bound analogue of pantolactone.[3]

The use of chiral catalysts to induce stereoselectivity in ketene esterification offers an attractive alternative to the use of stoichiometric chiral alcohols to achieve this result, and a major achievement in this quest came in 1960 when the brucine-catalyzed stereoselective addition of methanol to phenyl(methyl)ketene (**8**) forming the ester **9** was reported by Pracejus [Eq. (4)].[4a]
The selectivity was temperature dependent, ranging from 25% *ee* for the *S* ester at −110°C to 10% *ee* for the *R* ester at 80°C.[4a] This was improved to 76% *ee* for the *S* ester when benzoylquinine was used at −110°C.[4b,c] This discovery invited further improvements in the enantioselectivity using new catalysts,[4d–f] but it was a long wait before this was to take place.

Then in 1999 Fu and co-workers introduced a designed catalyst to supplement the use of cinchona alkaloids for the catalytic asymmetric synthesis of esters from ketenes. They reported that addition of methanol to aryl(alkyl)-ketenes **10** catalyzed by the azaferrocene catalyst **11** in the presence of 2,6-di(*tert*-butyl)pyridinium triflate gave up to 80% *ee* in the formation of esters **12** [Eq. (5)].[5a] It was proposed that this

(5)

(+)-**11**
reaction took place by a catalytic cycle with nucleophilic attack of the catalyst on the ketene forming the enolate **13**, which was protonated by the pyridinium triflate to form **14** stereoselectively, and then methanol displaced the catalyst to give the ester **12** [Eq. (6)].[5a]

(6)

This procedure was further improved for the esterification of ketenes **10** by phenols **15** using the second-generation catalyst **16**. Aryl esters **17** were obtained with a selectivity of 35–91% *ee*, and the highest *ee* value was achieved with 2-*tert*-butylphenol [Eq. (7)].[5b] Reactions of a variety of
(7)

(−)-**16**
ketenes with this phenol gave *ee* values of 79–94% and yields of 66–97%. The mechanism proposed for this process is different than that for the addition of methanol and involves deprotonation of the phenol, followed by phenoxide attack on the ketene forming enolate **18**, and proton transfer from the resulting ion pair forming **17** [Eq. (8)].[5b]

(8)
In a novel and unexpected extension of the search for catalyzed stereoselective esterification of ketenes, Schaefer and Fu have now discovered that alkyl-(aryl)ketenes **10** react with the readily enolizable aldehydes **19** and **20** with catalysis by (−)-**16** to give stereoselective formation of enol esters **21** [Eq. (9)].[5c] The reaction of phenyl-

(9)

21

R[1] = H: 55%, 92% *ee*
R[1] = Ph: 84%, 91% *ee*
(ethyl)ketene and diphenylacetaldehyde resulted in the formation of **21** in 84% yield and 91% *ee*. For other ke-

tenes the reaction was even more successful; the reaction of 2-tolyl-(ethyl)ketene gave 99% yield and 98% *ee* (Table 1).[5c]

Two possible mechanisms were proposed for this reaction, namely, initial addition of the catalyst to the ketene giving **22**, which stereoselectively abstracts a proton from the aldehyde giving **23**, which combines with the aldehyde enolate **24** [Eq. (10)]. Alternatively, addition of **24** to the ketene gives **25**, which is converted to **21** by stereoselective proton transfer by the protonated catalyst [Eq. (11)].[5c]

The use of diphenylacetaldehyde (**20**) is a shrewd choice for this reaction, as it exists in the enol form ($pK_a = 9.4$) to the extent of 10% in aqueous solution at 25°C.[6] Interestingly this is the same pK_a as for phenol and suggests that the mechanism of Equation (11), which resembles that of Equation (8) found for phenols, may be preferred.

There is precedent for the O-acylation of ketone enolates by ketenes,[7a–c]

(10)

(11)
Table 1: Stereoselective formation of vinyl esters from ketenes **10** and diphenylacetaldehyde (**20**) [Eq. (9)].[5c]

10		**21**		**10**		**21**	
Ar	R	Yield [%]	*ee* [%]	Ar	R	Yield [%]	*ee* [%]
Ph	Me	74	78	Ph	*t*Bu	96	88
Ph	Et	84	91	2-Tol	Et	99	98

including the involvement of ester enolates in the polymerization of dimethylketene.[7a] Also the reaction of phenyl(ethyl)ketene with lithium pinacolate at $-78\,°C$ followed by warming to $25\,°C$ and protonation with water gave the enol ester **28** in 57% yield, evidently through the intermediacy of the enolate **27** [Eq. (12)].[7c] When the potassium

$$(12)$$
enolate was reacted similarly, the diketone **30** from acylation on carbon was the observed product, indicating the intermediacy of the enolate **29** [Eq. (13)].[7c] Rearrangement of the initially formed enolates was also shown to occur.[7c] Catalyst **16** is reported not to promote rearrangement of the enol esters **21** formed in Equation (9) to 1,3-dicarbonyl compounds.[5c]

The unique features of the work by Schaefer and Fu suggest myriad possible extensions of their work. The enol esters derived from this reaction undergo fac-

$$(13)$$
ile hydrolysis to give chiral carboxylic acids, but this is wasteful of the interesting enol ester functionality contained in the molecule. Possibly stereoselective addition to the carbon–carbon double bond of the esters generating useful new functionality could be achieved. Other easily enolized carbonyl functions such as 1,3-dicarbonyl compounds or fluorinated ketones may be susceptible to this methodology. Further progress in this area can be expected.

Supramolecular Approaches to Generate Libraries of Chelating Bidentate Ligands for Homogeneous Catalysis

Bernhard Breit*

The process of catalyst discovery and development relying on combinatorial methods has suffered so far from the difficult access to structurally diverse and large libraries of ligands, in particular the structurally more complex class of bidentate ligands. A completely new approach to streamline the difficult ligand synthesis process is to use structurally less complex monodentate ligands that self-assemble in the coordination sphere of a metal center through noncovalent attractive ligand–ligand interactions to generate bidentate, chelating ligands. When complementary attractive ligand–ligand interactions are employed, it is even possible to generate libraries of defined chelate–ligand catalysts by simply mixing two different monomeric ligands. This Minireview summarizes the first approaches and results in this new field of combinatorial homogeneous catalysis.

1. Introduction

The evolution of modern homogeneous catalysis is driven by the quest for higher efficiency and selectivity. While enzymes are highly substrate specific, their scope is limited. Synthetic catalysts are of particular interest because of their potential for a broader range of substrates. However, in both fields no general catalyst giving optimal results for all kinds of substrates is available. Hence, to achieve the desired selectivity for a catalytic reaction of interest, the catalyst must be optimized and adjusted to the particular problem. Especially in the field of metal-complex catalysis, the choice of the right ligand, which shapes the microenvironment at the catalytically active metal center, is crucial.

However, despite significant progress in the field of theoretical and computational chemistry, there is still no rational way to model from scratch the best ligand for a given reaction and selectivity problem. So far, finding the optimal ligand is an unpredictable high-risk endeavor, which is driven to a large extent by various combinations of intuition, experience, hard labor, and in many cases serendipity. This is a long-standing problem and has, at least for asymmetric catalysis, a simple physicochemical origin. In 1983 Knowles noted:[1] "*Since achieving 95 % ee only involves energy differences of about 2 kcal, which is no more than the barrier encountered in a simple rotation of ethane, it is unlikely that before the fact one can predict what kind of ligand structures will be effective.*"

Inspired by developments in the pharmaceutical industry to accelerate lead discovery and optimization, scientists have adapted methods of combinatorial chemistry to homogeneous (and hetereogeneous) catalysis to speed up catalyst discovery and optimization.[2] Many elegant solutions for high-throughput screening of catalyst libraries are available today which facilitate the testing of large catalyst libraries for optimal activity and selectivity.[3] However, the full potential of the combinatorial approach for catalyst discovery has not been reached so far owing to the difficulty of accessing large and structurally diverse ligand libraries. This problem is particularly acute for the important class of bidentate ligands. Although monodenate ligands have gained increasing importance recently, a considerable number of catalytic reactions require a bidentate ligand for maximum selectivity. A prominent example for enantioselectivity control is the reduction of β-keto esters with ruthenium(II)–binap catalysts (Scheme 1a).[4] Another example is the control of regioselectivity for the industrially important rhodium-catalyzed hydroformylation of terminal alkenes, which requires tailor-made

bidentate ligands.[5] Among the few ligands known to achieve efficient regiocontrol is the xantphos system (Scheme 1b).

a) Enantioselectivity: binap
Scheme 1. Control of enantio- and regioselectivity with selected metal catalysts with bidentate ligands.

The problem in constructing ligand libraries is closely related to the number of synthetic steps required to synthesize a bidentate ligand. These steps are in many cases nontrivial synthetic operations that render the ligand synthesis unsuited for automation. A particular challenge is the synthesis of nonsymmetric bidentate ligands equipped with two different donor sites.[6,7]

Bernhard Breit obtained his doctorate in 1993 under the direction of Prof. M. Regitz at the University of Kaiserslautern. After postdoctoral training with Prof. B. M. Trost at Stanford University, he worked in Marburg with Prof. R. W. Hoffmann to obtain his habilitation. In 1998/99 he was a Visiting Professor at Harvard University, and subsequently he was Professor of Organic Chemistry at the University of Heidelberg. Since April 2001 he has held a chair in Organic Chemistry at the University of Freiburg. His awards include the Steinhofer award, the Heinz-Maier-Leibnitz award (DFG), the "Dozenten Award" of the Fonds der Chemischen Industrie, the Alfried Krupp award, and the Novartis European Young Investigator Award. His research interests focus on catalysis and organic synthesis.

2. Emulation of Chelation through Self-Assembly of Monodentate Ligands

Recently, attempts have been made to simplify access to bidentate ligands by a conceptually new approach: The basic idea is to use structurally less complex monodentate ligands, which imitate the situation of a bidentate ligand at the catalytically active metal center through a noncovalent connection between the two binding sites (Scheme 2). Nature provides a range of noncovalent interactions such as van der Waals interactions, π stacking, cation–π interactions, charge-transfer interactions, electrostatic interactions, hydrogen bonding, and coordinative interactions.[8] Thus, on going from a metal complex having two truly monodentate ligands with no attractive interaction between them, to a metal complex with a bidentate ligand having two covalently connected binding sites, there is a continuum of arrangements consisting of two donor ligands and a metal center that emulate chelation through noncovalent attractive ligand–ligand interactions. A differentiation within this continuum may be made according to the strength and nature of the attractive ligand–ligand interaction (Scheme 2).[8]
Scheme 2. Continuum of attractive ligand–ligand interactions in an MD_2 complex.

Beyond the benefit of a simplified ligand synthesis, the true potential of this approach now lies in the inherent possibility for the generation of combinatorial ligand libraries through simple ligand mixing. Thus, provided that two ligands are bound to one catalytically active metal center, one could obtain from a set of n different monodentate donor ligands a library of $(n^2 + n)/2$ ML^xL^y catalysts (Table 1).

If, however, the interaction between the two ligands bound to one metal center is *noncomplementary*, mixing the two different ligands will result in a mixture of the two homodimeric and the heterodimeric ligand metal complexes

Table 1: Ligand library generated by mixing n monodentate ligands L^x and L^y.

Ligand	L^1	L^2	...	L^n
L^1	L^1L^1			
L^2	L^1L^2	L^2L^2		
...	...	...	...	
L^n	L^1L^n	L^2L^n	...	L^nL^n
Scheme 3. Catalyst mixtures from mixing of two different ligands D¹ and D² and a metal source; noncomplementary D¹–D² interactions are represented by dotted red lines.

almost irrespective of the nature and strength of the attractive ligand–ligand interaction (Scheme 3). In this scenario three potential catalysts are present simultaneously. Only in cases when the heterocombination is more reactive and at the same time more selective than the homodimer is optimization towards a better catalyst possible.

To facilitate the evaluation of structure–activity relations and optimization strategies, it would be desirable to have a situation in which ligand mixing generates the heterodimeric ligand metal complex exclusively. Thus, shifting the equilibrium to the desired heterodimeric species completely would require two different sets of monodentate ligands with *complementary* binding sites in order to generate attractive ligand–ligand interactions (Scheme 4).

Scheme 4. Defined heterodimeric catalysts from mixing and self-assembly of monodentate ligands with complementary binding sites in the presence of a metal source.

Hence, a heterodimeric ligand system formed by complementary self-assembly could imitate a classical nonsymmetrical ligand system (Scheme 4). Furthermore, mixing *m* ligands of set D¹ with *n* ligands of set D² in the presence of a metal species would generate a library of *m*×*n* defined heterodimeric bidentate ligand metal complexes (Table 2).

It is the aim of this review to summarize the first accomplishments in this new field of combinatorial catalysis

with homogeneous metal complexes employing ligand libraries obtained through self-assembly.

3. Weak Ligand–Ligand Interactions: van der Waals, π Stacking, Dipole–Dipole Interactions

For almost three decades the field of homogeneous catalytic asymmetric hydrogenation has been dominated by chelating ligand systems such as diop,[9] dipamp[10] binap,[11] duphos,[12] and josiphos,[13] which have been shown to furnish excellent asymmetric induction for a number of substrates.
Already in 1972 Knowles and co-workers reported on a rhodium catalyst modified with the monodentate phosphine camp to yield enantioselectivities up to 90% for the hydrogenation of precursors of *N*-acetyl phenylalanine.[14] However, it was not before 2000 when the dominance of bidentate ligands was questioned independently by the research groups of Orpen and Pringle,[15] Reetz,[16] Feringa, Minnaard, and de Vries.[17] Chiral monodentate phosphinites, phosphates, and phosphoramidites showed excellent levels of enantioselectivity for the asymmetric rhodium-catalyzed hydrogenation of a number of substrates. A quadrant model was proposed based on an X-ray structure platinum(II) complex with a binol-derived phosphonite ligand (Figure 1).[15,16]

Interestingly, the two monodentate phosphorus ligands are *cis* coordinated at the platinum center, which is supposed to be a sterically less favorable arrangement than the alternative *trans* orientation. Hence, one may speculate that the preferred formation of the *cis* complex results from weak attractive ligand–ligand interactions based on van der Waals

interactions, π stacking, and/or dipole–dipole interactions of the P–O bond dipoles. As a consequence of the *cis* coordination mode, a conformational "locking" of the two monodentate ligands is achieved, thus mimicking the conformational properties of a bidentate ligand (Figure 1).

Figure 1. X-ray crystal structure of a *cis*-bisphosphonite platinum(II) complex and the proposed quadrant model. Pt green, Cl yellow, P orange, O red, C gray.

The full potential of this arrangement of two monodentate ligands mimicking a bidentate ligand was recognized and used soon afterwards by Reetz et al.[19] Thus, high structural diversity is achieved by mixing two different monodentate ligands in the presence of a metal salt. In this scenario an equilibrium mixture of three different catalysts is formed, the two homocombinations ML^{x}L^x and ML^{y}L^y as well as the heterocombination ML^{x}L^y. Thus, if ML^{x}L^y is more reactive and more enantioselective, one could expect an increased reaction rate and higher enantioselectivity. In fact, ligand mixtures of phosphonites **1** and phosphites **2** furnished catalysts that operated with higher enantioselectivities than those of the corresponding homocombinations. A few selected results for the asymmetric hydrogenation of *N*-acyl-enamines are given in Table 3.[19–21]

The same principle but with achiral ligands was applied recently to control regioselectivity in the rhodium-catalyzed hydroformylation of a methacrylate derivative (Table 4).[22] Thus, a library of mixtures of 14 monodentate P-donor ligands was screened. While the homocombinations (Table 4, entries 1–4) gave only moderate regioselectivity, interestingly the best results were obtained with ligand mixtures. Among the many combinations tested, optimal regioselectiviy in favor of the branched aldehyde **4** was achieved by combining triphenylphosphane (**6**) and the phosphinine **19** (Table 4, entry 5). The phosphabenzene **19** was introduced recently as an efficient modifying ligand for the rhodium-catalyzed hydroformylation of higher substituted alkenes.[23]
Almost simultaneously Feringa, Minnaard, et al. probed the same concept for mixtures of monodentate phosphor-

amidites in the course of asymmetric hydrogenation[24] and for rhodium-catalyzed conjugate addition of phenylboronic acid to enones.[25] Although in the latter case the enantioselectivities are still moderate (< 77%), again, ligand mixtures provided the best results (Table 5, entry 5).

Interestingly, in ^{31}P NMR investigations of the catalyst mixtures, preferred formation of the heterodimeric catalyst

was observed (up to 91%).[25] These significant deviations from the statistical 50:25:25 mixture, expected for the equilibrium mixture of the heterodimeric and the two homodimeric catalyst, have been explained by the complementary size and shape of the ligands. An additional explanation may invoke stronger attractive ligand–ligand interactions in the heterodimeric catalyst based on dipole–dipole, van der Waals, and π-stacking interactions. However, the complete shift of this equilibrium in favor of the exclusive formation of the heterodimeric catalyst could not be achieved so far.

4. Attractive Ligand–Ligand Interactions through Hydrogen Bonding

Recently, the in situ generation of bidentate ligands based on self-assembly through hydrogen bonding of monodentate ligands in the coordination sphere of a metal center was described.[26] As a platform for hydrogen bonding, the

tautomer system 2-pyridone (**23B**)/2-hydroxypyridine (**23A**) was employed. The parent system (D = H) is known to dimerize in aprotic solvents to form predominantly the symmetrical pyridone dimer **24** (Scheme 5).[27,28] However, if D were a donor atom capable of binding to a metal center (e.g. PPh₂), the equilibrium could be shifted towards the mixed hydroxypyridine/pyridone dimer **25**.[29] This intermediate may be stabilized by the chelation effect exhibited through coordinative binding to the metal center (Scheme 5).

In fact the reaction of 2 equiv of 6-diphenylphosphanyl-2-pyridone (6-DPPon, **23**, D = PPh₂) with [PtCl₂(cod)] (cod = cycloocta-1,5-diene) furnished quantitatively *cis*-[PtCl₂(**23**)₂], which showed the expected hydrogen-bonding network both in solution and in the solid state (Figure 2).[26]

Figure 2. X-ray crystal structure of *cis*-[PtCl₂(**23**)₂].

Scheme 5. Self-assembly of the 2-pyridone/2-hydroxypyridine system **23** through hydrogen bonding to generate complexes **25** for homogeneous catalysis.

A rhodium catalyst derived from the ligand **23** displayed the typical behavior of a bidentate ligand in the hydroformylation of terminal alkenes.[26] Thus, excellent regioselectivity in favor of the linear aldehyde was noted for hydroformylation of a range of functionalized terminal alkenes (Table 6). Among them, even those with functional groups capable of hydrogen bonding were tolerated (Table 6, entries 5–8). However, the hydrogen-bonding network in the ligands and thus the chelating binding mode can be disrupted by employing either temperatures above 110°C or protic solvents such as methanol and acetic acid; low regioselectivity results (Table 6, entries 9 and 10).[26]

Since the two tautomers—the hydroxypyridine **23A** and the pyridone **23B**—equilibrate rapidly, mixing two pyridone ligands with different donor sites would result in mixtures of the heterodimeric and homodimeric catalysts (cf. Scheme 3). If, however, one wanted to generate the heterodimeric catalyst exclusively, for example, to study structure–activity and structure–selectivity relations, then the pyridone self-assembly platform is unsuitable. The heterodimeric structure would require the self-assembly of two complementary species through hydrogen bonding—a principle employed by nature in DNA base pairing. Thus an A-T base-pair model relying on the aminopyridine **26**/isoquinolone **27** platform was selected to serve for specific heterodimeric ligand assembly (Scheme 6).[30]

When phosphine ligands based on this platform were mixed in the presence of a Pt^{II} salt, the heterodimeric complex *cis*-[PtCl$_2$(**28**)] formed exclusively. An X-ray structure of *cis*-[PtCl$_2$(**28aa**)] (D^x = D^y = PPh$_2$) shows the expected hydrogen-bonding network reminiscent of the Watson–Crick base

pairing of A and T in DNA (Figure 3). NMR studies provided support that a similar structural situation occurs in solution, too. On this platform the first 4 × 4 self-assembled ligand

bidentate from a monodentate binding mode, the hydroformylation of terminal alkenes was chosen as a test reaction (Table 8). Thus, the monodentate P-donor ligands alone or mixed with the monomeric zinc template **29** generated hydroformylation catalysts that displayed, as expected for monodentate donor ligands, low regioselectivity in the hydroformylation of 1-octene (Table 8, entries 1, 2, 4, and 6). Conversely, the combination of the dimeric zinc(II) porphyrin template **30** with two equivalents of the 3-pyridyl-functionalized phosphite donor **31b** led to good regioselectivity in favor of *n*-nonanal, which is the typical behavior expected for

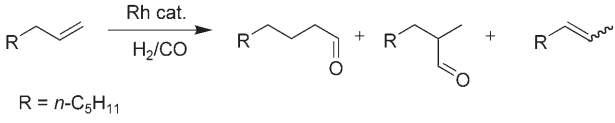
33

33   **34**

34   **35**

36

Scheme 8. Multicomponent assembly of zinc(II) porphyrin units for the construction of bidentate ligands.

a bidentate ligand. Unfortunately, the catalyst activity was low (Table 8, entry 7).[32]


Switching the roles of the zinc porphyrin template and N-donor adapter provides an alternative mode for the supramolecular construction of bidentate ligands (Scheme 8).[33] Thus, mixing two equivalents of the threefold zinc(II) porphyrin substituted phosphite **33** with 1,4-diazabicyclo-[2.2.2]octane (dabco, **34**) in the presence of a rhodium(I) salt formed the chelating metal complex **36** (Scheme 8). Again, the hydroformylation of 1-octene served as a test case (Table 9). Thus, when the phosphite ligand **33** was used with or without the monoamine donor **35**, low regioselectivities were noted (Table 9, entries 1 and 2). Conversely, addition of diamine **34** provided a catalyst that operated with reduced activity but significantly increased regioselectivity (Table 9, entries 3 and 4). These properties can be ascribed to the bidentate coordination of the ligand to the catalytically active metal center.[33]

Similarly, a set of zinc(II) porphyrin functionalized phosphites (**46–51**) and eight monodentate phosphorus donor ligands equipped with N-donor functions (**38–45**) were used to generate a library of 48 chelating ligands (Scheme 9).[34]

This library of bidentate ligand assemblies plus the catalysts derived from the monodentate ligands alone were tested by application to the asymmetric allylic alkylation of 1,3-diphenylallyl acetate (Table 10). The best heterodimer combinations gave up to 60% *ee* of either the *R* or *S* product depending on the absolute configuration of the ligand employed (Table 10, entries 2 and 6). Unexpectedly, optimal enantioselectivities (96–97% *ee*) were observed for the monodentate zinc(II)porphyrin substituted phosphite ligands **48** and **49** (Table 10, entries 1 and 5).[34]

chelating ligand systems was reported by Tacacs et al. (Scheme 10).[35] Thus, a bimetallic complex **52** is used in which M_c represents the catalytically active metal center and M_s functions as a structure-determining element. More

influence on the ligand topography around the palladium center.

6. Conclusion and Outlook

The quest in homogeneous transition-metal catalysis for the ultimate ligand to provide a catalyst with optimal activity and selectivity is a difficult task despite recent progress in rational ligand design. This is why combinatorial methods have gained increased importance in ligand design and discovery recently. However, the limiting step so far has been the generation of structurally meaningful and diverse ligand libraries, which has been particular difficult for the structurally more demanding class of bidentate ligands.

This review summarizes recent reports, in which the synthesis of chelating ligands has been simplified significantly and which rely on a new concept to emulate chelating ligands. The basic idea is to use two structurally less complex monodentate ligands, which are held together through non-covalent attractive interactions and imitate a bidentate ligand at the catalytically active metal center. There is a continuum of attractive ligand–ligand interactions, which span a range from weak van der Waals, π stacking, charge-transfer, and dipole–dipole interactions to hydrogen bonding and even stronger coordinative interactions.[37] Irrespective of the strength of the interaction, the specific formation of heterodimeric ligands requires two different sets of monodentate ligands with complementary binding sites. This concept was applied for the generation of the first bidentate ligand libraries based on self-assembly either through hydrogen bonding or coordinative interactions and has resulted in the identification of excellent catalysts for regioselective hydroformylation and asymmetric allylic alkylation.

This new field merges the principles of supramolecular chemistry, coordination chemistry, and catalysis for the generation of chelation-emulating ligand libraries for homogeneous metal catalysts. The proof of principle has been achieved, and the concept can now be used to develop larger ligand libraries to identify new tailor-made ligands for homogeneous catalysis in organic synthesis.

Scheme 10. Heterodimeric taddol–phosphite ligands based on a heterochiral metal complex template.

precisely, this structural element enforces an attractive ligand–ligand interaction through formation of zinc(II) complexes **53** with two chiral bisoxazoline ligands. Each of the bisoxazoline units **54** is connected through a spacer to a chiral phosphite donor (ligands **55–61A** and **B** based on (*R,R*)-taddol). Since the heterochiral zinc complex **53** is significantly more stable than the alternative homochiral complex, the selective formation of heterodimeric chelating ligands based on this template is possible.[35,36]

A library of 50 combinations of heterodimers from subunits **55–61A** and **B** was screened in the palladium-catalyzed asymmetric allylic amination of racemic carbonate **62** to give allylic sulfonamide **63** (Scheme 11). 50 Ligand combinations were tested, and the enantioselectivities ranged from 20 up to 97% *ee*, although the chiral diphosphite ligands differed in the structure of the ligand backbone only. Thus, seemingly subtle changes in the ligand backbone have a major

The Impact of Bacterial Genomics on Natural Product Research

Helge B. Bode and Rolf Müller*

Dedicated to Prof. Dr. Eckhard Leistner

"There's life in the old dog yet!" This adage also holds true for natural product research. After the era of natural products was declared to be over, because of the introduction of combinatorial synthesis techniques, natural product research has taken a surprising turn back towards a major field of pharmaceutical research. Current challenges, such as emerging multidrug-resistant bacteria, might be overcome by developments which combine genomic knowledge with applied biology and chemistry to identify, produce, and alter the structure of new lead compounds. Significant biological activity is reported much less frequently for synthetic compounds, a fact reflected in the large proportion of natural products and their derivatives in clinical use. This Review describes the impact of microbial genomics on natural products research, in particularly the search for new lead structures and their optimization. The limitations of this research are also discussed, thus allowing a look into future developments.

From the Contents

1. Introduction

Without medically applied natural products[+] human life would be less comfortable and definitely much shorter: More than 75 % of all antibacterial and approximately 50 % of all anticancer compounds currently in clinical use are either natural products themselves or derivatives thereof.[1] Clinically useful antibacterial natural products are often the drugs of last resort for the treatment of multidrug-resistant and, without treatment, often deadly microorganisms. However, resistance against new antibiotics, including those representing our last line of defence, is emerging. Even with the adoption of antibiotics with novel mechanisms of action, we do not have to ask the question *if* resistance will develop but only *when* it will occur. This situation is mainly a consequence of the enormous speed at which microorganisms exchange and mutate their genes. The more often antibiotics are used, the more rapidly resistance is spread.[2] It is predictable that the winner in this game will always be the microbe, simply because of its huge numbers, short generation times, and mutation rates. Nevertheless, pharmaceutical research must try to fight back to maintain the status quo. However, to find a promising new natural product for the treatment of any kind of disease is an expensive and difficult challenge,[3,4] which has led major pharmaceutical companies to rely solely on synthetic chemicals.[5,6]

The reason for this can be seen in several disadvantages that natural products appear to have compared to synthetic chemicals: 1) The isolation and characterization is often laborious and, therefore; 2) it is not possible to obtain as many natural products as synthetic chemicals in the same time; 3) by definition there is a biological source involved in the production of any natural product, which requires experienced handling plus specialized and expensive equipment.

However, these disadvantages are more than balanced by the positive aspects of natural products, and some of the arguments against them can in fact be turned into strong advantages: 1) Natural products occupy a complementary region of chemical space compared with synthetic compounds as discussed extensively in recent reviews.[7–12] These differences range from simple features such as elemental composition and molecular weight to specific structural elements such as ring size and type, and overall complexity and stereochemistry in general. 2) Natural products have evolved in a biological context and the percentage of biologically active natural products is much higher than that of synthetic compounds (although not all of them have an identified biological activity).[13] These two findings result in a new trend of "natural productlike" synthetic strategies: new lead compounds can be identified from natural product scaffolds or by creating analogues to natural products.[14–16] These approaches have also led to a cooperation between natural product research and combinatorial chemistry, the latter of which was earlier thought to completely replace the need for novel natural products. In general, it is now accepted that both disciplines support, fertilize, and rely on one another.[10,17] 3) The biological source of the compound is often renewable and thus opens up the possibility to scale-up production. This is especially true if the producing organism is easy to cultivate, and is a major reason why bacteria and fungi are the dominant source of the natural products in clinical use. Furthermore, because of our increased understanding of genetics and the principles of biological regulation the production of these compounds can be optimized (see Section 2.5). The biosynthesis of the compounds themselves can also be manipulated to yield new derivatives with possibly superior qualities (see Section 2.6). Possible ways to obtain

[+] The expressions natural product and secondary metabolite are used interchangeably throughout this Review.

these goals for pharmacologically relevant natural products are the focus of this Review and will be described in later sections. Most of the work cited was performed with polyketides and nonribosomally biosynthesized peptides. Since these natural products are derived from enzymatic systems called polyketide synthases (PKSs) and nonribosomal peptide synthetases (NRPSs), these enzymes and the resulting secondary metabolites are introduced briefly (Scheme 1). It should be noted that many bacterial natural products are derived from other pathways, such as the isoprenoid or shikimate pathways.[18–20]

Bacterial PKSs (type I) are multifunctional enzymes that are organized into modules, each of which harbors a set of distinct, non-iteratively acting activities responsible for several biosynthetic steps during the catalysis of one cycle of the polyketide chain elongation.[21] Type I PKSs are involved in the biosynthesis of macrolides, polyethers, and polyenes. Type II PKSs are multienzyme complexes that carry a single set of iteratively acting proteins and are involved in the biosynthesis of aromatic and often polycyclic polyketides.[22,23] Type III PKSs, also known as chalcone synthase like PKSs, are homodimeric enzymes which iteratively act as condensing enzymes, as exemplified by the formation of flaviolin.[23] NRPSs are similar to the type I PKSs in that they are multifunctional enzymes that are organized into modules with sets of non-iteratively acting activities for the incorporation and processing of one amino acid per module.[24,25]

Figure 1. Currently finished genomes ordered according to their intermediate taxonomic rank. Classes and orders that harbor experimentally verified secondary metabolite producing members are shown in gray.

1.1. Increase in Sequence Information

Since the publication of the first complete microbial genome sequence of *Haemophilus influenzae* in 1995,[31] more than 250 fully sequenced genomes have been reported (Figure 1) and more than 600 prokaryotes and 460 eukaryotes are currently being sequenced.[32] Although there was a clear focus on pathogenic bacteria in the early days of genome sequencing, biotechnology is catching up rapidly: currently 47% of all bacterial-sequencing projects deal with organisms having industrial applications, including secondary metabolism (52% of the projects remain focused on pathogens and about 1% involve the sequence of exotic organisms).[32] The value of the exponentially growing sequence information is immeasurable because bioinformatic methods, along with large-scale approaches such as transcriptomics and proteomics, are only just beginning to reveal insights into numerous important research topics such as virulence genes, host–pathogen interactions, new molecular targets, and novel ways to produce secondary metabolites. Sequence data from multiple isolates or different strains of a single pathogen are accumulating. This type of information has proven invaluable for providing new insights into the genetic variability present in a particular species as well as facilitating correlations between genotype and phenotype.[33]
Unexpectedly, genome sequencing of known producers of secondary metabolites (*Streptomyces* sp.[34,35] and *Arabidop-*

Helge B. Bode was born in 1973 and studied chemistry and biology in Göttingen and Stockholm. After his Diploma and PhD (2000) studies in natural product chemistry with Prof. A. Zeeck, he received a Diploma in molecular microbiology with Prof. G. Braus in 2001. After postdoctoral research with R. Müller in Braunschweig and Prof. D Kaiser in Stanford, he was appointed Junior professor for Natural Product Biotechnology at Saarland University in April 2004. His research focuses on the elucidation of the biochemical basis of the complex life cycle of myxobacteria.

Rolf Müller studied pharmacy at Bonn University and received his PhD with Prof. E. Leistner in 1994. He worked for two years as a research fellow of the DFG with Prof. H. Floss in Seattle, and then studied myxobacteria at the German Research Centre for Biotechnology (GBF) for his Habilitation (TU Braunschweig, 2001). In 2003 he received the BioFuture prize of the BMBF and in the same year was appointed head of the Department of Pharmaceutical Biotechnology at Saarland University. His recent work focuses on the biotechnological exploitation of myxobacterial genome projects and the heterologous expression and modification of complex megasynthetases in pseudomonads and fast-growing myxobacteria.

sis[36]) revealed the capacity to synthesize many more secondary metabolites than were actually known from these organisms. Even more surprising, many organisms that were not known as secondary metabolite producers, habor the typical genes and often huge biosynthesis gene clusters for the production of several hypothetical or unidentified natural products. A possible explanation for this might be that only a few taxa (plants, fungi, and some bacterial taxa) have been investigated with respect to secondary metabolism. Almost all bacteria, fungi, and plants sequenced to date show at least some biosynthesis genes typical for secondary metabolite production, thus indicating the old evolutionary origin of these genes.

1.2. Plants—Potential and Problems

Plants have the greatest potential to produce any type of natural product. This situation is exemplified by the enormous variety of low- molecular-weight compounds present in most plant materials.[37] The complexity of plant metabolomes is far beyond those from other organisms. However, the organization of the genes in a typical plant genome makes research dealing with plant secondary metabolism a major challenge: 1) The genes for the production of secondary metabolites are not found in one genomic region (that is, as a biosynthetic gene cluster, such as those usually present in bacteria or fungi) but scattered throughout the entire genome. Therefore, the

identification of a complete biosynthetic pathway in plants is extremely tedious and time-consuming. 2) The exon/intron structure of the genes leads to a number of problems. Therefore, it is necessary to work with cDNA which is generated from enriched mRNA pools to identify the genes of interest.

A good example of these challenges is the potent anticancer agent paclitaxel (taxol), which was isolated from the bark of the pacific yew as a pure compound in 1971. This source is environmentally unfriendly and gave rise to serious supply issues, and today it is produced by a semisynthetic approach starting from 10-deacetylbaccatin III, which can be isolated from yew tree needles (and thus a renewable source) in large quantities.[38] The broad use of paclitaxel in breast cancer treatment has triggered several efforts to produce this valuable compound more efficiently, either in plant cell cultures[39] or alternatively in fast-growing bacterial hosts after heterologous expression of the required biosynthetic machinery. Unfortunately, the complex biosynthesis of taxol requires approximately 19 biosynthetic steps, which explains that despite groundbreaking efforts, especially by the Croteau research group, several genes for the biosynthesis are still unknown (Scheme 2).[40–43] Interestingly, endophytic fungi have been isolated from various trees that produce paclitaxel. Despite their small production titers, these fungi open up the possibility to study paclitaxel biosynthesis in comparison to the plant system and lead to potential biotechnological processes.[39]

1.3. Fungi—The Promised Land?

Fungi have been a major source of natural products used in food processing and medicine as well as for religious rituals since the very early days of human culture. The modern era of fungal natural product research started with the well-known story of a contaminated agar plate in Alexander Fleming's laboratory in 1928, which eventually led to the clinical use of penicillin to treat bacterial infections.[44] Since then, fungi have been an impressive source of biologically active lead structures for pharmaceutical development, including the immunosuppressant cyclosporin[45] and the cholesterol-lowering agent lovastatin.[46]

Fungal genomics started with the availability of the complete sequence of the model yeast *Saccharomyces cerevisiae* in 1997.[47] Since then genome sequences of additional model strains used to study fungal molecular biology and/or fermentative biotechnology have been reported (*Schizosaccharomyces pombe* (2002),[48] *Neurospora crassa* (2003),[49] *Phanerochaete chrysosporium* (2004),[50] *Yarrowia lipolytica* (2004), and *Kluyveromyces lactis* (2004)[51]).

The first complete sequence of a fungus that produced secondary metabolites was the white-rot fungus *Phanerochaete chrysosporium* in 2004.[50] More than 50 genes involved in secondary metabolite biosynthesis including several genes encoding PKS and NRPS have been identified in the 30 Mbp genome. It is noteworthy that the biosynthesis of polyketides often involves post-PKS assembly steps, including the action of cytochrome P450 like enzymes, and an impressive number
Scheme 2. Biosynthesis of paclitaxel (taxol). Enzymatic activities encoded by genes that have not been cloned yet are shown in bold.[40–43]

of corresponding genes (more than 100) have been identified in this genome. Fortunately, most genes for secondary metabolite biosynthesis in *P. chrysosporium* and in fungi in general are clustered on the chromosome so that the identification and study of complete secondary metabolite biosynthetic pathways is much easier than in plants.

Currently 113 fungal genome projects are in progress worldwide.[32] The majority of these involve classical secondary metabolite producers (for example, *Penicillium chrysogenum* and 13 different *Aspergillus* sp.) or plant pathogenic strains which are also known for the production of natural products (for example, *Fusarium* sp., *Botrytis* sp., and *Magnaporthe* sp.). These projects will undoubtedly add valuable insights into fungal secondary metabolite biosynthesis, which is currently little studied relative to related bacterial systems.

One forseeable problem with fungal systems is the lack of genetic methods for the manipulation of many strains and the fact that in some cases the biosynthetic genes are not clustered on the chromosome. Nevertheless, there is enormous potential in fungal systems, and most of the advantages discussed below with respect to bacteria also apply for fungi.

1.4. Bacteria—The Bigger the Better?

Research focussing on bacteria and in particular on bacterial secondary metabolism has a number of advantages in comparison to plants and fungi: 1) Genes for the biosynthesis of the desired compounds are mostly clustered; 2) the coding density of bacterial genomes is high and thus sequence costs can be reduced; 3) no introns are present, thus enabling expression methods starting directly from chromosomal DNA; 4) the compact genetic composition allows the fast identification of bacterial gene clusters and their transfer into different expression hosts; and 5) fermentation processes can be developed, thus enabling large-scale production (which is also true for fungi).

Many more bacteria have been sequenced than eukaryotes because of their relatively small genome sizes. Early sequencing efforts focused mostly on pathogenic bacteria, while 47% of all current bacterial sequencing projects deal with biotechnologically relevant strains. Up to now only a few species have been sequenced that were known in advance to be secondary metabolite producers. However, the sequencing of these strains revealed a plethora of biosynthetic gene clusters for the production of additional unknown secondary metabolites (Figure 2). The best studied examples are *Strep-*

tomyces coelicolor and *S. avermitilis*, which were known to produce 4 and 3 secondary metabolites, respectively, but actually possess 20 and 25 clusters for secondary metabolite biosynthesis, respectively.[34, 35] A detailed post-genomic examination of the production profile of *S. coelicolor* has already led to the isolation of two additional compounds, the existence of which had been postulated after genome annotation.[52, 53]

Statistical analysis of all bacterial genomes sequenced to date revealed that there is a positive correlation between the genome size and the number of genes involved in the biosynthesis of secondary metabolites.[54] Large genomes found in most producers of secondary metabolites might be a consequence of the complex ecological niches they occupy—requiring adaptation to several microenvironments and/or competition between species. Further ecologically relevant species need to be sequenced to learn more about this dependency.[55] However, two questions arise from the tremendous discrepancy between isolated compounds and genomic potential: How can we identify and obtain the hypothetical products that have not yet been isolated? How can we use the enormous genetic potential in the most efficient way? We will try to address these questions in the following sections by using selected examples from the recent literature.

2. Approaches to Explore the Genetic Potential

2.1. Random, but Simple and Successful

The easiest way to obtain more secondary metabolites from a single strain bearing the genetic potential to produce several compounds is to vary the culture conditions. The rationale behind this approach is that the production of secondary metabolites might be a specific response of the producing organisms to a changing environment.[13] For example, soil bacteria living in the rhizosphere have to compete with fungi for nutrients. Thus, the production of antifungal compounds would be advantageous in such an environment. In contrast, the artificial media composition, cultivation conditions, and high cell densities used under laboratory conditions might cause regulatory cascades in the cells thus enabling the production of some compounds but disabling the production of others that might be produced under different and perhaps more "natural" conditions. Since our knowledge of any ecological network is very poor, random approaches which vary the easily accessible cultivation parameters are chosen (media composition, aeration, addition of chemicals, etc.) to trigger the expression of latent biosynthetic genes. This approach might influence directly or indirectly the transcription, translation, and enzyme activity/specificity in the whole organism (Figure 3). Very similar techniques have been used widely for the optimization of the production of a desired compound, and their use in screening for novel natural products has led to some impressive examples of microbial chemical diversity. These methods are regularly used today by pharmaceutical and biotech companies.[15]

Figure 2. Selected fully sequenced prokaryotic secondary metabolite producers with numbers of isolated polyketides and nonribosomal peptides at the time of the genome sequence (black bars). Identified gene clusters encoding PKS and NRPS in the genome are shown as gray bars.[32] The data was taken from the original publications or generated by BLAST searches of KS, KR, TE, ACP, T, and A domains.
Figure 3. Possible ways to influence the production of secondary metabolites. Isolation of new producing strains and metagenome approaches prior to methods dealing with secondary metabolites are shown in gray. Genetic modifications and/or addition of genes leading to modified compounds are shown in red.

After the cultivation of the aspinonene producer *Aspergillus ochraceus* DSM7428 in different media and cultivation vessels (resulting in different aeration rates), 15 additional secondary metabolites belonging to unrelated structural and biosynthetic families were isolated. Of particular note was the static cultivation for several days which led to a completely different metabolite profile (Scheme 3).[56,57] Similar results were also obtained with another fungus which produced up to 2.6 g L^{-1} of a reduced precursor of the main metabolite (120 mg L^{-1} in shaking culture) under similar conditions.[58] Since variation of the growth conditions very often results in the production of several compounds by a single organism, this approach was termed "one strain—many compounds" (OSMAC).[56] Recently, the addition of organic solvents and signaling compounds to growth media was even used to increase the chemical diversity of selected strains.[59, 60]

2.2. Possible Ways to Use the Endless Resources

The microbial world cultured in the laboratory represents less than one percent of the microbial diversity in different natural environments.[61] The biosynthetic potential of this unexplored resource is nearly endless and raises the question: Why do we only work with this limited number of bacteria? The answer to this is that these "lab" strains behave well in artificial conditions and can be cultivated easily. Microorganisms currently in use grow fast in pure culture and reach high cell densities. However, fast growth is not advantageous when

nutrients are not available. Too much food might even kill cells if they require a specialized diet. In nature, poor nutrient conditions represent the rule and not the exception, and areas completely devoid of nutrients occur.

New techniques are currently being developed to cultivate and enrich formerly "not-yet-culturable" organisms.[62–65] The work required is very laborious and time-consuming. Therefore, additional techniques have been developed that circumvent the cultivation of organisms but still enable the exploration of chemical diversity. DNA libraries from environmental samples are generated bearing the genetic information of all organisms present at a specific location at the sampling time.[66–68] After sequencing such so called "metagenomes", the genetic information of single organisms can still be assembled and analyzed by using established bioinformatic tools, as was most impressively shown recently for the microbial community of the Sargasso Sea.[69] Furthermore, the DNA libraries generated in this way can be transferred into suitable host organisms that can then be tested for the production of the desired compounds and enzymes (see also Section 2.5). This methodology is especially important for those potent biologically active compounds which have been isolated from organisms not amenable to large-scale cultivation (for example, bryozoae, sponges, and molluscs).[70] Intriguingly, structural similarities exist between several marine natural products of unknown origin and compounds isolated from soil bacteria (Scheme 4). On the basis of genetic evidence, it is now generally accepted that several of the "marine" natural products from higher organisms are in fact
Scheme 3. Secondary metabolites isolated from *Aspergillus ochraceus* DSM7428 after variation of the cultivation parameters; Shaking culture (SK).[56]
Scheme 4. Examples of structurally related natural products isolated from bacteria and marine organisms (a)[73–77] and of natural products produced by noncultivated bacterial symbionts of higher organisms (b).[71, 72, 78, 79]

marine microbial products (for example, onnamide[71] and bryostatin[72]). Therefore, the isolation of the corresponding biosynthetic gene clusters and their heterologous production should become possible in the future, thus enabling the large-scale production of the corresponding natural products (see also Section 2.5).

2.3. Screening of Genomic DNA Leads to the Production of Novel Secondary Metabolites

The enormous amount of sequence data becoming available from all types of microbial sources has led to an increase in bioinformatic approaches to find novel secondary metabolites. Although this methodology is limited to the interpretation of biosynthetic genes typical for secondary metabolism, many novel secondary metabolic gene clusters can be found because they are frequently related to PKS and/ or NRPS pathways. Farnet and co-workers sequenced numerous biosynthetic gene clusters that were identified by their similarity to known genes by using a genome scanning approach. These researches have significantly increased the small number of known enediyne antibiotic producing strains[80] by growing the strains identified by genome scanning under different growth conditions and subsequent product analysis. Therefore, this approach resembles a combination of DNA sequencing with the OSMAC methodology described above (see Section 2.1).

In addition to the complete sequencing of novel biosynthetic gene clusters, small fragments of these genomic regions can be used to identify novel metabolites if the host strain can be genetically manipulated. Numerous strategies for the amplification of fragments from PKS and/or NRPS genes by using degenerate PCR have been described and nonsequenced genomic libraries can be probed and screened for the presence of PKS and/or NRPS gene fragments in single or multiple biosynthetic gene clusters. Once the genomic regions involved in natural product biosynthesis have been identified, the fragments can be used for gene inactivation studies and the resulting mutants and their wild-type strains can be compared for their production profile. At least three novel compounds were found in *Stigmatella aurantiaca*[81] by using this approach (myxochelin,[82] myxochromid,[83] and aurafuron[84]; see Figure 4).

It could be argued that these compounds could have been found in the strain by an intense variation of the culture conditions. However, the application of genetic knowledge has tremendously increased the chances of identifying novel compounds whose production is dependent on the corresponding genes. In the case of metabolites produced at low levels, it is difficult to define whether the "novel compounds" are indeed such or just components of the medium. The latter can be ruled out if production is dependent on an identified gene locus.

While many research groups focus on identifying and then sequencing novel biosynthetic pathways, bioinformaticians preferentially use the numerous new microbial genome sequences to predict new pathways by in silico methods. On the basis of PKS and NRPS enzymology logic,[21, 28, 85] even

Figure 4. HPLC traces with UV detection (200–400 nm) showing the correlation of biosynthesis gene clusters and the corresponding natural products in *S. aurantiaca* DW4/3-1 by comparison of wild types and mutants.[81]

structures of unknown compounds can theoretically be predicted depending on bioinformatic gene cluster analyses.[86–89] A biosynthetic gene cluster of unknown function was identified from *S. aurantiaca* that was predicted to be involved in iron chelator biosynthesis and was indeed found subsequently to be responsible for myxochelin formation in this strain.[82, 90] Bacillibactin was found in *Bacillus subtilis* on the basis of genome analysis,[91] and coelichelin has been predicted to be an iron chelator from *S. coelicolor*.[92] The latter compound was indeed found three years later.[53] Although this bioinformatics methodology for predicting structures seems very attractive and convincing at first, to date there are only very few examples for the subsequent identification of these "theoretical compounds". This situation is presumably a consequence of the limitations discussed below.

All predictions were based on the nonribosomal code and/ or in silico analyses of the corresponding biosynthetic PKS and NRPS gene clusters. It turns out that there are numerous exceptions to the commonly accepted "rules" for polyketide

and nonribosomal peptide biosynthesis.[93,94] One of these rules is the biosynthetic logic of "colinearity", which means that a correlation exists between the number and type of modules and the number and type of extender units incorporated by the megasynthetase. Nevertheless, module skipping[95] as well as iterative use of modules have been described in PKS systems. Prediction of substrates (for example, malonyl-CoA and methylmalonyl-CoA) is difficult, and modules or domains can be inactive or "missing".[94,96] Similarly, NRPS domains have been found to be inactive[83,97] and the nonribosomal code, although exceptionally useful in many cases, turns out to be not applicable in certain examples.[98,99] To make the situation even more complicated, nonclustering of bacterial biosynthetic genes also occurs, which would make a structure prediction impossible.[99–101]

In general, if biosynthetic systems closely related to those already described in the literature are found, predictions of similar structures using bioinformatics seems feasible. For more complicated cases, predictions will be very difficult using existing tools alone. For example, neither the mupirocin[102] nor the disorazol biosynthetic genes[103] could have been used to predict the structure of the compounds produced. A combined approach involving more experimental biochemistry coupled to advanced bioinformatics should improve the situation dramatically in the future.

2.4. Activation of "Silent" Biosynthetic Gene Clusters

As a viable alternative to the OSMAC and the genome scanning approaches[80] described above, the insertion of inducible promotors into the chromosome capable of driving the expression of so far uncharacterized "silent" biosynthetic gene clusters seems practicable. Although a random activation approach of gene expression has been described,[104] we are not aware of any proof of principle for this technology in natural product producing microorganisms. Therefore, this idea awaits practical exploitation, although problems with biosynthetic gene clusters requiring the insertion of numerous promotor regions for gene activation have to be expected.

Alternatively, influencing pleiotropic or direct regulatory mechanisms within the host cell should enable the artificial expression of uncharacterized genes and might lead to the (over)production of natural products. Whereas negative regulators might be inactivated, positive regulators can be overproduced. A recent example describes the partial activation of a silent angucycline-type gene cluster from a streptomycete.[105] A putative repressor gene was inactivated which resulted in the production of angucycline metabolites. The ferric uptake regulator (Fur) controls numerous regulatory genes, such as pvdS in Pseudomonas aeruginosa, which encodes an alternative sigma factor. A hierarchical cascade of direct and indirect iron regulation has been analyzed by transcriptome analysis in response to iron.[106] Strong iron regulation was observed for previously identified genes involved in biosynthesis or uptake of the siderophores pyoverdine and pyochelin. Iron-controlled regulatory genes include seven alternative sigma factors and five other transcriptional regulators.

Additionally, xenobiotics and pheromones can influence the expression of biosynthetic pathways.[107] Although the role of S-adenosyl methionine (SAM) in antibiotic production is far from understood, a correlation between actinorhodin production and the level of SAM in the cell has been reported.[108,109] Another example of defined chemicals that exhibit secondary metabolite regulatory functions in streptomycetes are the γ-butyrolactones.[110] Davies and co-workers have shown convincingly that even antibiotics themselves, when present at subinhibitory concentrations, influence the expression of numerous genes.[111] Secondary metabolites might very well be involved in the regulation of their own biosynthesis or of the biosynthesis of similar or totally unrelated compounds in different microorganisms and thus might be used to induce the production of additional compounds. Recently, Uchiyama et al.[112] have shown in an elegant approach that novel metagenomic catabolic gene clusters can be identified. They measured the expression of a metagenome reporter gene library after induction with a variety of chemicals. Next, they used a fluorescence-activated cell-sorting system (FACS) to identify clones in which expression was induced, and then characterized the activated gene's product(s). One can envisage cloning fragments of "silent" biosynthetic gene clusters in a similar approach and finding low-molecular-weight inducers that enable the expression of secondary metabolite genes. Once inducers of the respective promotors are identified, they could be used to trigger expression of the silent genes in the natural host. However, since the size of many biosynthetic gene clusters makes complete cloning difficult, this approach does not seem feasible for complete heterologous expression of a whole gene cluster (see Section 2.5).

The study of the regulatory mechanisms underlying secondary metabolism is still tedious and time-consuming for examples where genomic sequences are not available. This situation is changing rapidly because of a variety of ongoing functional genome projects of natural product producers (for example, S. coelicolor, S. avermitilis, B. subtilis, and Sorangium cellulosum). The availability of genomic information sets the stage to study complex regulatory mechanisms by using transcriptomic and proteomic tools. Moreover, the genome sequence from one species enables the identification of regulatory and metabolic proteins required for the biosynthesis of the desired compound from closely related strains.[113]

2.5. Heterologous Expression of Biosynthetic Gene Clusters

Numerous PKS and NRPS biosynthetic gene clusters have been cloned over the past decade, and the increasing biochemical knowledge from studies dealing with the corresponding enzymes has led to the emergence of combinatorial biosynthesis technologies that aim at generating novel compounds through genetic manipulation.[114,115] In principle, the availability of the genetic information makes heterologous expression possible in improved production hosts. This technology can also be used to express biosynthetic pathways

from currently not-yet-culturable microorganisms (see Section 2.2).

Genetic manipulation is straightforward in some model strains (for example, *S. coelicolor* and *B. subtilis*), but the genetic tools are insufficient or not developed for many microbial producers of natural products. A number of them are slow-growing or currently not-yet-culturable and thus not suited for genetic modification of biosynthetic pathways (for example, myxobacteria, cyanobacteria, and presumed bacterial symbionts as producers of "marine natural products"; see Section 2.2).

These circumstances and the rapidly increasing number of microbial genome sequences have led to a considerable demand in heterologous expression techniques for complete secondary metabolite pathways in natural product research and drug discovery. It is a viable alternative to the improvement of the strain and the fermentation process as well as to the genetic modification of the native producer strain.[116]

A number of strategies for the heterologous expression of secondary metabolite pathways have been described, which range from the targeted expression of specific natural products to the expression of large unknown DNA fragments (also termed the expression of the metagenome; see Section 2.2).[117] Bacterial artificial chromosome (BAC) shuttle vectors were used for constructing environmental libraries, followed by expression in multiple expression hosts (for example, pseudomonads, streptomycetes, and *Escherichia coli*).[67, 118] However, only products from relatively small biosynthetic gene clusters have been produced with this method to date, and the producing heterologous host has mostly been from the same genus as the natural producer (Scheme 5).[118]

Similarly, there are a number of reports on the heterologous production of biosynthetic pathways from bacteria in closely related genera. As an example, Marahiel and co-workers have expressed and engineered the bacitracin biosynthetic pathway from *Bacillus licheniformis* in *B. subtilis* which produces almost twice as much of bacitracin as the natural producer.[125] Salas and co-workers have recently generated more than 30 derivatives of the antitumor compound indolocarbazole in yields comparable to those from the original producer after heterologous expression of varying combinations of biosynthetic genes in *Streptomyces albus*.[126] Most of the examples in the literature relate to small type II PKS systems,[127–132] whereas the heterologous expression of large type I PKS and/or NRPS gene clusters has been achieved by coexpression from several plasmids, each harboring parts of the biosynthetic pathway.[133, 134] Expression of the epothilone biosynthetic gene cluster from *Sorangium cellulosum* in *Myxococcus xanthus*[135] is another example. The methodology employed relied on several rounds of cloning and heterologous host modification because no autonomously replicating units are known for myxobacteria. Whereas the yields in this case were only 1 % of that produced in *S. cellulosum*, optimization of the medium resulted in a respectable increase in epothilone titer up to the level of the original natural producer.[136] Nevertheless, it has to be considered that the original strain has in the meantime been significantly improved for production by classical methods,
Scheme 5. Low-molecular-weight compounds produced from fragments of different metagenomes.[119–124]

similarly to the soraphen-producing strain *S. cellulosum* So ce26.[137]

Only within the last few years has it been shown that the production of complex natural products in unrelated bacteria is feasible. In these elegant studies a genetically engineered *E. coli* host was used to produce the aglycone precursor of erythromycin.[116] Subsequently, precursors of ansamycin macrolactam were produced in *E. coli* after expression of part of the biosynthetic operon.[138] Epothilone as well as soraphen derived from myxobacteria that belong to the genus *Sorangium* have been produced in streptomycetes, although in very low yields.[139, 140] Despite increasing experience with the various hosts, the product yields have typically been much lower than those in the original producer. This might be a consequence of weaknesses in the natural promotor, problems with expression levels of correctly folded proteins,[141] difficulties with the essential posttranslational activation of carrier proteins,[142] differences in mRNA stability, or precursor supply, to name just a few possible drawbacks of the technique. Numerous ongoing studies in many laboratories are addressing these questions in various ways, including the

application of novel genetic engineering systems and the use of a variety of heterologous hosts.

In all of the studies mentioned above, classical and time-consuming cloning procedures were employed, and the expression of large secondary metabolite clusters was only achieved by coexpression from several genetic units. Recently, the application of recombinogenic engineering[143] in *E. coli* for cloning and manipulating large natural product assembly lines has been used successfully by several research groups. This technique is particularly suitable for large DNA molecules such as BACs and cosmids, as it does not rely on classical cloning procedures. After overexpression of proteins facilitating efficient homologous recombination (Red/ET) in *E. coli*, PKS and NRPS pathways can be altered and redesigned based on short homology arms.

Researchers at Cubist have applied this methodology to engineer the daptomycin biosynthetic pathway from *Streptomyces roseosporus* in *E. coli* on a BAC; they then expressed it in a daptomycin-negative mutant of *S. roseosporus* to produce novel and active lipopetides.[144] In this example, a closely related (here in fact the same) expression host was used, which is feasible and sensible when well-developed hosts are available. As this prerequisite has not been achieved in many areas of research, efficient heterologous expression of biosynthetic gene clusters from microbial producers is still a challenging task, especially for the slow-growing or not-yet-culturable sources. In a recent example, Red/ET recombineering[143] has also been used to rebuild the complete assembly line from the myxobacterial myxochromid PKS/NRPS hybrid gene cluster in one genetic unit and to introduce the elements required for conjugation, stable integration, and regulated expression in the heterologous host *Pseudomonas putida*.[97]

One of the important advantages of this method is that the whole secondary metabolite pathway is located on one construct, which can be accurately manipulated in *E. coli* and transferred into the heterologous host strain. Surprisingly, the fermentation time is reduced threefold when producing myxochromide S in *P. putida* while the product yield is fivefold higher relative to that of the natural producer *S. aurantiaca*. *P. putida* is able to produce all the required activated precursors for myxochromide S biosynthesis (acetyl-CoA, malonyl-CoA, and propionyl-CoA) and expresses a broad spectrum phosphopantetheinyl transferase which is necessary for activation of the carrier protein.[145] As genetic manipulation in *P. putida* is straightforward, it should be possible to engineer the strain to produce further precursors that are essential for the biosynthesis of other secondary metabolites (for example, unusual extension units and amino acids) from various sources. Therefore, this strategy, which combines the power of advanced DNA engineering and mutagenesis in *E. coli* with the utility of pseudomonads as the heterologous host, provides a new alternative for the analysis and mutagenesis of known and unknown secondary metabolite pathways.

Another alternative approach focuses on artificial DNA synthesis of complete biosynthetic gene clusters. This approach depends on the ability to synthesize long, accurate DNA sequences efficiently. The idea was validated by building a synthetic PKS gene cluster whose functionality

was demonstrated by its ability to produce the megaenzyme and its polyketide product in *Escherichia coli* by synthesizing approximately 5-kb segments of DNA, followed by their assembly into longer sequences by conventional cloning methods.[146]

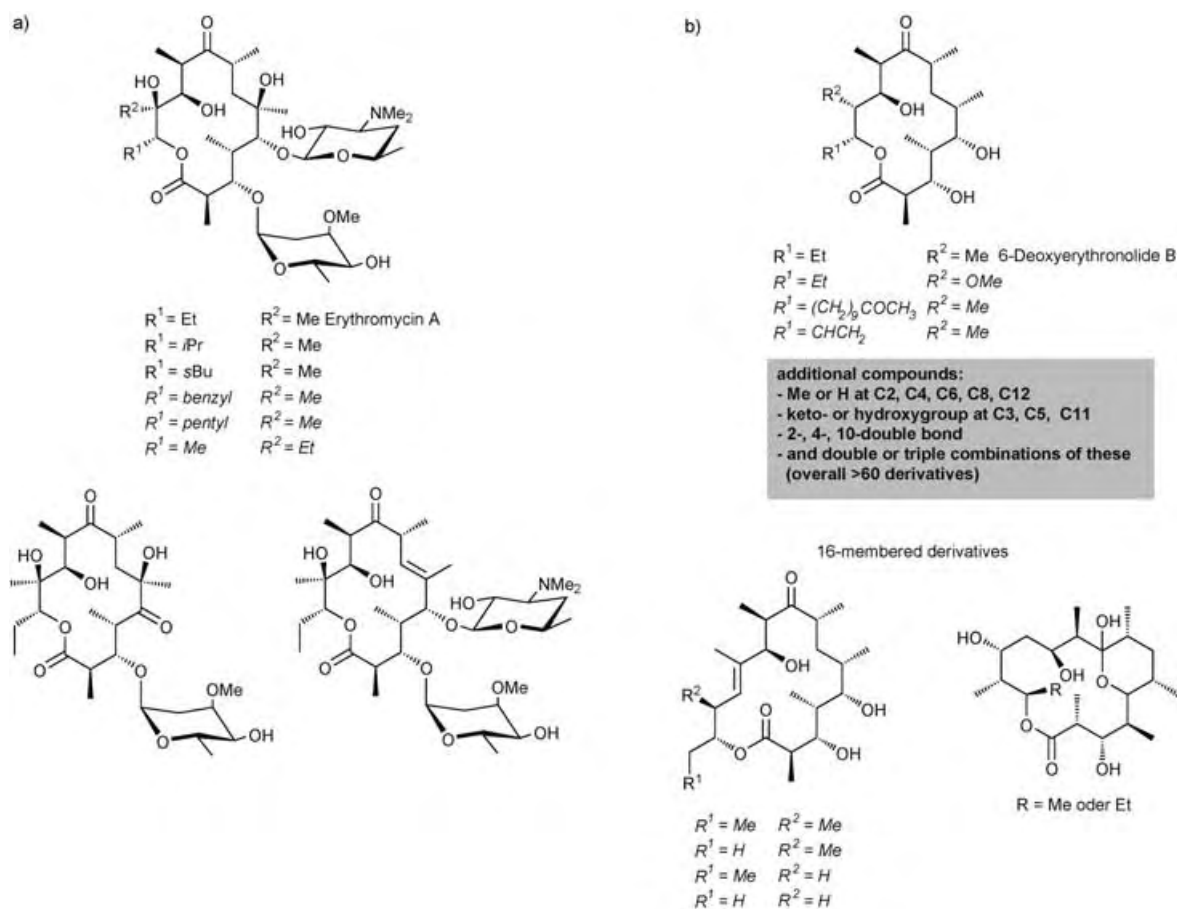
It should be pointed out that it is unlikely that there will be a single solution to the immense variety of heterologous expression problems in the future. Closely related and well-established production hosts which can be manipulated genetically may be regarded as first-choice organisms. However, since these are often unavailable, as many production hosts as possible should be further developed to provide a battery of possible expression technologies, the strength and weaknesses of which will become evident in the future.

