# Analysis of Thermally Induced Loss in Fiber-Optic Ribbons

By G. S. BROCKWAY* and M. R. SANTANA

(Manuscript received October 1, 1982)

*In this paper, added loss during temperature cycling in a given ribboned fiber is shown to be caused by thermally induced axial compressive strain imparted to the fiber. A microbending-sensitivity parameter $\delta$ is introduced which reduces all loss-strain curves corresponding to different fibers to one characteristic master curve. Thermoviscoelasticity theory is used to calculate the time- and temperature-dependent compressive strain imparted to a ribboned fiber during a standard environmental cycle. Combining these analytical results with environmental data, the functional relationship between fiber-compressive strain and the added loss for a fiber of any given $\delta$ in an Adhesive-Sandwich Ribbon (ASR) with Urethane-Acrylate (UA) coated fibers has been determined. Using this analysis, the added loss for a UA ASR can now be predicted for any environmental cycle. The critical material properties that dominate the environmental performance of ASRs are the tape shrinkback at elevated temperatures and the product $\alpha EA$ of the coefficient $\alpha$ of thermal expansion, the time- and temperature-dependent relaxation modulus $E$, and the area $A$ of the coating.*

## I. INTRODUCTION

Unless special precautions are taken, fiber-optic cables installed in the outside plant could experience temperatures ranging from −45°F

* Plastics Engineering Consultants, Inc., Lawrenceville, GA.

to +190°F. Thus, optical transmission loss resulting from this thermal history directly impacts the coating and ribbon choices for a particular system design. An understanding of the relationships among the thermally induced strains on the "ribboned" glass fibers, the resulting added transmission loss, and fiber parameters is crucial to properly evaluating candidate fiber-coating materials, ribbon structures, and/or ribbon-matrix materials. Moreover, it is desirable to be able to predict long-term behavior from short-term testing, thereby simplifying the environmental testing procedure.

The added loss in environmental testing is generally thought to be associated with the microbending of the axis of the fiber. Moreover, it has been shown by other investigators that when intimate contact is forced between a fiber and a microscopically rough surface, losses due to microbending can be substantial and are a function of the fiber geometric and optical parameters as well as the elastic modulus of the rough surface.[1,2] Therefore, thermally induced strains on the ribbon structure can indirectly result in added loss by increasing the contact forces between fibers. In addition, the sensitivity of a particular fiber to microbending loss is said to be associated with irregularities at the core-cladding interface, which may be due to core-diameter variations and/or refractive index variations.[3]

In this paper, a thermoviscoelastic analysis is used to compute the axial and transverse strains that are imparted to a fiber-optic ribbon when it is subjected to any given thermal cycle. This analysis shows that for the Bell System Adhesive-Sandwich-Ribbon[4] (ASR) construction with Urethane-Acrylate (UA) coated fibers, the transverse strain due to lowering the temperature results, contrary to one's expectation, in a reduction in the contact force between fibers. On the other hand, the resulting axial compressive strain evidently either increases this contact force or induces fiber buckling at the critical spatial wavelength, and thus creates added optical loss. Moreover, for a given ribboned fiber we establish herein the existence of a relationship between the environmental added loss and any measure of microbending sensitivity of the fiber. This equivalence enables us to predict the environmental performance of any ribboned fiber over a wide temperature-time span from data gathered over a relatively short time. In particular, the loss data collected from one excursion to −45°F can be combined with thermoviscoelastic data and analysis to predict the loss of any ribbon configuration with any choice of constituent materials, provided the tested fibers have a suitable range of microbending sensitivity.

## II. ENVIRONMENTAL TEST PROCEDURE

The intent of environmental testing is to determine the effect of thermal exposure on the optical performance of fiber-optic ribbons. All

Table I—Environmental test cycle

| Cycle Number | Exposure Temperature, $T$ (°F) | Exposure Time, $t$ (days) |
|---|---|---|
| I | 75 | 2 |
| | −45 | 2 |
| | −15 | 2 |
| | 15 | 2 |
| | 75 | 2 |
| | 170 | 30 |
| II | 75 | 2 |
| | −45 | 2 |

| | 75 | 2 |

the ribbons tested were placed in a 23-inch-diameter cardboard cylindrical container in a stem-pack fashion. The containers were then placed in a "walk-in" environmental chamber with both ends available for measuring purposes. Input and output array connectors[5] were fabricated to measure loss by the reference-fiber technique. Namely, the 0.63-$\mu$m loss of a fiber is obtained by taking the ratio of its output power to the average output power of ten reference fibers that are short enough to have negligible loss.

Table I is a summary of the environmental testing cycle used for this investigation. The loss of the ribboned fibers* was obtained at the end of each exposure. The change in loss for a typical ribboned fiber is plotted in Fig. 1 for each temperature in Cycles I, II, and III. The loss of the ribboned fibers increases with decreasing temperatures, the maximum loss occurring at the lowest temperature. As is evident in Fig. 1, the loss also increases with increasing cycle number. We subsequently show that this "pumping effect" is due to polyester-tape shrinkback† and stress relaxation effects during the high-temperature exposure between cycles.

It follows that for a 40-year design life, the worst-case environmental cycle would be a 40-year exposure at 190°F followed by a low-temperature exposure. This worst-case cycle is summarized in Table II. Note

* Fibers used in this study had cladding and core diameters of 110 and 55 $\mu$m, respectively.

† Shrinkback is the recovery of process-induced strains.

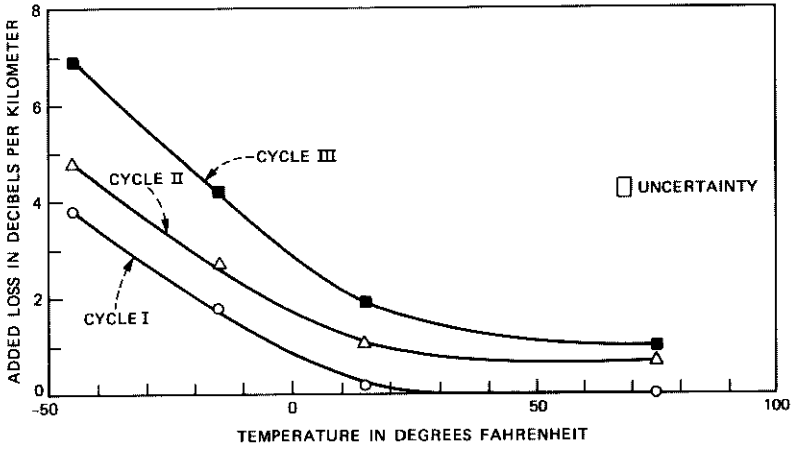

Fig. 1—Environmental added loss at 0.63 μm vs. temperature (UA-coated fiber, ASR construction).

Table II—Worst-case environmental cycle

| Exposure temperature, $T$ (°F) | Exposure Time, $t$ (days) |

| 15 | 2 |
| 75 | 2 |

that the cycle of Table II is not suggested for testing purposes but will only be used to predict the most pessimistic estimates of performance.

## III. DUALITY BETWEEN MICROBENDING SENSITIVITY AND STRAIN

A convenient means for measuring the microbending sensitivity of different fibers is to determine the wavelength-independent loss coefficient[6] of the fiber when wound in several layers on a 6-inch-diameter reel under a tension fixed for all fibers. Let $\delta$ denote the wavelength-independent loss coefficient measured under these conditions. This method was contrived to produce artificially high losses, thereby magnifying the loss contribution due to microbending. Of course, the losses for these same fibers will be substantially smaller when measured in a stress-free configuration.

The added-loss response to a given cycle (see Fig. 1) is characteristic of all fibers of a single given $\delta$ (as defined above) in a given structure

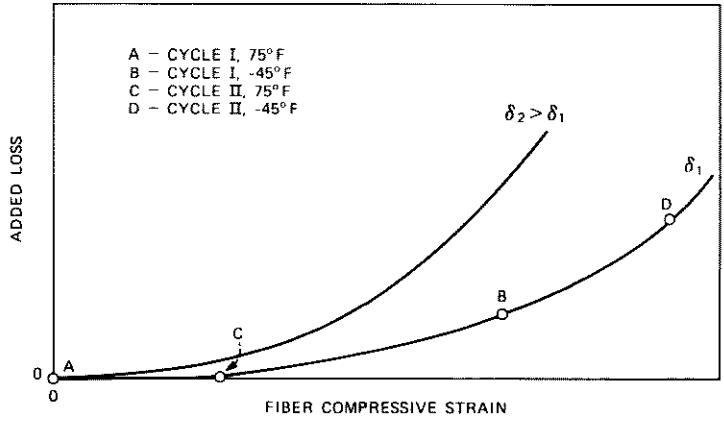

Fig. 2—Environmental added loss vs. fiber compressive strain.

but will change for fibers having different $\delta$'s. Moreover, examination of all the environmental data collected in this study indicates that the change in loss at a given point in any cycle increases with increasing $\delta$.

As is well known, microbending loss occurs when the axis of a fiber is bent into a curve whose spectrum contains a certain critical frequency.[3] Transverse pressure against a fiber on a microscopically rough surface has been shown to introduce loss in this way.[1,2] However, in the case of environmentally induced loss in an ASR ribbon, it is shown in the Appendix that the *transverse* strain due to thermal contraction *reduces* the contact forces between fibers. Thus, the added-loss response of Fig. 1 must be due to another mechanism. The only reasonable possibility is that the compressive axial strain induces microbending loss through fiber buckling. This loss would occur if the fiber buckling were at the critical wavelength or if buckling increases the contact forces between the fiber and its surroundings. It is not our intent to identify which of these means dominates the behavior of the fiber but only to characterize its manifestations. In other words, we simply correlate the added loss with the compressive strain imparted to the fiber.

Both the added loss and compressive strain increase with decreasing temperature; their relationship* is shown schematically in Fig. 2. Here, the losses at 75°F and −45°F in Cycle I are denoted by $A$ and $B$, respectively. After high-temperature exposure, the shrinkback of the polyester tape increases the strain on the fiber, so that $C$ and $D$

* If strain and added loss monotonically increase with decreasing temperature, then it is easy to show that the added loss monotonically increases with increasing strain.

represent 75°F and −45°F in the second cycle. This explains the increased loss with each cycle that is evidenced in Fig. 1. This phenomenon has been observed consistently in all environmental testing and, as previously noted, is called the pumping effect.

Since the loss increases with increasing $\delta$, the added-loss response to strain becomes steeper with increasing $\delta$, as illustrated in Fig. 2. The effect of $\delta$ in this graph is obviously a contraction of the strain scale with increasing $\delta$. As to whether this contraction is uniform or not is readily tested by plotting the loss versus logarithmic strain, where a uniform contraction would then appear as a horizontal, rigid translation of the added-loss curves with $\delta$. As will be demonstrated in Section V, the loss-strain data may indeed be reduced in this fashion. Since the strain-scale contraction factor is a function of $\delta$ alone (the contraction is uniform), it creates a one-to-one correspondence (duality) between $\delta$ and compressive strain, changes in $\delta$ being equivalent to changes in strain. With this in mind, we proceed to a calculation of the axial strain in the environmental cycle.

## IV. THERMOMECHANICAL ANALYSIS

This section is devoted to the summary of the formulas needed to calculate the axial strain history to which a fiber-optic ribbon is subjected during any environmental cycle. All of the plastics used in an ASR structure possess time- and temperature-dependent moduli, two examples of which are shown in Fig. 3. If the plastic is instantaneously strained, the stress required to sustain that strain relaxes with time according to the given curve. Notice that the relaxation that occurs in the UA modulus at 140°F in one hour takes more than 40 years at room temperature. The relaxation at −45°F is slower yet, so that the UA coating is as stiff as the polyester tape over significant time periods at these low temperatures.

On the other hand, the coefficients of thermal expansion of these plastics are constant with time provided the temperature changes do not encompass their glass transition temperatures, $T_g$. Even so, by virtue of the time dependence of the plastic moduli, the ribbon itself exhibits time- and temperature-dependent thermal expansion and contraction during the thermal cycle. This situation is depicted in Fig. 4. Since the expansion coefficients $\alpha_P$ of the plastics are much greater than that ($\alpha_G$) for glass, the fibers restrain the contraction of the plastic, the net contraction $\alpha \Delta T$ of the ribbon being determined by equilibrium (force balance) in the structure. The relatively high short-time modulus of the plastic (see Fig. 3) causes the initial contraction (expansion) to be high. As the modulus of the plastic relaxes, the energy stored in the glass causes the ribbon to recover some of this high initial strain. Of course, the rate of this recovery depends on the temperature at which it occurs.

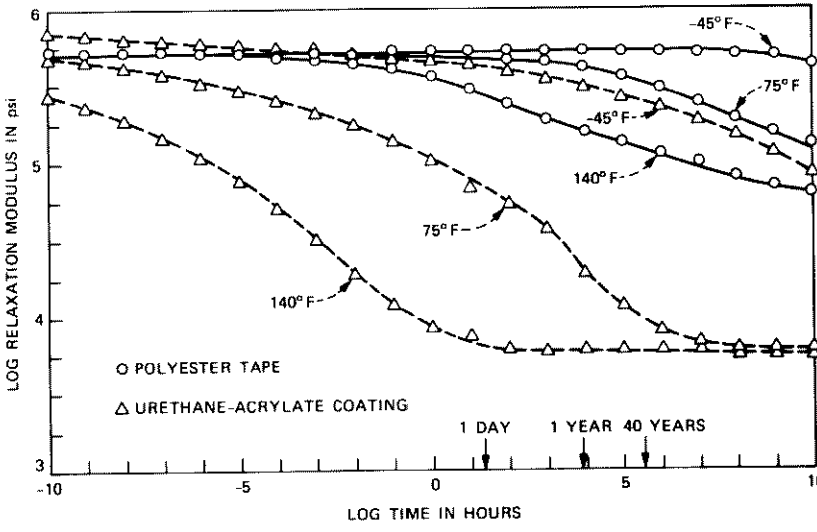

Fig. 3—Time dependence of moduli for ribbon constituents at various temperatures (generated by time-temperature superposition from data collected by R. P. DeFabritis).

The glass also resists shrinkback $\epsilon_S^{TA}$ of the polyester tape during exposure to elevated temperatures. If it were unrestrained, the tape would shrink back according to the results in Fig. 5. As illustrated in Fig. 6, the shrinkback $\epsilon_S$ that the ribbon experiences is much less than that of the free tape.

The compressive strain induced in the ribbon by its thermal contraction upon an excursion to −45°F is thus increased in each subsequent cycle by the shrinkback during the high-temperature exposure. We now proceed to a calculation of these strains.

### 4.1 Axial thermal expansion

If the plastic phases were considered to be elastic, the axial tensile modulus of a fiber-optic ribbon would be approximated well by the *rule of mixtures*

$$E_e = \frac{\sum_i E_i A_i}{\sum_i A_i}, \tag{1}$$

where $E_i$ is the modulus of the $i$th constituent, $A_i$ its area, and the summation is taken over all phases. In reality, (1) is a lower bound for the effective elastic modulus, being exact if all the constituents have the same Poisson's ratio.[7] Furthermore, eq. (1) can be derived in an elementary fashion by considering the equilibrium of the ribbon if one ignores Poisson's effect and assumes that all constituents are equally strained.

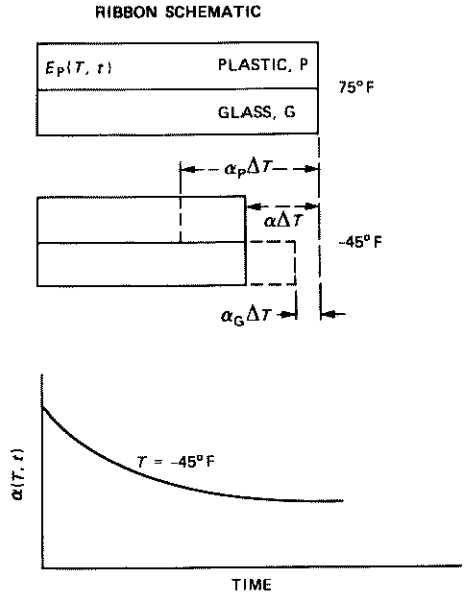

Fig. 4—Mechanics of ribbon thermal contraction.

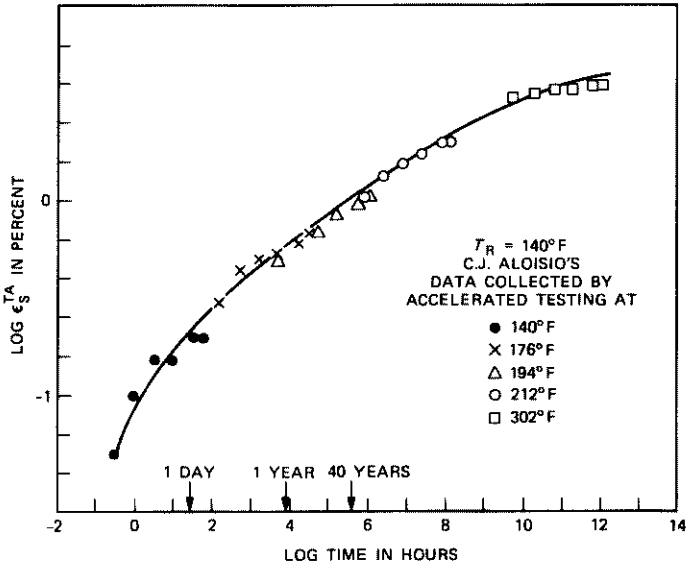

Fig. 5—Shrinkback strain vs. time for 3M No. 5 polyester tape.

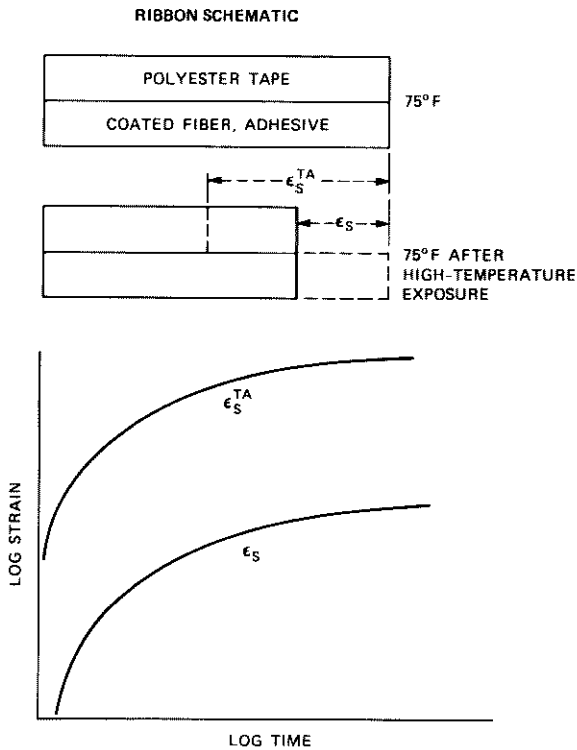

Fig. 6—Mechanics of ribbon shrinkback.

This same kind of elementary argument leads to the formula

$$\alpha_e = \frac{\sum_i \alpha_i E_i A_i}{\sum_i E_i A_i} \tag{2}$$

for the coefficient of thermal expansion of the ribbon, given elastic phases with moduli $E_i$, areas $A_i$ and coefficients of thermal expansion $\alpha_i$. Schapery has shown that (2) is exact if each phase has the same Poisson's ratio and is a very good approximation in any case.[7] These elastic results may be used to generate their viscoelastic counterparts. To see this, assume that all constituents obey constitutive equations of the *form*[8]

$$\sigma(t) = \int_0^t E(T(t), t - \tau)\dot{\epsilon}_o(\tau)d\tau$$

$$E(T, t) = a_G(T)E(T_R, \xi), \qquad \xi = \int_0^t \frac{d\tau}{a_T(T(\tau))} \tag{3}$$

and

$$\epsilon_\sigma(t) = \epsilon(t) - \alpha[T(t) - T_0], \qquad T_0 = T(0), \tag{4}$$

where $\epsilon$, $\sigma$, and $E(T, \cdot)$ are the strain, the stress and the relaxation modulus at temperature $T$, respectively. Here, a superposed dot on a function denotes differentiation with respect to its argument. On a log-log plot of modulus versus time, $\log a_G(T)$ and $\log a_T(T)$ represent, respectively, the vertical and horizontal distances that the curve for a temperature $T$ must be translated to lay over that for the reference temperature $T_R$. All the materials considered here, including glass as a trivial case, conform to this hypothesis.

When (3) and (4) are met, it is readily shown that equation (1) continues to hold in the viscoelastic case, so that

$$E(T, t) = \frac{\sum_i E_i(T, t)A_i}{\sum_i A_i} \tag{5}$$

is exact (Poisson's effect being ignored). Moreover, as long as the curve of the logarithm of the modulus versus logarithmic time has small curvature, a good approximation to $\alpha(T, t)$ is provided by the so-called quasi-elastic approximation[8]

$$\alpha(T, t) = \frac{\sum_i \alpha_i E_i(T, t)A_i}{\sum_i E_i(T, t)A_i}. \tag{6}$$

The strain in the ribbon due to a temperature history $T$ in the absence of stress is characterized by

$$\epsilon(t) = \int_0^t \alpha(T(t), t - \tau)\dot{T}(\tau)d\tau. \tag{7}$$

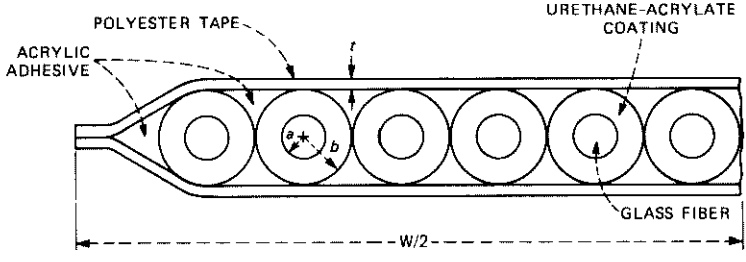
Notice that the ribbon has a time-dependent expansion coefficient even though we have supposed that the constituent plastics do not. This latter assumption is valid as long as the temperature excursion does not encompass the glass transition temperature $T_g$ of any constituent. Equation (6) can easily be shown to continue to hold even if the constituents have time-dependent expansion coefficients. One need only replace each $\alpha_i$ by $\alpha_i(T, t)$. For the purposes of this investigation, it is sufficient to assume each $\alpha_i$ to be constant.

The data needed to calculate the effective modulus $E$ and coefficient $\alpha$ of thermal expansion of the ribbon at −45°F and 75°F for a time of 10 hours is given in Table III. The geometric data of Table III was calculated using the nominal dimensions shown on the cross-sectional view of a typical ribbon in Fig. 7. Notice that although the glass makes far and away the most significant contribution to the stiffness of the

Table III—Geometric and material properties of ribbon constituents

| | $A$ ($10^{-4}$ in.$^2$) | $\alpha$ ($10^{-5}$ °F$^{-1}$) | Ten-Hour Modulus $E$($10^5$ psi) | | $EA$($10^2$ lb) | | $\alpha EA$ ($10^{-3}$lb/°F) | |
|---|---|---|---|---|---|---|---|---|
| | | | −45°F | 75°F | −45°F | 75°F | −45°F | 75°F |
| 3M No. 5 Polyester Tapes | 3.00 | 1.06 | 5.27 | 4.67 | 1.58 | 1.40 | 1.67 | 1.48 |
| 3M No. 5 Acrylic Adhesive | 3.60 | 7.72 | 0.00 | 0.00 | 0.00 | 0.00 | 0.00 | 0.00 |
| Urethane-Acrylate Coatings | 5.87 | 3.33 | 4.22 | 0.74 | 2.48 | 0.43 | 8.26 | 1.43 |
| Glass Fibers | 1.77 | 0.028 | 107 | 107 | 18.94 | 18.94 | 0.53 | 0.53 |
| Total | 14.24 | | | | 23.00 | 20.77 | 10.46 | 3.44 |

Thus, eq. (6) $\rightarrow \alpha = \frac{\sum \alpha EA}{\sum EA} = \frac{4.55 \times 10^{-6}\ °F^{-1} @ -45°F}{1.66 \times 10^{-6}\ °F^{-1} @ 75°F}$



| DIMENSIONS |
|---|
| $a$ = 2.17 mils |
| $b$ = 9.00 mils |
| $t$ = 1.00 mil |
| w = 150 mils |

Fig. 7—Cross section of a twelve-fiber ribbon.

ribbon, other constituents play a major role in the calculation of $\alpha$. Indeed, at −45°F the $\alpha EA$ of the glass may well be neglected in comparison with that of the coating. At 75°F, on the other hand, the tape, coating and glass make comparable contributions to the effective thermal expansion coefficient.

In Fig. 8, $\alpha$ and $E$ are plotted logarithmically against the logarithm of time at 75°F. It is evident that the change in $\alpha$ with respect to temperature and time is much more significant than the change in ribbon modulus. The coefficients of thermal expansion listed for each of the constituents in Table III are for temperatures below their respective glass transition temperatures, since our interests are in

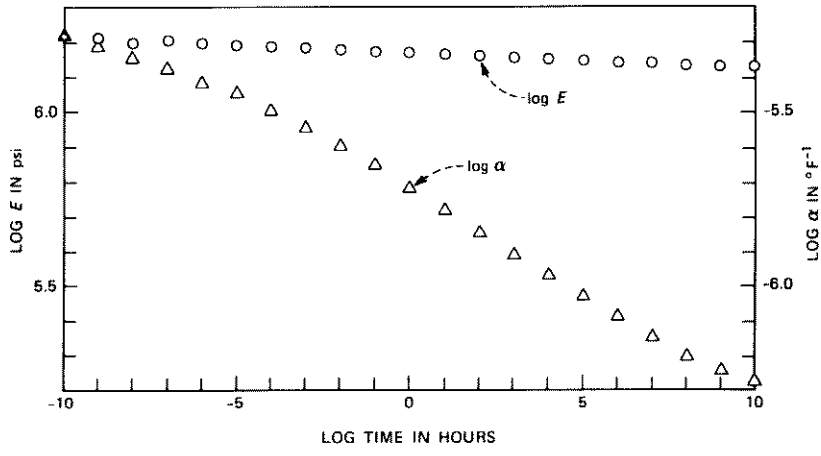


Fig. 8—Time dependence of the modulus and the coefficient of thermal expansion for the ribbon at 75°F (UA-coated fibers, ASR construction).

calculating the compressive strains imparted to the fiber during the low-temperature excursion.

If the ribbon is exposed to the temperature history

$$T(t) = T_0 + \sum_{k=1}^{n} (T_k - T_{k-1})H(t - t_k),\ H(t) = \begin{cases} 0 & t < 0 \\ 1 & t \geq 0 \end{cases} \tag{8}$$

$0 < t_1 < t_2 < \cdots < t_n < t$, the resulting strain history is

$$\epsilon(t) = \sum_{k=1}^{n} (T_k - T_{k-1})\alpha(T_n, t - t_k), \tag{9}$$

as found from substituting (8) into (7). Observe that eq. (9) contains all relaxation effects associated with the temperature history in (8).

### 4.2 Axial shrinkback

We now set out to calculate the shrinkback induced in the ribbon by the shrinkage of the polyester tape during high-temperature exposure. Denote by $\epsilon_S^{TA}(T_R, t)$ the shrinkback (see Fig. 5) the tape would experience in the time period $[0, t]$ at some reference temperature* $T_R$ if it were unrestrained. At any other temperature $T$, the unrestrained shrinkback in the same time period would be

$$\epsilon_S^{TA}(T, t) = \epsilon_S^{TA}(T_R, t/a_T(T)), \tag{10}$$

where $a_T$ is the temperature-dependent scale-contraction factor. If the tape is subjected to temperature $T_1$ for a time $t_1$ and then to $T_2$ for $t_2$, the total shrinkback would be

* $T_R = 60°$ in Fig. 5.

$$\epsilon_S^{TA}(T_R, t_1/a_T(T_1) + t_2/a_T(T_2)).$$

For the polyester tape used in the ASR construction, shrinkback is observable in the environmental cycle only during the high-temperature exposures, the time scales being much too long at the lower temperatures.

An analysis similar to that outlined in Section 4.1 for the time-dependent modulus and coefficient of thermal expansion of the ribbon can be used to obtain the approximate formula for the shrinkback strain of the ribbon $\epsilon_S$.

$$\epsilon_S(t) \cong S(T, t)\epsilon_S^{TA}(t), \tag{11}$$

where

$$S(T, t) = \frac{E_{TA}(T, t)A_{TA}}{\sum_i E_i(T, t)A_i}. \tag{12}$$

A double logarithmic plot of the ribbon shrinkback function $S$ as calculated from (12) is shown in Fig. 9 for $T = 140°F$. Observe that the shape of $\log S(T, \cdot)$ is very much like that of the logarithm of the polyester modulus in Fig. 3. The ribbon shrinkback during any high-temperature exposure can be calculated by substituting the appropriate mechanical and shrinkback data (e.g., Figs. 3 and 5) into eqs. (11) and (12). The error made in using eq. (11) at 140°F has been shown to decrease monotonically from 10 percent at two hours to 8.8 percent at ten hours. The approximation of eq. (11) increasingly improves as time goes on and as temperature increases. Since our interest is in times greater than forty-eight hours at temperatures over 170°F, (11) is quite acceptable.

### *4.3 Calculation of fiber compressive strains in the environmental test cycle*

As discussed in Section III, a compressive strain applied to a riboned fiber induces added optical loss. This strain $\epsilon_F$ for the temperature history $T$ [see eq. (8)] is given by

$$\epsilon_F(t) = \epsilon_R(t) - \alpha_F[T(t) - T_0], \tag{13}$$

where $\alpha_F$ is the linear coefficient of thermal expansion of the glass fiber and

$$\epsilon_R(t) = \epsilon(t) + \epsilon_S(t) \tag{14}$$

is the ribbon strain. In (14), $\epsilon$ is the strain due to the thermal contraction of the ribbon [eq. (9)], and $\epsilon_S$ is the ribbon shrinkback strain [eq. (11)].

Thermoviscoelastic data on each of the constituent materials were incorporated into computer-programmed versions of eqs. (6), (9), (11),

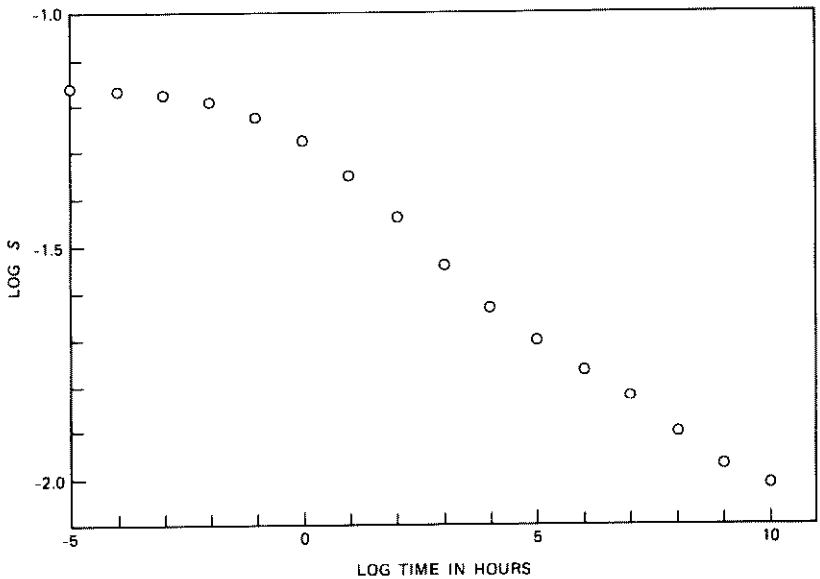

Fig. 9—Time dependence of ribbon-shrinkback function at 140°F (UA-coated fibers, ASR construction).

(12), and (13) to obtain the fiber strains on each excursion to −45°F. The results are plotted in Fig. 10.

## V. THE MASTER CURVE FOR ADDED LOSS VERSUS COMPRESSIVE STRAIN

The purpose of this section is to construct the curve of added loss versus compressive strain (master curve) for a fiber having an arbitrary value of the microbending sensitivity parameter $\delta$. This will be done by demonstrating that the effect of $\delta$ on the loss-strain curve is to uniformly contract the strain scale, which appears as a rigid shift (translation) of the curves with $\delta$ when the loss data are plotted against logarithmic strain. This master curve together with the $\delta$-shift curve can then be used to predict the performance of any fiber ($\delta$ known) in any environmental cycle.

In Fig. 11, the environmental added-loss data for five fibers are plotted versus the logarithm of the axial compressive strain on the glass fiber as calculated in Section IV (Fig. 10). These data include all the measurements for Cycles I through III according to Table I. Neither of the points for 75°F in Cycle I appears in these figures because for the first the strain is zero and for the second it is tensile (negative), so that both logarithms are undefined.

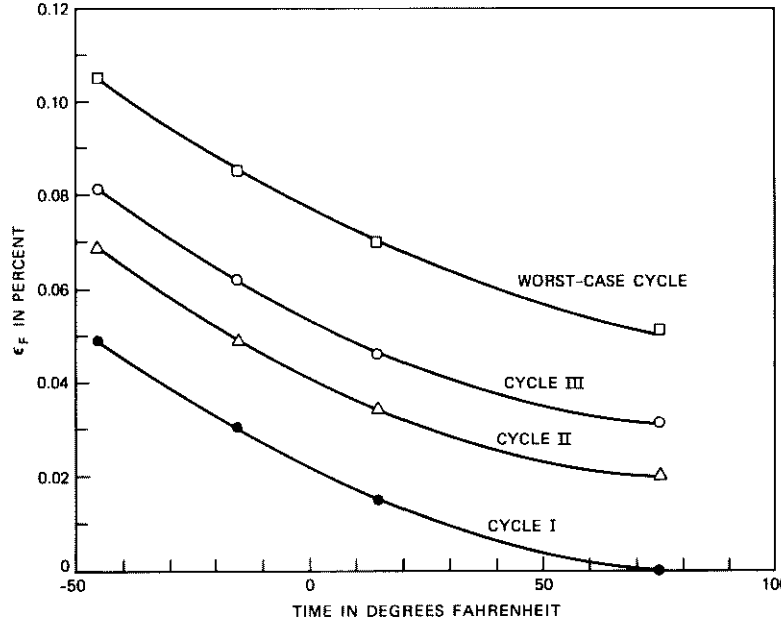

Fig. 10—Calculated fiber compressive strain vs. temperature in the environmental cycle (UA-coated fiber, ASR construction).