2.6. Combinatorial Biosynthesis
2.6.1. Genetic Engineering of the Natural Host

The modularity and versatility of PKS and NRPS as well as challenges and opportunities in combinatorial biosynthesis have been discussed in excellent reviews.[24, 147–153] To illustrate our growing knowledge related to the genetic engineering and the production of novel compounds with altered structures, we refer here to some studies that have been published in recent years. Further examples of combinatorial biosynthesis approaches are presented in Section 2.5 (heterologous expression techniques).

The Leadlay and Staunton research groups have extended their pioneering work in PKS research by engineering starter unit specificity in the erythromycin-producing PKS in vivo.[154] They were even able to show in the same biosynthetic system that a longer polyketide chain can be generated after insertion of an extra module into the PKS.[155] The same research group was also able to produce ivermectin-like drugs after domain exchange in the avermectin PKS of *S. avermitilis* although in a reduced overall yield.[156] In yet another example they employed the loading domain of the soraphen PKS, which was speculated to load benzoyl-CoA onto the megasynthase from *S. cellulosum*.[157] To prove this hypothesis, this domain was used to make a DEBS1-TE hybrid (fusing the thioesterase domain of DEBS3 to DEBS1 and exchanging the erythromycin-loading module against the soraphen loading module), which resulted in the production of 5-phenyltriketide lactone with a yield of approximately 1% of the regular DEBS1-TE triketide.[158] Subsequent studies showed that additional phenyl-substituted polyketides could also be made.[159]

Researchers at Kosan Biosciences and Stanford University have performed equally impressive work in PKS engineering.[160, 161] They were able to reengineer the genes that encode the erythromycin formation to produce the antiparasitic agent megalomicin in *Saccharopolyspora erythraea* in better yields than could be obtained from the natural producer.[162] They also performed studies to understand the substrate specificity of PKS modules by generating hybrid multimodular synthases.[163] Katz and co-workers produced a new epothilone derivative in good yields by engineering the epothilone megasynthetase (albeit not in the natural pro-

ducer, see above).[164] The combinatorial biosynthesis of pikromycin-related macrolides in *Streptomyces venezuelae* has also been studied[165] and led to the generation of multiple bioactive macrolides by hybrid modular PKSs in this strepto-mycete.[166]


Combinatorial biosynthesis using type II PKSs is the focus of several research groups.[114, 115, 131, 167] Chromomycin ana-logues differing in the methylation, acylation, and glycosyla-tion pattern were recently made by manipulating the respec-tive post-PKS genes.[168, 169] Other examples of the engineering of biosynthetic pathways using such post-PKS enzymes are derived from the characterization of glycosyl transferases, which can be employed to generate novel structures in vivo and in vitro (see Section 2.6.2).[170, 171] It can be expected that genomic information from natural product producers will provide increasing knowledge about nature's secondary metabolite assembly tool box which can be applied in various ways to rational pathway engineering.

All the examples reported in this section have resulted in the production of new compounds, however, there may be many more examples that did not work at all and will presumably never appear in the literature. A failed example of pathway engineering is related to various manipulations of the myxothiazol megasynthetase in *S. aurantia*ca. Although relatively simple genetic manipulations were performed, neither intermediates nor expected derivatives of the biosyn-

thetic pathway could be observed, no matter what part of the biosynthetic gene cluster was manipulated (Scheme 6).[172]

2.6.2. In Vitro Studies Using Biosynthetic Enzymes

Biosynthetic genes identified in the search for new secondary metabolic gene loci are widely used for the expression of catalytic modules and domains for in vitro studies with purified enzymes. These recombinant proteins were initially employed to decipher the biochemistry of biosynthetic pathways[28, 173, 174] and in vitro reconstitutions of complex natural product biosyntheses were reported.[90, 175, 176] In vitro combinatorial biosynthesis techniques have mostly relied on genetic engineering and mutation in *E. coli* because this technique is much faster than the engineering of most, or probably all, typical secondary metabolite producers. Con-sequently, most functional biochemical and also combinato-rial studies have been performed with proteins that could be actively expressed in *E. coli*. Pioneering work by the Marahiel and Walsh research groups has shown that recombinant NRPS and PKS proteins can be engineered to produce novel and altered products.[30, 174, 177] The feasibility of combinatorial biosynthesis to make commercially useful compounds has been shown by creating a recombinant NRPS capable of synthesizing in vitro α-L-aspartyl-L-phenylalanine, the pre-cursor of the artificial sweetener aspartame.[178] New inter-

Scheme 6. Selected variations of erythromycin (a) and its aglycone 6-deoxyerythronolide B (b) obtained by combinatorial biosynthesis and muta-synthesis (italics). Overall, more than 100 derivatives have been generated by using combinatorial biosynthesis and mutasynthesis.

Angew. Chem. Int. Ed. **2005**, *44*, 6828–6846

mediates of epothilone[179] and rifamycin[180,181] biosynthesis, but with alternative starter units, were made using purified proteins from the respective gene clusters. In another study, the modification of the acyl carrier protein with alternative starter units enabled the biosynthesis of novel polyketides with 16 (instead of 14) carbon atoms by employing the minimal actinorhodin type II PKS.[182] An alternative way to generate chemical diversity using purified bacterial biosynthetic proteins is exemplified by recent in vitro studies using the iterative and relatively small type III PKSs. These "plant-like PKSs" were first described by the Horinouchi research group.[27,183] It was realized that these enzymes are commonly found in bacteria[23,184–186] and that they are versatile systems for generating novel products.[187–190] Up to 14 compounds of different structural types (pyrones and phenoles varying in side-chains length) have been produced in vitro by using RppA (type III PKS involved in red-brown pigment production) to elongate five different starting units with malonyl-CoA.[187] Type III PKS are also involved in the formation of precursors of glycopeptides by NRPS; such enzymes from the balhimycin and the vancomycin biosynthetic gene clusters were identified as synthases of 3,5-dihydroxyphenylacetic acid, which serves as a precursor for the unusual amino acid 3,5-dihydroxyphenylglycine[191,192] that is part of the glycopeptide backbone.

Recently, proteins or excised catalytic domains from natural product biosynthetic pathways have also been used in chemoenzymatic syntheses. PKSs and NRPSs responsible for the production of macrocyclic compounds often employ their C-terminal thioesterase (TE) domain to catalyze enzymatic cyclization of a linear precursor.[193] Walsh and co-workers showed that excised TE domains retain their autonomous ability to catalyze the macrocyclization of linear peptide thioesters with native peptide sequences. Additionally, they can cyclize peptide analogues with alterations in the peptide sequence and peptide/polyketide-like hybrids with longer chain lengths.[194] Thus, these macrocyclization catalysts raise the prospect of using TE catalysis for the generation of macrocyclic peptide libraries.[195] Isolated TEs can also catalyze the cyclization of linear peptides immobilized on a solid-phase support, which offers the possibility to merge natural product biosynthesis with combinatorial solid-phase chemistry.[196] In an extension of this approach, even glycosylated glycopeptides could be cyclized in good yields.[197]

Glycosyltransferases are frequently found as tailoring enzymes associated with products derived from PKS and NRPS. They play a key role in the decoration of natural product core structures with sugar moieties that are often essential for biological activity. The corresponding proteins utilize activated sugars and can be altered genetically to accept and glycosylate a variety of substrates. Thorson and co-workers pioneered this approach and called it "glycorandomization" (Scheme 7).[198,199] Progress in the understanding of deoxyhexose and aminosugar biosynthesis will facilitate the future use of new sugars or those which are difficult to prepare chemically.[200,201]

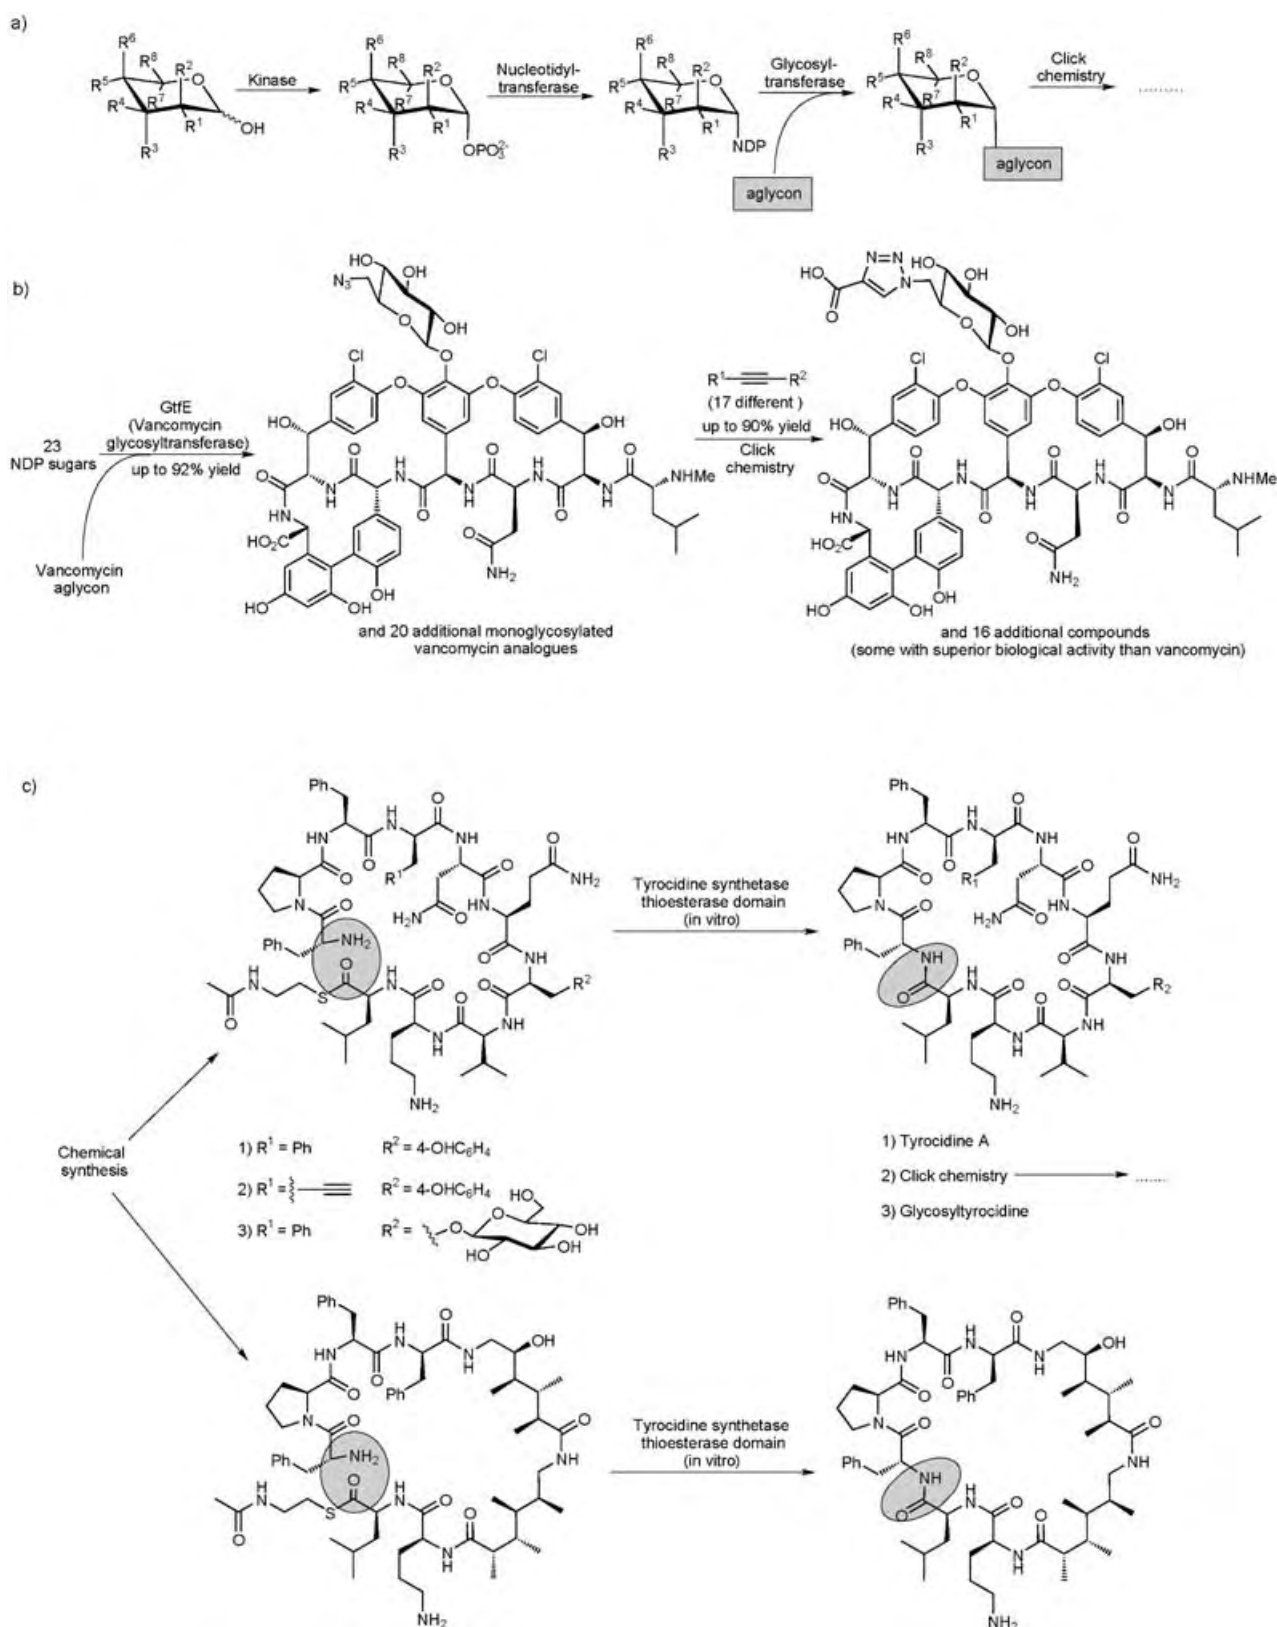
In general, it can be expected that any type of tailoring enzyme capable of decorating the product of a megasynthe-tase (for example, glycosyl transferases, methyl transferases, hydrolases, P450-dependent enzymes, or prenylating enzymes) can be used for similar in vitro studies in the future. As genome sequencing efforts reveal more and more of the genetic basis of microbial biochemical diversity, the corresponding biosynthetic genes await exploitation in combinatorial approaches.

2.7. Mutasynthesis

The extraordinary possibilities of the combination of genomic techniques with "old-fashioned" mutasynthesis[204] has been excellently reviewed.[205,206] We will thus only provide some recent examples which best exemplify the potential of this approach.

Biosynthesis of synthetic precursors has been used extensively in polyketide and nonribosomal peptide producing organisms using precursors that are activated as *N*-acetylcysteamine (NAC) thioesters which mimic the carrier-protein-bound biosynthetic intermediates.[207–212] In mutasynthesis approaches, the efficiency of the incorporation of an intermediate which is fed to a culture can be significantly increased if the biosynthesis of the natural precursor is blocked by mutagenesis. Hertweck and co-workers generated the novel cytostatic compound aureonitrile using *p*-cyanobenzoyl-SNAC as an unnatural starter unit of the aureothin biosynthesis in a mutant unable to produce the natural primer *p*-nitrobenzoyl-CoA.[213] The authors showed that the addition of *p*-cyanobenzoate is sufficient for the production of aureonitrile, presumably because the endogenous *p*-nitrobenzoate CoA ligase can activate both precursors (Scheme 8).

The biosynthesis and the mode of attachment of a wide range of PKS starter units in bacteria are covered in a recent review by Moore and Hertweck.[215] A prominent example of the practical application of a combined mutasynthesis/combinatorial biosynthesis approach is the production of the unnatural natural compound doramectin, a derivative of the anthelmintic type I polyketide avermectin that differs in the starting unit.[216]

Avermectin biosynthesis is usually primed with thioesters of activated short branched-chain carboxylic acids which are derived from the degradation of branched-chain amino acids. Once this degradation pathway is inactivated, avermectin production is stalled. However, the lack of precursors can be overcome by the addition of cyclohexylcarboxylic acid (or other related precursors), which leads to the production of doramectin, a broad-spectrum antiparasitic compound with activity superior to avermectin. After a pathway involved in the biosynthesis of cyclohexylcarboxyl-CoA has been identified in *Streptomyces collinus*,[217] Reynolds and co-workers transferred these genes into the *S. avermitilis* mutant impaired in the production of the natural starter unit. This approach led to the direct production of doramectin in excellent yields that were comparable to those found after the exogenous addition of cyclohexylcarboxylic acid to the *S. avermitilis* mutant.[214] The experiment represents metabolic engineering rather than mutasynthesis, because no precursor or intermediate is added to the fermentation broth.


Scheme 7. In vitro derivatization and synthesis of natural products. a) General outline of the glycorandomization approach.[198] b) Glycorandomization applied to vancomycin.[202] c) Generation of tyrocidine analogues by using a combination of chemical synthesis and thioesterase-catalyzed cyclization.[194,197,203]
Scheme 8. Generation of aureonitrile by mutasynthesis (a) and doramectin by metabolic engineering (b).[213,214]

Combinations of mutational and chemoenzymatic approaches have been exploited to generate new rapamycins[218] and aminocoumarins.[219,220] Novel glycopeptides were made using the biosynthetic potential of halogenases.[221]

The potential of mutasynthesis can be evaluated prior to in vivo experiments in studies employing recombinant biosynthetic enzymes, in an analogous way to the work described in Section 2.6.2. Walsh and co-workers could show in vitro that the first modules of the epothilone synthetase can utilize alternative starter units and substrates to generate novel intermediates.[179,222] It will be interesting to see whether these experiments will lead to the large-scale production of novel epothilones in vivo as well.

As can be deduced from the examples given above, there often appears to be no clear borderline between the types of approaches described. Several commonly used phrases such as "combinatorial biosynthesis" and "mutasynthesis" are not well defined and might be summarized as different forms of "metabolic (or biosynthetic) engineering" techniques. The strengths of the experimental ideas lie in the application of combined techniques for the particular problem to be solved.

3. Be Prepared! Natural Product Research in the Postgenomic Era

The impact of increasing genomic information as well as biosynthetic and regulatory studies that decipher the molec-

ular basis of natural product formation have been described in this Review, and technologies exploiting this knowledge for the generation of new natural products with biological activity have been summarized. These techniques have already led to the production of several novel compounds. The prerequisite of rational pathway engineering is a comprehensive understanding of complex natural product biosynthesis at the molecular level, but since this has not been achieved in many cases, numerous manipulations of biosynthetic pathways are ineffective or lead to low production yields; thus, further in depth biochemical studies are needed. Furthermore, exponentially increasing sequencing information, novel cultivation techniques, metagenomic approaches, and progress in heterologous expression and molecular biology in general are expected to give natural products research a promising future. The rapid progress in all areas of metabolic/biosynthetic engineering offers opportunities to alter and/or derivatize auspicious natural product leads in vivo and in vitro. Considering the structural complexity of natural products, this approach might well become a cornerstone of pharmaceutical lead development in the future.

Two new additions to the family of large palladium–carbonyl–triethylphosphine clusters, with Pd_{52} and Pd_{66} cores, have been prepared from the common parent precursor $[Pd_{10}(CO)_{12}(PEt_3)_6]$. For a detailed discussion on the geometrical variety of such nanosized homometallic clusters, see the Communication by E. G. Mednikov, L. F. Dahl, and co-workers on the following pages.

Palladium Clusters

Nanosized [Pd$_{52}$(CO)$_{36}$(PEt$_3$)$_{14}$] and [Pd$_{66}$(CO)$_{45}$(PEt$_3$)$_{16}$] Clusters Based on a Hypothetical Pd$_{38}$ Vertex-Truncated ν_3 Octahedron**

Evgueni G. Mednikov,* Sergei A. Ivanov,
Irina V. Slovokhotova, and Lawrence F. Dahl*

Dedicated to Professor Giuliano Longoni

Palladium is a unique transition metal in that it forms an exceptionally versatile family of high-nuclearity palladium carbonyl phosphine clusters (i.e., with cores of at least 10 metal atoms with direct metal–metal bonding) that display a truly remarkable diversity of geometries about the metal cores.[1a–h] Fifteen distinctly different geometries have been identified crystallographically for Pd$_n$ cores with $n = 10$,[2a–c] 12,[2d,e] 16,[2f,g] 23 (two different metal cores have been observed),[2h–j] 29,[2e] 30,[2k] 34,[1a,2l] 35,[2g] 38,[2m] 39,[2g] 54,[2k] 59,[2g,n] 69,[2o] and 145.[2p] All but two of these highly condensed palladium clusters have close-packed frameworks that contain metal fragments whose structural units may be described as ccp (cubic close-packed), mixed ccp/hcp (hexagonal close-packed) stacking layers (which include layer sequences corresponding to capped octahedra, centered cuboctahedra, or centered anti-cuboctahedra), and as icosahedra. One exception is the Pd$_{38}$ cluster, which has a highly irregular geometry about the metal core;[1a,2m] the other exception is one of the Pd$_{23}$ clusters, which has a highly distorted body-centered-cubic metal framework.[2j] Close-packed structural units of the Pd$_n$ cores also include "twinned interpenetrating" centered cuboctahedral and icosahedral geometries as well as one mixed, face-fused icosahedral/octahedral Pd$_{59}$ architecture, which consists of two centered icosahedra that *trans*-cap a bioctahedron.[2g,n] The largest known crystallographically determined discrete metal cluster, Pd$_{145}$, contains a capped three-shell 145-atom metal core, whose geometry closely conforms to I_h icosahedral symmetry.[2p]

A most impressive stereochemical aspect of this extraordinary family of [Pd$_n$(CO)$_x$L$_y$] clusters, where L denotes phosphine ligands, is that practically all of the above-mentioned members of the Pd$_n$ series have been prepared with the same phosphine ligand, L = PEt$_3$, which is sterically non-bulky and also a good σ donor. The exceptions reported to date are the Pd$_{12}$ cluster, which was isolated only with PnBu$_3$[2d] and PPh$_3$,[2e] and the Pd$_{35}$,[2g] Pd$_{39}$,[2g] and Pd$_{59}$[2g,n] clusters, which were obtained only with sterically smaller PMe$_3$ ligands. Furthermore, all of the triethylphosphine-containing [Pd$_n$(CO)$_x$L$_y$] (L = PEt$_3$) clusters may be obtained from reactions with the same tetracapped octahedral Pd$_{10}$ precursor, [Pd$_{10}$(CO)$_{12}$(PEt$_3$)$_6$],[2b,c] through different kinetically controlled synthetic pathways to give relatively thermodynamically stable products in most cases. For the majority of the Pd$_n$ clusters, reasonably good yields (at least 30%) were ultimately obtained by optimization of the reaction conditions and in particular cases by the structure-to-synthesis approach from different synthetic routes.

Herein, we report the synthesis of two new extraordinary members to the series of palladium carbonyl phosphine clusters, namely, [Pd$_{52}$(CO)$_{36}$(PEt$_3$)$_{14}$] (**1**) and [Pd$_{66}$(CO)$_{45}$(PEt$_3$)$_{16}$] (**2**), from the precursor [Pd$_{10}$(CO)$_{12}$(PEt$_3$)$_6$] (**3**). Cluster **1** was prepared as an extremely minor product (< 5% yield) from the reaction of **3** with [Pd$_2$(dba)$_3$] (dba = dibenzylideneacetone) at 50°C.[3] Subsequent attempts to increase the yield of **1** were unsuccessful; in the best cases, reactions usually (but not always) afforded **1** as a minor product in powder samples. Initial attempts to prepare the Pd$_{66}$ cluster **2** were carried out by Mednikov and Kanteeva from the reproducible deligation of **3** with CF$_3$CO$_2$H/Me$_3$NO under optimized ratios of **3**/CF$_3$CO$_2$H and **3**/Me$_3$NO at 1:120 and 1:16, respectively (42% yield; note that the product obtained by this procedure is labeled as **2′** (see below)).[2l] However, at that time attempts to characterize the product by X-ray diffraction were unsuccessful. Crystals of this unknown cluster **2′** were again isolated from the above-stated reaction,[4] and new efforts were undertaken to determine both its atomic arrangement and stoichiometry. However, we experienced great difficulty in obtaining the entire crystal structure. Complete X-ray data sets (two with synchrotron radiation) were collected from at least 10 monoclinic crystals (different preparations): despite poor refinements, solutions of the structure from several data sets confirmed the {Pd$_{66}$P$_{16}$} architecture of **2′** but did not provide any information concerning the number and coordination modes of the carbonyl ligands. Major problems included unusually high diffuse-scattering background and merohedral twinning (i.e., due to a monoclinic unit cell with $\beta \approx 90°$), which was taken into account in least-squares refinements. Nevertheless, the entire crystal structure was eventually established from monoclinic crystals (with a larger angle $\beta = 90.9°$) that were obtained from a different preparative route, through the reaction of **3** with [Pd(MeCN)$_4$](BF$_4$)$_2$,[5] to give **2**. Although the IR spectra of **2** and **2′** are virtually identical and their crystallographic unit-cell parameters are analogous, it should be noted that the Pd$_{66}$ cluster **2′** obtained from the reaction of

3 with CF_3CO_2H and Me_3NO may possibly contain a different number of carbonyl ligands to that found in **2**.[6]

The molecular structures[7] of **1** and **2** are based upon a common hypothetical Pd_{38} kernel that can be formally derived by vertex-truncating of a likewise unknown ν_3 Pd_{44} octahedron, where ν_n refers to $n+1$ equally spaced atoms (namely, four) along each of the 12 octahedral edges. This cubic O_h-symmetric Pd_{38} kernel contains six {100} square Pd_4 faces and eight {111} centered hexagonal Pd_7 faces, and has six interior (encapsulated) metal atoms that are located at the vertices of a regular octahedron.

The Pd_{52} core in **1** (Figure 1) formally arises from the remaining 14 Pd atoms, which form two monocapped ν_2 Pd_7 triangles that sequentially condense on centrosymmetrically opposite, *trans*-oriented {111} centered hexagonal Pd_7 faces[8] of the Pd_{38} kernel. This *trans* attachment of the two Pd_7 triangles to the Pd_{38} kernel lowers the symmetry of the resulting Pd_{52} core, which has crystallographically imposed C_{3i} ($\bar{3}$) symmetry, from pseudo-O_h to pseudo-D_{3d} ($\bar{3}2/m$). The Pd_{52} core contains eight interior Pd atoms that conform to a *trans*-bicapped octahedron.

The Pd_{66} core in **2** is formally constructed by the sequential condensation of the same monocapped ν_2 Pd_7 triangles on four non-adjacent (tetrahedral) {111} centered hexagonal Pd_7 faces of the Pd_{38} kernel (Figure 2). The crucial stage is the condensation of the second triangular Pd_7 fragment which must occur on any of three tetrahedrally oriented {111} faces of the Pd_{38} core. As a result, further condensation of the remaining two ν_2 Pd_7 triangles can sterically occur only on the remaining two tetrahedral centered hexagonal Pd_7 faces to thereby complete the Pd_{66} core of **2**. Because the probability of the condensation of the second ν_2 Pd_7 triangle on one of the tetrahedrally oriented centered hexagonal faces of the Pd_{38} kernel is three-times greater than that on the opposite face, this formal construction of the Pd_{66} core is significantly favored over that of the Pd_{52} core. Hence, it is not surprising that this building-block scheme is consistent with the good synthetic reproducibility of the Pd_{66} cluster as well as with its preparation from different procedures. In contrast, the Pd_{52}
Figure 1. a) Crystallographic C_{3i} and pseudo-D_{3d} geometry of the nanosized Pd_{52} core in $[Pd_{52}(CO)_{36}(PEt_3)_{14}]$ (**1**). Symmetry-independent Pd atoms are numbered. The maximum diameter of the metal core is 1.58 nm parallel and 0.84 nm perpendicular to the principal threefold axis that passes through Pd(10), Pd(2) and the crystallographic inversion centre; the latter is situated between the two middle 12-atom Pd layers. b) Molecular structure of **1** displaying the arrangement of 14 PEt_3 ligands (P pink; ethyl substituents not shown) and 36 bridging carbonyl ligands (O red, C black) about the Pd_{52} core. Two crystallographically independent carbonyl ligands are each disordered between two sites with occupancy factors of 0.54/0.46 and 0.76/0.24; only their main orientations are shown.

Figure 2. a) Geometry of the nanosized Pd_{66} core in $[Pd_{66}(CO)_{45}(PEt_3)_{16}]$ (**2**). The maximum diameter of the metal core of this spherically shaped Pd_{66} cluster is approximately 1.14 nm along each of the four tetrahedral body-diagonal $\langle 111 \rangle$ directions. b) Molecular structure of **2** exhibiting the arrangement of 16 PEt_3 ligands (P pink; ethyl substituents not shown) and 45 bridging carbonyl ligands (O red, C black) about the Pd_{66} core. Four carbonyl ligands are each disordered between two sites with occupancy factors of approximately 0.5/0.5 in each case; only one of the two orientations is shown.

cluster **1** is difficult to isolate. A close examination of the particular orientations of the four monocapped Pd_7 triangles relative to the Pd_{38} kernel in **2** reveals that the Pd_{66} core has

approximately C_{3v} symmetry instead of the expected T_d symmetry. However, the 10 interior (encapsulated) atoms ideally conform to a tetracapped T_d Pd_{10} octahedron, which alternatively may be viewed as a ν_2 Pd_{10} tetrahedron with three equally spaced Pd atoms along each of the six tetrahedral edges.

The resulting metal arrangements of the entire Pd_{52} core along the threefold axis in **1** and of each of the four $\{Pd_{38}Pd_7\}$ fragments with the common Pd_{38} kernel along the $\langle 111 \rangle$ directions in **2** may be considered as mixed ccp/hcp layer-stacking structures. Figure 1 shows that the eight layers in **1** adopt an ababcaca stacking sequence. In **2**, which has pseudo-C_{3v} symmetry, the alternation of the stacked layers (Figure 2) depends on the $\langle 111 \rangle$ direction: namely, the layer-stacking sequence along the proper C_3 axis is abacba, whereas along each of the other three symmetry-equivalent $\langle 111 \rangle$ directions the sequence is ababca. Similar four-, five-, and six-layer stacking sequences involving mixed ccp/hcp metal arrangements have been observed in other large carbonyl clusters, including $[Rh_{22}(CO)_{37}]^{4-}$ (abcb),[9a] $[Pd_{13}Ni_{13}(CO)_{34}]^{4-}$ (abcac),[9b] $[Pd_{16}Ni_{16}(CO)_{40}]^{4-}$ (abcbca),[9c] $[Ni_{32}Pt_{24}(CO)_{56}]^{6-}$ (abacbc sequence along its threefold axis),[9d] and neutral $[Pd_{54}(CO)_{40}(PEt_3)_{14}]$ (abaca).[2k]

Overall mean Pd–Pd distances of 2.80 Å (range: 2.70–2.95 Å) and 2.81 Å (range: 2.66–3.00 Å) in **1** and **2**, respectively, are typical for palladium carbonyl phosphine clusters, as exemplified by the overall mean Pd–Pd distance of 2.81 Å previously reported for the ccp Pd_{30} and ccp/hcp Pd_{54} clusters.[2k] The significantly shorter mean Pd–Pd distances of 2.74 Å in the interior (encapsulated) bicapped Pd_8 octahedron in **1** and 2.77 Å in the interior (encapsulated) tetracapped Pd_{10} octahedron (ν_2 tetrahedron) in **2**, which are essentially identical to the Pd–Pd distance of 2.75 Å in ccp Pd metal,[10] are consistent with the interior Pd_n atoms presumably having metallic character.

In **1**, four PEt_3 ligands are attached to each of the two monocapped ν_2 Pd_7 triangles, with one to the capped Pd atom and the other three to the corner atoms of the Pd_6 triangles. The six other PEt_3 ligands are coordinated to the six $\bar{3}$ (S_6)-equivalent Pd(6) atoms (see Figure 1) in the middle two Pd_{12} layers. In **2**, the 16 PEt_3 ligands are equally distributed among the four monocapped ν_2 Pd_7 triangles in coordination modes that are analogous to those found in **1**.

The 36 CO groups in **1** were all located without any difficulties. They comprise 12 doubly bridging μ_2-CO groups and 24 triply bridging μ_3-CO groups (Figure 1), and under crystallographically $\bar{3}$ (S_6) site symmetry, they may be divided into the following three distinct groups: 1) Six μ_2-CO groups (one independent), with three of these connecting each of the two monocapped μ_3-Pd atoms to the three inner Pd atoms of the triangular Pd_6 layer.[11] 2) Twelve μ_3-CO groups (two independent), with six of these connecting each of the two monocapped ν_2 Pd_7 triangles to a centered hexagonal Pd_7 face of the Pd_{38} kernel. This carbonyl arrangement may be readily visualized as six edge-bridging CO groups that span the six Pd–Pd pairs in each Pd_6 triangle being formally converted into face-capped μ_3-CO groups by each becoming attached to one of the six hexagonal Pd atoms of the centered hexagonal face. 3) Twelve μ_3-CO groups (two independent) and six μ_2-CO

groups (one independent) joined to the six "open" symmetry-related centered hexagonal faces of the Pd_{38} kernel. These consist of two μ_3-CO groups, which connect the centered Pd atom of a given Pd_7 face with four of the Pd atoms in the hexagon, and one μ_2-CO group that links the remaining two Pd atoms. These bridging carbonyl ligands in **1** are consistent with the observation of only one strong broad CO band in the solid-state IR spectrum at 1856 cm^{-1} with a shoulder at 1875 cm^{-1}.

In sharp contrast, the ultimate location of all 45 independent carbonyl ligands in the Pd_{66} cluster **2** (Figure 2) proved to be difficult and time-consuming. Nevertheless, a careful examination of their composite steric dispositions provides complete reassurance for the presence of 45 CO groups in **2**. Particularly intriguing is that normally 44 CO groups would be predicted from general symmetry considerations, thus the 45th CO group in **2** constitutes an unexpected extra one.[12] It is most convenient to initially describe the carbonyl arrangement of the 44 normal CO groups in **2** and then consider the observed major steric deformations of two CO groups that allow for the addition of the extra 45th CO ligand. In this analysis the carbonyl ligands in **2** are likewise separated into the same three groups: 1) Eight μ_2-CO groups, of which two edge-bridge each of the four monocapped μ_2-Pd atoms that are coordinated to only two of the three inner triangular Pd atoms within the four ν_2 Pd_7 triangles. 2) Twenty-four μ_3-CO groups with six face-capped ones connecting each of the four monocapped ν_2 Pd_7 triangles to a centered hexagonal Pd_7 face of the Pd_{38} kernel, as described above in **2**. 3) Six μ_3-CO groups and three μ_2-CO groups attached (as found in **1**) to three of the four "open" centered hexagonal Pd_7 faces of the Pd_{38} kernel; the fourth "open" face has three μ_3-CO ligands instead of one μ_2-CO and two μ_3-CO groups. This above description accounts for 44 of the 45 CO units found in **2**. To provide sufficient space for the addition of the extra (45th) μ_3-CO ligand, the one-bond-connectivity of each of two adjacent normally disposed μ_3-CO groups that connect one monocapped ν_2 Pd_7 triangle to its centered hexagonal Pd_7 face is broken, such that these two adjacent μ_3-CO groups are then transformed into μ_2-CO units that are highly bent above the ν_2 Pd_6 triangle (away from the centered hexagonal Pd_7 face) to increase intraligand contact distances and thereby minimize steric repulsions. This extensive localized deformation thus allows the extra μ_3-CO unit to face-cap the resulting Pd_3 triangle, which is composed of the two adjacent Pd atoms of the centered hexagonal Pd_7 face and the central atom of the ν_2 Pd_6 triangle that is also linked to the two highly bent μ_2-CO groups. These bridging CO coordinations give rise to only one broad strong CO band at 1884 cm^{-1} in the solid-state IR spectrum of **2**.[11–13]

This comparative analysis of the carbonyl ligands in **1** and **2** discloses two important stereochemical features that originated from the observed {111} face-condensations of the hypothetical Pd_{38} vertex-truncated ν_3-octahedral kernel: 1) in **1**, each triply bridging monocapped Pd atom connected to the three inner Pd atoms of the Pd_6 triangle contains *three* edge-bridged μ_2-CO groups, whereas in **2** each of the four doubly bridging monocapped Pd atoms connected to two of the three inner Pd atoms of the Pd_6 triangle contains *two*

Communications

edge-bridged μ_2-CO ligands; 2) the observed localized carbonyl rearrangement in **2** which sterically allows the presence of the extra (45th) CO ligand suggests that the geometry of the nanosized Pd_{66} core with 44 normal CO groups may potentially accommodate up to four additional carbonyl ligands without any substantial changes in the architecture of the metal core.[6] In fact, a current investigation has indicated the formation of another Pd_{66} cluster with 47 CO groups (three extra) from the reaction of **3** with dicobalt octocarbonyl.[13]

The possibility of variable numbers of carbonyl ligands for close-packed nanosized $[Pd_n(CO)_x(PR_3)_y]$ clusters without the need for significant geometrical changes in the common $\{Pd_n(PR_3)_y\}$ fragments was recently observed for the cuboctahedral $[Pd_{23}(CO)_x(PEt_3)_{10}]$ clusters with $x = 20, 21, 22$.[6] The arrangements of their composite carbonyl groups revealed that the formal addition of an extra CO ligand produces considerable localized displacements of certain neighboring CO ligands (with concomitant changes in their coordination modes) in order to increase intraligand contacts and thereby minimize steric effects. The geometric effects of the expanded carbonyl ligation in the Pd_{66} cluster also have special relevance to the well-known Muetterties cluster–science analogy[14] that chemisorbed CO molecules are not static but undergo both dissociative processes and nondissociative migratory processes about the metal surface as a function of the CO pressure.

Of particular relevance to our hypothesized modular construction of **1** and **2** from the hypothetical Pd_{38} vertex-truncated ν_3 octahedron is that the congeneric Pt_{38} core of the classic Chini $[Pt_{38}(CO)_{44}]^{2-}$ dianion displays this same O_h geometry.[15] More-recent comprehensive synthetic, stereochemical, spectroscopic, and electrochemical studies by Longoni, Zanello, and co-workers[16,17] have revealed the only other known cluster with a 38-atom metal core that displays the truncated ν_3 octahedral geometry; namely, the ordered $[H_2Ni_{24}Pt_{14}(CO)_{44}]^{4-}$ cluster for which the 24 Ni atoms occupy the 24 equivalent square corner sites and the 14 Pt atoms occupy the six vertices of the encapsulated octahedron and the centers of the eight hexagonal faces.[9d,16,18] They also prepared and characterized heterometallic 44-atom ν_3 octahedral clusters that contain a ccp 38-atom truncated ν_3 octahedral $M_{38-x}M'_x$ kernel with six additional Ni atoms capping the six {100} square faces. These include $[H_{6-n}Ni_{38}Pt_6(CO)_{48}]^{n-}$ $(n = 4–6)$[17a,b] and $[Ni_{35}Pt_9(CO)_{48}]^{6-}$,[17c] both with an encapsulated Pt_6 octahedron, and $[Ni_{36}Pd_8(CO)_{48}]^{6-}$[17c] with an encapsulated Pd_6 octahedron and with the other two Pd atoms occupying two of the eight centered sites of the crystal-disordered 10-atom ν_3 octahedral faces.

The salient structural feature of **1** and **2** is that their hypothesized formation from the Pd_{38} truncated ν_3 octahedron occurs through six-atom condensations of monocapped Pd_7 triangles on {111} octahedral faces instead of one-atom metal condensations on six {100} square faces, as found in the $\{Ni_{38}Pt_6\}$,[17a,b] $\{Ni_{35}Pt_9\}$,[17c] and $\{Ni_{36}Pd_8\}$[17c] clusters. The resulting condensation pattern of 44 metal atoms comprises eight "open" triangular ν_3 $\{Ni_{10-x}M'_x\}$ faces, which are only occupied by ligands. Stereochemical analysis of the known

$[Pd_n(CO)_xL_y]$ clusters reveals that, in general, Pd_n cores do not form such relatively large triangular 10-atom "open" faces, but they prefer instead to undergo face condensations.

In general, the formation of different kinds of large ligated close-packed metal clusters critically depends upon the subtle interplay of cohesive energies, electronegativities, and relative sizes of the metal atoms, the electronic and steric properties of the ligands, and, of course, the reaction conditions. The dissimilar growth processes presented above in the formal construction of the Pd_{52} and Pd_{66} clusters **1** and **2**, respectively, versus that of the 44-atom Ni–Pt and Ni–Pd carbonyl clusters from their nonisolated precursors with the same 38-atom vertex-truncated ν_3 octahedral geometry may be largely attributed to the markedly weaker metal–metal and metal–carbonyl interactions in palladium carbonyl/triethylphosphine clusters compared to those in nickel and platinum carbonyl clusters.

[3] a) A mixture of $[Pd_{10}(CO)_{12}(PEt_3)_6]$ (**3**)[3b] (0.200 g, 0.095 mmol) and $[Pd_2(dba)_3]$ (0.304 g, 0.332 mmol) in Me_2CO (7 mL) and iPr_2O (2 mL) was stirred for 4.5 h under N_2 at 50°C. The resulting brown solution was filtered from the black precipitate of $[Pd_{34}(CO)_{24}(PEt_3)_{12}]$ (**4**) and left under H_2O vapor. Black block crystals of **1** were isolated and washed with MeOH (estimated yield < 5%); IR (nujol): $\tilde{v} = 1875$ (sh), 1856 cm^{-1} (s). The black precipitate of **4** (0.182 g, 67% yield based on combined content of palladium in **3** and $[Pd_2(dba)_3]$, or 114% based on **3**) was identified by its IR spectrum (nujol): $\tilde{v} = 1892$ (s), 1867 (s), 1837 (s), 1810 cm^{-1} (s–m).[2l] The yield of **4** calculated on the basis of **3** unambiguously indicates its formation from both **3** and $[Pd_2(dba)_3]$. A crystal of **1** of dimensions $0.30 \times 0.20 \times 0.20$ mm^3 was used for the determination of the crystal structure; b) E. G. Mednikov, N. K. Eremenko, *Izv. Akad. Nauk SSSR Ser. Khim.* **1982**, 2540. [*Bull. Acad. Sc. USSR Div. Chem. Sc. (Engl. Transl.)* **1982**, *31*, 2240].

[4] In a typical experiment $[Pd_{10}(CO)_{12}(PEt_3)_6]$ (**3**; 0.150 g, 0.071 mmol) and $Me_3NO\cdot 2H_2O$ (0.127 g, 1.143 mmol) were dissolved in a mixture of Me_2CO (7.5 mL), THF, iPr_2O or Et_2O (2.5 mL), and CF_3CO_2H (0.66 mL, 8.57 mmol) in a 100-mL flask with 4–6 min of ultrasonication or heating (≈ 35°C) under Ar. After ten days, black plate arrow-end crystals of **2′** were isolated by decanting the mother liquors and washed with acetone (50–55 mg, 45–50%). Elemental analysis (Zelinsky Institute of Organic Chemistry): calcd (%) for $Pd_{66}(CO)_{46}$-$(PEt_3)_{16}$: C 16.72, H 2.37, P 4.86, Pd 68.84; found: C 16.38, H 2.30, P 4.89, Pd 69.28; IR (nujol): $\tilde{v} = 1883$–1881 cm^{-1} (s br). Crystals obtained from this procedure were monoclinic with a β angle close to 90°; for example, $a = 20.417(5)$, $b = 35.711(9)$, $c = 30.877(11)$ Å, $\beta = 90.04(2)$°, $V = 22512(12)$ Å^3; or $a = 20.48(1)$, $b = 35.48(4)$, $c = 30.55(2)$ Å, $\beta = 90.10(5)$°, $V = 22194(49)$ Å^3, etc. Solution of the structural data from their X-ray data sets could not be refined but did disclose the $\{Pd_{66}P_{16}\}$ fragment of **2′**.

[5] $[Pd_{10}(CO)_{12}(PEt_3)_6]$ (**3**; 0.150 g, 0.071 mmol) and $[Pd(MeCN)_4]$-$(BF_4)_2$ (0.063 g, 0.142 mmol) were dissolved in a mixture of THF (10 mL) and Me_2CO (5 mL) under N_2. On the next day, the solvent was evaporated and the black residue was extracted with MeCN. Crystallization in the presence of vapor from a 1:1 mixture of iPr_2O/hexane gave black needlelike crystals of **2** (15 mg, 13%). IR (nujol): $\tilde{v} = 1884$ cm^{-1} (s br) with shoulders at 1916 and 1867 cm^{-1}. A crystal of dimensions $0.61 \times 0.28 \times 0.18$ mm^3 was used for the determination of the X-ray crystal structure.

[6] On a related note, a recent systematic preparative/structural investigation[2i] has provided compelling geometrical evidence for a previously unknown stereochemical example involving close-packed, nanosized cuboctahedral-based $[Pd_{23}(CO)_x$-$(PEt_3)_{10}]$ clusters that comprise structurally analogous $\{Pd_{23}$-$(PEt_3)_{10}\}$ fragments with variable numbers of carbonyl ligands ($x = 20, 21, 22$). This observed expanded capacity of CO coordination on the same centered Pd_{23} polyhedron from the thermodynamically stable structure with 20 CO ligands to the kinetic products with additional CO ligands ($x = 21, 22$) without notable changes in the geometry of the common $\{Pd_{23}(PEt_3)_{10}\}$ fragment was attributed to the nanosized (≈ 0.8–0.9 nm) architecture of the metal core.

[7] a) **1**: trigonal; $R\bar{3}$; $a = b = 17.303(2)$, $c = 51.067(13)$ Å, $\alpha = \beta = 90$°, $\gamma = 120$°, $V = 13240(4)$ Å^3; $Z = 3$, $\rho_{calcd} = 3.083$ Mg m^{-3}. Mo$_{K\alpha}$ data collected at 173(2) K with Bruker SMART CCD-1000 area-detector diffractometer by 0.3ω scans over a 2θ range from 2.40 to 46.62°; empirical absorption correction (SADABS) applied; μ(Mo$_{K\alpha}$) = 5.328 mm^{-1}; max/min transmission, 0.416/0.298. Full-matrix least-squares refinement (SHELXTL)[7c] (300

parameters; 27 restraints) on 4253 independent reflections converged at $\omega R_2(F^2) = 0.176$ with $R_1(F) = 0.071$ for $I > 2\sigma(I)$; GOF (on F^2) = 1.03; max/min residual electron density 8.87/-5.10 e Å^{-3}. All non-hydrogen atoms were refined anisotropically, except for those of disordered carbonyl groups and disordered ethyl substituents; b) **2**: monoclinic; $P2_1/n$; $a = 20.717(2)$, $b = 35.756(4)$, $c = 30.623(4)$ Å, $\beta = 90.904(1)$°, $V = 22682(5)$ Å^3; $Z = 4$, $\rho_{calcd} = 2.979$ Mg m^{-3}. Mo$_{K\alpha}$ data collected at 100(2) K with Bruker SMART CCD-1000 area-detector diffractometer by 0.3ω scans over a 2θ range from 1.76 to 46.36°; empirical absorption correction (SADABS) applied; μ(Mo$_{K\alpha}$) = 5.247 mm^{-1}; max/min transmission, 0.452/0.142. Full-matrix least-squares refinement (SHELXTL)[7c] (1540 parameters; 236 restraints) on 31516 independent reflections converged at $\omega R_2(F^2) = 0.278$ with $R_1(F) = 0.108$ for $I > 2\sigma(I)$; GOF (on F^2) = 0.894; max/min residual electron density 3.48/-2.41 e Å^{-3}. Palladium and phosphorus atoms were refined anisotropically. CCDC 276453 (**1**) and 276454 (**2**) contain the supplementary crystallographic data for this paper. [11] An anisotropic pancake-shaped displacement ellipsoid observed for the crystallographically independent monocapped Pd(10) atom, which lies on the crystallographic C_3 axis of **1** (Figure 1), is attributed to it being randomly disordered among three sites toward each of the three equivalent inner Pd(4) atoms in the Pd$_6$ triangle. Nevertheless, we consider its site displacements from the threefold axis to be relatively small such that Pd(10) still undergoes μ_3 coordination with three threefold-related edge-bridging carbonyl ligands that span the three Pd(10)–Pd(4) edges. This premise is based upon the least-squares refinement, which indicates that the carbon and oxygen atoms of the crystallographically independent doubly bridging carbonyl group that connects Pd(10) to the inner Pd$_3$ triangle have whole-weighted occupancy factors.

[12] a) The $[Cu_xNi_{35-x}(CO)_{40}]^{5-}$ cluster ($x = 3$ or 5)[12b] provides another striking example of a nanosized close-packed metal-core carbonyl cluster that contains an extra carbonyl ligand. The presence of the extra CO moiety on one of three otherwise symmetry-equivalent sides of the metal core results in a markedly different arrangement on the side of the extra CO to the similar arrangements of CO groups on the other two sides. Its inclusion lowers the symmetry of the 35-atom triangular stacking-layer sequence from pseudo-D_{3h} to C_s symmetry (i.e., a pseudo-vertical mirror plane); b) P. D. Mlynek, M. Kawano, M. A. Two-Component Graded Deposition of Biomolecules with a Double-Barreled Nanopipette**

Kit T. Rodolfa, Andreas Bruckbauer, Dejian Zhou, Yuri E. Korchev, and David Klenerman

There is currently great interest in depositing submicron features of biological molecules on surfaces for miniaturized assays[1–6] and to assemble new structures from biological building blocks.[7] Several methods that have been used to produce these features are based on scanning probe microscopy (SPM) and use either the tip of an atomic force microscope (AFM) or a nanopipette. Dip-pen lithography operates in air and uses an AFM tip to write features of sizes less than 100 nm.[1,5,8–14] Fountain pen lithography has been developed by using apertured AFM tips to produce sub-100-nm features[14] or nanopipettes[6] to produce features of around 300 nm. In both cases, the fountain pen lithography operates in air.

Nanopipettes have also been used for deposition in a buffer solution by using a method based on scanning ion-conductance microscopy (SICM).[15] In this case, voltage-driven deposition gives fine control for delivery at the single-molecule level; however, diffusion of molecules in solution and over the surface broadens the feature size when compared with deposition in air and results in features no smaller than 800 nm.[16–18] The nanopipette, however, has the advantage that it eliminates the need for conditioning of the tip (as is required by dip-pen nanolithography (DPN) for deposition) and provides a large reservoir of molecules. Registry is a common problem with all of these methods and makes it difficult to deposit a different type of molecule on top of or at a defined position relative to another feature. This is, however, a key requirement for the production of complex patterns on surfaces and the assembly of structures made from biological molecules. Currently, this difficulty has been addressed with DPN, by using nanofabricated surfaces with defined topographic features to give registry,[10] or through the use of a 'multiple-pen' array.[11] In our own two-component work, we have addressed this problem by using nanopipettes with fluorescent imaging to provide registry.[17] All of these solutions, however, require the use of a second tip to deposit an additional species.

Herein we present a methodology that eliminates the registry problem for the deposition of two different species on a surface. This is accomplished with a new form of scanning probe microscopy that we developed based on a double-barreled pipette. In this case, two species are independently delivered from each of the pipette barrels of a single tip. Furthermore, fine voltage-driven control of the deposition of two types of biomolecules can be achieved, in the absence of a bath, by creating a potential between the two barrels of the pipette. Operation in air provides smaller feature sizes than deposition in liquid as lateral diffusion is avoided. These advantages allow complex 'two-color' graded patterns to be written with biomolecules.

Double-barreled pipettes are fabricated from glass capillaries (diameter of 1.5 mm, with a septum down the center) by using a pipette puller (Sutter Instruments, Model P-2000). These pipette tips were imaged with scanning electron microscopy (SEM), and the barrels maintained their D-shape throughout pulling (see Figure 1 inset). The heights of the individual barrel openings (when oriented as shown in the Figure 1 inset) ranged from 140 to 185 nm and widths from 100 to 125 nm. As depicted in Figure 1, both barrels are filled with electrolyte solution and a potential (V) is created between the Ag/AgCl electrodes that are placed in the two barrels. When the pipette is held above a surface, a liquid droplet forms automatically at the tip (Figure 1 A). This allows the electrolyte to flow between the barrels and hence provides an ion current (I_{DC}) for control over the surface

Figure 1. Schematic representation of the apparatus. A) A voltage (*V*) applied between Ag/AgCl electrodes in the two barrels of a glass-fabricated nanopipette creates an ion current (I_{DC}) through a droplet which forms at the tip. B) When the tip is brought into contact with a surface, modulation in the *z* direction creates a modulated ion current (I_{MOD}), which provides the feedback signal for control. C) Experimental approach curve for the double-barreled pipette obtained over a PDMS surface. Notice the steep dependence of I_{MOD} on the distance between the tip and the surface. The inset shows an SEM image of a gold-coated pipette tip.

without the need to insert the sample into a bath of conducting solution. As the pipette approaches the surface, a meniscus is formed between the tip and surface (Figure 1 B). I_{DC} is diminished as the tip moves closer to the surface.

To provide more robust distance control, the tip was modulated in the *z* direction (usually with an amplitude of ± 50 nm), and a modulated ion current (I_{MOD}) was detected with a lock-in amplifier (Model SR 830, Stanford Research

Systems).[19] Generally, these pipettes are controlled at 75–125 nm above the sample, as determined by approach curves to the surface. Figure 1 C shows the steep dependence of the modulated ion current on the distance between the tip and the surface. The graph reaches a maximum when the tip just touches the surface at the peak of its modulation. Feedback control of the tip–surface distance is obtained by using a piezoelectric translation stage that adjusts the *z* position of the sample to maintain a constant value of I_{MOD} (indicated on the graph with 'Set Point'; usually around 50 pA, which corresponds to a tip–surface distance of 100 nm).

To test the feedback control of this system, a sample surface fabricated from polydimethylsiloxane (PDMS) and consisting of ridges of 2 μm in width and 1.2 μm in height was imaged with the double-barreled pipette and tapping-mode AFM in air.[20] Figure 2 shows the correspondence between the images obtained with the two techniques. Notably, the pipette cannot track up steep slopes or tight grooves quite as well as the AFM, and as such the ridges appear wider at their bases. This is understood to be a result of the differences in the size and geometry of the tips and has also been observed with single-barreled pipettes.[21] Nonetheless, the agreement in feature heights and spacing is good; in particular, the pipette successfully characterized the smaller peaks in the grooves. These results indicate that double-barreled pipettes can be reliably controlled over a surface while operating in air and allows not only topographical scanning but also deposition of biomolecules.

A droplet must form at the tip of the pipette to produce an ion current, and as such it is not clear whether a significant residue of the solution is left behind as the tip moves across the surface, or whether the surface tension causes the solution to dewet as the tip moves away. To investigate this, a fluorescent dye (alexa 488) was added to both barrels and excited with 488-nm laser light while the pipette was scanned across a glass surface. No fluorescent trail was observed (with a highly sensitive CCD camera) as the tip moved across the glass, which indicates that dewetting was occurring. To deposit materials on a surface, therefore, we must functionalize the surface to interact with the molecules to be deposited. To achieve this, the glass surface was coated with a positively charged polymer, polyethyleneimine (PEI), and both barrels were loaded with alexa 488-labeled rabbit immunoglobulin G (IgG, which is known to adhere to positively charged surfaces).[22] It was observed that the IgG migrated, due to electroosmotic flow, away from the positive electrode and towards the negative one[17] so that the protein was only seen to come out of one barrel at any time. Alteration in the direction of the applied voltage, however, would switch the barrel in which the protein was seen to exit (Figure 3 A). As expected, the IgG delivered from the pipette adhered to the PEI-modified glass surface and left fluorescent IgG molecules deposited on the surface as the pipette was moved across it.

As the double-barreled pipette operates in air, we expected a finer feature size than that obtained with single-barreled pipettes operating in solution. In solution, molecules will spread through three-dimensional diffusion to the surface or two-dimensional diffusion on the surface and thus broaden the feature size.[17] Previously, in solution we measured a spot

Figure 3. A) Principle of double-barreled pipette deposition. The two barrels of the nanopipette are filled with different fluorophore-labeled antibodies for deposition onto a PEI-coated glass surface. The voltage between the two barrels produces the distance–feedback control current and controls the molecular delivery. Note that antibodies are delivered only from one barrel at a time as they flow to the negative electrode. (B) & (C) show fluorescence images of alexa 488-labeled IgG spotted onto a PEI-coated glass surface. B) Spots at deposition times of 5, 10, 20, 40, 80, and 160 s and 2.0-V tip potential (inset) and linear fit to fwhm diameters of the spots. C) Spots deposited at 0.5-, 1.0-, 1.5-, and 2.0-V tip potentials for 10 s (inset) and linear fit to integrated intensities of the spots. Scale bars in both images are 5 μm. The error bars represent the error in Gaussian fits. Data are representative for an individual pipette; however, fit parameters can vary between pipettes.

size (full width at half-maximum, FWHM) of 1.3 μm with single-barreled pipettes and IgG (830 ± 80 nm for biotinylated DNA on a streptavidin-coated glass surface).[16] In these experiments, performed in air, the feature size deposited on

the surface was found to depend on both the applied voltage and the deposition time. Dots spotted at a fixed voltage of 2.0 V on the surface with dwell times of 5, 10, 20, 40, 80, and 160 s are shown in the inset in Figure 3B. Gaussian fits of the profiles of these spots yielded detected feature sizes that ranged from 440 to 630 nm and were linearly distributed with the deposition time ($R^2 = 0.9965$, from 5 to 80 s) as shown in Figure 3B.[23]

A major advantage of the SICM-based writing method is the possibility for voltage control of the amount of material that is delivered. Voltage control of IgG delivery was tested through the application of 2.0, 1.5, 1.0, and 0.5 V across the two barrels with a deposition time of 10 s at each spot on the glass surface. At voltages lower than 500 mV, the ion current was too low to maintain control of the pipette and resulted in the pipette crashing into the surface. The inset in Figure 3C shows the fluorescent image from these dots. The integrated intensities of the Gaussian fits of the spot profiles were distributed linearly ($R^2 = 0.9864$, Figure 3C) with the applied voltage and shows that the amount of material being deposited can be controlled by variation of the voltage applied. The data shown in Figure 3B and 3C are representative of individual pipettes; the parameters were obtained by linear fits to these data and can vary between pipettes.[24]

The feature sizes observed here are significantly smaller than those previously obtained with single-barreled pipettes. This is because molecules deposited by a double-barreled pipette operating in air reach the surface through a small liquid meniscus and cannot diffuse laterally beyond its boundary while still in transit. With increased deposition time, the material has a greater opportunity to diffuse throughout the volume of the meniscus and reach the surface. However, as seen in the 160-s point in Figure 3B, the amount of material being deposited and the resultant feature size reaches a natural plateau as the material fills out the limited volume of the meniscus and saturates the surface of its footprint. At constant deposition time, increased voltage is understood to affect feature size by simply speeding up the rate at which molecules are driven towards the surface by electroosmotic flow.

More-complex features can be achieved by using biotinylated, fluorescently labeled DNA deposited onto a streptavidin-coated glass surface. Although we found that DNA gave comparable feature sizes to that of IgG (25 dots with a 5-s deposition time yielded an average spot size of 510 ± 40 nm, individual spot sizes ranged from 350 to 600 nm (data not shown)),[25] graded deposition was far more reliable with the DNA/streptavidin system. For instance, Figure 4A shows an example of a grayscale square of alexa 647-labeled DNA that was produced by writing several concentric squares of different sizes. Although graded depositions have been produced with a complex technique based on microfluidics,[26] to our knowledge the only previous report of this ability with an SPM method is our work with single-barreled pipettes.[16, 17]

Furthermore, because double-barreled writing opens up the possibility for deposition of two separate species from the same tip, we explored this advantage by using DNA. The DNA was observed to migrate towards the positive electrode, only coming out of one barrel at a time, therefore allowing
Figure 4. Fluorescence images of DNA deposited onto a streptavidin-coated glass surface. A) Gray-scale deposition of alexa 647-labeled DNA that was created by printing several squares on top of each other. B) Two DNA species, one labeled with alexa 647 and the other with rhodamine green were used to print a two-color image of the University of Cambridge crest. C) An image of Sir Isaac Newton downsized with Adobe Photoshop to 75×62 pixels. D) Double-barreled pipette-printed reproduction of the image shown in (C). The image was written with alexa 647-labeled DNA with 1-μm pixels (printed area is 75×62 μm^2). This image took 27 min to produce. E) An image of the painting "Degas Dancers" by Gina Candelori, downsized with Photoshop to 75×61 pixels and the blue channel removed. F) Double-barreled pipette-printed reproduction of the image in (E) with green and red channels written consecutively in rhodamine green and alexa 647-labeled DNA with 1-μm pixels (printed area is 75×61 μm^2). This image took 35 min to produce.

different DNA species to be driven from each barrel by a change in the sign of the applied voltage. Two different (noncomplementary) sequences of biotinylated DNA, one labeled with the fluorophore alexa 647 and the other with Rhodamine green, were loaded into the barrels and then delivered onto a streptavidin-coated glass surface. Figure 4B shows an example of two-color writing. In this case, the outline of the crest and lions were first drawn in green (Rhodamine green labeled DNA) and the red regions

(alexa 647-labeled DNA) then filled in after switching the sign of the tip potential. The yellow regions were produced where data from the two channels overlapped. The final image was created by measurement of the fluorescence on each channel individually (cross talk between the channels was measured as $<1\%$), scaling the data on a linear grayscale, and by using the two resulting images as 'red' and 'green' channels of an image in Photoshop (ver. 6.0.1, Adobe Systems Inc.) which overlays the two channels (with the third, the 'blue' channel, left blank). As Figure 4 indicates, it is easy to use this system to deliver different species to the same point on a surface. Registry problems are minimized because the tip location is always controlled by the x and y closed-loop piezos that can then be used to return the pipette to a given location after the voltage has been switched. This provides a significant advantage over our previous work with two-color deposition in which the switching of species was only possible by manually switching the pipettes and carefully placing the new tip in the same location.[17]

The many advantages of the double-barreled writing can be combined with lithography software to produce highly complex grayscale and two-color patterning of surfaces. The original and DNA-on-streptavidin reproduction of an image of Sir Isaac Newton are shown in Figure 4C and D, respectively (see the Experimental Section for details). Although several regions of pixels are missing in the image (particularly in the lower right-hand corner), the general fidelity to the original is quite high and the image is clearly recognizable. The missing pixels are likely due to nonuniform coating of streptavidin on the surface, which results in bare patches where the DNA cannot adsorb. The Degas Dancers, shown in Figure 4F, represents another example of a complex pattern written with biomolecules on the submicron scale (presented in the same way as Figure 4B). The images in Figure 4 demonstrate that the double-barreled pipette can produce complex graded patterns of biomolecules on the submicron scale.

The methods described herein significantly improve upon previously published nanopipette methods. We have shown that double-barreled pipettes, when operated in air, can be used for both topographical imaging and reliable deposition of DNA and protein onto modified surfaces. Through the minimization of lateral diffusion, we observed smaller feature sizes in these deposition experiments than could be obtained with a single-barreled pipette operating in solution. Furthermore, the creation of a potential between the two barrels of the pipette presents the opportunity to fill the barrels with different materials and write in two 'colors' by simply switching the direction of the voltage to change the color of the 'ink'. As noted above, this is particularly beneficial because such in situ switching minimizes the registry errors inherent in attempting to bring a new tip to the same place on the surface. Naturally, many of the advantages described herein could be expanded to systems with more than two barrels—pullers currently exist that are capable of creating tips with as many as seven barrels.[27] Such systems could use separate electrodes for control and delivery which would allow several species to be delivered simultaneously. The potential to deposit a larger number of species with the same

pipette also greatly increases the complexity of patterns that can be produced. Furthermore, the possible application to nanoscale biological assays and combinatorial chemistry would allow advancement in bionanotechnology.

Experimental Section

The apparatus consists of an inverted fluorescence microscope in which nanopipettes can be mounted and controlled over the sample stage by using closed-loop piezos.[17] The PDMS stamp for topographical imaging was prepared by replicating a standard photolithography patterned photoresist master with sylgard 184 prepolymers (Dow Corning) through a literature procedure.[20] Surfaces for the IgG writing experiments were prepared by immersing a glass coverslip in an aqueous solution of polythyleneimine (PEI, $2.2\ \mathrm{mg\,mL^{-1}}$) for approximately 15 min and then washing with deionized water. alexa 488-labeled rabbit IgG and streptavidin-coated glass surfaces were prepared as described previously.[16, 17] Fluorophore-labeled DNA was purchased from MWG Biotech AG (Ebersberg, Germany) and the following sequences were used: biotin-5′-AGT CAA GCC ATT GTA GTC CCG CAA CAC ACT CGA GA-3′-alexa 647 and 5′-CTA TGC AGC CAT TGT AGT CC-3′-rhodamine green. IgG or DNA solutions were prepared in phosphate buffer solution (10 mM phosphate, 150 mM NaCl, 2 mM NaN_3, pH 7.2) and routinely delivered from the pipette by using a tip bias of 1 to 2 V.

The images shown in Figure 4C–F were prepared as follows. The original image (not shown) was reduced with Adobe Photoshop to 75 pixels in height and 61 pixels in width, Microcal Origin 7.0 was then used to convert the resulting bitmap into an 8-bit integer ASCII matrix. The relative intensity of each pixel was then scaled to a dwell time between 0 and 1 s over individual pixels. The ASCII data was converted into a lithography file for RHK Lithoedit (RHK Technologies; MI, USA) by using the 'find and replace' function in Microsoft Word to produce the code for 1-µm step sizes between pixels. For the image of Degas Dancers in Figure 4F the blue channel of the original (not shown) was removed with Adobe Photoshop. The red and green channels were processed separately as described above to produce two sets of lithography code that could be run individually to draw first one channel, then the other.

Regio- and Chemoselective 6′-N-Derivatization of Aminoglycosides: Bisubstrate Inhibitors as Probes To Study Aminoglycoside 6′-*N*-Acetyltransferases**

*Feng Gao, Xuxu Yan, Oliver M. Baettig, Albert M. Berghuis, and Karine Auclair**

Aminoglycosides are among the most commonly used broad-spectrum antibiotics.[1] The biological activity relies on their high affinity for the major groove of bacterial 16S rRNA,[2] thereby impeding protein synthesis. A number of aminoglycosides also display antiviral activity owing to specific interactions with viral RNA.[3] The rapid emergence of aminoglycoside resistance in the treatment of infections, however, is a serious threat.[4] In clinical isolates of aminoglycoside-resistant strains, the most frequently observed cause of resistance is the expression of *N*-acetyltransferases.[5] For example, aminoglycoside 6′-*N*-acetyltransferase type Ii (AAC(6′)-Ii) is chromosomally encoded in *Enterococcus faecium*, which is one of the leading causes of hospital-acquired infections.[6] Studies by Wright and co-workers suggest that catalysis by AAC(6′)-Ii occurs through an ordered bi-bi mechanism in which acetyl coenzyme A (Ac-CoA) must bind the enzyme before the aminoglycoside.[5,7] Next, attack of the aminoglycoside 6′-NH$_2$ at the thioester of Ac-CoA is believed to generate a tetrahedral intermediate that collapses to yield an 6′-*N*-acetylaminoglycoside and CoA. Although crystal structures have been reported for complexes of AAC(6′)-Ii with either Ac-CoA or CoA, crystallization experiments of enzyme–aminoglycoside complexes have not been successful.[8] It was envisaged that either 6′-*N*-(S-CoA)aminoglycoside derivatives or bisubstrates (Scheme 1) would facilitate the study of this important class of enzymes. Bisubstrate analogues have exhibited inhibition of serotonin

Scheme 1. Target aminoglycoside–CoA bisubstrates **1–3**. Ade = adenine.

built from neamine (**4**), kanamycin A (**5**), and ribostamycin (**6**), which are examples of nonsubstituted, 4,6-substituted, and 4,5-substituted aminoglycosides, respectively, and are AAC(6′)-Ii substrates. The key step in the synthesis of **1–3** from **4–6** is the preparation of the bromide intermediates **8a**, **9**, and **10**, respectively (Scheme 2). The trifluoroacetic acid (TFA) salt of intermediate **8a** has been synthesized previously by using orthogonal protection in four steps, and with a resultant very low yield (11.6%).[14] As a more-efficient alternative to orthogonal protection/deprotection schemes, we envisaged the use of N-(2-bromoacetyl)oxy-5-norbornene-endo-2,3-dicarboximide (bromoacetyl-NBD ester, **7a**) to transfer regioselectively a bromoacetyl group to the 6′-NH$_2$ of the aminoglycosides. The Boc-NBD ester has been reported to effect regioselective Boc protection of aminoglycosides;[15] however, NBD esters have not been employed for direct aminoglycoside derivatization.

Remarkably, simply mixing the free base neamine and reagent **7a** in either acetone/H$_2$O or acetonitrile/H$_2$O (1:1) at room temperature and in a vial open to the air for a few minutes (monitored by ESI MS) was sufficient to complete the reaction. In contrast, extended reaction times yielded complicated mixtures, possibly arising from the nucleophilic attacks of amino groups at the newly formed bromide. The desired N-6′-bromoacetylneamine (**8a**) was isolated in good yield (70%) by quenching of the reaction mixture with TFA

acetyltransferase,[9] GCN5 histone acetyltransferase,[10] and carnitine acetyltransferases.[11] 3-N-(2-S-CoA-acetyl)gentamicin C$_{1a}$, the only aminoglycoside-CoA derivative reported so far, was prepared enzymatically by using AAC(3)-I (3 mg) to yield the desired product (0.89 mg),[12] which was subsequently found to inhibit AAC(3)-I with high affinity. To date, however, there are no reports of chemical syntheses of CoA-aminoglycoside derivatives. Naturally occurring aminoglycosides are complex molecules, and their regioselective modification remains challenging. Currently, the use of judicious functional-protection chemistry is common; however, the overall yields are low.[13] Herein we report an efficient procedure for the regioselective derivatization of unprotected aminoglycosides at the 6′-NH$_2$ position. This strategy was shown to proceed with high chemoselectivity towards the assembly of CoA-aminoglycoside derivatives **1–3** and **11a–c** (Scheme 2 and Scheme 3). Activity assays of these bisubstrates reveal novel nanomolar tight-binding competitive inhibition of AAC(6′)-Ii.

The target bisubstrates **1–3** were designed based on the proposed tetrahedral intermediate that results from the attack of the aminoglycoside 6′-NH$_2$ on the thioester carbonyl of Ac-CoA in the active site of the enzyme.[5] As the crystal structures of AAC(6′)-Ii[8] did not reveal a potential oxyanion hole, it was envisaged that a bisubstrate containing an amide-based linker could mimic the intermediate. The targets were

after 10 min and subsequent purification by reversed-phase HPLC. To avoid the isolation step and potential decomposition, a one-pot synthesis of **1** from **4** and CoA through **8a**, was evaluated. Bisubstrate **1** was obtained in excellent yield (83%) after purification by HPLC (the crude sample was more than 85% pure (Figure 1a)). The reaction proceeded equally well with the aminoglycosides **5** and **6** (72 and 67%, respectively). In spite of their significant structural differences, kinetic studies revealed that **1–3** showed nanomolar

tight-binding competitive inhibition of AAC(6′)-Ii (Table 1). This observation is consistent with the fact that AAC(6′)-Ii has a broad substrate specificity.[5]

Table 1: The AAC(6′)-Ii-inhibition constants (K_i) for the bisubstrates.

Inhibitor	K_i [nM]	Inhibitor	K_i [nM]
1	76 ± 25	**11a**	43 ± 23
2	111 ± 28	**11b**	161 ± 98
3	119 ± 14	**11c**	7990 ± 2663

The size and geometry of linkers in serotonin-CoA bisubstrates have been reported to show important effects on the inhibition of serotonin *N*-acetyltransferase.[9,16] A similar effect was expected for AAC(6′)-Ii and was investigated by using bisubstrates **1** and **11a–c** (Scheme 3). Unfortunately, the procedure described herein for the synthesis of bisubstrates **1–3** was not easily applicable to the preparation of **11a–c**. The major products observed when synthesis of **11a** was attempted were: an ammonium bromide (likely from the addition of triethylamine to 6′-*N*-(3-bromo-*n*-

propanoyl)neamine); 6′-*N*-acryloyl neamine (the elimination product); and a propanoyl-conjugated neamine dimer (either through S$_N$2 substitution at the bromide by a second neamine function or by Michael addition of a second neamine group to 6′-*N*-acryloyl neamine). Similar products resulted during the initial efforts to prepare **11b** and **11c**. A difference in the reactivities of these longer linkers was expected.[17] Indeed, the 3-bromo-*n*-propanoyl, 4-bromo-*n*-butyroyl, and 5-bromo-valeroyl neamine derivatives (**8b–d**, from the reaction of neamine with **7b–d**) are much less electrophilic than **8a**. Moreover, triethylamine may be too nucleophilic and used in too large an amount, which may favor *N* alkylation over *S* alkylation. As most reported chemoselective *S*-/*N*-alkylation procedures[17] are not compatible with our reagents, we reasoned that a less-nucleophilic base at a lower concentration may favor *S* alkylation. Model studies were performed by using *N*-acetylcysteine as a mimic of CoA, and an array of bases were screened, including KHCO$_3$, NaHCO$_3$, diisopropylethylamine (DIPEA), 1,4-diazabicyclo[2.2.2]octane (DABCO), 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), and 4-dimethylaminopyridine (DMAP). Excellent yields resulted when DIPEA (20 equiv) was used and the mixture was ultrasonicated (5 min). When applied to CoA, these conditions allowed the preparation of **11a**, **11b**, and **11c** in moderate to excellent yields (91, 52, and 93%, respectively). The HPLC trace of crude **11a** is shown in Figure 1b.

AAC(6′)-Ii-inhibition assays showed that **11a** is the most potent bisubstrate inhibitor of this series. Remarkably, the enzyme binds **11a** ≈ 200-fold tighter than its natural substrate Ac-CoA ($K_m = 9.6$ μM). A further increase in the length of the linker, however, rapidly leads to a decrease in activity (Table 1). To demonstrate the usefulness of these inhibitors as structural and mechanistic probes, they were studied by X-ray crystallographic analysis. Although previous crystallization experiments of AAC(6′)-Ii–aminoglycoside complexes had not been successful,[8b,c] bisubstrates **1–3** and **11a–c** crystallized well with the enzyme, providing X-ray diffraction data to ≈ 2.0-Å resolution. Preliminary analysis of the diffraction data for the complex with bisubstrate **11a** (Figure 2) suggests that the conformation of the aminoglycoside bound to AAC(6′)-Ii is very different from that reported for AAC(6′)-Iy,[18] even though both enzymes catalyze the same reaction. Detailed structural and mechanistic analysis of these structures will be reported elsewhere.

After the success of this methodology in the preparation of CoA-aminoglycoside bisubstrates, its general applicability to acylation was investigated (Scheme 4). Most of the acyl groups tested were transferred regioselectively to neamine with excellent yields. NBD esters of highly hindered acyl groups such as 2-methylbenzoyl and 2,6-dichloro-benzoyl, however, did not react at all. The regioselectivity of the transfer to kanamycin A, ribostamycin, and neomycin was tested with benzoyl-NBD and showed excellent selectivity for *N*-6′-acylation.

In conclusion, we have described a highly efficient synthetic strategy for the regioselective acylation of aminoglycosides at the 6′-NH₂ group. This process was successfully applied to the one-pot synthesis of 6′-*N*-(*S*-CoA)aminoglycoside analogues. Most of these bisubstrates were nanomolar tight-binding competitive inhibitors of AAC(6′)-Ii, an important enzyme leading to antibiotic resistance. The high potency of these bisubstrate inhibitors and the crystal structure of enzyme-bound **11a** suggest that they may be good mimics of one of the enzymatic reaction intermediates.[5] The bisubstrates reported here have allowed crystallization of AAC(6′)-Ii with aminoglycoside derivatives. The resulting structures should provide valuable guidance in further studies of this enzyme and other members of this family.

Immunoassays

Sandwich Immunoassay as a High-Throughput Screening Method for Cross-Coupling Reactions**

Paola Vicennati, Nicolas Bensel, Alain Wagner, Christophe Créminon, and Frédéric Taran

Combinatorial and parallel methods have become an important focus of research in catalysis. In particular, techniques that allow the simultaneous screening of numerous catalyst candidates have gained particular attention as they may accelerate the identification and optimization of active catalysts. To fully realize the potential of combinatorial approaches for catalyst discovery, general and powerful high-throughput screening (HTS) is therefore essential.[1] In this context, several techniques, including IR thermography,[2] capillary electrophoresis,[3] mass spectrometry,[4] image analysis,[5] and chemosensing[6] have been developed. The use of chromogenic[7] and fluorogenic[8] substrates is also a very popular approach for monitoring chemical transformations.

We recently demonstrated that, aside from spectroscopic or chemosensor-based methods, techniques that exploit the specific-binding properties of antibodies might be valuable tools for the high-throughput screening of enantioselective catalysts.[9] Herein, we report a new versatile enzyme immunoassay (EIA) format that is suitable for the fast screening of coupling reaction.

One of the most convenient methods to screen reactions that involve bond formation is fluorescence resonance energy transfer (FRET).[10] Although this method has many advantages, false positives caused by intermolecular quenching from the catalytic system may occur.[11]

As our aim was to provide a more-general analytical tool, we chose to adapt sandwich immunoassays, a well-known diagnostic technique for antigen detection, for the high-throughput screening of cross-coupling reactions. Typically, sandwich immunoassays require two specific monoclonal antibodies (mAbs), one that ensures the capture of the

antigen onto a solid phase and the second that acts as a detector. Both antibodies can simultaneously bind the antigen through the recognition of two distinct epitopes. The principle of this assay might easily be extended to catalyst discovery through the use of substrates that are conveniently tagged with haptens. If hapten moieties (tags) are linked to the chemical functional groups **A** and **B**, which react through covalent-bond formation in the presence of a catalyst, the double-tagged product **A**–**B** is formed. This product should then be detected through a direct sandwich immunoassay with the help of two specific antitag antibodies (Figure 1).
Figure 1. Schematic depiction of the HTS procedure by using a sandwich immunoassay.

In the first step, the crude chemical mixture is added to a microtitre plate that was previously coated with an antitag 1 antibody. The wells are washed with phosphate buffer (10mM, containing 0.05% tween 20) to remove reactant **B** and any unbound material. The second antibody (antitag 2), labeled with an enzyme is then added. The concentration of the product **A**–**B** can now be determined from the absorbance signal, which is related to the activity of the solid-phase-bound enzyme. Thus, the yields of a reaction that involves any kind of covalent bond formation can be easily determined by using an inexpensive and automated absorbance plate reader.

To illustrate the efficiency of this concept, we applied this method to the screening of palladium-based catalysts for the Sonogashira reaction, which was chosen as the model coupling reaction. The alkyne and aryl iodide partners were tagged with imidazole-based (tag 1)[12] and guaiacol-based (tag 2)) haptens, respectively, to form **1** and **2**. Specific monoclonal antibodies had been produced previously in our laboratories for these haptens.[13] The feasibility of this assay depends on the possibility of the product **3** being bound by the two antibodies. Although routinely used for protein or virus detection, sandwich immunoassays for small molecules are less developed[14] because of a common misconception that very small haptens, such as compound **3**, are not large enough to be simultaneously bound by two antibodies. To the best of our knowledge, the smallest molecule previously detected by sandwich immunoassay is angiotensin II, an octapeptide with a molecular weight of 1048 Da.[15]

As several antibodies raised against tags 1 and 2 were available, we investigated a variety of combinations of antibodies (see Supporting Information). The couple,

Communications

mAb 203 (antitag 1) and mAb 46 (antitag 2), provided the best specific signal and demonstrated an efficient simultaneous binding of product **3** (Figure 2). The wells of a microtitre plate were directly coated with mAb 203, and

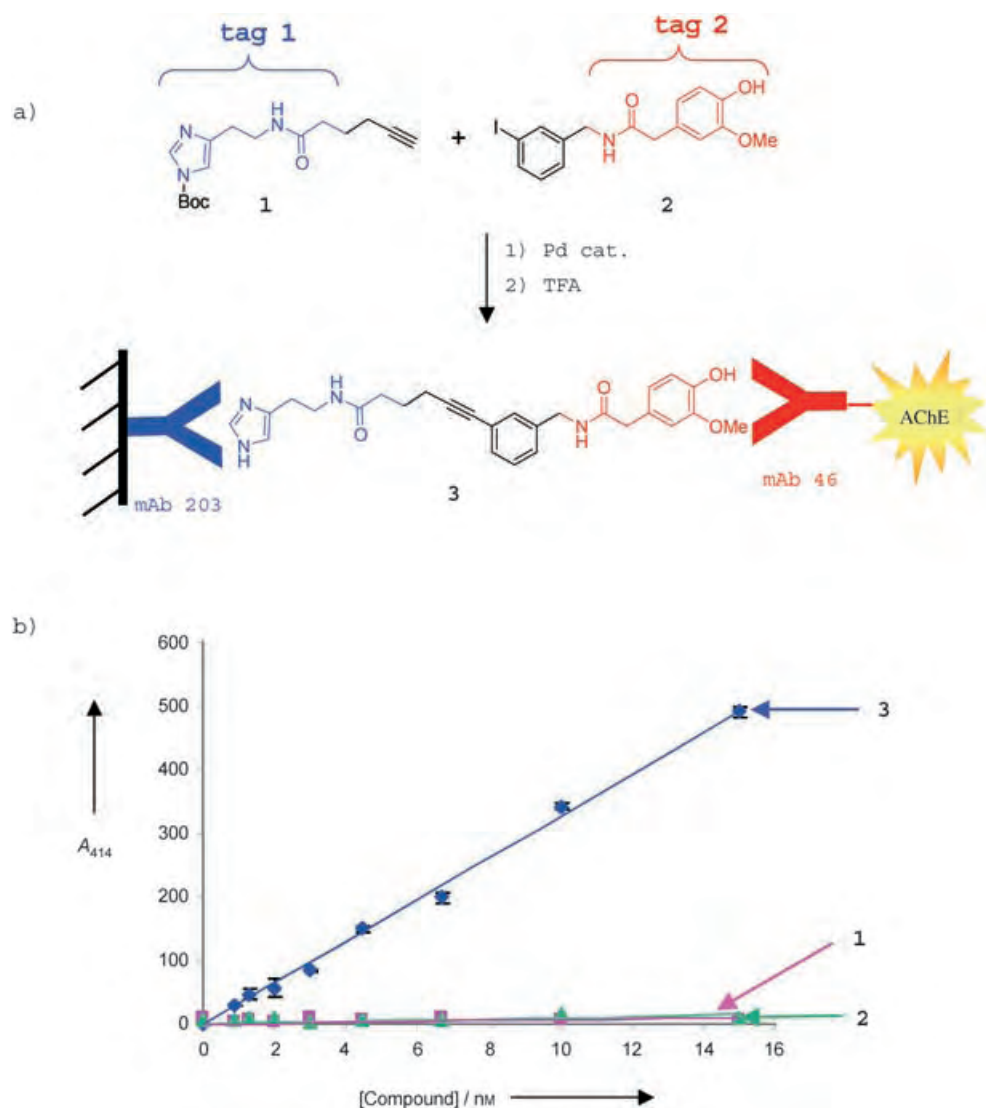

Figure 2. Schematic depiction of the HTS procedure by using sandwich immunoassay. a) the target reaction; b) the standard curves that were obtained with product **3** and reagents **1** and **2**. Boc = *tert*-butoxycarbonyl.

mAb 46 was conjugated to acetylcholinesterase (AChE). Through the use of a conventional sandwich immunoassay protocol and the Ellman reagent (colorimetric enzymatic substrate), product **3** was detected in a dose-dependent manner (Figure 2). This assay could detect **3** at concentrations as low as 10 nM (detection limits: ≈0.5 nM) and no signal was detected for reagents **1** and **2**. The high sensitivity and selectivity of this sandwich assay allowed us to cover a large array of reaction conditions without interference from the substrates, solvent, or catalysts. Thus the yields of the coupled products could be determined without the need for any workup of the reactions.

The Sonogashira reaction, one of the most widely used carbon–carbon bond-forming reactions, usually proceeds in the presence of a homogeneous palladium catalyst and Cu^I salts.[16] We were interested to evaluate the cross-coupling capabilities of heterogeneous palladium catalysts with the aid of the EIA described above. Although the low cost, ease of handling, and high recovery are previously established advantages of heterogeneous catalysts, their use in the Sonogashira reaction is not well documented.[17]

The catalyst library was prepared through the combination of a set of four homogeneous and eight solid-supported palladium sources as well as eight cocatalysts (copper, silver, or gold sources). These 96 catalytic reactions were run in a parallel manner, quenched by the addition of trifluoroacetic acid (TFA), diluted to the appropriate concentration with phosphate buffer, and assayed directly by a sandwich immunoassay (see Experimental Section). The results are shown in Figure 3.

The screening results indicate that under our reaction conditions, the activity of heterogeneous catalysts was similar to or greater than that of homogeneous catalysts. This was confirmed by HPLC analysis and subsequently reproduced on a larger scale. Among the tested catalytic systems, Pd/C combined with CuI or $CuBr\cdot Me_2S$ gave the best yields. We therefore carried out 192 more catalytic reactions in the presence of these two heterogeneous systems. The ligands, base, and solvents were varied to optimize the reaction conditions, the results of which are summarized in Figure 4. These experiments highlight the crucial role of all the tested reaction parameters. PPh_3/TMG in acetonitrile was found to be the most efficient system for both the palladium sources, and **3** was obtained in yields greater than 80%. The reactions were reproduced on the mmol scale without any significant decrease in yield.

To validate our technique, we compared the results of sandwich EIAs with those from HPLC analysis for 68 representative samples from the crude catalyzed reaction mixtures. A good correlation was obtained for EIA and HPLC analysis (Figure 5), with a linear regression that follows the equation $EIA = 1.04\,HPLC + 0.88$ ($r^2 = 0.94$, $n = 68$), for the yield determination. The precision of the measurement was evaluated to be $\pm 3\%$.

Figure 5. Graphical representation of the correlation between the yields determined by HPLC and EIA.

The most efficient catalytic system (Pd/C, CuBr·Me$_2$S, TMG, CH$_3$CN/H$_2$O) was finally and successfully applied to nontagged substrates. Good to high yields were attained for a variety of alkynes and aryl halides by using the optimized catalytic system (see Supporting Information).

In conclusion, we have demonstrated the usefulness of sandwich immunoassays as a highly efficient method of screening catalysts for cross-coupling reactions. We believe that antibody-based immunoassays remain one of the most desirable noninvasive methods for accurate, sensitive, and routine analysis. Although the assay presented herein is restricted to conditions and catalysts that are at least partially compatible with tag structures, we expect that its versatility and efficiency will be of great help in the discovery of catalysts and reactions. Improvement of the presented method would require the production of antibodies directed against chemically inert tags. Furthermore, the high sensitivity of this type of immunoassay allows the exploration of reactions that occur under very dilute conditions (up to 100 nM for the reaction described herein), an advantage that is of great importance in the search for new reactions compatible with bioconjugation.[18]

Figure 3. Sandwich immunoassay screening of the catalyst library for the formation of product **3** from reagents **1** and **2**. Catalyses were carried out in DMF/H$_2$O (95:5) in the presence of 3% of Pd and cocatalyst (10% (w/w)) at 80°C for 20 h. PEI = polyethylenimine.

Figure 4. Sandwich immunoassay screening of the catalyst library for the formation of product **3** from reagents **1** and **2**. Catalyses were carried out in DMF/H$_2$O or CH$_3$CN/H$_2$O (95:5) in the presence of Pd source (3%) and cocatalyst (10% (w/w)) at 80°C for 20 h. TMG = methyl-1-thioβ-D-galactopyranoside, DIPEA = diisopropylethylamine.

Experimental Section

Typical procedure: Pure base (1.5 equiv; 6.6 μL in the case of DIPEA), ligand (0.15 equiv; 19 μL

Communications

from a 0.2 M stock solution in DMF), and alkyne **1** (1.2 equiv; 36 µL from a 0.84 M stock solution in DMF), supported Pd source (3 mg of 10%), cocatalyst source (1 mg), and a mixture of DMF/H_2O (95:5; 1 mL) were added to a 24-vial Miniblock reactor (solution phase synthesizer) that contained aryl iodide **2** (10 mg, 25.2 mM). After two cycles of purging with argon, the reaction mixture was stirred for 20 h at 80°C.

The crude mixtures were then quenched by TFA (100 µL), diluted in EIA buffer (phosphate buffer (0.1 M) and BSA (1 mg mL^{-1}), pH 7.4) in a ratio 1:2 × 10^6. The diluted solutions (100 µL) were transferred to the wells of a microtitre plate that were previously coated with mAb 203 (antitag 1; direct adsorption to the polystyrene support). After 3 h of incubation at room temperature, the plates were washed with phosphate buffer (10 mM, containing 0.05% tween 20, pH 7.4) and the antitag 2 (mAb 46)–AChE conjugate (100 µL) was added. The AChE–mAb conjugate was prepared and stored as previously described.[19] After 12 h of immunological incubation at 4°C, the plates were washed, and Ellman reagent was added. The resultant absorbance (related to the solid-phase-bound AChE activity) was measured at 414 nm. The immunological reagents (antibody for the capture step and enzyme conjugate antibody) were used in excess. All measurements for the standards and samples were made in duplicate.

Cluster Compounds

$[Re_{12}CS_{17}(CN)_6]^{n-}$ ($n = 6$, 8): A Sulfido–Cyanide Rhenium Cluster with an Interstitial Carbon Atom**

Yuri V. Mironov, Nikolai G. Naumov, Svetlana G. Kozlova, Sung-Jin Kim, and Vladimir E. Fedorov**

The first compound with an octahedral sulfide–cyanide rhenium cluster, $KCs_3[Re_6S_8(CN)_6]$, was synthesized ten years ago.[1] Since then, the chemistry of chalcocyanide cluster complexes $[Re_6Q_8(CN)_6]^{n-}$ (Q = S, Se, Te; $n = 3$, 4) has developed intensively.[2–6] A remarkable feature of the $[Re_6Q_8(CN)_6]^{n-}$ complexes is their ability to coordinate the transition-metal and post-transition-metal atoms through ambidentate CN^- ligands. Such coordination leads to the formation of cyanide-bridged polymeric structures with various dimensionalities and architectures. Many complex compounds containing similar octahedral chalcocyanide clusters have now been synthesized and their crystal structures and properties studied in detail.[7]

The general approach for the synthesis of rhenium octahedral chalcocyanide complexes is to treat polymeric solids containing $\{Re_6Q_8\}$ cluster cores with molten KCN or NaCN. A similar method was applied to the synthesis of $[Re_6Te_8(CN)_6]^{4-}$ from $[Re_6Te_{15}]$[3,8] and $[Re_6Q_8(CN)_6]^{4-}$ (Q = S, Se) by using $[Re_6Q_8Br_2]$[2] as precursors.

A few years ago,[9] it was found that ReS_2 and $ReSe_2$ react with molten KCN to form octahedral rhenium-cluster chalcocyanides with bridging S and Se_2 ligands in polymeric layered $K_4[\{Re_6S_8\}(CN)_4S_{4/2}]$ and chainlike $K_4[\{Re_6Se_8\}(CN)_4(Se_{2/2})_2]$ structures. Our further systematic study of phase formation in similar systems has culminated in the discovery of a unique rhenium sulfido–cyanide compound,

$K_8[Re_{12}CS_{17}(CN)_6]$ (**1**), which contains a C-centered $\{Re_{12}\}$ cluster unit.

The diamagnetic compound **1** was prepared by treating ReS_2 with molten KCN with a mass ratio ReS_2/KCN of 1:2.[10] Single crystals suitable for a structural study were found in the reaction mixture and the single crystal structure of **1** has been solved by X-ray diffraction.[11] The cluster unit of **1** (Figure 1a) consists of two $\{Re_6\}$ octahedra bonded by three μ_2-S
Figure 1. a) Structure of the $[Re_6(\mu_6\text{-}C)S_{17}(CN)_6]^{8-}$ ion in **1**. b) Structure of $[Re_6(\mu_6\text{-}C)S_{17}(CN)_6]^{6-}$ anion in **3**. For average bond lengths and angles, see Table 1. (Displacement ellipsoids are drawn at the 50% probability level.)

bridges and one common μ_6-C atom. Each $\{Re_6\}$ cluster is capped by seven μ_3-S atoms and additionally by the centered μ_6-C ligand; thus, a typical octahedral cluster core analogous to $\{Re_6Q_8\}$ (i.e., $\{Re_6S_7C\}$) is formed. Through such bonding and coordination, we recognize trigonal μ_6-C-centered prisms, $\{Re_6C\}$, in which the triangle faces belong to two adjacent $\{Re_6\}$ octahedra. Six outward Re atoms (three from each $\{Re_6\}$ cluster unit) are coordinated by CN ligands.

The Re−Re interatomic distances in the $\{Re_6S_7C\}$ fragments are comparable with those of $\{Re_6S_8\}$ cluster cores; their mean values are 2.595 Å for Re^{outer}–Re^{outer}, 2.591 Å for Re^{inner}–Re^{inner}, and 2.622 Å for Re^{outer}–Re^{inner} (see Table 1). These values are within the range for Re−Re single bonds observed in octahedral rhenium clusters (in $[Re_6(Q_8(CN)_6]^{4-}$ mean Re−Re distances are 2.599, 2.633, and 2.684 Å for Q = S, Se, and Te, respectively[7a]).

In the trigonal-prismatic $\{Re_6C\}$ units, the long Re···Re separations are 3.1576(17), 3.1722(17), and 3.1740(17) Å. Re−(μ_3-S) bond lengths range from 2.401(6) to 2.445(6) Å. These separations are comparable with those found in other $Re_6S_8L_6$ cluster units, for example $[Re_6S_8(CN)_6]^{4-/3-}$ [4] and $[Re_6S_8Br_6]^{4-}$,[12] and polymeric $K_4[\{Re_6S_8\}(CN)_4S_{4/2}]$[9] and $Li_4[\{Re_6S_8\}S_{6/2}]$.[13] The mean Re−(μ_2-S) bond length of **1**, 2.425 Å is close to Re−S bond lengths found in numerous Bronger phases.[14] Re−(μ_6-C) bond lengths in the trigonal prism, $\{Re_6C\}$, range from 2.16(2) to 2.21(2) Å.

Dissolution of **1** in water resulted in fast oxidation of the $[Re_{12}CS_{17}(CN)_6]^{8-}$ ion and formation of the $[Re_{12}CS_{17}(CN)_6]^{6-}$

Table 1: Experimental and calculated interatomic distances [Å] and angles [°] in the clusters $[Re_{12}(\mu_6\text{-}C)S_{17}(CN)_6]^{n-}$.

	Experimental			Calculated

[a] Difference between values for anions with $n=8$ and $n=6$.

ion, which was isolated as a diamagnetic potassium or cesium salt—$K_6[Re_{12}CS_{17}(CN)_6]\cdot20H_2O$ (**2**) or $Cs_6[Re_{12}CS_{17}(CN)_6]$ (**3**); single crystals of **2** and **3** were obtained by recrystallization of **1** from aqueous solutions.

Crystal structures of **2** and **3** contain the $[Re_{12}CS_{17}(CN)_6]^{6-}$ cluster unit (Figure 1 b). The removal of two electrons from the $[Re_{12}CS_{17}(CN)_6]^{8-}$ ion leads to remarkable changes in the interatomic distances of the cluster, and at the same time, the interatomic distances in the trigonal prism, $\{Re_6C\}$, are most sensitive to these redox transformations. For example, in the $[Re_{12}CS_{17}(CN)_6]^{8-}$ ion, the Re···Re distances are 3.168 Å while in the oxidized complex, $[Re_{12}CS_{17}(CN)_6]^{6-}$, they are shortened to 2.902 Å. The mean bond lengths in these anions are presented in Table 1. These changes in interatomic distances are in a good agreement with DFT calculations for $[Re_{12}CS_{17}(CN)_6]^{8-}$ and $[Re_{12}CS_{17}(CN)_6]^{6-}$ ions with idealized D_{3h} symmetry.

The most surprising feature in these compounds is the presence of a carbon atom inside the cluster unit of the product. Its origin may be explained by the partial decomposition of KCN. If that is the case, a nitrogen atom might also be found in the cluster unit. However, X-ray diffraction studies did not identify the μ_6 interstitial atom. Therefore we studied by NMR spectroscopy solids enriched with ^{13}C and ^{15}N isotopes. Several samples of **2** were synthesized from $K^{13}CN$ and $KC^{15}N$ starting materials. The ^{13}C NMR spectrum of **2** (Figure 2) displays two signals at $\delta=127$ and 435 ppm with relative intensities close to 6:1. The signal at $\delta=127$ ppm corresponds to coordinated CN ligands whereas the signal at $\delta=435$ ppm may be attributed to the interstitial carbon atom.[15]

The potassium salt of **2** readily dissolves in water and methanol, which allowed us to study its properties by solution-chemistry methods. The ESI mass spectrum (positive
Figure 2. ^{13}C MAS NMR spectrum of **2**. Satellite signals are marked by asterisks.

mode) of a solution of **2** in a mixture of water and acetonitrile is shown in Figure 3. The most intense peak corresponds to the dicationic $\{K_8Re_{12}CS_{17}(CN)_6\}^{2+}$ ($m/z=1630.35$, 100%).
Figure 3. ESI mass spectrum of **2** in a H_2O/CH_3CN solution.

The spectrum contains also two sets of less intense peaks: one set can be attributed to adducts with acetonitrile, $\{K_8Re_{12}CS_{17}(CN)_6(CH_3CN)_n\}^{2+}$, $n=2$ ($m/z=1671.38$, 35%), $n=4$ ($m/z=1712.40$, 24%), $n=6$ ($m/z=1753.40$, 17%); the other set belongs to a protonated species, $\{(H_3O)K_7Re_{12}CS_{17}(CN)_6(CH_3CN)_n\}^{2+}$.

Cyclic voltammograms for aqueous solutions of **2** show two quasi-reversible waves: the $[Re_{12}CS_{17}(CN)_6]^{6-}$ ion exhibits one reduction wave with the $[Re_{12}CS_{17}(CN)_6]^{6-/8-}$ couple centered at $E_{1/2}=-0.56$ V ($\Delta E=200$ mV). The negative value of this potential is consistent with the fact that $K_8[Re_{12}CS_{17}(CN)_6]$ is not stable in aqueous solution but rapidly converts into the $[Re_{12}CS_{17}(CN)_6]^{6-}$ ion. The voltammogram for a solution of $[Re_{12}CS_{17}(CN)_6]^{6-}$ has one oxidation wave at $E_{1/2}=0.70$ V ($\Delta E=100$ mV). This wave corresponds to further oxidation of the $[Re_{12}CS_{17}(CN)_6]^{6-}$ ion, which was

confirmed by chemical oxidation with bromine. Isolation and characterization of this oxidized anion is in progress.

Density functional theory (DFT) calculations[16] performed on the complexes $[Re_{12}CS_{17}(CN)_6]^{6-}$ and $[Re_{12}CS_{17}(CN)_6]^{8-}$ gave bond energies of -309.2 and -285.1 eV, respectively. For the $[Re_{12}CS_{17}(CN)_6]^{6-}$ complex, the $13a_2'$ highest occupied molecular orbital (HOMO) consists predominantly of S and 3p orbitals ($\approx 80\%$) with a small contribution from the Re 5d orbitals. There is no contribution from the μ_6-C states (Figure 4). The HOMO orbital of
Figure 4. Calculated energy level diagrams and HOMO orbitals:
a) $[Re_{12}CS_{17}(CN)_6]^{8-}$: The $31a_2''$ MO is shown perpendicular to the C_3 axis. Calculated charges: Re^{inner} ($+0.083$), Re^{outer} ($+0.054$), μ_6-C (-0.209). b) $[Re_{12}CS_{17}(CN)_6]^{6-}$: The $13a_2'$ MO is shown perpendicular to the C_3 axis. Arrows represent the forbidden (dotted) and allowed (solid) electronic transitions. Calculated charges: Re^{inner} ($+0.090$), Re^{outer} ($+0.049$), μ_6-C (-0.212).

$[Re_{12}CS_{17}(CN)_6]^{8-}$ ($31a_2''$) consists of mainly Re 5d orbitals, the μ_6-C $2p_z$ orbital, and μ_2-S $3p_z$ orbitals. In prismatic $\{Re_6C\}$, short Re–Re and Re–(μ_6-C) contacts have bonding character while long Re···Re contacts along edges of the prism are strongly antibonding. Thus the removal of two electrons from the HOMO of complex **1** results in significant changes in the interatomic distances of cluster anions, mainly within the $\{Re_6C\}$ prism (Table 1). Removal of electrons elongates the Re^{inner}–Re^{inner} bond and contracts the long prismatic Re···Re contacts and the Re–(μ_6-C) bond due to the strong antibond-

ing nature of Re···Re interaction. The calculated HOMO–LUMO gap is 1.08 eV for the $[Re_{12}CS_{17}(CN)_6]^{6-}$ ion and 1.44 eV for the $[Re_{12}CS_{17}(CN)_6]^{8-}$ ion. One interesting feature of the cluster is the position of $31a_2''$ orbital, which strongly depends on the charge of anion (Figure 4) and correlates with the length of the Re···Re interactions.

The absorption bands in the visible region of the electronic spectrum of $[Re_{12}CS_{17}(CN)_6]^{6-}$ are in good agreement with the calculated electronic structure. According to symmetry rules for D_{3h} symmetry, the electron–dipole transitions from occupied $13a_2'$ to the next unoccupied $14a_2'$ and $45e'$ levels are allowed. Energies of calculated transitions (Figure 4) are close to the observed absorption band at 740 nm; very weak absorption at 1150 nm may be attributed to the forbidden $13a_2' \rightarrow 31a_2''$ transition.

A simple valence electron count shows that in the $[Re_{12}CS_{17}(CN)_6]^{8-}$ ion the rhenium atoms have a charge of $+3$.[17] Accordingly, the $[Re_{12}CS_{17}(CN)_6]^{6-}$ ion contains slightly oxidized rhenium atoms ($Re^{3.17+}$), which correlate with charges of rhenium atoms calculated by DFT.

Vibrational spectra of the complexes display CN valence stretch vibrations and group vibrations associated with the $\{Re_{12}CS_{17}\}$ cluster core. The bands at 403–406 cm^{-1} may be attributed to ReS stretching. The decrease of anion charge leads to increase of CN stretching vibrations (from $\tilde{\nu} = 2114$ for **1** to 2120 cm^{-1} for **3**). This change is less than that for the $[Re_6S_8(CN)_6]^{4-/3-}$ octahedral ions for which the difference is about 18 cm^{-1} (ν(CN): $\tilde{\nu} = 2119$ cm^{-1} for $[Re_6S_8(CN)_6]^{4-}$ with 24 electrons per $\{Re_6\}$ cluster and 2137 cm^{-1} for $[Re_6S_8(CN)_6]^{3-}$ with 23 electrons per $\{Re_6\}$ cluster).[4,7b] The group of lines in the range 640 to 950 cm^{-1} may be assigned to "breathing" vibrations of the $\{Re_{12}C\}$ cluster core.

Several dodecanuclear cluster chalcogenide complexes of Co, Mo, W, and Re were described earlier.[18–22] However, the bonding in all of these clusters is different from that in the clusters described above: two octahedral $\{M_6Q_8\}$ units are bridged by a $\{M_2Q_2\}$ rhomblike Chevrel phase. The formation of atom-centered trigonal prisms has been found in some related anions with interstitial atoms—$[W_6(\mu_6\text{-}Q)Cl_{18}]^{n-}$ (Q = C, $n = 0$–3; Q = N, $n = 1$–3),[23] $[Nb_6(\mu_6\text{-}S)Br_{17}]^{3-}$[24]—and in polymeric chalcohalides of niobium $]Nb_6(\mu_6\text{-}S)I_9]_\infty$[25] and molybdenum $[Mo_6(\mu_6\text{-}Se)I_6Se]_\infty$.[26] There are many other clusters, for example carbonyl compounds, with interstitial atoms around which atom-centered trigonal prisms are formed.

In summary, we have synthesized novel cluster complexes with a unique structure that may represent a new family of $\{Re_{12}\}$ clusters. The presence of terminal cyano ligands favors the use of these anions as building blocks for the formation of cyano-bridged polymeric materials such as those of the $[Re_6Q_8(CN)_6]^{4-}$ family.[7] Ions larger than $[Re_6S_8(CN)_6]^{4-}$, such as $[Re_{12}CS_{17}(CN)_6]^{n-}$ ions, may give polymers with larger voids and high porosity.

Experimental Section

ReS$_2$ was prepared from Re and S in an evacuated quartz tube at 650°C. Commercially available reagent-grade KCN was used. UV/Vis spectra were recorded on Shimatzu 3101PS spectrometer. IR spectra

[10] The reaction of ReS$_2$ with KCN has been studied in the temperature range from 650 to 800°C by using different ReS$_2$/KCN ratios. We found that for mass ratios of ReS$_2$/KCN from 1:2 to 1:20 the main product of the reaction was K$_8$[Re$_{12}$CS$_{17}$(CN)$_6$]. To understand the conditions that yield [Re$_{12}$CS$_{17}$(CN)$_6$]$^{8-}$, KCs$_3$[Re$_6$S$_8$(CN)$_6$] was used as the starting material. It was found that [Re$_6$S$_8$(CN)$_6$]$^{4-}$ transforms into [Re$_{12}$CS$_{17}$(CN)$_6$]$^{8-}$ if the temperature rises to between 700 and 800°C. Furthermore, the reaction of [Re$_6$S$_8$Br$_2$] with KCN at high temperature also gave the [Re$_{12}$CS$_{17}$(CN)$_6$]$^{8-}$ cluster , whereas below 650°C [Re$_6$S$_8$(CN)$_6$]$^{4-}$ formed. These data indicate that [Re$_{12}$CS$_{17}$(CN)$_6$]$^{8-}$ cluster is thermodynamically stable within the 650 to 800°C range.

[15] To determine isotropic chemical shifts of carbons the ^{13}C magic-angle spinning (MAS) NMR measurements were made by using a BRUKER Bio-Spin Avance 400 MHz solid-state NMR spectrometer. The spinning rate was 20 kHz, the π/2 pulse duration was 5 s, the relaxation delay was 10 s. About 200 free induction decays were accumulated at room temperature. TMS was used as a reference. The ^{15}N NMR spectrum contained one sharp signal at 311 ppm (relative to NH$_3$), which corresponds to coordinated cyano ligands. No signal attributable to an interstitial nitrogen atom was found. The diamagnetic properties of

compounds **1**–**3** indicated the presence of an interstitial atom with an even number of electrons.

Redox Chemistry

Aqueous $Fe^{IV}=O$: Spectroscopic Identification and Oxo-Group Exchange**

Oleg Pestovsky, Sebastian Stoian, Emile L. Bominaar, Xiaopeng Shan, Eckard Münck,* Lawrence Que, Jr.,* and Andreja Bakac*

An aqua oxoiron(IV) species is believed to play important roles in environmental and catalytic chemistry, and has been proposed by some researchers as an alternative to HO• as the Fenton oxidant, that is, the intermediate produced in the reaction between Fe_{aq}^{2+} and H_2O_2 in aqueous solution.[1–8] The existence of a ferryl intermediate, most probably $[(H_2O)_5Fe^{IV}=O]^{2+}$, has not been established independently in acidic and neutral solutions. Such a complex is, however, believed to be generated in the $[Fe(H_2O)_6^{2+}]$/ozone reaction,[9–11] which simultaneously yields one equivalent of O_2,[10] a fact that rules out the description of the intermediate as an ozonide complex. The ozone-generated transient species decays exponentially ($\tau \approx 10$ s in acidic aqueous solution),[10,11] bears a 2+ charge,[11] and oxidizes organic and inorganic substrates.[11,12] All of these findings support the formulation of $[(H_2O)_5Fe^{IV}=O]^{2+}$, but the decisive spectroscopic data have not been available until now.

The species of interest, which we call **Z**, was generated at pH 1 in aqueous solution from $[Fe(H_2O)_6]^{2+}$ and O_3[10,11] [Eq. (1)]

$$[Fe(H_2O)_6]^{2+} + O_3 \rightarrow [(H_2O)_5Fe^{IV}=O]^{2+} (\mathbf{Z}) + O_2 + H_2O \quad (1)$$
The sample preparation for Mössbauer spectroscopy and other experimental details are described in the Supporting Information. In addition to **Z**, the samples also contained up

to 50% $[Fe(H_2O)_6]^{3+}$, produced mainly by the decomposition of **Z** during sample preparation and handling (see Supporting Information).

Figure 1 shows the Mössbauer spectra recorded at 4.2 K in magnetic fields applied parallel to the observed γ-radiation.
Figure 1. Mössbauer spectra of a sample at 4.2 K containing 250 μM **Z**, prepared by the rapid freeze–quench technique (see Supporting Information). The solid lines (red for **Z**, representing ca. 50% of total Fe) are simulations based on Equation (2). The contribution from $[Fe(H_2O)_6]^{3+}$ is shown in blue. We found the following parameters for **Z**: $D = 9.7(7)$ cm^{-1}, $A_x/g_n\beta_n = A_y/g_n\beta_n = -20.3(3)$ T, $\Delta E_Q = -0.33(3)$ mm s^{-1}, $\delta = 0.38(2)$ mm s^{-1}. For the 8.0-T spectrum, the theoretical curves for **Z** and $[Fe(H_2O)_6]^{3+}$ were added (black).

The spectra shown have contributions from two species: a paramagnetic complex (**Z**) with integer electron spin and a high-spin ferric species with parameters identical to those reported for $[Fe(H_2O)_6]^{3+}$.[13] The most prominent feature in the 0.05-T spectrum is a doublet with quadrupole splitting of $\Delta E_Q = 0.33(3)$ mm s^{-1} and isomer shift of $\delta = 0.38(2)$ mm s^{-1}, relative to Fe metal at 298 K. This doublet represents the reactive species **Z** and, as expected, was absent in a sample that was allowed to age for several minutes at room temperature before freezing. The solid lines drawn through the data are spectral simulations (red for **Z**, blue for $[Fe(H_2O)_6]^{3+}$)

based on the spin Hamiltonian H, where H_Q describes the quadrupole interactions [Eq. (2)].

$$H = D[(S_z^2 - S(S+1)/3) + E(S_x^2 - S_y^2)] + 2\beta S \cdot B +$$
$$S A \cdot I - g_n \beta_n B \cdot I + H_Q \qquad (2)$$

The spectra of **Z** in the presence of applied fields exhibit paramagnetic hyperfine structure. The internal magnetic field, $B_{int} = -\langle S \rangle \cdot A/g_n\beta_n$, is negative (namely, opposed to the applied field **B**), and increases with increasing applied field **B**. The outermost absorption lines of the spectrum of **Z** are remarkably sharp, thus showing that B_{int} is axial, and implying that $E \approx 0$ and $A_x \approx A_y$ in Equation (2). The Mössbauer spectra measured at 12 K (see Supporting Information) show that the fluctuation of the electronic spin of **Z** is slow. In the slow-fluctuation limit, the 0.05-T Mössbauer spectrum of a mononuclear ferric complex (a Kramers system) must exhibit (in the same way as $[Fe(H_2O)_6]^{3+}$ in Figure 1) paramagnetic hyperfine structure, whereas non-Kramers systems (such as Fe^{IV} complexes) usually exhibit quadrupole doublets. Our data thus imply that **Z** has integer spin, and suggest that it is (formally) an Fe^{IV}–oxo complex. The theoretical curves (red) for **Z** are spectral simulations generated for $S = 2$ by using the parameters quoted in the caption to Figure 1. The Mössbauer spectra show that **Z** is a pure species and rule out an equilibrium mixture of two forms, such as $\{Fe^{IV}=O\}^{2+}/\{Fe^{IV}(OH)_2\}^{2+}$. The paramagnetic states of Fe^{IV} have spins of either $S = 2$ or $S = 1$. The latter spin can be ruled out because Equation (2) would yield $A_x = A_y \approx -38$ T, which is substantially larger than the largest A values reported for any Fe^{IV}–oxo complex (-25 T).[14,15] The parameters obtained for **Z** are similar to those for the $S = 2$ $\{Fe^{IV}=O\}$ intermediate of *E. coli* taurine: α-ketoglutarate dioxygenase (TauD);[16] $D = 10.5$ cm^{-1}, $A_x/g_n\beta_n = A_y/g_n\beta_n = -18.0$ T, $\Delta E_Q = -0.88$ mm s^{-1}, $\delta = 0.31$ mm s^{-1}. Most plausibly, **Z** is formulated as $[(H_2O)_5Fe^{IV}=O]^{2+}$.

X-ray absorption spectroscopy was carried out on two samples for which Mössbauer spectroscopy established **Z**/$[Fe(H_2O)_6]^{3+}$ ratios of 50/50 and 58/42. Figure 2 shows the

**Figure 2.** Normalized XANES spectra (Fe K-edge) of **Z** (solid line) and $[Fe(H_2O)_6]^{3+}$ (dashed line). The spectrum of **Z** was obtained by subtraction of 50% of the spectrum of $[Fe(H_2O)_6]^{3+}$ from the spectrum of the 1:1 **Z**/$[Fe(H_2O)_6]^{3+}$ sample. The inset shows a magnification of the $1s \rightarrow 3d$ region.

X-ray absorption near-edge structures (XANES) of [Fe-$(H_2O)_6$]$^{3+}$ (dashed line) and **Z** (solid line). The edge energy for [Fe$(H_2O)_6$]$^{3+}$ was found to be 7129 eV. In contrast, Fe^{III} complexes with N/O coordination have edges around 7123 eV.[17] On the basis of density functional theory (DFT) calculations (see Supporting Information) we attribute the higher-energy edge of [Fe$(H_2O)_6$]$^{3+}$ to its high ionic character.[13] Notably, the edge energy of **Z**, at 7126 eV, is midway between that for [Fe$(H_2O)_6$]$^{3+}$ and the range reported for non-heme {Fe^{IV}=O} complexes (7123 eV for the high-spin intermediate of the enzyme TauD,[18] and 7124–7125 eV for the synthetic non-heme low-spin complexes[15,17]). The reduction in the edge energy of **Z** relative to that of [Fe$(H_2O)_6$]$^{3+}$ arises from the strong covalent bonding interaction with the terminal oxo group[19] (see Supporting Information).

Another notable feature in the XANES spectrum of **Z** is its pronounced 1s→3d transition (Figure 2). The intensity of this feature reflects the deviation of the metal center from centrosymmetric geometry; the intensity generally increases upon conversion from octahedral into tetrahedral geometry[20] or upon the introduction of an oxo ligand into a six-coordinate complex.[15,17] The pre-edge feature of [Fe-$(H_2O)_6$]$^{3+}$ has a measured area of eight units, which is typical of nearly centrosymmetric, six-coordinate complexes. For the spectrum of **Z** we found an area of 60–70 units, which is the highest area yet for an iron center. This value is distinctly larger than those observed for known six-coordinate oxo-iron(IV) species (25 to 38 units)[15,17] and suggests an oxo-iron(IV) center with substantial deviation from centrosymmetric geometry.

DFT calculations were performed on **Z** as an [$(H_2O)_5$Fe^{IV}=O]$^{2+}$ species (see Supporting Information). The results can be summarized as follows: 1) Geometry optimization (Figure 3) yields an Fe=O bond length of 1.62 Å, which is similar to the Fe=O bond lengths in other non-heme oxoiron(IV) complexes[14]. 2) DFT calculations yield a ground state with $S = 2$, which is in agreement with the Mössbauer analysis. 3) The hyperfine parameters are equal to those obtained from the Mössbauer spectra. 4) The zero-field splitting of the $S = 2$ ground state is correctly predicted on the basis of electronic excitation energies involving an ($S = $ 1)/($S=2$) spin-mixing mechanism similar to that functioning in the $S = 1$ complex [Fe^{IV}(O)(tmc)(MeCN)]$^{2+}$ (tmc = 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane). 5) The experimental values for δ, ΔE_Q, and the contact contribution to the A-tensor A_c are different for [Fe^{IV}(O)(tmc)(MeCN)]$^{2+}$ and **Z** in ways that the theory predicts if the equatorial sites in tmc are replaced by aqua ligands (see Supporting Information), that is, $\delta(\text{tmc}) < \delta(\mathbf{Z})$, $\Delta E_Q(\text{tmc}) > 0 > \Delta E_Q(\mathbf{Z})$, and $|A_c(\text{tmc})| < |A_c(\mathbf{Z})|$. 6) DFT analysis of the K-edge energy supports the [$(H_2O)_5$Fe^{IV}=O]$^{2+}$ formulation for **Z**.

The reaction between [$(H_2O)_5$Fe^{IV}=O]$^{2+}$ (0.10 mM) and an excess (6–470 mM) of $(CH_3)_2$SO or $(CH_3)(p\text{-tolyl})$SO in 0.10 M aqueous HClO$_4$ produced the corresponding sulfone and regenerated [Fe$(H_2O)_6$]$^{2+}$ quantitatively. The combination of this oxygen-atom-transfer step and the O$_3$/[Fe$(H_2O)_6$]$^{2+}$ reaction constitutes a catalytic cycle for the oxidation of $(CH_3)_2$SO by ozone.

The catalytic oxidation was carried out in H$_2$^{18}O (97 % ^{18}O enrichment, pH 1) and utilized 0.4–7 mM [Fe$(H_2$^{18}O$)_6$]$^{2+}$ as catalyst under continuous bubbling with ^{16}O$_3$ until approximately 30 % of the $(CH_3)_2$S^{16}O (initial concentration 0.1 M) was oxidized. The direct oxidation of $(CH_3)_2$SO by O$_3$ under these conditions contributes ≪ 1 % to the overall process. The products, identified and quantified by GC-MS, were $(CH_3)_2$S^{16}O$_2$ (88 %) and $(CH_3)_2$S^{16}O^{18}O (12 %), irrespective of the concentration of [Fe$(H_2O)_6$]$^{2+}$. With a substrate concentration of 0.010 M, the proportion of $(CH_3)_2$S^{16}O^{18}O increased to 48 %, which is as expected if the intermediate [$(H_2O)_5$Fe^{IV}=O]$^{2+}$ undergoes both reaction with the substrate and oxygen exchange with water (Scheme 1). The data at the

Scheme 1.

two concentrations of $(CH_3)_2$SO were fitted to an equation for competition kinetics (see Supporting Information) and provided an estimate for the rate constant for oxygen exchange as $k_{exch} \approx 10^3$ s^{-1}.

The nearly quantitative yield of $(CH_3)_2$S^{16}O$_2$ at high concentrations of $(CH_3)_2$SO confirms the presence of one unique oxygen atom in the reactive form of the catalyst, which is most consistent with the [$(H_2O)_n$Fe^{IV}=O]$^{2+}$ formulation. Other possible formulations, such as [$(H_2O)_m$Fe^{IV}(OH)$_2$]$^{2+}$, in which at least one of the two hydroxo groups would have to be derived from the ^{18}O-labeled water, would permit the incorporation of at most 50 % ^{16}O into the product sulfone, and is thus ruled out by our observations. These conclusions are in accord with the Mössbauer data, which show that only one major Fe^{IV} species is present in our samples.

Figure 3. Proposed structure for **Z**, [$(H_2O)_5$Fe^{IV}=O]$^{2+}$, calculated with the B3LYP functional and the 6-311G basis set with C_{2v} symmetry.

Communications

With the identification of **Z** as $[(H_2O)_5Fe^{IV}=O]^{2+}$, the question of its participation in Fenton chemistry was addressed by studying the kinetic patterns and products for three substrates, namely $[Fe(H_2O)_6]^{2+}$, $(CH_3)_2SO$, and (CH_3)-(p-tolyl)SO, in the Fenton reaction and in the reaction with $[(H_2O)_5Fe^{IV}=O]^{2+}$ under identical and carefully selected conditions.