### *5.1 Shifting with δ to form the master curve*

The plots in Fig. 11 were laid over one another and shifted horizontally by hand until they formed a single, smooth curve. The amount of shift log $a_\epsilon(\delta)$ required for each of the five values of $\delta$ is shown in Fig. 12 referenced to $\delta = 1.0$ dB/km. The linear, least-squares fit shown in Fig. 12 results in an excellent approximation of the shift data. For simplicity this linear approximation is used in the subsequent construction of the master curve.

The resulting master curve is shown in Fig. 13. The data points for the five different fibers are shown with different symbols on this plot. This master curve together with the $\delta$-shift curve of Fig. 12 can be used to obtain the added-loss-versus-strain profile for a fiber of any given $\delta$. A fourth-order polynomial has been fitted to the master curve data and is included in Fig. 13. Observe that the scatter about the best-fit polynomial is within the loss measurement uncertainty. Notice also that there is significant overlap in the data from fiber to fiber. On account of the functional relationship between $a_\epsilon$ and $\delta$ (illustrated in Fig. 12), we may view the master curve of Fig. 13 as added loss versus strain for a fixed value of $\delta$ or added loss versus $\delta$ for a fixed level of strain. This makes precise the $\delta$-strain duality alluded to in Section III.

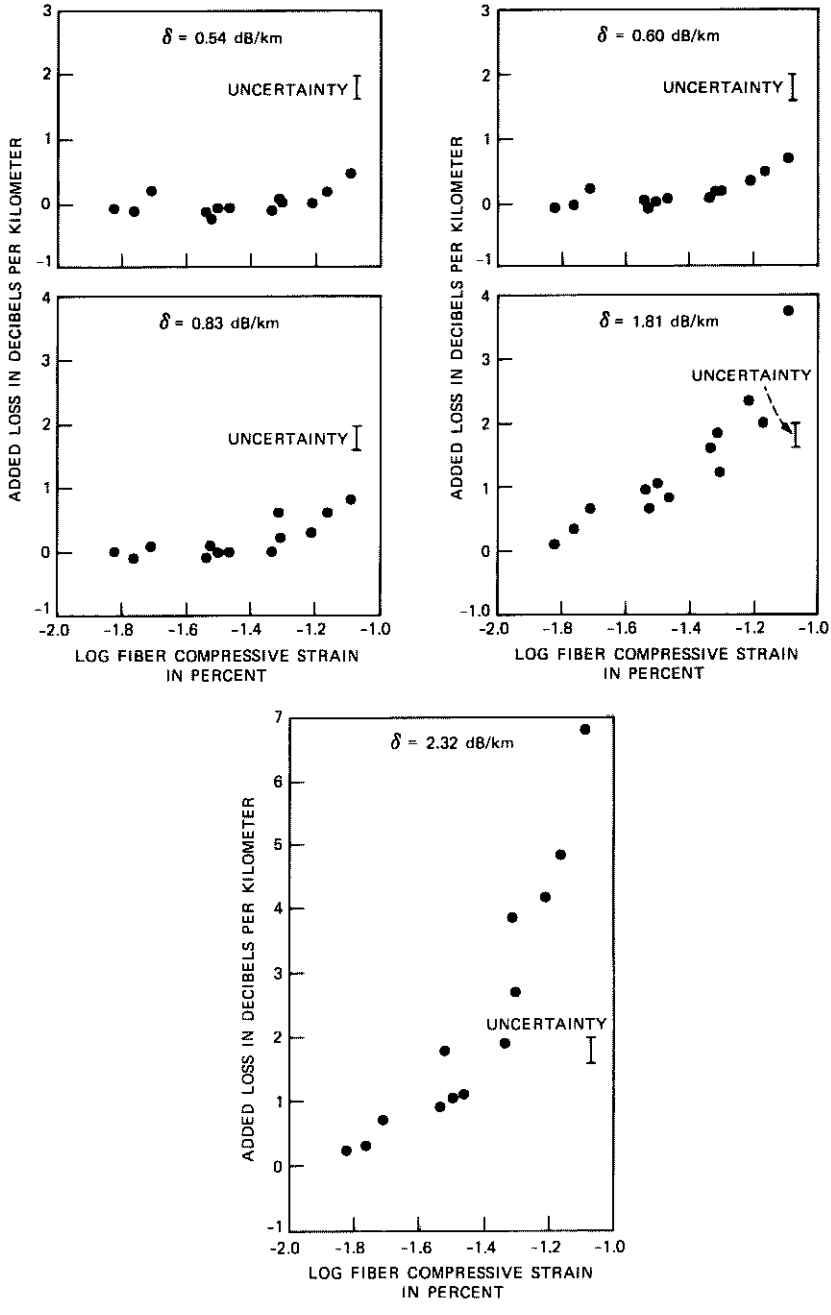

Fig. 11—Environmental added loss at 0.63 μm vs. calculated fiber strain in the environmental test (UA-coated fibers, ASR construction).

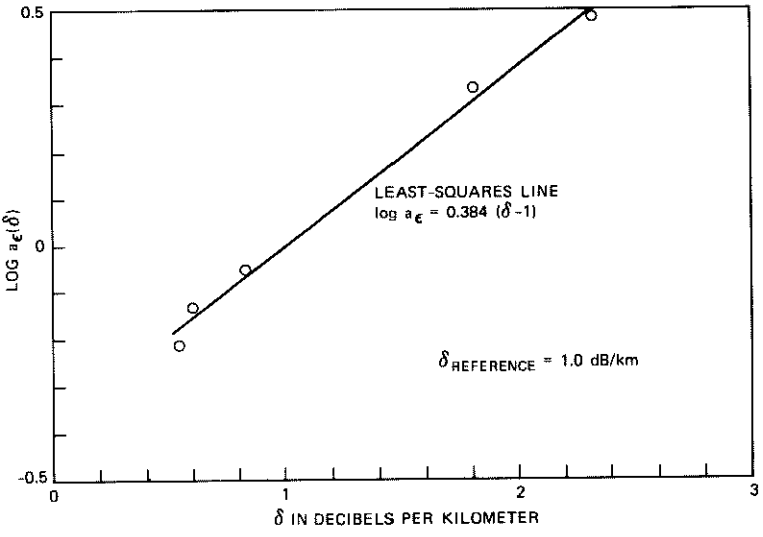

Fig. 12—Strain-scale-contraction factor vs. microbending sensitivity parameter $\delta$ (referenced to $\delta$ = 1.0 dB/km, UA-coated fibers, ASR construction).

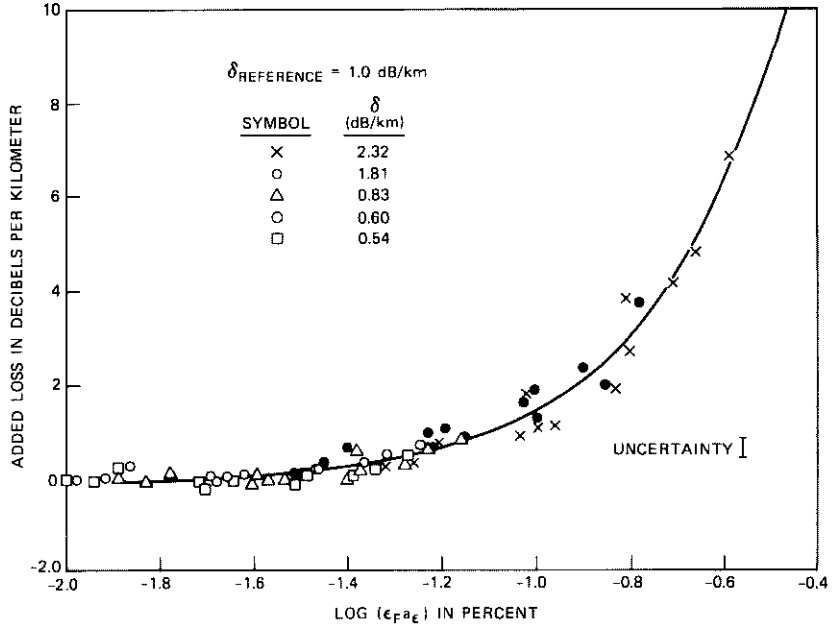

Fig. 13—Environmental added loss vs. $\delta$-reduced fiber strain (referenced to $\delta$ = 1.0 dB/km, UA-coated fibers, ASR construction).

Although the master curve of Fig. 13 has been constructed from data collected in all three cycles, this was not necessary. Indeed, a polynomial fit through Cycle I is virtually indistinguishable from the one shown in Fig. 13. Thus, we are led to conclude that only one low-temperature excursion is necessary to complete an analysis of the type presented here, provided fibers having a suitable range of $\delta$'s are tested. This observation greatly simplifies the environmental-testing procedure for fiber-optic ribbons.

### *5.2 Prediction of loss in the worst-case cycle*

We are now in a position to predict the behavior of a UA ASR in the worst-case environmental cycle. To do this we need only add to the strain associated with each temperature and time (see Fig. 10) the shift factor associated with the appropriate value of $\delta$ (see Fig. 12) for the fiber in question. The loss can then be read off the master curve (Fig. 13). For example, the strain $\epsilon_F$ in the worst-case cycle at −45°F obtained from Fig. 10 is 0.105%. The shift corresponding to a $\delta$ of 2.32 dB/km from the equation in Fig. 12 is $\log a_\epsilon(2.32) = 0.51$. Thus, the log of the $\delta$-reduced strain [$\log \epsilon_F a_\epsilon(2.32)$], −0.47, yields an added loss of 9.8 dB/km from Fig. 13. This procedure was employed to generate the curves in Fig. 14 for the ribbon behavior in the worst-case cycle for different values of $\delta$.

Notice for a $\delta$ of 2.32 dB/km in Fig. 14 that the loss in the worst-case cycle is much worse than that of Cycle III shown in Fig. 1. This

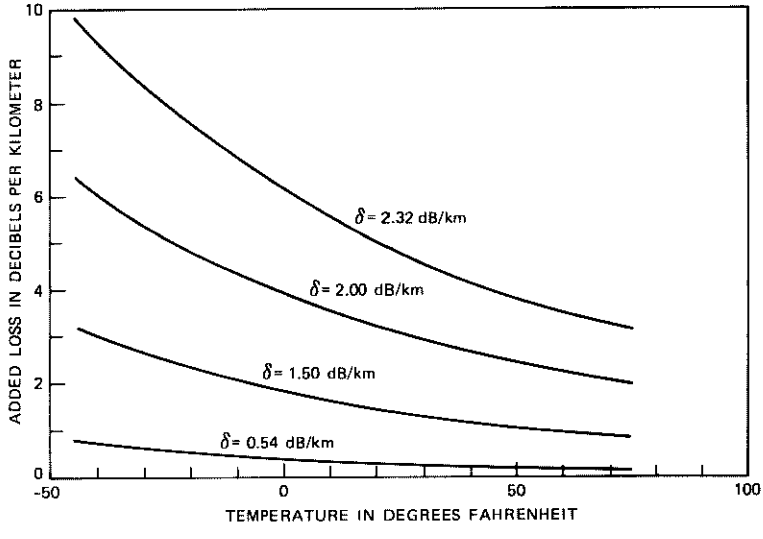

Fig. 14—Environmental added loss at 0.63 μm vs. temperature in the worst-case cycle (UA-coated fibers, ASR construction).

of course is the shrinkback effect previously discussed. Also, observe from comparing Figs. 11 and 14 that a fiber with $\delta = 0.54$ dB/km would meet a 0.5 dB/km added-loss criterion after Cycle III but not after the worst-case cycle. It is therefore clear that data sufficient to allow long-term predictions are essential to any meaningful ribbon evaluation. Finally, we remark that the added loss for a UA ASR can be predicted in the way demonstrated above for *any* environmental cycle provided one calculates the appropriate strain history by means of the formulas in Section IV.

## VI. APPLICATIONS

### 6.1 A Criterion for coating/ribbon-structure comparisons

If one were to choose a ribbon-performance requirement of 1.0 dB/km in the worst-case cycle, then it is clear from Fig. 14 that an ASR made with a population of UA-coated fibers having high $\delta$'s would be unacceptable. The same structure manufactured with low-$\delta$ fibers would satisfy the requirement. Thus, one can easily err out of ignorance of the strong effect arising from the sensitivity of the fiber to microbending (as reflected in $\delta$). Obviously, for a given performance requirement there is a maximum permissible $\delta$-value, $\beta$. That is, if ribbons are manufactured from a fiber selection having $\delta$'s less than $\beta$, the given performance requirement will be met. Clearly then, it is not a question of whether the UA-ASR structure is acceptable or not, but rather how restrictive the value of $\beta$ is. The parameter $\beta$ is therefore an effective criterion for comparing various coating and ribbon-structure combinations.

To calculate this maximum permissible $\delta$-value, $\beta$, for the UA ASR given a 1.0 dB/km added loss in the worst-case cycle, we enter into the master curve (Fig. 13) at a loss of 1.0 dB/km and read off the associated reduced strain

$$\log \epsilon_F a_\epsilon(\beta) = -1.09. \tag{15}$$

Next, introduce the equation for the $\delta$-shift curve (Fig. 12),

$$\log a_\epsilon(\beta) = 0.384(\beta - 1)$$

into (15) to arrive at

$$\beta = 1 - \frac{1.09 + \log \epsilon_F}{0.384}. \tag{16}$$

Now the $-45°$F strain in the worst-case cycle is 0.105 percent, so that (16) yields

$$\beta = 0.7 \text{ dB/km}.$$

Similarly, for a performance requirement of 0.5 dB/km, one finds

$$\beta = 0.2 \text{ dB/km}.$$

Thus, UA-coated fibers selected with $\delta$'s less than $\beta$ could be used in an ASR and satisfy the chosen performance requirement for a 40-year design life.

### 6.2 Critical material and geometric properties

The maximum permissible $\delta$, $\beta$, can also be used to evaluate how material and geometric properties might be altered to improve environmental performance. It is obvious that a reduction in polyester-tape shrinkback would reduce environmental added loss. This is illustrated dramatically in Fig. 15, where the parameter $\beta$ is plotted versus shrinkback normalized with respect to that of the present tape in the worst-case cycle (see Fig. 5). The two curves are for performance standards of 0.5 and 1.0 dB/km in the worst-case cycle. Notice that a 50-percent reduction increases $\beta$ from 0.2 to 0.5 dB/km for the 0.5 dB/km performance requirement, while elimination of the shrinkback

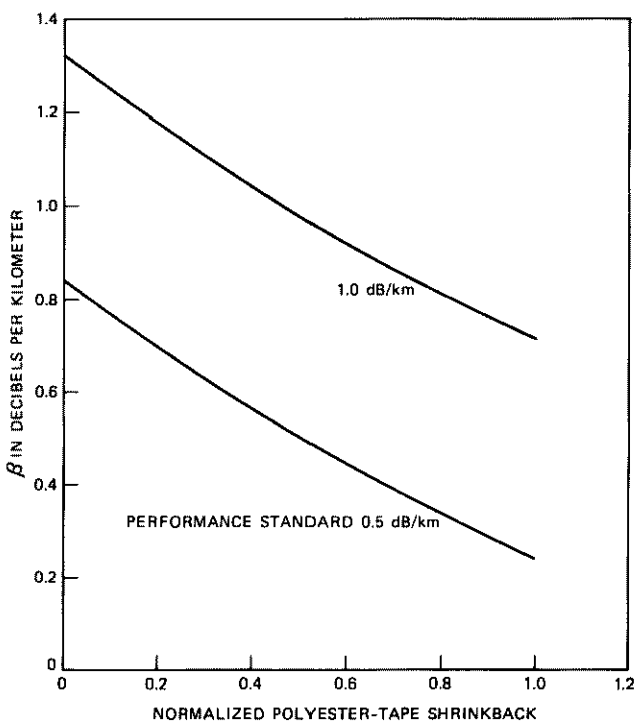

Fig. 15—Effect of shrinkback on the maximum permissible $\delta$-value for the worst-case cycle (UA-coated fibers, ASR construction).

altogether increases $\beta$ to 0.8 dB/km. Observe from eqs. (11) and (12) that the ribbon shrinkback is linear with respect to the area of the tape. Thus, Fig. 15 can also be viewed as a plot of $\beta$ versus reduced area normalized to that of the present tape (see Table III).

A consideration of Table III reveals that reducing the $\alpha EA$ product of the coating will likewise diminish the strain on the fibers, since the coefficient of thermal expansion of the ribbon would then be reduced. The coefficients $\alpha$ of thermal expansion are essentially the same for all plastics though the moduli $E$ can vary substantially from one material to another. Notice further that the area $A$ of the coating is greater than that of any other ribbon constituent. As to whether this reduction in fiber strain is accompanied by an environmental performance improvement depends on the extent to which the added-loss-versus-compressive-strain master curve and its associated $\delta$-shift characteristic are influenced by the changes adopted to reduce the fiber strain. Changing $\alpha$ of the coating has no effect on these curves while changing coating modulus $E$ and/or the ribbon geometry may have a substantial effect. The variation in the shape of these curves with changes in these various parameters can be ascertained only by completing a characterization of the type carried out here for the UA ASR.

Figure 16 shows how strong an effect reducing thermal contraction can be when the change in the added-loss-reduced-strain characteristic is negligible. Here we have plotted $\beta$ against the coated-fiber outer diameter holding the fiber diameter constant. Observe that if the outer diameter of the coated fiber is reduced from 9 to 6 mils the effect on $\beta$ is bigger than the effect of a 50-percent reduction in tape shrinkback. Letting the coating thickness tend to zero results in an increase in $\beta$ from 0.2 to 1.0 dB/km for the 0.5 dB/km performance requirement. If a 50-percent reduction in tape shrinkback is combined with a reduction in coated-fiber outer diameter to 6.5 mils, one can show that $\beta$ increases from 0.2 to 0.9 dB/km. Finally, we remark that these same dramatic effects should occur with reductions in the coating modulus.

Other investigators have established that dual-coated fibers having a soft primary coating are less sensitive to microbending than fibers having a hard, single coating.[1] Such dual-coated fibers in an ASR should also behave well environmentally. To see this, consider a secondary coating of UA over silicone where the area of the UA skin is $1.56 \times 10^{-5}$ in.$^2$ Neglecting the stiffness of the silicone (it is three orders of magnitude smaller than that of UA), we obtained an effective single-coated UA diameter of 6.4 mils. The corresponding increase in $\beta$ (Fig. 16) is from 0.2 to 0.6 dB/km for the 0.5 dB/km performance criterion. As previously mentioned these conclusions are predicated upon the assumption that the basic loss-strain characteristic of the ASR structure is relatively insensitive to changes in coating modulus.

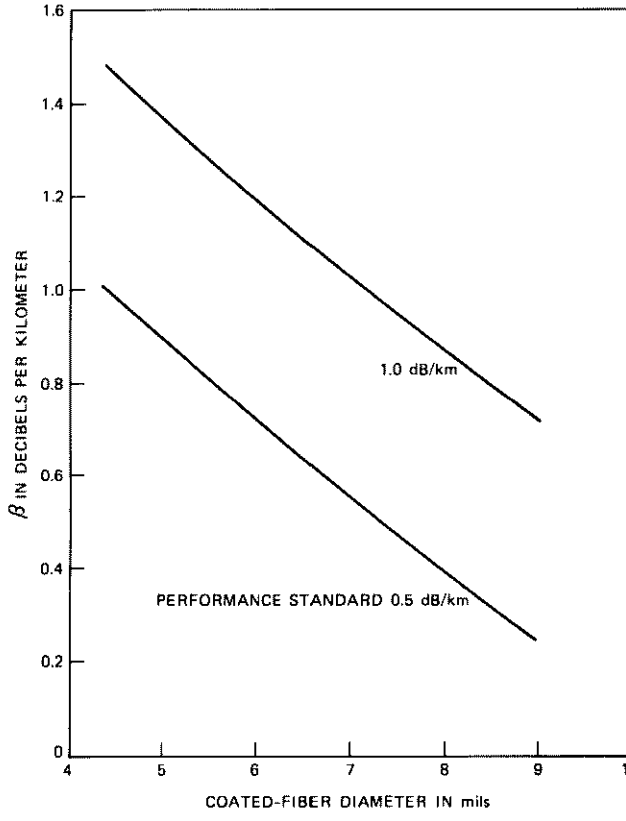

Fig. 16—Effect of coating thickness on the maximum permissible $\delta$-value for the worst-case cycle (UA-coated fibers, ASR construction, fiber diameter = 4.33 mils).

## VII. CONCLUSIONS AND RECOMMENDATIONS

We have shown that:

(*i*) Environmental added loss in an ASR is associated with axial compressive strain (not transverse strain) imparted to the fibers by thermal contraction of the ribbon in the low-temperature excursion and ribbon shrinkback together with relaxation during the high-temperature exposure.

(*ii*) There is a duality between a measure $\delta$ of the microbending sensitivity of a fiber and the fiber-compressive strain; viz., the effect of $\delta$ on the characteristic added-loss response to compressive strain is a uniform contraction of the strain scale.

(*iii*) Points (*i*) and (*ii*) above result in a master curve of environmental added loss versus $\delta$-reduced fiber strain together with a plot of the strain-scale contraction factor versus $\delta$-value. We are thus led to the algorithm depicted schematically in Fig. 17. Therefore, when

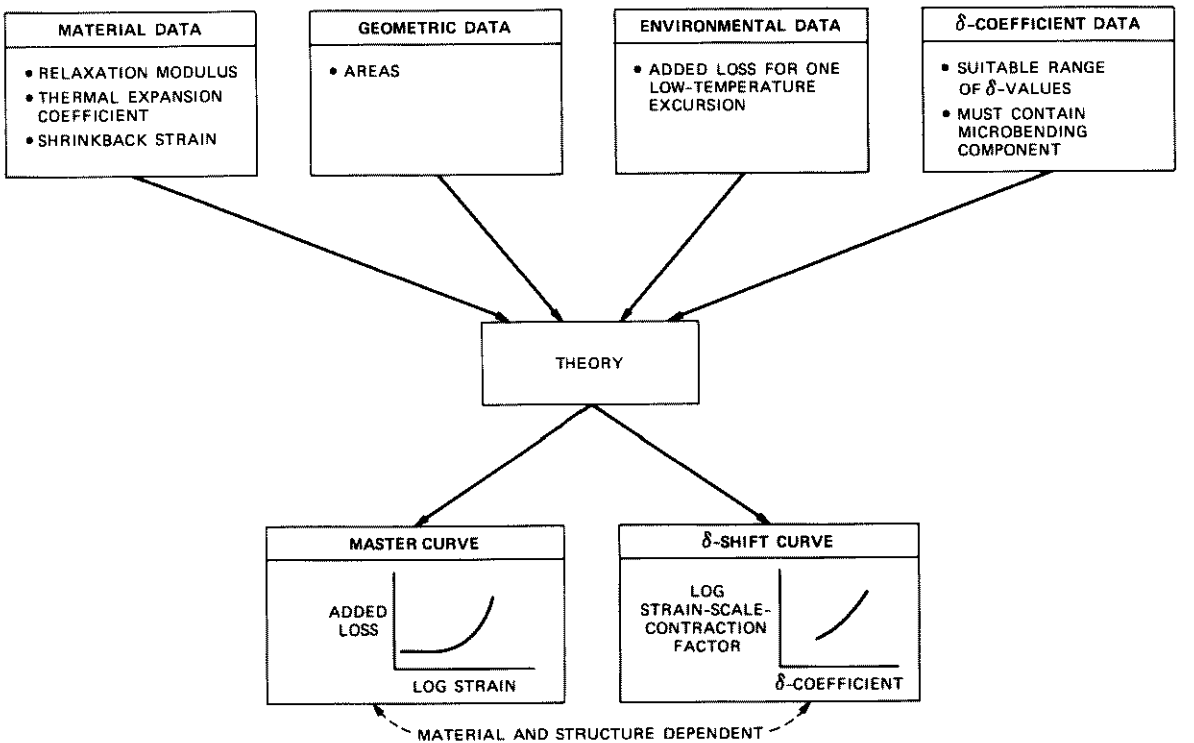

Fig. 17—Schematic of new environmental testing algorithm.

suitable material, geometric, environmental, and optical data are synthesized by way of our theory, we obtain a master curve and a $\delta$-shift curve that are sufficient to predict the environmental added loss for the candidate ribbon configuration for any desired environmental cycle. Notice that this environmental-testing scheme eliminates the necessity for long-term testing, only one low-temperature excursion being required.

(*iv*) There is a maximum value of $\delta$ that a particular ribbon design can accommodate and still meet a given performance requirement. This maximum permissible $\delta$-value is an excellent criterion for making coating/ribbon-structure comparisons.

By application of these techniques, we have found:

(*v*) The critical material and geometric parameters in ASR design are the shrinkback of the polyester tape and the product $\alpha EA$ of the coefficient $\alpha$ of thermal expansion, the time- and temperature-dependent relaxation modulus $E$, and the area $A$ associated with the fiber coating.

(*vi*) Any method of reducing the $\alpha EA$ product of the coating such as introducing a soft, single coating or a dual system with a soft primary coating should improve environmental performance.

## APPENDIX

### *Transverse Thermal Contraction of an Adhesive-Sandwich Ribbon*

Consider a section of an ASR containing two coated fibers as shown in Fig. 18. If the temperature is instantaneously lowered by an amount

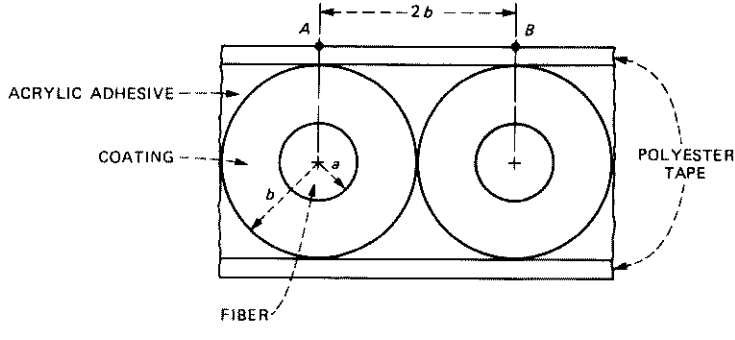

Fig. 18—Two-fiber portion of an ASR cross section prior to thermal contraction.

$|\Delta T|$ ($\Delta T < 0$) from the temperature $T_0$, the section $AB$ of tape would have an unstressed length $l_{TA}$ of

$$l_{TA} = 2b(1 + \alpha_{TA}\Delta T), \tag{17}$$

where $b$ is the outer radius of the coated fiber and $\alpha_{TA}$ is the coefficient of transverse thermal expansion of the polyester tape.

A coated fiber would also shrink in diameter, the final radius $b_f$ conforming to

$$b_f = b(1 + \alpha_*\Delta T), \tag{18}$$

where $\alpha_*$ is a number somewhere between the coefficients of thermal expansion of the glass and the plastic coating. To estimate $\alpha_*$ we appeal to linear thermoelasticity theory.

Denote by $u$ and $\sigma$ the radial displacement and stress fields (assumed axisymmetric) in the coating after the temperature is lowered. The stress field $\sigma$ is to vanish at $r = b$, and it must match the stress in the glass fiber at $r = a$. The displacements must also match at this fiber-coating interface. Since the glass is many times stiffer than the plastic, we approximate the boundary conditions at $r = a$ by supposing the glass-coating interface to shrink with the glass coefficient of thermal expansion. Thus,

$$u(a) = a\alpha_F\Delta T, \sigma(b) = 0, \tag{19}$$

where $\alpha_F$ is the coefficient of thermal expansion of the glass fiber.

When the axisymmetric solution to the requisite field equations[9] is substituted into (19), a pair of simultaneous, linear algebraic equations for two unknown constants result. Solving these equations and doing some algebra, one deduces that

$$u(b) = \alpha_* b\Delta T, \tag{20}$$

where

$$\alpha_* = \frac{4}{3b^2/a^2 + 1}[(b^2/a^2 - 1)\alpha + \alpha_F] \tag{21}$$

when Poisson's ratio of the plastic is taken as 1/3.

For the case at hand, we use the values for $a$ and $b$ from the table in Fig. 7 and select $\alpha$ and $\alpha_F$ for the urethane-acrylate coating and the glass, respectively, from Table III. Substitution of these numbers into (21) gives

$$\alpha_* = 3.18 \times 10^{-5}\ {}^\circ F^{-1}, \tag{22}$$

which is 95 percent of the urethane-acrylate value.

If the final length $l_{TA}$ of the tape segment is less than the final diameter $2b_f$ of the coated fiber, pressure will be created between the

fibers and microbending loss may result. Otherwise, the fibers will separate. Thus, the critical quantity is

$$d = l_{TA} - 2b_f. \tag{23}$$

Incorporating eqs. (17) and (18) into (23) results in

$$d = 2b\Delta T(\alpha_{TA} - \alpha_*). \tag{24}$$

For the case at hand $\alpha_{TA} < \alpha_*$ since the transverse thermal expansion coefficient for the tape is even less than the axial value reported in Table III. We thus conclude from (24) that $d$ is positive (recall that $\Delta T < 0$).

Thus as the temperature is lowered the fibers separate and microbending loss from transverse contraction is therefore impossible. As the temperature is raised, however, the fibers obviously approach one another since at high temperatures $\alpha_{TA}$ is still less than $\alpha_*$, but now $\Delta T > 0$. Moreover, there is transverse shrinkback at high temperatures. There is indeed environmental loss data which indicate increased loss at high temperatures.

# Adaptive Linearization of Power Amplifiers in Digital Radio Systems

By A. A. M. SALEH and J. SALZ

(Manuscript received October 5, 1982)

*High-frequency power amplifiers operate most efficiently at saturation, i.e., in the nonlinear range of their input/output characteristics. This phenomenon has traditionally dictated the use of constant envelope modulation methods for data transmission, resulting in circular signal constellations. This approach has inherently limited the admissible data rates in digital radio. In this paper we present a method for solving this problem without sacrificing amplifier power efficiency. We describe and analyze an adaptive linearizer that can automatically compensate for amplifier nonlinearity and thus make it possible to transmit multilevel quadrature amplitude modulated signals without incurring intolerable constellation distortions. The linearizer utilizes a real-time, data-directed, recursive algorithm for predistorting the signal constellation. Our analysis and computer simulations indicate that the algorithm is robust and converges rapidly from a blind start. Furthermore, the signal constellation and the average transmitted power can both be changed through software.*

## I. INTRODUCTION

Progress in high-speed data transmission over radio channels has lagged behind that of the voiceband channel. Inherent difficulties associated with implementing automatic equalizers are partially responsible, but the application of multilevel quadrature amplitude modulation (QAM) also has been inhibited by the amplitude (AM/AM) and phase (AM/PM) nonlinearities present in radio-frequency (RF) power amplifiers.

Recent work[1] has evolved design principles showing a possibility of substantial improvements in QAM performance over linear fading radio channels. A crucial obstacle to achieving these gains is the nonlinear distortion introduced by power amplifiers. Attempts to re-

alize high-speed data transmission over these channels force consideration of methods to cope with this nonlinear distortion.

One approach is to back off from saturation sufficiently so that the signal level is restricted to the linear range of amplification. The required amount of power back-off can be several decibels, resulting in an inefficient operation of the power amplifier. Moreover, the achievement of a given desired level of average transmitted power would require the use of a large, expensive, and high-power-consuming amplifier.

It has been realized[2-7] that some improvements in this regard can be obtained by using fixed signal predistortion circuits prior to amplification. Such circuits, however, cannot compensate for drifts in power amplifier nonlinearities caused by temperature changes, dc power variations, and component aging. These fluctuations can considerably degrade performance of systems employing constellations with large numbers of points, say 64 or higher, and the use of an adaptive technique is necessary in these applications.

Conceptually, the nonlinear distortion introduced by the power amplifier can be minimized at the receiver by an adaptive nonlinear equalizer. Such schemes have been proposed and studied in voiceband data transmission[8] and for filtered PSK signals operating over satellite channels.[9] This approach does not seem to be reasonable or necessary in our application, since the source of the nonlinearity is at the transmitter. Thus, it would appear logical to equalize the nonlinearity at the transmitter, where it occurs and where the transmitted bits are available.

Thus, this paper focuses on the problem of adaptive predistortion linearization. We describe a transmitter-based recursive algorithm for predistorting the signal constellation, thereby rendering a virtually linear transmitter. The algorithm operates in real time and is data directed. The predistortion is accomplished within a digital memory, which is used to generate the desired baseband signal. This maximizes the use of digital technology, and increases the reliability and flexibility of the system. For example, it is possible to change the signal constellation and the average transmitted power through software. Our treatment applies only to single-valued, memoryless nonlinearities.

The idea of adaptive predistortion of signal constellations has been previously suggested.[10] In this reference, the predistortion of each point of the constellation is accomplished by switching the RF or intermediate-frequency (IF) input signal to a separate path containing an adjustable diode attenuator and an adjustable diode phase shifter. The analog hardware required for such an implementation would be quite involved, especially for a large number of points. We have also found in the patent literature[11] a description of a digital adaptive

predistorter that appears to be similar to the one we present here. However, no detailed description of the algorithm or its behavior is provided.

Our basic ideas are described in Section II. Mathematical analysis is provided in Section III, and simulation results of the adaptive linearizer with finite-precision arithmetic are given in Section IV.

## II. GENERAL DESCRIPTION AND REQUIREMENTS OF OPERATION

A block diagram of a QAM transmitter with the proposed predistortion linearizer is shown in Fig. 1. A random access memory (RAM) contains the predistorted values of the in-phase and quadrature voltages of each point on the QAM constellation. A memory-lookup encoder obtains each input data symbol and generates the RAM addresses of the desired signal point. The corresponding stored, predistorted voltage values are converted to analog voltages using a pair of digital-to-analog (D/A) converters. These voltages drive a quadrature modulator, which generates the desired predistorted RF signal for the duration of the input symbol. That signal is then amplified, filtered, and transmitted. This part of the linearizer is similar in operation to a recently proposed memory-based encoder described in Ref. 12.

To update the RAM information, the amplifier output is sampled by a directional coupler and demodulated using the same local oscillator used for the modulator, which eliminates the need for carrier recovery. The output in-phase and quadrature voltages of the demodulator are converted to digital form using a pair of analog-to-digital (A/D) converters. A linearizing processor, which is the heart of the linearizer, receives this information, compares it with the input data, and computes the resulting error. A recursive algorithm, which is discussed in the next section, uses the error to update the voltage values in the RAM corresponding to the particular data point under consideration. Note that each point on the signal constellation is treated separately. Thus, the linearizer can support any desired constellation.