Stopped-flow mixing of O_3 (0.25 mM) and a large excess of $[Fe(H_2O)_6]^{2+}$ (0.10 M) in $HClO_4$ (0.090 M) produced, within the mixing time $(k = 4.3 \times 10^4 \, M^{-1} \, s^{-1})$,[11] a mixture of $[Fe(H_2O)_6]^{3+}$ (84% of total Fe^{III}) and the hydrolytic dimer, $[(H_2O)_4Fe(\mu\text{-}OH)_2Fe(H_2O)_4]^{4+}$ (16%), followed by hydrolysis of the dimer[21] to $[Fe(H_2O)_6]^{3+}$ with $k = 0.76 \, s^{-1}$[11] (Scheme 2).

Scheme 2.

In an otherwise identical experiment with H_2O_2 in place of O_3, no dimer was produced, thus ruling out $[(H_2O)_5Fe^{IV}=O]^{2+}$ as a reactive intermediate in the Fenton reaction (see Supporting Information).

The sole products of the oxidation of $(CH_3)_2SO$ and $(CH_3)(p$-tolyl)SO by $[(H_2O)_5Fe^{IV}=O]^{2+}$ in both acidic and neutral solutions were the corresponding sulfones (see Supporting Information). The Fenton reaction with $(CH_3)_2SO$ under air-free conditions yielded mostly ethane, methylsulfinic acid, and small amounts of methane and dimethyl sulfone, that is, products known to be derived from OH radicals.[22,23] The yields of all the products decreased in the presence of O_2, and no sulfone was detected.

In summary, we have generated $[(H_2O)_5Fe^{IV}=O]^{2+}$, characterized it spectroscopically, theoretically, and chemically, and developed criteria that made it possible to distinguish between hydroxyl radicals and aqueous ferryl-oxo species. These criteria have allowed us to settle a long-standing debate and unambiguously rule out $[(H_2O)_5Fe^{IV}=O]^{2+}$ as a crucial Fenton intermediate in acidic and neutral aqueous solutions.[24]

Cluster Chemistry

Holding onto Lots of Hydrogen: A 12-Hydride Rhodium Cluster That Reversibly Adds Two Molecules of H₂**

Simon K. Brayshaw, Michael J. Ingleson, Jennifer C. Green, Paul R. Raithby, Gabriele Kociok-Köhn, J. Scott McIndoe, and Andrew S. Weller*

The boundary between catalysis by nanocluster and molecular materials is an area of science that is attracting considerable attention.[1] Much of this interest has centered on the role that such species play in hydrogenation reactions (especially arene hydrogenation), and in particular the nature of the actual species in catalysis (nanocluster versus molecular cluster).[2] Given the inherent difficulty in characterizing nanocluster species at atomic resolution, well-defined molecular clusters that can be considered as models for hydrogen attachment to a metal surface are key to understanding the chemistry of these species. Despite this, molecular cluster species that reversibly take up dihydrogen,[3,4] or have a hydrogen content that approaches that expected for a metal surface covered in chemisorbed H₂, are rare.[5,6] We have previously described the complex $[Rh_6(PiPr_3)_6(\mu\text{-}H)_{12}]^{2+}$ (**1a**)—a cluster complex that not only has an unexpected geometry and cluster electron count (76 cluster valence electrons (cve), 10 lower than expected for an octahedral late-transition-metal cluster) but

also a rather high hydrogen content.[7] We now report that this complex, and its PCy₃ (Cy = cyclohexyl) analogue, reversibly add two molecules of H₂ to give discrete clusters with exceptionally high hydride counts: $[Rh_6(PR_3)_6H_{16}][BAr^F_4]_2$ (R = Cy, iPr; Ar^F = 3,5-$(CF_3)_2C_6H_3$; Scheme 1).

The tricyclohexylphosphine analogue of **1a**, $[Rh_6(PCy_3)_6H_{12}][BAr^F_4]_2$ (**2a**), is prepared in a similar manner to **1a** in modest ($\approx 30\%$) yield by gentle heating of $[(PCy_3)_2Rh(\eta^2\text{-}H_2)H_2][BAr^F_4]$[8] in fluorobenzene. Cluster **2a** was characterized by NMR spectroscopy and ESI mass spectrometry, both of which unambiguously identify the cluster as having
Scheme 1.

12-hydride ligands. Addition of dihydrogen (≈ 1 atm) to **1a** or **2a** in solution (CH_2Cl_2) results in the immediate formation of the sixteen-hydride cluster complexes $[Rh_6(PR_3)_6H_{16}][BAr^F_4]_2$ (**1b**, R = iPr and **2b**, R = Cy) in quantitative yield—in which two molecules of H₂ have been added to the octahedral cluster. Hydrogen uptake also occurs in the crystalline form but at a much slower rate (hours). The ESI MS of CH_2Cl_2 solutions were unambiguous in the characterization of **1b** and **2b** (Figure 1 for **2a/2b** pair), and clearly demonstrate the quantitative formation of a dicationic 16-hydride species: with "flagpole" spectra observed showing excellent matches to the calculated isotope distribution patterns.

The ¹H NMR spectra of both **1b** and **2b** confirm the hydride count from the ESI MS experiments. These spectra show upfield signals that integrate to a total of 16 H relative to the alkyl phosphine protons. In the room-temperature ¹H NMR spectrum, two hydride signals are consistently (for five independently synthesized samples) observed in the ratio 15:1. Figure 2 shows the spectrum for the **1a/1b** pair. This 15:1 ratio suggests a structure in which fifteen hydrides are mutually exchanging on the NMR timescale and one is not. A plausible structure that accounts for this observation is one that invokes an interstitial hydride[9,10] with 15 hydride ligands decorating the outside of the Rh₆ octahedron. On cooling the NMR sample to 200 K the hydride resonances in **1b** and **2b** become broader and resolve into many separate signals with an overall integral lower than 16 H. The broad line width of some these signals indicate that any fluxional processes occurring are not completely frozen out at low temperature. T_1 measurements at 200 K indicate that all the observed

Figure 1. ESI mass spectra of **2a** and **2b**. Insets show observed isotopomer pattern overlaid with the calculated pattern (gray bars).

signals are best assigned to hydride ligands ($T_1 > 230$ ms). At higher temperatures (323 K) the 15:1 pattern is still observed, while heating further results in decomposition.

Preliminary density functional theory (DFT) calculations on model compounds $[Rh_6(PH_3)_6H_{16}]^{2+}$ and $[Rh_6(PH_3)_6H_{12}]^{2+}$ support the interstitial hydride assignment, indicating that a cluster with 15 hydride ligands on the surface and one interstitial is significantly more stable than one with 16 hydrides on the surface. Calculations also reveal the electronic reasons underlying the uptake of two molecules of H_2.
Similar to recently reported $[Pt_3Re_2(CO)_6(PtBu_3)_3]^{[6]}$ which takes up three molecules of H_2 and has five low-lying unoccupied molecular orbitals, the 12-hydride octahedral clusters reported herein have a small HOMO–LUMO gap (0.50 eV) and a degenerate pair of LUMO orbitals available for the uptake of four electrons (that is, two molecules of H_2; Figure 3). The resulting 16-hydride species (80 cve) has a larger HOMO–LUMO gap (1.3 eV) and thus would be expected to take up additional H_2 less readily. This result is confirmed experimentally; under higher pressures (100 bar H_2) **1b** is the only hydride species observed in solution.

Despite repeated and extended attempts using a variety of counterions and solvents, suitable single crystals of **1b** were not forthcoming. However, crystals of **2b** were eventually obtained by using the [1-H-*closo*-CB$_{11}$Me$_{11}$]$^-$ counterion and the structural refinement showed that the $\{Rh_6(PCy_3)_6\}^{2+}$ octahedral cluster core is retained (Figure 4a) in this high-hydride species, although it is somewhat distorted showing a wide range of Rh–Rh bond lengths (2.720(1)–3.132(1) Å). A similar span of bond lengths is observed in the DFT calculated structure of $[Rh_6(PH_3)_6H_{16}]^{2+}$. The Rh–Rh bonds in $[Rh_6(PH_3)_6H_{12}]^{2+}$ show a much narrower distribution, suggesting that the observed distortion is due (in part) to the distribution of the hydride ligands in the high-hydride species. Unfortunately, the hydride ligands could not be located reliably, a common problem in cluster chemistry given the low scattering factor associated with hydrogen and the fact that the hydrides are very often distributed asymmetrically in the solid-state leading to partial occupancy of sites. This situation is taken to the extreme with the 16 hydride ligands around the octahedral core in **1b** and **2b**.

The 16-hydride complexes **1b** and **2b** are stable under an argon atmosphere, but under vacuum both **1b** and **2b** lose two molecules of H_2 to quantitatively regenerate **1a** and **2a**. This

process occurs both in solution and in the crystalline state, and is reversible; pressurizing with H_2 quantitatively (NMR spectroscopy, ESI MS) regenerates the H_{16} species. For **1b** H_2 loss is facile (hours), however for **2b** the process is longer (days) and this may be related to the increased steric shielding the cluster core receives from the cyclohexyl groups compared to the isopropyl groups (Figure 4b). Loss of two hydrogen molecules is also affected by addition of hydrogen acceptors such as *tert*-butylethene (tbe) or 1-hexene, as monitored by NMR spectroscopy and ESI MS (Figure 5). Interestingly, even with a large excess of alkene (>100-fold) **1a** and **2a** remain—showing that these clusters holds onto the remaining twelve hydrides very strongly.
Figure 5. Stacked plot of ESI MS of **1b** on addition of the hydrogen acceptor tbe ($\approx$100-fold excess) in CH_2Cl_2 solution. The uppermost spectrum is 5 min after addition of tbe and the bottom after 24 h.

Although there are a significant number of cluster species known with a high hydride count (that is ≥ 5 hydride ligands)[5,6,11] and some are formed by addition of H_2 to very unsaturated cluster species,[6] only one has been shown to reversibly release H_2, $[Pt_4H_7(PtBu_3)_4][BF_4]$,[4] affording a cluster with one hydride. The species reported herein are thus unique in that H_2 uptake and loss is facile and the "low"-hydride species that result still have an exceptionally high number of hydride ligands. They thus have relevance for the modeling of surfaces that are catalytically active for hydrogenation reactions as well as hydrogen-spillover processes that result in supported catalysts showing enhanced activities.[12] The cluster pairs **1a/1b** and **2a/2b**[14] could also potentially serve as models for chemically reversible hydrogen-storage materials, albeit with a low ($\approx 0.25\%$ based on the Rh_6 dication) reversible hydrogen-storage capacity.

Experimental Section

Crystallographic data: Crystals were grown from CH_2Cl_2/pentane under a H_2 atmosphere. Intensity data were collected at 150 K on a Nonius Kappa CCD diffractometer, using graphite monochromated

1b: ^{1}H NMR (400 MHz, CD_2Cl_2): $\delta = 7.71$ (m, 16 H, BAr$^F_4$), 7.55 (m, 8 H, BAr$^F_4$), 2.27 (m, 18 H, PCH), 1.24 (dd, $J = 15.4$ Hz, $J = 7.1$ Hz, 108 H, CH$_3$), -21.46 (s, full width at half maximum height (fwhm) $= 40$ Hz, 15 H, Rh-H), -29.81 ppm (br s, fwhm $= 200$ Hz, 1 H, Rh-H). ^{31}P{^{1}H} NMR (162 MHz, CD_2Cl_2): $\delta = 109.2$ ppm (d, J(RhP) 140 Hz). ESI MS calcd for $[P_6Rh_6C_{54}H_{142}]^{2+}$ 797.2; found: 797.3.

2a: ^{1}H NMR (400 MHz, CD_2Cl_2): $\delta = 7.71$ (m, 16 H, BAr$^F_4$), 7.55 (m, 8 H, BAr$^F_4$), 0.8–2.5 (m, 198 H, PCy$_3$), -27.20 (br s, fwhm $= 230$ Hz, 9 H, Rh-H), -28.9 ppm (br s, fwhm $= 330$ Hz, 3 H, Rh-H). ^{31}P{^{1}H} NMR (162 MHz, CD_2Cl_2): $\delta = 91.9$ ppm (d, J(RhP) 102 Hz). ESI MS calcd for $[P_6Rh_6C_{108}H_{210}]^{2+}$ 1155.5; found: 1155.7

2b: ^{1}H NMR: $\delta = 7.71$ (m, 16 H, BAr$^F_4$), 7.55 (m, 8 H, BAr$^F_4$), 1.0–2.4 (m, 198 H, PCy$_3$), -21.59 (br s, fwhm $= 390$ Hz, 15 H, Rh-H), -28.37 ppm (br s, fwhm $= 210$ Hz, 1 H, Rh-H). ^{31}P{^{1}H} NMR: $\delta = 107.4$ (br s, fwhm $= 1100$ Hz, 2 P), 89.0 ppm (br s, fwhm $= 900$ Hz, 4 P). ESI MS calc for $[P_6Rh_6C_{108}H_{214}]^{2+}$ 1157.5, obs. 1157.8.

[14] Note added in proof, August 31, 2005: The solid-state structure of **2a** has been determined and shows it to be an essentially regular octahedron, in line with the DFT calculated structure (Rh−Rh bond lengths span the range 2.719–2.755 Å).
(MOF)[1c–g] materials. However, purely organic structures with such dimensions are rare, especially if macrocyclic molecules are excluded.[2] We now report a new class of nanoporous organic crystals with chiral, unidirectional channels, tunable to diameters in excess of 14 Å.

This discovery arose from our program on steroid-based anion receptors.[3] The "cholapod" **1** belongs to a series of compounds derived from cholic acid **2**, in which hydrogen-

bond donor units are deployed on the bile acid scaffold. The urea groups at C7 and C12 are constrained by the axial orientation of the C–N bond, such that the NH groups point towards each other. The amide moiety at C3 can also point inwards, thus cooperating in hydrogen-bond donation to anionic guests. Molecules from this family are powerful anion receptors,[4] and also act as anion carriers across bilayer membranes.[5]
Cholapod **1** was prepared from **2** via intermediate **3**[6] (see the Supporting Information; Boc = *tert*-butoxycarbonyl).

Spiraling Steroids: Organic Crystals with Asymmetric Nanometer-Scale Channels**

*Adam L. Sisson, Vicente del Amo Sanchez, Germinal Magro, Alex M. E. Griffin, Shilen Shah, Jonathan P. H. Charmant, and Anthony P. Davis**

Crystalline microporous (or nanoporous) solids are widely sought and studied.[1] Such materials provide challenges for crystal engineering and find applications in catalysis, separation techniques, gas storage, sensors, lasers, and so forth. Robust structures with large voids are especially interesting, as they are able to accommodate the widest range of guests. Channels that measure ≥ 1 nm in diameter are fairly common in inorganic[1a–c] and, especially, metal–organic-framework

Crystallization from methyl acetate, which contained small amounts of water, gave needles up to 5 mm long and approximately 0.2 mm wide. The crystal structure was solved in the $P6_1$ space group.[7] The individual molecules were found to bind one molecule of water (see Figure 1a). The trifluoroacetamide unit rotates such that the carbonyl group points inwards acting as an hydrogen-bond acceptor, whereas the urea groups act as hydrogen-bond donors to the oxygen atom from the water molecule. The hydrated steroids form columns parallel to the crystallographic c axis, reinforced by hydrogen-bonding interactions between the free O–H group of a water molecule contained in one complex and a carbonyl oxygen atom of a urea group in the next (Figure 1b). The columns then pack in a hexagonal array to give channels centered on the c axis, defined by a right-handed spiral of steroids (Figure 1c).[8] The internal surfaces possess an average diameter of 16.4 Å, with a minimum value of 14.3 Å (Figure 1d).[7] The surfaces are formed mainly from hydrophobic CH and CF units, but also feature the carbonyl oxygen atoms from the ester groups. Around 30% of the crystal volume is accessible to guests. The channels are filled with delocalized electron density, consistent with disordered solvent molecules. Face indexing of a single crystal showed
Figure 1. Representations of the crystal structure of **1**: a) A single molecule of **1** with the bound water molecule (red sphere; hydrogen atoms bound to carbon have been removed for clarity). b) Columns of **1**·H_2O parallel to the channel axis shown from two perspectives (the steroid molecules are shown in green and blue and the hydrogen-bonding interactions in red). c) The packing of columns to give channels, viewed along the channel axis (steroid molecules in one column are highlighted in green and blue). d) Interior surface of a channel, calculated by using a 1.4-Å probe; the surface is color coded according to the underlying atoms (red: oxygen, blue: nitrogen, green: fluorine).
above. Inclusion complexes of bile acid derivatives are well known and well studied,[12] but the formation of such large, physically robust pores is unprecedented. The crystals are chiral and also lack any regular axis of symmetry, so the pores are aligned in one direction. Finally, the interactions which govern the packing do not seem to involve the terminal CF_3 and methyl ester groups, both of which point into the channels. This suggests a generalizable motif 4, with potential for tuning. These interactions suggest the generalized motif of **4**, which can be potentially used to tune channel width and properties by variation of the R^1 and R^2 groups.

Considering this last point, we examined other steroids of type **4** from our anion-receptor program. Compounds **5**[13] and **6**[7]

that, as expected, the channel axis coincided with the long axis of the needles.

The contents of the channels were investigated by ^{1}H NMR spectroscopic analysis. Crystals of **1** were removed from the solvent, air-dried,[9] and dissolved in deuterated acetone (99.96 atom % D) under anhydrous conditions.[7] Integration of the NMR spectrum implied a composition of **1**·0.75 MeOAc·3.5 H_2O.[10] Even allowing for the single H_2O molecule bound to each molecule of **1**, this result implies that water is concentrated in the channels and explains our observation that small amounts of water aid crystallization. The solvent was lost and the crystals became opaque on vacuum drying;[11] however, X-ray powder diffraction showed that the channel structure was maintained.[7] Solvent exchange was also demonstrated. Samples removed from MeOAc were washed with diethyl ether or toluene, air-dried,[9] and analyzed by ^{1}H NMR spectroscopy. In both cases, the MeOAc had disappeared and the replacement solvent was present (approximately 0.5 equiv). Vacuum-dried samples suspended in toluene also absorbed the solvent. When these toluene-solvated crystals were washed briefly (approximately 30 s) with CH_2Cl_2, the toluene was retained. Thus, solvent exchange is slow, which is consistent with absorption into the nanoporous framework.

The structure of **1** is notable in several respects. First, the channels are among the largest observed for purely organic systems. Second, they are persistent and accessible, as shown

channel-forming motif

4

substituents for channel tuning

5: R^1 = NHPh
6: R^1 = OtBu

crystallized as needles and were subjected to X-ray crystallographic studies. Both **5** and **6** formed nanoporous structures in which the disposition of the steroid nuclei was almost identical to that in **1**. However, the variation of the R^1

group induced significant changes. In the case of **5**, the bulky NHPh group protrudes into the channel and, more importantly, displaces the OMe unit from the channel wall. The ester group rotates to create a more irregular, narrower pore with an average diameter of 15.7 Å (minimum diameter = 11.6 Å; Figure 2).[7] In the case of **6**, the O*t*Bu group seems to

Figure 2. a) Orientation of the methyl ester groups in **1** and **5**. b) Interior surface of **5**. In contrast to **1** (see Figure 1d) the OMe groups are directed inwards, thus creating protrusions in the channel wall.

create an intermediate situation, in which the ester groups are randomly distributed between the two orientations. If an alternating arrangement is assumed, the average and minimum diameters are 16.4 and 12.3 Å, respectively.[7] The crystal structures of **1**, **5**, and **6** are compared in Figure 3, which highlights the position of the terminal R^1 groups at the channel surfaces.

To conclude, we have found a new steroid-based motif which generates robust, asymmetric, and nanoporous structures of unusual dimensions. The channels are codirected[14] and large enough to accommodate a wide variety of organic molecules, including, for example, dyes or substrates for catalysis. We will investigate such possibilities in future investigations, with a view to the development of novel functional organic materials.

[14] This term is used to imply that the channels are both directional (namely, asymmetric with respect to direction of view along the *c* axis) and aligned (pointing in the same direction).

A Germanate Framework Containing 24-Ring Channels, Ni−Ge Bonds, and Chiral [Ni@Ge$_{14}$O$_{24}$(OH)$_3$] Cluster Motifs Transferred from Chiral Metal Complexes**

Zhi-En Lin, Jie Zhang, Jing-Tai Zhao,
Shou-Tian Zheng, Chun-Yang Pan,
*Guo-Ming Wang, and Guo-Yu Yang**

Microporous materials have been extensively studied due to their widespread applications in ion exchange, separation, and catalysis.[1] Since the discovery of the first aluminum phosphates (AlPOs) VPI-5 with 18-membered rings (18-MR) in 1988, some porous materials with larger rings, such as JDF-20 (20-MR), cloverite (20-MR), VSB-1 (24-MR), ND-1 (24-MR), VSB-5 (24-MR), NTHU-1 (24-MR), FDU-4 (24-MR), ASU-16 (24-MR), and SU-12 (24-MR), have been made.[2] Recently, the replacement of framework O^{2-} with S^{2-} (Se^{2-}, Te^{2-}) anions has resulted in a new class of porous materials with giant cavities and channels.[3] In general, the cations and anions of the above frameworks are linked to each other by T-X-T linkage modes, while framework containing T-M-T linkages are unexplored so far (where T and M are cations, and X anions).

Chiral metal complex (CMC) templates have shown great advantages in the synthesis of unusual open-framework materials, because the CMCs not only have unique spatial configurations, various charges, different flexibilities, and hydrogen-bonding sites, but can also induce a chiral environment in the host framework.[4] Metal phosphates templated by an optically pure CMC or a racemic mixture of CMCs have been reported for AlPOs,[4a,5] GaPOs,[6] ZnPOs,[4b,c,7] and BPO.[8] Lately, the synthesis of open-framework germanates has made great progress,[2h–j] but to our knowledge little attention has been paid to the possibility of using CMCs as

templates in the synthesis of germanates.[9] To introduce CMCs into germanates and understand their role in determining the frameworks, we focused on the synthesis of germanates templated by CMCs and obtained the chainlike germanate $[Ge_7O_{13}(OH)_2F_3]^{3-}\cdot2[Ni(dien)_2]^{2+}$ (dien = diethylene triamine).[9d] As a continuation of this work, by using a racemic mixture of a $[NiCl_2(L)_3]$ complex [L = ethylenediamine (en), 1,2-diaminopropane (enMe)] as template, we have made two novel germanate frameworks $Ni@Ge_{14}O_{24}(OH)_3\cdot2Ni(L)_3$ (L = en/enMe, denoted FJ-1a/FJ-1b), in which chiral $[Ni@Ge_{14}O_{24}(OH)_3]^{4-}$ ($Ni@Ge_{14}$) clusters (Figure 1a,b) containing Ni−Ge bonds are connected to each other to form a three-dimensional (3D) framework with 24-ring windows (Figure 1c,d). FJ-1 is the first example of porous materials having T-M-T linkages (where T-M-T = Ge-Ni-Ge).

Figure 1. a) View of the coordination environments of the Ni and Ge atoms in the $Ni@Ge_{14}$ cluster (50% thermal ellipsoids). Selected bond lengths [Å] and angles [°]: Ni1−Ge3 2.251(2), Ni1−Ge4 2.317(2); Ge3-Ni1-Ge3A 180, Ge3-Ni1-Ge4 90, Ge4-Ni1-Ge4A 120. b) Polyhedral and ball-and-stick view of the $Ni@Ge_{14}$ unit. GeO_4, green. c) View of the 24-ring channel constructed from three pairs of enantiomers of adjacent $Ni@Ge_{14}$ motifs in FJ-1a. d) Topological framework of FJ-1a showing the 24-ring channels and the $Ni@Ge_{14}$ motif. e) View of one pair of enantiomers for adjacent $Ni@Ge_{14}$ motifs with Δ and Λ configurations in the ab plane in FJ-1a. f) The chiral octahedral $[Ni2(en)_3]^{2+}$ complexes with Δ and Λ configurations arranged along the c axis (Δ, Ni2 yellow; Λ, Ni2 purple). g) View of the orderly separation of chiral $[Ni2(en)_3]^{2+}$ complexes in the center of the 24-ring channel and achiral trigonal prismatic $[Ni3(en)_3]^{2+}$ complexes occluded between the same chiral structural motifs along the c axis (N2 blue, N2' yellow). The H atoms of C and N atoms are omitted for clarity.

Yellow hexagonal crystals of FJ-1a/FJ-1b (see the Supporting Information) were obtained by the solvothermal reaction of $[NiCl_2(L)_3]\cdot2H_2O$ and GeO_2 in mixed solvents of ethylene glycol and L at 170°C. X-ray crystal analysis revealed that FJ-1a and FJ-1b are isostructural and crystallize in the high-symmetry hexagonal space group $P\bar{6}2c$. Therefore, only the structure of FJ-1a is described in detail. The $Ni@Ge_{14}$ unit consists of one Ni^+ and five Ge^{2+} ions reduced from Ni^{2+} and Ge^{4+} by amine under solvothermal conditions, nine Ge^{4+} ions, and three H and 27 O atoms (Figures 1a and Supporting Information). The Ni1 atom is located in the center of the $Ni@Ge_{14}$ unit and is bonded to five Ge^{2+} (three Ge4 and two Ge3) atoms to yield a trigonal-bipyramidal $\{Ni@Ge_5\}$ core (Figures 1a,b and Supporting Information). The Ni^+–Ge^{2+} distances vary in the range 2.251(2)–2.317(2) Å, which is close to the sum of covalent radii for these elements and similar to the Ni^0–Ge^{2+} bonds (2.206–2.291 Å) in nickel germylene complexes,[10] but considerably shorter than a normal Ge−Ge bond or twice the covalent radius of Ge (2.44 Å).[11] Thus, it is reasonable to identify the central atom of $Ni@Ge_{14}$ as Ni. The Ge:Ni ratio obtained from electron probe microanalysis agrees with this assignment. Of the fourteen Ge atoms, five Ge3/Ge4 atoms around Ni1 are tetrahedrally coordinated by one μ_5-Ni1 and three O atoms (Ge−O 1.803(9)–1.849(7) Å). The 4s electron lone pair of Ge^{2+} permits five Ge^{2+} atoms to function as novel ligands to the Ni1 atom with unusual Ge-Ni-Ge linkages. The remaining nine Ge1/Ge2 atoms are typical Ge^{4+} ions and are bonded to four O atoms; the Ge−O distances (1.722(10)–1.766(7) Å) and O-Ge-O angles (99.3(4)–115.3(6)°) are in agreement with those of four-connected germanates.[12] Assuming the valences of nine Ge1/Ge2, five Ge3/Ge4, one Ni1, two Ni2/Ge3, twenty-seven O, and three H to be +4, +2, +1, +2, −2, and +1, respectively, in $Ni@Ge_{14}O_{24}(OH)_3\cdot2Ni(L)_3$, the framework stoichiometry of $[Ni@Ge_{14}O_{24}(OH)_3]^{4-}$ creates a net framework charge of −4, which can just be balanced by two $[Ni(L)_3]^{2+}$ complex cations, that is, the low-valent Ni^+ and Ge^{2+} ions indeed exist in the $\{Ni@Ge_5\}$ core, as is further confirmed by magnetic and luminescence measurements (see below). In FJ-1a, three GeO_4 tetrahedra are linked together by sharing vertices to form a trimer (Ge_3O_{10}). Three trimers are linked alternately to three $Ge(4)O_3Ni$ tetrahedra around the Ni1 atom in the ab plane to form a $NiGe_{12}O_{24}(OH)_3$ cluster that is further capped by two Ge3 atoms above and below the ab plane to form a novel $Ni@Ge_{14}$ unit (Figure 1b). Each $Ni@Ge_{14}$ building block is bridged to six others through O2 atoms to yield a 3D open framework with 24-ring channels (Figures 1c,d and Supporting Information) with dimensions of about 8.3×13.6 Å (see Supporting Information), which intersect with two 12-ring channels running along the a and b axes (see Supporting Information). The construction of 24-ring channels can also be understood as shape-controlled synthesis templated by octahedral $[Ni2(en)_3]^{2+}$ complex. The propellane-like shape of the 24-ring channel around the $[Ni2(en)_3]^{2+}$ templates is delimited by eighteen GeO_4 and six GeO_3Ni tetrahedra (Figures 1c,d and Supporting Information), which matches the shape of the $[Ni2(en)_3]^{2+}$ complex and is unique and different from that of known porous materials templated by amines.[2]

Interestingly, there are two types of chiral Ni@Ge$_{14}$ motifs and two types of [Ni(en)$_3$]$^{2+}$ complexes (Figure 1 e,g) in FJ-1a. The [Ni2(en)$_3$]$^{2+}$ template located in the center of the 24-ring is chiral (Figures 1g and Supporting Information). The enantiomers of [Ni2(en)$_3$]$^{2+}$ complexes are alternately arranged as Δ and Λ configurations in the 24-ring channels along the *c* axis (Figures 1 f and Supporting Information), and further interact with chiral Ni@Ge$_{14}$ motifs through H-bonding interactions (N1···O6, 3.072(16 Å). The Δ-[Ni2(en)$_3$]$^{2+}$ complex forms hydrogen bonds to six adjacent Ni@Ge$_{14}$ motifs with both Δ and Λ configuration, or vice versa (see Supporting Information), while the [Ni3(en)$_3$]$^{2+}$ cations residing in the 12-ring channels (see Supporting Information) are achiral and separated by Ni@Ge$_{14}$ motifs along the *c* axis. Adjacent [Ni3(en)$_3$]$^{2+}$ complexes in the *ab* plane exhibit different orientations (Figures 1g and Supporting Information). The [Ni3(en)$_3$]$^{2+}$ complex also interacts with the Ni@Ge$_{14}$ motifs through hydrogen-bonding interactions (N2···O3 3.142(18) and N2′···O3/O4 3.144(9)–3.167(20) Å, see Supporting Information).

The chiral [Ni2(en)$_3$]$^{2+}$ complexes with regular octahedral and achiral [Ni3(en)$_3$]$^{2+}$ complex with rare trigonal-prismatic geometry in FJ-1a respectively have D_3 and D_{3h} symmetry (see Supporting Information), and the chiral Ni@Ge$_{14}$ motif has C_3 symmetry (Figure 1a and Supporting Information). It appears that the symmetry of the Ni@Ge$_{14}$ motif is a good match with those of the chiral and achiral metal complex templates (Figures 1g and Supporting Information). This suggests that the complex template can impose its individual symmetry constraint on the structural motifs,[4] which have a subgroup of point-group symmetry of the complex template.[4c] In addition, the configuration of the chiral Ni@Ge$_{14}$ motif is also matched with that of the chiral [Ni2(en)$_3$]$^{2+}$ complex template (see Supporting Information). Furthermore, the orderly separation of chiral [Ni2(en)$_3$]$^{2+}$ and achiral [Ni3(en)$_3$]$^{2+}$ complexes in FJ-1a (Figures 1g and Supporting Information) indicates that the host framework has molecular-recognition capability and stereospecificity for guest templates. From insight into the structure of FJ-1a and other metal phosphates templated by CMCs,[4–7] it is found that the CMCs are responsible for the formation of the chiral motif/framework in the crystallization process and can impart their chirality and symmetry to an inorganic motif/framework, as well as leading to the existence of stereospecificity and molecular recognition between the inorganic host and CMC guest, while the achiral metal complex only transfers its symmetry to the inorganic motif. It is believed that the hydrogen bonding between the complex template and the host is the origin of the above phenomena.[4–7]

Variable-temperature magnetic measurements on FJ-1a showed that the product of molar magnetic susceptibility and temperature $\chi_M T$ remains nearly constant down to 50 K and then rapidly decreases on further cooling (see Supporting Information). The magnetic data can be fitted well to the Curie–Weiss law with $\theta = -1.21$ K, which indicates weak antiferromagnetic coupling between metal centers. This is consistent with isolated Ni^{2+} centers and a long distance (10.71 Å) between Ni$^+$ centers in adjacent Ni@Ge$_{14}$ units. The high-temperature value of $\chi_M T$ is 1.74 cm^{3}K mol^{-1}, much smaller than that calculated for two Ni^{2+} ($S = 1$, d^8 configuration) and one Ni$^+$ ions ($S = 1/2$, d^9 configuration) without magnetic interaction (2.375 cm^{3}K mol^{-1}, $g = 2$). This suggests that one Ni^{2+} ion should be in the nonmagnetic state, which might originate from the structural disorder of the trigonal-prismatic coordination of the Ni3^{2+} ion. The experimental value of 1.74 cm^{3}K mol^{-1} is in good agreement with the spin-only value expected for one Ni^{2+} and one Ni1$^+$ ions with an average *g* value of 2.25 that is within the generally observed range for Ni^{2+} and Ni$^+$ ions.[13,14] In view of the regular octahedral geometry around the Ni2^{2+} ion, the zero-field splitting effect on the Ni^{2+} ion should be very small,[15] and the sharp decrease in $\chi_M T$ at low temperature could be attributed to a weak antiferromagnetic interaction between Ni$^+$ ions.[16]

FJ-1a exhibits blue luminescence in the solid state at room temperature. On excitation at 200 nm, the luminescence of FJ-1a has two strong emission bands at 482 and 523 nm and one shoulder at 458 nm (see Supporting Information) that differ from those of reported open-framework phosphates and germanates, which usually show a single emission peak,[17] that is, a more complex mechanism is involved in FJ-1a. Unlike crystalline porous materials incorporating organic dyes or doped with metal activators,[18] the luminescence of phosphates and germanates is generally attributed to the presence of lattice defects.[17] For FJ-1a, apart from lattice defects, low-valent Ge^{2+} with s^2 configuration and Ge^{2+}(4s)→ Ni$^+$(3d) metal–metal charge transfer in the Ni@Ge$_{14}$ cluster should also make contributions to the luminescence.[19,20]

In summary, we have successfully made two novel germanate open frameworks with 24-MRs by using a metal complex as template under solvothermal conditions. The key points of the synthetic procedures have been well established. These are rare examples of metal–metal bonds in porous materials, and the presence of Ge-Ni-Ge linkages makes them different from other open-framework materials that only contain T-X-T linkages. This study may open up possibilities for the synthesis of novel frameworks with T-M-T linkages. FJ-1 exhibits stereospecificity and chiral molecular recognition between guest CMC and inorganic structural motif. The chirality and symmetry of the guest CMC template can induce that of the inorganic motif/framework. In addition, the symmetry of the achiral guest was transferred to the inorganic motif. These phenomena originate from hydrogen bonding between the guest and the inorganic motif/framework.

Communications

Electron-probe microanalysis (EPMA) was performed on a Shimadzu electron microprobe EPMA-8705QH$_2$ to analyze Ge and Ni contents. Different points were selected, both from different areas of the same crystal and from different crystals. The Ge:Ni ratio obtained by EPMA are in agreement with the formula of FJ-1a obtained from the structure refinement (obsd Ge:Ni = 1:0.208, calcd Ge:Ni = 1:0.214).

Crystal data for FJ-1a: Ni@Ge$_{14}$O$_{24}$(OH)$_3$·2 Ni(en)$_3$, $M_r =$ 1988.04, hexagonal, space group $P\bar{6}2c$, $a = 13.5567(4)$, $c = 14.6138(5)$ Å, $V = 2325.96(13)$ Å^3, $Z = 2$, $\rho = 2.839\,g\,cm^{-1}$, $\mu = 10.173\,cm^{-1}$, $F(000) = 1910$, GOF = 1.171. $\theta_{max} = 25.01°$. A total of 5454 reflections (1417 independent, $R_{int} = 0.0418$) were measured at 293 K. Final agreement indices were $R1$ ($wR2$) = 0.0405 (0.0829) for 120 parameters and 1288 reflections [$I > 2\sigma(I)$].

Crystal data for FJ-1b: Ni@Ge$_{14}$O$_{24}$(OH)$_3$·2 Ni(enMe)$_3$, $M_r =$ 2072.19, hexagonal, space group $P\bar{6}2c$, $a = 13.6681(8)$, $c = 14.5642(7)$ Å, $V = 2356.3(2)$ Å^3, $Z = 2$, $\rho = 2.921\,g\,cm^{-1}$, $\mu = 10.049\,cm^{-1}$, $F(000) = 2006$, GOF = 1.047. $\theta_{max} = 27.53°$. A total of 9190 reflections (1861 independent, $R_{int} = 0.1042$) were measured at 293 K. Final agreement indices were $R1$ ($wR2$) = 0.0741 (0.1684) for 103 parameters and 1422 reflections [$I > 2\sigma(I)$].

Data were collected on a Siemens SMART CCD diffractometer with graphite-monochromated Mo$_{K\alpha}$ radiation ($\lambda = 0.71073$ Å) at room temperature. All absorption corrections were performed with the SADABS program. The structure was solved by direct methods and refined by full-matrix least-squares methods on F^2 using the SHELXTL97 program package. All non-hydrogen atoms (except N1, N2, N2′, C1, C2, C3, C4 in FJ-1b) were refined anisotropically. The unique N atoms coordinated to Ni3 in FJ-1a and FJ-1b occupy two split positions (N2, N2′) and have occupancies of 0.5. The C2 and C4 (methyl group of enMe) atoms of FJ-1b have occupancies of 0.5. The positions of H atoms (except those on C2 in FJ-1a and N1, N2, N2′, C1, C3 in FJ-1b) were placed geometrically and refined in a riding model. CCDC-277021/280327 (FJ-1a/FJ-1b) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Redox-Switchable Phase Tags for Recycling of Homogeneous Catalysts**

*Marcus Süßner and Herbert Plenio**

*Dedicated to Professor H. W. Roesky
on the occasion of his 70th birthday*

A fundamental problem of homogeneous catalysis is the difficulties associated with the recovery of the molecular catalyst after product formation, thus leading to loss of the catalyst and contamination of the reaction products with heavy-metal impurities.[1,2] This problem is aggravated by the fact that increasingly sophisticated complexes with tailor-made ligands result in high-value catalysts. Consequently, numerous concepts have been tested to overcome the imminent problem of catalyst/product separation,[3,4] such as soluble polymeric catalysts,[5,6] biphasic solvent systems which involve various solvent combinations (namely, organic/organic,[7] fluorous/organic,[8] ionic liquids/supercritical fluids,[9] aqueous/organic[10,11]), nanofiltration,[12,13] incarcerated nanoparticles,[14,15] interphase catalysts,[16] supported liquid films,[17] and immobilization of molecular catalysts on organic[18] or inorganic supports.[19]

Clearly, these approaches rely on manipulation of the solubility properties;[20] most often, distinct solubility properties are imposed by so-called phase tags, such as sulfonate groups (in triphenyl phosphorothionates),[21] fluorous pony-tails,[8] or polar and nonpolar soluble polymers.[22,23]

Such solubility-determining groups are referred to as phase tags and are an important tool in separation strategies.[24] Despite the success of this approach, certain disadvantages of this concept are apparent. Clearly, two solvents are required in biphasic systems, one to hold the product and the other for the tagged catalyst complex. Both solvents need to be compatible with the catalytic reaction, their mutual solubility should be low, the leaching of the catalyst into the product-containing solvent has to be minimized, and the partition coefficient of the reactants/products needs to be in a suitable range. Alternatively, the tagged catalyst can be precipitated from the reaction solvent by addition of another solvent after the catalytic transformation. However, very large amounts of this second solvent are typically needed to effect the quantitative precipitation of the tagged catalyst.

To avoid these problems, we propose herein a strategy for the separation of homogeneous catalysts from the products of the reaction based on a new class of solubility-determining groups, which we term redox-switchable phase tags. In contrast to other phase tags, the solubility properties of redox-switchable phase tags can be altered through the employment of tag-centered reactions, thus resulting in drastic changes in the polarity of the respective solubility-determining group. In this manner, it should be possible to exert perfect control over the solubility behavior of catalysts[25] by using a single solvent. We decided to utilize tag-centered redox reactions which mutate neutral (lipophilic) tags into charged (lipophobic) tags and back. One significant advantage of such an approach is that drastic changes in the solubility behavior can be effected with only very small amounts of switching reagent, which is stoichiometric with respect to the catalytic amounts of catalyst complex present in a reaction mixture.

To illustrate this principle, we chose a ruthenium-based catalyst of the Grubbs–Hoveyda type for olefin metathesis as numerous recycling concepts have been tested on these high-value catalysts because of their effectiveness.[26–32] Prior to the synthesis of a modified olefin-metathesis catalyst of the Grubbs–Hoveyda type with redox-switchable tags, a suitable redox-active group needed to be found. We chose a ferrocene (Fc) unit because such metallocenes are well-behaved outer-sphere redox reagents that display a high degree of reversibility. Furthermore, the redox potential of the ferrocene unit can be varied readily over a large potential range through the attachment of different substituents on the cyclopentadienyl rings,[33] which is clearly a very important property as the redox potential of the redox tag must be fine-tuned to avoid electron-transfer reactions that involve the catalytically active metal center. The Fe^{II}/Fe^{III} redox couple of the ferrocene unit should differ by between 236 mV (ratio of Fe/Ru oxidation = 100:1) and 354 mV (1000:1) from that of the olefin-metathesis catalyst to be useful. Thus, the Ru^{II}/Ru^{III} redox potential of the Grubbs–Hoveyda catalyst was first established by cyclic
Grubbs–Hoveyda catalyst

voltammetry (CV). The CV waves are well behaved, that is, they are fully reversible and the redox potential was +0.85 V in CH_2Cl_2 (Figure 1). As the redox potential of ferrocene itself is +0.46 V under the same conditions, we conclude that any ferrocene compound with electron-donating substituents can undergo independent Fe^{II}/Fe^{III} redox reactions that do not interfere with the catalytically active Ru^{II} center.

The synthesis of a ferrocenyl-tagged olefin-metathesis catalyst is shown in Scheme 1. We chose a monoalkylated ferrocene as the redox tag, as its redox potential fulfils the
Figure 1. Cyclic voltammogram of the diferrocenyl-tagged Grubbs–Hoveyda-type catalyst **1**. $\Delta E_{1/2}$ (Fe^{II}/Fe^{III}) = +0.410 V (70 mV), $\Delta E_{1/2}$ (Ru^{II}/Ru^{III}) = +0.847 V (60 mV) referenced versus FcMe$_8$ (−0.010 V) in CH$_2$Cl$_2$.

Scheme 1. Synthesis of the ferrocenyl-tagged olefin-metathesis catalyst **1** of the Grubbs–Hoveyda type: a) NEt$_3$, EtOH, HCOOH, 24 h; b) 1. LiAlH$_4$, THF; 2. HCl; c) HC(OEt)$_3$, 130 °C, 24 h; d) FcCCH, Na$_2$PdCl$_4$, CuI, Ad$_2$PBn·HBr, DMSO, HNiPr$_2$, 80 °C, 24 h; e) Pd/C 5 bar H$_2$, 5 h, RT; f) KOtBu, Grubbs I catalyst, toluene, THF; g) 2-isopropoxystyrene, CuCl, CH$_2$Cl$_2$, 40 °C, 1 h. Cy = cyclohexyl, Ad = adamantyl, DMSO = dimethyl sulfoxide.

criteria defined above. 4-Bromo-2,6-dimethylaniline was treated with glyoxal to give the respective 1,2-diimine in 75% yield, which was reduced to the corresponding 1,2-diamine in 80% yield using LiAlH$_4$. Ring-closure with HC(OEt)$_3$ yielded the respective imidazolinium salt in 75% yield. For the introduction of the redox tag, the aryl bromide

functionalities of this salt underwent Sonogashira coupling to ferrocenyl acetylene, thus giving the coupled product in 85% yield. It should be noted that the reaction conditions for the Sonogashira coupling are critical: First, the imidazolinium chloride displays solubility only in a few polar solvents, and second, the number of suitable bases is rather limited because the competing deprotonation of the imidazolinium ring must be suppressed as the corresponding N-heterocyclic carbene appears to inhibit the Pd catalyst.

Next, the acetylene linker was reduced with H$_2$ over Pd/C to the −C$_2$H$_4$− bridge in almost quantitative yield. The reason for this transformation is threefold: 1) an alkyl substituent attached to the ferrocene unit is electron donating rather than electron withdrawing, which consequently leads to an increase in the difference in the redox potential between the Fe^{II}/Fe^{III} and Ru^{II}/Ru^{III} redox couple; 2) the hydrogenation of the acetylene linker electronically decouples the redox-active ferrocene group from the catalytically active center to avoid any undesired influence of the ferrocene cation on the catalytically active center after oxidation; 3) the absence of a triple bond avoids potential problems in olefin metathesis.

Finally, the imidazolinium cation is deprotonated with KOtBu and treated with the Grubbs I catalyst; subsequently, the remaining PCy$_3$ ligand and the benzylidene in the resulting complex are substituted with 2-isopropoxystyrene to yield the desired redox-tagged Grubbs–Hoveyda-type catalyst **1**.

The catalytic properties of **1** are demonstrated in the ring-closing metathesis (RCM) reaction of N-tosyldiallylamide (Figure 2). The unperturbed reaction (●) proceeds to completion exactly as expected for such catalysts. In a second run (■), a solution of two equivalents of oxidation reagent ([FcCOCH$_3$][CF$_3$SO$_3$] as a 10% solution in 0.1 mL of CH$_2$Cl$_2$ (ΔE = +0.73 V)) with respect to the catalyst was added after exactly 60 minutes. The two ferrocenyl tags were oxidized virtually instantaneously, and the resulting dication **1^{2+}** precipitates from the solution of toluene within a few seconds. The precipitated catalyst does not display significant catalytic activity, as can be seen in the plot of conversion versus time (Figure 2, ■). The product of the catalytic reaction can be readily separated from the precipitated catalyst by filtration, which is preferably done after completion of the reaction. The catalyst can be reactivated (namely, redissolved) at any time by addition of two equivalents of a reducing agent (1,1′,2,2′,3,3′,4,4′-octamethylferrocene (FcMe$_8$)), which was carried out after 135 minutes in our experiment. It can be seen that the catalytic activity is
Figure 2. Switching of the olefin-metathesis catalyst **1** in toluene, monitored by GC: unperturbed RCM (●), off/on switched RCM (■). Ox. and red. denote the respective oxidation and reduction of the redox tag with [FcCOCH$_3$][CF$_3$SO$_3$] and FcMe$_8$. Ts = *p*-toluenesulfonyl.[35]

immediately restored to its initial value and the reaction proceeds to completion (not shown in Figures 2 and 3).[34]

Following this procedure, the catalyst can also be switched off and on[36,37] several times after completion of the RCM reaction, thus allowing multiple recycling of the catalyst. We tested redox-switching of the phase tag for three consecutive reaction cycles composed of 1) olefin metathesis, 2) oxidation with an acetyl ferrocene cation, 3) precipitation and separation, and 4) reduction and redissolution of the catalyst, and we observed quantitative yields for all the reaction steps. We probed the identity of the recycled catalyst after a single oxidation/reduction sequence **1**→**1**$^{2+}$→**1** and identified the initial Grubbs–Hoveyda-type catalyst **1** by ^{1}H NMR spectroscopy.

Furthermore, it is also possible to adjust the rate of the catalytic transformation as desired by reversible precipitation of a limited amount of the catalyst after addition of substoichiometric amounts of the oxidation reagent. Although the curve denoted by ■ in Figure 3 displays a single off/on switching event, the double-switched RCM reaction in the curve denoted by ● shows an off/on switching event during the first 30 minutes and a partial-off event after 50 minutes, with a full restoration of catalytic activity after 75 minutes.

Instead of monitoring the switching events by gas-chromatographic or NMR spectroscopic analysis, the removal of the catalyst from the solution can be followed readily by
monitoring the UV/Vis spectrum of the reaction mixture; catalyst **1** is characterized by a strong Ru-centered absorption band at 375 nm, the intensity of which reflects the concentration of the catalyst in solution.

As an alternative to chemical redox switching, which requires stoichiometric amounts of redox reagent (only with respect to the catalyst), electrochemical triggering of the tag switching only requires an applied current. Ideally, the catalyst is electrodeposited on the surface of an electrode on oxidation and is redissolved on application of a reductive potential. In this manner, the transfer of the loaded electrode from a solution containing the product into a solution containing fresh reactants allows efficient reuse of the catalyst. For the coulometric deposition of a redox-tagged catalyst, solvents are needed that display a reasonable conductivity after addition of supporting electrolytes. Consequently, electrolysis in toluene is not possible as the currents observed are far too small to effect electrolysis within a reasonable time frame, and so slightly more polar solvents are required. We tested a number of solvents of intermediate polarity and were able to quantitatively oxidize **1** electrochemically. However, the minute concentrations of catalytically active dication used for the RCM reactions are soluble in solvents of intermediate polarity (e.g., CH$_2$Cl$_2$). Therefore, the synthesis of new catalysts with multiple redox tags is required to solve these problems.[38]

In conclusion, we have demonstrated that redox-switchable phase tags, whose solubility properties are controlled by redox reagents or electrochemical redox processes, can be used to effectively switch the catalytic activity of an olefin-metathesis catalyst of the Grubbs–Hoveyda type on and off. More importantly, this approach allows the efficient separation of such catalysts from the products of a catalytic reaction at any time during the reaction and after its completion. We expect the principle of redox-switchable phase tags to become a general concept for control over solubility properties and, consequently, the recyclability of a wide variety of homogeneous catalysts. We are currently working towards the application of this principle several to other types of homogeneous catalytic processes, such as enantioselective hydrogenation and various Pd-mediated cross-coupling reactions.

Figure 3. Switching of the olefin-metathesis catalyst **1** in C$_6$D$_6$, monitored by ^{1}H NMR spectroscopy: single-switch RCM (■), off/on/partially-off/on switched RCM (●). Ox. = oxidation and red. = reduction for the redox tag with [FcCOCH$_3$][CF$_3$SO$_3$] and FcMe$_8$, respectively. Two equivalents of the oxidant were added to switch off the catalyst and one equivalent to partially switch off the catalyst.

[34] Dynamic phase-tag switching of **1**: Diallyltosylamide (25 mg, 0.1 mmol) was added to a solution of **1** (0.8 mg, 1 mol%) in toluene (10 mL), and the reaction mixture was warmed to 35°C. After 3 h, the solution was cooled to room temperature with subsequent addition of [FcCOCH$_3$][BF$_4$] (2 equiv) in CH$_2$Cl$_2$ (200 mL; $c = 0.01$ mol L^{-1}) to oxidize/precipitate **1**$^{2+}$. The solution was filtered over cotton wool, and the volatiles were evaporated to obtain the crude product. The cotton wool was rinsed with CH$_2$Cl$_2$ (0.5 mL) to dissolve **1**$^{2+}$, which was subsequently treated with a solution of FcMe$_8$ (2.1 equiv) in toluene (300 mL; $c = 7.0 \cdot 10^{-3}$ mol L^{-1}) to regenerate **1**. After addition of fresh toluene (10 mL) and diallyltosylamide (25 mg, 0.1 mmol), a new reaction cycle was started. The whole procedure was repeated three times, and quantitative product formation was observed after each cycle. The switching on/off of catalyst **1** during the reaction was carried out by addition of solutions of [FcCOCH$_3$][BF$_4$] (**1** → **1**$^{2+}$ = off) and FcMe$_8$ (**1**$^{2+}$ → **1** = on) as oxidizing and reducing agents, respectively. Spectroscopic data of **1**: ^{1}H NMR (500 MHz, C$_6$D$_6$): $\delta = 1.37$ (d, 6H, J = 6.0 Hz, (C*H$_3$*)$_2$CHOAr), 2.61 (bs, 12H, *ortho*-CH$_3$), 2.73 (m, 4H, CH$_2$), 2.86 (m, 4H, CH$_2$), 3.47 (s, 4H, NCH$_2$CH$_2$N), 4.03 ("t", 4H, J = 1.8 Hz, FcH), 4.09 (s, 10H, FcH), 4.12 ("t", 4H, J = 1.8 Hz, FcH), 4.52 (sept, 1H, J = 6.2 Hz, (CH$_3$)$_2$C*H*OAr), 6.35 (d, 1H, J = 8.3 Hz, sp^2 CH), 6.73 (t,1H, J = 7.4 Hz, sp^2 CH), 7.05 (s, 4H, *meta*-CH), 7.10 (m, 1H, sp^2 CH), 7.20 (dd, 1H, J = 7.6, 1.6 Hz, sp^2 CH), 16.74 ppm (s, 1H, RuCHAr); ^{13}C NMR (125.75 MHz, C$_6$D$_6$): $\delta = 19.5$, 20.2, 29.5, 36.6, 50.0, 66.4, 67.1, 67.6, 73.7, 87.5, 111.9, 120.7, 121.1, 123.2, 127.7, 142.0, 144.5, 151.3, 211.6, 293.5 ppm.

[35] The rates of the catalytic reactions depicted in Figures 2 and 3 are different as the concentration of the catalyst and substrates were individually adjusted to suit the sensitivity of GC-FID (Figure 2) and ^{1}H NMR spectroscopic detection (Figure 3).

tion are affected in seasonal epidemics. Some devastating outbreaks recorded in history even claimed millions of lives worldwide.[2] Influenza viruses are typically spherical with a diameter of about 100 nm.[3] The pathogenic properties of the viruses have been extensively investigated.[4] Significant advances in therapeutic treatments and in the detection of the viruses have been made in recent years as a result of this information. Among the limited number of proteins that are encoded by the viral RNA segments, two surface glycoproteins, namely, hemagglutinin (HA) and neuraminidase (NA), have often been the focus of research. These two surface glycoproteins play important roles in the infection process; HA is responsible for the binding of viruses to the host cells, whereas NA is involved in the budding process.[5] Although the surface antigens of the viruses mutate frequently to avert attacks from the immune system of the hosts, the critical catalytic activity of NA has to be maintained for successful infection and propagation. This special feature makes it an excellent candidate for research.[6]

NA (sialidase, *N*-acylneuraminosyl glycohydrolase, EC 3.2.1.18) is an *exo*-glycosidase that hydrolyzes the linkage of sialic acid residues, which are mostly found as terminal constituents of glycoconjugates. X-ray crystallographic information about the active site of NA has revealed important residues involved in the recognition and binding of sialic acid.[7] This has assisted in the development of several reversible inhibitors of NA, such as zanamivir and oseltamivir, which have been approved for the treatment of influenza.[8] Recently, McKimm-Breschkin et al. have demonstrated that ligands derived from biotin-conjugated zanamivir were able to bind influenza virion on microtiter plates; this could in turn serve as a basis for a diagnostic method.[9] Besides influenza viruses, many NA-containing microorganisms are pathogenic and it has been proposed that this enzyme plays an important role in the pathogenicity of these infections.[10] We therefore envision that the development of activity probes that selectively form a covalent linkage with NA would be of great value, as demonstrated by the application for capturing the virus particles in this report.

Chemical probes that are able to form covalent linkages with hydrolase subfamilies have proven to be a powerful tool in modern proteomics studies.[11] We have previously developed activity probes for hydrolases such as phosphatases and β-glucosidase.[12] The concept for the design of these activity probes originated from suicide substrates, or mechanism-based inhibitors, of enzymes.[13] This approach is unique as the probes themselves are also the substrates of the corresponding hydrolases. The probes can be selectively activated once the recognition head is cleaved by the targeting hydrolase, thereby leading to covalent modifications of the hydrolase.[14] More importantly and closely related to this report, the mechanism-based approach has been successfully applied in the screening and selection of biocatalysts from phage-displayed libraries, such as in the selection of mutant β-lactamases and in the search for catalytic antibodies with β-galactosidase activity.[15] Earlier studies have shown that compound **1** was a mechanism-based inhibitor of *Clostridium perfringens* NA.[16] We thus developed probe **2** as a mechanism-based probe for NA. Probe **2** carries four structural units

in its design; a sialic acid recognition head, which is connected to an *ortho*-difluoromethylphenyl latent trapping device, a linker, and a biotin reporter group. The biotin reporter group

serves two functions. On one hand, it is used to visualize the labeled NA after Western blotting with streptavidin-conjugated peroxidase chemiluminescence. On the other hand, it could be used to attach the probe to the microtiter plates through avidin–biotin interactions during the virus-capturing study. When the designated glycosidic bond is cleaved by NA, the released intermediate **3** would undergo 1,4-elimination with removal of a fluoride ion to generate a reactive quinone methide, **4**. The highly reactive quinone methide intermediate **4** would alkylate nearby nucleophiles of the enzyme, thereby resulting in biotinylated adduct **5** (Scheme 1). Since the viral surface is spiked with NA, covalent attachment through NA would then lead to the capture of virus particles.
Scheme 1. Mechanism for selective activation and alkylation of neuraminidase with probe **2**.

The synthesis of probe **2** begins with a commercially available *N*-acetylneuraminic acid **6** (Scheme 2). All the synthetic procedures were combinations of efforts from previous publications.[17] In brief, fully protected glycosyl chloride **8** was prepared and used directly for coupling with 2-hydroxy-5-nitrobenzaldahyde in a CHCl$_3$/H$_2$O biphasic system by using tetrabutylammonium bromide as the phase-transfer catalyst to give compound **9**. The formyl group of compound **9** could be converted into the difluoromethyl moiety of the trapping device by the DAST reagent. The structure of the difluoromethylphenyl group in compound **10**
Scheme 2. Synthesis of probe **2** for neuraminidase. Conditions: a) MeOH, IR-120 (H⁺) resin, 92%; b) AcCl, AcOH; c) 2-hydroxy-5-nitrobenzaldehyde, Cs₂CO₃, Bu₄NBr, H₂O/CHCl₃, 67% for two steps; d) DAST, CH₂Cl₂, 47%; e) H₂, 5% Pd/C, MeOH, 95%; f) succinic anhydride, TEA, CH₂Cl₂, 94%; g) EDCI, HOBt, **13**, DIEA, DMF, 75%; h) Na₂CO₃, MeOH; aqueous Na₂CO₃, 52%. TFA = trifluoroacetic acid; TEA = triethylamine; EDCI = 3-(3-dimethylaminopropyl)-1-ethylcarbodiimide; HOBt = 1-hydroxy-1*H*-benzotriazole; DIEA = *N*,*N*-diisopropylethylamine; DMF = *N*,*N*-dimethylformamide; DAST = (diethylamino)sulfur trifluoride.

was supported by its ^{1}H NMR spectroscopic data which showed a triplet at $\delta = 6.86$ ppm with a coupling constant of $^2J_{\mathrm{H,F}} = 54.9$ Hz, a typical value for H–F coupling. A triplet at $\delta = 109.9$ ppm ($^1J_{\mathrm{C,F}} = 237.2$ Hz) in the ^{13}C NMR spectrum of **10** further confirmed the presence of the CHF₂ moiety. The nitro group of compound **10** was then reduced by catalytic hydrogenation to give amine **11**. Attachment of the linker and biotin reporter group yielded the fully protected probe **14**. Final deprotection under alkaline conditions offered the desired probe **2** after LH-20 purification.

Probe **2** was first tested for its ability to biotinylate NA obtained from *Arthrobacter ureafaciens*. *Arthrobacter ureafaciens* neuraminidase (0.8 U, Sigma) was incubated in the presence or absence of probe **2** (200 μM) at 4°C in 100 mM ammonium acetate buffer (10 μL). Bovine serum albumin (BSA) was used as a negative control. Labeled samples were applied to a 10% polyacrylamide gel, which was then subjected to sodium dodecylsulfate (SDS) PAGE. After electrophoresis, the proteins were transferred from the gel onto a polyvinylidene fluoride (PVDF) membrane. The PVDF membrane was blocked, washed, and developed by using the enhanced chemiluminescence (ECL). Western blotting protocols as recommended by the supplier (Amersham Biosciences). The result of the Western blot analysis only shows biotinylated proteins (Figure 1). In this experiment, three biotinylated bands corresponding to isoenzymes at 88, 66, and 52 KDa were observed for NA (Lane 1).[18] Probe **2** had no effect on BSA, as

Figure 1. Western blot analysis of probe **2** labeling the *Arthrobacter ureafaciens* neuraminidase.

shown by the lack of labeled bands (Lane 2). In the absence of the probe, neither NA nor BSA was biotinylated (Lanes 3 and 4). This result firmly supports the alkylation process described in Scheme 1. The actual labeling site was not further determined in this study, because a number of biological applications utilizing the same latent trapping device have already established the covalent-bond-forming feature.[15,19] Moreover, Lee and co-workers recently used this activity-probe approach to characterize the catalytic domain of β-galactosidases from *Xanthomonas manihotis*, *Escherichia coli*, and *Bacillus circulans*, with the identification of mainly single modifications on Arg, Glu, and Glu residues, respectively.[20]

We also compared the inhibitory effect of probe **2** and zanamivir on the activity of NA from influenza A virus (A/WSN/33, H1N1), as well as from *Arthrobacter ureafaciens* (AU), *Clostridium perfringens* (CP), and *Vibro cholerae* (VC; Figure 2). Both compounds were tested at 3.3 mM in the NA inhibition assays with 2′-(4-methylumbelliferyl)-α-D-*N*-acetyl-

Figure 2. Inhibition study of NA activities from *A. ureafaciens* (AU), *C. perfringens* (CP), *V. cholerae* (VC), and influenza A virus (Inf A) with probe **2** (gray), zanamivir (white), and the control (black). Virus, suspended in 32.5 mM β-morpholinoethanesulfonic acid buffer (pH 6.5) was incubated with either probe **2** or zanamivir (3.3 mM) at room temperature for 45 min and then incubated with MUNANA at 37°C for 30 min. The residual NA activity is expressed as the percentage of activity relative to that obtained in the absence of reagent. Assays for AU, CP, and VC were similarly carried out, except in 80 mM acetate buffer (pH 5.0).

neuraminic acid (MUNANA, Sigma) as the substrate.[21] All samples were measured in duplicate and fluorometric determinations were performed with a fluorometer (ThermoLab systems, Sweden). The excitation wavelength was 355 nm and the emission wavelength was 460 nm. Probe **2** inhibited all four NA activities (H1N1, AU, CP, VC) with IC₅₀ values of 1.7, 0.68, 0.08, and 0.53 mM, respectively. These results indicate that probe **2** interferes with the activity of NA isolated from various sources at the active site, regardless of the variations the enzymes might have. On the other hand,

zanamivir effectively inhibited viral NA activity with an IC_{50} value of 2–3 nM, but it displayed weak inhibitory effects on the three bacterial NA activities, a result suggesting that the original strong binding interactions could be greatly compromised by possible variations in the active site. It must be emphasized that although one of the targets in this study, the influenza virus, is the same as one in the study of McKimm-Breschkin et al.,[9] the concept and approach of the current strategy offers a versatile alternative for future applications. The labeling event in this study was a result of an activation step forming the reactive quinone methide and did not rely on the strong noncovalent binding which is a critical requirement in the previous approach, a fact which makes the current approach a more general one in targeting NA activities. It is especially worth noting that the advantage of the current approach becomes more prominent with the advent of zanamivir-resistant viruses.[22]

Having established the efficacy of probe **2** to biotinylate NA and thus influenza virus A virions, we next studied the capturing performance by utilizing the covalent-bond-forming feature. The tests were carried out by a modified ELISA method as described previously.[9] Briefly, a streptavidin-coated 96-well ELISA plate (NUNC Immobilizer) was saturated with probe **2**. BSA–biotin conjugate provided a negative control. After 1 hour of incubation, the plate was blocked with 0.1 % BSA/phosphate-buffered saline (PBS) for 1 hour and washed with PBS. Serial twofold dilutions of influenza A virus (A/WSN/33) were added and incubated for 1 hour at room temperature. After another wash, the captured viruses were detected by treatment with a polyclonal anti-FluA antibody, followed by a goat anti-rabbit IgG horseradish peroxidase (HRP) conjugate and a NeA-Blue tetramethylbenzidine substrate (TMB, Clinical Science Products, Inc.). The results indicated that probe **2** bound to the microplate wells could successfully capture influenza virus A and the intensity of the responding signal was proportional to the number of virus particles present (Figure 3). The wells loaded with BSA–biotin conjugate gave a negative response. The possibility of any noncovalent bindings could be ruled out by the modest IC_{50} value (1.7 mM) on the viral NA. More importantly, when the same procedure was applied to a mixture of influenza virus and a non-NA-containing Japanese encephalitis virus, only influenza virus was selectively cap-
tured and detected on the plate, a result strongly supporting the theory that the capture of virus particles was both probe and NA dependent. This conclusion was further supported by the experiment during which probe **2** failed to biotinylate influenza viruses that were preincubated with zanamivir, which effectively blocked the active site of NA on the viral surface. The results represent the first example of the use of a covalent-bond-forming mechanism for the capture of influenza virus particles. In addition, such covalent interactions between captured virus particles and the probe are known to be tolerant to harsh conditions,[15] thus making this methodology amenable for further manipulations.

In summary, we have designed and synthesized a mechanism-based activity probe **2** for neuraminidase, which uses a latent quinone methide as the trapping device and forms a biotinylated adduct with *Arthrobacter ureafaciens* neuraminidase in a model study. By taking advantage of the essential role played by the NA activity in the life cycle of the influenza virus, we evaluated the interaction between probe **2** and the virus. The covalent-labeling event led to diminished NA activities. Furthermore, it serves as the basis for capturing influenza virus particles on microplate wells. This novel approach of capturing the influenza virus, which provides a stronger interaction between virus and the stationary phase, will certainly offer opportunities for developing new applications, such as rapid screening of antibodies against this group of viruses, and the development of sensitive and rapid diagnostic methods.

Figure 3. ELISA-based detection of influenza A (A/WSN/33) captured with probe **2** bound to streptavidin-coated microplate wells and detected with an anti-FluA antibody-HRP conjugate. PFU stands for plague-forming unit.

Reactions of Gold(III) Oxo Complexes with Cyclic Alkenes**

Maria A. Cinellu, Giovanni Minghetti, Fabio Cocco, Sergio Stoccoro, Antonio Zucca, and Mario Manassero*

As pointed out in a recent review, metal-mediated olefin oxidation is still a subject of great interest.[1] Various classes of mechanisms have been envisaged for different metal systems. Among these, that involving metallaoxetanes (1-metalla-2-oxacyclobutanes) as a key intermediate in the oxygen-transfer reaction has been recently corroborated by experimental evidence.[2] While an oxametallacycle has been identified as the crucial surface intermediate in the ethylene epoxidation on Ag,[3] a platinaoxetane, obtained from the reaction of a platinum(II) oxo complex with norbornene, has been structurally characterized.[4] The same oxo complex has been found to stoichiometrically oxidize ethylene to acetaldehyde, thus providing a rare example of alkene oxidation by isolated late-transition-metal oxo complexes.[5] Metallaoxetanes have also been obtained from the reaction of iridium(I) and rhodium(I) alkene complexes with molecular oxygen or hydrogen peroxide.[6]

Gold oxo species are likely to be involved in oxidations catalyzed by gold supported on metal oxides,[7] as, for example, in the direct epoxidation of propene with molecular oxygen.[7d,8] As soluble oxo complexes are valuable models for species involved in heterogeneous catalytic oxidation systems, we studied the reactions of a series of gold(III) oxo complexes[9] with olefins.[10] The model reaction of $[Au_2(bipy^R)_2(\mu\text{-}O)_2](PF_6)_2$ ($bipy^R = 6\text{-R-}2,2'$-bipyridine; see Scheme 1 for R) with styrene yielded novel cationic gold(I) alkene complexes $[Au(bipy^R)(\eta^2\text{-}CH_2=CHPh)](PF_6)$ and oxygenated styrene derivatives.[11,12] After these encouraging results, we searched

for the supposed oxametallacyclic intermediate.[13] A growing number of papers have appeared on the homogeneous gold-catalyzed addition of oxygen nucleophiles to C–C multiple bonds of alkynes or alkenes.[14] Active gold–alkyne (gold–alkene) and cyclic organogold species, which have been suggested as key intermediates in the C−O bond formation,[14f,i–n,q] have never been isolated.

Herein we describe the reaction of $[Au_2(bipy^R)_2(\mu\text{-}O)_2]$-$(PF_6)_2$ [$\mathbf{1}\text{-}(PF_6)_2$: R = Me (**1a**), $CHMe_2$ (**1b**), CH_2CMe_3 (**1c**), $C_6H_3Me_2\text{-}2,6$ (**1d**)] with the strained cyclic alkenes norbornene (nb) and 2,5-norbornadiene (nbd) to give alkene complexes and unprecedented metallaoxetanes (Scheme 1).[15] A dinuclear complex $[Au_2(bipy^R)_2(\mu\text{-}\eta^2,\eta^2\text{-}$

Scheme 1. Oxo complexes $\mathbf{1}\text{-}(PF_6)_2$ (only the *trans* isomer is depicted; **1a** and **1b** are mixtures of the *cis* and *trans* isomer) and products of the reaction with 2,5-norbornadiene, $\mathbf{2}\text{-}(PF_6)_2$, and with norbornene, $\mathbf{3}\text{-}PF_6$ and $\mathbf{4}\text{-}PF_6$.

nbd)]$(PF_6)_2$ [$\mathbf{2}\text{-}(PF_6)_2$: R = Me (**2a**), $CHMe_2$ (**2b**), CH_2CMe_3 (**2c**)] with a bridging nbd ligand is the main product of the reaction as shown by NMR spectra and other analytical data; signals attributable to trace amounts of a second species are sometimes observed in the ^1H NMR spectra.

In the case of the nb derivatives, the ^1H NMR spectra indicate the presence of two species, the ratio of which depends on the preparative conditions and the nature of the substituent of the bipyridine ligand. The main product is the alkene complex $[Au(bipy^R)(nb)](PF_6)$ [$\mathbf{3}\text{-}PF_6$: R = Me (**3a**), $CHMe_2$ (**3b**), CH_2CMe_3 (**3c**), $C_6H_3Me_2\text{-}2,6$ (**3d**)]. When signals from the minor species, **4**, are not observed in the ^1H NMR spectrum, as in the case of the 6-(2,6-xylyl)-2,2′-bipyridine derivative, **4** is detected in the mass spectrum in which, besides the molecular ion, M^+, corresponding to the nb complex (**3d**), a peak of low to medium intensity is found at $[M+16]^+$. Under comparable preparative conditions, significant amounts of the latter species are obtained from $\mathbf{1a}\text{-}(PF_6)_2$.[15] To separate the two species, different methods were employed in the case of the 6-methyl-2,2′-bipyridine (bipy^{Me}) derivatives $\mathbf{3a}\text{-}PF_6$ and $\mathbf{4a}\text{-}PF_6$. Crystals of $\mathbf{3a}\text{-}PF_6$ and $\mathbf{4a}\text{-}PF_6$, obtained by slow diffusion of diethyl ether into an acetonitrile solution of the mixture, were separated and subjected to X-ray diffraction analyses. Although full refinement of the structure of $\mathbf{3a}\text{-}PF_6$ has not been accomplished,

the main feature of the coordination geometry has been established.[16] The second species, $\mathbf{4a}\text{-}PF_6$, proved to be the auraoxetane, $[Au(bipy^{Me})(\kappa^2\text{-}O,C\text{-}2\text{-}oxynorbornyl)](PF_6)$.[17]

The structure consists of the packing of **4a** cations and PF_6 anions in the molar ratio of 1:1 with normal van der Waals contacts. The molecular structure of **4a** is shown in Figure 1. The gold atom has a square-planar coordination environment with a slight square-pyramidal distortion; maximum deviations from the best plane are $+0.024(8)$ and $-0.027(1)$ Å for O and Au atoms, respectively. Carbon atom C13 lies in the metal coordination plane, and the oxametallacycle is strictly planar, as reported for other late-transition-metal metallaoxetanes.[18] The Au−O bond length of 1.967(7) Å is very similar to the Au−O bond lengths of 1.971(4) and 1.960(6) Å found in $[Au(bipy)(OMe)_2](PF_6)$,[19] and the Au−C12 separation of 2.055(8) Å is comparable with the Au−C bond length of 2.028(7) Å found in $[Au\{N_2C_{10}H_7(CMe_2CH_2)\text{-}6\}Cl]^+$ (**5**), in which $N_2C_{10}H_7(CMe_2CH_2)\text{-}6$ is a cyclometalated 6-*tert*-butyl-2,2′-bipyridine ligand.[20] The Au−N1 and Au−N2 bonds (2.026(6) and 2.183(6) Å, respectively) can be compared with corresponding interactions in **5** (1.976(5) and 2.151(5) Å, respectively).

As the isolation of oxametallacycles is unprecedented in the chemistry of gold, we tried to synthesize $\mathbf{4a}\text{-}PF_6$ in better yields in order to study its reactivity.[21] In

Figure 1. Molecular structure (ORTEP) of cation **4a**. Ellipsoids are drawn at the 30% probability level. Principal bond lenghts [Å] and angles [°]: Au–N1 2.026(6), Au–N2 2.183(6), Au–O 1.967(7), Au–C12 2.055(8), C12–C13 1.550(14), C13–O 1.433(12); N1-Au-N2 78.2(3), N1-Au-C12 103.9(3), N1-Au-O 172.9(3), N2-Au-O 108.2(3), N2-Au-C12 177.7(3), C12-Au-O 69.6(3), Au-C12-C13 91.2(5), C12-C13-O 100.7(7), C13-O-Au 98.5(6).

reactions using different ratios of nb to **1a**-(PF$_6$)$_2$ and at different concentrations of **1a**-(PF$_6$)$_2$, in both CH$_3$CN and in CH$_3$CN/H$_2$O, we established a general trend.[22] During the reaction of *trans*-[**1c**-(PF$_6$)$_2$] (the most soluble complex) with nb in CD$_3$CN, we observed by ¹H NMR spectroscopy that the ratio of **3** to **4** remains unchanged. Signals for **3c**-PF$_6$ and **4c**-PF$_6$ were detected after about 40 h (**3c**-PF$_6$/**4c**-PF$_6$ = 2:1); a resonance at $\delta = 9.58$ ppm (d, $J_{H-H} = 1.9$ Hz), which is typical of an aldehyde proton, appeared at the same time. Isolation of the organic fraction obtained from the same reaction in MeCN identified *exo*-2,3-epoxynorbornane (**6**)[23] as the main product accompanied by at least three aldehydes, **7**, **8**, and **9**.[24] The main aldehyde species was cyclopentane-1,3-dicarbaldehyde (**7**, M^+ 126)[25], the others were likely to be 3-methylene-cyclopentane carbaldehyde (**8**, M^+ 110)[26] and 3-methyl-2-cyclopentene carbal-dehyde (**9**, M^+ 110). The epoxide and the dialdehyde were also the main products of the same reaction in MeCN in the presence of a small amount of water (3%). When a larger amount was added ($\geq 10\%$), a 6:1 mixture of *cis-endo*-2,3-norbonanediol (**10**) and *trans*-2,3-norbonanediol (**11**) is obtained. GC–MS and LC–MS analyses showed peaks of $M^+ = 128$, which correspond to C$_7$H$_{12}$O$_2$.

Formation of the epoxide in solution and direct loss of a C$_7$H$_{10}$O fragment from the molecular ion of [Au(bipy^{Me})(C$_7$H$_{10}$O)]$^+$ in the gas phase—shown by the FAB mass spectrum of **4a**—point to the oxaaura-cycle **4** being the origin of both the oxygenated products and the olefin complex **3**. Accordingly, the olefin complex **3a**-PF$_6$, 2,3-epoxynorbornane (**6**), and small amounts of aldehydes **8** and **9** were slowly formed when a MeCN solution of **4a**-PF$_6$ was treated with excess nb.[27] To the best of our knowledge, elimination of an epoxide from an isolated oxametallacycle has never been previously observed.[1,2b] Aldehydes or ketones are formed by isolated Rh^{III} and Ir^{III} 2-metalla-oxetanes.[6e,f,28] Plausible reaction pathways for the formation of the auraoxetane, **4**, and the alkene complex, **3**, are given in Scheme 2.

Attempts to obtain **4a** by reaction of **3a** with O$_2$[6a] or H$_2$O$_2$[6b–d] in neutral MeCN solution were unsuccessful: partial decomposition of the alkene complex was observed in both cases.

Complexes **4a–4c** are the first isolated auraoxacyclobu-tanes. Their formation by the reaction of gold oxo complexes with alkenes may lead to a better understanding of the oxidation of olefins mediated by late-transition-metal com-plexes. Moreover, both the gold(ɪ) alkene complex and the auraoxetane provide evidence for intermediates in the gold-catalyzed addition of oxygen nucleophiles to alkenes and alkynes.
Scheme 2. Proposed reaction pathways for the formation of **3**, **4**, and oxy-genated organic products **6–11**: A) in MeCN/H$_2$O and B) in MeCN. **I** and **II** are supposed intermediates.

[12] Analogous alkene complexes are likewise obtained with other 1-alkenes, whereas no reaction occurs with linear internal alkenes; a small amount of an oxygenated gold species is also detected by ^{1}H NMR spectroscopy and FAB-MS of the α-methylstyrene derivative. Oxygenated organic products were characterized. Styrene derivatives: phenylacetaldehyde (main product) and benzaldehyde, reaction in MeCN; phenylacetaldehyde dimethyl acetal, reaction in MeCN/MeOH; styrene glycol, reaction in MeCN/H_2O. α-Methylstyrene derivatives: acetophenone, reaction in MeCN; 2-phenyl-1,2-propanediol, reaction in MeCN/H_2O; this diol converts almost completely into methylbenzylketone after a prolonged reaction time.

[21] **4a**-PF$_6$ was isolated in low yield after elaborate workup of the mixture. **4a**-BPh$_4$ which conversely can be obtained in fairly good yields, is not stable enough in solution for carrying out a reactivity study.[15]

[22] General trend: 1) high **1a**-(PF$_6$)$_2$ conversions (high **3a** + **4a** yields) require a long reaction time (at least 15 days) a temperature of 10–15 °C and high nb/**1a** ratio (20:1–30:1) both in MeCN and in MeCN/H_2O. 2) Under the same preparative conditions the overall yield (**3a** + **4a**) is only slightly higher in MeCN/H_2O; nevertheless, the **3a**/**4a** ratios are remarkably different: 6.5:1 (averaged) in MeCN and 1.5:1 in MeCN/H_2O. 3) Under the same nb/**1a** ratio and time conditions higher **4a** yields are obtained from concentrated solutions; the overall yield (**3a** + **4a**) was slightly lower than that from dilute solutions.

[23] Signals of the epoxide could not be detected in the spectrum of the reaction mixture (CD$_3$CN) as they overlapped with those of **1c**, **3c**, and **4c**.

[24] ^{1}H NMR spectra were recorded soon after workup of the reaction mixture. Aldehyde signals (CDCl$_3$): **7**: 9.64 (d, 2.0 Hz; 2H); **8** or **9**: 9.63 (d, 2.4 Hz; 1H); **9** or **8**: 9.62 ppm (d, 2.4 Hz; 1H). Intensities: **7** ≥ (**8** + **9**); **7** ≤ **6** (molar ratio based on CHH-7 of the epoxide at δ = 0.70 ppm).

[25] ^{1}H NMR and GC-MS spectra were compared to those of an authentic sample prepared according to: S. Göksu, R. Altundas, Y. Sütbeyaz, *Synth. Commun.* **2000**, *30*, 1615–1621.

[26] Oxidation of nb with N$_2$O to give 3-methylenecyclopentane carbaldehyde (and norbornanone) has recently been reported: E. V. Starokon, K. A. Dubkov, D. E. Babushkin, V. N. Parmon, G. I. Panov, *Adv. Synth. Catal.* **2004**, *346*, 268–274. In default of ^{1}H NMR data for these aldehydes, the experimental spectra have been compared to the simulated ones obtained by ChemDraw 9.0 (CambridgeSoft).

[27] Complex **3a** and **6** also form upon addition of nb and a catalytic amount (5%) of HBF$_4$·Et$_2$O to **4a**; in this case small amounts of diols **10** and **11** are formed.

Thiazole Synthesis by Cyclocondensation of 1-Alkynyl(phenyl)-λ^3-iodanes with Thioureas and Thioamides**

Kazunori Miyamoto, Yoshio Nishi, and Masahito Ochiai*

In 1996, Wipf and Venkatraman reported an efficient method for the synthesis of thiazoles, which involved the cyclocondensation of hypervalent 1-alkynyl(phenyl)-λ^3-iodanes with thioureas or thioamides.[1] For instance, the reaction of phenylethynyl(phenyl)(mesylato)-λ^3-iodane (**1a**) (X = OMs, Ms = methanesulfonyl) with thiourea in methanol in the presence of triethylamine at 0 °C directly afforded 2-amino-4-phenylthiazole (**2**; R = Ph, R′ = NH$_2$) in a good yield (Scheme 1). 1-Hexynyl-λ^3-iodane **1b** (X = OMs) also pro-

1a: R = Ph
1b: R = *n*Bu
1c: R = *t*Bu

Scheme 1. Synthesis of thiazoles.

duced the thiazole **2** (R = *n*Bu, R′ = NH$_2$ or Ph) by reaction with thiourea or thiobenzamide. This direct method for the synthesis of thiazoles based on the cyclocondensation of 1-alkynyl-λ^3-iodanes was applied to the synthesis of 2-mercaptothiazoles and selenazoles.[2]

The one-step thiazole synthesis developed by Wipf and Venkatraman is a very useful reaction, as many biologically active natural products contain thiazole moieties.[3] They proposed a reaction mechanism that involves a unique [3,3]-sigmatropic rearrangement of an initially formed 1-alkynyl(iminothio)-λ^3-iodane **3** through ligand exchange on the hypervalent iodine. Reductive elimination of the resulting vinyliodonium ylide **4** generates an α-thioamido alkylidene carbene **5**, which undergoes an intramolecular cyclization to yield 2,4-disubstituted thiazole **2** (Scheme 2, pathway A).[4]

The more common Michael addition pathway with the initial formation of an isomeric vinyliodonium ylide **6** was discarded, and it was proposed that this Michael addition pathway would provide thiazoles **8** with an inverse C4,C5-substitution pattern through successive reductive elimination of iodobenzene and intramolecular 1,5 N−H insertion of the alkylidene carbene **7** (pathway B).[1]

It occurred to us that a third mechanism (pathway C) that involved the Michael addition of thio nucleophiles followed by a 1,2-rearrangement of the iminothio group in the alkylidene carbene **7**, instead of the intramolecular 1,5 N−H insertion, thus yielding the alkynyl sulfide **9**, seems to be a more attractive alternative. Further intramolecular cyclization of **9** probably provides **2** selectively. In fact, the 1,2-rearrangement of sulfenyl groups in alkylidene carbenes is known to be a facile and very rapid process because of the excellent migratory aptitude of sulfenyl groups.[5] Furthermore, it has been shown that soft sulfur nucleophiles, such as thiolates,[6] thiosulfonates,[7] phosphorodithioates,[8] thiocyanates,[9] and sulfinates,[10] preferentially undergo Michael additions towards 1-alkynyl(phenyl)-λ^3-iodanes. We report herein some evidence that **9** is a reactive intermediate in the cyclocondensation of hypervalent 1-alkynyl(phenyl)-λ^3-iodanes with thioureas or thioamides and that the thiazole synthesis probably proceeds through pathway C.

The cyclocondensations of 1-alkynyl(phenyl)-λ^3-iodanes with thioureas or thioamides that yield **2** were carried out in the presence of a base, such as potassium carbonate or triethylamine.[1] The reaction course, however, dramatically changed without a base being present. Thus, when the reaction of phenylethynyl-λ^3-iodane **1a** (X = OMs) with thiourea (1 equiv) was carried out in dichloromethane at −78→10 °C under nitrogen in the absence of triethylamine, no formation of **2** (R = Ph, R′ = NH$_2$) was observed; instead, a hitherto unknown *S*-(phenylethynyl)isothiouronium mesylate **9**-MsOH (R = Ph, R′ = NH$_2$) was isolated in 82 % yield after repeated decantation with hexane.[11] The IR spectrum of this salt showed the characteristic peak of the triple bond at 2180 cm^{-1}, as well as the strong absorption of the iminium group at 1683 and 1662 cm^{-1}, whereas the ^{13}C NMR spectra revealed two peaks of acetylenic carbon atoms at δ = 65.8 and 106.6 ppm.
Single crystals of **9**-MsOH for X-ray structural analysis were grown from a mixture of methanol/dichloromethane/hexane.[12] Figure 1a illustrates a planar *S*-(1-alkynyl)isothiouronium structure with the sum of the C(9)-centered bond angles Σ°C(9) = 359.97°. Interestingly, the phenyl and the isothiouronium groups lie almost on the same plane, with a dihedral angle of 8.19(3)°.

It should be noted that exposure of *S*-(phenylethynyl)-isothiouronium mesylate (**9**-MsOH) to an aqueous saturated solution of NaHCO$_3$ at room temperature produced a moderate yield (51 %) of 2-amino-4-phenylthiazole (**2**) through an intramolecular 5-endo digonal cyclization. The same type of intramolecular cyclization in substituted *S*-alkynylisothiouronium salts has been reported.[11, 13] These results suggest that methanesulfonic acid generated from λ^3-iodane **1a** (X = OMs) during the reaction with thiourea (Scheme 2) probably inhibits the intramolecular cyclization of **9** (R = Ph, R′ = NH$_2$) under our conditions by formation of

Scheme 2. Possible reaction mechanisms.

**Figure 1.** ORTEP drawing of a) isothiouronium salt **9**-MsOH (R = Ph, R′ = NH₂) and b) thiobenzimidonium salt **10**. Selected interatomic distances [Å] and angles [°]: **9**-MsOH: C(7)-C(8) 1.193(1), S(1)-C(8) 1.6888(8), S(1)-C(9) 1.7695(7), C(8)-S(1)-C(9) 102.19(4); **10**: C(8)-C(9) 1.187(2), S(1)-C(8) 1.691(2), S(1)-C(1) 1.752(1), C(8)-S(1)-C(1) 101.69(7).

the **9**-MsOH. Treatment with a base regenerates the free sulfide **9** which undergoes spontaneous cyclization at room temperature. The isolation and cyclization of **9**-MsOH clearly indicate that this alkynyl sulfide **9** is probably a reactive intermediate in the one-step 2-aminothiazole synthesis in the presence of a base, which is compatible with the alkylidene carbene pathway C.

Comparable results were obtained from the reaction with thioamides. Reaction of 1-decynyl(tetrafluoroborato)-λ^3-iodane (**1d**)[14] (X = BF₄) with thiobenzamide in dichloromethane at −78 °C→room temperature afforded a 69:31 mixture of *S*-(1-decynyl)thiobenzimidonium tetrafluoroborate (**9**-HBF₄; R = *n*-C₈H₁₇, R′ = Ph) and 4-octyl-2-phenylthiazolium tetrafluoroborate (**2**-HBF₄; R = *n*-C₈H₁₇, R′ = Ph) quantitatively (as shown by ¹H NMR spectroscopic analysis of a crude reaction mixture). The thioimidonium salt **9**-HBF₄ is highly labile and tends to undergo intramolecular cyclization; thus, even the attempted purification of the crude

product by decantation with hexane/diethyl ether at room temperature resulted in partial cyclization, and the ratio of **9**-HBF₄/**2**-HBF₄ was reversed to 31:69 (91 % yield). Treatment with a base (Na₂CO₃/H₂O) accelerates the cyclization and gave 4-octyl-2-phenylthiazole (**2**)[15] in 93 % yield. Reaction of 1-hexynyl-λ^3-iodane **1b** (X = BF₄) with thiobenzamide also afforded a 94:6 mixture of labile *S*-(1-hexynyl)thiobenzimidonium tetrafluoroborate **9**-HBF₄ and 4-butyl-2-phenylthiazolium tetrafluoroborate **2**-HBF₄ (for each R = *n*Bu, R′ = Ph), which on treatment with a solution of 5 % aqueous Na₂CO₃ produced 4-butyl-2-phenylthiazole (**2**)[1] in a high yield (87 %).

Isolation and full characterization of the labile *S*-(1-alkynyl)thiobenzimidonium salts were achieved by reaction of the more-sterically demanding 3,3-dimethyl-1-butynyl-λ^3-iodane **1c** (X = BF₄) with thiobenzamide, followed by acidification of the reaction mixture with HBF₄·Me₂O (1 equiv). This procedure makes the quantitative isolation of *S*-(3,3-dimethyl-1-butynyl)thiobenzimidonium tetrafluoroborate (**9**-HBF₄) as pale-yellow needles possible. Treatment with a base (Na₂CO₃/H₂O) afforded 4-*tert*-butyl-2-phenylthiazole (**2**)[16] in 96 % yield.

N,N-Dimethylthiobenzamide seems to be an attractive nucleophile in the reaction, because the resulting *N,N*-dimethylthiobenzimidonium salts cannot undergo the intramolecular 5-endo digonal cyclization. In fact, *S*-(3,3-dimethyl-1-butynyl)thiobenzimidonium salt **10** was isolated as stable colorless plates by the reaction of *N,N*-dimethylthiobenzamide with 3,3-dimethyl-1-butynyl-λ^3-iodane **1c** (X = BF₄) in 98 % yield (Scheme 3). The structure of the

Communications
Scheme 3. Synthesis of (S)-(3,3-dimethyl-1-butynyl)thiobenzimidonium salt **10**.

salt **10** was firmly established by solid-state structure analysis (Figure 1b).[12]

All of these results indicate that the one-step thiazole synthesis using 1-alkynyl(phenyl)-λ^3-iodanes **1** developed by Wipf and Venkatraman involves the intermediate formation of the alkynyl sulfides **9** (and/or their salts), probably produced through the Michael addition of thioureas or thioamides and 1,2-shift in the alkylidene carbenes **7**. This Michael addition has been well established as the most common reaction pathway for 1-alkynyl-λ^3-iodanes with soft nucleophiles.[17,18]

An alternative mechanism that leads to the formation of **9** involves a tandem ligand exchange and ligand-coupling process at the iodine(III) center (Scheme 4). This tandem
Scheme 4. A mechanism that involves tandem ligand exchange and ligand-coupling reactions.

process does not, however, seem to take place, as the attempted reaction of diphenyl-λ^3-iodane **11** with thiobenzamide did not show any evidence of the formation of the ligand-coupling product **12** and **11** was recovered (95%). Further evidence against the ligand-coupling mechanism was reported recently:[19] that is, the reaction of (E)-1-decenyl-(phenyl)-λ^3-iodane **13** with thiourea resulted in unusual vinylic S_N2 displacement that yields the inverted (Z)-(S)-vinylisothiouronium salt **14** stereoselectively in a good yield (Scheme 4). In this reaction, no formation of the ligand-coupling product, the (E)-(S)-vinylisothiouronium salt, was detected.

In conclusion, the isolation and the intramolecular cyclization of (S)-(1-alkynyl)isothiouronium and (S)-(1-alkynyl)thiobenzimidonium salts indicate that these species are probably involved in the cyclocondensation of hypervalent 1-alkynyl(phenyl)-λ^3-iodanes with thioureas or thioamides yielding thiazoles.

great number of covalently linked oligomacrocycles (e.g. porphyrins or phthalocyanines) have so far been prepared, only a few such molecules have been tested for the exploitation of long-range magnetic coupling.[2,3] One difficulty in the use of these metalated macrocycles for magnetic coupling may be exemplified by the work of Eaton et al., in which a $-J$ value of only about 0.5 cm^{-1} was detected for a face-to-face coplanar bis-Cu^{II} diporphyrin with a short center-to-center distance of around 4.1 Å.[2a] However, suitably arranged intervening bridges may help magnetic communication between distant metal centers.[3]

In recent years, we have explored a series of directly linked diporphyrins, including the *meso–meso* singly linked diporphyrin **1**,[4a] the *meso–β* singly linked diporphyrin **2**,[4b,e] the *meso–β, β–meso* doubly linked diporphyrin **3**,[4c,e] and the *meso–meso, β–β, β–β* triply linked diporphyrin **4**.[4d,e,f] Because of their direct covalent linkages, these diporphyrins exhibit a large electronic interaction, which increases in the order **2** < **1** ≪ **3** ≪ **4**, as judged from the absorption spectra.[4] In these diporphyrins, two metal centers that are connected by various σ-bond networks are kept strictly apart due to the center-to-center distances of 8.34, 8.91, 8.60, and 8.42 Å for **1**, **2**, **3**, and **4**, respectively.[5] Herein we report antiferromagnetic coupling in bis-Cu^{II} and bis-Ag^{II} complexes of **1–4**. It is known that the unpaired spin of both Cu^{II} and Ag^{II} porphyrins is localized in the d$_{x^2-y^2}$ orbital, which leads to a situation where the unpaired electrons can be delocalized into the porphyrinic π-electronic network only through a σ-bond pathway.[6] In this context, the diporphyrins **1–4** constitute a nice set for systematic studies on the dependence of antiferromagnetic interactions on a direct linkage.

The free-base diporphyrins **1–4** were prepared by the reported methods[4] and metalated with Cu(OAc)$_2$ and AgOAc to afford **1Cu–4Cu** and **1Ag–4Ag**, respectively (Scheme 1). The effective magnetic moments (χT) at 300 K

Scheme 1. Directly linked porphyrins **1M–5M**. M: Cu^{II}, Ag^{II}.

were determined to be 0.82–0.87 emu K mol^{-1} for **1Cu–4Cu**, thus indicating the presence of two magnetically uncoupled spin doublets (Figure 1a; see also Supporting Information (SI)). Variable-temperature magnetic susceptibility measurements revealed that the χT values of **1Cu**, **2Cu**, and **3Cu** are nearly temperature-independent in the range 2–300 K, with essentially constant values of about 0.8 emu K mol^{-1}.

Figure 1. Variable-temperature magnetic susceptibility measurements in the range 2–300 K: a) **3Cu** and **3Ag**, b) **4Cu** and **4Ag**. The solid lines represent the fitting curves based on the Bleaney–Bowers equation.

The mean g values in the EPR spectra of **1Cu**, **2Cu**, and **3Cu** in frozen toluene at 4.0 K were 2.08, 2.13, and 2.13 (see SI), respectively, which were reproduced as a simple sum of an isolated Cu^{II} porphyrin. In contrast, the χT value of **4Cu** was found to drop sharply at temperatures below 20 K and to reach a value of 0.34 emu K mol^{-1} at 2.0 K (Figure 1b). This temperature dependence is indicative of Curie law behavior with a weak antiferromagnetic coupling between the two copper(II) ions. A least-squares fit with the Bleaney–Bowers equation gave a $-J$ value of 1.43 cm^{-1} for **4Cu**. In line with the χT measurement, the EPR spectrum of **4Cu** at the mean g value of 2.11 could not be reproduced as a sum of isolated Cu^{II} porphyrins but as two magnetically interacting Cu^{II} porphyrins. This means that the spectrum of **4Cu** is due to the thermally populated $S = 1$ triplet state above the $S = 0$ ground state.

The magnetic properties of **1Ag–4Ag** were also examined. In the range 2–300 K, the χT values of **1Ag–3Ag** are temperature independent (ca. 0.8 emu K mol^{-1}; Figure 1a), thus indicating the presence of two magnetically uncoupled spin doublets, while the χT values of **4Ag** exhibit a sharp drop below 20 K, reaching a value of 0.09 emu K mol^{-1} at 2.0 K (see SI and Figure 1b). The mean g values in the EPR spectra of **1Ag–4Ag** in frozen toluene are 2.06, 2.07, 2.06, and 2.06, respectively. The spectra of **1Ag–3Ag** were reproduced as a simple sum of isolated Ag^{II} porphyrins, whereas that of **4Ag** could be reproduced as two magnetically interacting Ag^{II}

porphyrins, similarly to the case of **4Cu** (see SI). The least-squares fit with the Bleaney–Bowers equation gave a $-J$ value of 3.64 cm^{-1} for **4Ag** (Figure 1b).

The marked differences observed between the magnetic coupling behaviors of **4M** and **1M–3M** led us to consider the importance of a β–β bond for effective long-range magnetic coupling, since such a linkage only exists in **4M**. We thus prepared a new β–β singly linked diporphyrin **5M** from a β-borylated porphyrin precursor.[7] Both bis-metalated complexes **5Cu** and **5Ag** exhibit long center-to-center distances of around 9.63 Å and the lowest excitonic coupling in the absorption spectra in the series. Nevertheless, as shown in Figure 2, both the χT values of **5Cu** and **5Ag** exhibit

Figure 2. Variable-temperature magnetic susceptibility measurements in the range 2–300 K: a) **5Cu** and b) **5Ag**. The solid lines represent the fitting curves based on the Bleaney–Bowers equation.

temperature-dependent behavior at low temperature, reaching values of 0.65 and 0.24 emu K mol^{-1} at 2.0 K, respectively. The least-squares fit of the χT values with the Bleaney–Bowers equation provided $-J$ values of 0.55 and 1.73 cm^{-1}, respectively. These results clearly indicate the critical role of a direct β–β bond in the long-range antiferromagnetic coupling.

Although excited triplet states are present in **4Cu**, **4Ag**, **5Cu**, and **5Cu**, no EPR signal was observed at the half field. This can be accounted for in terms of a small fine-structure interaction $|D|$ in the triplet states (see SI) of these diporphyrins.[8] The $|D|$ value should become smaller with increasing spin–spin distance. Actually, a simple estimation of $|D|$ for **4M** and **5M** led to a prediction that the "forbidden transition" at the half field is hardly observed in these cases (see SI); this seems to be a general feature of diporphyrins with a large center-to-center distance.

The critical importance of a direct β–β bond can be explained in terms of the spin densities of Cu^{II} and Ag^{II} porphyrin monomers, as calculated by the DFT method at the B3LYP level. The 6-31G* basis set was employed except for Cu and Ag, for which a basis set consisting of the Stuttgart effective core potential was used. In both cases, the calculations confirmed that the unpaired electron in the $d_{x^2-y^2}$

orbital develops only at the β position and not at the *meso* position (see SI), thus highlighting the importance of a direct β–β bond. In fact, the calculated singly occupied MOs (SOMOs; Figure 3) of a model compound for **4Cu**, in which

Figure 3. Two calculated SOMOs of a model for **4Cu** in the $S = 1$ state.

all *meso* substituents were replaced with hydrogen, indicate that the spin orbital of the copper porphyrin interacts only through the β–β bond in the $S = 1$ state (Figure 3a). In addition, the DFT calculations support our interpretation of the EPR measurements, namely that the $S = 0$ ground state lies below the $S = 1$ state.

The antiferromagnetic couplings are larger in the Ag^{II} complexes than in their Cu^{II} counterparts. Since the spin distribution patterns are similar due to the spin location in the $d_{x^2-y^2}$ orbital, the observed difference may be attributed to different spin densities. The spin density distribution via the σ-contact contribution can be estimated by a ^2H NMR method. Typically, the ^2H NMR spectrum of $Cu^{II}(tpp)$ exhibits the pyrrole β-^2H signal at around $\delta = 41$ ppm as a broad signal,[9] while the signals of $Ag^{II}(tpp)$ are too broad to be detected, thus indicating that the σ-contact contribution is larger for Ag^{II} porphyrin than Cu^{II} porphyrin. The fact that **5Ag** lies roughly on the long-range limit predicted by the Coffman–Buettner equation[10] suggests that the direct β–β bond allows an effective σ-bond pathway for long-range antiferromagnetic coupling between distal paramagnetic metal ions in porphyrins (see SI).

In conclusion, we have shown that antiferromagnetic coupling is only effective for **4Cu**, **4Ag**, **5Cu**, and **5Ag**, thus underlining the crucial importance of a direct β–β bond. However, even in the extensively π-conjugated diporphyrins **4Cu** and **4Ag**, the long-range antiferromagnetic interaction is considered to propagate via a β–β σ-bond pathway. These results will be quite useful for further molecular design of magnetically coupled molecules. The exploration of higher

Cu^{II} and Ag^{II} porphyrin arrays is an attractive subject that is actively being pursued in our laboratory.

Molecular and Polymeric Hybrids Based on Covalently Linked Polyoxometalates and Transition-Metal Complexes**

*Jeonghee Kang, Bubin Xu, Zhonghua Peng,** Xiaodong Zhu, Yongge Wei, and Douglas R. Powell*

We report a rational synthetic approach to novel molecular and polymeric hybrids containing polyoxometalate (POM) clusters and transition-metal complexes covalently linked by an organic π-conjugated bridge. There continues to be extensive interest in hybrids containing both POMs and organometallic components.[1–3] The motivation lies not only in chemists' steady desire to bring different structural units together but also in the prospect of generating new functional and multifunctional materials,[4] although the overwhelming interest in organometallic/POM hybrids has so far been focused to their catalytic activity.[1,5] A significant number of organometallic/POM hybrids have already been reported, most of which anchor the organometallic component by either the surface oxygen atoms of POM clusters or active metal centers incorporated within the POM cluster.[1–5] The commonly adopted synthetic approach relies on a self-assembly process in which attachment of the organometallic component and assembly of the POM cluster occur simultaneously.[1–5] Although various other preparation methods have been reported,[6] one which allows rational design and predetermination of structure and properties remains elusive.

One fascinating aspect of POM clusters is their structural diversity, not only in the cluster frame itself but also in the ways of derivatizing them.[1] Among the many types of organically functionalized POMs, organoimido derivatives are particularly interesting.[7] Aside from remarkable stability of the imido metal–nitrogen linkage, which makes further structural modification on the cluster-anchored organic

component possible,[8] delocalization of organic π electrons on the POM cluster may lead to a new class of electronic hybrid materials.[9] Indeed, we have recently shown that organoimido derivatives with remote functionality can be used as building blocks to construct hybrid dumbbells,[10] charge-transfer hybrids,[11] and polymer hybrids[12] which have been demonstrated to be photovoltaic materials. Here we report that the building block approach can be extended to the preparation of organometallic POMs with predetermined structures. In particular, we describe the synthesis and optical properties of the first molecular and polymeric hybrids (**3** and **6** in Schemes 1 and 2, respectively) in which POM clusters and transition-metal complexes are linked by an organic π-conjugated bridge. Such hybrids were designed to take advantage of the metal-to-ligand charge-transfer (MLCT) transitions of transition-metal complexes,[13] the electron-accepting properties of POM clusters, and the charge-transport properties of π-conjugated systems, to realize systems with efficient photoinduced charge separation.

Schemes 1 and 2 show the structures and syntheses of molecular hybrid **3** and polymeric hybrid **6**, respectively. Polyoxometalate clusters functionalized with one or two iodo functional groups (**1** and **4**, respectively) were prepared according to previously reported procedures.[14,15] Pd-catalyzed coupling of 4′-ethynyl-2,2′,6′,2″-terpyridine with **1** and **4** yielded terpyridine-functionalized clusters **2** and **5**, respectively. The crystal structure of hybrid **2** was communicated previously.[16] Hybrid **5** was characterized by ^{1}H NMR spectroscopy (see Experimental Section), electrospray ionization mass spectrometry (ESI-MS), and X-ray single-crystal diffraction.

The mass spectrum of **5** shows isotopic clusters centered at m/z 853.05 (100), 1707.73 (9), and 1953.09 (3%). These signals can be assigned to the cluster anion M^{2-} ($M = [Mo_6O_{17}N_8C_{58}H_{52}]$, calcd m/z: 854.36), $M^{2-}+H^+$ (calcd m/z: 1709.72), and $M^{2-}+Bu_4N^+$ (calcd m/z: 1952.17), respectively, consistent with its structure.

Hybrid **5** crystallizes in the triclinic space group $P\bar{1}$[17] with two formula units per asymmetric unit of the cell. The anions of the two formula units adopt rather different configurations (Figure 1). Most notable are the different dihedral angles between one terpyridine system (2-3-4) and the adjacent phenyl ring (ring 1). In configuration a, the dihedral angle between rings 1 and 2 is only 19.7°, while the corresponding two rings are nearly perpendicular to each other in configuration b.

Coordination of hybrids **2** and **5** with Fe^{2+} was carried out in acetonitrile or dimethyl sulfoxide (DMSO) at room temperature. ^{1}H NMR titration (see Supporting Information (SI) for details) indicates that the terpyridine ligand in **2** almost completely coordinates with Fe^{2+} to form Fe^{2+} bis(terpyridine) complex when 0.5 equiv of Fe^{2+} (vs **2**) is added. Further addition of Fe^{2+} does not result in the dissociation of the bis(terpyridine) complex; this indicates a high kinetic barrier and thus kinetic inertness of $[Fe(tpy)_2]^{2+}$ complexes.[18] Hybrid **3**, however, has a net −2 charge. Excess Fe^{2+} can replace Bu_4N^+ and form ion pairs with **3**. Indeed, when an excess of $FeCl_2$ (10 equiv) was added to a solution of **2** in acetonitrile, a green precipitate immediately formed,

**Scheme 2.** Synthesis of a polymer hybrid by metal–ligand coordination.

Figure 1. ORTEP representation for the two anion configurations in hybrid **5**. Selected dihedral angles [°]: I–II, 25.1 (a), 25.6 (b); II–III, 18.8 (a), 17.2 (b); II–IV, 6.7 (a), 16.8 (b); 1–2, 19.7 (a), 81.6 (b); 2–3, 3.8 (a), 6.4 (b); 2–4, 35.2 (a), 33.6 (b).

whose ^{1}H NMR spectrum shows no proton signals of Bu_4N^+ (see the Supporting Information). A UV/Vis titration experiment (see the Supporting Information) also points to the formation of **3**-Fe^{2+} ion pairs when an excess of Fe^{2+} is added. These results indicate that, to form **3** with Bu_4N^+ as the counterion, the appropriate ratio of Fe^{2+}/**2** is 1:2.

Hybrid **3** with the Bu_4N^+ counterion is soluble in dimethyl formamide (DMF) and DMSO. Its structure was confirmed by ^{1}H NMR and ESI-MS measurements. As shown in Figure 2, both hybrids **2** and **3** show nearly identical signals in the region of chemical shifts between 0 and 4 ppm, where protons in the Bu_4N^+ counterion (labeled a, b, c, d) and the benzyl methyl protons (proton 8) appear. The cluster-bound aryl protons (proton 7) also exhibit similar chemical shifts. Protons in the terpyridine ligands, however, show drastic changes in chemical shifts after Fe^{2+}–terpyridine coordination. By comparison with the ^{1}H NMR spectrum of Fe^{2+}–bis(terpyridine) model complex **7**, one can clearly identify the similarity in the aromatic region between **3** and **7**, assign all signals accordingly, and thus unambiguously confirm Fe^{2+}–terpyridine complexation. The lack of signals corresponding to free terpyridine ligands in the ^{1}H NMR spectrum of **3** indicates rather complete coordination. The integration ratio of signals associated with the hybrid anion versus those corresponding to the counterion also offers useful structural information. For example, the integration ratios of signal 3′ over b are 1:7.76 for **2** and 1:3.82 for **3**, that is, one Fe^{2+} ion
Figure 2. ¹H NMR spectra of **2** and **3**. The middle spectrum is the ¹H NMR spectrum of **7**. All spectra were recorded in [D₆]DMSO.

indeed binds to two terpyridyl ligands (the theoretical ratios of 3′ over b for **2** and **3** are 1:8 and 1:4, respectively).

The structure of **3** is also confirmed by ESI-MS measurements. The ESI mass spectrum of hybrid **3** shows two major isotopic clusters centered at m/z 1265 and 1239.2. The first signal can be assigned to the cluster anion M^{2-} of **3** ($M^{2-} =$ $[Mo_{12}O_{36}N_8C_{50}H_{36}Fe]^{2-}$, calcd m/z: 1266.0), while the second is attributed to hybrid **2** ($[2]^{2-} + H^+$, $[Mo_6O_{18}N_4C_{25}H_{19}]^-$, calcd m/z: 1239.1). The relative intensity of these two signals depends strongly on probe potential. Under relatively high probe potential (15 V), the signal corresponding to free hybrid ligand **2** dominates (1239.2, 100%; 1265, 55%), while under low probe potential (8 V), the relative intensity of the two signals reverses (1239.2, 38%%; 1265, 100%); hence, the appearance of signals corresponding to noncoordinated hybrid **2** is due to in-source decomposition of **3**. Great efforts were made to grow single crystals of **3**, but all attempts so far were unsuccessful.

Unlike **3**, coordinated hybrid **6** exhibits poor solubility in common organic solvents. When the coordination of **5** with FeCl₂ is carried out in acetonitrile, the coordinated product precipitates immediately as a green solid, and the overlying clear solution becomes colorless. ¹H NMR measurements on the clear solution show no signals for aromatic proton but only for tetrabutylammonium counterion, indicating that all starting hybrid **5** has reacted and precipitated. Hybrid **6** does show slight solubility in DMSO, however. When the coordination process of hybrid **5** with FeCl₂ was carried out in [D₆]DMSO, a green precipitate was again produced. The color of the solution, however, remained green. After mixing with FeCl₂ for only 20 min, the ¹H NMR spectrum of the solution (see the Supporting Information) shows that the signals corresponding to free terpyridine ligands have completely disappeared, that is, all terpyridine ligands have coordinated with Fe²⁺. The peaks in the aromatic region show chemical shifts nearly identical to those of hybrid **3**, further confirming the formation of iron(II)–bis(terpyridine) complexes. The overwhelming counterion signals in the solution indicate that, as coordinated hybrid **6** precipitates from solution, the tetrabutylammonium counterion remains.

Indeed, the ¹H NMR spectrum of **6** (the green precipitate), obtained after days of data collection due to its poor solubility, shows no signals attributable to the counterion, while signals consistent with iron(II)–bis(terpyridine) complex can be identified. Note that the lack of free terpyridyl ligands in **6** may also indicate the formation of cyclic oligomers.

The electronic properties of hybrids **3** and **6** were studied by UV/Vis absorption measurements. As shown in Figure 3,

Figure 3. UV/Vis absorption spectra of hybrids **2**, **3**, **5**, **6**, and model Fe²⁺–bis(terpyridine) complex **7** in DMSO.

terpyridine-anchored clusters **2** and **5** both show a maximum absorption at 392 nm, which is assigned to the ligand-to-metal charge-transfer (LMCT) transition associated with Mo−N π bonding. After coordination with Fe²⁺, the resulting hybrids **3** and **6** show two new absorption bands, one at 595 nm and the other at 333 nm. The first band is attributed to MLCT, while the second is due to the ligand-centered (LC) transition, both associated with the Fe²⁺–bis(terpyridine) complex. These assignments are confirmed by the UV/Vis absorption spectrum of model complex **7**, which shows two similar absorption bands. The MLCT bands of **3** and **6** are red-shifted by nearly 40 nm compared to that of **7**. The electron-withdrawing nature of the Mo≡N bond lowers the π* orbital of the ligand and thus decreases the MLCT band gap and results in its bathochromic shift.[19] The more extended π conjugation of the ligands in **3** and **6** than in **7** also contributes to the red shift.[20]

The electrochemical behavior of hybrids **3** and **6** was studied by cyclic voltammetry. Figure 4 shows the cyclovoltammogram of **6**, measured on its polymer film, together with those of **3**, model complex **7**, and hybrid **2**, measured in DMSO solutions. In the range −2.0–1.5 V (vs Ag/Ag⁺), **7** shows one metal-localized (Fe²⁺/Fe³⁺) reversible oxidation wave at 0.805 V ($\Delta E = 0.11$ V) and two ligand-localized reversible reduction waves at −1.47 V ($\Delta E = 0.10$ V) and −1.62 V ($\Delta E = 0.10$ V).[21] In the same potential range, hybrid **2** exhibits no oxidation process. Besides one semireversible reduction process at −1.60 V, which can be attributed to the reduction of the terpyridine ligand, a reversible reduction wave at a much lower potential of −0.80 V ($\Delta E = 0.17$ V) is
Figure 4. Cyclic voltammograms of **2**, **3**, and **7**.

observed. This reduction process is associated with the POM cluster.[7] Under the same conditions and in the same potential range, hybrid **3** shows redox waves of both **2** and **7**. The observation of the $Fe^{2+/3+}$ oxidation wave, the POM-associated reduction wave, and the two ligand-centered reduction waves once again confirms the structure of **3**. For **6**, the $Fe^{2+/3+}$ oxidation wave is still noticeable, and the reduction peak at -1.12 V is consistent with diimido derivatives of POMs.[7,12]

In conclusion, we have successfully prepared the first hybrid in which a POM cluster and transition-metal complexes are linked through an extended π-conjugated bridge. A coordinated POM-containing hybrid polymer is also demonstrated. The hybrids exhibit low-lying MLCT transitions associated with the transition-metal complexes and LMCT transitions located at the cluster/organic Mo≡N junction. This rational building-block approach may be extended to the preparation of hybrids with other metal ions, particularly those coordinating with terpyridine ligands at room temperature with large binding constants.

Perovskite Hollow-Fiber Membranes for the Production of Oxygen-Enriched Air**

Haihui Wang, Steffen Werth, Thomas Schiestel, and Jürgen Caro*

Oxygen-enriched air with 30–50 vol % O_2 is used in a number of industrial processes, for example, in the synthesis of ammonia, the Claus process, and the regeneration of the catalyst for the fluid-catalytic-cracking (FCC) process.[1,2] Another application of O_2-enriched air is the most efficient use of methane in high-temperature furnaces or cement kilns.[2] There are different methods for producing O_2-enriched air, mainly by mixing air with pure O_2 obtained from a cryogenic technique or pressure swing adsorption (PSA). However, these techniques require high capital investment and operational costs. Depending on the O_2 concentration and the amount of the O_2-enriched air needed, membrane technology can be competitive. As organic polymeric hollow-fiber membranes have a separation factor between 2 and 6, a single-stage membrane permeation gives an O_2 concentration typically of the order of 30–50 vol % under a pressure difference of about 10 bar.[3] Although higher O_2 concentration and permeability can be achieved by increasing the feed flow rate, by reducing the membrane thickness, or by increasing the pressure difference, these actions increase the separation costs. Furthermore, the organic polymeric membrane cannot be used for the recovery of heat from exhaust gas in high-temperature processes.

Herein we propose a new technique to produce O_2-enriched air by using a mixed-ion and electron-conducting (MIEC) perovskite membrane. The basic idea is shown in Figure 1. At elevated temperatures, under a slight difference in air pressure (1–2 bar) O_2 can be transported through a MIEC perovskite membrane in the form of oxygen ions from

Figure 1. O_2 enrichment with perovskite mixed-conducting membranes.

the side of high air pressure to the side of low air pressure. Simultaneously, electrons are transported in the opposite direction to maintain electric neutrality. The permeated O_2 increases the O_2 concentration to typically 30–50 vol % in the sweep air that forms the O_2-enriched air on the low-pressure side. Therefore, the perovskite membrane combines the in situ O_2 supply with permeated O_2 and air in one unit thus simplifying the process of O_2 enrichment and reducing the operational and capital costs.

The obvious advantage of using perovskite membranes is their 100 % selectivity for O_2. Usually, polymeric membranes also transport noble or inert gases such as Ar or CO_2, which can be disadvantageous depending on the process. Synthesis gas for ammonia production, for example, is prepared at a pressure level of about 30 bar and afterwards compressed to a pressure of typically 170–190 bar. Any inert gases contained within the synthesis gas are also compressed to a higher pressure and fed into the synthesis loop. This in turn increases the energy expenditure for compression, the necessary loop volume, and the purge flow used to get rid of the inert components in the synthesis loop.

Moreover, compared with hollow-fiber membranes made from organic polymers, the perovskite hollow-fiber membrane requires a lower pressure difference (1–2 bar) across the membrane and can work at elevated temperatures, thus allowing high-temperature heat exchange. O_2-enriched air is used mostly in high-temperature oxidation processes such as in the generation of synthesis gas for ammonia production in which O_2-enriched air is used to run a secondary reformer typically operated at 1000 to 1100 °C. Therefore, in this process the temperature required to operate the perovskite hollow fiber is already available and can be used by heat exchange. Furthermore, the heat used for the O_2 enrichment is not consumed, for example, in an endothermic reaction and can be regained by heat exchange with the product streams that leave the O_2-permeation-membrane module. A similar setup may also apply to other applications for O_2 enrichment with perovskite membranes, for example, the temperature increase of firing systems in power plants or industrial furnaces.

The perovskite of composition $BaCo_xFe_yZr_zO_{3-\delta}$ (BCFZ; $x+y+z=1.0$) is a novel O_2-permeable membrane with high O_2 permeation fluxes and excellent thermal and mechanical stability.[4,5] BCFZ was used in a hollow-fiber configuration as

the membrane, which showed an O_2 permeation flux of 6.5 cm^3 min^{-1} cm^{-2} at 875 °C.[6] This flux is higher than those of Ba$_{0.5}$Sr$_{0.5}$Co$_{0.8}$Fe$_{0.2}$O$_{3-\delta}$ (BSCF)[7] and La$_{1-x}$Sr$_x$Co$_{1-y}$Fe$_y$O$_{3-\delta}$ (LSCF)[8] hollow-fiber membranes under similar conditions with a nonreactive sweep gas. The preparation and characterization of the hollow-fiber membrane was recently reported.[6]

The performance of perovskite membranes for O_2 enrichment can be characterized by the O_2 permeation rate, the production rate of O_2-enriched air, and the O_2 concentration on the permeate side. The force that drives O_2 transport through perovskite membranes is the gradient of the chemical potential, that is, the difference between the O_2 partial pressures across the perovskite membranes. Instead of separating O_2 by using inert sweep gases, it is possible to obtain O_2-enriched air by using air as the sweep gas and applying a difference in air pressure as the driving force as shown in Figure 2. When the difference in air pressure

Figure 3. Influence of the temperature on the production of O_2-enriched air. Air flow rates: Feed side = 100 cm^3 min^{-1}; permeate side = 10 cm^3 min^{-1}, membrane surface area = 3.50 cm^2, pressure difference = 1.5 bar.
Figure 2. Influence of the pressure difference on the production of O_2-enriched air. Air flow rate: feed side = 100 cm^3 min^{-1}; permeate side = 10 cm^3 min^{-1}, membrane surface area = 3.50 cm^2, T = 950 °C.

Figure 4. Influence of the air flow rate at the permeate side on the production of O_2-enriched air. Air flow rate: feed side = 100 cm^3 min^{-1}; permeate side = 10–40 cm^3 min^{-1}, membrane surface area = 3.50 cm^2, T = 875 °C, pressure difference = 1.5 bar.

increases from 0.5 to 3.0 bar, the O_2 concentration on the permeate side almost doubles from 30 to 55 vol%, and the O_2 permeation rates rise from 0.5 to 2.2 cm^3 min^{-1} cm^{-2}. Accordingly, the production rate of O_2-enriched air increases from 3.3 to 5.0 cm^3 min^{-1} cm^{-2}. Silicone rubber—the polymeric membrane used most often commercially—with a thickness of 25 μm shows an O_2 permeation flux of about 0.11 cm^3 min^{-1} cm^{-2} bar^{-1} with an O_2 concentration of 35 vol% under a pressure difference of 9.0 bar.[9] However, the perovskite hollow-fiber membrane with a thickness of around 180 μm can give an O_2 concentration higher than 38 vol% with a production rate of 3.7 cm^3 min^{-1} cm^{-2} by applying only a pressure difference of 1.0 bar.

Figure 3 shows the influence of the temperature on O_2 enrichment under a fixed pressure difference of 1.5 bar. As expected, the O_2 permeation rate increases with rising temperature, which leads to an increase in both the production rate of the O_2-enriched air and the O_2 concentration in the effluent air. Figure 4 shows how the rate of air flow on the permeate side affects the production of O_2-enriched air at a constant pressure difference of 1.5 bar at 875 °C. It was previously found that the O_2 permeation flux increases with
raising the rate of He flow when He was fed to the permeate side as the sweep gas.[10] The reason for this increase is that the partial pressure of O_2 on the permeate side decreases with an increase in He flow.[10] As shown in Figure 4, the O_2 concentration decreases sharply when the air flow on the permeate side increases. This decrease leads to an increase in the rate of O_2 permeation when the air flow on the permeate side rises. Accordingly, the rate of production of O_2-enriched air increases. An air flow of about 22 cm^3 min^{-1} on the permeate side gives a good compromise between the O_2 concentration ($\approx$ 35 vol%) and the rate of production of O_2-enriched air (7.5 cm^3 min^{-1} cm^{-2}).

Teraoka et al.[11,12] first reported O_2 permeability through perovskite membranes based on La$_{1-x}$A$_x$Co$_{1-y}$Fe$_y$O$_{3-\delta}$. Since then, there have been numerous reports on perovskite membranes.[13–17] An attractive goal is the integration of perovskite membranes and the partial oxidation of methane (POM) to synthesis gas into a single reactor. Although a lot of effort has been made to apply perovskite membranes to an industrial POM process,[18,19] so far there are no plants using this methodology. The formidable problem for this technology lies in the poor stability of the perovskite membranes at elevated temperatures under a reducing atmosphere (e.g., a

Communications

mixture of hydrogen and carbon monoxide).[20] A further problem is the poor operational safety of such systems. In the event of a membrane leak, air, methane, and synthesis gas would mix at 800 °C, thus causing serious trouble if not handled properly. However, these stability and operational-safety problems are avoided in the above-proposed O$_2$-enrichment process because both sides of the perovskite membranes are exposed to an oxidizing atmosphere (air).

As expected, the perovskite membranes exhibit excellent stability (Figure 5). A perovskite membrane operated steadily
Figure 5. Long-term stability of perovskite hollow fibers for the production of O$_2$-enriched air. Air flow rate: feed side = 100 cm^3 min^{-1}; permeate side = 10 cm^3 min^{-1}, membrane surface area = 3.50 cm^2, pressure difference = 1.5 bar, T = 875 °C.

for more than 800 h at 875 °C under a constant pressure difference of 1.5 bar. During this operation, the O$_2$ concentration in the O$_2$-enriched air reached around 42 vol% with an O$_2$ permeation rate of about 1.0 cm^3 min^{-1} cm^{-2} and an O$_2$-enriched air production rate of about 4.0 cm^3 min^{-1} cm^{-2}. It should be pointed out that although we had to stop the test, the perovskite membrane was still working after 800 h. XRD and element maps obtained from scanning electron microscopy–energy-dispersive X-ray spectra (SEM–EDX) of the spent hollow-fiber membrane show no structural change and no significant element segregation (see Supporting Information).