The memory-lookup encoder and the D/A converters have to operate, of course, at the full signaling rate. However, the linearizing processor and the A/D converters can operate at a much reduced rate, since the updating process is only needed to compensate for drifts that occur on a much slower time scale than the data rate.

We now emphasize a crucial point. The proper operation of the linearizer as described above assumes that the amplifier is memoryless, and requires that the signal not be filtered before the power amplifier. Thus, all pulse shaping and filtering must be performed by the combination of the post-amplifier, RF bandpass filter, and the receiver filters. The former filter should be designed just to meet FCC (or

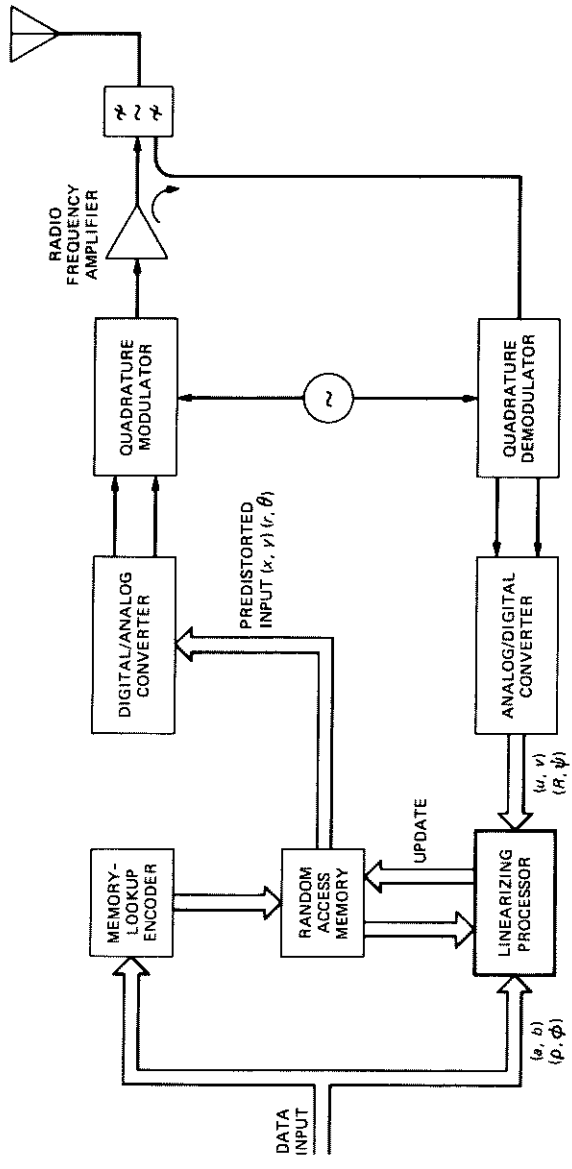

Fig. 1—Schematic representation of the adaptive, digital, predistortion linearizer.

other) emission rules for square input pulses, as described in Ref. 13. Such an implementation may require an automatic equalizer at the receiver to eliminate residual intersymbol interference. It was shown[1] that, even with ideal filtering, adaptive equalization would still be necessary to compensate for multipath fading using QAM signals with large numbers of levels. Thus, the elimination of pre-amplifier pulse shaping appears to be a mild constraint.

Because of the more stringent requirement on the post-amplifier, RF bandpass filter, its loss would of course be increased over that of the conventional case where preamplifier filtering does the spectrum shaping. However, computations[14] based on practical filters[15] operating in the 6-GHz band show that the RF filter loss would only increase from about 0.5 dB to 1.5 dB. However, we will see in Section IV that the linearizer in our system would allow the operation of the power amplifier to approach saturation. This would result in several decibels of power increase, which would more than compensate for the one-decibel increase in the filter loss.

## III. THE RECURSIVE ALGORITHM

As we already mentioned, our approach is applicable to any signal constellation. However, for clarity of exposition, we restrict our analysis to a rectangular constellation. Referring to Figs. 1 and 2, we denote a point on the rectangular QAM constellation by the complex number

$$a + ib = \rho e^{i\phi},$$

where, for an $L^2$-level system, $a$ and $b$ assume values on the lattice $\pm 1 \pm 3 \pm 5 \pm \cdots \pm (L-1)$. We denote the predistorted point by the

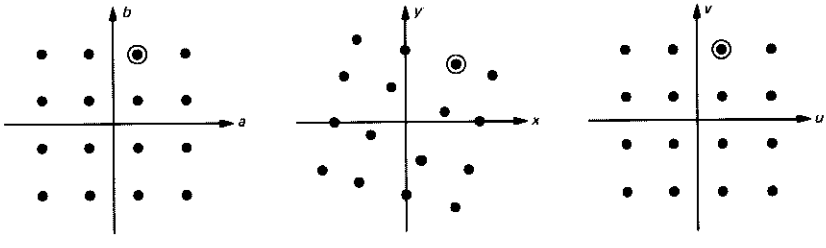

Fig. 2—The signal constellations at various points in the linearizer of Fig. 1. (a) Quadrature amplitude modulation data. (b) Digital/analog data. (c) Analog/digital data.

complex number

$$x + iy = re^{i\theta}.$$

A sequence of these points amplitude and phase modulates a carrier at frequency $f_c$ and the resulting signal,

$$S(t) = \sum_m r^{(m)} p(t - mT) e^{i[2\pi f_c t + \theta^{(m)}]}, \tag{1}$$

is applied to the amplifier. In (1), $p(t)$ is a rectangular pulse, $1/T$ is the signaling rate, and $r^{(m)}$, $\theta^{(m)}$ represent the amplitude and phase of the $m$th data symbol.

The amplifier is customarily represented by a pair of memoryless nonlinear functions.[16,17] The amplitude function, $A(r)$, causes amplitude distortion (AM/AM) and the phase function, $\Phi(r)$, causes amplitude to phase conversion (AM/PM). Thus the signal, (1), after amplification becomes

$$S_o(t) = \sum_m A(r^{(m)}) p(t - mT) e^{i\{2\pi f_c t + \theta^{(m)} + \Phi[r^{(m)}]\}}. \tag{2}$$

Figure 3 shows sketches of typical curves $A(r)$ and $\Phi(r)$ for a traveling-wave tube (TWT) power amplifier.

We remark that if the functions $A(\cdot)$ and $\Phi(\cdot)$ were known exactly we could choose transformations $g(\cdot)$ and $h(\cdot)$ from points $(\rho, \phi)$ to

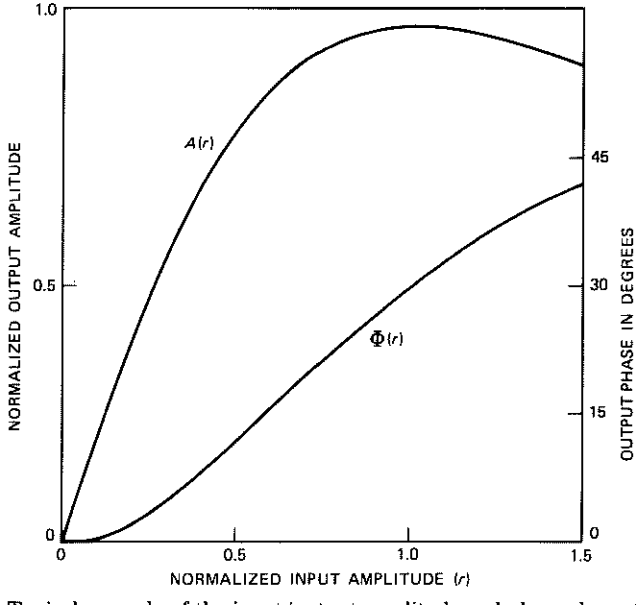

Fig. 3—Typical example of the input/output amplitude and phase characteristics of a TWT amplifier.

$(r, \theta)$ so that

$$A(r) = A[g(\rho)] = G\rho, \tag{3}$$

where

$$r = g(\rho)$$

and

$$\Phi(r) + h(\phi, \rho) = \phi + \zeta, \tag{4}$$

where

$$\theta = h(\phi, \rho).$$

The constant gain, $G$, in (3) is some desired gain, taking into account the linear gain of the power amplifier and the coupling factor of the sampling directional coupler. The fixed phase shift, $\zeta$, in (4) is arbitrary and can be set to zero without loss of generality.

Finally, let the measured data point from the A/D converter be

$$u + iv = Re^{i\psi}.$$

The object of the predistortion is to find a solution

$$r = \hat{r}$$

and

$$\theta = \hat{\theta},$$

such that

$$Re^{i\psi} = G\rho e^{i\phi}. \tag{5}$$

We now describe an iteration procedure that converges to (5).

Since data are usually scrambled, a specific data point $(\rho, \phi)$ will occur at random. Let $(r_n, \theta_n)$ be the predistorted RAM data point and $(R_n, \psi_n)$ be the measured data point at the $n$th time the desired data point $(\rho, \phi)$ occurs. The measured output radius $R_n$ is then

$$R_n = A(r_n) + \nu_n \tag{6a}$$

while the measured angle is

$$\psi_n = \Phi(r_n) + \theta_n + \mu_n, \tag{6b}$$

where $\nu_n$ and $\mu_n$ are zero-mean measurement errors. If the measurements were perfect and noiseless, we would simply solve the following two nonlinear equations

$$f(\hat{r}) = A(\hat{r}) - G\rho = 0 \tag{7}$$

and

$$\Phi(\hat{r}) + \hat{\theta} - \phi = 0 \tag{8}$$

for $\hat{r}$ and $\hat{\theta}$.

A great number of iterative procedures are known for solving the nonlinear equations given in (7) and (8). In the presence of measurement noise (with convex functions $A$ and $\Phi$), stochastic approximation algorithms[18] provide efficient methods. So, if one chooses step sizes $\alpha_n$ and $\beta_n$, which behave as $o(1/n)$, the following recursions are known to converge to the true solutions $\hat{r}$ and $\hat{\theta}$ in a mean-square sense:

$$r_{n+1} = r_n - \alpha_n(R_n - G\rho) \tag{9a}$$

$$\theta_{n+1} = \theta_n - \beta_n(\psi_n - \phi). \tag{9b}$$

To provide a rationale for the above recursions we analyze, in some detail, the behavior of (9a). The behavior of (9b) is similar. Since $f(X)$, eq. (7), is continuous on $(X_0, X_{\max})$ and if, by hypothesis, the derivative $f'(X)$ of $f(X)$ exists on this interval, then there is a $\xi$ such that

$$X_0 \le \xi \le X_{\max}$$

$$f'(\xi) = \frac{f(X_{\max}) - f(X_0)}{X_{\max} - X_0}. \tag{10}$$

Applying this mean-value theorem to $f(r_n)$, eq. (7), we get

$$f(r_n) = A(r_n) - G\rho = f(\hat{r}) + f'(\xi_n)(r_n - \hat{r}), \tag{11}$$

where $\xi_n$ lies between $r_n$ and $\hat{r}$. Substituting this into (9a) we get

$$r_{n+1} - \hat{r} = r_n - \hat{r} - \alpha_n[A'(\xi_n)(r_n - \hat{r}) + \nu_n]. \tag{12}$$

In (12) we made use of the fact that $f(\hat{r}) = 0$ and subtracted $\hat{r}$ from both sides of the equation.

Letting $\alpha_n A'(\xi_n) = \gamma_n$, $r_n - \hat{r} = \delta_n$ and then iterating (12) we obtain

$$\begin{aligned}\delta_{n+1} &= (1 - \gamma_n)\delta_n - \frac{\gamma_n \nu_n}{A'(\xi_n)} \\ &= \delta_1 \prod_{i=1}^{n} (1 - \gamma_i) - \sum_{k=1}^{n} \frac{\nu_k}{A'(\xi_k)} \frac{\gamma_k}{1 - \gamma_k} \prod_{i=k}^{n} (1 - \gamma_i).\end{aligned} \tag{13}$$

We now compute the mathematical expectation of $\delta_n$ and the variance:

$$\begin{aligned}\bar{\delta}_{n+1} = E\{\delta_{n+1}\} &= E\{\delta_1\} \prod_{i=1}^{n} (1 - \gamma_i) \\ &\le E\{\delta_1\} e^{-\sum_{i=1}^{n} \gamma_i}\end{aligned} \tag{14}$$

and

$$\sigma_{n+1}^2 = E\{\delta_{n+1} - \bar{\delta}_{n+1}\}^2 = \sigma_\nu^2 \sum_{k=1}^{n} \frac{\gamma_k^2}{[A'(\xi_k)]^2(1 - \gamma_k)^2} \prod_{i=k}^{n} (1 - \gamma_i)^2, \tag{15}$$

where $\sigma_\nu^2 = E\{\nu_n^2\}$. We see from (14) and (15) that rapid convergence of the algorithm is critically dependent on the step-size sequence, $\gamma_n$, which in turn depends on the derivative of the nonlinearity in the neighborhood of the solution. While the derivative is unknown, in most applications it can be bounded away from zero and this makes it possible to estimate the best step-size sequence. We see from (14) that, even in the absence of noise, the algorithm is guaranteed to converge to the true solution only if the step-size series diverges, i.e.,

$$\sum_{i=1}^{n} \gamma_i = \sum_{i=1}^{n} \alpha_i A'(\xi_i) \to \infty, \qquad n \to \infty. \tag{16}$$

If $\alpha_i$ and $A'(\xi_i)$ are restricted to be positive, (16) is equivalent to requiring $\sum_{i=1}^{n} \alpha_i$ to diverge. So it follows that the structure of the sequence can be of the form

$$\alpha_n = \frac{a}{n^\eta}, \tag{17}$$

where $a$ is a positive constant and $0 \le \eta \le 1$. It can be shown that for this choice of $\alpha_n$, and for $c = aA'(\hat{r})$,

$$\frac{E\{\delta_{n+1}\}}{E\{\delta_1\}} = e^{-\frac{cn^{(1-\eta)}}{1-\eta} + cq(\eta)}, \qquad (0 \le \eta < 1) \tag{18}$$

and

$$[A'(\hat{r})]^2 \frac{\sigma_{n+1}^2}{\sigma_\nu^2} = \frac{c}{2n^\eta}, \qquad (0 < \eta < 1), \tag{19}$$

where

$$q(\eta) = \lim_{n \to \infty} \left\{ \frac{n^{1-\eta}}{1-\eta} - \sum_{k=1}^{n} \frac{1}{k^\eta} \right\};$$

e.g., $q(0) = 0$ and $q(1/2) \approx 1.46$. Table I shows the behavior of the statistics for the special cases $\eta = 0$ and $\eta = 1$, where (18) and (19) are not applicable.

Table I—Behavior of statistics for $\eta = 0$ and $\eta = 1$

| $\eta$ | $c = aA'(\hat{r})$ | $\frac{\bar{\delta}_{n+1}}{\bar{\delta}_1}$ | $\frac{\sigma_{n+1}^2}{\sigma_\nu^2}[A'(\hat{r})]^2$ |
|---|---|---|---|
| 0 | $0 < c < 2$ | $(1-c)^n < e^{-cn}$ | $\frac{c}{2-c}[1-(1-c)^{2n}] \sim \frac{c}{2-c}$ |
| 1 | $c > \frac{1}{2}$ | $e^{-0.577}/n^c$ | $\frac{c^2}{2c-1} \times \frac{1}{n}$ |
| 1 | 1 | $e^{-0.577}/n$ | $\frac{1}{n}$ |
| 1 | 1/2 | $e^{\frac{0.577}{2}}/\sqrt{n}$ | $\frac{ln(n)}{4n}$ |

It is noted from eqs. (17) through (19) and Table I that the choice of a fixed step size ($\eta = 0$) gives the fastest convergence of the mean, $\bar{\delta}_{n+1}$, but results in a finite variance, $\sigma^2_{n+1}$, as $n \to \infty$. On the other hand, a variable, progressively smaller step size ($\eta \neq 0$) gives a slower convergence of the mean, but results in a variance approaching zero as $n \to \infty$. Thus, a fixed step size should be used if the measurement error variance, $\sigma^2_\nu$, is very small, and a variable step size should be used if the variance is large. Actually, when finite-precision arithmetic is employed, the choice of a progressively smaller step size can lead to large errors.[19] Thus, in our particular application where the measurement error can be made small, and where the use of finite-precision arithmetic is necessary, a fixed step size is more suitable.

We note that our algorithm, (9), is based on the polar representation of the data symbols, while the hardware implementation of Fig. 1 is based on the rectangular representation. Thus, the linearizing processor is required to convert back and forth between the two representations. One could avoid this conversion by replacing (9) by the rectangular-based algorithm

$$x_{n+1} + iy_{n+1} = x_n + iy_n - (\alpha_n + i\beta_n)[u_n + iv_n - G(a + ib)].$$

Unfortunately, however, the convergence of this algorithm is not guaranteed, even for some well-behaved amplifier characteristics.

## IV. SIMULATIONS

Here we present the results of computer simulations of the algorithm, (9), with fixed step sizes and finite-precision arithmetic. The precision is limited by the finite number of bits of the D/A and A/D converters (Fig. 1). As an example, we consider a TWT amplifier with normalized amplitude and phase nonlinearities of the form[17]

$$A(r) = \frac{2r}{1 + r^2}, \tag{20a}$$

$$\Phi(r) = 60^\circ \frac{r^2}{1 + r^2}, \tag{20b}$$

which are sketched in Fig. 3. Note that at saturation, $r = 1$, $A(r) = 1$, and $\Phi(r) = 30^\circ$. Figure 4 shows the severe distortion of the output constellation obtained with such an amplifier for a 64-QAM input signal driven with its corner point at saturation.

Figures 5, 6, and 7 show the simulated results of the output signal constellations after the application of (9) for three different cases (explained below). In all cases the amplifier drive is maintained at saturation. The four quadrants in each figure represent different combinations of the numbers of bits of the D/A and A/D converters, as indicated in Table II.

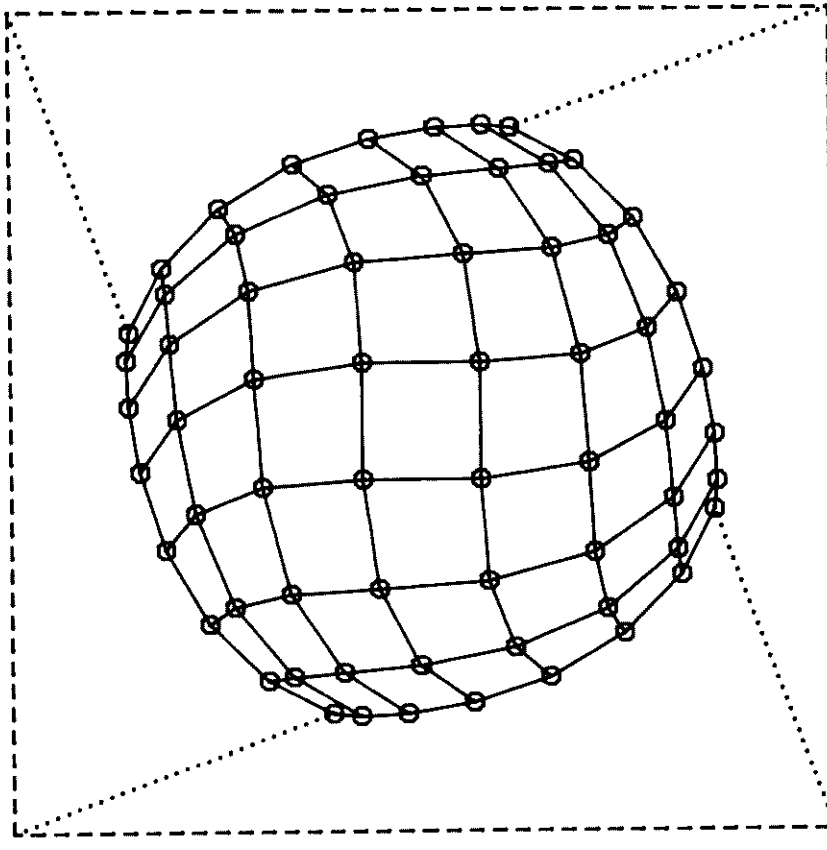

Fig. 4—The distortion of the signal constellation obtained with the amplifier of Fig. 3 for a 64-QAM input signal with its corner points at saturation.

Figure 5 corresponds to the case of no measurement error, i.e., $\nu_n = \mu_n = 0$ in (6). The step sizes used in (9) are $\alpha_n = 0.5$ and $\beta_n = 1.0$. Since the normalized small-signal gain, $A'(r)$, of the amplifier is about 2, the choice of $\alpha_n = 0.5$ results in a value for $c$ of about 1. This results in the fastest convergence of (9a), as can be seen from the first row of Table I. Similarly, the choice of $\beta_n = 1.0$ results in the fastest convergence of (9b) since that equation is linear in $\theta$. The initial guesses of $r$ and $\theta$ for each constellation point in Fig. 5 were chosen at random, i.e., from a blind start. The results indicated in the figure are those after 25 iterations for each constellation point. The point scatter shown is entirely due to the finite resolution of the D/A and A/D converters since no measurement errors were assumed.

It is clear from Fig. 5 that the use of 8 bits for both the D/A and A/D converters (fourth quadrant) gives quite an acceptable performance for 64 QAM. The use of 9 bits for each converter (first quadrant)

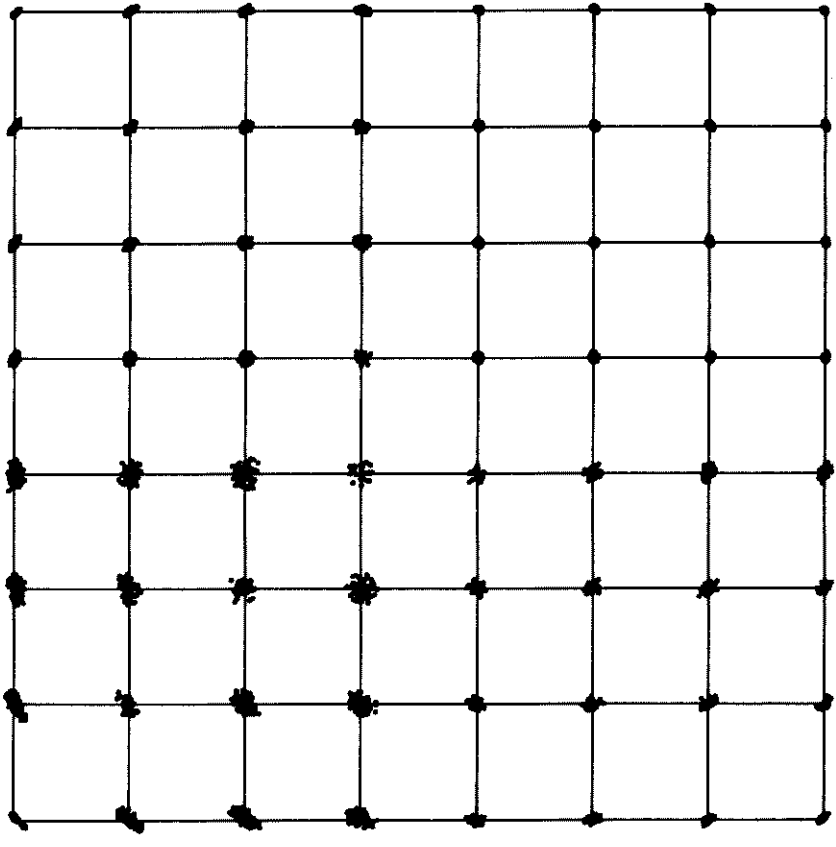

Fig. 5—Simulated results of the output signal constellation after 25 iterations with no measurement errors, and for step sizes $\alpha_n = 0.5$ and $\beta_n = 1.0$. The number of bits of the D/A and A/D converters are different in each quadrant as indicated in Table 2.

results in an almost perfect output constellation. In general, for $L^2$-QAM, where $L = 2^M$, D/A and A/D converters with $(M + 5)$ bits are needed for acceptable performance, and $(M + 6)$ or more bits are needed for almost perfect performance.

In Fig. 6, the step sizes employed are $\alpha_n = 0.5$ and $\beta_n = 1.0$, as in Fig. 5. However, a measurement error was introduced that is equivalent to a 30-dB signal-to-noise ratio at the corner points of the constellation. With the normalization used for $A(r)$ in (20a), this noise corresponds to $\sigma_\nu^2 = A^2(r)\sigma_\mu^2 = 0.0005$, where $\sigma_\nu^2$ and $\sigma_\mu^2$ are the variances of the errors $\nu_n$ and $\mu_n$ defined in (6). It is clear from Fig. 6 that such a level of noise, in combination with the large step sizes employed, gives unacceptable results.

In Fig. 7, the same noise level as that of Fig. 6 is employed. However, the step sizes were reduced by a factor of 10, i.e., $\alpha_n = 0.05$ and $\beta_n =$

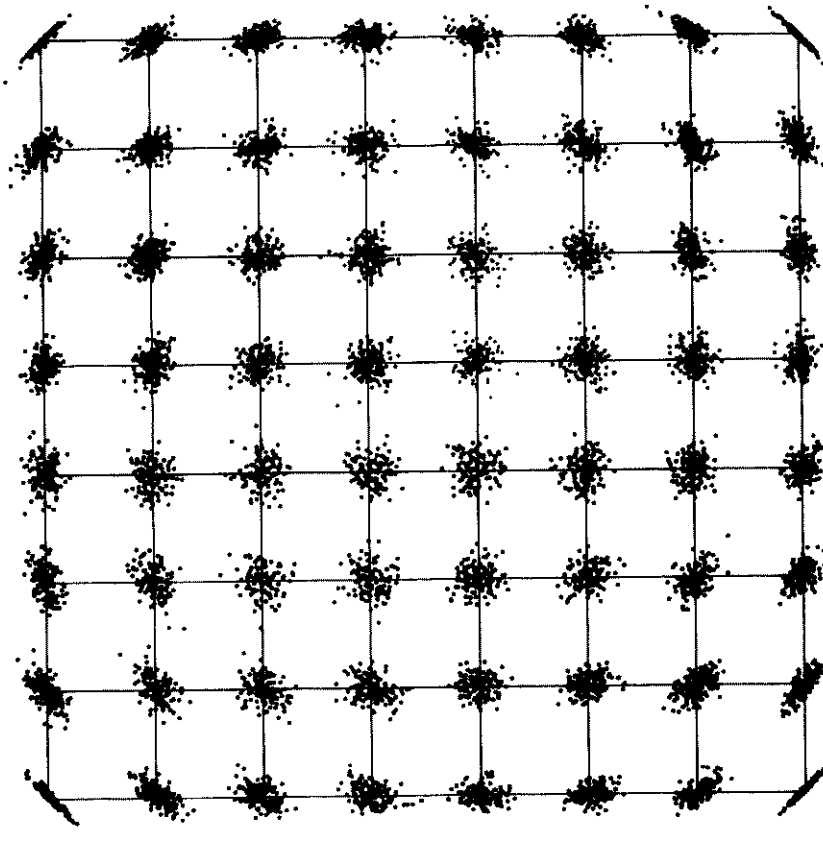

Fig. 6—Same as Fig. 5, but with a measurement error equivalent to 30-dB of signal-to-noise ratio at the corner points of the constellation.

0.1, resulting in a greatly improved performance. About 100 steps of iteration were needed in this case to reach convergence. Note that in spite of the measurement noise, the performance in the third quadrant of Fig. 7 is better than the corresponding performance in Fig. 5, where no noise is present. This is due to the reduced step sizes, and to the fact that the noise tends to smooth out quantization errors.

## V. SUMMARY AND CONCLUSIONS

We have proposed and analyzed a transmitter-based, adaptive linearizer, which automatically compensates for power amplifier nonlinearity in digital radio systems employing multilevel quadrature amplitude modulation. The linearizer utilizes a real-time, data-directed recursive algorithm for predistorting the signal constellation. The algorithm is robust and results in rapid convergence, even from a blind

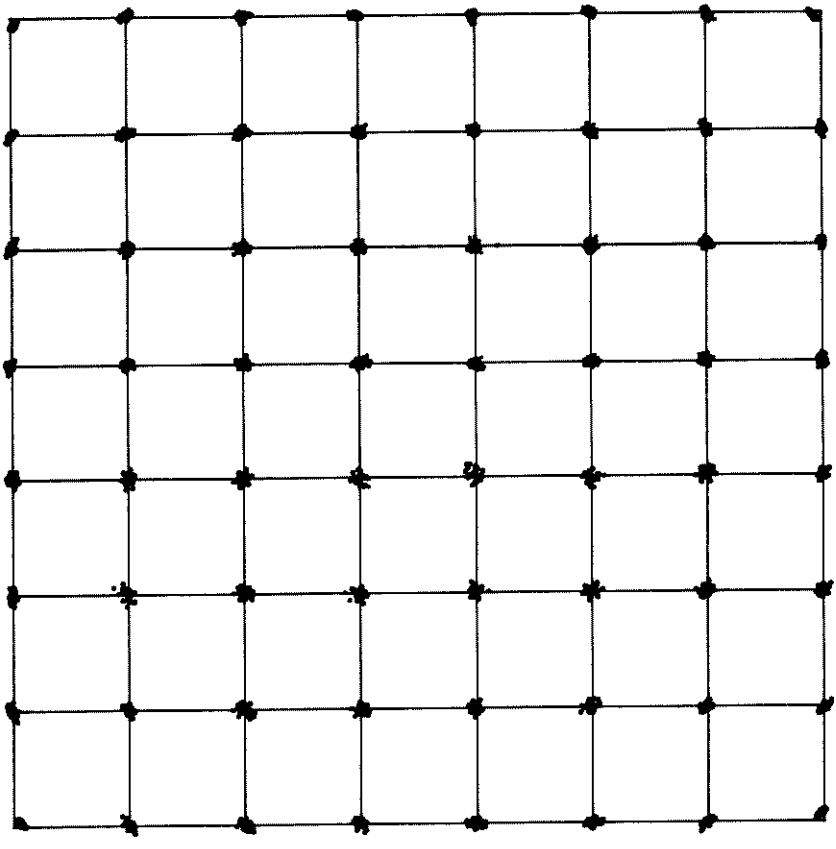

Fig. 7—Same as Fig. 6, but with the step sizes reduced by a factor of 10, i.e., $\alpha_n = 0.05$ and $\beta_n = 0.1$. About 100 iteration steps were needed for convergence.

Table II—Number of bits of the D/A and A/D converters for the four quadrants of Figs. 5, 6, and 7

| Quadrant Number | Number of Bits of the D/A Converter | Number of Bits of the A/D Converter |
|---|---|---|
| 1 | 9 | 9 |
| 2 | 9 | 7 |
| 3 | 8 | 6 |
| 4 | 8 | 8 |

start. The digital nature of the linearizer allows both the signal constellation and the average transmitted power to be changed through software.

The proposed linearizer is only suitable for amplifiers with essen-

tially memoryless and single-valued nonlinearities. Consequently, pulse shaping is not permitted before amplification. In our approach the task of pulse shaping is relegated to the combination of the transmit RF filter, a receiver-based filter, and an automatic equalizer. The latter is presumed to be required anyway to deal with multipath fading, especially for signals having a large number of levels.

Our principal conclusion is that high-power RF amplifiers can operate at saturation, where they are most efficient, provided that an adaptive predistortion linearizer is used. We have demonstrated that such a system is feasible and have provided a theory and a methodology for assessing its performance.

# An Introduction to the Application of the Theory of Probabilistic Functions of a Markov Process to Automatic Speech Recognition

By S. E. LEVINSON, L. R. RABINER, and M. M. SONDHI

(Manuscript received September 10, 1982)

*In this paper we present several of the salient theoretical and practical issues associated with modeling a speech signal as a probabilistic function of a (hidden) Markov chain. First we give a concise review of the literature with emphasis on the Baum-Welch algorithm. This is followed by a detailed discussion of three issues not treated in the literature: alternatives to the Baum-Welch algorithm; critical facets of the implementation of the algorithms, with emphasis on their numerical properties; and behavior of Markov models on certain artificial but realistic problems. Special attention is given to a particular class of Markov models, which we call "left-to-right" models. This class of models is especially appropriate for isolated word recognition. The results of the application of these methods to an isolated word, speaker-independent speech recognition experiment are given in a companion paper.*

## I. INTRODUCTION

It is generally agreed that information in the speech signal is encoded in the temporal variation of its short-duration power spectrum. To decode the signal, then, requires techniques for both estimation of power spectra and tracking their changes in time. This paper is concerned with the application of the theory of probabilistic functions of a (hidden) Markov chain to modeling the inherent nonstationarity of the speech signal for the purposes of automatic speech recognition (ASR).

The use of hidden Markov models for ASR was proposed by Baker[1,2] and, independently, by a group at IBM.[3–12] The theory on which their work rests is due to Baum et al.[13–17] Its first appearance in the literature occurred several years before Baker's studies and has since been

explored in some detail.[18,19] Our previous work in ASR has used temporal alignment procedures based on dynamic programming techniques,[20] and we hoped that through studying the new (to us) body of material we could improve the performance and/or capabilities of our present ASR systems.

Our initial goal, therefore, was to understand the theory of hidden Markov models sufficiently well to enable us to implement a new ASR system that could be compared directly to our existing ones. We have, in fact, been able to accomplish that goal, and a description and the results of our experiments are reported in a companion paper.[21] In the course of our studies, we have collected and integrated a number of loosely related mathematical techniques pertinent to Markov modeling. We have also modified and adapted these techniques to the specific ASR problems we wished to study. Our purpose in writing this tutorial, then, is to present this synthesis in a way that will be enlightening to those not familiar with the theory of hidden Markov models. We also hope that this treatment will provide for a better understanding of our companion paper. Finally, we hope to make the presentation general enough so that the theory is seen to be applicable to more than the problem of ASR.

We shall proceed as follows. We begin by defining probabilistic functions of a (hidden) Markov[22] chain and then show how they may be used in a natural way to model the speech signal. Once this is done, our task is reduced to solving two specific and well-defined mathematical problems: (i) computing the parameters of a proposed model conditioned on a sequence of observations assumed to have been generated by the model, and (ii) calculating the probability that a given set of observations was produced by a particular model.

First we review the solution to these problems as originally given by Baum,[13] who treated them as problems in statistical estimation. Lest the problems be too narrowly construed, we look at them as problems of classical constrained optimization. This allows us to give a partial geometrical interpretation to the Baum-Welch algorithm and to relate it to other studies of the problem by Baum and Eagon[14] and Baum and Sell.[17] It also makes clear that there are other methods of solution available that may, in certain instances, have advantages over the Baum-Welch algorithm. Finally, we discuss the dynamic programming algorithm of Viterbi[23] as an alternative to the so-called "forward-backward" method of Baum[13] for computing the probability of a sequence of observations conditioned on a specific model.

The treatment of these problems in the existing literature, and as recounted here, can lull a prospective user of the theory into a false sense of security. The equations look innocuous enough but, in reality, they overlook two problems that, though uninteresting from a theo-

retical standpoint, are of great significance for a robust implementation. We believe it is worthwhile to address, first, a numerical problem arising from the evaluation of certain frequently occurring algebraic expressions, and then an experimental difficulty precipitated by the inescapable reality of finite training-data set.

The numerical problem arises because, regardless of the method of solution chosen, one is required to evaluate a product of stochastic matrices involving a number of factors proportional to the number of observations. In any real computer, this will ultimately result in underflow. Fortunately, the computation can be scaled using a technique that subsequently will be seen to have some very useful properties.

The problem of insufficient training data can be ameliorated by changing the constraints on the optimization problem. This can be simply and directly accomplished in the classical methods. We show that the Baum-Welch algorithm, too, can be modified to produce the same result. Both of these methods appear to be simpler in implementation than the technique proposed by Jelinek and Mercer.[9]

Finally, under the heading of implementational considerations, we discuss techniques for model averaging. These can be used both for block processing of observations in case one is subject to storage limitations, and for increasing model stability under some circumstances.

The speech recognition experiment that we had in mind was on a speaker-independent, isolated word recognition system with a small vocabulary. Oddly enough, this is a simpler task than those to which the theory had already been applied by Baker[1] and the IBM group.[3-12] Perhaps our choice of a manageable problem is responsible for the degree of success reported in the companion paper.[21] We determined that for our ASR task it is advantageous to use a particular kind of hidden Markov model, which we call a left-to-right model. In such a model there are strong temporal constraints on the Markov chain. First, any state, once left, cannot be later revisited. Second, there is a final absorbing state in which all observation sequences are assumed to terminate. These restrictions on the sequences affect both parameter estimation and probability computation procedures. We show how the Baum-Welch algorithm, the Viterbi algorithm, and the classical methods can all be adapted for use with left-to-right models.

We conclude our presentation with several sample solutions to some artificial but nontrivial problems that illustrate concepts treated in the foregoing discussion.

## II. A REVIEW OF THE THEORY

A probabilistic function of a (hidden) Markov chain is a stochastic

process generated by two interrelated mechanisms, an underlying Markov chain having a finite number of states, and a set of random functions, one of which is associated with each state. At discrete instants of time, the process is assumed to be in some state and an observation is generated by the random function corresponding to the current state. The underlying Markov chain then changes states according to its transition probability matrix. The observer sees only the output of the random functions associated with each state and cannot directly observe the states of the underlying Markov chain; hence the term hidden Markov model.

In principle, the underlying Markov chain may be of any order and the outputs from its states may be multivariate random processes having some continuous joint probability density function. In this discussion, however, we shall restrict ourselves to consideration of Markov chains of order one, i.e., those for which the probability of transition to any state depends only upon that state and its predecessor. We shall also limit the discussion to processes whose observations are drawn from a discrete finite alphabet according to discrete probability distribution functions associated with the states.

It is quite natural to think of the speech signal as being generated by such a process. We can imagine the vocal tract as being in one of a finite number of articulatory configurations or states. In each state a short (in time) signal is produced that has one of a finite number of prototypical spectra depending, of course, on the state. Thus, the power spectra of short intervals of the speech signal are determined solely by the current state of the model, while the variation of the spectral composition of the signal with time is governed predominantly by the probabilistic state transition law of the underlying Markov chain. For speech signals derived from a small vocabulary of isolated words, the model is reasonably faithful. The foregoing is, of course, an oversimplification intended only for the purpose of motivating the following theoretical discussion.

Let us say that the underlying Markov chain has $N$ states $q_1, q_2, \cdots, q_N$ and the observations are drawn from an alphabet, $\mathbf{V}$, of $M$ prototypical spectra, $v_1, v_2, \cdots, v_M$. The underlying Markov chain can then be specified in terms of an initial state distribution vector $\pi' = (\pi_1, \pi_2, \cdots, \pi_N)$ and a state transition matrix, $A = [a_{ij}]$ $1 \leq i, j \leq N$. Here, $\pi_i$ is the probability of $q_i$ at some arbitrary time, $t = 0$, and $a_{ij}$ is the probability of transiting to state $q_j$ given current state, $q_i$, that is $a_{ij} = \text{prob}(q_j \text{ at } t + 1 | q_i \text{ at } t)$.

The random processes associated with the states can be collectively represented by another stochastic matrix $B = [b_{jk}]$ in which for $1 \leq j \leq N$ and $1 \leq k \leq M$, $b_{jk}$ is the probability of observing symbol $v_k$ given current state $q_j$. We denote this as $b_{jk} = \text{prob}(v_k \text{ at } t | q_j \text{ at } t)$. Thus a

hidden Markov model, $\mathbf{M}$, is identified with the parameter set $(\pi, A, B)$.

To use hidden Markov models to perform speech recognition we must solve two specific problems: observation sequence probability estimation, which will be used for classification of an utterance; and model parameter estimation, which will serve as a procedure for training models for each vocabulary word. Both problems proceed from a sequence, $\mathbf{O}$, of observations $O_1O_2 \cdots O_T$ where each $O_t$ for $1 \leq t \leq T$ is some $v_k \in \mathbf{V}$.

Our particular classification problem is as follows. We wish to recognize utterances known to be selected from some vocabulary, $W$, of words $w_1, w_2, \cdots, w_V$. We are given an observation sequence, $\mathbf{O}$, derived from the utterance of some unknown $w_i \in W$ and a set of $V$ models $\mathbf{M}_1, \mathbf{M}_2, \cdots, \mathbf{M}_V$. We must compute $P_i = \text{prob}(\mathbf{O}|\mathbf{M}_i)$ for $1 \leq i \leq V$. We will then classify the unknown utterance as $w_i$ iff $P_i \geq P_j$ for $1 \leq j \leq V$.

The training problem is simply that of determining the models $\mathbf{M}_i = (\pi_i, A_i, B_i)$ for $1 \leq i \leq V$ given training sequences $\mathbf{O}^{(1)}, \mathbf{O}^{(2)}, \cdots, \mathbf{O}^{(V)}$, where $\mathbf{O}^{(i)}$ is known to have been derived from an utterance of word $w_i$ for $1 \leq i \leq V$.

One could, in principle, compute $\text{prob}(\mathbf{O}|\mathbf{M})$ by computing the joint probability prob $(\mathbf{O}, \mathbf{s}|\mathbf{M})$ for each state sequence, s, of length $T$, and summing over all state sequences. Obviously this is computationally intractable. Fortunately, however, there is an efficient method for computing $P$. Let us define the function $\alpha_t(i)$ for $1 \leq t \leq T$ as $\text{prob}(O_1O_2 \cdots O_t$ and $q_i$ at $t|\mathbf{M})$. According to the definition $\alpha_1(i) = \pi_i b_i(O_1)$, where $b_i(O_1)$ is understood to mean $b_{ik}$ iff $O_1 \equiv v_k$; then we have the following recursive relationship for the "forward probabilities":

$$\alpha_{t+1}(j) = \left[\sum_{i=1}^{N} \alpha_t(i)a_{ij}\right] b_j(O_{t+1}) \qquad 1 \leq t \leq T-1. \tag{1}$$

Similarly, we define another function, $\beta_t(j) = \text{prob}(O_{t+1}O_{t+2} \cdots O_T|q_j$ at $t$ and $\mathbf{M})$. We set $\beta_T(j) = 1\ \forall\ j$ and then use the backward recursion

$$\beta_t(i) = \sum_{j=1}^{N} a_{ij}b_j(O_{t+1})\beta_{t+1}(j) \qquad T-1 \geq t \geq 1 \tag{2}$$

to compute the "backward probabilities."

The two functions can be used to compute $P$ according to

$$P = \text{Prob}(\mathbf{O}|\mathbf{M}) = \sum_{i=1}^{N}\sum_{j=1}^{N} \alpha_t(i)a_{ij}b_j(O_{t+1})\beta_{t+1}(j) \tag{3}$$

for any $t$ such that $1 \leq t \leq T-1$. Equations (1) to (3) are from Baum[13] and are sometimes referred to as the "forward-backward" algorithm.

Setting $t = T - 1$ in (3) gives

$$P = \sum_{i=1}^{N} \alpha_T(i) \tag{4}$$

so that $P$ can be computed from the forward probabilities alone. A similar formula for $P$ can be obtained from the backward probabilities by setting $t = 1$. These and several other formulas in this section may be compactly written in matrix notation (see Appendix A). For instance,

$$P = \pi' B_1 A B_2 A \cdots A B_T \mathbf{1}, \tag{5}$$

where $\mathbf{1}$ is the $N$-vector $(1, 1, 1, \cdots, 1)'$ and

$$B_t = \begin{pmatrix} b_1(O_t) & & & \\ & b_2(O_t) & & \mathbf{O} \\ & & \ddots & \\ \mathbf{O} & & & b_N(O_t) \end{pmatrix} \tag{6}$$

for $1 \le t \le T$. From (5) it is clear that $P$ is a homogeneous polynomial in the $\pi_i$, $a_{ij}$, and $b_{jk}$. Any of eqs. (3) through (5) may be used to solve the classification problem. The forward and backward probabilities will prove to be convenient in other contexts.

When we compute $P$ with the forward-backward algorithm, we are including the probabilities of all possible state sequences that may have generated $\mathbf{O}$. Alternatively, we may define $P$ as the maximum over all state sequences $i = i_0, i_1, \cdots i_T$ of the joint probability $P(\mathbf{O}, i)$. This distinguished state sequence and the corresponding probability of the observation sequence can be simultaneously computed by means of the Viterbi[23] algorithm. This dynamic programming technique proceeds as follows: Let $\phi_1(i) = \pi_i b_i(O_1)$ for $1 \le i \le N$. Then we can perform the following recursion for $2 \le t \le T$ and $1 \le j \le N$

$$\phi_t(j) = \max_{1 \le i \le N} [\phi_{t-1}(i) a_{ij}] b_j(O_t) \tag{7a}$$

and

$$\psi_t(j) = i^*, \tag{7b}$$

where $i^*$ is a choice of an index $i$ that maximizes $\phi_{t-1}(i)$.

The result is that $P = \max_{1 \le i \le N} [\phi_T(i)]$. Also the maximum likelihood state sequence can be recovered from $\psi$ as follows. Let $q_T = i^*$, where $i^*$ maximizes $P$. Then for $T \ge t \ge 2$, $q_{t-1} = \psi_t(q_t)$. If one only wishes to compute $P$, the linked list, $\psi$, need not be maintained as in (7b). Only the recursion (7a) is required.

The problem of training a model, unfortunately, does not have such a simple solution. In fact, given any finite observation sequence as training data, we cannot optimally train the model. We can, however,

choose $\pi$, $A$, and $B$ such that prob($\mathbf{O}|\mathbf{M}$) is locally maximized. For an asymptotic analysis of the training problem the reader should consult Baum and Petrie.[15]

We can use the forward and backward probabilities to formulate a solution to the problem of training by parameter estimation. Given some estimates of the parameter values we can compute, for example, that the expected number of transitions, $\gamma_{ij}$, from $q_i$ to $q_j$, conditioned on the observation sequence is just

$$\gamma_{ij} = \frac{1}{P} \sum_{t=1}^{T-1} \alpha_t(i) a_{ij} b_j(O_{t+1}) \beta_{t+1}(j). \tag{8}$$

Then, the expected number of transitions, $\gamma_i$ out of $q_i$, given $\mathbf{O}$, is

$$\gamma_i = \sum_{j=1}^{N} \gamma_{ij} = \frac{1}{P} \sum_{t=1}^{T-1} \alpha_t(i) \beta_t(i), \tag{9}$$

the last step of which is based on (2). The ratio $\gamma_{ij}/\gamma_i$ is then an estimate of the probability of state $q_j$, given that the previous state was $q_i$. This ratio may be taken as a new estimate, $\bar{a}_{ij}$, of $a_{ij}$. That is,

$$\bar{a}_{ij} = \frac{\gamma_{ij}}{\gamma_i} = \frac{\sum_{t=1}^{T-1} \alpha_t(i) a_{ij} b_j(O_{t+1}) \beta_{t+1}(j)}{\sum_{t=1}^{T-1} \alpha_t(i) \beta_t(i)}. \tag{10}$$

Similarly, we can make a new estimate of $b_{jk}$ as the frequency of occurrence of $v_k$ in $q_j$ relative to the frequency of occurrence of any symbol in state $q_j$. Stated in terms of the forward and backward probabilities we have

$$\bar{b}_{jk} = \frac{\sum_{t \ni O_t = v_k} \alpha_t(j) \beta_t(j)}{\sum_{t=1}^{T} \alpha_t(j) \beta_t(j)}. \tag{11}$$

Finally, new values of the initial state probabilities may be obtained from

$$\bar{\pi}_i = \frac{1}{P} \alpha_1(i) \beta_1(i). \tag{12}$$

As we shall see in the next section, the reestimates are guaranteed to increase $P$, except at a critical point.

### 2.1 Proof of the reestimation formula

The reestimation formulas (10), (11), and (12) are instances of the Baum-Welch algorithm. Although it is not at all obvious, each application of the formulas is guaranteed to increase $P$ except if we are at a critical point of $P$, in which case the new estimates will be identical

to their current values. Several proofs of this rather surprising fact are given in the literature.[13,17] Because we shall need to modify it later to cope with the finite sample size problem, we shall briefly sketch Baum's proof[13] here. The proof is based on the following two lemmas:

*Lemma 1: Let* $u_i$, $i = 1, \cdots, S$ *be positive real numbers, and let* $v_i$, $i = 1, \cdots, S$ *be nonnegative real numbers such that* $\sum_i v_i > 0$. *Then from the concavity of the log function it follows that*

$$\ln\left(\frac{\sum v_i}{\sum u_i}\right) = \ln\left[\sum_i \left(\frac{u_i}{\sum_k u_k}\right) \cdot \frac{v_i}{u_i}\right]$$

$$\geq \sum_i \frac{u_i}{\sum_k u_k} \ln\left(\frac{v_i}{u_i}\right)$$

$$= \frac{1}{\sum_k u_k}\left[\sum_i (u_i \ln v_i - u_i \ln u_i)\right]. \tag{13}$$

Here every summation is from 1 to $S$.

*Lemma 2: If* $c_i > 0$ $i = 1, \cdots, N$, *then subject to the constraint* $\sum_i x_i = 1$, *the function*

$$F(\mathbf{x}) = \sum_i c_i \ln x_i \tag{14}$$

*attains its unique global maximum when*

$$x_i = \frac{c_i}{\sum_i c_i}. \tag{15}$$

The proof follows from the observation that by the Lagrange method

$$\frac{\partial}{\partial x_i}\left[F(\mathbf{x}) - \lambda \sum_i x_i\right] = \frac{c_i}{x_i} - \lambda = 0. \tag{16}$$

Multiplying by $x_i$ and summing over $i$ gives $\lambda = \sum_i c_i$, hence the result.

Now in Lemma 1, let $S$ be the number of state sequences of length $T$. For the $i$th sequence let $u_i$ be the joint probability

$$u_i = \text{Prob}[\text{state sequence } i, \text{ observation } \mathbf{O} \mid \text{model } \mathbf{M}]$$

$$= P(i, \mathbf{O} \mid \mathbf{M}).$$

Let $v_i$ be the same joint probability conditioned on model $\bar{\mathbf{M}}$. Then

$$\sum_i u_i = p(\mathbf{O} \mid \mathbf{M}) \triangleq P(\mathbf{M})$$

$$\sum_i v_i = p(\mathbf{O} \mid \bar{\mathbf{M}}) \triangleq P(\bar{\mathbf{M}}) \tag{17}$$

and the lemma gives

$$\ln \frac{P(\bar{\mathbf{M}})}{P(\mathbf{M})} \geq \frac{1}{P(\mathbf{M})} \cdot [Q(\mathbf{M}, \bar{\mathbf{M}}) - Q(\mathbf{M}, \mathbf{M})], \tag{18}$$

where

$$Q(\mathbf{M}, \bar{\mathbf{M}}) \triangleq \sum_i u_i \ln v_i. \tag{19}$$

Thus, if we can find a model $\bar{\mathbf{M}}$ that makes the right-hand side of (18) positive, we have a way of improving the model $\mathbf{M}$. Clearly, the largest guaranteed improvement by this method results for $\bar{\mathbf{M}}$, which maximizes $Q(\mathbf{M}, \bar{\mathbf{M}})$ [and hence maximizes the right-hand side of (18)]. The remarkable fact proven in Ref. 13 is that $Q(\mathbf{M}, \bar{\mathbf{M}})$ attains its maximum when $\bar{\mathbf{M}}$ is related to $\mathbf{M}$ by the reestimation formulas (10) through (12). To show this let the $s$th-state sequence be $s_0, s_1, \cdots, s_T$, and the given observation sequence be $O_{k_1}, \cdots, O_{k_T}$. Then

$$\ln v_s = \ln p(s, \mathbf{O}|\bar{\mathbf{M}}) = \ln \bar{\pi}_{s_0} + \sum_{t=0}^{T-1} \ln \bar{a}_{s_t s_{t+1}} + \sum_{t=0}^{T-1} \ln \bar{b}_{s_{t+1}}(O_{t+1}). \tag{20}$$

Substituting this in (19) for $Q(\mathbf{M}, \bar{\mathbf{M}})$, and regrouping terms in the summations according to state transitions and observed symbols, it can be seen that

$$Q(\mathbf{M}, \bar{\mathbf{M}}) = \sum_{i=1}^{N} \sum_{j=1}^{N} c_{ij} \ln \bar{a}_{ij} + \sum_{j=1}^{N} \sum_{k=1}^{M} d_{jk} \ln \bar{b}_j(k) + \sum_{i=1}^{N} e_i \ln \bar{\pi}_i. \tag{21}$$

Here

$$c_{ij} = \sum_{s=1}^{S} p(s, \mathbf{O}|\mathbf{M}) n_{ij}(s) \tag{22a}$$

$$d_{jk} = \sum_{s=1}^{S} p(s, \mathbf{O}|\mathbf{M}) m_{jk}(s) \tag{22b}$$

$$e_i = \sum_{s=1}^{S} p(s, \mathbf{O}|\mathbf{M}) r_i(s), \tag{22c}$$

and for the $s$th-state sequence

$n_{ij}(s)$ = number of transitions from state $q_i$ to $q_j$

$m_{jk}(s)$ = number of times symbol $k$ is generated in state $q_j$

$r_i(s)$ = 1 if initial state is $q_i$

= 0 otherwise.

Thus, $c_{ij}$, $d_{jk}$, and $e_i$ are the expected values of $n_{ij}$, $m_{jk}$, $r_i$, respectively, based on model $\mathbf{M}$.

The expression (21) is now a sum of $2N + 1$ independent expressions of the type maximized in Lemma 2. Hence, $Q(\mathbf{M}, \bar{\mathbf{M}})$ is maximized if

$$\bar{a}_{ij} = \frac{c_{ij}}{\sum_j c_{ij}} \tag{23a}$$

$$\bar{b}_j(k) = \frac{d_{jk}}{\sum_k d_{jk}} \tag{23b}$$

$$\bar{\pi}_i = \frac{e_i}{\sum_i e_i}. \tag{23c}$$

These are recognized as the reestimation formulas.

### 2.2 Solution by optimization techniques

Lest the reader be led to believe that the reestimation formulas are peculiar to stochastic processes, we shall examine them briefly from several different points of view. Note that the reestimation formulas update the model in such a way that the constraints

$$\sum_{i=1}^{N} \pi_i = 1 \tag{24a}$$

$$\sum_{j=1}^{N} a_{ij} = 1 \quad \text{for} \quad 1 \le i \le N \tag{24b}$$

and

$$\sum_{k=1}^{M} b_{jk} = 1 \quad \text{for} \quad 1 \le j \le N \tag{24c}$$

are automatically satisfied at each iteration. The constraints are, of course, required to make the hidden Markov model well defined. It is thus natural to look at the training problem as a problem of constrained optimization of $P$ and, at least formally, solve it by the classical method of Lagrange multipliers. For simplicity, we shall restrict the discussion to optimization with respect to $A$. Let $Q$ be the Lagrangian of $P$ with respect to the constraints (24b). We see that

$$Q = P + \sum_{i=1}^{N} \lambda_i \left( \sum_{j=1}^{N} a_{ij} - 1 \right), \tag{25}$$

where the $\lambda_i$ are the as yet undetermined Lagrange multipliers.

At a critical point of $P$ on the interior of the manifold defined by (24a through c), it will be the case that for $1 \le i, j \le N$

$$\frac{\partial Q}{\partial a_{ij}} = \frac{\partial P}{\partial a_{ij}} + \lambda_i = 0. \tag{26}$$

Multiplying (26) by $a_{ij}$ and summing over $j$ we get

$$\sum_{j=1}^{N} a_{ij} \frac{\partial P}{\partial a_{ij}} = -\left[\sum_{j=1}^{N} a_{ij}\right] \lambda_i = -\lambda_i = \frac{\partial P}{\partial a_{ij}}, \tag{27}$$

where the right-hand side of (27) follows from substituting (24b) for the sum of $a_{ij}$ and then replacing $\lambda_i$ according to (26). From (27) it may be seen that $P$ is maximized when

$$a_{ij} = \frac{a_{ij} \dfrac{\partial P}{\partial a_{ij}}}{\displaystyle\sum_{k=1}^{N} a_{ik} \frac{\partial P}{\partial a_{ik}}}. \tag{28}$$

A similar argument can be made for the $\pi$ and $B$ parameters.

While it is true that solving (28) for $a_{ij}$ is analytically intractable, it can be used to provide some useful insights into the Baum-Welch reestimation formulas and alternatives to them for solving the training problem. Let us begin by computing $\partial P/\partial a_{ij}$ by differentiating (3), according to the formula for differentiating a product,

$$\frac{\partial P}{\partial a_{ij}} = \sum_{t=1}^{T-1} \alpha_t(i) b_j(O_{t+1}) \beta_{t+1}(j). \tag{29}$$

Substituting the right-hand side of (29) for $\partial P/\partial a_{ij}$ in (28), we get

$$a_{ij} = \frac{\displaystyle\sum_{t=1}^{T-1} \alpha_t(i) a_{ij} b_j(O_{t+1}) \beta_{t+1}(j)}{\displaystyle\sum_{j=1}^{N} \sum_{t=1}^{T-1} \alpha_t(i) a_{ij} b_j(O_{t+1}) \beta_{t+1}(j)}. \tag{30}$$

Then changing the order of summation in the denominator of (30) and substituting in the right-hand side of (2) we get

$$a_{ij} = \frac{\displaystyle\sum_{t=1}^{T-1} \alpha_t(i) a_{ij} b_j(O_{t+1}) \beta_{t+1}(j)}{\displaystyle\sum_{t=1}^{T-1} \alpha_t(i) \beta_t(i)}. \tag{31}$$

The right-hand side of (31) is thus seen to be identical to that of the reestimation formula (10). Thus, at a critical point, the reestimation formula (10) solves the equations (31). Similarly, if we differentiate (3) with respect to $\pi_i$ and $b_{jk}$ we get

$$\begin{aligned} \frac{\partial P}{\partial \pi_i} &= \sum_{j=1}^{N} b_i(O_1) a_{ij} b_j(O_2) \beta_2(j) \\ &= b_i(O_1) \beta_1(i) \end{aligned} \tag{32}$$

and

$$\frac{\partial P}{\partial b_{jk}} = \sum_{t \ni O_t = v_k} \sum_{i=1}^{N} \alpha_t(i) a_{ij} \beta_{t+1}(j) + \delta(O_1, v_k) \pi_j \beta_1(j), \tag{33}$$

respectively. In (33) $\delta$ is understood to be the Kronecker $\delta$ function.

By substituting (32) and (33) into their respective analogs of (28), we obtain the reestimation formulas (12) and (11), respectively, at a critical point. Thus it appears that the reestimation formulas may have more general applications than might appear from their statistical motivation.

Equation (28) suggests that we define a transformation, $\mathbf{T}$, of the parameter space onto itself as

$$\mathbf{T}(x)_{ij} = \frac{x_{ij} \dfrac{\partial P}{\partial x_{ij}}}{\sum_{k=1}^{N} x_{ik} \dfrac{\partial P}{\partial x_{ik}}}, \tag{34}$$

where $\mathbf{T}(\mathbf{x})_{ij}$ is understood to mean the $i, j$th coordinate of the image of $\mathbf{x}$ under $\mathbf{T}$. The parameter space is restricted to be the manifold such that $x_{ij} \geq 0$ for $1 \leq i, j \leq N$ and $\sum_{j=1}^{N} x_{ij} = 1$ for $1 \leq i \leq N$. Thus, the reestimation formulas (10), (11), and (12) are a special case of the transformation (34), with $P$ a particular homogeneous polynomial in the $x_{ij}$ having positive coefficients. Here the $x_{ij}$ include the $\pi_i$, the $a_{ij}$, and the $b_{jk}$. Baum and Eagon[14] have shown that for any such polynomial $P[\mathbf{T}(\mathbf{x})] > P(\mathbf{x})$ except if $\mathbf{x}$ is a critical point of $P$. Thus the transformation, $\mathbf{T}$, is appropriately called a growth transformation. The conditions under which $\mathbf{T}$ is a growth transformation were relaxed by Baum and Sell[17] to include all polynomials with positive coefficients. They further proved that $P$ increases monotonically on the segment from $\mathbf{x}$ to $\mathbf{T}(\mathbf{x})$. Specifically, they showed that $P[\eta \mathbf{T}(\mathbf{x}) + (1 - \eta)\mathbf{x}] \geq P(\mathbf{x})$ for $0 \leq \eta \leq 1$. Other properties of the transformation (34) have been explored by Passman[18] and Stebe.[19] There may be still less restrictive general criteria on $P$ for $\mathbf{T}$ to be a growth transformation.

We can give $\mathbf{T}(\mathbf{x})$ a simple geometric interpretation. For the purposes of this discussion we shall restrict ourselves to $\mathbf{x} \in \mathbf{R}^N$, $x_i \geq 0$ for $1 \leq i \leq N$, and the single constraint $G(\mathbf{x}) = \sum_{i=1}^{N} x_i - 1 = 0$. We do so without loss of generality, since constraints such as those of (24a, b, and c) are disjoint, i.e., no pair of constraints has any common variables. As shown in Fig. 1, given any $\mathbf{x}$ satisfying $G(\mathbf{x}) = 0$, $\mathbf{T}(\mathbf{x})$ is the intersection of the vector $\mathbf{X}$, or its extension, with the hyperplane $\sum_{i=1}^{N} x_i - 1 = 0$, where $\mathbf{X}$ has components $x_i \dfrac{\partial P}{\partial x_i}$ for $1 \leq \mathrm{i} \leq N$.

This may be shown by observing that a line in the direction of $\mathbf{X}$ passing through the origin has the equation $\mathbf{y} = r\mathbf{X}$, where $r$ is a non-

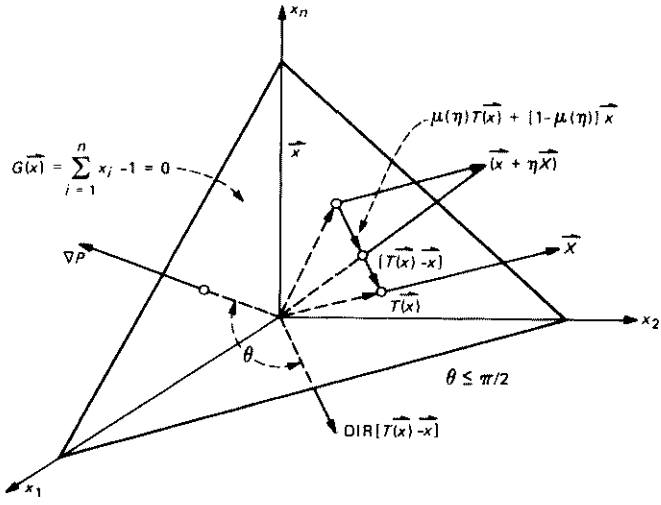

Fig. 1—Geometrical relationship of the quantities involved in the reestimation formulas.

negative scalar. Component-wise this is equivalent to

$$y_i = r x_i \frac{\partial P}{\partial x_i} \quad \text{for} \quad 1 \leq i \leq N. \tag{35}$$

We can find that $r$ for which $\mathbf{y}$ intersects the hyperplane $G(\mathbf{x}) = 0$ by summing over $i$. Thus

$$\sum_{i=1}^{N} y_i = r \sum_{i=1}^{N} x_i \frac{\partial P}{\partial x_i} = 1, \tag{36}$$

since $\mathbf{y}$ lies on the hyperplane $G(\mathbf{x}) = 0$. Rearranging (36) we have

$$r = \frac{1}{\sum_{i=1}^{N} x_i \frac{\partial P}{\partial x_i}} \tag{37}$$

and

$$y_i = \frac{x_i \frac{\partial P}{\partial x_i}}{\sum_{j=1}^{N} x_j \frac{\partial P}{\partial x_j}}. \tag{38}$$

Furthermore, as also shown in Fig. 1, the vector $[\mathbf{T}(\mathbf{x}) - \mathbf{x}]$ is the set of intersections of the vector $(\mathbf{x} + \eta\mathbf{X})$ with the hyperplane $G(\mathbf{x}) = 0$ for $0 \leq \eta \leq +\infty$ with $\mathbf{T}(\mathbf{x})$ corresponding to $\eta = +\infty$ and $\mathbf{x}$ to $\eta = 0$.

Finally, in view of the result of Baum and Sell, quoted above, the vector $\mathbf{T}(\mathbf{x}) - \mathbf{x}$ must also have a positive projection on $\nabla P$. This,

too, is easily seen. If $P$ is a polynomial with positive coefficients, then $\partial P/\partial x_i \geq 0$ for $1 \leq i \leq N$. From the definition of T it is clear that

$$\mathbf{T}(\mathbf{x})_i \geq x_i \quad iff \quad \frac{\partial P}{\partial x_i} \geq \sum_{j=1}^{N} x_j \frac{\partial P}{\partial x_j} = r, \tag{39}$$

where $r$ is some constant. Then it must be true that

$$\sum_{i=1}^{N} [\mathbf{T}(\mathbf{x})_i - x_i] \left( \frac{\partial P}{\partial x_i} - r \right) \geq 0 \tag{40}$$

since both factors in each summand are of the same sign. Rearranging (40) we have

$$\sum_{i=1}^{N} [\mathbf{T}(\mathbf{x})_i - x_i] \frac{\partial P}{\partial x_i} \geq r \sum_{i=1}^{N} [\mathbf{T}(\mathbf{x})_i - x_i] = 0. \tag{41}$$

The right-hand side is zero since $\sum_{i=1}^{N} \mathbf{T}(\mathbf{x})_i = \sum_{i=1}^{N} x_i = 1$. Thus $[\mathbf{T}(\mathbf{x}) - \mathbf{x}] \cdot \nabla P \geq 0$, proving that a step of the transformation has a positive projection along the gradient of $P$.

This merely guarantees that we can move an infinitesimal amount in the direction of $[\mathbf{T}(\mathbf{x}) - \mathbf{x}]$ while increasing $P$. The theorem of Baum and Eagon, however, guarantees much more, namely that we can take a finite step and be assured of increasing $P$. We may, in fact, be able to continue past $\mathbf{T}(\mathbf{x})$ while still increasing $P$. We are unable, at present, to give a geometrical interpretation of this fact.

While the reestimation formulas provide an elegant method for maximizing $P$, their success depends critically on the constraint set (24a, b, and c). As we will suggest later, in some cases there may be advantages in using classical optimization methods.

The principle of the classical methods is to search along the projection of $\nabla P$ on the constraint space, $G$, for a local maximum. The method of Rosen,[24] for example, uses only $\nabla P$ and a crude search strategy. The method of Davidon is one of many quasi-Newton techniques that uses the Fletcher-Powell[25] approximation to the inverse of the Hessian of $P$ and an exact line search with adaptive step size. There are many collections of general purpose subroutines for constrained optimization that can be used to solve the training problem. We have successfully used a version of the Davidon procedure from the Harwell Subroutine Library.[26] However, for the constraints that $\pi$, $A$, and $B$ be stochastic, the computation can be greatly simplified.

We illustrate this by outlining the gradient search algorithm for the case where $P$ is a function of the variables $x_1, \cdots, x_N$ subject to the constraints $x_i \geq 0$ for $1 \leq i \leq N$ and $\sum_{i=1}^{N} x_i - 1 = 0$. For convenience we will call the last constraint $G_1$, and the inequality constraints on $x_1, \cdots, x_N$ as $G_2, \cdots, G_{N+1}$, respectively.