In summary, the results presented here demonstrate the possibility of applying perovskite membranes to high-temperature O$_2$ enrichment. The O$_2$ concentration reached around 35 vol% with a production rate of 7.5 cm^3 min^{-1} cm^{-2} of O$_2$-enriched air at 875 °C under a pressure difference of 1.5 bar. The O$_2$ concentration and the rate of production can be adjusted by controlling the temperature, air pressure difference, and gas flow rates. It is important to note that hollow-fiber membranes can give very high values of the membrane area per unit volume (up to 5.000 m^2 per m^3 of permeator; based on the densest packing of fibers with outer diameters of 0.75 mm). Economic goals such as a price of well below 1000 € per m^2 of membrane area can be also met by using this perovskite membrane. We estimate that 700 tons of O$_2$-enriched air (35 vol%) can be produced per day in a permeator volume of about 1 m^3. The long-term stability found in our experiments indicates that perovskite membranes have the potential to replace the current O$_2$-enrichment systems for high-temperature applications because they can integrate O$_2$ separation and mixing in one application.

Experimental Section

BCFZ was obtained by simple hydrolysis of Ba, Co, Fe, and Zr nitrates in a solution of ammonium hydroxide. It was then mixed with a solution of polysulfone in N-methylpyrrolidone and ball-milled for 16 h. The resulting slurry was spun through a spinneret and the green BCFZ perovskite fiber, thus obtained, was cut into 0.5-m pieces before being sintered above 1200 °C. On sintering, the length shrank to 0.33 m and the outer diameter went from around 1.75 mm to around 0.90 mm.

O$_2$-enrichment experiments were carried out in a high-temperature permeator (Figure 6). The two ends of the hollow-fiber

Figure 6. Scheme of the permeator for the O$_2$ enrichment at high temperatures.

membrane were sealed by two silicone rubber rings. Preheated air (100 cm^3 min^{-1}) was fed into the shell side and different air pressures were obtained by adjusting the needle valve on the air outlet. The air pressures on the shell side were between 1.5 and 4.0 bar. Preheated air (10–40 cm^3 min^{-1}) was fed to the core side and the air pressure was fixed at 1.0 bar. Due to the difference in air pressure between the shell side and the core side, the O$_2$ on the shell side permeates through the hollow-fiber membrane to the core side and mixes with air to form O$_2$-enriched air. The rate of O$_2$ permeation, J_{O_2} (cm^3 min^{-1} cm^{-2}), can be calculated with Equation (1) in which $F_{air,inlet}$ (cm^3 min^{-1}) is the rate

$$J_{O_2} = \frac{F_{air,inlet}\,(C_{O_2}-20.9)}{S\,(100-C_{O_2})} \tag{1}$$

of air flow at the inlet of the core side; C_{O_2} (vol%) is the O$_2$ concentration at the outlet of the core side, which can be determined by GC; S (cm^2) is the effective membrane surface area of the hollow fiber for O$_2$ permeation.

The O$_2$-enriched air production rate, R_{OEA} (cm^3 min^{-1} cm^{-2}), is defined in Equation (2) in which F_{outlet} (cm^3 min^{-1}) is the flow rate at

$$R_{OEA} = \frac{F_{outlet}}{S} \tag{2}$$

the outlet of the core side, which can be measured by soap film meter.

Helicate Ligands

Allosteric-Controlled Metal Specificity of a Ditopic Ligand**

Christian J. Baylies, T. Riis-Johannessen,
Lindsay P. Harding, John. C. Jeffery, Ryan Moon,
Craig R. Rice, and Martina Whitehead*

There are numerous examples in the field of metallosupramolecular chemistry that demonstrate that careful design of ligands can produce species that are selective to certain metal ions.[1] For example, Lehn et al. demonstrated that a mixture of two ligands that contain three bipyridine units and are linked either by aliphatic or ether units form only homonuclear and homoleptic trinuclear double and triple helicates upon reaction with Cu^+ and Ni^{2+} ions, respectively.[2] Another approach to enhance metal specificity is to introduce discrete binding domains within a ligand strand such that each domain is specific to a particular metal ion.[3] However, when using the latter strategies, the information contained within the ligand system, that is, its "programming", is finalized at the synthetic stage and cannot be altered thereafter. Herein, we describe a ditopic ligand L^1, whose selectivity for different transition-metal ions can effectively be "reprogrammed" by the addition of the larger s-block-metal ions to the crown ether moiety. This approach is related to the allosteric effect demonstrated by Rebek et al., in which the ability of a crown ether to coordinate Group 1 metal ions is influenced by coordination of a remote bipyridine coordination domain.[4] In this case, however, the reverse occurs as coordination of the crown ether unit controls the ability of a remote nitrogen-donor unit to act as either a tetradentate or bisbidentate domain. Other reprogrammable systems have been shown to control the formation of helicates[5] and modulate their pitch length.[6]

The reaction of L^1 (Scheme 1) with an equimolar amount of $[Cu(MeCN)_4]PF_6$ in MeCN gave a dark-red solution, and ESI-mass-spectrometric analysis showed the formation of a dinuclear double helicate with an ion at m/z 1497 consistent with $\{[Cu_2(L^1)_2](PF_6)\}^+$. In addition, the crown ether moiety

Scheme 1. Conditions: a) penta(ethylene glycol) di-*para*-toluenesulfonate, DMF, NaH (60/45%); b) *m*CPBA, CH_2Cl_2 (70%); c) TMSCN, PhCOCl, CH_2Cl_2 (83%); d) H_2S, Et_3N, EtOH (90%); e) chloroacetone, EtOH (76%). DMF = dimethylformamide, *m*CPBA = *meta*-chloroperoxybenzoic acid, TMSCN = trimethylsilyl cyanide.

can coordinate barium ions as the reaction of this copper-containing helicate with excess $Ba(ClO_4)_2$ gives rise to ions in the ESI mass spectrum of m/z 1788 and 2124, which correspond to $\{[Cu_2(L^1)_2Ba](ClO_4)_3\}^+$ and $\{[Cu_2(L^1)_2Ba_2](ClO_4)_5\}^+$, respectively. The formation of the complex $[Cu_2(L^1)_2Ba_2(H_2O)](ClO_4)_6\cdot 2\,MeCN\cdot 0.5\,Et_2O$ has been established by a single-crystal X-ray diffraction study (Figure 1).[7] In the solid
Figure 1. Crystal structure of the complex cation in $[Cu_2(L^1)_2Ba_2]$-$(ClO_4)_6\cdot 2\,MeCN\cdot 0.5\,Et_2O$.

state, the ligand splits into two bisbidentate binding domains with two Cu^I ions coordinated by two bridging ligands in a double helicate arrangement with an average interdomain torsion angle of 108.9° (N-C-C-N). Each of the Cu^I centers has a distorted-tetrahedral geometry formed by coordination of one bidentate pyridyl–thiazole nitrogen-donor unit from each ligand (Cu−N: 1.985(7)–2.158(8) Å). Furthermore, both of the crown ether units coordinate to barium ions (O−Ba$O_{(crown ether)}$: 2.760(8)–2.978(12) Å), with the longest bonds arising from coordination of the "benzylic" oxygen atoms (Ba−$O_{(methylene)}$: 2.791(9)–2.978(12) Å).

The ^{1}H NMR spectrum of $[Cu_2(L^1)_2]^{2+}$ in CD_3CN shows three aromatic signals for the pyridyl–thiazole moiety, con-

sistent with a highly symmetrical double helicate complex in which all four of the thiazole–pyridyl fragments are chemically equivalent (Figure 2a). The two doublets ascribed to the pyridyl protons show a characteristic upfield shift that arises

Figure 2. Selected regions of the ^{1}H NMR spectra (CD_3CN) of a) $[Cu_2(L^1)_2]^{2+}$, b) $L^1 + Cu^+ + Zn^{2+}$, and c) $[Zn(L^1)]^{2+}$.

because these protons are shielded by the aromatic-ring currents of a thiazole moiety in the adjacent ligand strand. In addition, the diastereotopic "benzylic" -CH_2O- protons give rise to two comparatively upfield doublets. The addition of barium ions affords a similar ^{1}H NMR spectrum, in which the "benzylic" -CH_2O- protons show a characteristic downfield shift because of the coordination of the electronegative Ba^{2+} ions in the crown ether cavities (Figure 3a).

Figure 3. Selected regions of the ^{1}H NMR spectra (CD_3CN) of a) $[Cu_2(L^1)_2]^{2+}$ + excess Ba^{2+} ions, b) $L^1 + Cu^+ + Zn^{2+}$ + excess Ba^{2+} ions, c) $L^1 + Cu^+ + Zn^{2+}$ + excess Sr^{2+} ions, and d) $[Zn(L^1)]^{2+}$ + excess Ba^{2+} ions.

Reaction of L^1 with an equimolar amount of $[Zn(H_2O)_6]$-$(ClO_4)_2$ in MeCN gave a pale-yellow solution, and ESI-MS analysis showed an ion of m/z 776 consistent with the formation of the mononuclear $\{[Zn(L^1)](ClO_4)\}^+$ complex. The ^{1}H NMR spectrum of $[Zn(L^1)]^{2+}$ in CD_3CN (Figure 2c) shows more deshielded pyridyl proton resonances than the Cu

helicate $[Cu_2(L^1)_2]^{2+}$, thus reflecting an absence of the aromatic shielding caused by interstrand π stacking of the ligands in the latter complex. In addition, the "benzylic" -CH₂O- protons appear as a broad singlet, which indicates that rapid conformational movement about the bipyridyl backbone occurs on the NMR timescale, thus rendering these methylene protons chemically equivalent. Upon addition of $Ba(ClO_4)_2$ to $[Zn(L^1)]^{2+}$, an ion of m/z 1112 that corresponds to $\{[Zn(L^1)Ba](ClO_4)_3\}^+$ is observed in the ESI mass spectrum, thus indicating that a Ba^{2+} ion is again coordinated in the host cavity of the crown ether. Consistent with this observation, the ^{1}H NMR spectrum in CD_3CN shows small but significant changes as the "benzylic" -CH₂O- protons resolve into two doublets on addition of Ba^{2+} ions (Figure 3d). This change could be ascribed to the restricted conformational mobility induced by coordination of a Ba^{2+} ion into the crown host cavity. Treatment of $[Zn(L^1)]^{2+}$ with excess $Ba(ClO_4)_2$ followed by crystallization afforded the complex $[Zn(L^1)Ba(H_2O)_2](ClO_4)_4 \cdot MeCN \cdot 0.5 Et_2O \cdot 0.75 H_2O$, the structure of which has been established by single-crystal X-ray diffraction studies.[8] In the solid state, the ligand coordinates to the equatorial plane of the Zn^{2+} center through all four nitrogen-donors, and two water molecules occupy the axial positions (Figure 4). The ligand is almost

Figure 4. Crystal structure of the complex cation in $[Zn(L^1)Ba(H_2O)_2]$-$(ClO_4)_4 \cdot MeCN \cdot 0.5 Et_2O \cdot 0.75 H_2O$.

planar and exhibits only a shallow helical twist about the metal center, which is caused by unfavorable steric interactions between the methylene substituents on the central bipyridine core (N-C-C-N dihedral angle is approximately 31.0°). The arrangement of equatorial nitrogen-donors and axial water ligands generates a distorted-tetragonal geometry about the Zn^{2+} center (Zn−N: 2.178(5)–2.237(6) Å; Zn−O: 2.060(5) and 2.095(5) Å) similar to the geometry observed by Baxter et al. for the Zn^{II} complex of the analogous crown-free ligand.[9] The Ba−O separations are distributed over a narrower range than for $[Cu_2(L^1)_2Ba_2]^{6+}$ (Ba−O in $[Zn(L^1)Ba]^{4+}$: 2.803(4)–2.893(4) Å), which is consistent with the barium ion being located more centrally within the crown ether in $[Zn(L^1)Ba]^{4+}$ (compare with, the range 2.736–2.875 Å for the Ba−O separations observed in the barium complex of [18]crown-6).[10]

As the ligand can partition into either tetradentate or bisbidentate binding domains, we decided to investigate its specificity towards different metal ions. The reaction of ligand L^1 with $[Cu(MeCN)_4]PF_6$ and $[Zn(CF_3SO_3)_2]$ (in the ratio 1:1:1) in CD_3CN gave an orange solution whose ^{1}H NMR spectrum showed six aromatic-proton environments that correspond to two different L^1-containing complexes. Comparison of the ^{1}H NMR spectrum of the mixed system with that of the individual $[Cu_2(L^1)_2]^{2+}$ and $[Zn(L^1)(H_2O)_2]^{2+}$ complexes showed that both these species were present in the ratio 1.5:1 (Figure 2b). This observation is also supported by the ESI mass spectrum, in which ions are present for both copper- and zinc-containing species. Upon the addition of $Ba(ClO_4)_2$, the color of the solution became paler and the ^{1}H NMR spectrum revealed new signals for the barium-containing species $[Cu_2(L^1)_2Ba_2]^{6+}$ and $[Zn(L^1)Ba]^{4+}$ in a 1:10 ratio, respectively (Figure 3b). Analysis by ESI MS showed that ions are present for the mononuclear zinc complex $\{[Zn(L^1)Ba](ClO_4)_3\}^+$, whereas ions that correspond to any copper-containing complexes were virtually nonexistent. Interestingly, the addition of excess $Sr(ClO_4)_2$ to a stoichiometric mixture of L^1, $[Cu(MeCN)_4]PF_6$, and $[Zn(CF_3SO_3)_2]$ resulted in virtually total conversion into the zinc-containing species $([Cu_2(L^1)_2Sr_2]^{6+}/[Zn(L^1)Sr]^{4+}, 1:>20$; Figure 3c).

Thus, upon addition of excess Zn^{2+} and Cu^+ ions, the ligand can act as either a tetradentate or bisbidentate donor unit to generate a mixture of the Cu^I helicate and Zn^{II} mononuclear species. However, upon addition of barium or strontium ions, the ligand is effectively reprogrammed to act as a tetradentate donor which is specific to Zn^{2+} ions.

As with similar systems,[5,6] such control over the ligand coordination domains may be attributed to one or two effects. Firstly, an electrostatic effect is plausible given that the copper helicate will form a 6+ ion $[Cu_2(L^1)_2M_2]^{6+}$ in the presence of excess Ba^{2+} or Sr^{2+} ions, whereas the zinc complex $[Zn(L^1)M]^{4+}$ carries an overall charge of only 4+. Thus, electrostatic destabilization of the highly charged helicate with respect to the mononuclear Zn^{2+} species results in the formation of the lesser charged species. However, the change in specificity could also be attributed to an allosteric effect, whereby coordination of a guest s-block ion to the crown ether unit is mechanically coupled to the bipyridine inter-annular bond in such a way as to impede the necessary partitioning required for helicate formation. Although the crystal structure of $[Cu_2(L^1)_2Ba_2(H_2O)](ClO_4)_6 \cdot 2 MeCN \cdot 0.5 Et_2O$ clearly demonstrates that barium ions can coordinate to the crown ether region when the ligand is acting as a bisbidentate donor, careful comparison of the solid-state structures of the barium-containing helicate species $[Cu_2(L^1)_2Ba_2]^{6+}$ and monozinc(II) species $[Zn(L^1)Ba]^{4+}$ reveals that separations between the barium ions and the methylene oxygen atoms are marginally shorter for the latter (mean Ba−$O_{(methylene)}$ distances in $[Cu_2(L^1)_2Ba_2]^{6+}$: 2.895(2) Å; $[Zn(L^1)Ba]^{4+}$: 2.863(9) Å). Tentative extrapolation from these observations could imply that when acting as a tetradentate donor (compare with, bisbidentate), there is an effective contraction of the crown ether unit which serves to optimize the Ba^{2+}/etherate interactions. If sufficient, the difference in the binding energies between the barium/crown ether associations in the respective helicate and monomer (ligand) conformers could also account for the observed shift in equilibrium from the dicopper(I) helicate to the zinc(II) monomer. The apparent "mutual dependence" of effective

crown ether size and remote binding events has been previously suggested for related ditopic systems[4] and is further supported by the observed increase in metal specificity when a smaller Sr^{2+} ion is employed (compare with, Ba^{2+} ions); therefore, the latter suggests that the Sr^{2+} ion is more sensitive to the difference in the effective size of the helicate and the monomer host cavities than the Ba^{2+} ion. Barium/strontium ion inclusion into the crown ether host of L^1, thus, appears to influence the conformational preferences of the nitrogen-donor domains, such that the preferred coordination mode is tetradentate in the presence of a guest ion.

Other s-block-metal ions also exert measurable effects: the addition of Li^+ and Na^+ ions result in the formation of equal amounts of copper and zinc complexes, whereas the zinc complex is again favored ($[Cu_2(L^1)_2K_2]^{6+}$/$[Zn(L^1)K]^{4+}$, 1:4) upon addition of K^+ ions. Comparison of the effects of the addition of Ba^{2+} versus K^+ ions shows that, although both significantly alter the equilibrium composition and favor the formation of the zinc-containing species, the change in monomer/helicate ratio is more apparent for Ba^{2+} ions. In view of the fact that both ions have similar ionic radii, the stronger influence of Ba^{2+} ions must reflect the difference in ionic charge, thus highlighting the importance of both electrostatic and allosteric factors in the modification of ligand specificity.

In conclusion, we have shown that a ditopic system can change its preference for different transition-metal ions upon addition of a range of s-block-metal ions at a remote site.

[7] Single-crystal X-ray diffraction data were collected on a Bruker APEX-CCD area detector diffractometer under a stream of cold nitrogen. Crystal data for $[Cu_2(L^1)_2Ba_2(H_2O)](ClO_4)_6 \cdot 2MeCN \cdot 0.5Et_2O$: $M_r = 2361.14$, triclinic, $P\bar{1}$, $a = 13.54(5)$, $b = 18.91(7)$, $c = 21.35(8)$ Å, $\alpha = 65.91(7)$, $\beta = 72.42(7)$, $\gamma = 85.18(7)°$, $V = 4754(31)$ Å^3, $Z = 2$, $\rho_c = 1.650$ Mg m^{-3}, $F(000) = 2374$, $\mu(Mo_{K\alpha}) = 1.602$ mm^{-1}, $T = 100$ K. A total of 54400 reflections were measured in the range $1.09 \leq \theta \leq 27.54°$ (*hkl* range indices $-17 \leq h \leq 17$, $-24 \leq k \leq 24$, $-27 \leq l \leq 27$), 21383 independent reflections ($R_{int} = 0.0386$). The structure was refined on F^2 to $R_w = 0.1603$ $R = 0.0582$ (16371 reflections with $I > 2\sigma(I)$) and GOF = 0.785 on F^2 for 1121 refined parameters, largest difference peak and hole 2.087 and -2.552 e Å^{-3}. As with many supramolecular crystal structures, all of those described herein contain regions of disorder associated with diffuse-lattice solvent species (acetonitrile/non-coordinating perchlorate counterions) and the conformationally flexible crown ether fragments. Accordingly, geometric restraints and/or constraints were employed (in several cases throughout all stages of refinement) in attempt to model disorder where appropriate. Where such attempts failed to account for persistent peaks in the electron density map, a diffuse solvent correction was applied by using the SQUEEZE routine in PLATON. A full description of the refinement details is given in the Supporting Information.

[8] Single-crystal X-ray diffraction data were collected on a Bruker SMART-CCD area detector diffractometer under a stream of cold nitrogen. Crystal data for $[Zn(L^1)(H_2O)_2Ba](ClO_4)_4 \cdot MeCN \cdot 0.5Et_2O \cdot 0.75H_2O$; $M_r = 1340.66$, monoclinic, $P2_1/c$, $a = 18.431(1)$, $b = 17.981(1)$, $c = 17.614(1)$ Å, $\beta = 101.4330(10)°$, $V = 5721.5(6)$ Å^3, $Z = 4$, $\rho_c = 1.56$ Mg m^{-3}, $F(000) = 2705$, $\mu(Mo_{K\alpha}) = 1.442$ mm^{-1}, $T = 173$ K. A total of 59644 reflections were measured in the range $1.13 \leq \theta \leq 27.54°$ (*hkl* range indices $-23 \leq h \leq 23$, $-23 \leq k \leq 23$, $-22 \leq l \leq 22$), 13134 independent reflections ($R_{int} = 0.0858$). The structure was refined on F^2 to $R_w = 0.1888$ $R = 0.0702$ (7506 reflections with $I > 2\sigma(I)$) and GOF = 1.007 on F^2 for 667 refined parameters, largest difference peak and hole 1.347 and -1.045 e Å^{-3}. CCDC-278717 and -278718 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

Recyclable Palladium Catalyst for Highly Selective α Alkylation of Ketones with Alcohols**

*Min Serk Kwon, Namdu Kim, Seong Hyeok Seo,
In Soo Park, Ravi Kumar Cheedrala, and Jaiwook Park**

Carbon–carbon bond-forming reactions are fundamental in organic synthesis. The α alkylation of enolates derived from ketones with electrophiles such as alkyl halides is the conventional method to form C–C bonds.[1] The metal-catalyzed α alkylation of ketones with alcohols is attracting much attention because of its critical advantage over the conventional α-alkylation method, which suffers from problems with waste salts. Recently, several groups have reported the use of homogeneous catalysts for the α alkylation of ketones with alcohols.[2] However, these catalytic systems often suffer from low yield, low product selectivity, and/or the need for additives and strong bases. As a related C–C coupling reaction, Kaneda and co-workers developed an α alkylation of nitriles with primary alcohols using a Ru-grafted hydrotalcite as the catalyst.[3] Herein, we report a heterogeneous and recyclable palladium catalyst, which does not require ligands or additives, for the α alkylation of ketones with primary alcohols. Furthermore, our catalyst is active in the presence of oxygen and can produce enones selectively under 1 atm O_2, whereas ketones are the major product under argon (Scheme 1).
Scheme 1. Palladium-catalyzed coupling of acetophenone and benzyl alcohol.

Recently, we reported a heterogeneous palladium catalyst, Pd/AlO(OH) (**1**), that is composed of palladium nanoparticles entrapped in aluminum hydroxide[4] and is highly active for both alkene hydrogenation and aerobic alcohol oxidation. We envisioned that **1** would be applicable to the

α alkylation of ketones with primary alcohols as it is able to produce aldehydes from primary alcohols and hydrogenate intermediate enones formed from the coupling of aldehydes and ketones in the presence of a base.[2d] In fact, 1,3-diphenylpropan-1-one was obtained in 97% yield in the reaction of acetophenone with 1.2 equivalents of benzyl alcohol in the presence of **1** (0.2 mol% of Pd) and K_3PO_4 (3 equiv) for 8 h at 80°C under argon. Notably, the same reaction under 1 atm O_2 produced chalcone in 95% yield after 20 h.

The reaction conditions were optimized for the alkylation of acetophenone with benzyl alcohol through variation of the base, temperature, and solvent. Among the bases tested, K_3PO_4 was found to be the best. Strong bases such as KOH, NaOH, and CaH_2 dissolved the aluminum hydroxide matrix, whereas the alkylation product was not detected in reactions with weak bases, such as K_2HPO_4, K_2CO_3, Na_2CO_3, and triethylamine. The reaction rate was affected by the amount of K_3PO_4;[5] thus, three equivalents were needed to complete the reaction within 8 h at 80°C. The temperature was also an important factor for the reaction rate: as the temperature was raised to 110°C, the alkylation was completed in 2.5 h. Studies on the effect of the solvent revealed that toluene is more effective than trifluorotoluene, *n*-heptane, 1,4-dioxane, or water.

The high efficiency of **1** for the coupling of acetophenone and benzyl alcohol relative to commercially available catalysts and the α-alkylation catalysts reported previously was shown clearly (Table 1). Low selectivities (< 71%) and yields (< 55%) of 1,3-diphenylpropan-1-one (**2**) were observed for the reactions with commercially available heterogeneous palladium catalysts (entries 2–4). The reaction with [RuCl$_2$-(PPh$_3$)$_3$] requires the addition of 1-dodecene to increase the selectivity.[2c] The production of 1,3-diphenylpropane-1-ol increases as the amount of benzyl alcohol is increased for the reactions with [RuCl$_2$(PPh$_3$)$_3$] and [Ru(dmso)$_4$]Cl$_2$ (dmso = dimethyl sulfoxide),[2f] and phosphine ligands were needed with [{IrCl(cod)}$_2$] (cod = cyclooctadiene).[2e] The ruthenium-grafted hydrotalcite is a notable catalyst for α alkylation in the absence of a base, although a long reaction time at high temperature is required.[3]

The main advantage of **1**, besides its selectivity, is its recyclability—it can be recovered by filtration or decantation (Table 2). To the best of our knowledge, **1** is the first recyclable catalyst for the α alkylation of ketones with alcohols.[9] When the recovered catalyst was used without any treatment, the reaction rate decreased considerably (entry 2), whereas the addition of K_3PO_4 lead to resumption of the rate. Therefore, for each successive use, one equivalent of K_3PO_4 relative to acetophenone was added. Catalyst **1** retained its activity even during its sixth use, as **2** was prepared in 96% yield after 20 h.

With suitable reaction conditions established, a series of ketones and alcohols were employed to investigate the scope of the reaction (Table 3). Our catalytic system was effective for a wide combination of ketones and alcohols that produced the corresponding α-alkylated products under anaerobic conditions. It was also effective for the selective production of *trans* enones under 1 atm O_2, although the reaction rates

were relatively slow (entries 5, 11, and 13). The alkylation of 4′-(trifluoromethyl)acetophenone was somewhat less selective, as the expected ketone was obtained in 87% yield along with the corresponding alcohol in 6% yield (entry 6).[6] Indanone was alkylated successfully at the α-methylene position (entry 7). Acetophenone was also alkylated by aliphatic alcohols in high yield (entries 8 and 9). Furthermore, aliphatic ketones were alkylated by an aliphatic alcohol as well as by aromatic alcohols in high yields and with high selectivities (entries 10–15). Alkylation occurred almost exclusively at the methyl positions, and the coupling of acetone with 1-butanol produced undecan-6-one in 92% yield (entry 16). The reactions of aliphatic primary alcohols were slower than those of aryl methanol derivatives. In particular, the coupling between an aliphatic ketone and an aliphatic alcohol required a reaction time about eight times longer than for the coupling between aryl methyl ketones and aryl methanol derivatives (entry 15). A noticeable example is the coupling of 5-pregnen-3β-ol-20-one with benzyl alcohol,[7] as the secondary hydroxy group and the C=C bond are compatible with the coupling conditions (entry 17). Furthermore, the epimerization at C17 was negligible.[8]

In summary, we have demonstrated a highly efficient α alkylation of ketones with primary alcohols by the use of a recyclable palladium catalyst that is easily prepared from readily available reagents. We are currently investigating

## Water Oxidation Catalyzed by a Dinuclear Mn Complex: A Functional Model for the Oxygen-Evolving Center of Photosystem II**

*Allan K. Poulsen, Annette Rompel, and Christine J. McKenzie**

Multinuclear manganese complexes have played an important role in the search for structural analogues of the active site of the oxygen-evolving complex (OEC) of photosystem II.[1] However, the discovery of a functional biomimetic manganese complex that catalyzes the oxidation of water to dioxygen remains a challenge with enormous scientific implications. Reported here is the discovery that a dimanganese complex of the ligand *N*-methyl-*N'*-carboxymethyl-*N,N'*-bis(2-pyridylmethyl)ethane-1,2-diamine (mcbpen⁻) catalyzes the oxidation of water by *tert*-butylhydrogenperoxide (TBHP) or cerium nitrate to dioxygen. Furthermore, we have directly measured the evolved O_2 concentration in solution by using the relatively new method of membrane inlet mass spectrometry (MIMS). The isotopomer distribution is quantified with this method and shows that the reaction is highly specific: One oxygen atom in the evolved dioxygen comes from water, and the other is derived from the oxidant.

It did not escape our attention that a series of dinuclear manganese complexes of the new pentadentate ligand mcbpen⁻,[2] for which we have identified complexes with the
mcbpen⁻

oxidation states Mn^{II}/Mn^{II}, Mn^{III}/Mn^{III}, Mn^{III}/Mn^{IV}, and Mn^{IV}/Mn^{IV}, is highly relevant as a model system for the OEC. Two molecules of water are coordinated in the stable, crystallo-

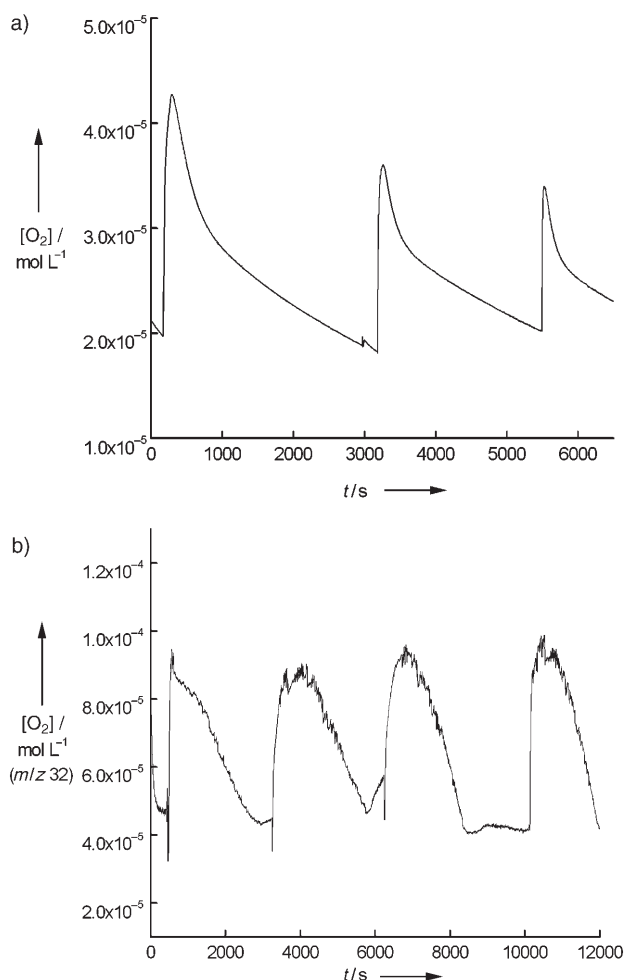
⬜ Supporting information (ESI mass spectra of reaction solutions containing TBHP and $(NH_4)_2[Ce(NO_3)_6]$ in water, labeled water, and acetonitrile; further MIMS traces) for this article is available on the WWW under http://www.angewandte.org or from the author.

graphically characterized $[Mn^{II}_2(mcbpen)_2(H_2O)_2](ClO_4)_2$ (**1**-$(ClO_4)_2$). The X-ray crystal structure of **1**-$(ClO_4)_2$ shows two seven-coordinate Mn^{II} atoms with the carboxylate arms of mcbpen bridging the metal centers through one of the oxygen atoms to give a Mn···Mn separation of 4.0914(9) Å in the dinuclear structure. Manganese complexes of mcbpen⁻ with a formal metal oxidation state higher than Mn^{II} are unstable, but have sufficiently long lifetimes in solution for spectroscopic (ESR and UV/Vis), spectrometric (ESIMS), and electrochemical characterization.[2] A plausible precursor for dioxygen, two oxides in a Mn_2O_2 rhombus, is present in an unstable Mn^{IV}/Mn^{IV} complex $[Mn^{IV}_2(O)_2(mcbpen)_2]^{2+}$, which has been identified in solutions of **1**-$(ClO_4)_2$ treated with TBHP in acetonitrile. The present work arose from our efforts to delineate the decomposition pathway of $[Mn^{IV}_2(O)_2(mcbpen)_2]^{2+}$: Does this occur through release of O_2? In this scenario, $[Mn^{II}_2(mcbpen)_2(H_2O)_2]^{2+}$ can be considered a low-valent complex with a substrate (H_2O) coordinated, and $[Mn^{IV}_2(O)_2(mcbpen)_2]^{2+}$ the appropriate higher formal oxidation state species with the product precursors coordinated. As such, the mcbpen⁻ dinuclear system is unique in manganese chemistry and pertinent to modeling the OEC.

We have now used both a Clark electrode and MIMS[3–6] to prove that O_2 is evolved from aqueous solutions containing **1**-$(ClO_4)_2$ and two separate chemical oxidants. The complex catalyzes the oxidation of water. When **1**-$(ClO_4)_2$ is mixed with 5–100 equivalents of TBHP in water, the initially pale solutions turn dark brown and bubbles are observed with the higher amounts of TBHP. The solutions generally bleach within 24 h and **1**-$(ClO_4)_2$ can be reisolated. Figure 1 shows the profiles of the O_2 evolution in the reaction of an aqueous solution of **1**-$(ClO_4)_2$ treated with periodic additions of TBHP (20 equivalents). The evolution of O_2 ceases approximately 25 min after each addition, and essentially the same amount of O_2 is repeatedly produced on each addition. The pH value of the system was 4.75 and did not change during the experiment. Control experiments in which an aqueous solution of manganese(II) perchlorate at the same pH value is used produces no O_2 on addition of 20 or more equivalents of TBHP. The shape of the traces in the MIMS experiments indicates evolution of O_2 rather than a surge, for example, from its introduction by the syringe.[7] The fact that there is little decay in the response to each TBHP addition implies convincingly that the system is turning over.[8] To date, evolution of 10–20 equivalents of O_2 has been recorded with no detectable catalyst decomposition or inhibition.

A strength of the MIMS technique is that ^{18}O labeling experiments can be carried out to investigate the source of the O atoms in the evolved O_2. The $^{18}O^{16}O$ isotopomer is produced exclusively when ^{18}O-labeled water (min. 95 % ^{18}O) is used. No significant levels of $^{16}O_2$ and $^{18}O_2$ are detected. Thus, one oxygen atom in the O_2 evolved in the **1**-$(ClO_4)_2$ catalyzed oxidation of water by TBHP is derived from water. The reaction was carried out in pure water, and the measuring cell was purged with Ar, so the only other source of oxygen atoms was the oxidant, TBHP.[9] In these experiments, the concentration of one substrate, water, is in large excess (172-fold) of the other substrate TBHP. It is not realistic to change these ratios such that the reaction stoichiometry might


a)

b)

Figure 1. Measurement of O$_2$ concentration in an Ar-purged aqueous solution of **1**-(ClO$_4$)$_2$ with TBHP additions followed over time. a) Evolution measured by using a Clark electrode with injections of TBHP (2.7 μL, 1 M) at $t=0$, 50, and 90 min to **1**-(ClO$_4$)$_2$ (0.2 mM, 3.2×10^{-7} mol) b) Evolution of ^{16}O$_2$ measured by means of MIMS with injections of TBHP (10 μL, 0.323 M, 3.2×10^{-6} mol) at $t=8$, 54, 104, and 169 min to **1**-(ClO$_4$)$_2$ (0.5 mM, 1.67×10^{-7} mol). ^{18}O^{16}O (m/z 34) and ^{18}O$_2$ (m/z 36) concentrations were followed but are not present in detectable amounts. The first, second, third, and fourth additions of TBHP generate 2.52×10^{-7}, 2.9×10^{-7}, 2.58×10^{-7}, and 2.62×10^{-7} mol of ^{16}O$_2$ respectively (total: 1.062×10^{-6} mol ^{16}O$_2$). Note: The relative concentrations of TBHP and **1**-(ClO$_4$)$_2$ in the two experiments are different, therefore, the measurement scales of the two experiments cannot be directly compared.

be experimentally verified because increasing the oxidant concentration will give an unreliable measurement, as MIMS, similar to an O$_2$ electrode, detects only the oxygen dissolved in the liquid and not the oxygen expelled as bubbles. Thus, with water as the solvent we were limited to using the concentrations of the THBP and **1**-(ClO$_4$)$_2$ shown in Figure 1 in the quantitative experiments. It is likely that greater yields are achievable.

On the basis of our earlier characterization of the transient mononuclear and dinuclear Mn^{III} and dinuclear Mn^{IV} complexes of mcbpen$^-$ generated by oxidation of **1**-(ClO$_4$)$_2$ with TBHP in acetonitrile and water (see Supporting

Information and ref. [2]), we propose the speculative reaction mechanism outlined in Scheme 1. Oxidation of **1**-(ClO$_4$)$_2$ with TBHP cleaves the bridging carboxylate-O ligands of **1**[10] and produces the transient mononuclear hydroxide [Mn^{III}-(mcbpen)OH]$^+$ (**2**). ESIMS studies of the reaction in both
Scheme 1. A speculative mechanism for water oxidation by *t*BuOOH catalyzed by **1**-(ClO$_4$)$_2$.

D$_2$O and H$_2$^{18}O clearly show that the oxygen atom in **2** is derived from water and not the oxidant, as the major ion generated is [Mn^{III}(mcbpen)OD]$^+$ (m/z 386.5) and [Mn^{III}-(mcbpen)^{18}OH]$^+$ (m/z 387.3) in D$_2$O and H$_2$^{18}O, respectively. The next step in the catalytic cycle is dimerization and dehydration of **2** to give [Mn^{III}$_2$(mcbpen)$_2$(O)]$^{2+}$ (**3**). The dehydration in aqueous solution of manganese(III) and iron(III) complexes containing terminal hydroxides to give dinuclear mono-oxide bridged complexes is well documented. We have shown that reaction of **1**-(ClO$_4$)$_2$ with TBHP in water and acetonitrile produces the very short lived **3** as verified by ESIMS and UV/Vis spectroscopy.[2] A facile oxidation of **3** on the basis of the known instability of such species to oxidation is expected, and differs from the first oxidation step, in that the TBHP may in this case act as an oxygen atom donor to give the dimeric [Mn^{IV}$_2$(O)$_2$(mcbpen)$_2$]$^{2+}$ (**4**). It is likely that during the **3**→**4** reaction step the carboxylate arms are concomitantly displaced to accommodate the two μ-oxo ligands. Thus, an arrangement similar to other, known bis(μ-oxo)-dimanganese complexes of linear N$_4$ bispicen-based[11] ligands (Mn···Mn = 2.7 Å)[12–14] is achieved. The anticipated facile oxidation of **3** (oxidase activity) can be invoked to explain the slightly different curve shape in the first evolution step (the front of the peak shows a spike, which indicates an initial rapid reduction in O$_2$ concentration). This spike might

Communications

be caused by an initial trace amount of O_2 in the solution which oxidizes **3** in the first cycle.

Spontaneous collapse of **4** followed by release of dioxygen and coordination of two molecules of water will result in re-formation of **1** in aqueous solution. We imagine that the carboxylate arms of mcbpen⁻ are not innocent in the O_2-elimination reaction; by swinging in and recoordinating the manganese atoms, as depicted in the resonance structures **4** and **5** (Scheme 1), the formation of a bond between the two oxide bridges might be favored as a Mn−O(Mn) bond at each Mn atom is displaced. Similar resonance in copper bis(μ-oxo)/μ-peroxo systems has been proposed.[15,16] Oxygen release from the μ-peroxo-Mn^{III}_2 complex **5** to give a Mn^{II}_2 species would then ensue. A notable feature of this mechanism is the involvement of the coordinatively flexible carboxylate arm of the mcbpen⁻ ligand: Bridging, terminal, and noncoordinated modes support the various dinuclear and mononuclear structures proposed, and the oxidation states deduced exper-imentally, in a chemically logical fashion. This is analogous to the so-called "carboxylate shift" proposed to be important in the mechanisms of several non-heme iron enzymes. Of course any mechanistic proposal is speculative; however, we have spectroscopic evidence for all the species in Scheme 1 except **5**. Furthermore, the species are all chemically reasonable, comprising water/hydroxo/oxo ligands on metal centers of the appropriate oxidation state.

The overall reaction for the mechanism proposed in Scheme 1 including an ^{18}O label is described by Equa-tion (1).[17]

$$2\,t\text{BuOOH} + 2\,H_2^{18}O \xrightarrow{\textbf{1-(ClO}_4)_2} 2\,t\text{BuOH} + {}^{18}O^{16}O + H_2O + H_2^{18}O \quad (1)$$

Equation (1) simplifies to Equation (2):

$$2\,t\text{BuOOH} + H_2^{18}O \xrightarrow{\textbf{1-(ClO}_4)_2} 2\,t\text{BuOH} + {}^{18}O^{16}O + H_2O \quad (2)$$

The attempt to establish the source of the O atoms in the evolved O_2 is clearly problematic where a terminal oxidant containing an O atom is used. We therefore tested $(NH_4)_2$-$[Ce(NO_3)_6]$ as the oxidant. This Ce^{IV} source has been used in the studies of the oxidation of $[(bpy)_2(H_2O)RuORu(H_2O)$-$(bpy)_2]^{4+}$ (bpy = 2,2′-bipyridine) by Meyer and co-work-ers[18,19] and recently in the report by Yagi and Narita that $[Mn_2O_2(terpy)_2(H_2O)_2](NO_3)_3\cdot6H_2O$ (terpy = 2,2′:6′,2″-ter-pyridine) adsorbed onto kaolin clay produces O_2 from water.[20] When $(NH_4)_2[Ce(NO_3)_6]$ was used as the oxidant, the evolution of O_2 from water catalyzed by **1**-$(ClO_4)_2$ was again detected, however, in lower yields than in the TBHP reaction. The pH value of the reaction mixture with $(NH_4)_2$-$[Ce(NO_3)_6]$ drops rapidly to 1 and this is most likely the cause of the lower yields—at low pH values, the formation of high-valent oxo-bridged Mn species is not favored. Furthermore, ligand decoordination caused by competing protonation is suggested by the ESI mass spectra of reaction mixtures containing $(NH_4)_2[Ce(NO_3)_6]$ which show the presence of the free ligand mcbpenH_2^+ at m/z 315.4 in addition to $[Mn_2$-$(mcbpen)_2]^{2+}$ at 368.3 and $[Mn^{III}(mcbpen)NO_3]^+$ at 430.2 (see Supporting Information). Figure 2 follows the concentration of the $^{18}O^{16}O$ isotopomer with time in experiments with

Figure 2. Trace of $^{18}O^{16}O$ evolution over time from a solution contain-ing **1**-$(ClO_4)_2$ (2 mM, 7.1×10^{-7} mol) in 95% $H_2^{18}O$ after injections of $(NH_4)_2[Ce(NO_3)_6]$ (20 μL, 0.6 M) in 95% $H_2^{18}O$ at $t = 2$, 25, and 60 min. Total amounts of evolved oxygen are much lower, and the decrease in productivity with each addition of oxidant is evident from the comparison of the curve shape to that of Figure 1b. The evolution of $^{16}O_2$ (m/z 32) and $^{18}O_2$ (m/z 36) was under detectable limits.

$(NH_4)_2[Ce(NO_3)_6]$. Again, and initially surprisingly, the $^{18}O^{16}O$ isotopomer is produced exclusively in the ^{18}O labeling experiments with $(NH_4)_2[Ce(NO_3)_6]$.

As the reaction is carried out in 95% $H_2^{18}O$ water, the only source of one ^{16}O atom is the nitrate[21] anion in the Ce^{IV} salt. Thus, the exclusive production of $^{18}O^{16}O$ in the reactions with Ce^{IV} as the oxidant can be only explained by the involvement of nitrate as an O-atom donor.[22] Thus, we propose that the water oxidation is coupled with both Ce^{IV} and nitrate reduction as shown in Equation (3). Inspection of the redox potentials of Ce^{IV} reduction and nitrite oxidation indicates any nitrite produced would be rapidly reoxidized to nitrate in the presence of excess Ce^{IV} [Eq. (4)].

$$2\,Ce^{IV} + 2\,H_2^{18}O + NO_3^- \xrightarrow{\textbf{1-(ClO}_4)_2}$$
$$2\,Ce^{III} + {}^{18}O^{16}O + H_2^{18}O + 2\,H^+ + NO_2^- \quad (3)$$

$$2\,Ce^{IV} + H_2^{18}O + NO_2^- \rightarrow 2\,Ce^{III} + N^{18}O^{16}O_2^- + 2\,H^+ \quad (4)$$

By combining Equations (3) and (4), the overall reaction for the **1**-$(ClO_4)_2$ catalyzed oxidation of water, including labels, by $(NH_4)_2[Ce(NO_3)_6]$ is that in Equation (5), which can be simplified to Equation (6).

$$4\,Ce^{IV} + 3\,H_2^{18}O + NO_3^- + NO_2^- \xrightarrow{\textbf{1-(ClO}_4)_2}$$
$$4\,Ce^{III} + {}^{18}O^{16}O + H_2^{18}O + 4\,H^+ + NO_2^- + N^{18}O^{16}O_2^- \quad (5)$$

$$4\,Ce^{IV} + 2\,H_2^{18}O + NO_3^- \xrightarrow{\textbf{1-(ClO}_4)_2} 4\,Ce^{III} + {}^{18}O^{16}O + 4\,H^+ + N^{18}O^{16}O_2^- \quad (6)$$
Aqueous solutions of $[Mn_2O_2(terpy)_2(H_2O)_2]$-$(NO_3)_3\cdot6H_2O$, (**6**) have been shown to evolve dioxygen (without turnover) in the presence of aqueous sodium hypochlorite[23] and oxone.[24] In the presence of high concen-

trations of oxone ($KHS^{16}O_5$) (100:1 oxone:**6**) negligible amounts of labeled dioxygen were formed in the presence of $H_2^{18}O$, thus suggesting that oxone was the likely source of the O atoms in the O_2 produced under these conditions. However, by lowering the ratio of the oxone:**6** to 20:1, labeled dioxygen was detected, with the highest yielding mixtures containing doubly-labeled $^{18}O_2$ (12% ±6%), mixed-labeled $^{18}O^{16}O$ (39% ±15%), and $^{16}O_2$ (49% ±19%).[24] Solutions of **6** in these reactions decompose rapidly to give permanganate. These results are in contrast to those we report for the Mn/mcbpen⁻ system. In neither of the oxidation reactions with TBHP or Ce^{IV} as oxidant and **1**-$(ClO_4)_2$ as catalyst was permanganate produced as a decomposition product of the catalyst; the reaction is highly specific as only one isotopomer is produced, and there is turnover.

Notably, mcbpen⁻ is mononegative and provides one carboxylate donor for each Mn ion, which is analogous to the protein donors for all the Mn atoms of the 3+1 OEC cluster.[25] The flexible carboxylate donor means that dinuclear manganese complexes of mcbpen⁻ show the potential to change between 6 and 7 coordination as needed, depending on the Mn oxidation state and the presence of exogenous ligands. The Mn···Mn separations may vary between 4.0914(9) Å (Mn^{II}/Mn^{II}) and 2.7 Å (Mn^{IV}/Mn^{IV}). These features are a significant advance in ligand design for an OEC model and may in fact be crucial to the functionality of this system. The dinuclear complexes in the proposed catalytic cycle (Scheme 1) are all plausible intermediates and have structural precedents with either mcbpen⁻ itself or related ligand systems. The highly specific and catalytic oxidation of water catalyzed by **1**-$(ClO_4)_2$ is a noteworthy advance in the mimicry of the activity of the OEC.

Experimental Section

All solutions were prepared using doubly deionized water. $H_2^{18}O$ (95 atom%) was purchased from ISOTEC (Sigma Aldrich). All other chemicals were purchased from Aldrich and used without further purification. Solutions of *tert*-butylhydrogenperoxide (TBHP) in decane (6M) or water (1M and 0.32M) were used. **1**-$(ClO_4)_2$ was synthesized as reported previously.[2] **Caution!** Perchlorate salts of metal complexes with organic ligands are potentially explosive!

Electrospray Ionization Mass spectra were obtained using a Finnigan TSQ 700 triple-quadrapole instrument equipped with a Finnigan API source in nanoelectrospray mode. The oxygen concentration was measured with an MI-730 oxygen electrode from Microelectrodes Inc., USA and by means of membrane inlet mass spectrometry (MIMS). In the MIMS experiment, the sample cell had a volume of 500 µL and was made of stainless steel. The solution was stirred with an impeller connected through a stirring shaft to an electric motor operating at 400 rpm. The sample cell was mounted on a vacuum flange, and the only separation between the liquid in the sample cell and the vacuum chamber of a single-quadrapole mass spectrometer (Balzers QMG 420) was a 51-µm thick silicone membrane (SIL-TEC Sheeting, Technical products Inc., USA). The inlet was thermostatically controlled at 30°C. The concentration of O_2 was determined by using the calibration method described by Degn and Lauritsen.[26]

[6] MIMS is a method that allows the analysis of volatile compounds in liquid media. The only separation between the polar media and the mass spectrometer is a thin polymer film. Volatile and hydrophobic compounds dissolve in the membrane, diffuse through it, and evaporate into the ion source of the mass spectrometer, where they are ionized and analyzed according to their mass-to-charge ratios. The method is highly suited for measuring gases and organic compounds in aqueous media, and enables measurements in the low-ppm range. The response time is only a few seconds, and the method has been used for studies of complex chemical reactions[26] and for online measurements in microbial media.[5] We have attempted to assess the electron-impact mass spectrometry (EIMS) methods used in the analysis of ^{18}O-labelling experiments in references [20,23,24]. Unfortunately, insufficient detail was provided (in supplementary information) to describe the experimental protocols. Thus, we assume that the gas in the head space over the reactions was analyzed. This method is fundamentally different to MIMS and is not quantitative.

[7] A deliberate injection of O_2 into the system does not invoke this response, rather the surge is recorded, and this immediately decays exponentially.

[8] We are currently designing a new cell so that a continuous supply of TBHP can be added in order to attain a steady state of catalytic activity. Visual inspection of the reactions indicates that the concentrations used in the MIMS experiments are not optimal and the system potentially produces much greater amounts of product.

[9] We have not found determinations of O-exchange between water and *t*BuOOH in the literature. However, the specific production of one isotopomer observed in our work is indirect evidence that any exchange of this nature is not kinetically relevant. If there was significant exchange then a distribution of isotopes, $^{16}O_2$, $^{18}O^{16}O$, and $^{18}O_2$, would be observed. Furthermore we have monitored the reaction solution at *m/z* 92, which corresponds to singly ^{18}O-labeled TBHP. No trace was detected (and we do see unlabeled TBHP at *m/z* 90). Therefore competing homolytic cleavage of the O–O bond in TBHP and consequent radical Haber–Weiss chemistry can be eliminated in mechanistic considerations. Furthermore oxidation is observed with the Ce^{IV} oxidant.

[10] The complex is dimeric in solution as well as in the solid state as evidenced by solution ESR spectroscopy.[2]

[21] The nitrate complex $(NH_4)_2[Ce(NO_3)_6]$ is that normally used as a source of Ce^{IV} in oxidation reactions. However, participation by the nitrate ion is not normally considered.

[22] As mentioned in the text, the nitrate-containing $[Mn^{III}(mcbpen)NO_3]^+$ is in fact observed in the ESI mass spectra of the reaction solutions. This fact cannot be regarded as evidence for Mn activation for nitrate reduction. However, it does suggest a higher concentration of $[Mn^{III}(mcbpen)NO_3]^+$ than the iso-electronic $[Mn^{III}(mcbpen)OH]^+$, which is seen in the TBHP reactions. An attempt to verify the possible involvement of nitrate in the water oxidation was made by adding a 100-fold excess of sodium nitrate to the reaction. This resulted in complete inhibition of the reaction. This observation is not surprising if nitrate is capable of substituting the water ligands of **1**-2$(ClO_4)_2$ and consequently inhibiting the reaction. We have also attempted to detect the $N^{18}O^{16}O_2^-$ isotopomer by negative-ion ESIMS. Unfortunately, in the presence of such large excess of the unlabeled nitrate, this experiment was beyond the resolution capabilities of our instrument.

Communications

Selective Sensing of Zinc Ions with a PARACEST Contrast Agent**

*Robert Trokowski, Jimin Ren, Ferenc Krisztián Kálmán, and A. Dean Sherry**

Divalent zinc, the second most abundant transition-metal ion in seawater and in humans, is an essential integral component of numerous functional proteins involved in a wide range of physiological systems.[1–4] Zinc ions also bind to many membrane receptors, transporters, and channels, and modulate their activity.[5] Therefore, it is not surprising that zinc deficiency affects many organs, including the digestive, immune, and neuronal systems.[4,6,7] Free Zn^{II} ions are released from loosely bound metal–protein complexes found in selected cell types and cell organelles in brain and other tissues.[8] Various indirect evidence indicates that the concentration of free Zn^{II} ions ranges from 10^{-12} to 10^{-5} M in undifferentiated mammalian cells to approximately 0.3 mM in hippocampal-nerve synaptic vesicles.[9,10] Understanding the importance and control of the release of Zn^{II} ions in living cells will require suitable detection and imaging reagents.[11–13]

In the past two decades, magnetic resonance imaging (MRI) has grown into one of the most powerful techniques in diagnostic medicine and biomedical research. One of the first designs for sensing Zn^{II} ions by MRI was based on a Gd^{III} complex that showed an approximately 30% decrease in water relaxivity in the presence of Zn^{II} ions.[14] The ligand in this complex was prepared by treating diethylenetriamine-pentaacetic acid (dtpa) bisanhydride with *N,N*-bis(2-pyridyl-methyl)ethylenediamine to form a ligand having both a Gd^{III} site and a Zn^{II} site, which is presumably formed by the four pyridine donors situated above the water molecule bound to the Gd^{III} ion. On the basis of recent success at creating imaging agents that respond to changes in water-exchange

rates rather than relaxation rates, we decided to test the hypothesis that a chemical exchange saturation transfer (CEST) agent may be advantageous for measuring the levels of free Zn^{II} ions in tissues.[15–18] Here, we report a first-generation paramagnetic CEST agent, [Eu(dotampy)] (dotampy = 1,7-bis(N,N-bis(2-pyridylmethyl)aminoethylcarbamoylmethyl)-4,10-bis(butylcarbamoylmethyl)-1,4,7,10-tetraazacyclododecane, **1**), as a novel sensor for Zn^{II} ions.

1
The CEST profile of [Eu(dotampy)] is typical of a system exhibiting intermediate to slow water exchange between a Eu^{III}-bound water species with a resonance at $\delta = 50$ ppm and that of bulk water at $\delta = 0$ ppm (Figure 1). Somewhat surprisingly, addition of Zn^{II} ions to this complex in buffered solution at pH 7.1 resulted in broadening of the resonances of both the Eu^{III}-bound water molecule ($\delta = 50$ ppm) and the bulk water ($\delta = 0$ ppm), suggestive of more rapid water exchange. As a result, the most dramatic changes that are observed in the CEST spectrum upon addition of Zn^{II} ions occur in the region between these two exchanging water signals (15–30 ppm). This effect was even more dramatic when Zn^{II} ions were added to [Eu(dotampy)] at pH 8.0 (Figure 1). In this case, water (or proton) exchange is so fast that the entire CEST signal at $\delta = 50$ ppm disappeared upon addition of Zn^{II} ions. The sensitivity of CEST to base catalysis was not anticipated for this system nor was the origin of this effect immediately apparent. One possibility is that if a Zn^{II} ion forms a mononuclear complex by coordinating the four pyridine donors, such binding could introduce "strain" around the Eu^{III} coordination complex and perhaps alter the geometry of [Eu(dotampy)] from a square-antiprism (SAP) structure with intermediate-to-slow water exchange to a twisted-square-antiprism (TSAP) structure with faster water exchange. A high-resolution ^{1}H NMR spectrum of [Eu(dotampy)] shows a single, highly shifted resonance near $\delta = 25$ ppm that is characteristic of the four axial macrocyclic protons in a SAP coordination geometry (Figure 2) and no indication of even a small population of a TSAP coordination isomer.[19–22] Addition of Zn^{II} ions to [Eu(dotampy)] resulted in a slight shift of this resonance to low field and a broadening into three or more nearly resolved signals. This result indicates that [Eu(dotampy)] is less symmetric in the presence of Zn^{II} ions but, again, no new resonances were present in the region between $\delta = 12$ and 15 ppm, as would be anticipated if

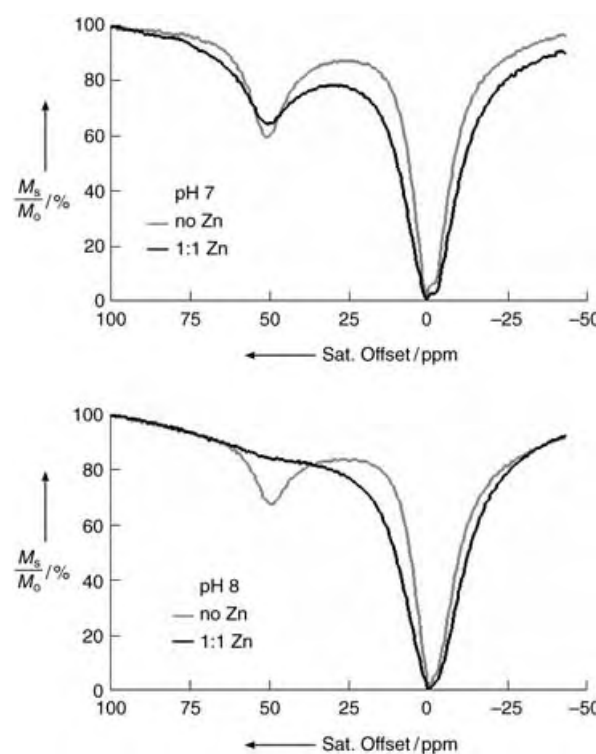

Figure 1. Top: Z-spectra of 20 mM [Eu(dotampy)] in the absence (gray line) and in the presence (black line) of 20 mM Zn^{II} ions in 1,4-piperazinebis(ethanesulfonic acid) (PIPES) buffer (100 mM; pH 7.1) at 25°C. Bottom: Z-spectra of 20 mM [Eu(dotampy)] in the absence (gray line) and in the presence (black line) of 20 mM Zn^{II} ions in 2,4,6-tris[(dimethylamino)methyl]phenol (DMP) buffer (100 mM; pH 8.0) at 25°C. The CEST profiles were collected by using a 2-s frequency-selective hard pulse ($B_1 = 1000$ Hz) followed by a non-frequency-selective 60° read-out hard pulse. $M_s =$ bulk-water magnetization when a presaturation pulse is applied; $M_o =$ equilibrium magnetization without presaturation.
Figure 2. Low-field portion of a ^{1}H NMR spectrum (400 MHz, 25°C) of 100 mM [Eu(dotampy)] in the absence (upper) and in the presence (lower) of 100 mM of Zn^{II} ions at pH 6.95.

there had been a change in structure from SAP to TSAP.[23] Thus, the enhanced water-exchange characteristics of the [Eu(dotampy)]–Zn^{II} adduct cannot be traced to a switch in the coordination geometry of the complex.

A second possible reason why water (or proton) exchange is faster in the [Eu(dotampy)]–Zn^{II} adduct is that the Zn^{II} ion may itself have a coordinated water molecule that is partially deprotonated at these pH values, thereby positioning a $Zn^{II}OH$ species near the Eu^{III}-bound water molecule (a hypothetical model is illustrated in Scheme 1). Such a species
Scheme 1. Hypothetical structures of [Eu(dotampy)] in the presence and absence of Zn^{II} ions.

could act to catalyze prototropic exchange between the Eu^{III}-bound water molecule and the bulk solvent. Other ligand systems containing two *N,N*-bis(2-pyridylmethyl)amine (dpa) units frequently form dinuclear complexes with Zn^{II} ions, in which each dpa arm provides three nitrogen donors and the fourth coordination site is occupied by a bridging hydroxide ion.[24–27] However, all of our data on this system (potentiometry, spectroscopy, and CEST titrations, see below) show that a mononuclear species is formed between [Eu(dotampy)] and Zn^{II} ions under all experimental conditions examined. Molecular modeling studies of the [Eu(dotampy)]–Zn^{II} adduct suggest that the positions of the tertiary amines on each side-arm are constrained by the size of bridging {Eu-(dotam)} moiety and are therefore not likely to be coordinated to the Zn^{II} ion. This would leave only the four pyridyl nitrogen atoms and perhaps one or two water molecules available to form a complex with the Zn^{II} ions. Attempts to isolate crystals of [Eu(dotampy)]–Zn^{II} suitable for X-ray crystallographic analysis to confirm the structure illustrated in Scheme 1 have been unsuccessful.