An initial starting point $\mathbf{x}$ is chosen and the "active" constraints

identified. For our case $G_1$ is always active. For $i > 1$, $G_i$ is active if $x_{i-1} = 0$. Let $G_{n_j}$, $j = 1, \cdots, \ell$ be the active constraints (with $n_1 = 1$) at the initial point. Let $Q = P + \sum_{j=1}^{\ell} \lambda_j G_{n_j}$. Then according to the Kuhn-Tucker theorem,[27] the Lagrangian multipliers, $\lambda_j$, are determined by demanding that $\nabla Q$ be orthogonal to $\nabla G_{n_j}$ for $1 \le j \le \ell$. Now

$$\begin{aligned} \nabla Q &= \nabla P + \sum_{j=1}^{\ell} \lambda_j \nabla G_{n_j} \\ &= \nabla P + \Gamma\lambda, \end{aligned} \tag{42}$$

where $\Gamma$ is the $N \times \ell$ matrix with $\Gamma_{ij} = (\nabla G_{n_j})_i = \partial G_{n_j}/\partial x_i$, and $\lambda$ is the vector with components $\lambda_j$ for $j = 1, \cdots, \ell$. Thus the Kuhn-Tucker requirement is equivalent to

$$\Gamma'\nabla Q = 0 \tag{43}$$

or, from (42),

$$\lambda = -(\Gamma'\Gamma)^{-1}\Gamma'\nabla P. \tag{44}$$

For our special constraints we have

$$\Gamma_{i1} = 1 \quad \text{for} \quad 1 \le i \le N \tag{45}$$

and, for $j \neq 1$

$$\Gamma_{ij} = \begin{cases} 1 & \text{if} \quad i = n_j - 1 \\ 0 & \text{otherwise.} \end{cases} \tag{46}$$

With $\Gamma$ defined this way

$$\Gamma'\Gamma = \begin{pmatrix} N & 1 & 1 & \cdots & 1 \\ 1 & 1 & & & \\ 1 & & 1 & \mathbf{O} & \\ \vdots & \mathbf{O} & & \ddots & \\ 1 & & & & 1 \end{pmatrix} \tag{47}$$

and $(\Gamma'\Gamma)^{-1}$ may be shown to be

$$(\Gamma'\Gamma)^{-1} = \frac{1}{N - \ell + 1} \begin{pmatrix} 1 & -1 & -1 & \cdots & -1 \\ -1 & N - \ell & 1 & \cdots & 1 \\ -1 & 1 & N - \ell & 1 & 1 \\ \vdots & & & \ddots & 1 \\ -1 & 1 & 1 & & N - \ell \end{pmatrix}. \tag{48}$$

Substituting (48) into (44) gives $\lambda$. When this $\lambda$ is substituted back into (42), it turns out that the resulting vector $\nabla Q$ can be computed by the following simple steps:

(*i*) Compute $\nabla P$ and let $S$ be the sum of all components of $\nabla P$ *except* $(\nabla P)_{n_{j-1}}$, $j = 2, \cdots, \ell$.

(*ii*) Then

$$(\nabla Q)_i = 0 \qquad i = n_j, \qquad j = 2, \cdots, \ell$$
$$= (\nabla P)_i - \frac{S}{N - \ell + 1} \qquad \text{otherwise.}$$

Finally, the values of $P$ are searched along the line

$$\mathbf{x}(\eta) = \mathbf{x} + \eta \frac{\nabla Q}{\|\nabla Q\|} \tag{49}$$

for a maximum with respect to $\eta$. The procedure is repeated at this new point.

In applying this technique to the actual training problem, there will be $2N + 1$ stochasticity constraints analogous to $G_1$ and a corresponding number of positivity constraints analogous to $G_2$, $G_3$, $\cdots$ $G_{N+1}$. In this case we have the option of treating all the parameters and their associated constraints together, or we may divide them into disjoint subsets and determine search directions for each subset independently.

Notice that this derivation does not require $P$ to be of any special form. This may prove to be an advantage since the Baum-Welch algorithm is not applicable to all $P$. Furthermore, the constraints may be changed. Although, as we shall see later, the Baum-Welch algorithm can be somewhat generalized in this respect, it does not generalize to work with arbitrary linear constraints.

## III. CONSIDERATIONS FOR IMPLEMENTATION

From the foregoing discussion it might appear that solutions to the problems of hidden Markov modeling can be obtained by straightforward translation of the relevant formulas into computer programs. Unfortunately, for all but the most trivial problems, the naive implementation will not succeed for two principal reasons. First, any of the methods of solution presented here for either the classification or the training problem require evaluation of $\alpha_t(i)$ and $\beta_t(i)$ for $1 \le t \le T$ and $1 \le i \le N$. From the recursive formulas for these quantities, (1) and (2), it is clear that as $T \to \infty$, $\alpha_T(i) \to 0$, and $\beta_1(i) \to 0$ in exponential fashion. In practice, the number of observations necessary to adequately train a model and/or compute its probability will result in underflow on any real computer if (1) and (2) are evaluated directly. Fortunately, there is a method for scaling these computations that not only solves the underflow problem but also greatly simplifies several other calculations.

The second problem is more serious, more subtle, and admits of a less gratifying, though still effective, solution. Baum and Petrie[15] have shown that the maximum likelihood estimates of the parameters of a hidden Markov process are consistent estimates (converge to the true

values as $T \rightarrow \infty$) of the parameters. The practical implication of the theorem is that, in training, one should use as many observations as possible which, as we have noted, make scaling necessary. In reality, of course, the observation sequence will always be finite. Then the following situation can arise. Suppose a given training sequence of length $T$ results in $b_{jk} = 0$. (It is, in fact, possible for a local maximum of $P$ to lie on a boundary of the parameter manifold.) Suppose further that we are subsequently asked to compute the probability that a new observation sequence was generated by our model. Even if the new sequence was actually generated by the model, it can be such that $\alpha_{t-1}(i)a_{ij}$ is nonzero for only one value of $j$ and that $O_t = v_k$, whence $\alpha_t(j) = 0$ and the probability of the observation then becomes zero. This phenomenon is fatal to a classification task; yet, the smaller $T$ is, the more likely is its occurrence. Jelinek and Mercer[9] have dealt with this problem in a slightly different context. Here, we offer the much simpler solution of constraining the parameter values so that $x_{ij} \geq \epsilon_{ij} > 0$.

Finally, in this section we discuss the related problem of model stability. Baum and Eagon[14] note that successive applications of the reestimation formulas converge to a connected component of the local maximum set of $P$. In case there are only a finite number of such extrema, the point of convergence is unique to within a renaming of the states. The component of the local maximum set to which the iteration converges as well as which of the $N!$ labelings of the states is determined by the initial estimates of the parameters. If we wish to average several models resulting from several different starting points to achieve model stability, we must be able to match the states of models whose states are permuted. We have devised a solution to this problem based on a minimum-weight bipartite matching algorithm.[28]

### 3.1 Scaling

The principle on which we base our scaling is to multiply $\alpha_t(i)$ by some scaling coefficient independent of $i$ so that it remains within the dynamic range of the computer for $1 \leq t \leq T$. We propose to perform a similar operation on $\beta_t(i)$ and then, at the end of the computation, remove the total effect of the scaling.

We illustrate the procedure for (10), the reestimation formula for the state transition probabilities. Let $\alpha_t(i)$ be computed according to (1) and then be multiplied by a scaling coefficient, $c_t$, where say,

$$c_t = \left[ \sum_{i=1}^{N} \alpha_t(i) \right]^{-1} \tag{50}$$

so that $\sum_{i=1}^{N} c_t\alpha_t(i) = 1$ for $1 \leq t \leq T$. Then, as we compute $\beta_t(i)$ from (2), we form the product $c_t\beta_t(i)$ for $T \geq t \geq 1$ and $1 \leq i \leq N$. In terms

of the scaled forward and backward probabilities, the right-hand side of (10) becomes

$$\frac{\sum_{t=1}^{T-1} C_t \alpha_t(i) a_{ij} b_j(O_{t+1}) \beta_{t+1}(j) D_{t+1}}{\sum_{t=1}^{T-1} \sum_{\ell=1}^{N} C_t \alpha_t(i) a_{i\ell} b_\ell(O_{t+1}) \beta_{t+1}(\ell) D_{t+1}}, \tag{51}$$

where

$$C_t = \prod_{\tau=1}^{t} c_\tau \tag{52}$$

and

$$D_t = \prod_{\tau=t}^{T} c_\tau .$$

This results from the individual scale factors being multiplied together as we perform the recursions of (1) and (2).

Now note that each summand in both the numerator and the denominator has the coefficient $C_t D_{t+1} = \prod_{\tau=1}^{T} c_\tau$. These coefficients can be factored out and canceled so that (51) has the correct value $\bar{a}_{ij}$ as specified by (10). The reader can verify that this technique may be equally well applied to the reestimation formulas (11) and (12). It should also be obvious that, in practice, the scaling operation need not be performed at every observation time. One can use any scaling interval for which underflow does not occur. In this case, the scale factors corresponding to values of $t$ within any interval are set to unity.

While the above described scaling technique leaves the reestimation formulas invariant, (3) and (4) are still useless for computing $P$. However, $\log P$ can be recovered from the scale factors as follows. Assume that we compute $c_t$ according to (50) for $t = 1, 2, \cdots T$. Then

$$C_T \sum_{i=1}^{N} \alpha_T(i) = 1 \tag{53}$$

and from (53) it is obvious that $C_T = 1/P$. Thus, from (52) we have

$$\prod_{t=1}^{T} c_t = \frac{1}{P}. \tag{54}$$

The product of the individual scale factors cannot be evaluated but we can compute

$$\log P = -\sum_{t=1}^{T} \log c_t. \tag{55}$$

If one chooses to use the Viterbi algorithm for classification, then $\log P$ can be computed directly from $\pi$, $A$, and $B$ without regard for

the scale factors. Initially, we let $\phi_1(i) = \log[\pi_i b_i(O_1)]$ and then modify (7a) so that

$$\phi_t(j) = \max_{1 \le i \le N} [\phi_{t-1}(i) + \log a_{ij}] + \log[b_j(O_t)]. \tag{56}$$

In this case $\log P = \max_{1 \le i \le N} [\phi_T(i)]$.

If the parameters of the model are to be computed by means of classical optimization techniques, we can make the computation better conditioned numerically by maximizing $\log P$ rather than $P$. The scaling method of (50) makes this straightforward.

First note that if we are to maximize $\log P$, then we will need the partial derivatives of $\log P$ with respect to the parameters of the model. So, for example, we will need

$$\frac{\partial}{\partial a_{ij}} (\log P) = \frac{1}{P} \frac{\partial P}{\partial a_{ij}} = C_T \frac{\partial P}{\partial a_{ij}}. \tag{57}$$

Substituting the right-hand side of (29) for $\partial P / \partial a_{ij}$ in the right-hand side of (57) yields

$$\begin{aligned} \frac{\partial}{\partial a_{ij}} (\log P) &= C_T \sum_{t=1}^{T-1} \alpha_t(i) b_j(O_{t+1}) \beta_{t+1}(j) \\ &= \sum_{t=1}^{T-1} C_t \alpha_t(i) b_j(O_{t+1}) \beta_{t+1}(j) D_{t+1} \\ &= \sum_{t=1}^{T-1} \left( \prod_{\tau=1}^{t} c_\tau \right) \alpha_t(i) b_j(O_{t+1}) \beta_{t+1}(j) \left( \prod_{\tau=t+1}^{T} c_\tau \right). \end{aligned} \tag{58}$$

So that if we evaluate (29) formally, using not the true values of the forward and backward probabilities but the scaled values, then we will have the correct value of the partial derivatives of $\log P$ with respect to the transition probabilities. A similar argument can be made for the other parameters of the model and, thus, the scaling method of (50) provides a means for the direct evaluation of $\nabla(\log P)$, which is required for the classical optimization algorithms. Later we shall see that the combination of maximizing $\log P$ and this scaling technique simplifies the solution of the left-to-right Markov modeling problem as well.

### *3.2 Finite training sets*

We now turn our attention to solving the problems created by finite-training-set size. As we noted earlier, the effect of this problem is that observation sequences generated by a putative model will have zero probability conditioned on the model parameters. Since the cause of the difficulty is the assignment of zero to some parameters, usually

one or more symbol probabilities, it is reasonable to try to solve the problem by constraining the parameters to be positive.

We can maximize $P$ subject to the new constraints $a_{ij} \geq \epsilon > 0$; $b_{jk} \geq \epsilon > 0$, most easily using the classical methods. In fact, the algorithm described earlier based on the Kuhn-Tucker theorem is unchanged except that the procedure for determining the active constraints is based on $\epsilon$ rather than zero.

While the Lagrangian methods are perfectly adequate, it is also possible to build the new constraints into the Baum-Welch algorithm. We can show how this is done by making a slight modification to the proof of the algorithm given earlier (Section 2.1). Recall that the proof of the Baum-Welch algorithm was based on maximization of $2N + 1$ expressions of the type maximized in Lemma 2, eq. (14). Since these expressions involve disjoint sets of variables chosen from $A$, $B$, $\pi$, it suffices to consider any one of the maximizations. In fact, it suffices to show how Lemma 2 gets modified. Thus we wish now to maximize

$$F(\mathbf{x}) = \sum_i c_i \ln x_i \tag{59}$$

subject to the constraints

$$\sum_i x_i = 1 \tag{60a}$$

and

$$x_i \geq \epsilon, \qquad i = 1, \cdots N. \tag{60b}$$

(From the following discussion it will be obvious that a trivial generalization allows $\epsilon$ to depend on $i$.)

Now without the inequality constraints (60b), Lemma 2 showed that $F(\mathbf{x})$ attains its unique global maximum when $x_i = c_i / \sum_i c_i$. Suppose now that this global maximum occurs outside the region specified by the inequality constraints (60b). Specifically, let

$$\bar{x}_i = \frac{c_i}{\sum_{j=1}^{N} c_j} \geq \epsilon \quad \text{for} \quad i = 1, \cdots, N - \ell \tag{61a}$$

$$< \epsilon \quad \text{for} \quad i = N - \ell + 1, \cdots, N. \tag{61b}$$

From the concavity of $F(\mathbf{x})$ it follows that the maximum, subject to the inequality constraints, must occur somewhere on the boundary specified by the violated constraints (61b). Now it is easily shown that if $\bar{x}_i$ for some $i > N - \ell$ is replaced by $\epsilon$, then the global maximum over the rest of the variables occurs at values *lower* than those given above. From this we conclude that we must set

$$\bar{x}_i = \epsilon \quad \text{for} \quad i > N - \ell \tag{62}$$

and maximize

$$\tilde{F}(\mathbf{x}) = \sum_{i=1}^{N-\ell} c_i \ln x_i \tag{63}$$

subject to the constraint $\sum_{i=1}^{N-\ell} x_i = 1 - \ell\epsilon$. But this, analogously to Lemma 2, occurs when

$$\bar{x}_i = (1 - \ell\epsilon) \frac{c_i}{\sum_{j=1}^{N-\ell} c_j} \qquad i \leq N - \ell. \tag{64}$$

If these new values of $\bar{x}_i$ satisfy the constraints, we are done. If one or more become lower than $\epsilon$, they too must be set equal to $\epsilon$, and $\ell$ augmented appropriately.

Thus the modified Baum-Welch algorithm is as follows. Suppose we wish to constrain $b_{jk} \geq \epsilon$ for $1 \leq j \leq N$ and $1 \leq k \leq M$. We first evaluate $B$ using the reestimation formulas. Assume that some set of the parameters in the $j$th row of $B$ violates the constraint so that $b_{jk_i} < \epsilon$ for $1 \leq i \leq \ell$. Then set $\bar{b}_{jk_i} = \epsilon$ for $1 \leq i \leq \ell$ and readjust the remaining parameters according to (64) so that

$$\bar{b}_{jk} = (1 - \ell\epsilon) \frac{b_{jk}}{\sum_{i=1}^{N-\ell} b_{ji}} \qquad \forall k \notin \{k_i \mid 1 \leq i \leq \ell\}. \tag{65}$$

After performing the operation of (65) for each row of $B$, the resulting $\bar{B}$ is the optimal update with respect to the desired constraints. The method can be extended to include the state transition matrix if so desired. There is no advantage to treating $\pi$ in the same manner since, for any single observation sequence, $\bar{\pi}$ will always be a unit vector with exactly one nonzero component. In any case, (65) may be applied at each iteration of the reestimation formulas, or once as a post-processing stage after the Baum-Welch algorithm has converged.

### *3.3 Combining models*

The final implementational issue that we shall consider in this section is that of combining models for improved stability. There are several circumstances under which it may be desirable to combine several models into one. In spectral estimation, for example, to compute a long-term average spectrum of a stationary signal, it may be convenient to average a number of spectra computed over shorter intervals. It seems quite natural to apply similar block-processing techniques to the Markov modeling problem if the source is assumed to be ergodic. We may, for example, divide a long sequence of observations into contiguous subsequences, estimate model parameters for each subsequence, and combine the results.

Whether or not the source is ergodic, we may still attempt to increase the robustness of our model by averaging the parameter estimates derived from multiple initial values and/or independent observation sequences.

In any case, the difficulty that will be encountered is that even if there are finitely many isolated local maxima of $P$, they are only unique to within a renaming of the states. For two different observation sequences, $q_i$ and $q_j$ may be topologically equivalent, but $i \neq j$. We might try to avoid this problem by using the final parameter values for one observation sequence as the initial values for the next in hopes that this will restrict the search to a neighborhood of a single local maximum. This method, unfortunately, is not reliable. A better approach is that of finding a renaming of the states that minimizes, in some sense, the difference between two models.

Suppose $\mathbf{b}_j$ and $\bar{\mathbf{b}}_j$, $1 \leq j \leq N$ are, respectively, the rows of two estimates of $B$. Let $p(j)$ be a permutation of the state index, $j$, and let $d(\cdot,\cdot)$ be some distance metric. Then we seek the permutation, $p$, of $(q_1, q_2, \cdots, q_N)$ such that

$$D = \sum_{j=1}^{N} d[\mathbf{b}_j, \bar{\mathbf{b}}_{p(j)}] \tag{66}$$

is minimized. The naive solution is to try all possible $N!$ permutations and select the best one in the sense of (66). However, for $N > 10$ the computation becomes intractable. The problem can be brought within reach, however, by transforming it into a minimum-weight bipartite-graph-matching problem on $2N$ vertices. In the literature on combinatorial optimization (see, e.g., Ref. 28), several algorithms are available for accomplishing such a match in a number of operations that grow as $N^3$. In Appendix B, we describe one such algorithm based on an outline provided to us by R. E. Tarjan.

## IV. LEFT-TO-RIGHT HIDDEN MARKOV MODELS

For the purposes of isolated word recognition, it is useful to consider a special class of absorbing Markov chains that leads to what we call left-to-right models. These models have the following properties:

(*i*) The first observation is produced while the Markov chain is in a distinguished state called the starting state, designated $q_1$.

(*ii*) The last observation is generated while the Markov chain is in a distinguished state called the final or absorbing state, designated $q_N$.

(*iii*) Once the Markov chain leaves a state, that state cannot be revisited at a later time.

The simplest form of a left-to-right model is shown in Fig. 2, from which the origin of the term left-to-right becomes clear.

In this section we shall consider two problems associated with these

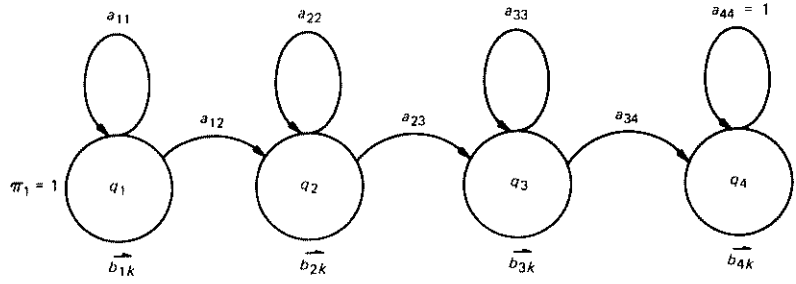

Fig. 2—The simplest form of left-to-right model.

special hidden Markov models. Note that a single, long-observation sequence is useless for training such models, because once the state $q_N$ is reached, the rest of the sequence provides no further information about earlier states. The appropriate training data for such a model are a *set* of observation sequences obtained by several starts in state $q_1$. In the case of isolated word recognition, for instance, several independent utterances of the same word provide such a set. We wish, therefore to modify the training algorithm to handle such training data. We also wish to compute the probability that a single given observation sequence, $O_1$, $O_2$ $\cdots$, $O_T$, was produced by the model, with the assumption that $O_1$ was produced in state $q_1$ and $O_T$ in state $q_N$. The three conditions mentioned above can be satisfied as follows:

Condition $(i)$ will be satisfied if we set $\pi = (1, 0, \cdots, 0)$ and do not reestimate it. Condition $(ii)$ can be imposed by setting

$$\beta_T(j) = \begin{cases} 1 & \text{for } j = N \\ 0 & \text{otherwise.} \end{cases} \tag{67}$$

Condition $(iii)$ can be guaranteed in the Baum-Welch algorithm by initially setting $a_{ij} = 0$ for $j < i$ (and in fact for any other combination of indices that specify transitions to be disallowed). It is clear from (34) that any parameter once set to zero will remain zero. For the gradient methods the appropriate $a_{ij}$'s are just set to zero and only the remaining parameters are adjusted.

The modification of the training procedure is as follows: Let us denote by $\mathbf{O} \equiv [\mathbf{O}^{(1)}, \mathbf{O}^{(2)}, \cdots \mathbf{O}^{(K)}]$ the set of observation sequences, where $\mathbf{O}^{(k)} = O_1^{(k)} O_2^{(k)} \cdots O_{T_k}^{(k)}$ is the $k$th sequence. We treat the observation sequences as independent of each other and then we adjust the parameters of the model $\mathbf{M}$ to maximize

$$P = \prod_{k=1}^{K} \text{Prob}(\mathbf{O}^{(k)} | \mathbf{M}).$$
$$= \prod_{k=1}^{K} P_k. \tag{68}$$

Since the Baum-Welch algorithm computes the frequency of occurrence of various events, all we need to do is to compute these frequencies of occurrence in each sequence separately and add them together. Thus the new reestimation formulas may be written as

$$\bar{a}_{ij} = \frac{\sum_{k=1}^{K} \sum_{t=1}^{T_k-1} \alpha_t^k(i) a_{ij} b_j(O_{t+1}^{(k)}) \beta_{t+1}^k(j)}{\sum_{k=1}^{K} \sum_{t=1}^{T_k-1} \alpha_t^k(i) \beta_t^k(i)} \tag{69}$$

and

$$\bar{b}_{ij} = \frac{\sum_{k=1}^{K} \sum_{t, \ni O_t(k)=v_j} \alpha_t^k(i) \beta_t^k(i)}{\sum_{k=1}^{K} \sum_{t=1}^{T_k} \alpha_t^k(i) \beta_t^k(i)}. \tag{70}$$

As noted above, $\pi$ is not reestimated.

Scaling these computations requires some care since the scale factors for each individual set of forward and backward probabilities will be different. One way of circumventing the problem is to remove the scale factors from each summand before adding. We can accomplish this by returning the $1/P$ factor [which appears in (8) and (9) and was cancelled to obtain (10)] to the reestimation formula. Using the reestimation formula for the transition probabilities as an example, (69) becomes

$$\bar{a}_{ij} = \frac{\sum_{k=1}^{K} \frac{1}{P_k} \sum_{t=1}^{T_k-1} \alpha_t^k(i) a_{ij} b_j(O_{t+1}^{(k)}) \beta_{t+1}^k(j)}{\sum_{k=1}^{K} \frac{1}{P_k} \sum_{t=1}^{T_k-1} \alpha_t^k(i) \beta_t^k(i)}. \tag{71}$$

If the right-hand side of (71) is evaluated using the scaled values of the forward and backward probabilities, then each term in the inner summation will be scaled by $C_t^k D_{t+1}^k$, which will then be cancelled by the same factor which multiplies $P_k$. Thus, using the scaled values in computing (69) results in an unscaled $\bar{a}_{ij}$. The procedure is easily extended to computation of the symbol probabilities. Also note that for the purposes of classification only one subsequence is to be considered so that either (55) or (56) may be used unaltered to compute $P$.

To apply Lagrangian techniques to left-to-right models we note that upon taking logarithms of (68) we have

$$\log P = \sum_{k=1}^{K} \log P_k. \tag{72}$$

The derivatives needed to maximize $\log P$ in (72) can be obtained by evaluating expressions for the derivatives of each individual subse-

quence and summing. For example, for $a_{ij}$ we have [cf. (57) and (58)]

$$\frac{\partial}{\partial a_{ij}}(\log P) = \sum_{k=1}^{K} \frac{\partial}{\partial a_{ij}}(\log P) = C_T^k \sum_{t=1}^{T_k-1} \alpha_t^k(i) b_j(O_{t+1}^{(k)}) \beta_{t+1}^k(j). \quad (73)$$

As in all previous cases an analogous formula may be derived for the other parameters.

In practice, $A$ and $B$ for left-to-right models are especially sparse. Some of the zero values are so by design but others are dependent on $\mathbf{O}$. Parameters of this type will be found one at a time by standard line search strategies. We have found that the convergence of the Lagrangian techniques can be substantially accelerated by taking large enough steps so that several positivity constraints become binding. The corresponding variables are then clamped and (65) is applied before beginning the next iteration.

## V. NUMERICAL EXAMPLES

In this section, we give some instructive examples of the behavior of several of the algorithms discussed above. The algorithms were all coded in FORTRAN 77 on a Data General MV-8000, which uses a 32-bit floating point word. The data used in the tests came from either a Monte Carlo simulation of a hidden Markov chain or from a portion of a newspaper text that was edited to include only the 26 characters of the English alphabet and a special character denoting an interword space. The simulations have the valuable property that the model is known a priori, so that simple models may be used for checking program correctness while the more complicated ones can elicit some subtle and important numerical and methodological characteristics of the algorithms.

In our experiments we used the following procedure to generate observation sequences by means of a random number generator whose output is uniform on [0, 1] and specified values of $\pi$, $A$, $B$, $T$, and $V$:

(*i*) Partition the unit interval proportionally to the components of $\pi$. Generate a random number and select a start state, $q_i$, according to the subinterval in which the number falls. Set $t = 1$.

(*ii*) Partition the unit interval proportionally to the components of the $i$th row of $B$. Generate a random number and select a symbol, $v_k$, according to the subinterval in which the number falls. Set $O_t = v_k$.

(*iii*) Partition the unit interval proportionally to the components of the $i$th row of $A$. Generate a random number and select the next state, $q_j$, according to the subinterval in which the number falls.

(*iv*) Increment $t$. If $t \leq T$ set $q_i = q_j$ and repeat (*ii*) through (*iv*); otherwise stop.

Using this observation generator, several two- and three-state Markov models were simulated. These simulations were used to verify that

the parameter estimation algorithms were working correctly and to study the effects of the scaling interval on the accuracy of the algorithms. In this study we found that all scaling intervals that were sufficiently short to prevent underflow yielded numerically identical results. Thus one can, at one extreme, scale the forward and backward probabilities after each observation or, at the other, wait until a threshold signaling that underflow is imminent is exceeded and only then perform the scaling operation.

We next proceeded to study a pair of four-state ($N = 4$), four-symbol ($M = 4$) models shown below and referred to as SRC44 and SRC45.

SRC44:

$$A = \begin{bmatrix} 0 & 0 & 0.5 & 0.5 \\ 0.5 & 0 & 0 & 0.5 \\ 0.5 & 0.5 & 0 & 0 \\ 0 & 0.5 & 0.5 & 0 \end{bmatrix} \qquad B = \begin{bmatrix} 0.5 & 0.5 & 0 & 0 \\ 0 & 0.5 & 0.5 & 0 \\ 0 & 0 & 0.5 & 0.5 \\ 0.5 & 0 & 0 & 0.5 \end{bmatrix}$$

$$\pi = [0.25 \quad 0.25 \quad 0.25 \quad 0.25]$$

and

SRC45:

$$A = \begin{bmatrix} 0 & 0 & 0.25 & 0.75 \\ 0.15 & 0 & 0 & 0.85 \\ 0.2 & 0.8 & 0 & 0 \\ 0 & 0.22 & 0.78 & 0 \end{bmatrix} \qquad B = \begin{bmatrix} 0.25 & 0.75 & 0 & 0 \\ 0 & 0.15 & 0.85 & 0 \\ 0 & 0 & 0.1 & 0.9 \\ 0.2 & 0 & 0 & 0.8 \end{bmatrix}$$

$$\pi = [0.25 \quad 0.25 \quad 0.25 \quad 0.25].$$

The state transition diagrams for these models are shown in Fig. 3.

Model SRC44 is a balanced model in the sense that all permissible transitions and symbols are equally likely, whereas model SRC45 is skewed in that it distinctly favors some transitions and symbols over others.

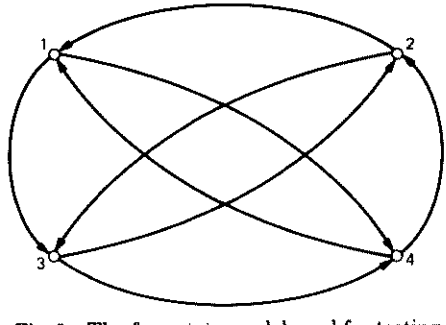

Fig. 3—The four-state model used for testing.

For each of these sources we processed observation sequences ranging in length from 100 to 4000 with the Baum-Welch algorithm. Initial values for $A$, $B$, and $\pi$ were chosen at random and the algorithm was terminated in one of two ways; either when the change in log $P$ from one iteration to the next fell below an arbitrary threshold, or when the number of iterations exceeded a specified maximum value. The maximum number of iterations was varied from 100 to 1000. For each estimate, $\hat{B}$, of the source matrix $B$, a measure of estimation error

$$\|\hat{B} - B\| = \left\{ \frac{1}{M \cdot N} \sum_{j=1}^{N} \sum_{k=1}^{M} \left[ \hat{b}_{jk} - b_{p(j)k} \right]^2 \right\}^{1/2} \tag{74}$$

was computed, where $p(j)$ is the state permutation that minimizes the

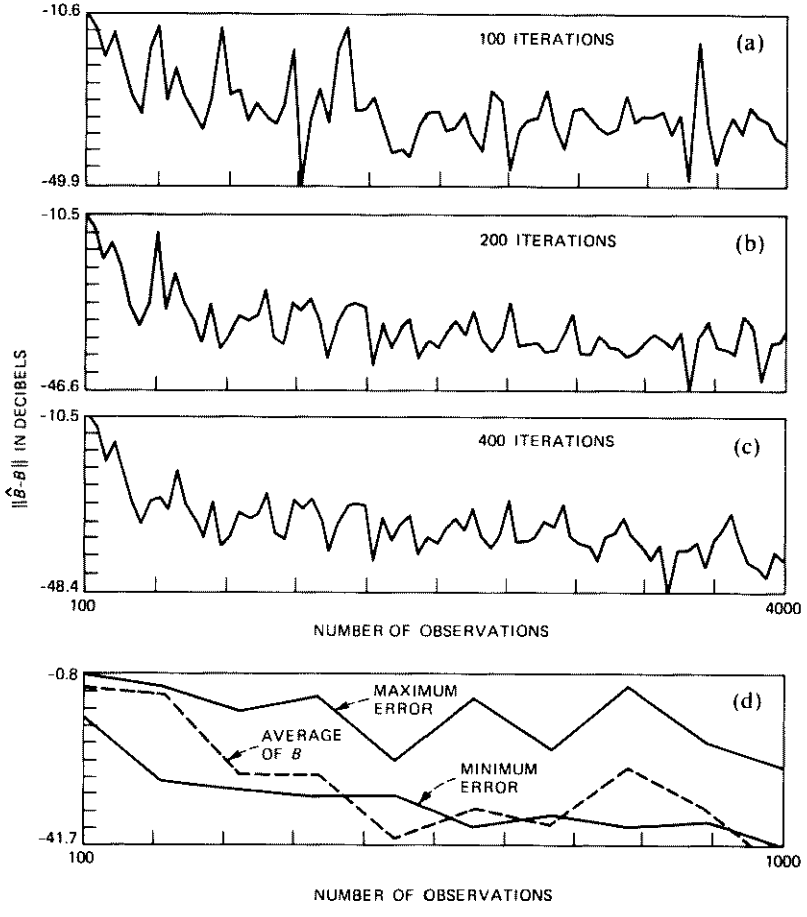

Fig. 4—Estimation error as a function of number of observations for source SRC44 for: (a) 100 iterations maximum, (b) 200 iterations, (c) 400 iterations, and (d) 10 random initial starts with 200 iterations maximum.

estimation error. The technique of minimum bipartite matching (see Appendix B) was used to determine the optimum state permutation.

Plots of the quantity $\|\hat{B} - \mathrm{B}\|$ (on a log scale) versus $T$, the number of observations, are given in Fig. 4 for source SRC44. Separate results are shown for 100 iterations maximum (part a) of the $BW$ reestimation procedure, 200 iterations (part b), and 400 iterations (part c). Also shown in Fig. 4d are the results of using 10 random initial starts with 200 iterations maximum. Shown in Fig. 4d are the maximum and minimum estimation errors for each $T$ and the estimation error for the average of all 10 $B$ matrices. (The reader should note that $T$ goes to 4000 in parts a through c, but only to 1000 in part d of Fig. 4.)

The curves given in Fig. 4 show several very interesting properties of the reestimation procedure. First we see that as the number of observations increases, a slow decrease in the average estimation error is obtained. However, we can see that statistical fluctuations (owing to different initial guesses for the model parameters) are often of larger magnitude than the slowly decreasing components of the curve. As the maximum number of iterations increases, the magnitude of the statistical fluctuations decreases, especially for larger values of $T$.

The curves of Fig. 4d show that although there is a wide range in the value of the estimation error for multiple starting choices, averaging the $B$ matrices (after appropriate state alignment) leads to estimation errors comparable with the best single estimates.

Figure 5 shows a similar set of results for the Markov source SRC45. Figure 5a shows a curve of estimation error versus number of observations for a maximum of 400 iterations, Fig. 5b shows the same curve with a maximum of 1000 iterations, Fig. 5c shows the curve when the initial estimates of both $A$ and $B$ are set to the source values exactly, and Fig. 5d shows maximum and minimum estimation errors for 10 random starting points.

Although the general trends of the data in Fig. 5 are similar to those of Fig. 4, there are several key differences. From Fig. 5b it can be seen that even for 1000 iterations, the variation in model estimates is enormous (36-dB variations). This result suggests that it is significantly more difficult to estimate parameters of a skewed Markov model than those of a fairly uniform model. The curves of Fig. 5c, in which the initial conditions were set to the source generator values, show that extremely good solutions could be obtained if the reestimation procedure could start in the neighborhood of the "exact" solution. Obviously this situation (i.e., starting near the correct parameter values) is not enforceable for real data.

The curves of Fig. 5d, in which multiple estimates of the Markov model are averaged, show that averaging the individual parameter estimates does not lead to a low error estimate for SRC45. This is

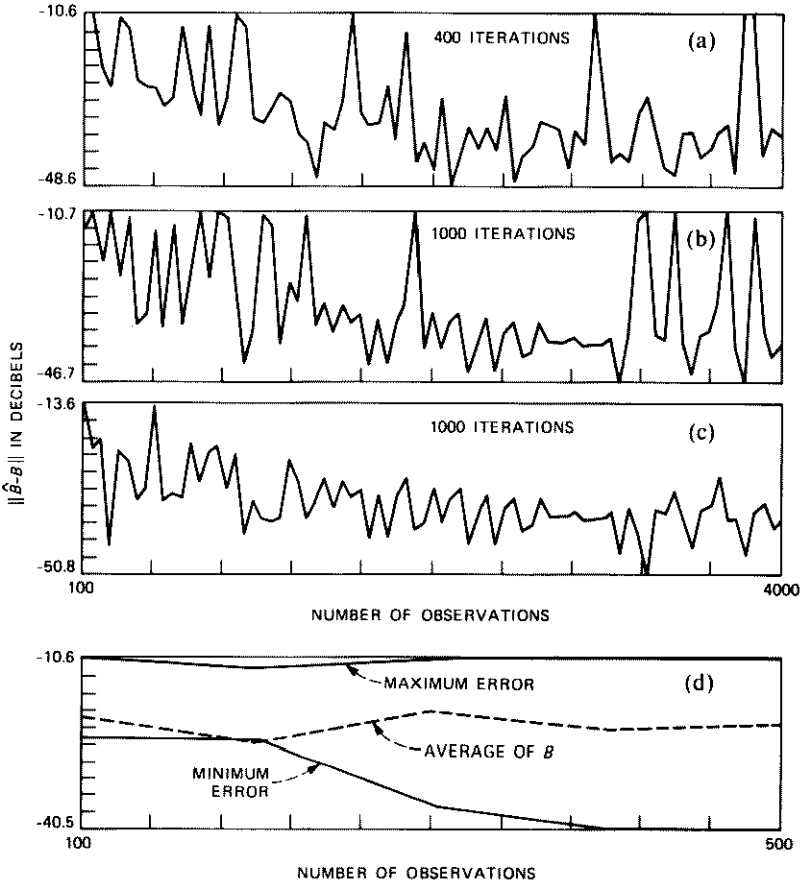

Fig. 5—Estimation error as a function of number of observations for source SRC45 for: (a) 400 iterations maximum, (b) 1000 iterations maximum, (c) initial estimates of $A$ and $B$ set to source values, and (d) maximum and minimum estimation errors for 10 random starting points.

undoubtedly because of the parameter estimates with high errors that occur and which have an undue influence on the average.

### *5.1 Left-to-right Markov source estimation*

The second series of experiments dealt with the left-to-right Markov models, as would be appropriate for our intended application to isolated word recognition. Figure 6 shows four such models. For each of these models (denoted as SRC195, SRC295, SRC395, and SRC495 in Fig. 6), the specifications were:

$$N = 5, M = 9, \pi = \{1, 0, 0, 0, 0\}$$

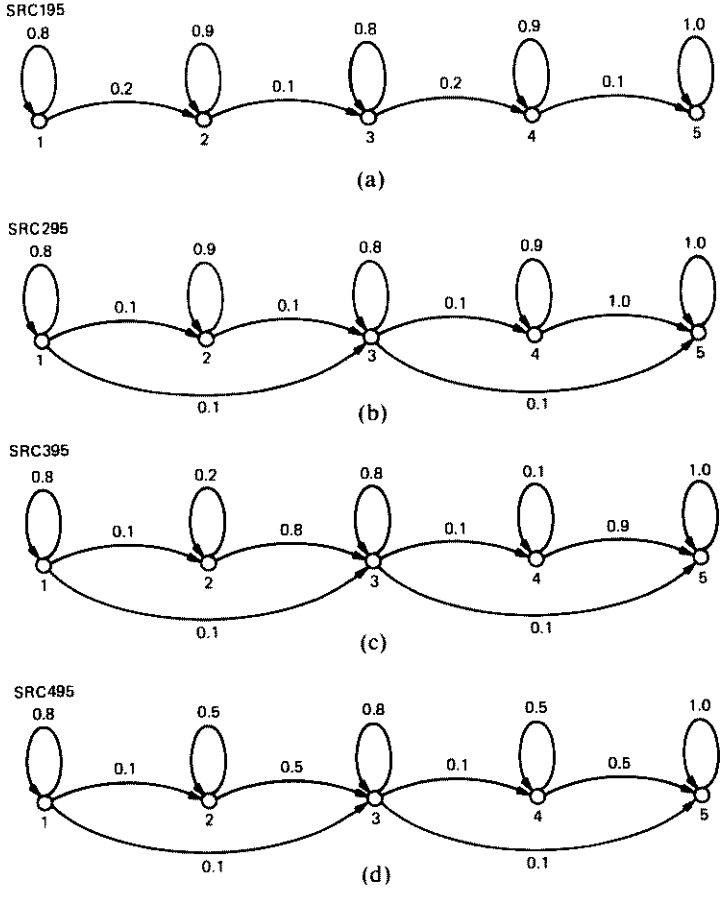

Fig. 6—Left-to-right models used for testing for: (a) SRC195, (b) SRC295, (c) SRC395, and (d) SRC495.

and

$$B = \begin{bmatrix} 0.7 & 0.3 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0.8 & 0.2 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0.2 & 0.8 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.3 & 0.7 \end{bmatrix}.$$

The state transition probabilities were those shown in Fig. 6. The SRC195 model is a left-to-right model. The SRC295 model allows a transition between states 1 and 3 and states 3 and 5, as well as transitions between sequentially numbered states. Both the SRC395 and SRC495 models include states whose self-transition probabilities

($a_{ii}$) are very small. We will see below that the average occupancy of such states is only 1 to 2 observations. For these non-ergodic models the concept of occupancy of the transient (i.e., non-absorbing) states is important.

If we denote the probability of a transition from a state to itself as $p$, then the probability of a transition out of that state at time $T + 1$ (assuming the state was entered at time $t = 0$) is

$$\text{Prob}(q_i \text{ at } t = 0, 1, 2, \cdots, T \quad \text{and} \quad q_j \neq q_i \text{ at } T + 1) = p^T(1 - p)$$

for models of the form of SRC195. Hence the average occupancy of a state is given by

$$\bar{d} = \sum_{t=1}^{\infty} (t + 1)p^t(1 - p)$$

$$= \frac{1}{1 - p}. \tag{75}$$

For $p = 0.9$ we get $\bar{d} = 10$, for $p = 0.8$ we get $\bar{d} = 5$, for $p = 0.5$ we get $\bar{d} = 2$, and for $p = 0.1$ we get $\bar{d} = 1.1$. Standard formulas are available for computing average state occupancies for arbitrary transition matrices. We will not consider them here; however, it is clear that states 2 and 4 in models SRC395 and SRC495 are of low occupancy.

To test the reestimation procedure on the Markov sources of Fig. 6, a set of $K$ sequences were generated for each model, where $K$ was the set (10, 25, 50, 100). Each sequence was generated using the Markov sequence generator described earlier, modified slightly to ensure that each sequence terminated in state 5 (the final state) and stayed there for 5 observations. The sequences were, however, of variable duration, depending on the exact sequence of state transitions that occurred.

The results showed that for sequences generated from model SRC195, the correct model parameters (to within small estimation errors) were obtained for all values of $K$ from 10 to 100. For sequences generated from model SRC295 only the 10 observation training sequence yielded grossly incorrect model parameter estimates. All other sequences ($K$ = 25, 50, 100) yielded the correct parameter values.

For both source models SRC395 and SRC495, however, no completely correct parameter estimates were obtained. In particular, the states whose expected occupancy was small (i.e., states 2 and 4 in both models) were merged with either the preceding or the following state (or both), while other states whose expected occupancy was larger were often split into 2 states, each with the same set of output symbols. These experiments indicate that it is difficult to reliably estimate parameters of a state, in a left-to-right model, whose average occupancy is very much smaller than that of the states to which it is connected.

### 5.2 Tests on a non-Markov source

In the experiments described above, the observations were in fact generated by a known probabilistic function of a Markov chain. A more difficult test of these techniques was performed in which the observations were 5000 characters from a newspaper article edited to contain only the letters of the alphabet and spaces. We used the observation sequence to train a four-state, 27-symbol model. Of course, the "true" underlying model is not known, as it was in the tests previously described. Nor is it likely that the four-state model is complex enough to model the richness of structure of written English. Even if it were, it is unlikely that 5000 characters is sufficient to capture the structure. Unfortunately, these are exactly the limitations with which the experimenter will be faced in trying to model "real" processes. Our hope was that the text analysis problem would reveal some of the ambiguities that will be encountered in making hidden Markov models of natural phenomena.

The text was first analyzed using the Baum-Welch reestimation formulas with a randomly chosen starting point. The algorithm converged in 310 iterations with $\log P = -1.317 \times 10^4$. For purposes of comparison, we analyzed the same data with a quasi-Newton optimization routine, VE01A, from the Harwell Library.[26] It required 125 iterations to obtain a maximum value of $\log P$ of $-1.356 \times 10^4$. In this case some care was required with the parameter values. The finite precision arithmetic occasionally results in a parameter value of $-10^{-7}$, which appears to satisfy the positivity constraints. Such a value is fatal to the computation of $\log P$ since it will result in an attempt to take a logarithm of a negative quantity. Fortunately, this condition is readily detected in the scaling routine and corrected by setting the offending parameter to zero.

Finally, we applied the Lagrangian technique described earlier to the same observation sequence but with a different set of initial parameter values. After 136 iterations, a still different model with $\log P = -1.327 \times 10^4$ is obtained. These results illustrate some important features of hidden Markov modeling. The computational methods used to obtain the models are roughly equivalent. All of the resulting models capture some of the structure of the data being analyzed. There are many different possible models with very little evidence for selecting the "best" one. For even very simple models, the likelihood function is too complicated to attribute the selection of one model or another by one algorithm or another to its properties. Finally, we note that all of the algorithms tested make large improvements to $P$ during the early iterations and only slight incremental improvements later. In fact, the last half of the iterations provides no significant change to the model. We have used a convergence criterion

of $10^{-7}$ on the relative increment between iterations. This may be relaxed substantially, resulting in many fewer iterations with no attendant degradation in the model.

## VI. CONCLUSION

We have presented some of the salient theoretical and practical issues associated with modeling data by probabilistic functions of a Markov chain. In our presentation we have concentrated on three issues: alternatives to the Baum-Welch reestimation algorithm, critical facets of implementation, and behavior of Markov models on certain artificial but realistic signals.

We have observed that, while most of the discussion of parameter estimation for Markov models in the open literature is devoted to the Baum-Welch algorithm, classical optimization techniques are not only a viable alternative but may even be preferable in some cases. In particular, classical techniques are virtually unrestricted by the forms of either the likelihood function or the constraints. The reestimation formulas may be growth transformations for a wider class of functions and constraints than has heretofore been proven; however, it is not likely that a universal reestimation formula exists. For applications to continuous density functions (c.f. Liporace[29]), the classical techniques may have still other advantages.

The open literature has provided only a perfunctory, if any, discussion of some crucial numerical and implementational problems associated with Markov modeling. We have given details of methods of dealing with floating point loss of significance, finite-training-set size, and model stability. Wherever possible we have made our techniques formal and algorithmic.

Finally, we have given several examples of the behavior of Markov modeling techniques on some reasonably realistic data. The most important lesson that can be drawn from these experiments is that even under ideal conditions (i.e., when the data are associated with a known hidden Markov process) and all the more so under realistic conditions, the computed models may contain artifacts and may not faithfully represent the inherent structure of the data. Thus, great caution and empirical validation is required in using these techniques.

Despite this caveat, hidden Markov models may be beneficial in studying many diverse problems. In our companion paper[21] we recount a successful application of this body of theory to a problem in automatic speech recognition.

## APPENDIX A

Several of the formulas derived in the text are much more compact in matrix notation. Let $'$ denote matrix transposition, as usual, and let the column vectors $\pi$ and $\mathbf{1}$, and the matrices $A$, $B_t$, $t = 1, \cdots, T$ be defined as in the text. Also let $\alpha_t$ and $\beta_t$ be column vectors with components $\alpha_t(i)$, $i = 1, \cdots, N$ and $\beta_t(i)$, $i = 1, \cdots, N$, respectively. Then the recursion for $\alpha_t$ is

$$\alpha_{t+1} = B_{t+1}A'\alpha_t, \qquad t = 1, \cdots, T-1. \tag{76}$$

The recursion for $\beta_t$ is

$$\beta_t = A\,B_{t+1}\beta_{t+1} \qquad t = T-1, \cdots, 1. \tag{77}$$

The starting values are

$$\alpha_1 = B_1\pi$$

$$\beta_T = 1. \tag{78}$$

The probability $P$ is given by

$$P = \beta_t'\alpha_t \qquad \text{for any } t \text{ in } (1, T). \tag{79}$$

The special cases $t = 1$ and $t = T$ give

$$P = \pi' B_1\beta_1 \tag{80}$$

and

$$\begin{aligned} P &= \mathbf{1}'\alpha_T \\ &= \mathbf{1}'B_T A' B_{T-1} \cdots A' B_1\pi. \end{aligned} \tag{81}$$

In each of these formulas $P$ can be regarded as the trace of a $1 \times 1$ matrix, which [as expanded in (81)], is a product of several matrices. The fact that the trace of a product of matrices is invariant to a cyclic permutation of the matrices can be used to advantage in finding the gradient of $P$. Define $\nabla_A P$ as the matrix whose $ij$th component is $\partial P/\partial a_{ij}$. Similarly, define $\nabla_B P$ and $\nabla_\pi P$. Then it is straightforward to show that

$$\begin{aligned} \nabla_\pi P &= B_1\beta_1 \\ \nabla_A P &= \sum_{t=1}^{T-1} \alpha_t\beta_{t+1}' B_{t+1} \\ (\nabla_B P)_{jk} &= \sum_{t \ni O_t = k} (A'\alpha_{t-1})_j (\beta_t)_j. \end{aligned} \tag{82}$$

In the last equation, if $O_1 = v_k$ then the corresponding term in the sum is just $\pi'\beta_1$.

## APPENDIX B

As we mentioned in Section 3.3, it is frequently necessary to compare (or average) two different estimates $B$ and $\tilde{B}$ of the symbol matrix. The optimization procedures, in general, relabel the states; therefore the rows of $\tilde{B}$ may, in general, be permuted relative to those of $B$. Before comparison, therefore, the optimum permutation must be found. This is defined as one that minimizes the distance $D$ defined in eq. (66). The problem of finding this permutation can be converted to a network optimization problem called "bipartite weighted matching." To this end define $w_{ij}$ as the distance of the $i$th row of $B$ from the $j$th row of $\tilde{B}$. As we have done in Fig. 7, draw two sets $P$ and $Q$ of $N$ vertices each. For $1 \leq i, j \leq N$, draw an edge from the $i$th vertex in $P$ to the $j$th vertex in $Q$, and label this edge with the weight $w_{ij}$. The resulting graph is a complete weighted bipartite graph, and the problem is to find an $N$-match (i.e., one to one matching with $N$ edges) such that it has minimum weight.

Suppose that $\mathbf{Z}_k$ is a $k$-match ($k \leq N$). With respect to this match make the following definitions:

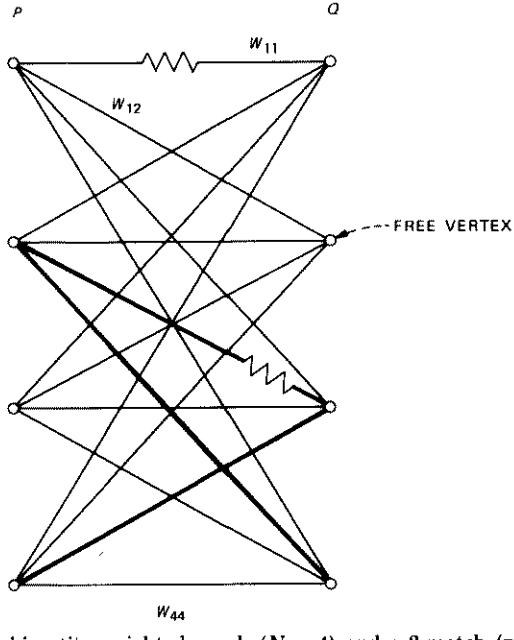

Fig. 7—Complete bipartite weighted graph ($N = 4$) and a 2-match (matched edge →). Path shown in heavy lines is an alternating path for the 2-match. It also happens to be an augmenting path.

(*i*) A matched edge is an edge in $\mathbf{Z}_k$.

(*ii*) A free vertex is one that is not on a matched edge.

(*iii*) An alternating path is a path along edges that alternately belong to $\mathbf{Z}_k$ and do not belong to $\mathbf{Z}_k$. [N.B. the number of matched edges, $m$, on an alternating path may have any value $m \leq k$. The degenerate case $m = 0$ is also valid.]

(*iv*) An augmenting path is an alternating path between two free vertices. Again note that a single edge connecting two free vertices is a valid augmenting path.

An augmenting path has the structure

$$p_1 U q_1 M p_2 U q_2 \cdots U q_j. \tag{83}$$

Here $U$ represents an unmatched edge, $M$ represents a matched edge, and $p_1$ and $q_j$ are the only free vertices on the path. (Here $p_i$ is the $i$th $P$-vertex along the path. The $q_i$ are similarly defined.) Note that the number of $U$'s on an augmenting path is exactly one more than the number of $M$'s. Hence the total number of edges in an augmenting path is always odd.

Suppose we are given a $k$-match $\mathbf{Z}_k$ and an augmenting path **ap** of length $2j + 1$. Then we can obtain a $(k + 1)$-match $\mathbf{Z}_{k+1}$ by a complementary labeling of the edges of **ap** (i.e., by changing every $U$ to $M$ and vice versa). If $w_1, w_2, \cdots, w_{2j+1}$ are the weights along **ap**, then the weight $\mathbf{Z}_{k+1}$ exceeds that of $\mathbf{Z}_k$ by the amount $w_1 - w_2 + w_3 - \cdots + w_{2j+1}$.

This method of obtaining a $(k + 1)$-match from a $k$-match has the following key property (proof given below): Suppose $\mathbf{M}_k$ is a minimum-weight $k$-match. Let **apm** be an augmenting path for $\mathbf{M}_k$ with minimum incremental weight. Then the match $\mathbf{M}_{k+1}$ obtained from $\mathbf{M}_k$ and **apm** is a minimum weight $(k + 1)$-match.

Assuming this property for the moment, a minimum-weight $N$-match can be determined by the following $N$-step algorithm:

For $k = 1, 2, \cdots, N$ generate $\mathbf{M}_k$ by finding an optimum augmenting path for $\mathbf{M}_{k-1}$. (Note that $\mathbf{M}_0$ is an empty set.)

We now show that finding an optimum augmenting path is equivalent to a shortest path problem. With reference to Fig. 8 let us generate a directed graph by directing each edge in $\mathbf{M}_k$ to the left and each unmatched edge to the right. Also let us multiply the weights of all matched edges by $-1$. Finally, add two vertices labeled **s** and **t**. Connect **s** to all *free* vertices in $P$ by right-going edges of zero weight. Similarly, connect all *free* vertices of $Q$ to **t** by right-going edges of zero weight. In this directed graph any path from **s** to **t** is an augmenting path for the matching $\mathbf{M}_{k-1}$. Hence, if we interpret the weights as lengths, it is clear than an optimum augmenting path is a shortest path from **s** to **t**.

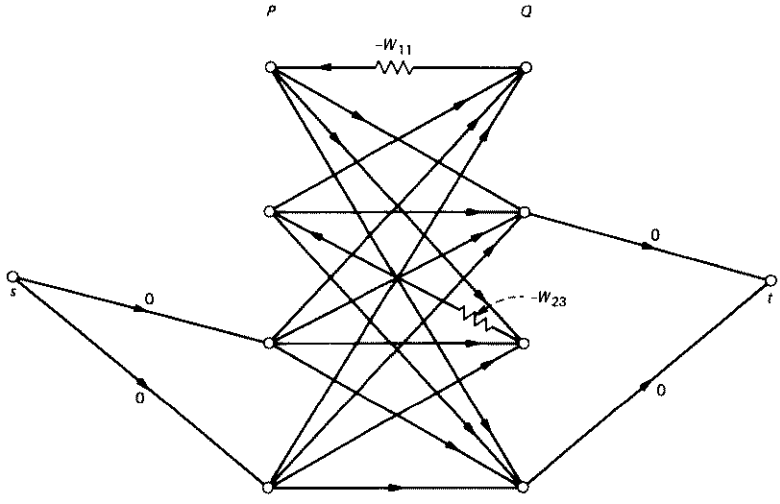

Fig. 8—Directed graph obtained from Fig. 7. Every path from **s** to **t** is an augmenting path of the 2-match (except for the dummy edges of 0 weight from $s$ and to $t$). Interpreting weights as lengths, the length of a path from **s** to **t** is the incremental weight of the corresponding augmenting path.

A shortest path problem can be solved in polynomial time. However, the problem can be solved much more easily and efficiently if the path lengths are all nonnegative. In that case the problem can be solved in $N^2$ time by Dijkstra's method.[28]

It is possible to avoid negative distances in our problem by the method of assigning a "potential" $f(v)$ to each vertex. Suppose that at step $k$ the graph has nonnegative weights, and the edges corresponding to $\mathbf{M}_{k-1}$ have zero weight. Then use Dijkstra's method to find shortest paths to all vertices (including **t**) from **s**. Define $f(v)$ for the vertex **v** as its shortest distance from **s**. Next, modify the weight $w_{ij}$ of the edge from $i$ to $j$ to

$$w'_{ij} = w_{ij} + f(i) - f(j). \tag{84}$$

It is easily seen that this procedure leaves all weights nonnegative, does not alter shortest paths, and all shortest paths have weight 0. Reversing a shortest path from **s** to **t** gives us a matching $\mathbf{M}_k$, and the new graph has nonnegative weights and zero weights for the matched edges. Now $\mathbf{M}_0$ trivially has the postulated properties. Therefore, at every step the graph will have these properties.

An important property of the above procedure is that if a vertex $p$ (or $q$) is on some matched edge in $\mathbf{M}_k$, then it will be on some matched edge in $\mathbf{M}_{k+1}$ also. In writing the actual computer program, this property simplifies the bookkeeping considerably.

Another important property concerns the vertex potentials. Suppose

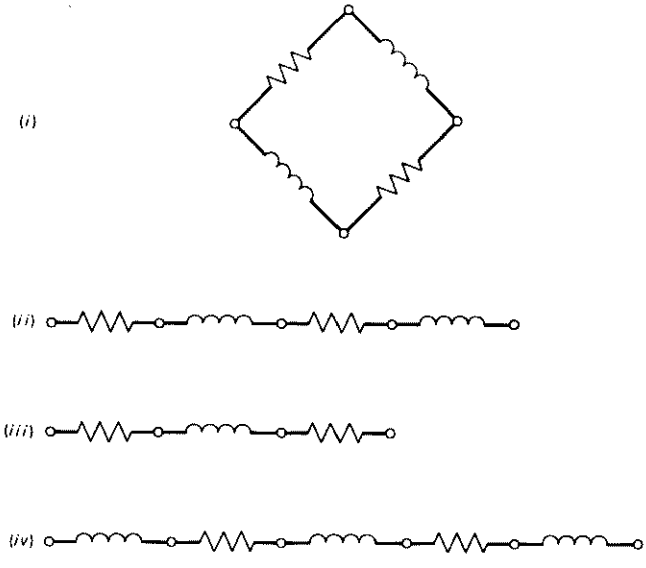

Fig. 9—Types of paths in the symmetric difference between $\mathbf{M}_k$ and $\mathbf{N}_{k+1}$. ($\wwv \in \mathbf{M}_k$, $\sim\sim \in \mathbf{N}_{k+1}$.) There must be exactly one more path of type (*iv*) than of type (*iii*).

$F(v)$ is the sum of the potentials assigned to vertex $v$ at each of the $N$ steps. Suppose $w_{ij}$ and $d_{ij}$ are the original and final weights, respectively, of the edge connecting vertex $i$ to vertex $j$. Then

$$d_{ij} = w_{ij} + F(i) - F(j) \geq 0, \tag{85}$$

and $d_{ij} = 0$ for every edge in the final $N$-match. The numbers $F(v)$ thus provide a simple proof that the final match is indeed an optimum match.

We turn now to a proof of the key property mentioned above. Let $\mathbf{M}_k$ be an optimum $k$-match and let $N_{k+1}$ be *any optimum* $k+1$-match. Then we will show that there is a $k+1$-match obtained from an augmenting path of $\mathbf{M}_k$ such that its weight is equal to that of $N_{k+1}$. For this purpose define $\mathbf{S}$ as the set of edges in the symmetric difference of $\mathbf{M}_k$ and $\mathbf{N}_{k+1}$. (Recall that the symmetric difference of two sets, $\mathbf{A}$ and $\mathbf{B}$, is the set of elements that belong either to $\mathbf{A}$ or to $\mathbf{B}$ but not to both.)

From the geometry of a bipartite graph three properties of the set $\mathbf{S}$ are obvious:

(*i*) The number of edges in $\mathbf{S}$ which belong to $\mathbf{N}_{k+1}$ must exceed the number that belongs to $\mathbf{M}_k$ by exactly 1.

(*ii*) The edges on any path in $\mathbf{S}$ must alternate between $\mathbf{M}_k$ and $\mathbf{N}_{k+1}$.

(*iii*) A vertex on an edge in **S** cannot be shared with any edge in $\mathbf{M}_k$ or $\mathbf{N}_{k+1}$ that does not belong to **S**.

From the first two of these properties it follows that there can be four types of paths in **S** (see Fig. 9).

(*i*) Circuits, each consisting of an even number of edges;

(*ii*) Open paths, each with an even number of edges;

(*iii*) Open paths, each with an odd number of edges beginning with an edge in $\mathbf{M}_k$;

(*iv*) Open paths, each with an odd number of edges beginning with an edge in $\mathbf{N}_{k+1}$. The number of such paths must be exactly one more than the number of paths of type (*iii*).

It is easily seen that the incremental weight of every path of type (*i*) or (*ii*) must be exactly zero. (If it is negative then the weight of $\mathbf{M}_k$ can be decreased by a complementary labeling of the path; if positive then the weight of $\mathbf{N}_{k+1}$ can be decreased in the same way. But this contradicts the hypothesis that $\mathbf{M}_k$ and $\mathbf{N}_{k+1}$ are optimum matches.)

In view of this and property (3), $\mathbf{N}_{k+1}$ can be modified by replacing its edges on all paths of types (*i*) and (*ii*) by the corresponding edges of $\mathbf{M}_k$. The modified $k + 1$-match has exactly the same weight as that of $N_{k+1}$; however, the symmetric difference between $\mathbf{M}_k$ and the modified $k + 1$-match has no paths of type (*i*) or (*ii*).

The same argument applies to pairs of paths, one path each of types (*iii*) and (*iv*). Thus a final modified $k + 1$ match is obtained whose symmetric difference with $\mathbf{M}_k$ is exactly one path of type (*iv*). The weight of this final modified $k + 1$-match is exactly the same as that of the original $\mathbf{N}_{k+1}$, and is obtained from an augmenting path of $\mathbf{M}_k$.

We have written a subroutine that implements the above procedure. The timing, from a number of test runs, is approximately $0.063N^3$ ms central processing unit (CPU) time on the MV-8000. Thus for $N = 40$ about 4 seconds of CPU time is needed.

# On the Application of Vector Quantization and Hidden Markov Models to Speaker-Independent, Isolated Word Recognition

By L. R. RABINER, S. E. LEVINSON, and M. M. SONDHI

(Manuscript received September 10, 1982)

*In this paper we present an approach to speaker-independent, isolated word recognition in which the well-known techniques of vector quantization and hidden Markov modeling are combined with a linear predictive coding analysis front end. This is done in the framework of a standard statistical pattern recognition model. Both the vector quantizer and the hidden Markov models need to be trained for the vocabulary being recognized. Such training results in a distinct hidden Markov model for each word of the vocabulary. Classification consists of computing the probability of generating the test word with each word model and choosing the word model that gives the highest probability. There are several factors, in both the vector quantizer and the hidden Markov modeling, that affect the performance of the overall word recognition system, including the size of the vector quantizer, the structure of the hidden Markov model, the ways of handling insufficient training data, etc. The effects, on recognition accuracy, of many of these factors are discussed in this paper. The entire recognizer (training and testing) has been evaluated on a 10-word digits vocabulary. For training, a set of 100 talkers spoke each of the digits one time. For testing, an independent set of 100 tokens of each of the digits was obtained. The overall recognition accuracy was found to be 96.5 percent for the 100-talker test set. These results are comparable to those obtained in earlier work, using a dynamic time-warping recognition algorithm with multiple templates per digit. It is also shown that the computation and storage requirements of the new recognizer were an order of magnitude less than that required for a conventional pattern recognition system using linear prediction with dynamic time warping.*

## I. INTRODUCTION

There currently exist two standard approaches to isolated word recognition, namely, feature extraction methods and statistical pattern recognition models. A statistical pattern recognition approach has the property of being a nonparametric approach to recognition and therefore is widely used in most commercial and industrial recognizers.[1-6] The feature-based approach to recognition has been primarily used in the (computationally) less expensive systems, and as a basis for recognition of continuous speech (in conjunction with segmentation and labeling algorithms).[4-9]

In the past few years a new approach to speech processing has been proposed, namely, using probabilistic functions of Markov models. This approach has been applied at the Institute for Defense Analyses for speaker recognition,[10] and at Carnegie Mellon University and IBM to solve problems in continuous speech recognition[11,12] with good success. Based on its success in these related areas of speech processing, a question that arises naturally is how well these probabilistic models would work on problems in isolated word recognition.

It is the prime purpose of this paper to provide an answer to the question posed above. Before discussing the approach we have taken to get at the answer, we must first describe the structure of a word recognition system based on (hidden) Markov models (HMM). As in most recognition systems we assume we have a labeled training set of data from which we build a series of Markov models, one for each vocabulary word. Then when we want to recognize an unknown token, we compute a probability score for each word HMM on that token, and choose as the recognized word the one corresponding to the model with the highest probability score (i.e., the most likely word HMM). Techniques for training and scoring such HMMs are discussed both here and in the companion paper.[3]

In a conventional pattern recognition system the unknown test token is time-aligned in turn to each reference pattern via some form of time-warping procedure, typically, dynamic time warping (DTW). By contrast, no such direct alignment is performed in the HMM system; only an indirect time alignment is obtained based on the probabilistic scoring. Thus it is interesting to study the relationship between probabilistic scoring and DTW as applied to isolated word recognition. As we shall see, there is no simple relationship. We will point out several similarities and differences in the two approaches.

The organization of this paper is as follows. In Section II we briefly review the conventional DTW word recognizer based on LPC modeling, since this will be the focus of comparison throughout the paper. In Section III we review the basic ideas behind the use of HMMs for isolated word recognition. It is the purpose of this section to establish

notation and terminology that will define the basic parameters of interest in the HMM system. Section III shows that one inherent feature of the HMM recognizer (as we have implemented it) is that the models need a discrete, finite set of observations (input data) to obtain the best model parameters for each word in the vocabulary. A vector quantizer (VQ) was used to transform the continuous set of linear predictive coefficient (LPC) vectors into a finite observation set. Therefore, in Section IV we describe the key ideas behind vector quantization of LPC sets, and discuss the particular implementation that we used. In Section V we describe the overall structure of the HMM isolated word recognizer. In Section VI we describe a series of experiments used to evaluate the performance of the HMM word recognizer and compare it to the performance of a DTW recognizer on the same vocabulary. The effects, on performance, of several parameter variations in the HMM and VQ are also described in this section. In Section VII we discuss the results of the performance evaluation and comparison experiments. The strengths and weaknesses of the HMM word recognizer are discussed, along with computational and storage comparisons of HMM and DTW word recognizers. We attempt, in this section, to determine the fundamental relationships between the HMM and DTW systems.

## II. REVIEW OF CONVENTIONAL DTW WORD RECOGNIZER BASED ON LPC MODELING

Figure 1 shows a block diagram of the LPC-based isolated word recognizer.[2,3] The input speech signal, $s(n)$, recorded over a standard dialed-up telephone line, is bandpass-filtered between 100 and 3200 Hz, and digitized at a 6.67-kHz rate. The first step in the processing is

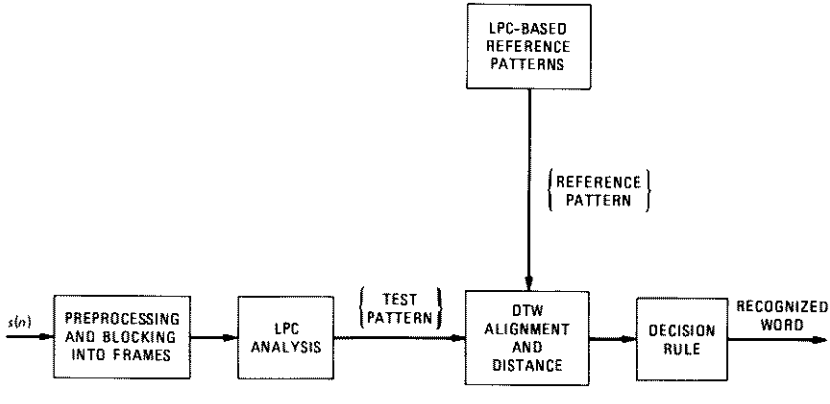

Fig. 1—Block diagram of conventional LPC-based word recognizer using a standard dynamic time-warping algorithm for registering test and reference patterns.

the preprocessing block, a first-order digital network, which provides a high-frequency pre-emphasis to the speech. The pre-emphasized signal is blocked into frames of 45 ms (300 samples) with each consecutive frame spaced 15 ms (100 samples) apart. An 8-pole LPC analysis (autocorrelation method) is performed on each frame of the word (after isolating it with an endpoint detector[14]), thus creating the test pattern. This test pattern is compared with each reference pattern using a DTW alignment algorithm that simultaneously provides a distance score associated with the alignment. The distance scores for all the reference patterns are sent to a decision rule, which provides a classification of the spoken word, and possibly an ordered (by distance) set of the best $n$ candidates.

The word reference patterns for the recognizer of Fig. 1 are created by a training algorithm. For speaker-trained applications, typically a single reference pattern is created for each word in the vocabulary using a robust training algorithm.[15] For speaker-independent applications, a set of $Q$ reference patterns is created for each vocabulary word using a clustering procedure.[16,17] Typically, about 12 templates per word are sufficient for recognizing words from a fairly homogeneous adult population of native American talkers.

## III. BASICS OF HMM FOR WORD RECOGNITION

We assume we have a finite sequence, $\mathbf{O}$, of observations,

$$\mathbf{O} = O_1 O_2 \cdots O_T, \tag{1}$$

where each observation is a discrete symbol drawn from a finite alphabet of symbols. (For the system we will be describing, the observations are the indices of the LPC vectors obtained from an LPC vector quantizer.) We further assume that the sequence of observations may be modeled as a probabilistic function of an underlying Markov chain whose state transitions are not directly observable; hence the name "Hidden Markov Model." Figure 2 shows such a model, $\mathbf{M}$, which is characterized by the following:

($i$) $N$ = the number of states in the model. For the model of Fig. 2, $N = 5$.