Potentiometric titrations of [Eu(dotampy)] were performed in the absence and presence of Zn^{II} ions to examine whether either a Eu^{III}- or Zn^{II}-coordinated water molecule can be titrated over the pH range employed in the CEST studies (see Supporting Information). In the absence of Zn^{II} ions, [Eu(dotampy)] displays three stepwise protonation constants (logK_a = 3.60 ± 0.03, 5.75 ± 0.03, 11.29 ± 0.02) over the usual pH range covered by potentiometry. The logK_a values of 3.60 and 5.75 are consistent with protonations

occurring at the two tertiary nitrogen atoms on the side-arms whereas the logK_a value of 11.29 likely corresponds to deprotonation of the Eu^{III}-bound water molecule.[28] A fit of the titration data collected in the presence of a stoichiometric amount of Zn^{II} ions gave a stability constant of logK_{st} = 7.59 ± 0.02 for the [Eu(dotampy)]–Zn^{II} adduct. The potentiometric data also provided evidence for formation of a Zn^{II}OH species above approximately pH 6 which could act as a catalyst for the exchange of protons between the Eu^{III}-bound water molecule and the bulk solvent. A similar mechanism has been proposed for proton catalysis by the appended phosphonate groups in [Gd(dota-4amp)] (dota-4amp = 1,4,7,10-tetrakis(*N*-methylphosphate)-1,4,7,10-tetraazacyclo-dodecane).[29] Spectrophotometric titrations of [Eu-(dotampy)] at pH 7.1 confirmed this potentiometric binding model. The absorbance between 225 and 285 nm changed linearly with an increase in the Zn^{II} concentration up to a [Eu(dotampy)]/Zn^{II} mole ratio of 1:1, with isosbestic points at 248, 267, and 272 nm, but then remained unchanged with further increases in Zn^{II} concentration. A Job plot of these binding data provided further evidence for the formation of a 1:1 complex (see Supporting Information). Finally, additional support is given by the Z-spectra collected after incremental additions of Zn^{II} ions at pH 7 (Figure 3); the CEST effect was
Figure 3. A plot of relative CEST magnitude versus Zn^{II} concentration for 20 mM [Eu(dotampy)] in PIPES buffer (100 mM; pH 7).

quenched linearly with addition of up to one equivalent of Zn^{II} ions, but then relatively small changes were observed upon further increases in the Zn^{II} concentration. This observation demonstrates that a 1:1 complex is formed both at 20 mM (the concentrations used to collect the CEST spectra) and 0.1–2.0 mM (the concentrations used in the potentiometric and UV/Vis experiments).

To demonstrate that Zn^{II} binding can be sensed in a CEST imaging experiment, a phantom consisting of four plastic tubes (i.d. 4 mm), each containing 20 mM [Eu(dotampy)] and different amounts of Zn^{II} ions, was prepared. Images were acquired after applying a selective Gaussian-shaped presaturation pulse at δ = 50 ppm followed by a spin-echo gradient imaging sequence. A second image was collected after presaturation at δ = 25 ppm and CEST images were generated by pixel-by-pixel subtraction of the two SE images. The image intensities (Figure 4) show a clear gradation that

Figure 4. Left: CEST images of phantoms containing 20 mM [Eu-(dotampy)] and either 0, 5, 10, 20 mM Zn^{II} ions. Right: CEST images of phantoms containing 20 mM [Eu(dotampy)] plus stochiometric amounts of Zn^{II}, Mg^{II} or Ca^{II} ions. PIPES (100 mM) was used to buffer the solution at pH 7.1. A 1 s (left image) or 0.5 s (right image) frequency-selective Gaussian shaped pulse (B$_1$ = 1000 Hz) was used to presaturate the sample prior to applying spin-echo (SE) imaging pulses. The CEST images represent the intensity difference between the SE images for saturation at $\delta = 50$ ppm and $\delta = 25$ ppm from the bulk water. Other imaging parameters included: TR/TE 1300 ms/13 ms, thickness 2 mm, FOV 30×30 mm, data matrix 128×128, 4 dummy scans, each image was the average of 2 scans. TR = repetition time; TE = echo time; FOV = field of view.

parallels the Zn^{II} concentrations in each sample. To test for selectivity, CEST images were also collected by replacement of Zn^{II} ions with either Mg^{II} or Ca^{II} ions. Those ions could not be detected by CEST imaging.

Finally, one needs to consider the practical use of this system for imaging of Zn^{II} ions in a real biological system. From the CEST results illustrated above, one can estimate that a minimum of approximately 2 mM agent would be needed to satisfy the sensitivity limits for detection of Zn^{II} ions by MRI. Given that the CEST MRI signal would only detect changes in total Zn^{II} concentration covering the range from 0.4 to 1.6 mM (as set by the sensitivity limits of MRI) and that $\log K_{st} = 7.59 \pm 0.02$ for the [Eu(dotampy)]–Zn^{II} system, one can then estimate that the effective sensitivity range for this sensor in detecting changes in concentration of "free" Zn^{II} ions varies from 5 nM to 0.12 μM—a reasonable concentration range for levels of free Zn^{II} ions in tissues. Of course, the practicality of this detection method remains to be proven, but the idea—detection of the catalysis of proton exchange by a nearby coordinated hydroxide group, as demonstrated in the current Zn^{II} system—serves as an attractive model for the design other responsive PARACEST imaging agents.

Deracemization of Quaternary Stereocenters by Pd-Catalyzed Enantioconvergent Decarboxylative Allylation of Racemic β-Ketoesters**

Justin T. Mohr, Douglas C. Behenna, Andrew M. Harned, and Brian M. Stoltz*

Enantioconvergent catalysis is a powerful synthetic method that converts a racemic stereogenic substrate into an enantiomerically enriched product with a theoretical yield of 100% in a single operation.[1] Conceptually, a catalytic system for such a reaction must achieve a stereomutation[2] or stereoablation[3,4] of the substrate (or an intermediate), followed by an enantioselective conversion into product (Figure 1, compare pathways I

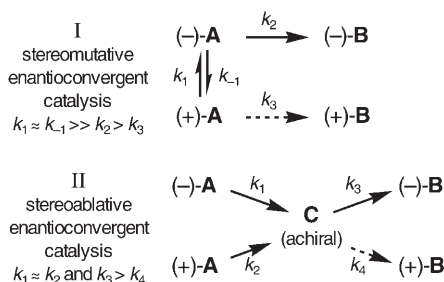

Figure 1. Stereomutative versus stereoablative enantioconvergent catalysis.

and II). A number of catalytic processes of this type have been developed, including chemical, enzymatic, and chemoenzymatic strategies.[1,2,4] Racemic compounds that contain quaternary carbon centers are typically unsuitable substrates for enantioconvergent catalysis because of the difficulty associated with C−C bond cleavage in the stereomutative or

stereoablative process.[5,6] Herein, we describe the first catalytic system for the deracemization of quaternary carbon stereocenters. Our enantioconvergent method converts racemic α-substituted 2-carboxyallylcyclohexanones into highly enantioenriched cycloalkanones that bear quaternary stereocenters through catalytic asymmetric decarboxylative allylation.

We recently reported the first catalytic asymmetric allylation methods for the synthesis of 2-alkyl-2-allylcycloalkanones (Scheme 1).[7] These reactions, based on racemic

transformations reported in the early 1980s by Tsuji,[8] use enol carbonates and silyl enol ethers along with various allyl carbonates and a Pd⁰ catalyst supported by a chiral phosphinooxazoline ligand (e.g., **1**).[9–11]

To demonstrate the utility of this methodology, we have started to employ these allylations as the key enantioselective reaction in multistep syntheses. In one such project, we required the substituted cyclohexenone **6** (Scheme 2). Unfortunately, the preparation of the allylation precursor **4** (R = CO₂allyl or SiMe₃) was hampered by nonselective enolization of **3** to form inseparable mixtures of **4** and **5**, which resulted in significant amounts of **7** after allylation.
Prompted by the need for better position control in these synthetic sequences, we sought mechanistically guided alternatives to the reactions depicted in Scheme 1. To this end, we synthesized dideuterated carbonate **8** and trideuterated carbonate **9**. When **8** was subjected to our standard conditions for allylation, the deuterium label was almost evenly scrambled between the termini of the allyl fragment in the product (Scheme 3a).[12] In a separate crossover experiment, the reaction of equimolar amounts of carbonates **8** and **9** was performed under our standard allylation conditions. As expected, NMR spectroscopic analysis of the product showed deuterium scrambling between the allyl termini, but interestingly, mass spectrometric analysis of the product showed an almost perfect statistical distribution of enolate and allyl fragment pairs with four possible masses (Scheme 3b).[12] Thus, all six possible products were formed in the reaction including those derived from crossover reactions. Although the specific details associated with the enantiodiscrimination remain unclear, we hypothesized that a discrete achiral ketone enolate (namely, **10**) must exist in solution for some period to explain our observations.[13]

We took this mechanistic insight into account, and so reasoned that the putative prochiral enolate needed for the

information, coupled with the product yield of over 50% and high enantiomeric excess, clearly demonstrates the enantioconvergent nature of the system (Figure 1, pathway II).

With the enantioconvergent decarboxylative allylation of (±)-**12** established, we investigated the scope of this unusual asymmetric transformation. In general, the system is highly tolerant to an array of functionalities and substitution patterns (Tables 1 and 2). A variety of α-substituted 2-carboxyallylcyclohexanones can be converted into products with high enantiopurity in excellent yields under the conditions for decarboxylative allylation (Table 1). The presence of enolizable functional groups (entries 4 and 5) and β-heteroatom substitution (entry 9) is of particular note. Furthermore, the 2-fluoro derivative (entry 10) allows for the high-yielding synthesis of stereodefined tertiary fluorides.

In addition to changes at the α position, variation of the cyclic and allylic portions of the quaternary β-ketoester is tolerated (Table 2). Examples in which the cyclohexane ring has been substituted (entries 1–4), unsaturated (entry 5), appended (entry 6), or enlarged (entry 7) proceed to products in high yield and enantioselectivity. Finally, substrates with internal allylic substitution (entries 8 and 9) and a racemic heterocycle (entry 10) also afford products in excellent yield and enantioselectivity.

With a general procedure for enantioconvergent decarboxylative allylation in hand

synthesis of **6** (namely, **4**; R = anion) could be derived through decarboxylation of a racemic β-ketoester precursor, such as (±)-**12** (Scheme 4).[14] Moreover, this route would solve the enolization problem outlined above because the position-

Scheme 4. β-Ketoester synthesis and enantioconvergent decarboxylative allylation. LDA = lithium diisopropylamide.

selective α-alkylation of ketoester **11** would be facile. We prepared β-ketoester (±)-**12** by acylation and alkylation of enone **2** to test the reaction (Scheme 4).[15] To our delight, treatment of (±)-**12** with the complex derived from [Pd₂-(dba)₃] and (S)-tBu-phox ligand **1** in Et₂O exclusively produced allyl ketone (−)-**6** in 73% yield and with 86% ee. Importantly, β-ketoester **12** remained racemic throughout the course of the reaction, thus indicating that significant kinetic resolution of the starting material had not occurred. This

and given our interest in tandem reactions and catalysis,[16] we designed a substrate that could undergo a double allylation cascade to afford a product that possesses two all-carbon quaternary stereocenters. Thus, we prepared (±)-**13**, a substrate that contains a reactive enol carbonate and a latent β-ketoester moiety (Scheme 5).[12] Treatment of (±)-**13** under our catalytic asymmetric conditions provided the double alkylation product in 76% yield as a 4:1 mixture of C₂/meso diastereomers.[17] Gratifyingly, the major diaster-

eomer (−)-**14** was obtained with 92% *ee* and bears two quaternary stereocenters set by a single catalytic asymmetric transformation.

In conclusion, we have developed the first example of a catalytic enantioconvergent synthesis of quaternary stereo-centers from racemates with quaternary stereocenters. The decarboxylative allylation reaction described herein is an example of an enantioconvergent process in which the same catalyst is intimately involved in both the stereoablative (C−C bond-breaking) and stereoselective (C−C bond-forming) steps. The availability of racemic β-ketoesters of the type employed in this study greatly increases the practical value of these Pd-catalyzed allylations for the enantioselective synthesis of cyclic ketones with one or more quaternary stereo-centers. The utility of this methodology for enantioselective synthesis of complex targets is currently under investigation.

Lattice Expansion of Clathrate Hydrates of Methane Mixtures and Natural Gas**

Satoshi Takeya,* Tsutomu Uchida, Yasushi Kamata, Jiro Nagao, Masato Kida, Hirotsugu Minami, Hirotoshi Sakagami, Akihiro Hachikubo, Nobuo Takahashi, Hitoshi Shoji,* Oleg Khlystov, Mikhail Grachev, and Valery Soloviev

Clathrate hydrates are inclusion compounds consisting of a hydrogen-bonded crystal of water molecules with cages that contain a guest molecule. The crystal structures of types I, II, and H are well known,[1] and two other types of clathrate hydrate have recently been reported.[2] Guest–host interactions play a crucial role in the crystal structure, and thus clathrate hydrates are thermodynamically stable only when guest molecules are encaged in the host cages. The relation between structural type of clathrate hydrate and guest molecule is categorized according to the size of the guest molecule.[3] However, the use of these categories is not clear when applied to mixed hydrates; for example, a structural transition in methane (CH_4) + ethane (C_2H_6) mixed-gas hydrates from type I to II was observed, even though pure CH_4 and C_2H_6 each form type I.[4,5] There is not much

difference between the molecular size of CO_2 (ca. 5.1 Å) and C_2H_6 (ca. 5.5 Å) with respect to the cavities of the hydrate cages, but their effect on hydrate structure may be completely different. Additionally, recent studies have shown that even pure CH_4 and pure CO_2 form type I and type II hydrates in coexistence. It has been shown that the correlation of guest size and formed structure type is not straightforward for pure systems, too.[6]

The structural transitions of mixed-gas clathrates are interesting not only from a fundamental point of view but also from the practical viewpoint of natural gas resources and technology.[7] For instance, natural gas clathrate hydrates in oceanic sediments and permafrost, also called natural gas hydrate, are recognized as an alternative natural fuel resource because they contain significant amounts of natural gases. The main gas in the hydrates is CH_4, but they also contain CO_2, C_2H_6, and small amounts of other gases. In addition, $CH_4 + CO_2$ mixed-gas hydrates have been studied as a medium to remove CO_2 from air; in particular, natural gas hydrates can be converted to CO_2 hydrate, and thus a fuel is obtained and an unwanted combustion byproduct is removed.[8]

We present here our measurements of the lattice expansion of $CH_4 + CO_2$ and $CH_4 + C_2H_6$ hydrates as a function of mixed-gas composition. This is important because lattice expansion plays a crucial role in thermodynamic modeling of hydrate systems.[5,9] Data for natural gas hydrate from the sediments of Lake Baikal are also reported to examine the effect of small amounts of other gases and the kinetic effect under natural conditions on their crystal structures.

X-ray diffraction (XRD) patterns of $CH_4 + CO_2$ hydrate identified it as type I, which is composed of two 12-hedra and six 14-hedra with space group $Pm3n$ (Figure 1). The crystal structure of $CH_4 + C_2H_6$ hydrate changed from type I to type II with increasing C_2H_6 content in the mixed-gas hydrate, in agreement with previous studies.[4,5] (The type II structure (Figure 1) is composed of sixteen 12-hedra and eight 16-hedra with space group $Fd3m$.) Since the type I and type II hydrates have cubic structures, only one unit-cell parameter—the lattice constant a—need be determined.

The lattice constants are plotted in Figure 2. The lattice constant of $CH_4 + CO_2$ hydrate is roughly independent of gas composition, and this suggests that changes in the occupancy of CH_4 or CO_2 in the cages of the mixed-gas hydrate do not affect the lattice size of type I hydrate. In the case of $CH_4 + C_2H_6$ hydrate, a large increase in the lattice constant occurs at approximately 60 to 80% CH_4 content, which corresponds to the structural transition from type I to type II. In the region of high CH_4 content in $CH_4 + C_2H_6$ hydrate, from approximately 80 to 100%, the lattice constants of type I hydrate are almost the same as that of pure CH_4 hydrate. In the region of low CH_4 content in $CH_4 + C_2H_6$ hydrate, from approximately 0 to 40%, the lattice constants of type I hydrate are same as that of pure C_2H_6 hydrate and are approximately 0.07 Å larger than that of the high-CH_4 region. The deviation of the lattice constant of type I $CH_4 + C_2H_6$ hydrate corresponds to 0.6% of the value for a pure CH_4 hydrate crystal. This deviation may not seem large, but it corresponds to a pressure difference of several hundred megapascals, in accordance with the bulk modulus of CH_4 hydrate.[13]

Type I structure   12-hedral cages   14-hedral cages

Type II structure   12-hedral cages   16-hedral cages

Figure 1. Ball-and-stick representations of the host lattices of types I and II clathrate hydrates. Only oxygen atoms are drawn and solid lines indicate the unit cell of each structure. Middle and right figures show only the small and large cages, respectively, of each structure.

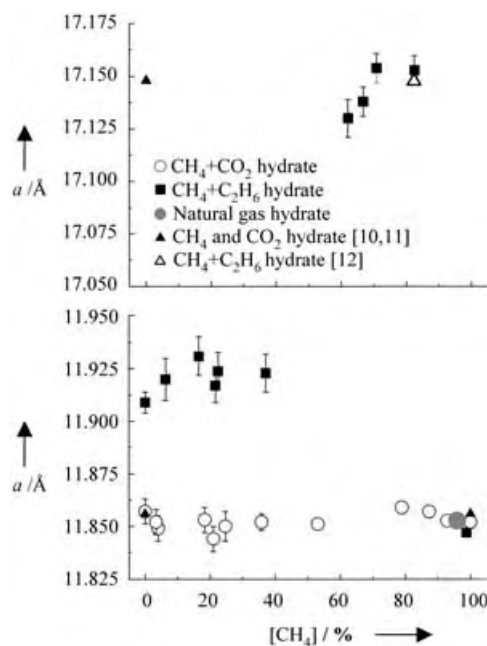

Figure 2. Variation of lattice constants of clathrate hydrates at 113 K as a function of CH_4 gas content in the hydrates. Lattice constants of $CH_4 + CO_2$ hydrate, $CH_4 + C_2H_6$ hydrate, and natural gas hydrate are from this study. Lattice constants of CO_2 hydrate ($CO_2 + D_2O$), deuterated methane hydrate ($CD_4 + D_2O$), and $CH_4 + C_2H_6$ hydrate (CH_4/C_2H_6 82:18; $CH_4 + C_2H_6 + D_2O$) were determined at different temperatures and converted to values at 113 K.

The results also suggest that a change in the occupancy of CH_4 or C_2H_6 in the cages of the mixed-gas hydrate does not affect the lattice size of type I hydrate. On the other hand, the lattice constant of type II hydrate seems to increase as the CH_4 occupancy in the $CH_4 + C_2H_6$ hydrate increases. This difference between type I and type II hydrates implies a major difference in guest–host or guest–guest interactions due to their different crystal structures. Differences in the properties of CO_2 and C_2H_6 molecules in the hydrate are also suggested. For example, the 12-hedral small cage has a large (ca. 71%) CO_2 occupancy but a small (ca. 5%) C_2H_6 occupation in pure CO_2 and C_2H_6 hydrate, respectively.[10,14] Also, different locations of disordered CO_2 and C_2H_6 molecules in 12-hedral and 14-hedral cages in pure CO_2 hydrate and C_2H_6 hydrate have been shown by assuming that each molecule rotates about the cage symmetry axis at a constant angle to the equatorial plane.[10,14] There may be several factors that affect the change of lattice constants of mixed gas hydrates.

We also analyzed the crystal structure of natural gas hydrate from the sediments of Lake Baikal (Figure 3). Using gas chromatography, we found that the gas content of the natural gas hydrate was 95.9% CH_4, 4.1% CO_2, and less than 500 ppm of C_2H_6 and C_3H_8. The XRD profile showed that the crystal structure of the natural gas hydrate in the sediment sample was type I (Figure 4). Also, the ^{13}C NMR spectrum of

Figure 3. Hydrate-bearing sample from the sediment of Lake Baikal. The white regions are a mixture of natural gas hydrate and ice, and the black regions are sediment.
Communications

Figure 4. X-ray diffraction profiles of a sample from the sediment of Lake Baikal at 113 K. The dot marks are the observed intensities, and the solid line was calculated from the best-fit model of the Rietveld refinements. The upper tick marks represent the calculated peak positions for the type I gas hydrate, and the lower tick marks those for hexagonal ice. The bottom curve is the difference between the observed and calculated intensities. The sample was 18% hydrate and 82% hexagonal ice by mass, whereby some of the ice came from trapped lake water that froze during cooling.

the natural gas hydrate showed that CH_4 is encaged in the gas hydrate with a large-cage occupancy of 0.94 and a small-cage occupancy of 0.99. CO_2, C_2H_6, and C_3H_8 were not detected by ^{13}C NMR spectroscopy. We used this ^{13}C NMR data in the Rietveld refinement of the XRD profile.[15] Thus, the lattice constant of the natural gas hydrate was estimated to be 11.8527(6) Å, and its density was calculated to be 0.948 g cm^{-3} at 113 K. The lattice constant of the natural gas hydrate is consistent with those of the artificially formed mixed-gas hydrates (see Figure 2), even though the differences in cage occupancies between artificial and natural gas hydrates is suggested experimentally to be due to differences in their formation conditions.[16] This also shows that the small amounts of C_2H_6 and C_3H_8 did not influence the structural transition or the lattice expansion. This result suggests that the knowledge of artificial clathrate hydrate structures can be applied to natural gas hydrates.

In the present study, the effect of guest molecules on the lattice constant of mixed-gas hydrates was measured for the first time. The dependence of lattice expansion on gas occupancies differs for different guest molecules. For instance, lattice expansion of $CH_4 + C_2H_6$ hydrate depends on the composition of the guest molecules, whereas no lattice expansion of $CH_4 + CO_2$ hydrate was observed. Even a small deviation of the lattice constant corresponds to a large pressure difference at constant temperature, and thus crystal structure data should be considered in detail for optimal thermodynamic modeling. However, the guest molecules are difficult to locate because of their rotational disorder and nonstoichiometry due to their random occupancy in each cage, even though the clathrate hydrate lattice may be well defined. Therefore, further analysis of the guest molecules in the hydrate cages will be required for a better understanding of mixed-gas hydrates.

Experimental Section

Mixed-gas hydrate samples were synthesized by our previously reported method.[5] Sediment samples containing natural gas hydrate were recovered by gravity coring at gas-vent fields in Lake Baikal in June 2002.[17] The samples are from the lake bottom at a water depth of 1393 m, and the site had latitude 51°55.203′ N and longitude 105°38.080′ E. After the cores were brought up, the gas hydrate-containing samples were immediately stored at about 100 K in an atmosphere of nitrogen gas to prevent hydrate dissociation.

For the XRD measurements, finely powdered hydrate samples were put in a quartz glass capillary cell (Hilgenberg; 2.0 mm, 0.01 mm thick) and then mounted on the goniometer of the XRD apparatus. The XRD measurements were performed with $Cu_{K\alpha}$ radiation (50 kV, 200 mA; Rigaku model Rint-2000) at 113 K and atmospheric pressure. Lattice constants were determined at 113 K by using a two-phase Rietveld refinement method with RIETAN-2000.[18] For this analysis, the lattice constant of hexagonal ice was fixed at 4.4793 Å for the *a* axis and 7.3216 Å for the *c* axis.[19]

For the natural gas hydrate sample, ^{13}C NMR spectroscopy was used to determine the composition of the encaged gas molecules in the cages. Powdered samples of natural gas hydrate were put in a tube-shaped zirconium sampler that was then placed in the NMR probe (100 MHz; JEOL model JNM-AL400 FT). CP-MAS ^{13}C NMR spectra were recorded at 183 K on an NM-AL40/BU spectrometer at a frequency of 100 MHz. Chemical shifts were then determined by assuming that the polydimethylsilane (PDMS) peak was at 0 ppm.

by two methods, that is, with low-valent transition metals by oxidative addition[2,5] or with metal–oxo species.[2,3]

Although various compounds can be used for the oxidation of amines, hydrogen peroxide is the oxidant that satisfies recent environmental and sustainable demands, because water is the sole by-product. Therefore, catalytic oxidation of substrates such as alkenes, alcohols, amines, sulfides, and alkanes with H_2O_2 has been explored extensively.[6,7] However, there are few examples for the introduction of an external functional group to substrates upon H_2O_2 oxidation.[7r,8] We report here that a carbon–carbon bond forms at the α position (with respect to the nitrogen atom) of tertiary amines under the H_2O_2 oxidation conditions. Thus, the ruthenium-catalyzed oxidative cyanation of tertiary amines with H_2O_2 in the presence of sodium cyanide or hydrogen cyanide gives the corresponding α-aminonitriles with high efficiency [Eq. (1)]. The reaction is, to the best of our knowledge, the first example of direct C−H activation and C−C bond formation under H_2O_2 oxidation conditions.
Ruthenium-Catalyzed Oxidative Cyanation of Tertiary Amines with Hydrogen Peroxide and Sodium Cyanide**

Shun-Ichi Murahashi, Naruyoshi Komiya, and Hiroyuki Terai*

There has been much interest in the development of clean and environmentally benign methods for the transformation of amines into the corresponding α-functionalized compounds. These compounds have proven to be versatile intermediates and have been widely used in the construction of biologically active nitrogen compounds such as alkaloids.[1] Direct introduction of a substituent at the α position of tertiary amines is performed in two steps: α-C−H activation to produce iminium ion intermediates and subsequent reaction with nucleophiles.[2–4] The initial C−H activation has been achieved

$$R^1R^2N-CH_2R^3 + \text{NaCN / AcOH or HCN} \xrightarrow[\substack{H_2O_2 \\ MeOH}]{RuCl_3\ (cat.)} R^1R^2N-CHR^3(CN) \qquad (1)$$

The catalytic activity for the oxidative cyanation of *N,N*-dimethylaniline with H_2O_2 in the presence of sodium cyanide was examined. $RuCl_3$ was found to be the most effective catalyst. $[RuCl_2(PPh_3)_3]$ and $Pr_4N[RuO_4]$ show moderate catalytic activity, while $K_4[Ru(CN)_6]$ retards the reaction. Methanol is the most effective solvent, although ethanol, ethyl acetate, and acetonitrile can also be used. The addition of acetic acid is necessary for the reaction with sodium cyanide, as otherwise no reaction takes place.

As shown in Table 1, various tertiary amines can be efficiently converted into the corresponding α-aminonitriles[9] with H_2O_2 in the presence of sodium cyanide. Reaction of substituted *N,N*-dimethylanilines bearing both electron-donating and electron-withdrawing substituents gave the corresponding cyanated products (entries 1–3). In the presence of other alkyl groups, the *N*-methyl group reacts predominantly. For example, the reaction of *N*-methyl-*N*-ethylaniline gave *N*-cyanomethyl-*N*-ethylaniline (**8**) along with a small amount of *N*-(1-cyanoethyl)-*N*-methylaniline (**9**; entry 4). The reaction can also be applied efficiently to cyclic amines: Piperidine, pyrrolidine, and tetrahydroisoquinoline derivatives can be converted into the corresponding α-cyanoamines (entries 5–8). In terms of the substrate, oxidative cyanation with H_2O_2 is more versatile than with molecular oxygen;[10] for example, molecular oxygen cannot be used for reactions with piperidine and pyrrolidine derivatives. The ruthenium-catalyzed oxidative cyanation of *N*-(4-methoxyphenyl)pyrrolidine (**14**) with H_2O_2 gave the corresponding α-cyanated amine **15** in 80% yield (entry 7), while the same reaction with molecular oxygen provided the product in only 23% yield.

To gain insight into the reaction mechanism, the relative reaction rates for the oxidative cyanation of four *para*-substituted *N,N*-dimethylanilines (p-$XC_6H_4NMe_2$; X = MeO,

Table 1: Results of the ruthenium-catalyzed oxidative cyanation of tertiary amines with hydrogen peroxide and NaCN [see Eq. (1)].[a]

Entry	Substrate	t [h]	Product	Yield [%][b]
1	**1**	2	**2**	90 (80)[c]
2	**3**	1.5	**4**	81

4[d]	**7**	1.5	**8**	63
5	**10**	2	**11**	69[e]
6[f]	**12**	1.5	**13**	73[e]
7[g]	**14**	1.5	**15**	80[e]
8	**16**	1.5	**17**	83[e]

[a] The reaction was carried out as follows: A 30% aqueous solution of H_2O_2 (2.5 mmol) was added dropwise over a period of 1 h to a mixture of amine (1.0 mmol), $RuCl_3$ (0.05 mmol), NaCN (1.2 mmol), and CH_3CO_2H (6 mmol) in MeOH (1.2 mL). The reaction mixture was then stirred for the given amount of time. [b] Determined by GLC using an internal standard. [c] Yield of the isolated product. [d] A small amount of **9** was also formed. [e] Determined by ^1H NMR spectroscopy. [f] 1.5 mmol of H_2O_2 was used. [g] 1.0 mmol of H_2O_2 was used.

Me, H, Br) with H_2O_2 in the presence of sodium cyanide were determined by ^1H NMR spectroscopy of the resulting cyanated products. The rate data correlate well ($R^2 = 0.998$) with the Hammett linear free energy relationship with use of σ values (Figure 1).

The ρ value was determined to be -3.61, indicating a cationic intermediate at the rate-determining step. The intramolecular deuterium isotope effect for the ruthenium-cata-
Figure 1. Hammett plot for the $RuCl_3$-catalyzed oxidative cyanation of the *para*-substituted *N,N*-dimethylanilines p-$XC_6H_4NMe_2$ (X = MeO, Me, H, Br) with H_2O_2 in the presence of NaCN.

lyzed oxidative cyanation of *N*-methyl-*N*-(trideuteriomethyl)aniline was found to be 4.1 by ^1H NMR spectroscopy. Similarly, the intermolecular deuterium isotope effect for the oxidative cyanation of an equimolar mixture of *N,N*-dimethylaniline and *N,N*-bis(trideuteriomethyl)aniline was determined to be 3.7. These intra- and intermolecular isotope effects are larger than those observed for *N*-demethylation with cytochrome P450 (1.6–3.1,[11] and 1.0–1.1[12]), suggesting that cleavage of the C–H bond proceeds via an intermediate bearing more ionic character. Under consideration of these data, the present reaction can be rationalized by assuming the cytochrome P450 type mechanism, as shown in Scheme 1. The
Scheme 1. The proposed reaction mechanism for the ruthenium-catalyzed oxidative cyanation of tertiary amines with H_2O_2.

low-valent ruthenium species [Ru^n] undergoes reaction with H_2O_2 to give the oxo–ruthenium species [Ru^{n+2}=O], which produces an iminium ion intermediate by electron transfer and subsequent hydrogen transfer. Nucleophilic attack by hydrogen cyanide on the iminium ion intermediate provides the corresponding α-cyanated products, water, and the [Ru^n] species to complete the catalytic cycle.

The participation of hydrogen cyanide, which is formed from sodium cyanide and acetic acid under the reaction conditions,[13] was confirmed by the following reactions: The ruthenium-catalyzed oxidation of *N,N*-dimethylaniline with H_2O_2 in the presence of hydrogen cyanide in methanol gave the corresponding α-aminonitrile **2** in 80% yield (Scheme 2). The analogous reaction with *N*-phenyltetrahydroisoquinoline provided the α-cyanated tetrahydroisoquinoline **17** in 97% yield.

The oxidative cyanation of tertiary amines provides a convenient method for synthesizing various compounds,
Scheme 2. The ruthenium-catalyzed oxidative cyanation of tertiary amines with H_2O_2 in the presence of HCN. Reaction conditions: $RuCl_3$ (5 mol%), H_2O_2 (1.5 equiv), MeOH, RT, 24 h (**1**→**2**) or 4 h (**16**→**17**).

including *N*-aryl-α-amino acids[14,15] and *N,N*-disubstituted 1,2-diamines. Upon hydrolysis, 2-cyano-*N*-4′-methoxyphenyl)pyrrolidine (**15**) can be converted into *N*-(4′-methoxyphenylproline (**18**) in 69% yield, while the reduction of **15** with LiAlH₄ provides 2-aminoethyl-*N*-(4′-methoxyphenyl)-pyrrolidine (**19**) in 99% yield. Quinoline skeletons can also be constructed from tertiary arylamines by iminium ion cyclization. Typically, the TiCl₄-promoted reaction of α-aminonitrile **2**, derived from oxidative cyanation of **1** with allyltrimethyl-silane in CH₂Cl₂ at −78°C, gave 1-methyl-4-trimethylsilyl-methyl-1,2,3,4-tetrahydroquinoline (**20**) in 75% yield.

In conclusion, we have demonstrated the novel ruthenium-catalyzed oxidative cyanation of tertiary amines with hydrogen peroxide. The reaction proceeds with high efficiency to give the corresponding α-cyanated amines, and thus provides a useful method for the synthesis of various nitrogen compounds from tertiary amines. Research is currently underway to elucidate the mechanism and to apply the principle to other catalytic systems.

Bulk Preparation of Si–SiO$_x$ Hierarchical Structures: High-Density Radially Oriented Amorphous Silica Nanowires on a Single-Crystal Silicon Nanocore**

Hui Wang, Xiaohong Zhang,* Xiangmin Meng, Shaomin Zhou, Shikang Wu, Wensheng Shi, and Shuittong Lee*

Assembling functional photoelectric nanodevices is of current interest in nanoscience and nanotechnology due to their potential applications in microelectronics and information science.[1] Generally, fabrication routes to a functional nanodevice can be classified into two types: the "top-down" approach and the "bottom-up" approach. The latter refers to assembly or scale up of nanoscale building blocks into functional devices, in which the dimensions of the functional domain can be controlled through the size of the building blocks. Various methods, such as self-assembly and Langmuir–Blodgett (LB) techniques, have been used for fabrication[2] with various degree of success, however, the small size of the nanoscale building blocks makes the fabrication process always costly and complex. Hierarchical nanostructures that have both the properties of nanoscale materials and ease of manipulation may facilitate assembly processes and provide an attractive alternative for bottom-up fabrication. They can be prepared directly by growing nanoscale structures of materials with different dimensions (nanoscale to microscale).[3] In addition, the core and branches of a hierarchical structure can be composed of different chemical elements, making them suitable for assembly into a nanodevice with multiple functions. A few homogeneous and heterogeneous hierarchically structured materials[3] have been fabricated. It is envisaged that these large hierarchical nanostructures could find applications in a variety of fields such as optoelectronics, sensors, and field emission.

Silicon and its oxides have long been of great interest for applications in microelectronic devices, and silicon-on-insulator (SOI) devices are playing an important role in the modern semiconductor industry. Recently, an SiO$_x$–Si hierarchical nanostructure described as "silicon nanowires standing on silica microwires" was fabricated.[4] However, oriented hierarchical nanostructures which are more amenable for device fabrication have yet to be reported. Herein, we report the synthesis of a highly ordered Si–SiO$_x$ columnlike hierarchical nanostructure which consists of high-density, radially oriented amorphous silica nanowires standing on a single-crystal Si nanocore. Unlike the previous hierarchical nanostructures, which were assumed to form by the two-step growth mechanism,[3] the growth of the present Si–SiO$_x$ hierarchical nanostructure appears to occur by two concurrent processes: the vapor–liquid–solid (VLS) mechanism and the oxide-assisted growth (OAG) process. Interestingly, this novel structure emits UV light at 378 nm on excitation by a femtosecond laser at 300 nm.

Si/SiO$_x$ strands were synthesized in a high-temperature tube furnace with tin as catalyst. The general morphology of the deposition product is shown in Figure 1 a–c, which reveals

Figure 1. SEM images of as-synthesized Si–SiO$_x$ hierarchical nanostructure.

that large-scale wirelike microsized structures are aligned on the substrate, and that the microstructures are long, straight, and smooth strands. The products have diameters of hundreds of nanometers to several micrometers and lengths up to several millimeters (with an aspect ratio exceeding 1.6×10^3). The cross-sectional SEM images (Figure 2 a and b) show that the strands have a columnlike, radially aligned hierarchical structure. Energy dispersive X-ray (EDX) spectroscopy (Figure 2 c and d) confirms the stoichiometric elemental composition of silicon for the core and SiO$_x$ ($x = 1.5–2$) for the branches of the strand. The SEM images further reveal that the strands have two different tip morphologies: one has a corn-shaped taper (Figure 1 d) and the other a spherical particle at the tip (Figure 1 c; EDX confirms the tip is made of Sn, as will be discussed below). It can also be observed that

Figure 2. Cross-sectional SEM image of the Si–SiO$_x$ hierarchical structure or strand (a and b) and the corresponding EDX spectra of the core (c) and shell (d) of the strand.

Figure 3. TEM images of the Si–SiO$_x$ hierarchical nanostructure. a) TEM image of the strands and corresponding selected-area electron diffraction pattern of the core (upper inset) and the shell (lower inset). b) TEM image of the aligned SiO$_x$ nanowires, detached from the shell of the cable by sonication. c) High-resolution TEM image of the amorphous SiO$_x$ nanowire showing its featureless structure.

An X-ray diffraction spectrum of the as-synthesized hierarchical structure is shown in Figure 4, which reveals that the sample is dominated by the cubic silicon phase. The spectrum also shows reflections due to the body-centered crystalline structure of Sn. These results are in good agreement with those of SAED and EDX.

To elucidate the growth mechanism of the hierarchical structure, the tip regions of the strands were examined in detail. Figure 5 shows a TEM image of a single strand

the SiO$_x$ on the strand has fleecy surfaces (Figure 1 d) and grows towards the tapered end where the strand diameter is less than 1 μm. When the diameter is more than 2 μm, the strand looks like a compact whisker or column, and the SiO$_x$ nanowires stand vertically on the strand core (whiskerlike or columnlike; see Figures 1 and 2).

The structure of the strand was further studied by TEM (Figure 3). The sharp selected-area electron diffraction (SAED) spots (Figure 3 a, upper inset) obtained from the center of the strand demonstrates that the solid Si core has a single-crystal structure, whereas the diffuse SAED pattern obtained from the edge of the strand (Figure 3 a, lower inset) reveals that the radially oriented SiO$_x$ nanowires standing on the core are an amorphous phase. According to statistical data from the TEM images, the Si core has an average diameter of 230 nm, and the SiO$_x$ nanowires in the shell have a uniform diameter of 10–20 nm and a length of hundreds of nanometers to several micrometers (with an aspect ratio of about 1000).

Figure 4. XRD spectrum of the Si–SiO$_x$ hierarchical nanostructure. The peaks marked by ■ belong to the body-centered crystalline structure of Sn, and the rest to crystalline Si. The weak, broad peak at 21° is due to amorphous SiO$_x$.
Figure 5. TEM image of the Si–SiO$_x$ hierarchical nanostructure or strand with a spherical Sn particle at the tip and Sn inside the strand.

segment, in which a spherical particle at the tip can be clearly observed. The chemical composition at several different positions was analyzed by EDX. The spherical particle at the tip of the strand is an Sn particle surrounded by Si. The Sn particle is considered to act as a catalyst for nanowire growth, because the corresponding eutectic Si–Sn alloy can form at low temperature (232 °C). The presence of a spherical metallic particle at the tip is usually considered to be a signature of the VLS mechanism.[5] The growth direction of the single-crystal Si core is (111), as determined by SAED, and is in good agreement with the VLS growth process.[5] The part of the nanotube partially filled with Sn between the spherical particle at the tip and the main product is due to the temperature change at the end of the preparation, as was previously observed.[5] Pan et al. also found that gallium catalyst could be wrapped inside Si in the synthesis of silicon oxide nanowire sandwich structures,[6] in which they attributed the growth of amorphous silicon oxide nanowires outside the Si core to oxidation of silicon. We suggest that the silicon oxide wires standing on the silicon core in the present case may also grow by the same oxidation process.

We now discuss why the SiO$_x$ nanostructure forms in a wirelike form instead of an agglomeration pattern. Previous models for explaining this phenomenon[6–11] suggested that Si reacts with oxygen to form SiO$_x$ particles, which then serve as nucleation sites to initiate the growth of SiO$_x$ nanowires. However, we suggest that the OAG process proposed by Lee et al.[12–14] may be more suitable to account for the formation of SiO$_x$ nanowires in the present work. In contrast to the conventional VLS mechanism, the OAG process relies on an oxide or a redox reaction instead of a catalytic metal or metal compound to assist the formation of nanowires. We propose that the Si nuclei formed at the Si droplet surface covered by the SiO$_2$ layer are similar to the nanoparticles, which then were oxidized to SiO$_x$ dots by reacting with the SiO$_2$ outside. Meanwhile, new Si extruded from the alloy would nucleate at the end of the nanoparticles. This recurrence or cycling process would maintain the continual growth of the amor-

phous SiO$_x$ nanowire. Meanwhile, the Si core would continue its growth along the axial direction, guided by the Sn catalyst and following the VLS mechanism, and only the surface nuclei could be formed when the core remained in the liquid state. Concurrent with core growth, the end of the SiO$_x$ nanowires grown from the surface nuclei would grow in the forward direction together. Consequently, the SiO$_x$ nanowires would form at an angle with respect to the growth direction of the core, just as was discussed above. According to the above analysis, we propose the following process for the formation of the Si–SiO$_x$ hierarchical structure, as shown schematically in Figure 6:

1) Thermal evaporation: vaporization of Sn and SiO powder to form Sn and SiO vapors.
2) Vapor deposition: deposition and formation of SiO-containing Sn liquid droplets in the low-temperature area (Figure 6a).
3) Separation: disproportionation of SiO into SiO$_2$ + Si and subsequent phase separation of Si and SiO$_2$, whereby SiO$_2$ wraps the alloy droplet (Si and Sn; Figure 6b).
4) Growth: precipitation and segregation of Si crystal from liquid Sn due to supersaturation of Si in the Sn + Si droplet (Figure 6c). Then the SiO$_2$ species on the surface react with Si nuclei or residual oxygen to form SiO$_x$ nanowires. At the same time the central Si core would continue to grow by the VLS mechanism. The two concurrent processes would make the product grow in axial and lateral directions, and finally form an Si–SiO$_x$ hierarchical structure (Figure 6d).

Figure 6. Proposed growth model for the Si–SiO$_x$ hierarchical structure. a) Sn and SiO vapors from the evaporation area (1320 °C) condense and form a liquid alloy droplet in the growing area (750–850 °C). b) More SiO vapor is absorbed into the droplet and disproportionates into Si and SiO$_2$, which are then phase-separated (at 800 °C, the concentration of Si in the Si/Sn alloy is about 1%). c) Si nucleates and oxide grows into a SiO$_x$ nanowire. d) Single-crystal Si core grows with assistance of the Sn catalyst, and SiO$_x$ nanowires grow concurrently.

Figure 7 shows the room-temperature photoluminescence (PL) spectrum of the as-synthesized Si–SiO$_x$ hierarchical structures on excitation by a femtosecond laser at 300 nm. The spectrum is dominated by only one narrow UV emission peak centered at 378 nm with a half-peak width of 6 nm. This PL spectrum is radically different from that of nonhierarchical amorphous SiO$_2$ nanostructures, which usually show
Figure 7. Photoluminescence spectrum of the Si–SiO$_x$ hierarchical nanostructure ($\lambda_{ex} = 300$ nm).

multipeak blue or green emissions.[6,15] The nature of the UV PL peak is not clear, although several luminescence bands with peak energies ranging from 743 to 328 nm have been observed in various types of silica by Nishikawa et al.[16] On the other hand, the present emission centered at 378 nm may also be attributable to oxygen vacancies.[16]

In conclusion, a novel hierarchical nanostructure consisting of high-density amorphous silica nanowires radially standing on a single-crystal silicon core were grown on a substrate in bulk (grams) quantity by a simple thermal evaporation process. The nanostructure shows a single sharp PL peak at 378 nm. The microsized hierarchically ordered nanostructures of Si and its luminescent oxide could serve as potential building blocks for ready assembly into various functional devices. Indeed, the Si–SiO$_x$ hierarchical nanostructure has been shown to be an outstanding template for chemical and biosensors[18] due to its large surface-to-volume ratio. The present facile growth process is expected to be readily extendable to fabricate similar functional hierarchical nanostructures of other semiconductors and oxides.

Experimental Section

The Si–SiO$_x$ strands were synthesized in a high-temperature tube furnace, as described previously.[9] An Al$_2$O$_3$ boat with a mixture of 3.00 g SiO (Aldrich, 325 mesh, 99.9%) and 0.50 g Sn was put in the center of an alumina tube and then mounted in the furnace. The system was pumped to 5×10^{-2} mbar and than heated to 1320°C at 40°C min^{-1}, then a mixture of argon (95%) and hydrogen (5%) at 350 mbar was kept flowing at a rate of 10 sccm. After growth for about 7 h, the furnace was cooled to room temperature at 40°C min^{-1}. A dark yellow product (ca. 0.5 g) was obtained on the silicon wafer and the inside wall of the alumina tube in the 750–850°C zone at the downstream end; the amount of product can be increased by lengthening the reaction time. The product was checked by SEM (Philips XL 30 FEG) and XRD (Siemens D500). Some of the sample was dispersed in ethanol and a drop of the dispersion was put on a carbon-coated copper TEM sample grid for examination by TEM (Philips, CM20, operated at 200 kV). To record the room-temperature photoluminescence spectrum, the sample was fixed between two crystal plates, and a 3941C-M1BB/Spitfire FF-1K/OPA-800CF-0.5 femtosecond laser (300 nm) was used as excitation source.

Solution-Phase Mixture Synthesis with Double-Separation Tagging: Double Demixing of a Single Mixture Provides a Stereoisomer Library of 16 Individual Murisolins**

Craig S. Wilcox,* Venugopal Gudipati, Hejun Lu, Serhan Turkyilmaz, and Dennis P. Curran*

Most small organic molecules are synthesized individually, but there is a compelling reason to synthesize molecules as mixtures—the effort conserved in a synthesis is directly proportional to the number of compounds that are mixed. "Split/mix" methods conduct reactions on mixtures of beads yet provide individual products at the end.[1] Recently, a general concept for solution-phase mixture synthesis[2] by separation tagging has been introduced[3] and put into practice with homologous fluorous tags.[4] Chemical reactions are conducted on tagged mixtures and the final reactions mixtures are demixed (sorted) in an orchestrated fashion by a tag-complementary separation technique. Finally, detagging provides the individual pure target products.

Generally, the availability of n tags in a single tagging strategy allows n compounds to be tagged (Figure 1, top). We

Figure 1. Single (top) and double (bottom) separation tagging.

define a tag "class" as a set of tags that all share a similarly useful response to a given separation process. The addition of m new tags to a given class of n tags increases the maximum possible size of a mixture to $n + m$.

Wilcox and Turkyilmaz recently introduced a new class of oligoethylene glycol (OEG; $(OCH_2CH_2)_nOCH_3$) tags. These were designed for solution-phase mixture synthesis, and a polarity-based demixing process was implemented.[5] The availability of two different classes of tags opens up the possibility for double-tagging strategies. The tagging of n precursors with a first class of tag and m precursors with a complementary second class of tag provides $n + m$ precursors. However, reaction of these two mixtures provides a new mixture of $n \times m$ products, each of which has a unique pair of tags (Figure 1, bottom). Isolation of the final products is achieved by double demixing with a separate demixing process that targets each tag class. We report herein the first example of double tagging with tandem separation. The ability to leverage available tags is shown by the preparation of 16 stereoisomers of the natural product murisolin in a single reaction flask with only eight tags, four fluorous tags and four OEG tags.

A crucial question in any multiple-tagging exercise is tag orthogonality; when combined in a single molecule, will the fluorous tags and OEG tags enable a separation as well as each does alone. To address this question, a mixture of 16 doubly tagged analogues of vanillic acid (4-hydroxy-3-methoxybenzoic acid) M-**1**[6] was created wherein each compound had one of four OEG tags on the phenolic hydroxy group ($n = 1–4$) and one of four homologous fluorous tags on the carboxylate group ($R^F = C_2F_5$, C_4F_9, C_6F_{13}, and C_8F_{17}). The resulting 16 compounds (4×4) are unique and differ by the combination of the OEG and fluorous tags.

The 16-compound mixture was demixed into its individual components according to the tags by using a series of two demixings, one targeted to each class of tag. TLC analysis of the reaction mixture on silica gel showed only four spots (Figure 2a). The mixture was separated by flash chromatography (pentane/EtOAc gradient) into four fractions based on the properties of the OEG tags. The least polar fraction contained all four molecules **1** that bear the OEG1 tag ($n = 1$) and the four different fluorous tags. The successive fractions each contained four molecules with the OEG2, OEG3, and OEG4 tags. Each of these four fractions was further demixed by fluorous HPLC chromatography on a FluoroFlash PF-C8 column.[7] As expected, the products from this chromatographic procedure were eluted in the order of the fluorous tag from C_2F_5 up to C_8F_{17}, thus providing all 16 individual vanillic esters **1**.

We observed that the order of the demixings can also be reversed, with the fluorous demixing being conducted before the OEG demixings. Figure 2b shows an HPLC trace of the 16-compound mixture M-**1** on a FluoroFlash PF-C8 column. The compounds emerge as four groups of four peaks. The larger separations correspond to the fluorous tags, with the four compounds bearing the C_2F_5 tag eluting well before the four compounds bearing the C_4F_9 tag, and so forth. The smaller separations within the groups of peaks correspond to OEG-tagged compounds, from the more polar $n = 4$ tag to the less polar $n = 1$ tag. The mixture was separated by semi-preparative fluorous HPLC. In this case, only four fractions that correspond to the four different groups of fluorous-tagged compounds were collected. Each of these fractions,
Figure 2. Demixing of 16 fluorous/OEG-tagged vanillic acid esters M-**1** and murisolin quasi-diastereomers **4**. a) TLC plate of the demixing of M-**1** on silica gel based on the OEG tags (pentane/EtOAc, 1:1). b) HPLC trace of the demixing of M-**1** on a FluoroFlash PF-C8 column based on the fluorous tags (CH$_3$CN/H$_2$O, 40:60 to 90:10). c) Photograph of a developed TLC plate of the mixture of 16 murisolin quasi-isomers **4** (silica gel; EtOAc/hexanes, 80:20); a small spot at the origin lies below the four spots that elute as groups of four fluorous-tagged compounds in order of increasing polarity for OEG $n = 1–4$.

which contain four molecules with one fluorous tag and all four OEG tags, were then separated by simple flash column chromatography to provide the same 16 individual products.

These proof-of-concept experiments are remarkable. It is well known that the addition of CF$_2$ groups decreases the polarity of molecules,[8] yet this effect is completely overwhelmed on silica gel by the presence of the OEG tag. Conversely, the large polarity effects of the OEG tags are

largely masked on the fluorous column, and the fluorine content rules. This complementarity suggests that fluorous tags and OEG tags are compatible partners in double-tagging strategies. To verify this hypothesis, we proceeded to synthesize 16 stereoisomers of the acetogenin murisolin in a single reaction flask. The pathway follows the recently completed fluorous mixture synthesis in which 16 stereoisomers were prepared in groups of four with the aid of four fluorous tags.[4e]

We planned to use a Kocienski–Julia reaction[9] to couple a mixture of four diastereomers of the dihydroxy THF subunit M-**2** with another mixture of four diastereomers of the hydroxybutenolide subunit **3** to give a doubly tagged 16-component mixture, in which the tag pairs encode the configurations and enable double demixing (Scheme 1). The tetrazolylsulfonyl component **2** was synthesized as four stereoisomers coded with a fluorous PMB (^FPMB) tag by using methods described recently.[4e] These stereoisomers all had the 15R,16R configuration, and all four possible isomers at C19 and C20 were present. In the first multistep OEG mixture synthesis, the aldehyde component **3** of the coupling was prepared as all four possible stereoisomers at C4,34 coded with the OEG-modified dimethyloxybenzyl group (hereafter called an OEG tag).

The Kocienski–Julia coupling of the four-compound fluorous-tagged mixture M-**2** and the four-compound OEG-tagged mixture M-**3** provided a 16-compound mixture, which was directly hydrogenated to saturate the new alkene. This sequence provided mixture M-**4** composed of 16 doubly tagged murisolins. A photograph of the TLC analysis of the mixture on silica gel shows the anticipated demixing into four spots (Figure 2c).[10] Flash column chromatography[11] sorted this mixture into four fractions based on the OEG tag from OEG1 (least polar) to OEG4 (most polar). Each of these four-compound mixtures was then demixed on a semipreparative FluoroFlash PF-C8 HPLC column[11] to provide all 16 individual tagged stereoisomers **4**. All pairs of peaks in the fluorous demixings were separated by 6 minutes or more, so quasi-isomer cross-contamination was not a problem. Even
Scheme 1. Preparation of the doubly tagged 16-component mixture and subsequent demixing. PMB = *para*-methoxybenzyl (CH$_2$C$_6$H$_4$OCH$_3$); HMDS = hexamethyldisilazide; DDQ = 2,3-dichloro-5,6-dicyano-1,4-benzoquinone; chrom. = chromatography.

Communications

though the tagged compounds **4** are now quasi-diastereomers,[10,12] the double demixing in Scheme 1 proceeded analogously to the model demixing of **1** in Figure 2.

Simultaneous removal of the PMB protecting group, the fluorous tag, and the OEG tag was effected by DDQ oxidation. The 16 stereoisomers of **5** were purified by semi-preparative HPLC to provide the target isomers on a scale of 1–3 mg.

The stereoisomer library was designed with four control compounds (the OEG1-tagged compounds with 4*R*,34*S* configuration), and these compounds were shown to be identical to authentic samples by spectroscopic and chiral HPLC analysis.[4e] The resulting data proved that the double demixing worked as expected and allowed the configurations of the remaining 12 new compounds to be assigned solely on the basis of their tag pairings and the associated demixing order. This identification was crucial because the ^{1}H and ^{13}C NMR spectra of many of the compounds in the library are identical with other members of this or the prior library. In our previous 16-compound library, we observed only six different ^{1}H and ^{13}C NMR spectra, and we predicted that six more sets of spectra were possible.[13] This predication was confirmed by observation of the other six spectra. Accordingly, none of the 32 possible diastereomers of murisolin is spectroscopically unique under standard NMR spectroscopic conditions.

Through combination of the known fluorous synthesis[4e] and the new double-tagging synthetic technique, we have prepared 28 of the 64 possible stereoisomers of murisolin. Although all the compounds were prepared from mixtures of intermediates, each isomer has been isolated in pure form and characterized by the usual spectroscopic and chromatographic means, including optical-rotation studies.

The ability to prepare 16 stereoisomers of a natural product as complex as murisolin in a single solution-phase synthesis (without splits) demonstrates the potential of these new mixture methods. Central to the potential of this technique is the newly introduced method of double tagging.

Gas-Phase Reactions

Bond- and Site-Selective Loss of H Atoms from Nucleobases by Very-Low-Energy Electrons (< 3 eV)**

*Sylwia Ptasinska, Stephan Denifl, Paul Scheier,
Eugen Illenberger,* and Tilmann D. Märk*

Excess charge deposited on gas-phase thymine (T) and uracil (U) by resonant attachment of low-energy (0–3 eV) electrons induces the loss of hydrogen, which exclusively takes place from the N positions. This bond selectivity can be made site selective by properly adjusting the electron energy. While electrons at 1 eV result in loss of hydrogen from N1, the reaction can be switched to loss of hydrogen from N3 by tuning the electron energy to 1.8 eV. We find that any energy (and charge) transfer is completely blocked when the N−H bond is replaced by N−CH$_3$. The present results have significant consequences for the exploration of the initial molecular processes leading to DNA damage, specifically in relation to recent observations of strand breaks in plasmid DNA induced by very low energy (0–4 eV) electrons.[1]

Recent gas-phase experiments on the isolated nucleobases (NBs) thymine (T), cytosine (C), adenine (A), guanine (G), and uracil (U) have demonstrated that they all effectively capture low-energy electrons in the range below 3 eV .[2–6] The generated transient negative ion (TNI) subsequently decomposes by the loss of a neutral hydrogen atom. The overall dissociative electron attachment (DEA) reaction can be expressed as Equation (1), in which NB$^{-\#}$ is the TNI of the

$$e^- \ (< 3\,eV) + NB \rightarrow NB^{-\#} \rightarrow (NB-H)^- + H \qquad (1)$$

corresponding nucleobase and (NB−H)$^-$ is the closed-shell anion formed by the ejection of a neutral hydrogen radical whereby the excess charge remains on the nucleobase. The reaction is effective already at energies below the threshold for electronic excitation (at subexcitation energies) and driven by the appreciable electron affinity of the (NB−H) radicals, which is in the range between 3 and 4 eV, dependent

on the site from which the hydrogen atom is ejected[2,6] (see below). Experiments with partly deuterated thymine[5] demonstrated that hydrogen abstraction occurs exclusively from the N sites, although H loss from the C sites is energetically accessible within that energy range. In the present contribution we demonstrate by means of methylated thymine and uracil that by properly adjusting the electron energy, the loss of hydrogen can be made even site selective with respect to the N1 and N3 positions. In light of strong efforts to induce cleavage of particular bonds by coherent laser control using tailored ultrafast pulses[7] the present result is very remarkable.

In addition to these basic aspects, our findings have direct implications for the molecular description of radiation damage in biological systems, more specifically, for DNA in living cells. It is well accepted that the main biological effect is usually not produced by the primary interaction of the high-energy quanta with the complex molecular network within a living cell, but rather by the action of the secondary species generated along the ionization track.[8] The interaction of these secondary species (ions, electrons, radicals) with DNA and its surrounding can cause mutagenic, genotoxic, and other potentially lethal DNA lesions such as single-strand breaks (SSBs) and double-strand breaks (DSBs).

Electrons are by far the most abundant of these secondary species and have an initial energy distribution extending to about 20 eV.[9,10] For the understanding of the effects of radiation in cells, it is therefore essential to investigate the action induced by these electrons on the vital cellular components such as water and DNA. In experiments directly exposing plasmid DNA on a surface to an electron beam of variable and well-defined energy, Boudaiffa et al.[11] showed that electrons below the ionization threshold can produce SSBs and DSBs. The same research group showed very recently that in plasmid DNA SSBs are produced at energies as low as the nominal zero-energy threshold of the electron beam and that the yield as a function of the energy exhibits a sharp peak at 0.8 ± 0.3 eV and a broader feature centered at 2.2 eV.[1]

On the other hand, the explicit molecular mechanism how low energy electrons damage DNA is yet unknown. Here we study in detail the processes that are initiated in isolated thymine (T) and uracil (U) by additional experiments on the compounds methylated at one of the N positions. These results have direct implications for the initial steps towards strand breaks in DNA.

The present investigations were performed in a crossed electron/molecule beams device previously described in detail.[12] The electron beam is formed in a hemispherical electron monochromator, operated at an energy resolution between 60 and 110 meV and an electron current of 5–8 nA. The molecular beam emanates from a source consisting of a temperature-regulated oven and a capillary. Evaporation at 385–400 K results in an effusive beam of intact molecules. Negative ions formed in the collision zone are extracted by a weak electric field toward the entrance of the quadrupole mass spectrometer and are detected by a single-pulse counting technique. The intensity of a particular mass-selected negative ion is then recorded as a function of the electron

energy. The electron energy scale is calibrated using the well-known Cl^-/CCl_4 signal near 0 eV. Methylated thymine and uracil were purchased from Sigma–Aldrich at a stated purity of 98 %.

Figure 1 shows the loss of a neutral hydrogen atom from thymine methylated at the N1 position (m1T) compared to

Figure 1. Plot of the ion yield of the fragment ion $(M{-}H)^-$ (loss of a hydrogen atom) from thymine methylated at the N1 position (m1T, ——) with that of thymine (T, - - - - -). E = electron energy.

the yield from (non-methylated) thymine (T), in both cases by measuring the yields of the corresponding anions $(M{-}H)^-$ [Eq. (1)]. For a detailed interpretation of these results we have to recall a previous study on thymine deuterated at the C positions[5] which demonstrated that hydrogen loss at sub-excitation energies occurs exclusively at the N positions. Figure 1 directly shows that in m1T hydrogen loss is completely suppressed below 1.4 eV, and we consequently assign the smooth feature peaking at 1.8 eV to H loss from the N3 position. H loss is hence not only exclusively restricted to the N−H bonds, it can further be made site selective by tuning the electron energy.

Accordingly, uracil methylated at the N3 position (m3U) shows a nearly complementary behavior (Figure 2); in other words, hydrogen loss primarily occurs within the sharp feature at 1.0 eV, which we consequently assign to H loss from the N1 site. It should be noted that the relative shape of the ion yields due to H loss in T and U are virtually identical (as is also apparent from the spectra for T and U in Figure 1 and Figure 2, respectively). While in m3U some intensity on the $(M{-}H)^-$ signal (N1−H loss) remains above 1.4 eV, that in m1T (N3−H loss) below 1.4 eV is completely suppressed. This complete site selectivity for N1−H loss is a result of the corresponding energy threshold, which we shall briefly consider.

The threshold E_0 for the DEA reaction [Eq. (1)] is given by Equation (2), in which D is the corresponding bond
$$E_0 = D - EA(M{-}H) \qquad (2)$$

Figure 2. Plot of the ion yield of the fragment ion $(M{-}H)^-$ (loss of a hydrogen atom) from uracil methylated at the N3 position (m3U, ——) with that of uracil (U, - - - - -). E = electron energy.

dissociation energy ((N-H)/(C-H)) and $EA(M{-}H)$ is the electron affinity of the radical formed by the loss of H from the particular site. E_0 refers to the energy threshold of the reaction at 0 K. The experimental threshold energy (the appearance energy of $(M{-}H)^-$) can be different from E_o as a result of two main effects: 1) the transient negative ion is formed by means of a Franck–Condon transition, which can be viewed as the activation energy for the DEA reaction with the tendency that the fragment ion is observed above E_0; and 2) the internal energy of the target molecule tends to lower the appearance energy.

Since there are no experimental numbers available for the different C−H and N−H bond dissociation energies in the nucleobases, we refer to recent high-level ab initio studies on T and U. With the G2MP2 method the following data were calculated for thymine:[6] D(N1-H) = 4.4 eV/EA(T-H) = 3.5 eV; D(N3-H) = 5.8 eV/EA(T-H) = 4.5 eV; D(CH$_2$-H) = 4.5 eV/EA(T-H) = 2.9 eV; D(C6-H) = 4.9 eV/EA(T-H) = 2.7 eV. From that the following energetic thresholds are obtained: E_0(N1-H) = 0.9 eV, E_0(N3-H) = 1.3 eV, E_0(CH$_2$-H) = 1.6 eV, and E_0(C6-H) = 2.2 eV.

In U the corresponding numbers are (also calculated with the G2MP2 method[2]): D(N1-H) = 4.4 eV/EA(U-H) = 3.6 eV; D(N3-H) = 5.4 eV/EA(U-H) = 4.0 eV; D(C5-H) = 5.2 eV/EA(U-H) = 2.5 eV; D(C6-H) = 5.0 eV/EA(U-H) = 2.8 eV leading to the following energy thresholds: E_0(N1-H) = 0.8 eV, E_0(N3-H) = 1.4 eV, E_0(C5-H) = 2.7 eV, and E_0(C6-H) = 2.2 eV.

On this basis, we arrive at the following conclusions:
a) Although H loss from the C sites is energetically accessible above 1.6 eV it is not observed within the entire resonant feature extending to more than 3 eV.
b) At energies below 1.4 eV the loss of H occurs exclusively from the N1 position, since the competing channel (loss from N3) is energetically only accessible above 1.4 eV.
c) At energies above 1.4 eV hydrogen loss takes place from both the N1 and N3 positions.

The fact that H loss from N1 occurs preferentially at low energy (1 eV) with respect to the range above 1.4 eV may be due to the different mechanisms contributing to reaction (1). Owing to the large dipole moment of uracil (≈ 4.5 D), it was recently proposed that a dipole-bound (DB) state could act as a doorway state for DEA.[13] Supported by ab initio calculations, the sharp peak at 1 eV was assigned as a dipole-bound vibrational Feshbach resonance (exciting three quanta of the N1-H stretch mode), which couples to the repulsive σ* (N1-H) valence state. The underlying broader feature would then be due to the π_2* shape resonance,[14] which can lead to DEA through vibronic mixing of the π states with the repulsive σ* anion states. The overall DEA reaction is then more effective via the initial DB state in comparison to the initial π* shape resonance leading to the dominant peak at 1 eV.

The fact that the loss of CH_3 is not observed when N1−H is replaced by N1−CH_3 has significant consequences for the molecular description of strand breaks by low-energy electrons. In a recent theoretical study[15] (modeling a section of DNA containing cytosine, the sugar ring, and the (neutralized) phosphate group), a low-lying anionic curve was predicted which connects the initial π* anion state of the base to a σ* state in the backbone. An electron captured by a DNA base may thereby be transferred to the backbone, which may lead to rupture of the C−O bond between the phosphate and the sugar. In DNA the N1 position is coupled to the sugar moiety, and according to the present findings transfer of charge and energy via the N1−C bond will not take place. This is also strongly supported by very recent gas-phase experiments[16] on thymidine (representing thymine coupled to a sugar moiety) which definitely exclude the transfer of electrons initially localized on thymine to the sugar moiety.

We therefore conclude that the direct migration of the excess charge from the π* anions of the nucleobases to the DNA backbone can be excluded as a mechanism leading to strand breaks. Instead electrons near 2 eV induce H loss at N3, which, in a biological environment, may initiate further reactions eventually leading to strand breaks. In addition, experiments on isolated deoxyribose show effective low-energy DEA processes.[17] If these DEA reactions are preserved for deoxyribose coupled within the DNA network, such processes will be of considerable importance for strand breaks.

Communications

Prominent examples in nature are the vision process, phototropism, photomorphogenesis, and circadian rhythms where the response to light is realized by a variety of enzymatic photoreceptors, including rhodopsins, phototropins, phytochromes, cryptochromes, and BLUF domains.[2] All of these photoreceptors rely on a functional chromophore as the photoactive element, which initiates a highly sophisticated signaling cascade with, for example, an electron transfer or a photochromic reaction as the primary step after light absorption.

In studying these biological systems chemists have recognized the superiority of signal processing by light in terms of velocity and efficiency, and they have strived to use light-driven and -controlled processes in artificial chromophoric ensembles at the molecular level for technological purposes such as molecular electronics and photonics, and artificial photosynthesis. Especially photochromic compounds have gained strong popularity here, for instance, in high-density optical data storage and multimode photoswitching.[3] Using light as a trigger medium and as a tool for readout, the latter typically by fluorescence, offers the advantages of the non-destructive control and processing of information. However, up to now, only a few systems that show photochromically modulated luminescence have been realized, and the efficiency of the modulation and the overall brightness of the systems is often rather poor.[4] Furthermore, to our knowledge, a photochromic ensemble in which the switching states are photocontrolled but the luminescence readout signal can be sampled by either optical or electrochemical excitation, i.e., by photo- or electrochemiluminescence (ECL), has not yet been reported. The latter feature would be a key link between OLEDs (organic light-emitting diodes) and conventional optical-gate technologies.

We realized our aim of a bright photochromic luminescent switch that can be either photo- or electrochemically excited by combining the photochromic system dihydroazulene/vinylheptafulvene (DHA/VHF; Scheme 1a) with the boron dipyrromethene (BDP) fluorophore in dyad 1 (Scheme 1b; for synthetic details see the Supporting Information). The DHA/VHF system shows UV/Vis photochromism that is particularly suitable for our present purposes and has been employed successfully in various molecular switches.[5] The photochromic conversion of the alternant π system DHA into the non-alternant VHF occurs by means of a 10-electron rearrangement of the carbon framework, which strongly influences the electronic properties of the substituents attached to the photochromic system.[6] The BDP chromophore provides favorable signaling features, as BDPs show green emission of high brightness and are also fluorophores that display photogenerated as well as electrochemically generated luminescence.[7] Furthermore, the spectral and redox properties of both subunits complement each other well for the intended performance.

UV/Vis-spectrophotometric measurements of **1a** in chloroform clearly reveal the independence of both subchromophores, with main bands centered at 376 nm for the DHA and 527 nm for the BDP moiety (Table 1, Figure 1). The substantial difference between the lowest energy absorptions of DHA and BDP guarantees exclusive excitation of the
Scheme 1. The photochromic system dihydroazulene/vinylheptafulvene DHA/VHF (a) is combined with the fluorophore boron dipyrromethene (BDP) to give dyads **1a** and **1b** (b). The nonswitchable derivative **2** and the model fluorophore **3** (c) were used in control experiments.

polarity of the solvent does not alter the spectroscopic properties significantly (Table 2). Furthermore, as the potential separation of BDP reduction and oxidation ($\Delta E_{ox-red} \approx 2.30$ mV) is also sufficient to populate the excited state of the BDP in **1a** electrochemically, the dyad shows electro-

	CH_2Cl_2[d]	0.27	1.72
	Et_2O[e]	0.67	4.13

[a] Relative to fluorescein 27 in 0.1 N NaOH (0.90 ± 0.03),[14] $\pm 5\%$ (**1a**, **2**) $\pm 15\%$ (**1b**). [b] At 298 K, ± 0.003 ns. [c] $\lambda_{abs}/\lambda_{em} = 523/536$ nm. [d] $\lambda_{abs}/\lambda_{em} = 526/540$ nm. [e] $\lambda_{abs}/\lambda_{em} = 524/536$ nm.

chemiluminescence (ECL) (Figure 2, discrete signals).[8] The strong fluorescence emission and electrochemically generated luminescence let us thus define **1a** as the ON state of the system.

Irradiation of **1a** at 366 nm induces the uniform photoconversion to **1b**, which is apparent from the isosbestic points, the decrease of the band at 376 nm, and the appearance of a new band at 476 nm in the absorption spectrum (Figure 1). The BDP absorption remains virtually unaffected, stressing the fact that both modules of dyad **1b** are also decoupled in the ground state. Again, cyclic voltammetry provides support: the BDP reduction ($E_{1/2} = -1610$ mV vs. Fc⁺/Fc) and oxidation ($E_{1/2} = +630$ mV vs. Fc⁺/Fc) are negligibly shifted relative to values for **1a**. Moreover, the typical irreversible reduction ($E_p = -1325$ mV vs. Fc⁺/Fc) and oxidation ($E_p = +760$ mV vs. Fc⁺/Fc) of the VHF unit of **1b** are found at far lower potentials than those of DHA in **1a**.[3c,5d] Photoconversion of **1a** to **1b** occurs with a quantum yield of ca. 0.01. This is quite low in comparison to other DHA/VHF systems and can be attributed to an overlap of the oscillator-weak $S_2 \leftarrow S_0$ transition localized on BDP[7e] and the intense $S_1 \leftarrow S_0$ transition of DHA. Furthermore, analysis of the fluorescence excitation spectra revealed that despite the very weak fluorescence of DHA at room temperature ($\Phi_f \approx 10^{-4}$),[6a] energy transfer from DHA to BDP might play an additional, competitive role here. The OFF state **1b** is thermally reconverted to **1a** with $t_{1/2} = 350$ min at room temperature.

In contrast to **1a**, **1b** shows a strongly reduced, typical green BDP emission upon excitation at $\lambda > 500$ nm.[9] Φ_f drops remarkably from 0.67 to 0.013 (Figure 3) and the fluorescence

Figure 3. Change of the emission intensity during the photoreaction of **1a** ($c = 1 \times 10^{-6}$ M in CH_2Cl_2) to **1b** with excitation of the BDP at 505 nm. Inset: Reversibility of the switch as shown by several cycles of irradiation and back-reaction.

lifetime is shorter (Table 2). The quenching mechanism can be rationalized in terms of intramolecular fluorescence resonance energy transfer (FRET). The broad absorption spectrum of the VHF fragment, which stretches well beyond 550 nm,[6] and the narrow emission band of the BDP unit, centered between 530 and 540 nm, show considerable overlap. Analysis of the FRET process and its features yields a spectral overlap integral $J = 2.6 \times 10^{14}$ M⁻¹ cm⁻¹ and an effective interaction radius $R_0 = 39$ Å.[10] Assuming that no other processes contribute significantly to the deactivation of the excited state of the BDP, we calculate the donor–acceptor distance of the FRET partners to be 15.1 Å,[11] which

Communications

corresponds within ± 0.2 Å to the distance between the BDP core and the center of the VHF unit as obtained for the ground-state geometry optimized by semiempirical AM1 calculations. Moreover, the absence of solvatokinetic behavior of **1b**, that is, that the quenching process is not significantly accelerated upon increasing the polarity of the solvent, led us to assume that photoinduced electron transfer (PET) plays a negligible role here. Control experiments with **2**, where the DHA/VHF moiety has been replaced with a nonswitchable dihydro-VHF group that isolates the *p*-dicyanovinylbiphenyl from the cycloheptatrienyl fragment (Scheme 1c), support these findings. The spectral characteristics of the BDP fluorophore in **2** are very similar to those of **1a/1b** (Table 2). Furthermore, the fluorescence of **2** in nonpolar solvents is as bright as that of **1a**. Upon increasing solvent polarity, a slight quenching of the BDP emission in **2** is observed. The latter is apparently connected to the moderate PET activity of the *para*-cyanovinylbiphenyl group,[12] emphasizing the fact that the entire VHF unit is mandatory for the performance of **1b**. As expected, after the photoreaction to **1b**, the latter remains ECL-silent, and **1b** thus represents the OFF state of the system.

In conclusion, we have presented a photochromic pair of BDP-DHA/VHF dyads as a versatile all-optically controllable switch, for which irradiation with near-UV light serves as the input and luminescence at 540 nm as the output. Furthermore, the readout signal of the ON state **1a** can be generated by conventional photoexcitation as well as electrochemically; in other words, the system shows photogated electrochemiluminescence. Light-induced conversion of **1a** to **1b** is accompanied by a 50-fold decrease of luminescence, defining the system as a true ON/OFF photoswitch. We have demonstrated here that the outstanding photo- and electrochemical properties of both modules, DHA/VHF and BDP, can be combined synergistically for highly interesting all-optical photochromic molecular switches. The ECL findings also indicate potential applications in gated organic light-emitting diodes (OLEDs).[13]

[8] The ECL measurements were carried out with an unstirred solution ($c = 1 \times 10^{-3}$ M; supporting electrolyte: 0.1M Bu$_4$NPF$_6$) in an electrochemical cell: Stefan Hien, PhD Thesis, University of Regensburg, **1995**. The potential was switched with alternation between the oxidation and reduction potentials (see inset of Figure 2, electrochemical switching frequency 1 s^{-1}, scan rate of the spectrometer: 240 nm min^{-1}). The spectrum consisting of discrete signals is the result of the relatively slow switching frequency. The bathochromic shift of ca. 20 nm between the fluorescence and the ECL spectrum is well known and can be attributed to reabsorption effects as a result of the higher dye concentration used in the ECL experiment and the different dielectric properties of the supporting electrolyte.

[9] VHF was reported to be entirely nonfluorescent, see ref. [6a].

[10] For a description of the analysis of FRET processes, see P. Wu, L. Brand, *Anal. Biochem.* **1994**, *218*, 1–13. The following equations apply: $k_{FRET} = (1/\tau_D)(R_0/r)^6$ with r being the distance between the FRET partners and τ_D the lifetime of the unperturbed donor **3** (5.15 ns in CH$_2$Cl$_2$). $R_0^6 = 8.875 \times 10^{-5}(\kappa^2 \Phi_D J/n^4)$ mit $J = \int F_D(\lambda)\varepsilon_A(\lambda)\lambda^4 d\lambda$, where J is the overlap integral between the fluorescence of the donor (i.e. **3** in CH$_2$Cl$_2$) and the absorption of the acceptor, obtained after deconvolution of the absorption spectrum of **1b**, $\kappa^2 = 2/3$ is a geometry factor for random orientation of the two subunits, Φ_D is the fluorescence quantum yield of the unperturbed donor (here, for model **3**: $\Phi_D = 0.95$ in CH$_2$Cl$_2$), and n is the refractive index of the solvent.

[11] If no other deactivation processes are present, k_{FRET} can be also expressed as $k_{FRET} = (1/\tau_{DA}) - (1/\tau_D)$ with τ_{DA} being the fluorescence lifetime of the FRET ensemble. By combining the equations in refs.[10] and [11] one may calculate a value for r.

Rhodium-Mediated Formation of Peroxides from Dioxygen: Isolation of Hydroperoxo, Silylperoxo, and Methylperoxo Intermediates[**]

Marcel Ahijado, Thomas Braun,* Daniel Noveski, Nikolaus Kocher, Beate Neumann, Dietmar Stalke, and Hans-Georg Stammler

Peroxo and hydroperoxo transition-metal complexes have been suggested to play a key role as intermediates in several oxygenation processes with molecular oxygen, including reactions mediated by cytochrome P450, the catalytic oxidation of olefins, and the generation of peroxides.[1,2] A hydroperoxo ligand can also be found in oxyhemerythrin which is produced when dioxygen is bound at the nonheme oxygen carrier hemerythrin.[3] The oxygen atoms of η^2-bound peroxo ligands at electron-rich transition metals are usually nucleophilic.[4] This is reflected in the formation of hydrogen peroxide or trityl peroxide from η^2-peroxo complexes and the corresponding electrophilic sources (trityl = triphenylmethyl).[4–6] Hydroperoxo and alkylperoxo complexes are thought to be intermediates in these reactions, but there is extremely little precedent on their identification.[4,7] The conversion of coordinated oxygen into an OOR ligand (R = alkyl, H) can be considered to be one of the key steps in these transformations, but even model reactions for the formation of oxygen-derived hydroperoxo and alkylperoxo species are very sparse.[2a,4,7–9] Stahl et al. showed that protonation of palladium η^2-peroxo species, bearing N-heterocyclic carbene ligands, with acetic acid leads to η^1-hydroperoxo compounds, which can be further protonated to give hydrogen peroxide.[7]

The presence of the η^1-hydroperoxo complex and of its ^{18}O-labeled isotopologue has been confirmed by comparison of the mass spectrometric data with simulated spectra. Otsuka et al. reported that the reaction of [Pt(O$_2$)(PR$_3$)$_2$] (R = Ph, Cy) with BrCPh$_3$ leads to the tritylperoxo complexes [PtBr-(OOCPh$_3$)(PR$_3$)$_2$].[4] These complexes can be converted into Ph$_3$COOCPh$_3$ and are presumably stabilized kinetically by the steric bulk of the trityl group. Moro-oka et al. found that a rhodium η^2-peroxo complex can be protonated with pyrazole.[9] The hydroperoxo species obtained is stabilized by a hydrogen bond between a pyrazole ligand and the β-oxygen in the hydroperoxo ligand. No further reactivity of this compound has been reported.

In this communication we report on the sequential conversion of molecular oxygen into hydrogen peroxide as well as into silyl and methyl peroxides via η^1-hydroperoxo, η^1-silylperoxo, and η^1-methylperoxo complexes. Not only the isolation of the intermediate species bearing an OOSiMe$_3$ or OOMe ligand is unprecedented, but also η^1-silylperoxo and η^1-methylperoxo complexes have for the first time been unambiguously characterized by IR spectroscopy and X-ray crystallography. The stabilizing effect of a tetrafluoropyridyl ligand bound at rhodium[10] presumably allows the isolation of the intermediates.

Exposure of a hexane solution of the tetrafluoropyridyl complex 1[10] to air or oxygen slowly leads to the generation of the dioxygen compound 2a within hours (Scheme 1). Similarly, treatment of 1 with ^{18}O$_2$ gives the peroxo complex *trans*-[Rh(^{18}O$_2$)(4-C$_5$F$_4$N)(CN*t*Bu)(PEt$_3$)$_2$] (2b). Note that Selke et al. reported the formation of the complex *trans*-[Rh-(SC$_6$F$_5$)(O$_2$)(CO)(PPh$_3$)$_2$], which is unstable at room temperature, using singlet oxygen.[11] In contrast, the formation of 2a and 2b is spin-forbidden and requires a triplet–singlet surface crossing on the reaction coordinate.[12] The ^{19}F NMR spectrum of 2a displays four signals for the tetrafluoropyridyl ligand indicating hindered rotation (Table 1).[10] The rhodium–phosphorus coupling constant of 87 Hz in the ^{31}P NMR spectrum suggests the formation of a rhodium(III) complex. In the IR spectrum of 2a an absorption band at 852 cm^{-1} can be detected. The band shifts to 805 cm^{-1} for the ^{18}O-labeled isotopologue 2b and can be assigned unequivocally to the O–O stretching vibration of the η^2-peroxo ligand.[9,13] The difference $\Delta\tilde{\nu} = 47$ cm^{-1} is fully consistent with a simple model for a diatomic harmonic oscillator.[14]

Figure 1 shows the molecular structure of 2a determined by X-ray crystallography.[15] The molecule exhibits a distorted octahedral structure, if the oxygen is treated as a bidentate ligand. Alternatively if the dioxygen is treated as occupying a single coordination site, the structure is approximately trigonal-bipyramidal with two phosphine ligands occupying the axial sites. The O–O distance of 1.452(3) Å is similar to the corresponding bond length found in *cis*-[Rh(CF$_3$)(O$_2$)-(CNXy)$_2$(PPh$_3$)] (1.438(3) Å; Xy = 2,6-Me$_2$C$_6$H$_3$) and is also in the same range as these observed in other rhodium η^2-peroxo complexes.[16] Treatment of complex 2a with a solution of HCl in Et$_2$O affords the dichloro compound 4 and H$_2$O$_2$ (Scheme 1). Low-temperature NMR experiments at 213 K reveal the formation of 3 as the initial product. A broad signal in the ^{1}H NMR spectrum at $\delta = 7.35$ ppm can be attributed to

Communications

Scheme 1. The synthesis and reactivity of rhodium peroxo compounds. **2b**, **5b**, and **6b** are ^{18}O isotopologues of **2a**, **5a**, and **6a**, respectively.

Table 1: Selected NMR spectroscopic data.[a]

2a: ^{19}F NMR (C_6D_6): $\delta = -98.1$ (m, 1F), -98.6 (m, 1F), -107.6 (m, 1F), -117.3 ppm (m, 1F); ^{31}P NMR (C_6D_6): $\delta = 24.6$ ppm (d, $^1J_{P,Rh} = 87$ Hz).

3:[b] ^{1}H NMR ([D_8]toluene): $\delta = 7.35$ ppm (br. s, OOH); ^{19}F NMR ([D_8]toluene): $\delta = -96.1$ (m, 1F), -97.8 (m, 1F), -115.3 (m, 1F), -120.4 ppm (m, 1F); ^{31}P NMR ([D_8]toluene): $\delta = 17.8$ ppm (d, $^1J_{P,Rh} = 87$ Hz).

4: ^{19}F NMR ([D_8]toluene): $\delta = -95.3$ (m, 1F), -97.6 (m, 1F), -110.3 (m, 1F), -112.3 ppm (m, 1F); ^{31}P NMR ([D_8]toluene): $\delta = 15.3$ ppm (dd, $^1J_{P,Rh} = 80$, $^4J_{P,F} = 4$ Hz).

5a: ^{19}F NMR ([D_8]toluene): $\delta = -97.8$ (m, 1F), -99.3 (m, 1F), -114.2 (m, 1F), -118.1 ppm (m, 1F); ^{31}P NMR ([D_8]toluene): $\delta = 18.7$ ppm (d, $^1J_{P,Rh} = 87$ Hz); ^{29}Si NMR (119.2 MHz, [D_8]toluene): $\delta = 26.5$ ppm (s).

6a: ^{1}H NMR ([D_8]toluene): $\delta = 3.64$ ppm (s, 3H, OOCH$_3$); ^{19}F NMR ([D_8]toluene): $\delta = -77.5$ (s, 3F, CF$_3$), -95.9 (m, 1F, CF), -97.9 (m, 1F, CF), -115.2 (m, 1F, CF), -120.0 ppm (m, 1F, CF); ^{31}P NMR ([D_8]toluene): $\delta = 20.4$ ppm (dd, $^1J_{P,Rh} = 86$, $^4J_{P,F} = 4$ Hz).

7: ^{1}H NMR ([D_8]THF): $\delta = 3.69$ ppm (s, 3H, OOCH$_3$); ^{19}F NMR ([D_8]THF): $\delta = -75.7$ (s, 3F, CF$_3$), -94.7 (m, 1F, CF), -96.0 (m, 1F, CF), -110.1 (m, 1F, CF), -116.0 ppm (m, 1F, CF); ^{31}P NMR ([D_8]THF): $\delta = 12.8$ ppm (d, $^1J_{P,Rh} = 85$ Hz).

[a] Recorded at 300 K; Measurement frequencies: ^{1}H NMR 500 MHz, ^{19}F NMR 470.4 MHz, ^{31}P NMR 202.4 MHz. [b] Recorded at 213 K.

Figure 1. Molecular structure of **2a** in the crystal (ORTEP plot, ellipsoids at the 50% probability level). Selected distances [Å] and angles [°]: Rh1–O1 2.0332(16), Rh1–O2 2.0147(16), O1–O2 1.452(3); O1-Rh1-O2 42.05(7), C13-Rh1-O2 144.08(8), C18-Rh1-O2 110.63(8).

the hydroperoxo ligand. When **2a** is treated with DCl instead of HCl the resonance is not present. At 273 K complex **3** reacts with more HCl to give H_2O_2 and **4**. However, even when no further HCl is present, the slow generation of **2a** and **4** is observed. This indicates that the formation of **3** from **2a** and HCl is reversible. The latter can react with more **3** to yield **4** and H_2O_2.

Compound **3** is unstable above 273 K, even in the solid state. However, crystals of **3** suitable for X-ray crystallog-
raphy were obtained from a THF/hexane solution at 193 K.[15] The molecular structure depicted in Figure 2 reveals that the η^1-bound hydroperoxo ligand is located in the *trans* position to the isocyanide ligand. Intermolecular hydrogen bonding of the hydroperoxo ligands also gives strong evidence for the presence of the OOH group. These interactions result in the formation of dimers with an intermolecular oxygen–oxygen separation of 2.680 Å (Figure S1, Supporting Information). The intramolecular oxygen–oxygen distance of 1.488(3) Å is greater than that found in complex **2a** but close to the value found for H_2O_2 (1.461(3) Å).[17] So far, only very few transition-metal complexes with an η^1-OOH ligand have been structurally characterized, for example, the rhodium compounds [(η^5-C$_5$Me$_5$)Ir(μ-pz)$_3$Rh(OOH)(dppe)][BF$_4$] and [Tp^{iPr}Rh(OOH)(pz)(pzH)] (pzH = pyrazole, dppe = 1,2-bis-(diphenylphosphanyl)ethane, Tp^{iPr} = hydrotris(3,5-diisopropylpyrazolyl)borato).[9,18]
Figure 2. Molecular structure of **3** in the crystal (ORTEP plot, ellipsoids at the 50% probability level). Selected distances [Å] and angles [°]: Rh1–O1 2.025(2), O1–O2 1.488(3); Rh1-O1-O2 110.31(17).

The reactions of **2a** and **2b** with Me₃SiCl at 213 K furnished the silylperoxo complexes **5a** and **5b**, respectively (Scheme 1). After warming up to 273 K the slow generation of **4** and bis(trimethylsilyl) peroxide was observed. The latter was identified by comparison of the NMR data with those of an authentic sample. Compound **5a** was characterized by NMR and IR (Table 1). Convincing evidence for the presence of a OOSiMe₃ unit is given by an absorption band at 901 cm⁻¹ (Figure 3).[19] The signal shifts to 884 cm⁻¹ for the isotopo-

Figure 3. Part of the IR spectra of **5a** (——) and **5b** (- - - -).

logue **5b**. For the configuration at rhodium in **5a** and **5b**, we assign a *trans* arrangement of the isocyanide and the silylperoxo ligand, as it was found for **3**. To our knowledge, complexes **5a** and **5b** are the first transition-metal silylperoxo compounds that have been characterized.[20]

Treatment of a toluene solution of **2a** and **2b** with MeOTf yields the methylperoxo compounds **6a** and **6b**, respectively. A weak absorption band at 1004 cm⁻¹ in the IR spectrum of **6b** can be assigned tentatively to the ¹⁸O¹⁸OMe unit. The high frequency might be attributed to a mixing of the O–O stretch and a bending vibration. The corresponding absorption band

in **6a** seems to be covered by a very strong broad band, which can be attributed to the triflate ligand at 1025 cm⁻¹.

The proposed structure of **6a** is further supported by its reactivity. Thus **6a** reacts smoothly with pyridine to give the cationic methylperoxo complex **7**. The structure of **7** was determined by X-ray crystallography.[15] A view of the geometry of the cation is depicted in Figure 4. As was found

Figure 4. Structure of the cation in **7** in the crystal (ORTEP plot, ellipsoids at the 50% probability level). Selected distances [Å] and angles [°]: Rh1–O1 2.0196(14), O1–O2 1.479(2), O2–C18 1.412(3); Rh1-O1-O2 111.55(10), O1-O2-C18 104.32(16).

for the hydroperoxo group in **3**, the methylperoxo ligand is located in the *trans* position to the isocyanide. We assume a comparable configuration at rhodium for **6a**. The oxygen–oxygen distance of 1.479(2) Å is similar to the O–O bond length in **3**. We note that Moro-oka et al. recently reported the crystal structure of a palladium complex with a {PdOO*t*Bu} unit.[18e] The structural data of two platinum compounds with OO*i*Pr and OO*t*Bu ligands were published earlier.[21] Although there are indications for the existence of transition-metal methylperoxo complexes mainly based on UV and NMR data, to our knowledge in none of these compounds has the OOMe moiety been identified by IR data or X-ray crystallography.[22]

Complex **6a** can also act as a source for organic peroxides. Thus, treatment of a solution of the triflato compound **6** with an excess HCl leads to complex **4** and the peroxide MeOOH, which was identified by comparison of its ¹H and ¹³C NMR data with those of an authentic sample. The conversion is quantitative according to the NMR data. We assume that the reaction proceeds via the triflato complex *trans*-[Rh(Cl)-(OTf)(4-C₅F₄N)(CN*t*Bu)(PEt₃)₂], which is readily converted into the dichloro compound **4**.

In conclusion, a η¹-hydroperoxo complex and for the first time η¹-silylperoxo and η¹-methylperoxo species have been characterized unambiguously by IR spectroscopy or X-ray crystallography. The compounds are generated quantitatively according to the NMR data and have been isolated as intermediates in the rhodium-mediated formation of peroxides from molecular oxygen. The selective synthesis of **3**, **5a**,

Communications

and **6a** discloses a route for the controlled preparation of alkyl hydroperoxides and possibly dialkyl peroxides or alkylsilyl peroxides. We believe that the stabilizing effect of the tetrafluoropyridyl ligand with its π-acceptor properties might be the main reason for the stability of the rhodium complexes bearing an η^1-bound peroxo unit.[10] This stability also makes it possible to control the reactivity of the peroxo species and accounts for the selectivity of the reactions. It is intriguing that despite the presence of the phosphines and the anionic carbon ligand the reactions proceed smoothly. Neither the phosphines nor the metal-bound tetrafluoropyridyl ligand are oxygenated.

Concise Syntheses of Meridianins by Carbonylative Alkynylation and a Four-Component Pyrimidine Synthesis**

Alexei S. Karpov, Eugen Merkul, Frank Rominger, and Thomas J. J. Müller*

Dedicated to Professor Franz Effenberger on the occasion of his 75th birthday

Pyrimidines constitute an important class of heterocycles,[1] and many of the 2,4-substituted pyrimidines have been recognized to be pharmaceutically highly active.[2] Particular attention has focused on meridianins A–G (indole alkaloids with a 2-aminopyrimidyl substituent which were recently isolated from the *Aplidium meridianum*, an ascidian collected in the South Atlantic; Scheme 1),[3] since they inhibit numerous protein kinases in a low micromolar range.[4] They are

A:	R^1 = OH, R^2 = H, R^3 = H, R^4 = H
B:	R^1 = OH, R^2 = H, R^3 = Br, R^4 = H
C:	R^1 = H, R^2 = Br, R^3 = H, R^4 = H
D:	R^1 = H, R^2 = H, R^3 = Br, R^4 = H
E:	R^1 = OH, R^2 = H, R^3 = H, R^4 = Br

Communications

related structurally to the variolins, alkaloids isolated from the Antarctic sponge *Kirkpatricka varialosa*[5] which display antitumor and antiviral activity. Among these alkaloids, variolin B is the most biologically active compound. It shows the inhibition of the growth of the P388 tumor cell line and is also active against *Herpes simplex* and the polio virus. In contrast, variolin D is completely inactive, emphasizing the importance of the 2-aminopyrimidine substituent for the biological activity.

Three approaches to meridianins and variolins are currently known. While the first two routes apply Stille[6,7] or Suzuki couplings[8] of suitable indole stannanes or boronates and halopyrimidine derivatives, the third more classical approach is based upon a Bredereck synthesis of the 2-aminopyrimidine moiety via β-enaminones.[9,10] Just recently, we have developed a straightforward consecutive one-pot three-component access to pyrimidines by means of a modified Sonogashira coupling of acid chlorides with terminal alkynes and the subsequent transformation of alkynone intermediates with amidinium salts.[11] Therefore, our diversity-oriented methodological approach to meridianin and variolin alkaloids suggests the use of trimethylsilylynones (TMS-ynones) as versatile synthetic equivalents of β-ketoaldehydes for the construction of the 2-aminopyrimidine ring (Scheme 2). Here, we report on the development of carbon-

Scheme 2. Retrosynthetic analysis of meridianins and variolins.

ylative alkynylation to give TMS-alkynones, its application to concise two-step syntheses of meridianins starting from 3-iodoindole derivatives, first kinase inhibition tests of meridianins, and a new one-pot four-component syntheses of pyrimidines.

Our initial route was based upon our established approach to TMS-alkynones[11] starting from acid chlorides. But we soon found that all attempts to prepare the required N-protected indolyl acid chlorides by standard Friedel–Crafts acylation[12] were less promising. Only the phenylsulfonyl group could withstand these drastic, extremely acidic conditions; however, it was not really compatible for the

subsequent coupling-cyclocondensation sequence. We therefore readjusted our retrosynthetic analysis and decided to conceptually switch to a highly convergent carbonylative coupling-cyclocondensation approach. A literature survey on carbonylative alkynylation revealed that either high pressures of carbon monoxide[13] are necessary, or for reactions under normal pressure a twofold excess of relatively precious aryl iodides is required.[14] Recently, Mori reported a practical approach to ynones by carbonylative coupling using 2 equiv of aqueous ammonia as a base.[15] However, our experience in the preparation of TMS-ynones by Sonogashira coupling suggested that we switch the base from ammonia to triethylamine in slight excess for the carbonylative Sonogashira coupling.

Upon reaction of *para*-anisyl iodide (**1a**) and 1-hexyne (**2a**) in THF at room temperature under 1 atm of carbon monoxide (a CO-filled balloon attached to the reaction vessel) and in the presence of 2 equiv of triethylamine and catalytic amounts of [Pd(PPh$_3$)$_2$Cl$_2$] and CuI the alkynone **3a** was obtained in 82% yield [Eq. (1)].
For carbonylative alkynylations with indoles *tert*-butoxycarbonyl(Boc)-protected 3-iodoindole derivatives **4** were identified to be the substrates of choice. Four representative indoles were prepared in a two-step sequence of iodination (79–99% yield) and subsequent Boc protection of the indole nitrogen (72–86% yield).[16,17] However, the Pd catalyst system had to be optimized for sufficient conversion of the iodoindoles **4** into the desired TMS-alkynones **5** [Eq. (2), Table 1].

The structures of the TMS-alkynones **5** were unambiguously supported by spectroscopic (^{1}H, ^{13}C and DEPT, COSY, HETCOR, and HMBC NMR experiments, IR, UV/Vis, mass spectrometry) and combustion analyses, and in addition by an X-ray structure analysis compound of **5d** (Figure 1).[18,19]

The standard catalyst system (5% [Pd(PPh$_3$)$_2$Cl$_2$]) appeared to be most efficient only for the pyrrolopyridine **4d** (entry 7), whereas in all other cases a mixture of 0.05 equiv of [Pd(PPh$_3$)$_2$Cl$_2$] and 0.01 equiv of [Pd(dppf)Cl$_2$] accelerated the catalysis. However, when [Pd(dppf)Cl$_2$] alone was applied the catalyst, the desired alkynone became the minor product and the formation of the TMS-ethynylindole dominated (entry 4). To date, the mechanistic influence of this peculiar catalyst cocktail on the selectivity of the carbonylative alkynylation is not clear. Apparently the electronic nature of the iodo substrates in conjunction with the Pd catalyst precursor plays a key role and will be the subject of thorough investigations. As a consequence of different rates in oxidative addition and from a methodological point of view, the presence of bromo substituents (entries 3 and 5) does not interfere with the regioselective carbonylative alkynylation at the carbon–iodine bond. Most critical, however, was the
$$(2)$$

[a] Reaction conditions: 3-iodoindole **4** (1.0 equiv), TMS-acetylene (1.5 equiv; 0.1 M in THF), triethylamine (1 equiv), CuI (0.02 equiv), and the Pd catalyst were stirred at room temperature for 48 h. [b] Yields refer to yields of compounds **5** isolated after flash chromatography on silica gel to be ≥95% pure as determined by NMR spectroscopy and elemental analysis and/or HRMS. [c] 56% of the alkynylation product.

application of only one equivalent of triethylamine as an HI-scavenging base.

With this three-component carbonylative alkynylation in hand, we set out to conclude the meridianin syntheses. First attempts to conduct the meridianin syntheses in a consecutive one-pot fashion failed, in particular, since the choice of the ideal solvent system for the concluding cyclocondensation step interferes with the carbonylative coupling step. Therefore, a separation of carbonylative coupling and cyclocondensation seemed to be reasonable. The TMS-alkynones **5** were treated with a 5M aqueous solution of guanidine (2.5 equiv) and Na$_2$CO$_3$ (1 equiv) at 80°C in a 1:1 mixture of tBuOH/CH$_3$CN, and the desired natural products **6** were isolated in 59–78% yield (Scheme 3). Most surprisingly, the pyrimidine formation occurs with the concomitant cleavage of both TMS and Boc groups. Interestingly, the use of CH$_3$CN/MeOH as a solvent mixture led to the predominant formation of a double Michael addition product of methanol.

This new two-step synthesis of meridianins and related variolins is not only apparently very general but also extremely concise. If one considers that the iodoindole derivatives can be prepared in another two steps from indole derivatives, the overall yield of the four steps

Figure 1. X-ray crystal structure of **5d**; thermal ellipsoids at 50% probability. Selected bond lengths [Å]: C10–N1 1.421, N1–C2 1.379, C2–C3 1.353, C3–C15 1.462, C15–C16 1.460, C16–C17 1.203, C17–Si1 1.849.

Scheme 3. Cyclocondensation of TMS-alkynones **5** to give meridianins and meridianin derivatives **6**.

starting from the indoles lies between 25 and 41%. A striking advantage over the β-enaminone pathway[9,10] is that substituents other than H can be introduced readily at position 6 of the pyrimidine ring by choosing substituted alkynes. Furthermore, the extremely mild conditions of TMS-alkynone formation are highly compatible with polar functional groups. Polar substituents represent a significant drawback if stannane and boronate intermediates are required.[6–8]

The structures of the meridianins 6a–c and variolin analogue 6d were unambiguously supported by their ^1H and ^{13}C NMR spectra, which are in full agreement with published data.[8,10]

Since we were aware of the biological activity of the natural-meridianines, we subjected the synthetic samples of compounds 6 to a screening assay with protein kinases,[20] which play a key role in the "metabolic syndrome" (hSGK1) and in oncogenesis. All four compounds inhibit these tested kinases at low micromolar and even nanomolar levels (Table 2).

Encouraged by the successful total syntheses of meridianines, we attempted the methodological advance to the one-pot four-component syntheses of pyrimidines by a carbonylative coupling–cyclocondensation sequence. Reaction of (hetero)aryl iodides 1 and terminal alkynes 2 in THF at room temperature under 1 atm of carbon monoxide (a CO-filled balloon attached to the reaction vessel) and in the presence of 2 equiv of triethylamine and catalytic amounts of [Pd(PPh$_3$)$_2$Cl$_2$] and CuI for 48 h followed by addition of the amidinium salts 7 in the presence of 2.5 equiv of sodium carbonate in acetonitrile/water gave the 2,4,6-trisubstituted pyrimidines 8 moderate to good yield [Eq. (3), Table 3].

The structures of the pyrimidines 8 were unambiguously sup-

(3)

ported by spectroscopic (^1H, ^{13}C and DEPT NMR experiments, IR, UV/Vis, mass spectrometry) and combustion analyses. It is noteworthy that this sequence proceeds efficiently only for neutral or electron-rich aryl iodides 1 (entries 1 and 2). When electron-deficient aryl iodides were examined, a 1:2 mixture of carbonylative and non-carbonylative products was isolated. On the other hand, attempts to replace the aryl iodides with aryl bromides to increase the selectivity led to the complete loss of reactivity, and only

starting material was recovered. Finally, after considerable experimentation, we found that stirring the electron-deficient aryl iodide **1e** for 5 days with only 1 mol% of [Pd(PPh$_3$)$_2$Cl$_2$] and in the absence of CuI predominantly led to the formation of carbonylative alkynylation product, which was subjected to the cyclocondensation, providing the desired pyrimidine in 28% yield (entry 5).

Although this pyrimidine synthesis based upon consecutive carbonylative alkynylation and cyclocondensation is lower yielding than the synthesis starting from acid chlorides,[11] it still can be considered as a complementary approach when acid-sensitive functionality cannot be tolerated.

In conclusion, we have developed concise syntheses of naturally occuring meridianins and derivatives based upon carbonylative alkynylation and subsequent cyclocondensation. Meridianins were found to inhibit "metabolic syndrome" and oncologically relevant protein kinases at low micromolar and even nanomolar levels. Furthermore, we have developed a novel one-pot four-component synthesis of 2,4,6-trisubstituted pyrimidines based upon a consecutive carbonylative coupling–cyclocondensation sequence. Studies addressing the methodological scope of this synthesis and syntheses of other unknown analogs of meridianins and variolins as well as thorough studies of the structure–activity relationship are currently underway.

Experimental Section

5b: In a Schlenk flask [Pd(PPh$_3$)$_2$Cl$_2$] (35 mg, 0.05 mmol), [Pd-(dppf)Cl$_2$·CH$_2$Cl$_2$] (8 mg, 0.01 mmol), CuI (4 mg, 0.02 mmol), Boc-protected iodo indole **4b** (422 mg, 1.00 mmol), and THF (5 mL) were placed under nitrogen. Carbon monoxide was bubbled through the solution for 5 min, and then TMS-acetylene (0.21 mL, 1.50 mmol) and triethylamine (0.14 mL, 1.00 mmol) were added successively. The reaction mixture became dark red and was stirred at room temperature for 48 h under 1 atm of carbon monoxide (balloon filled with CO). The reaction mixture was then diluted with brine (20 mL) and extracted with dichloromethane (5 × 20 mL). The combined organic layers were dried with sodium sulfate, concentrated to dryness, and subjected to column chromatography on silica gel (hexane/ethyl acetate, 12:1) to give **5b** (287 mg; 68%) as colorless crystals. M.p. 157–159°C. ^{1}H NMR (300 MHz, CDCl$_3$): $\delta = 0.32$ (s, 9H), 1.70 (s, 9H), 7.47 (dd, $J = 8.8$ Hz, 1.8 Hz, 1H), 8.00 (d, $J = 8.8$ Hz, 1H), 8.36 (s, 1H), 8.48 ppm (d, $J = 1.8$ Hz, 1H); ^{13}C NMR (75 MHz, CDCl$_3$): $\delta = -0.7$ (CH$_3$), 28.0 (CH$_3$), 86.1 (C$_{quat.}$), 97.0 (C$_{quat.}$), 101.3 (C$_{quat.}$), 116.5 (CH), 118.4 (C$_{quat.}$), 120.8 (C$_{quat.}$), 125.0 (CH), 128.1 (C$_{quat.}$), 128.9 (CH), 134.6 (C$_{quat.}$), 136.4 (CH), 148.4 (C$_{quat.}$), 171.5 ppm (C$_{quat.}$); EI-MS (70 eV): m/z (%): 421 [M]$^+$, ^{81}Br, (7); 419 [M]$^+$, ^{79}Br, (5); 365 [$M-C_4H_9$]$^+$, ^{81}Br, (58); 363 [$M-C_4H_9$]$^+$, ^{79}Br, (49); 321 [$M-C_4H_9-CO_2-H$]$^+$, ^{81}Br, (100); 319 [$M-C_4H_9-CO_2-H$]$^+$, ^{79}Br, (84); 306 (23); 304 (19); 57 [C$_4$H$_9$]$^+$ (99); elemental analysis calcd (%) for C$_{19}$H$_{22}$BrNO$_3$Si (420.4): C 54.29, H 5.28, N 3.33, Br 19.01; found: C 54.00, H 5.33, N 3.37, Br 19.27.

6b: To a solution of **5b** (185 mg, 0.44 mmol) in acetonitrile (1.5 mL) was added in succession sodium carbonate (47 mg, 0.44 mmol), *tert*-butyl alcohol (1.5 mL), and a 5 M aqueous solution of guanidine (0.22 mL, 1.1 mmol; prepared by dissolving guanidine hydrochloride (9.55 g, 0.10 mol) in water (20 mL) and neutralizing with sodium hydroxide (4.10 g, 0.10 mol). The reaction mixture was stirred at 80°C for 38 h. After conversion to the meridianin was complete (TLC), brine was added and the mixture was extracted with dichloromethane (3 × 20 mL). The combined organic layers were dried with sodium sulfate, and after evaporation of the solvents in

vacuo the residue was chromatographed on deactivated silica gel (ethanol/ammonia 9:1) with ethyl acetate/ethanol (9:1) to give **6b** (93 mg; 73%) as a light yellow solid (recrystallized from pentane). M.p. 238–240°C (103–106°C).[10] ^{1}H NMR ([D$_6$]DMSO, 300 MHz): $\delta = 6.52$ (br, 2H, NH$_2$), 7.00 (d, $J = 5.1$ Hz, 1H, H-5′), 7.29 (dd, $J = 1.8$, 8.5 Hz, 1H, H-6), 7.41 (d, $J = 8.8$ Hz, 1H, H-7), 8.10 (d, $J = 5.1$ Hz, 1H, H-6′), 8.26 (br, 1H, H-2), 8.76 (d, $J = 1.8$ Hz, 1H, H-4), 11.87 ppm (br s, 1H, NH); ^{13}C NMR ([D$_6$]DMSO, 75 MHz): $\delta = 105.3$ (CH), 113.3 (C$_{quat.}$), 113.4 (C$_{quat.}$), 113.8 (CH), 124.5 (CH), 124.6 (CH), 127.1 (C$_{quat.}$), 129.6 (CH), 135.8 (C$_{quat.}$), 157.2 (CH), 162.3 (C$_{quat.}$), 163.6 ppm (C$_{quat.}$); elemental analysis calcd (%) for C$_{12}$H$_9$BrN$_4$ (289.1): C 49.85, H 3.14, N 19.38; found: C 50.10, H 3.24, N 18.87.

8a: In a Schlenk flask [Pd(PPh$_3$)$_2$Cl$_2$] (35 mg, 0.05 mmol), CuI (4 mg, 0.02 mmol), *para*-iodoanisole (**1a**; 234 mg, 1.00 mmol), and THF (5 mL) were placed under nitrogen. Carbon monoxide was bubbled through the solution for 5 min, and then hexyne **2a** (0.14 mL, 1.20 mmol) and triethylamine (0.28 mL, 2.00 mmol) were added successively. The reaction mixture became dark red and was stirred at room temperature for 48 h under 1 atm of carbon monoxide (balloon filled with CO). Then the suspension was treated with Na$_2$CO$_3$ (265 mg, 2.50 mmol), amidinium salt **7a** (195 mg, 1.20 mmol), water (0.5 mL), and CH$_3$CN (5 mL), and the reaction mixture was heated at reflux for 24 h. After cooling to room temperature, the reaction mixture was diluted with brine (20 mL) and extracted with dichloromethane (5 × 20 mL). The combined organic layers were dried with sodium sulfate, concentrated to dryness, and subjected to column chromatography on silica gel (hexane/ethyl acetate, 6:1) to give **8a** (166 mg; 51%) as a light yellow solid. M.p. 84–86°C. ^{1}H NMR (CDCl$_3$, 300 MHz): $\delta = 0.97$ (t, $J = 7.4$ Hz, 3H), 1.38–1.56 (m, 2H), 1.74–1.85 (m, 2H), 2.80 (t, $J = 7.9$ Hz, 2H), 3.87 (s, 3H), 7.01 (d, $J = 8.9$ Hz, 2H), 7.14 (dd, $J = 5.0$, 3.7 Hz, 1H), 7.29 (s, 1H), 7.45 (dd, $J = 5.0$, 1.1 Hz, 1H), 8.08 (dd, $J = 3.7$, 1.1 Hz, 1H), 8.14 ppm (d, $J = 8.9$ Hz, 2H); ^{13}C NMR (CDCl$_3$, 75 MHz): $\delta = 13.9$ (CH$_3$), 22.5 (CH$_2$), 30.9 (CH$_2$), 37.8 (CH$_2$), 55.4 (CH$_3$), 111.6 (CH), 114.1 (CH), 128.0 (CH), 128.5 (CH), 128.7 (CH), 129.2 (CH), 129.5 (C$_{quat.}$), 144.4 (C$_{quat.}$), 161.0 (C$_{quat.}$), 161.8 (C$_{quat.}$), 163.1 (C$_{quat.}$), 171.4 ppm (C$_{quat.}$); EI-MS (70 eV): m/z (%): 324 [M]$^+$ (2); 309 [$M-CH_3$]$^+$ (4); 295 [$M-C_2H_5$]$^+$ (7); 282 [$M-C_3H_6$]$^+$ (100); elemental analysis calcd (%) for C$_{19}$H$_{20}$N$_2$OS (324.3): C 70.34, H 6.21, N 8.63, S 9.88; found: C 69.95, H 6.17, N 8.59, S 9.86.

[17] 3-Iodoindoles were obtained in almost quantitative yields as beige solids still containing traces of DMF and can be stored without decomposition at 0°C under nitrogen. However, it is advisable to convert them directly to the more stable *N*-Boc-protected 3-iodoindoles **4**, which were isolated as colorless solids by column chromatography on neutral aluminium oxide (column chromatography on silica gel leads to red color and accelerates the decomposition).

[18] Colorless crystal (polyhedron), dimensions $0.40 \times 0.30 \times 0.24$ mm^3, triclinic, $P\bar{1}$, $Z = 2$, $a = 9.8618(5)$, $b = 10.0262(5)$, $c = 11.1585(6)$ Å, $\alpha = 107.5620(10)$, $\beta = 103.5130(10)$, $\gamma = 103.2620(10)°$, $V = 967.76(9)$ Å^3, $\rho = 1.175$ g cm^{-3}, $T = 200(2)$ K, $\theta_{max} = 26.39°$, Mo$_{K\alpha}$ radiation, $\lambda = 0.71073$ Å, $0.3°$ θ scans with CCD area detector, covering a whole sphere in reciprocal space, 9354 reflections measured, 3954 unique ($R_{int} = 0.0282$), 2889 observed ($I > 2\sigma(I)$), intensities were corrected for Lorentz and polarization effects, an empirical absorption correction was applied using SADABS (program SADABS V2.03 for absorption correction, G. M. Sheldrick, Bruker Analytical X-ray-Division, Madison, Wisconsin, **2001**) based on the Laue symmetry of the reciprocal space, $\mu = 0.14$ mm^{-1}, $T_{min} = 0.95$, $T_{max} = 0.97$, structure solved by direct methods and refined against F^2 with a full-matrix least-squares algorithm using the SHELXTL-PLUS (5.10) software package (software package SHELXTL V5.10 for structure solution and refinement, G. M. Sheldrick, Bruker Analytical X-ray-Division, Madison, Wisconsin, **1997**), 223 parameters refined, hydrogen atoms were treated using appropriate riding models, goodness of fit 1.05 for observed reflections, final residual values $R1(F) = 0.045$, $wR(F^2) = 0.110$ for observed reflections, residual electron density -0.30 to 0.27 e Å^{-3}.

$Al_{20}Cp_8^*X_{10}$ (X = Cl, Br): Snapshots of the Formation of Metalloid Clusters from Polyhedral Al_nX_m Molecules?**

*Jean Vollet, Ralf Burgert, and Hansgeorg Schnöckel**

*Dedicated to Professor Peter Paetzold
on the occasion of his 70th birthday*

Two subgroups of Al-metal clusters with a predominant number of metal–metal bonds are known:[1] "naked" metal-atom clusters, which are produced from solid metal by laser ablation techniques, and metalloid clusters, which are formed in solution starting with Al^I species and, for example, subsequent reduction.[2,3] Here we present $Al_{20}Cp_8^*Br_{10}$ (**1**) and $Al_{20}Cp_8^*Cl_{10}$ (**2**) (Cp* = pentamethylcyclopentadienyl), two compounds of molecular, partially substituted subhalides belonging to the second group, which at first glance seem related to the species $Al_{13}I_x^{-}$ [4] and $Al_{14}I_x^{-}$ [5] ($x = 1$–12), which were generated in mass-spectrometric experiments. In both sets of compounds the halogen atoms form direct bonds to the Al atoms of the icosahedral Al_{12} cluster core. However, quantum-chemical calculations for "naked" anionic clusters, for example, the $Al_{13}I_x^{-}$ anion mentioned above, indicate that an additional Al atom is located in the center.

The structures of **1** and **2** are furthermore closely related to those of the recently characterized $Al_{22}X_{20}$ compounds (X = Cl, Br), for example, $Al_{22}Br_{20}$ (**3**)[6] because their cluster

Supporting information for this article is available on the WWW under http://www.angewandte.org or from the author.

centers contain icosahedral Al_{12} moieties without an additional Al atom. On the basis of the structural characterization of **1** and **2** the attempt will be made in the following a) to understand the formation of the $Al_{22}X_{20}$ species, as such intermediates are potential building blocks for a conceivable metastable non-metallic β-modification of aluminium;[7] and b) to identify similarities and differences of the Al_{20} clusters (**1** and **2**) and the Al_n clusters and their reaction products (e.g. with I_2), which were studied spectroscopically by Castleman et al.[5]

When freshly sublimed $[\{AlCp^*\}_4]$[8] and freshly isolated $[\{AlBr \cdot NEt_3\}_4]$ (**4**)[9] were heated in heptane, the pale yellow suspension slowly turned orange, an initially beige precipitate turned brown, and finally Al metal precipitated. From this reaction mixture an orange heptane extract was obtained, from which orange crystals of **1** precipitated. Yellow crystals of $[\{AlBr_2 \cdot NEt_3\}_2]$ (**5**) and colorless crystals of $[AlBr_3 \cdot NEt_3]$ (**6**) were also obtained (see the Supporting Information).[10]

The chloride analogue **2** of **1** is formed by adding $MgCp_2^*$ to a solution of "$AlCl \cdot Et_2O$", in which the proportion of ether has been reduced by several evacuation steps (see the Experimental Section). By means of evacuation, we thought that an ether-stabilized chloride analogous to **4** should be generated in situ, but this has not yet been isolated.

Crystal structure analysis for **1** and **2** proves[10] that both compounds have an almost regular icosahedron in the center with an average Al–Al distance of 268.5 pm (Figure 1). Structurally the central Al_{12} icosahedron consists of four Al^I atoms, which are coordinated terminally by a halogen atom, and eight Al^0 atoms, which are coordinated exclusively to an exohedral Al atom. Each of the eight exohedral Al atoms bears a Cp* ligand. While two ligand-bearing Al atoms are additionally terminally coordinated by halogen atoms, two pairs of the remaining six exohedral Al atoms are singly bridged and one pair is doubly bridged by halogen atoms. In summary, the Al_{12} icosahedron is surrounded by four halogen atoms, six $Al^{II}BrCp^*$ units, and two Al^ICp^* moieties. So in principle 26 skeletal electrons are available for the central Al_{12} icosahedron (4×2 e⁻ for bromine-bearing Al atoms + 6×2 e⁻ for $Al^{II}BrCp^*$-bearing Al atoms + and 2×3 e⁻ for Al^ICp^*-coordinated Al atoms). In accordance with Wade's Rules[11] this results in the bonding situation of a *closo* cluster. All relevant structural information for **1** and **2** is contained in Table 1 and in the Tables in the Supporting Information. The distances and bonding relationships in the Al_{12} icosahedron are in accordance with those of the $Al_{12}R_{12}^{2-}$ anion (268.6 pm, R = iBu)[12] and the $Al_{22}X_{20}$ species (270.1 pm).[6,7] Furthermore the experimentally determined distances listed in Table 1 agree well with those calculated.[13]

The observed ^{27}Al NMR spectra of **1** and **2** in solution each show only two signals, although in theory at least six different signals are expected (see the Supporting Information). The observed signals for **1** are in good agreement with calculated values,[13] and those for **2** show the expected shift to

Figure 1. Side and top view of **1**. Cp* groups are represented in simplified form for clarity.

Table 1: Average distances (min./max.) [pm] in **1** and **2**.

Distances[a]	**1** (X = Br)	**2** (X = Cl)	Calcd **2**[b]

lower frequencies (compared to **1**; see the Supporting Information).

The recently reported formation of $Al_{22}X_{20}$ species[6,7] (e.g. **3**) has been described generally as the phenomenon of internal disproportionation: starting from metastable AlX solutions, 22 AlX molecules provide the twelve Al^0 atoms of the icosahedral center and the ten peripheral AlX_2 units of this cluster species (Figure 2). In the compounds **1** and **2** the
Figure 2. Mechanism of the formation of **1** and the subhalide **3** starting with compound **4** based on experimental findings and quantum-chemical calculations. These three compounds (colored background) were structurally characterized; all other species were calculated.

With regards to pathway (a): All metalloid Al clusters with stabilizing $N(SiMe_3)_2$ ligands which are formed eventually in the disproportionation of AlX ($3\,AlX \rightarrow 2\,Al + AlX_3$) on the way to the metal[2,3,18] are part of this class.[2] Moreover the "naked" Al_n clusters observed in mass-spectrometric studies[4,5] should be mentioned here, of which the icosahedral Al_{13}^- cluster with a central Al atom is especially frequent. The formation of the latter clusters,[19] which basically can be considered as evaporation products of the bulk phase, happens in the opposite direction of the formation of metalloid clusters. Nevertheless, along both directions Al-centered species are obviously preferred.[20]

With regards to pathway (b): The possibility of the formation of a metastable, non-metallic β-Al modification (equivalent to the α-boron structure) based on a $Al_{22}X_{20}$ species (e.g. **3**) with a noncentered icosahedral Al_{12} core has been discussed and made plausible by quantum-chemical calculations.[21] If we partly insert sterically demanding groups such as AlCp* into the Al−Br bonds of the hypothetical halide intermediate "$Al_{12}Br_{12}$" presented in Figure 2, compound **1** is formed. Very similar conditions result in the formation of the $Al_{50}Cp^*_{12}$ cluster with its noncentered Al_8 core and its shell of twelve Cp* units, which inhibits further reaction towards elemental aluminum.[22] This metalloid Al_{50} cluster with its singular structure as well as the compounds **1** and **2** discussed here can be regarded as "molecular dead-ends", that is, snapshots of the complex reaction events of metastable AlX species on their way towards elemental aluminium via a hypothetical β-modification which is made possible only by ligand stabilization.

For the first time the degree of complexity of such reaction pathways becomes rudimentally evident through the isolation of the intermediates **1** and **2** as well as mass-spectrometric investigations. These initial results hint at the challenges to be overcome in synthesis, spectroscopy, and theory to thoroughly understand these reaction mechanisms.

first halogen atoms coordinated directly to an Al_{12} icosahedron are observed. The synthesis of **1** furthermore succeeds only[14] if one starts with the distinct halide [{AlBr·NEt$_3$}$_4$] (**4**).[9] Therefore we propose the mechanism of formation for the compounds **3** and **1** (and **2**) represented in Figure 1, in which the dehalogenation of **4** to give **1** could occur also as a result of an excess of AlCp*.[15] The isolation of **1** and **2** makes the intermediacy of an $Al_{12}Br_{12}$ species (in the disproportionation of AlX) seem feasible;[16] the $Al_{12}Br_{12}$ species could react to give $Al_{22}Br_{20}$, **3**, or compound **1**, depending on the reaction conditions (Figure 2).

Apart from the relevance of **1** and **2** to the understanding of the formation of an $Al_{22}X_{20}$ species, our results are of broader significance: They again indicate that the assumption that there are at least two different ways to reach the bulk phase of aluminium, which we presented earlier,[6,7,17] is correct. The first pathway (a) leads via Al-centered clusters to metallic Al. A second reaction channel (b) leads via Al_n clusters with an icosahedral Al_{12} center (without a central Al atom as in, for example, **3**) towards a hypothetical novel, non-metallic modification of Al (β-Al).

Tiny red crystals grew from the red pentane extract, and by careful, continuous concentration of the pentane solution crystals of **2** suitable for structural analysis could be isolated (90 mg, 0.044 mmol). ^{1}H NMR (300 MHz, C_6D_6): $\delta = 1.90$ ppm (s, 120 H, calc. 1.90 ppm); ^{13}C NMR (63 MHz, C_6D_6): $\delta = 15.1$ (Me_5C_5, calc. 14.6), 117.5 ppm (Me_5C_5, calcd 118.0); ^{27}Al NMR (78 MHz, C_6D_6): $\delta = 88$, 37, and -27 ppm.

[18] For example, $Al_{77}(N(SiMe_3)_2)_{20}^{2-}$: A. Ecker, E. Weckert, H. Schnöckel, *Nature* **1997**, *387*, 379.

[19] The energy difference between the more stable icosahedral Al_{13} cluster and the cuboctahedral Al_{13} cluster is only about 55 kJ mol^{-1} according to quantum-chemical calculations. Thus it can be expected that different conditions, for example, in solution or in the gas phase could yield cuboctahedral as well as icosahedral Al_{13} species: R. Ahlrichs, S. D. Elliott, *Phys. Chem. Chem. Phys.* **1999**, *1*, 13.

[20] This statement can, for example, be supported by the structures of both the $Al_{14}I$ anion, which was detected by mass spectrometry and calculated using quantum-chemical methods (see ref. [5]), and of the metalloid cluster [$Al_{14}I_6R_6$]$^{2-}$ (R = N[SiMe$_3$]$_2$), because both structures with their centered arrangement of Al atoms show similarities to the bulk phase (see the Supporting Information). [$Al_{14}I_6R_6$]$^{2-}$: H. Köhnlein, G. Stößer, E. Baum, E.