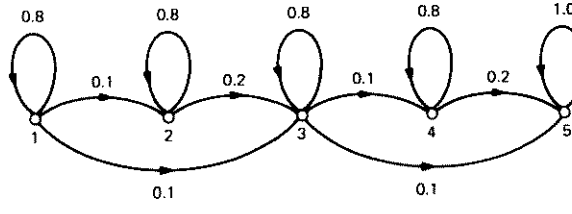

Fig. 2—A typical state diagram for a 5-state Markov model.

(*ii*) $M$ = the number of output symbols in the discrete alphabet of the model. For the present example, $M = 5$.

(*iii*) $A = \{a_{ij}\}$, the transition matrix of the underlying Markov chain. Here, $a_{ij}$ is the probability of making a transition to state $j$, given that the model is in state $i$. For the model of Fig. 2 we have

$$A = \begin{bmatrix} 0.8 & 0.1 & 0.1 & 0 & 0 \\ 0 & 0.8 & 0.2 & 0 & 0 \\ 0 & 0 & 0.8 & 0.1 & 0.1 \\ 0 & 0 & 0 & 0.8 & 0.2 \\ 0 & 0 & 0 & 0 & 1.0 \end{bmatrix}.$$

Note that only 11 of the 25 $a_{ij}$'s are nonzero.

(*iv*) $B = \{B_{jk}\} = \{b_j(k)\}$, the model output symbol probability matrix, where $b_j(k)$ is the probability of outputting symbol $k$, given that the model is in state $j$. For the example chosen,

$$B = \begin{bmatrix} 0.5 & 0.5 & 0 & 0 & 0 \\ 0 & 0.5 & 0.5 & 0 & 0 \\ 0 & 0 & 0.5 & 0 & 0.5 \\ 0.5 & 0 & 0 & 0.5 & 0 \\ 0 & 0 & 0 & 0.5 & 0.5 \end{bmatrix}.$$

(*v*) $\pi = \{\pi_i\}$, $i = 1, 2, \cdots, N$, the initial state probability vector. For the left-to-right models of the type shown in Fig. 2, we assume the system always begins in state 1, i.e., $\pi_1 = 1$, $\pi_i = 0$, $i \neq 1$.

Isolated word recognition using HMM consists of two phases, training and recognition (or classification). In the training phase, the training set of observations is used to derive a set of reference models of the above type, one for each word in the vocabulary. In the classification phase, the probability of generating the test observation is computed for each reference model. The test is classified as the word whose model gives the highest probability. The computations in each of these phases are fairly straightforward.

Let us begin with the classification phase. Given the observation sequence, $\mathbf{O}$, and a model, $\mathbf{M}$ (i.e., $N$, $M$, $A$, $B$, and $\pi$), the probability of $\mathbf{O}$ having been generated by model $\mathbf{M}$ is

$$P(\mathbf{O}|\mathbf{M}) = \sum_{i_1, i_2 \cdots i_T} \pi_{i_1} b_{i_1}(O_1) a_{i_1 i_2} \cdots a_{i_{T-1} i_T} b_{i_T}(O_T). \tag{2}$$

The summation in eq. (2) is more readily computed by defining a forward partial probability, $\alpha_t(i)$, as

$$\alpha_t(i) = P(O_1 O_2 \cdots O_t \text{ and state } i \text{ at time } t|\mathbf{M}). \tag{3}$$

This leads to the recursion

$$\alpha_{t+1}(j) = \left[ \sum_{i=1}^{N} \alpha_t(i) a_{ij} \right] b_j(O_{t+1}), \qquad t = 1, 2, \cdots, T-1 \tag{4}$$

by which eq. (2) can be expressed as

$$P(\mathbf{O}|\mathbf{M}) = P = \sum_{j=1}^{N} \alpha_T(j). \tag{5}$$

In the training phase an initial estimate of the model is made, and $P$ is computed for the training observation sequence according to eq. (5). Next the model is iteratively adjusted to increase $P$. The iterations are stopped when $P$ stops increasing significantly, or when some other stopping criterion is met (e.g., when the number of iterations exceeds a limit).

One remarkable algorithm for improving a trial model is the Baum-Welch reestimation algorithm.[18] However, maximizing $P$ can also be looked upon as a constrained optimization problem, for which many algorithms have been proposed. In the companion paper in this issue of the Journal,[13] we discuss the relative merits of these procedures.

We now discuss a number of factors that influence the performance of HMM recognizers.

### 3.1 Initial estimates of A and B

One factor of interest for the HMM recognizer is the choice of initial estimates for the elements of the matrices $A$ and $B$. The problem here is that although the training procedure is guaranteed to reach a critical point of $P$, the value of $P$ obtained is typically a local maximum. Hence, alternative starting values of $A$ and $B$ could yield models with higher (or lower) values of $P$. For our simulations we have chosen to start the training models with essentially random choices for the nonzero elements of both $A$ and $B$, normalized to satisfy the constraints

$$\sum_{j=1}^{N} a_{ij} = 1 \qquad i = 1, 2, \cdots, N \tag{6a}$$

$$\sum_{k=1}^{M} b_j(k) = 1 \qquad j = 1, 2, \cdots, N. \tag{6b}$$

An alternative starting condition could be

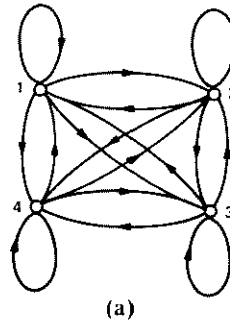
$$a_{ij} = 1/N + \epsilon \tag{7a}$$

$$b_j(k) = 1/M + \epsilon, \tag{7b}$$

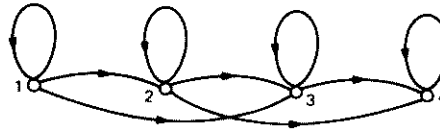
where $\epsilon$ is a uniformly distributed random variable whose peak is much smaller than either $1/N$ or $1/M$. [Again the $a_{ij}$'s and $b_j(k)$'s of eq. (7) must be normalized using eq. (6) prior to running the optimization.]

### 3.2 HMM structures and the number of states

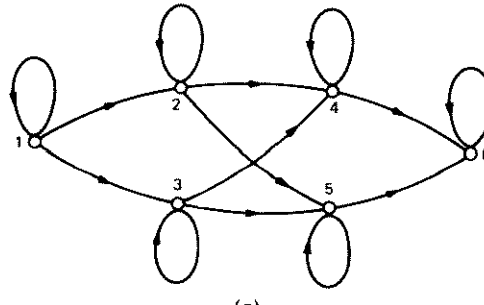
A second factor affecting the determination of optimum HMMs for each vocabulary word is the model structure and the number of states.



(a)



(b)



(c)

Fig. 3—State diagrams for: (a) unconstrained Markov model with four states, (b) constrained serial Markov model with four states, and (c) constrained parallel Markov model with six states.

We have considered three types of model structures, namely unconstrained, constrained serial, and constrained parallel. Typical examples of each of these models are shown in Fig. 3. In the unconstrained models (shown in Fig. 3a) a transition from any state to any other state can be made—i.e., all $a_{ij}$'s are allowed to be nonzero. Both the constrained serial models (shown in Fig. 3b) and the constrained parallel models (shown in Fig. 3c) are left-to-right models, i.e., the state transition matrix $A$ is upper triangular. The serial models generally proceed sequentially through the states (although individual states can be skipped over), whereas the parallel models allow multiple paths through the model, with each path skipping one or more model states. For example, there are four distinct paths through the model of

Fig. 3c, 1-2-4-6, 1-2-5-6, 1-3-4-6 and 1-3-5-6, each of which traverses four of the six model states.

Each of the model structures of Fig. 3 can be generalized to include an arbitrary number of states. Recall, however, that the number of free parameters of the Markov model is on the order of $N^2$ (for the $A$ matrix) plus $NM$ (for the $B$ matrix). Hence, if $N$ gets too large, accurate and reliable determination of the optimum $A$'s and $B$'s may become difficult for a fixed-size training set. However, within these constraints we have investigated models with as few as two states, and as many as 20 states. There appears to be no good theoretical way to choose the number of states needed for a word model, since the states need not be physically related to any single observable phenomenon.

### 3.3 Multiple observation sequences

A third factor affecting the determination of the optimum HMM for each vocabulary word is the observation sequence used for training. Since we are interested in obtaining speaker-independent models, the observation sequence, $\mathbf{O}$, actually consists of several independent sequences $\mathbf{O}^{(k)}$, $k = 1, 2, \cdots, K$, where $\mathbf{O}^{(k)}$ is the training sequence for talker $k$, and $K$ is the total number of talkers used for training. Typically, a value of $K = 100$ has been used in our clustering work for speaker-independent training. The way in which we handle multiple sequences is to calculate $P(\mathbf{O}^{(k)}|\mathbf{M})$, using eq. (5), for each sequence, and maximize the product of the probabilities, i.e.,

$$P = \prod_{k=1}^{K} P(\mathbf{O}^{(k)}|\mathbf{M}). \tag{8}$$

The implementation of the computation of eq. (8) is straightforward for the Baum-Welch reestimation procedure, as well as for the gradient methods.[13] Thus the fact that the training data consist of multiple sequences causes no problem in estimating the optimum HMM parameters.

### 3.4 Constraints on A, B matrices during training

As we show in Fig. 3 we have considered three general HMM structures. For the unconstrained structure the $A$ and $B$ matrix elements are allowed to assume any value consistent with the stochasticity constraints. For the constrained serial models we have considered two general constraints, namely:

$$\text{SC1: } a_{ij} = 0 \quad \text{for} \quad j < i \quad \text{and} \quad j \geq i + 3 \text{ (double skip allowed)} \tag{9a}$$

$$\text{SC2: } a_{ij} = 0 \quad \text{for} \quad j < i \quad \text{and} \quad j \geq i + 2 \text{ (single skip allowed).} \tag{9b}$$

These two cases are illustrated in Fig. 4 for a 5-state model. Constraints SC1 allow single- or double-state jumps when exiting a given state,

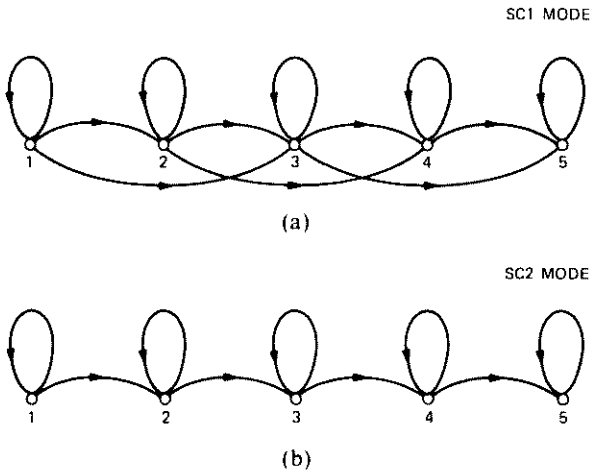


Fig. 4—Markov models for two types of serial constraints: (a) single and double transitions allowed, and (b) only single transitions allowed.

whereas constraints SC2 only allow single jumps when exiting a state. Hence, models of the type shown in Fig. 4a have somewhat more flexibility than those of the type shown in Fig. 4b.

For the constrained parallel models we have only considered transition matrices of the type illustrated in Fig. 3c, i.e., a given state can only exit to either of a pair of states in the next column of the grid.

For the most part we have not constrained the $B$ matrix. However, one problem arises if the $B$ matrix is left completely unconstrained. The problem is that a finite training sequence of length $T$ may result in $b_j(k) = 0$. In classification it can then be the case that $\alpha_{t-1}(i)\, a_{ij}$ is nonzero for only one value of $j$, and $O_t = k$, then the probability of that sequence arising from the model with $b_j(k) = 0$ is $P = 0$; hence a recognition error must occur. This is the so-called missing or inadequate training data problem. We handle this problem (see Ref. 13 for a justification) by using post-estimation constraints on the $b_j(k)$'s of the form

$$b_j(k) \geq \epsilon, \tag{10}$$

where $\epsilon$ is a suitably chosen threshold value. All $b_j(k)$'s are compared to the $\epsilon$ threshold and those that are below $\epsilon$ are replaced by $\epsilon_j$ for each $j$. After this replacement, each $b_j(k)$ that was not changed to the $\epsilon$ value is rescaled by the quantity $1 - R_j\epsilon$ [where $R_j$ is the number of $b_j(k)$'s changed for a given $j$] to properly normalize the $b_j(k)$'s.

It should be clear that all the constrained HMMs are left-right models in that the observations must begin in state 1, must proceed from state to state in a monotonically increasing manner, and must

end in state $N$. Thus, temporal information in the observation sequence is coded directly into the left-to-right HMM.

### 3.5 Multiple estimates of A, B, and averaging

As we mentioned earlier, the reestimation and gradient optimization procedures are guaranteed to find a critical point of $P$ for each HMM. However, in practice, a large number of such points exist in the parameter space. Thus, different initial conditions on $A$ and $B$ may lead to different solutions. To understand the variability in model parameters as well as its effects on overall recognition performance, a series of HMMs were obtained for each word by selecting $R$ random starting sets for $A$ and $B$, and solving for the optimum $A$ and $B$ in each case. By scoring each of the $R$ models individually, we can obtain an indication of the statistical variability in performance score owing to uncertainty in $A$ and $B$.

An alternative procedure to using multiple HMMs for each word, obtained from different random starting values for $A$ and $B$, is to average the $R$ sets of $A$ and $B$ to give an averaged model for each word. The effects of such averaging on word recognition accuracy will be discussed in Section 6.3.

### 3.6 Scoring of observation sequences

One way to score a given observation sequence, $\mathbf{O}$, is to use the iterative calculation of eqs. (4) and (5). We call this the Baum-Welch score, $P_{BW}$. For left-to-right models, eq. (5) is modified as

$$P_{BW} = \alpha_T(N) \tag{11}$$

because the sequence is constrained to end in state $N$.

An alternative scoring procedure for the observation sequence, $\mathbf{O}$, given the model, $\mathbf{M}$, is the Viterbi algorithm,[20] which may be compactly stated as:

($i$) Initialization—$\delta_1(i) = \log[\pi_i b_i(O_1)]$, $i = 1, 2, \cdots, N$

($ii$) Recursion—for $2 \le t \le T$, $1 \le j \le N$

$$\delta_t(j) = \max_{1 \le i \le N} \{\delta_{t-1}(i) + \log[a_{ij} b_j(O_t)]\}$$

($iii$) Termination—$P_{VI} = \delta_T(N)$ for left-to-right models

$$= \sum_{j=1}^{N} \delta_T(j) \text{ for unconstrained models.}$$

The above algorithm is a form of the well-known dynamic programming method and can be shown to have the property of determining the state sequence $\mathbf{i} = i_1 i_2 \cdots i_T$, which maximizes

$$P(\mathbf{i}|\mathbf{O}, \mathbf{M}).$$

It is easily shown that both the Baum-Welch and Viterbi scoring procedures require roughly the same amount of computation. The major differences are in the interpretation of the resulting solutions.

## IV. VECTOR QUANTIZATION OF LPC COEFFICIENTS

In Section III we noted that in our implementation of HMMs for isolated word recognition the inputs to the model are assumed to be sequences of discrete symbols chosen from a finite alphabet. We obtained these discrete symbols by using the method of vector quantization[19,21] of the LPC vectors measured as described in Section II. In this section we review the theory of vector quantization and discuss its implementation for isolated word recognition.

### *4.1 Theory of vector quantization*

Assume we have a training set of LPC vectors, $\mathbf{a}_i$, $i = 1, 2, \cdots, I$, which are a good representation of the types of LPC vectors that occur when the words in the vocabulary are pronounced by a wide range of talkers. The main idea behind vector quantization is to determine the optimum set of codebook LPC vectors, $\hat{\mathbf{a}}_m$, $m = 1, 2, \cdots, M$, such that for a given $M$, the average distortion in replacing each of the training set vectors, $\mathbf{a}_i$, by the closest codebook entry, $\hat{\mathbf{a}}_m$, is minimum.

More formally stated, if we define $d(\mathbf{a}_R, \mathbf{a}_T)$ as the distance between two LPC vectors, $\mathbf{a}_R$ and $\mathbf{a}_T$, then the goal of vector quantization is to find the set, $\hat{\mathbf{a}}_m$, such that

$$\|D_M\| = \min_{\hat{\mathbf{a}}_m} \left\{ \frac{1}{I} \sum_{i=1}^{I} \min_{1 \le m \le M} [d(\hat{\mathbf{a}}_m, \mathbf{a}_i)] \right\} \tag{12}$$

is satisfied. The quantity $\|D_M\|$ is the average distortion (distance) of the vector quantizer.

The way in which eq. (12) is solved, for a given value of $M$, is due to Juang et al.[21] The algorithm first finds the optimum solution for $M = 2$ (two codebook entries), then splits each optimum LPC vector into two components, and finds the optimum solution for $\hat{M} = 2 \cdot M$. This procedure iterates until $M$ is as large as desired. A flow diagram of the details of the codebook generation procedure is given in Ref. 21. The local distance used in our system was the likelihood distance,[2]

$$d(\mathbf{a}_R, \mathbf{a}_T) = \frac{\mathbf{a}_R V_T \mathbf{a}_R'}{\mathbf{a}_T V_T \mathbf{a}_T'} - 1, \tag{13}$$

where $V_T$ is the autocorrelation matrix of the sequence that gave rise to LPC vector $\mathbf{a}_T$.

### 4.2 Implementation of the vector quantizer

To train the vector quantizer we used a set of 39708 LPC vectors, obtained by using all the vectors in one complete set of 10 isolated digits uttered by each of 100 talkers (50 male, 50 female). Applying the algorithm of Juang et al.,[21] we generated vector quantizers of size $M = 2$, 4, 8, 16, 32, 64, and 128. During the course of running the algorithm, several performance criteria were monitored, including:

(*i*) Average distortion, $\|D_M\|$, of eq. (12)

(*ii*) Sigma ratio (cluster separation) of the resulting codebook entries (clusters), defined as

$$\sigma = \frac{\frac{1}{M}\sum_{i=1}^{M}\left(\frac{1}{M-1}\right)\sum_{j=1}^{M} d(\hat{\mathbf{a}}_i, \hat{\mathbf{a}}_j)}{\|D_M\|}, \tag{14}$$

where the numerator is the average intercluster distance, and $\|D_M\|$ is the average intracluster distance.

(*iii*) Cluster cardinality, $N_i$, defined as the number of tokens in the $i$th cluster (i.e., the cluster represented by the $i$th codebook entry).

(*iv*) Cluster distortion, $\tilde{d}_i$, defined as the average distortion (distance) for the $i$th cluster.

It should be clear that the average distortion, $\|D_M\|$, satisfies the relation

$$\|D_M\| = \frac{1}{I}\sum_{i=1}^{M} \tilde{d}_i \cdot N_i \tag{15}$$

and that the cluster occupancy satisfies the relation

$$\sum_{i=1}^{M} N_i = I. \tag{16}$$

Results of running the VQ algorithm on the training set of 39708 vectors are given in Figs. 5 through 8. Figure 5 shows plots of $\|D_M\|$ versus $M$ (on a log scale) (part a), and the $\sigma$-ratio versus $M$ (part b) for values of $M$ from 2 to 128. We can see that for values of $M \geq 32$ the average distortion falls below 0.3, and that for $M = 64$ the value of $\|D_M\| \approx 0.2$. If we use the conventional recognizer of Fig. 1, the average distance between repetitions of a word (after DTW alignment) has been found to be on the order of 0.3 to 0.4;[16] hence, values of $\|D_M\| < 0.3$ imply smaller error for the VQ than for interreplication variations of words. The $\sigma$-ratio plot shows ratios greater than 10 for $M \geq 32$; hence, extremely good cluster separation is achieved in the vector quantizer for these values of $M$.

Figures 6 through 8 show a detailed analysis of the statistics of the vector quantizer output for $M = 128$. Figure 6a shows the cluster

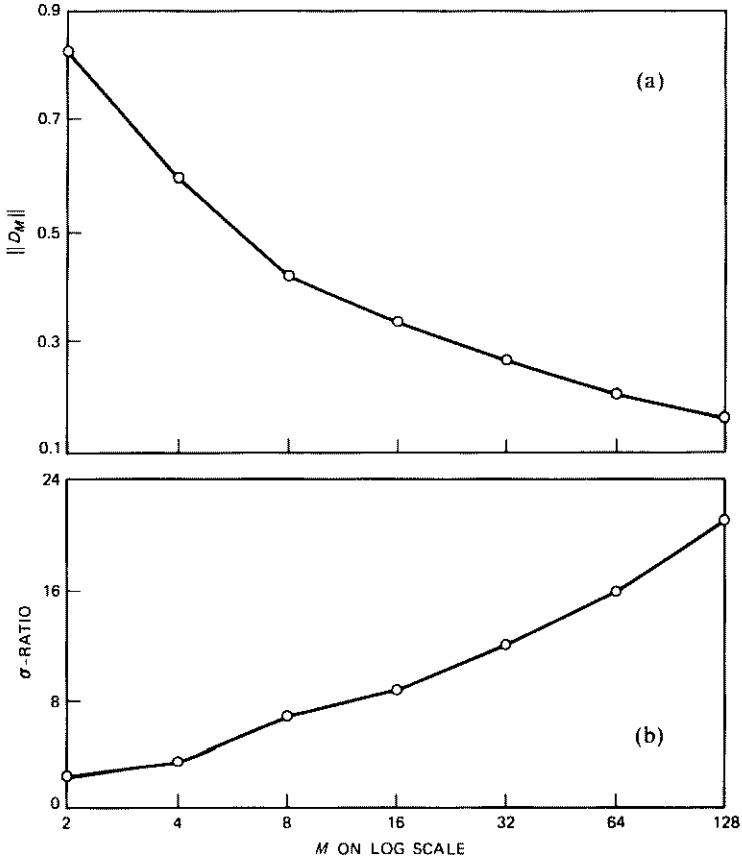

Fig. 5—Plots of vector quantizer performance versus size of codebook for: (a) average distortion, and (b) sigma ratio.

cardinality as a function of the VQ index, and Fig. 6b a histogram of cluster cardinality. The largest cluster has 857 tokens, whereas the smallest cluster has 119 tokens; hence, a spread of over 7 to 1 in cluster occupancy is obtained. The average cluster cardinality, for this case, is 310 tokens, as denoted by the dashed line in Fig. 6a. The histogram of cluster cardinality indicates that the vast majority of clusters have fewer than the average number of tokens.

Figure 7a shows the cluster distortion as a function of the VQ index, and Fig. 7b shows a histogram of cluster distortions. The largest distortion for any cluster is 0.303, whereas the smallest distortion is 0.047; hence, a spread of more than 6 to 1 is observed in cluster distortions. The dashed lines in Fig. 7 denote the average cluster distortion, which in this case is 0.165.

Finally, Fig. 8 shows a plot of the total cluster distortion, defined as

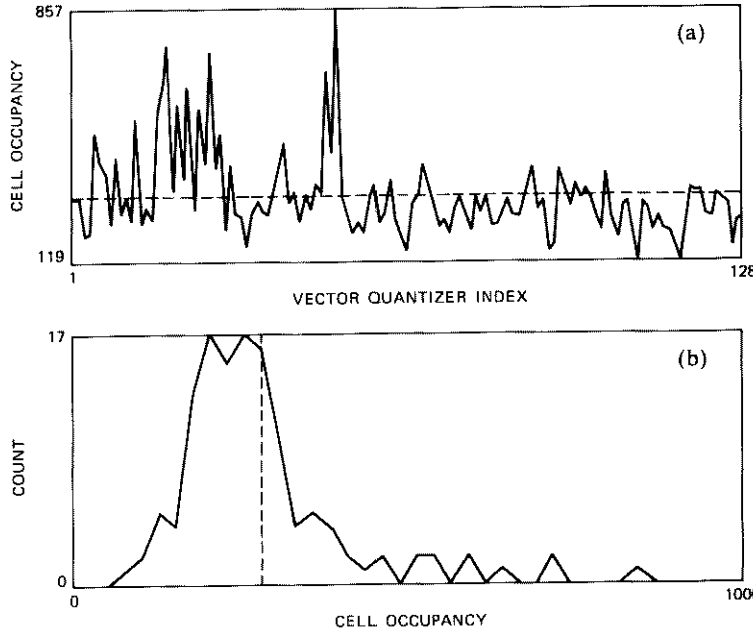

Fig. 6—Plots of (a) cell occupancy versus codebook index, and (b) histogram of cell occupancy for 128-codeword vector quantizer.

$N_i\tilde{d}_i$, versus VQ index. The range of total cluster distortion is from 25 to 72; hence, a spread of less than 3 to 1 is obtained. It is conjectured that the "ideal" vector quantizer seeks to determine the set of "optimum" codebook vectors such that the total cluster distortion is as close to uniform as possible. Hence, clusters with large average distortions should have low cardinality, whereas clusters with small average distortion should have high cardinality. It can be seen from Figs. 6 through 8 that the total cluster distortion statistics are much closer to uniform than are either the cardinality or the average cluster distortion statistics.

Based on the results shown in Figs. 5 through 8, it was decided to implement the HMM recognizer using a $M = 64$ VQ, since the small decrease in average distortion from $M = 64$ to $M = 128$ did not justify the increased computation owing to the larger codebook.

Figure 9 shows some properties of the LPC vectors in the codebook for $M = 64$. Shown in this figure are plots of the first few resonances of the 64 codebook entries (part a), and plots of first versus second resonance (part b), first versus third resonance (part c), and second versus third resonance (part d). As we anticipated, typical vowel resonances for the digits are seen clearly in the plots (e.g., high front

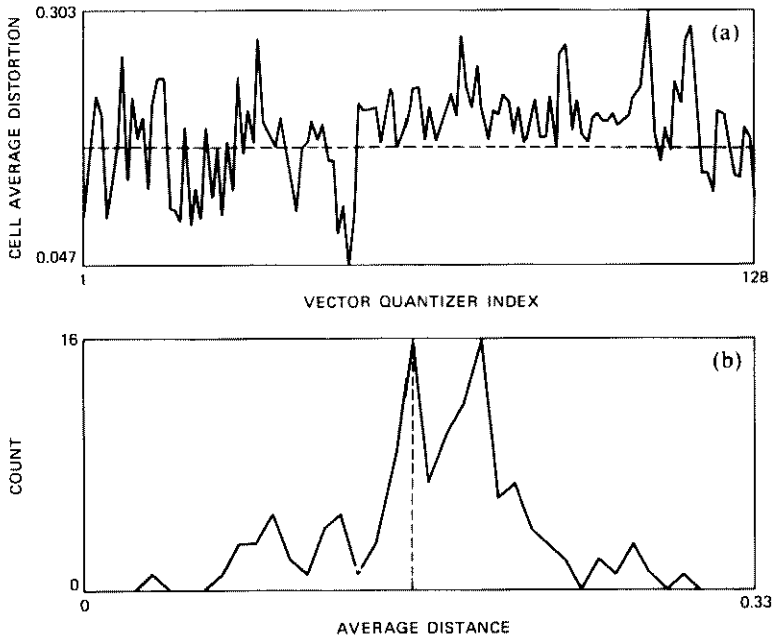

Fig. 7—Plots of (a) cell average distortion versus codebook index, and (b) histogram of cell average distortion for 128-codeword vector quantizer.

vowels, low back vowels, etc), along with characteristic resonances of transient and other nonvoiced sounds. Detailed examination of the spectra of the 64 codebook entries did not provide any further enlightenment as to the VQ properties.

## V. OVERALL HMM/VQ ISOLATED WORD RECOGNIZER

A block diagram of the overall HMM/VQ isolated word recognizer is given in Fig. 10. The recognizer operates as a speaker-independent word recognizer, which runs first in a training mode, to provide the codebook entries of the VQ, and the model coefficients of each word HMM.

In the classification mode the LPC sets of the unknown word are first sent through the vector quantizer (to give a finite set of VQ indices) and then scored on each word HMM (using either the Viterbi scoring or the Baum-Welch scoring) to give a probability score for each word model. The decision rule chooses the word whose model gives the highest probability.

In the next section we describe the results of several tests designed to measure the performance of the HMM/VQ word recognizer and to compare it with that of a conventional LPC/DTW recognizer.

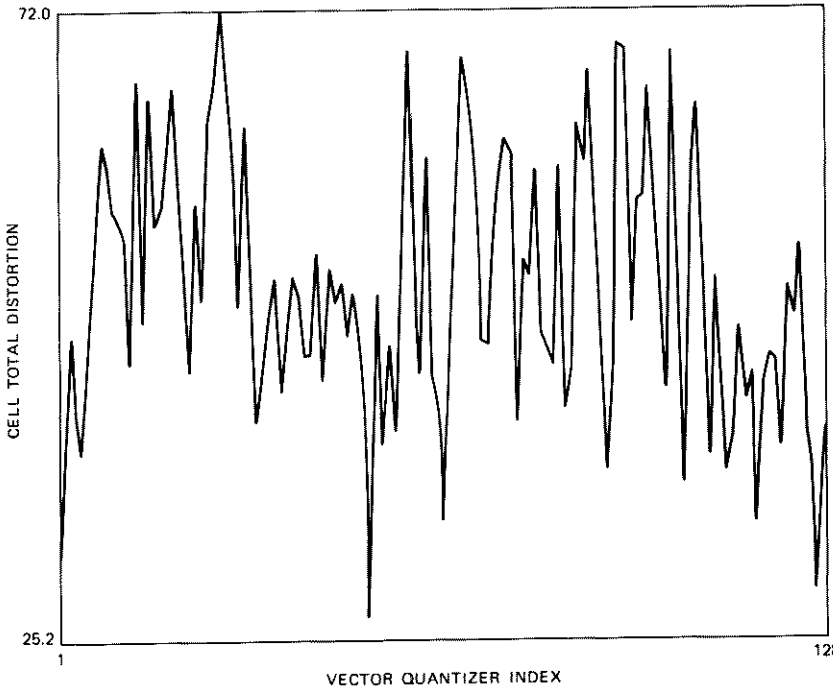

Fig. 8—Plot of cell total distortion versus codebook index for 128-codeword vect quantizer.

## VI. EVALUATION EXPERIMENTS AND RESULTS

Several evaluation tests were performed on the HMM/VQ and LPC/DTW isolated word recognizers. For most conditions a single test set of data, denoted as TS1, was used, consisting of one replication of each of the 10 digits by a set of 100 talkers. These talkers were the same ones used to train the recognizer; however, the test replication was recorded many days after the training replication. A second test set of data, denoted as TS2, was used in a couple of tests. This test set consisted of 20 replications of each of the 10 digits by a set of 10 new talkers (5 male, 5 female). Thus, TS2 contained twice as many test tokens as TS1, but represented only one-tenth the number of talkers; however, none of the talkers was included in the training set for either the VQ or the HMMs.

The results presented in this section are the output of a series of recognition tests in which one or more features of the HMM/VQ recognizer were varied. Following the presentation of the results of each of the individual experiments, we shall endeavor to provide a measure of coherency to the results.

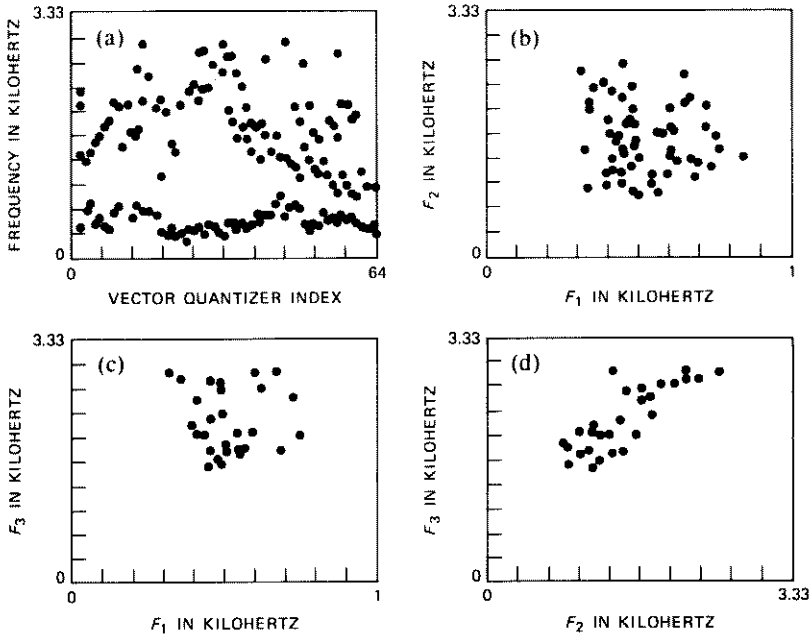

Fig. 9—Plots of locations of first three resonances of codebook vectors: (a) plotted as a function of the vector index, (b) plotted in the $F_1 - F_2$ plane, (c) plotted in the $F_1 - F_3$ plane, and (d) plotted in the $F_2 - F_3$ plane.

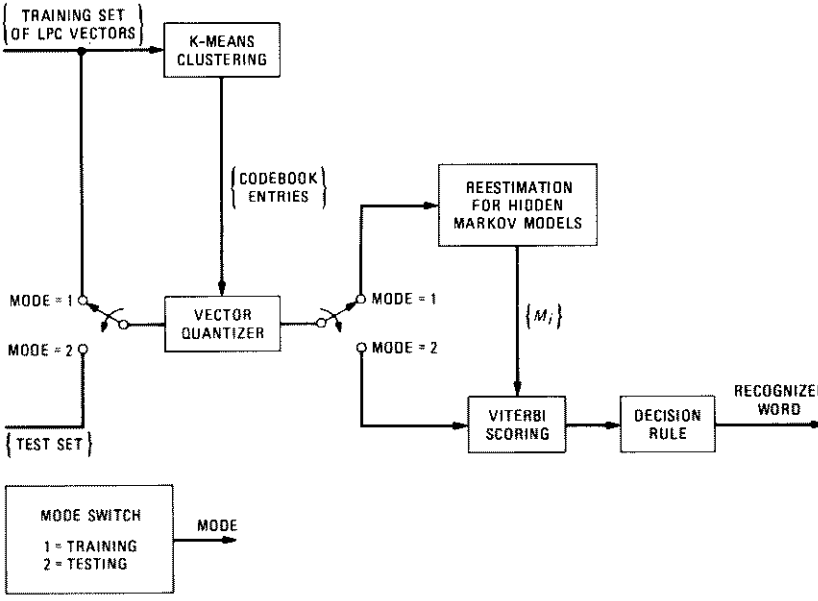

Fig. 10—Overall block diagram of the hidden Markov model—vector-quantizer isolated word recognizer.

### 6.1 Effects of constrained and unconstrained HMMs

The first set of experiments sought to understand the effects of placing constraints on the $A$ and $B$ matrices on the performance of the overall recognizer. As such, the HMM was trained for an $N = 5$ state model with the following constraints:

| | |
|---|---|
| UC model: | No constraints placed on $A$; epsilon constraints [of the type given in eq. (10)] placed on $B$. |
| CO model: | The constraints of eq. (9a) placed on $A$; epsilon constraints of eq. (10) placed on $B$. |
| UC.35 model: | Same as UC model but all training sequences with VQ distortions greater than 0.35 were eliminated. |
| CO.35 model: | Same as CO model but all training sequences with VQ distortions greater than 0.35 were eliminated. |

For each of the above four models, the 1000-digit sequences of TS1 were used to measure the overall error rate as a function of the $\epsilon$ constant parameter. The results are given in Fig. 11, which shows plots of error rate versus $\epsilon$ (on a log scale) for each of the four models. Several trends clearly emerge from these results. First, we can see that a nonzero value of $\epsilon$ is an absolute *necessity* for obtaining good performance. Whenever a symbol, $k$ (a VQ index), appears in a test word in a state, $j$, where $b_j(k) = 0$, the probability for that word model is multiplied by the $\epsilon$ value. If $\epsilon = 0$ then the word model is eliminated from consideration and an error occurs. For finite, nonzero values of $\epsilon$, however, such errors need not, and generally will not, occur. Hence,

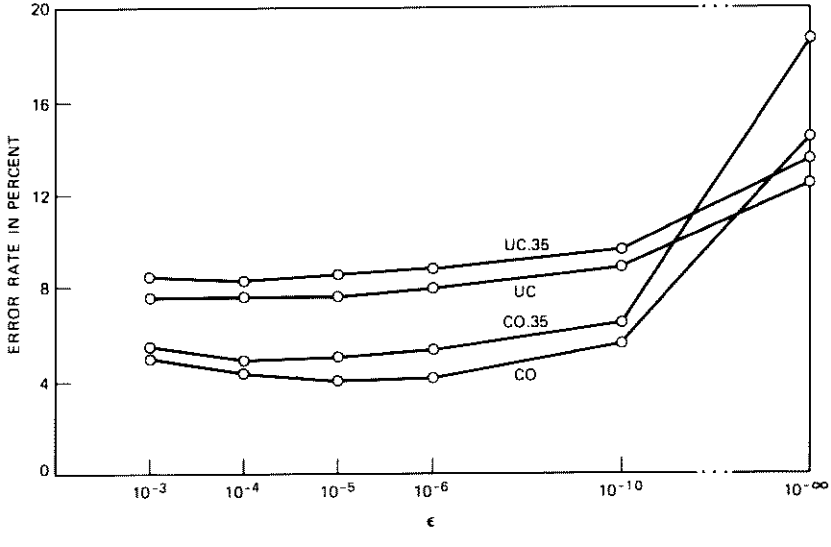

Fig. 11—Plots of average word error rate versus the minimum value of the symbol probability matrix, $\epsilon$, for four types of hidden Markov models, for TS1 data.

even for $\epsilon$ on the order of $10^{-10}$, the error rate is substantially smaller than for $\epsilon = 0$.

A second clear trend that can be seen in Fig. 11 is that the constrained serial models performed consistently better than the unconstrained models for all nonzero values of $\epsilon$. This result implies that the extra freedom of the unconstrained models tends to raise the probability scores for incorrect words more than for correct words. This is somewhat reminiscent of the fact that opening up the search region of a conventional DTW search helps the wrong words much more than it does the correct words.[16]

It can also be seen from Fig. 11 that it is *always* preferable to train with all available sequences. This result suggests that the more training data given to the HMM model estimation algorithm the better the estimates of the HMM parameters, even if some of the data are less than ideal.

The final trend that emerges from the curves of Fig. 11 is that there is a large range of values of $\epsilon$ for which essentially identical performance results. For example, in the range $10^{-10} \leq \epsilon \leq 10^{-3}$, for model CO, the recognition error rate changes by less than 1.6 percent. Thus, so long as $\epsilon$ is in this broad range, the exact value of $\epsilon$ is not overly significant.

Based on the results of this first series of experiments, we applied the following restrictions:

(*i*) Consider only constrained HMMs

(*ii*) Constrain $B$ matrix entries such that $b_j(k) \geq \epsilon = 10^{-5}$

(*iii*) Use all possible training sequences for the HMMs.

Before we proceed to the next series of experiments, some comments should be made about practical methods of implementing constraints on the $B$ matrix. In Ref. 13 we show how the constraints on the $b_j(k)$ coefficients, of the type given in eq. (10), can be incorporated directly into either the gradient or the Baum-Welch reestimation algorithm. We have also tried a post-normalization technique in which no constraints were placed directly on the $B$ matrix. Following convergence, the $B$ matrix was examined and all entries whose values were below $\epsilon$ were reset to the value $\epsilon$, and the rows of the matrix were suitably renormalized to sum to 1.0. Our recognition results indicate identical performance for both the direct and the post-normalization constraint methods. Hence, there appears to be no advantage to constraining the $B$ matrix directly.

### *6.2 Markov model with variable number of states*

The second set of experiments consider the effects on recognition accuracy of using the constrained serial HMMs with different numbers of states. In particular we computed the optimum SC1 model (see Fig.

4) for each digit where the number of states varied from 2 to 9. We also computed the optimum SC1 model for a 20-state model for each digit.

To evaluate these different models a recognition test was conducted in which each digit was represented by a single $N$-state HMM, where $N$ took on the values 2 to 9, and 20. The results of this experiment are given in Fig. 12a, which shows word error rate versus number of states in the HMM for the data of TS1. We see a steady but slow decrease in the average word error rate in this curve. We also see a statistical fluctuation in the curve owing to the sampling variability in the $A$'s and $B$'s for each word HMM. (We will return to this issue later in this section.)

A second recognition test was conducted in which each word was represented by *all* the word models with number of states up to some maximum value, *NMAX*. The results of this recognition test (again using TS1 data) are shown in Fig. 12b. A somewhat smoother curve of

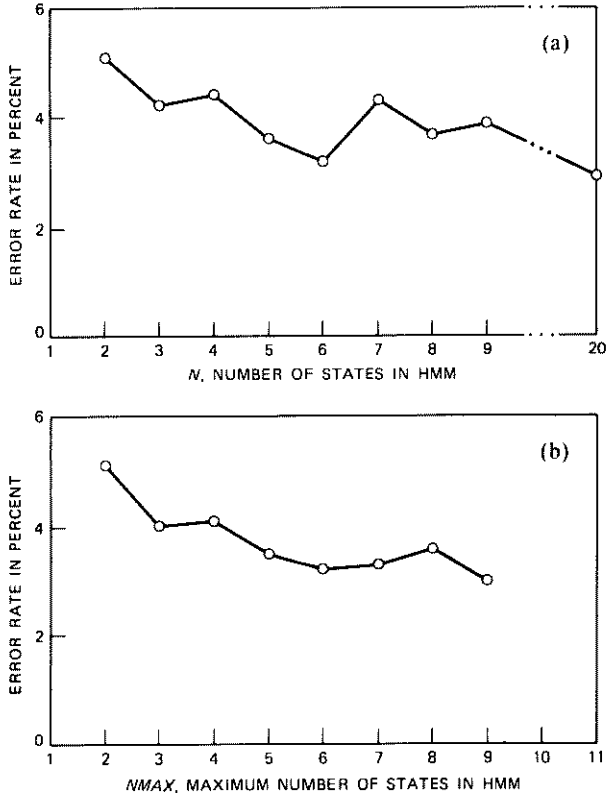

Fig. 12—Plots of (a) error rate versus the number of states in the HMM, and (b) error rate versus the maximum number of states in the HMMs for TS1 data.

errors versus *NMAX* is obtained in Fig. 12b than for the individual models of Fig. 12a; however, the general behavior of both curves is similar.

Figure 13 shows a breakdown of the error rates for each digit for the experiment in which a single HMM, with $N$ states, was used for each digit. There is a highly complex interaction between error rate and model size for all digits. Thus it cannot be argued, for instance, that digits like zero and seven (two syllables) need more states in their models than digits like two or one (monosyllables).

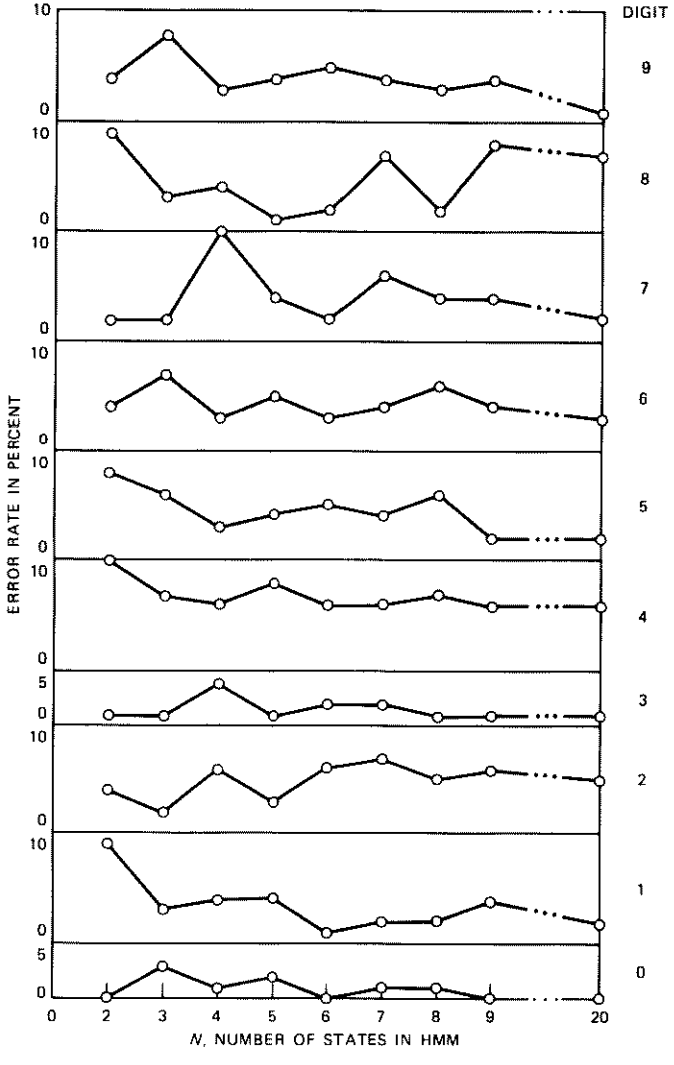

Fig. 13—Individual plots of digit error rates versus the number of states in the HMMs.

From the results shown in Figs. 12 and 13, it was concluded that there is very little gain in using HMMs with more than five or six states when the SC1 structure for each model is being used. It was also concluded that no simple relationship existed between word (digit) accuracy, number of sounds (syllables, etc) in the word, and number of states needed in the word HMM.

### *6.3 Effects of random starting points*

The third set of experiments was concerned with the statistical variability in the performance scores resulting from statistical variability in the parameters of the word HMMs because of different random initial estimates of the parameters. To quantify this effect, a 5-state SC1 model was generated for each digit using 10 different random starting sets of model parameters. Thus, for each digit, 10 "equivalent" HMMs were created.

A recognition test was then run, using TS1 data, in which each of the 10 models was tested separately. Also tested was the case in which all 10 models were used for each digit, as well as the case in which a single model was used for each digit, where the model parameters were obtained by averaging the parameter estimates for each of the 10 word models. The results of these recognition tests are given in Fig. 14, which shows word error rate versus the random start number. Also shown, as single isolated values, are the error scores for the average and the combined 10 state runs. The dashed line in Fig. 14 is the average error rate of the 10 individual models.

From the data of Fig. 14, we can see that the 10 individual models all performed identically to within ±1 percent; hence, the expected statistical variability in error rate scores, due to random starts, should

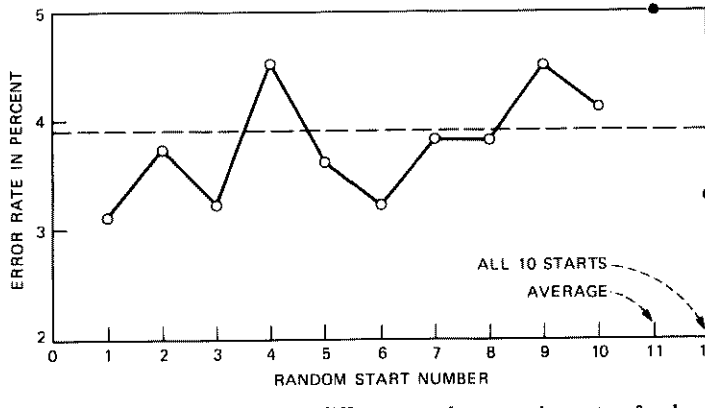

Fig. 14—Plots of error rate for 10 different random starting sets of values of the HMM parameters. Also shown are individual error rates for an averaged model and for combining 10 random start models.

be on the order of ±1 percent. We can also see that the performance of the "averaged" model (obtained by averaging HMM parameters for each word) was somewhat poorer than that of any of the 10 individual models. The fact that using all 10 word models for each digit gives an error rate comparable to that of the *best* word models indicates that multiple word models provide a small gain that comes at the cost of greatly increased computation.

Overall, the data of Fig. 14 suggest that a single model per word should be adequate for most purposes, and that the effects of different random starts on the overall error performance are small.

### *6.4 Parallel constrained HMMs*

The last factor investigated was the effect of using constrained parallel HMMs for each digit. The main idea was that a true parallel structure could model the effects of using a multiplicity of word models in much the same way as multiple templates are used in the conventional LPC/DTW word recognizer.

Figure 15a shows the 5-state constrained serial HMM that was used in previous experiments along with a 7-state, constrained parallel HMM (Fig. 15b), and an 8-state, constrained parallel model (Fig. 15c). The 7-state parallel structure was intended to represent four distinct 5-state word models, in that there were four sets of paths through the model, namely, 1-2-5-7, 1-2-6-7, 1-3-5-7, and 1-3-6-7. The 8-state parallel structure was intended to represent eight distinct 5-state word models in that there were eight sets of paths through this model, namely, 1-2-4-6-8, 1-2-4-7-8, 1-2-5-6-8, 1-2-5-7-8, 1-3-4-6-8, 1-3-4-7-8, 1-3-5-6-8, and 1-3-5-7-8.

Each of the three HMM structures of Fig. 15 was used to generate a word model for each of the digits. The three sets of models were then tested using TS1 data. The results showed each of the three systems obtained the same word error rate (3.5 percent) to within ±0.1 percent. These results indicated that there was really no advantage in using the parallel structure.

### *6.5 Comparison with LPC/DTW recognizers*

To provide some basis of comparison for the performance of the HMM/VQ recognizer with that of more conventional word recognizers, the data of TS1 was tested on the LPC/DTW recognizer of Fig. 1. The reference set consisted of 12 templates per digit, generated from a clustering analysis of the 100 tokens of each digit in the training set (the same training set used to train each word HMM). The decision rule was the nearest neighbor rule (KNN = 1).[17]

Tables I and II show average word recognition accuracies for the following three recognizers:

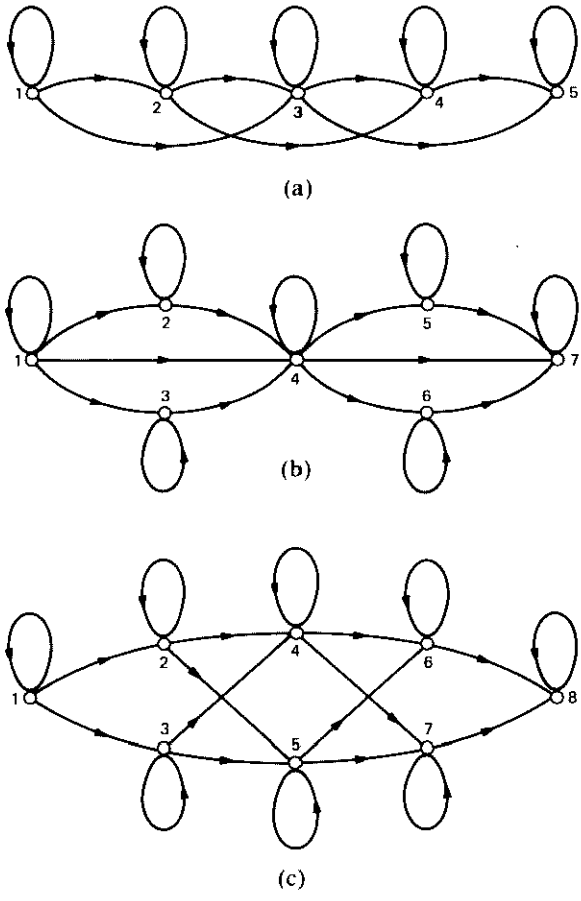

Fig. 15—State diagrams for (a) simple constrained serial 5-state model, (b) constrained parallel 7-state model, and (c) constrained parallel 8-state model.

(*i*) HMM/VQ using a constrained serial structure with five states for the HMM and the 64-element VQ.

(*ii*) LPC/DTW, the conventional recognizer.

(*iii*) LPC/DTW/VQ, the conventional recognizer with both reference and test patterns quantized using the same VQ used in the HMM case.

The results shown in Table I are for the 1000 digits of TS1, whereas those shown in Table II are for the 2000 digits (10 talkers) of TS2. The results given in Table I show that for TS1, both the LPC/DTW and HMM recognizers, when using the VQ, achieved essentially the same digit accuracy; however, the LPC/DTW system without the VQ achieved a 2-percent higher word accuracy. For TS2 in Table II the

Table I—Comparison of results on HMM/VQ and LPC/DTW word recognizers for [average word accuracy (%)] TS1, 100 talkers, 10 digits per talker

| | Recognizer | | |
|---|---|---|---|
| Digit | HMM/VQ | LPC/DTW | LPC/DTW/VQ |
| 0 | 98 | 99 | 99 |
| 1 | 98 | 98 | 99 |
| 2 | 96 | 100 | 96 |
| 3 | 99 | 99 | 97 |

| 7 | 99 | 100 | 94 |
| 8 | 92 | 98 | 96 |
| 9 | 95 | 98 | 96 |
| Average | 96.3 | 98.5 | 96.5 |

Table II—Comparison of results on HMM/VQ and LPC/DTW word recognizers for TS2, 10 talkers, 200 digits per talker

| | Recognizer | | |
|---|---|---|---|
| Talker | HMM/VQ | LPC/DTW | LPC/DTW/VQ |
| 1 | 74.5 | 96 | 87 |
| 2 | 99.5 | 100 | 99.5 |
| 3 | 94 | 99 | 97 |
| 4 | 89 | 99 | 91 |
| 5 | 95.5 | 100 | 100 |
| 6 | 95.5 | 99 | 99.5 |
| 7 | 100 | 100 | 99.5 |
| 8 | 91.5 | 96 | 93 |
| 9 | 91.5 | 99.5 | 93.5 |
| 10 | 96.5 | 98.5 | 98 |
| Average | 92.8 | 98.7 | 95.5 |

results show that the VQ led to a 3.2-percent reduction in accuracy for the LPC/DTW system, and an additional 2.7-percent loss in accuracy for the HMM system. A good deal of the loss in accuracy, however, was contributed by talker 1, whose accuracy was 87 percent for the LPC/DTW/VQ recognizer, and 74.5 percent for the HMM/VQ recognizer. With only 10 talkers, the influence of a single talker on the overall accuracy may be substantial.

An analysis of the actual errors of all three of the recognizers of Tables I and II shows the following:

(*i*) Of the 37 tokens misclassified by recognizer HMM/VQ in TS1, 31 were correctly identified by the LPC/DTW recognizer, and 27 were correctly identified by the LPC/DTW/VQ recognizer.

(*ii*) The vast majority (25) of the 37 errors made by recognizer HMM/VQ were cases in which the probability of the correct word was

lower than the probability of the incorrect word by a factor of $e^6$ or larger.

The results show that when the LPC/DTW recognizer (either with or without the VQ) has incorrectly identified the word, most of the time the HMM recognizer has correctly identified the word. Hence, a side result of this work is that the HMM/VQ model can be combined with an LPC/DTW model to provide word accuracies greater than either individual recognizer could obtain. In particular, for the data of TS1, the combined recognizer could have achieved a 99.4-percent word accuracy by using appropriate decision logic[22] on all cases in which both recognizers did not agree.

The same sort of trends are noted in the errors of TS2. Of the 124 errors made by the HMM/VQ recognizer, 113 were correct in the LPC/DTW or equivalently of the 26 errors made by the LPC/DTW recognizer, 15 were correct in the HMM/VQ system. Hence, again a combined system could potentially achieve an accuracy of about 99.5 percent on TS2 data. Considering that even the talkers in the TS2 data were different from those in the training set, this accuracy appears to be quite remarkable.

In summary, comparisons between the HMM/VQ and LPC/DTW recognizers indicate that without the VQ, the LPC/DTW recognizer achieves from 2- to 6-percent higher accuracy than the HMM/VQ system; with the VQ the differential in accuracy is from 0 to 3 percent.

## VII. DISCUSSION

In this paper we showed that the techniques of vector quantization of LPC vectors and hidden Markov modeling can be combined in a simple, straightforward manner to implement a speaker-independent, isolated word recognizer. With adequate training of the vector quantizer and the Markov model estimation algorithm, a digits vocabulary can be recognized, with accuracies of from 93 to 96 percent across a wide variety of talkers. Direct comparisons with a conventional linear predictive coding recognizer using dynamic time warping for time alignment with multiple templates for each vocabulary word showed that the HMM/VQ recognizer performs only a little worse (0.2 percent in one test, 2.7 percent in another) than the LPC/DTW recognizer when using the VQ. Without the VQ, the LPC/DTW recognizer was about 2 to 3 percent better than when the VQ was used.

Several general conclusions can be drawn from the results. The first is that the HMM/VQ recognizer performed exceedingly well on the difficult task of speaker-independent recognition of isolated digits. The fact that the overall performance of the HMM/VQ recognizer was somewhat poorer than the LPC/DTW/VQ recognizer appears to be primarily because of the insufficiency of the HMM training data.

Although 100 training sequences per word are adequate for a clustering analysis, as used in the conventional recognizer, they appear to be inadequate for obtaining good HMM models for these words. This suggestion is made plausible by considering what is being estimated in the HMM for each word. For an $N$-state Markov model, with $M$ finite symbols per state, a total of $N^2 + NM$ parameters must be estimated. (Of course with constraints there are somewhat fewer parameters.) For $N = 5$, $M = 64$, we need 345 parameters to be estimated from about $100 \times 40$ frames of VQ indices. The "curse of dimensionality" would imply that this amount of training data is woefully inadequate. [We have seen one consequence of this inadequacy in that we had to use the $\epsilon$-constraints of eq. (10) on any $b_j(k)$ whose value fell below the $\epsilon$ threshold.] In view of this, the fact that we achieve the results we are getting is rather remarkable.

A second conclusion that can be drawn from the results is that the use of the VQ on the LPC sets leads to a small, but not insignificant, degradation in performance of both the HMM/VQ and LPC/DTW/VQ recognizers as compared to the conventional LPC/DTW system. This suggests the need for using more than 64 vectors in the codebook or resorting to continuous models of the LPC parameters.

The results have shown that the errors made by the HMM/VQ and LPC/DTW recognizers are largely disjoint. Here there exists the potential of using some fairly standard techniques to combine the two recognizers into one whose accuracy is as good as the best of both recognizers on any given word.[22] This topic merits further consideration.

The experimentation with various forms of the Markov models used in the recognizer showed fairly conclusively that:

(*i*) Constrained models (with constrained transition matrices) performed consistently better than unconstrained models.

(*ii*) A finite minimum constraint on the state symbol probability matrix was a necessity for good system performance.

(*iii*) The effects of different random starting values for the HMM parameters were negligible in evaluating overall recognizer performance.

(*iv*) The required number of states in each word HMM needed to be on the order of 5. More states did not lead to significant improvements in performance.

(*v*) Parallel HMM structures yielded no real improvements over cascade structures, thereby indicating that an equivalent of multiple HMMs is not readily obtainable by simply changing the model structure.

(*vi*) The Viterbi scoring and the Baum-Welch scoring of test sequences give essentially identical performance.

### 7.1 Computational considerations of the HMM/VQ recognizer

It is worthwhile estimating the storage required and the computation needed to process an unknown test utterance using the HMM/VQ recognizer, and to compare them to the requirements of the conventional LPC/DTW recognizer. Our intention is to provide only a rough estimate of computational expense. A number of straightforward reductions in computation can be achieved for each recognizer through the judicious use of table storage. Also we ignore overhead owing to index computation, etc.

The first extra step in the HMM/VQ recognizer (after conventional LPC analysis) is vector quantization of the unknown test pattern. If we assume there are $T$ frames in the test word, and $M$ codebook entries in the VQ, then we need a total of

$$C_1 = M \cdot T(p + 1) \tag{17}$$

multiplications* (where $p$ = LPC order) to perform the $M \cdot T$ dot products required to get the best codebook entry for each frame.

Evaluation of the word HMM score, using the Viterbi scoring method with the constrained $A$ matrix, requires approximately

$$C_2 = T \cdot N \cdot 3 \tag{18}$$

multiplications and logarithms per word model, where $N$ is the number of states in the model, and the factor 3 accounts for the number of valid transitions into a given state. For a vocabulary of $V$ words a total of

$$C_* = M \cdot T \cdot (p + 1) + V \cdot T \cdot N \cdot 3 \tag{19a}$$

$$C_{\log} = V \cdot T \cdot N \cdot 3 \tag{19b}$$

multiplications and logarithms are required. For $M = 64$, $T = 40$, $V = 10$, $N = 5$, and $p = 8$, eq. (19) gives $C_* = 29040$ multiplies and $C_{\log} = 6000$ logarithms.

For a conventional LPC/DTW recognizer with $Q$ templates per vocabulary word, the computation for DTW processing is

$$C_3 \cong Q \cdot V \cdot T^2/3 \cdot (p + 1), \tag{20}$$

which for $Q = 12$ and other parameters the same as above gives $C_3 = 576000$ multiplications. Hence, the HMM/VQ recognizer requires about 17 times less computation (assuming logarithms are equivalent to multiplications) than the LPC/DTW recognizer.

With regard to storage, the HMM/VQ recognizer requires

* In this simplified analysis we neglect additions and comparisons of data and use multiplication count as the measure of computation.

$$S_1 = M(p + 1) \tag{20a}$$

$$S_2 = (M \cdot N + 3N) \cdot V, \tag{20b}$$

where $S_1$ is the storage (in words*) for the VQ codebook entries, and $S_2$ is the storage (in words) for the set of $V$ word HMMs. For the given values of the parameters, the total storage is $S = S_1 + S_2 = 4106$ words.

For the conventional LPC/DTW recognizer the storage is

$$S_3 = Q \cdot V \cdot T \cdot (p + 1), \tag{20c}$$

which gives 43,200 words for the assumed parameter values. Again we see a 10 to 1 reduction for the HMM/VQ model over the LPC/DTW model.

It should be noted that in our analysis of computation we have not included the computation of LPC coefficients. This computation must be performed in "real-time" and is independent of the vocabulary size, $V$. Hence, for a sufficiently large vocabulary the computation for scoring each word dominates the overall computation, and the rough analysis given above is appropriate. Furthermore, the computation for coding each LPC vector into the nearest codebook entry [eq. (17)] is also independent of vocabulary size and often could be performed in the "real-time" part of the recognizer. For such implementations the gain in computation of the HMM/VQ recognizer, over the conventional LPC/DTW recognizer, is even higher than our simple analysis predicts. Finally, it is straightforward to show that if we compare the computation of the HMM/VQ recognizer with that of the LPC/DTW/VQ recognizer, assuming that the VQ is done in real time and that tabular computation of products and logarithms is used, then by comparing the number of additions, the computational advantage of the HMM/VQ system over the LPC/DTW/VQ system still holds.

### *7.2 Some comments on the relationships between DTW and HMMs*

Contemporary research on speech recognition has produced two algorithmic procedures for dealing with the nonstationarity of the speech signal: temporal alignment techniques, and Markov modeling. These methods display certain superficial similarities (e.g., both use dynamic programming methods, can be cast in a Bayesian framework, and have a state transition network associated with them), as a result of which it has occasionally been claimed that they are identical. To the best of our knowledge, the experiments reported here represent the first direct comparison of the two methods. From these experiments it is abundantly clear that the methods are not identical. While

* Words of storage refer to unquantized floating point data.

their overall performances are comparable, they appear to make different errors and involve different amounts of computation and different complexities of training.

In all of these respects the two methods reflect the dichotomy between parametric and nonparametric methods of pattern recognition in the sense of Patrick.[23] In Markov modeling we assume that there is a family of models of a particular structure differing only in the values of their parameters. We use a large training set to estimate these parameters and assume that, if correctly done, the parameters will capture the structure of the data. The training procedure is computationally expensive but need be done only once. After training is complete, relatively little computation is required to determine whether an unknown observation was generated by the model.

Temporal alignment methods are opposite in the following ways. We assume that there is an underlying structure to the training data but its form is unknown. We attempt to capture that structure by simply storing one or more samples and measuring their "distance" to an unknown sample with a metric that is sensitive to the distinctive features of the categories that we seek to identify. The metric is monotonically related to the class conditional density functions so that minimum distance corresponds to maximum model probability. In this case training is a computationally simple data collection and storage process. Probability computation, on the other hand, is very costly since we must measure the distance to every prototype in the training set.

All of these characteristics are made manifest by our experiments. What remains to be determined is whether the parity of these methods extends to more difficult problems of speech recognition. We hope to answer that question by further experimentation.

## VIII. SUMMARY

We have described the results of an extensive investigation into the applicability of the techniques of vector quantization and hidden Markov modeling to speaker-independent, isolated word recognition. We have shown that, when properly designed, the resulting recognition system produces highly accurate word recognition on a vocabulary of isolated digits. We have also discussed the effects of variations of model parameters on system performance. Our experiments show that the resulting recognizer requires about 10 times less storage, and about 17 times less computation for classifying a test utterance than does an equivalent recognizer using LPC coding and dynamic time warping. These economies are obtained at the expense of only a slight increase in error rate.

# A Lithographic Mask System for MOS Fine-Line Process Development

By J. M. ANDREWS

(Manuscript received September 23, 1982)

*A mask set, incorporating a group of seven test chips, has been designed for fine-line process development and process control. Although six lithographic levels are available, the masks are generally intended to be used only in subsets of two or three levels to minimize the delay encountered in obtaining electrical test results for whichever processes require investigation. The mask levels serve a variety of purposes for special process development experiments. Available structures include: metal-oxide-semiconductor capacitors, p-n junctions, guarded and unguarded Schottky barrier diodes, ohmic contacts, van der Pauw patterns, insulated gate field-effect transistors, gated diodes, resistors for sheet resistance and linewidth variations, and tapped electromigration test strings. It is not anticipated that a process engineer should ever need more than a maximum of four levels to achieve an appropriate experimental structure for process development. It is not the purpose of these masks to establish fine-line design rules. The masks are intended to be used primarily with standard photolithographic processing, and most device structures have been designed to tolerate up to 5 μm in misalignment errors. However, certain selected features have been coded in a diminishing sequence to a minimum of 1.0 μm for special fine-line investigations. A salient feature of this mask system is the option to interleave rapid turnaround photolithographic steps with fine-line X-ray patterning; therefore, some mask levels have been reissued for X-ray lithography.*

## I. INTRODUCTION

In the past, the development of new silicon integrated circuit processes was impeded by the fact that an adequate set of simple test structures usually could not be fabricated without resorting to the full set of six lithographic levels required by the Poon Tester Chips.[1] This set sometimes requires several months to fabricate if X-ray lithography

is used. If device wafers could not be sacrificed, the processing engineer had to resort to simulating device structures, either by using metal dots of fixed areas on unpatterned oxides or deposited films, or by other schemes such as the use of offset circular windows using a pair of photolithographic steps.[2,3]

A set of photolithographic masks has been designed and is now available to fill the process development gap. The goal has been to provide the processing engineer with the means to simulate critical processing steps by introducing a monitor wafer, prepared in advance by one photolithographic step, and usually requiring only one more lithographic step of any type to obtain a structure ready for electrical testing.

The full set of fine-line process development masks consists of six photolithographic levels, but these have been designed to be utilized in subsets of 2, 3, or 4 levels only. Available structures include metal-oxide-semiconductor (MOS)* capacitors, contact windows, guarded and unguarded Schottky diodes, van der Pauw patterns, insulated gate field-effect transistors (IGFETs), gated diodes, and tapped electromigration test strings. Also available are large areas accessible for direct probing, for evaporation of MOS dots, or for Auger, scanning electron microscope (SEM), and transmission electron microscope (TEM) studies.

Section II contains a complete description of each of the devices that are available in the MOS mask set. The organization of the devices among each of seven test chips, the chip designations, the device assignments, wafer layout, design rules, and the alignment features are discussed in Section III. Section IV consists of a detailed description of each mask level separately, including the primary purpose for which the level is intended and the features available. Section IV also includes specific recommendations regarding which levels can be omitted with respect to the particular devices required or the experimental intent. Specific applications to silicon integrated circuit processing are discussed in Section V, and the MOS mask system is summarized in Section VI.

## II. DEVICE DESCRIPTION

Most of the test structures in the lithographic mask system are MOS capacitors, because such two-terminal devices are easily fabricated. Normally, only two photolithographic operations are needed, and the first could usually be done on a large number of wafers before specific experiments are planned. Furthermore, the same patterns can be used

* Acronyms and abbreviations are defined fully in the Glossary at the end of this paper. Tables and figures are located at the end of the text.

to fabricate p-n junctions, Schottky diodes, or ohmic contacts to the substrate by simply omitting the gate oxidation. All such devices, with dimensions ranging from 1 to 500 $\mu$m, are contained on a single chip designated A. Larger devices, with dimensions ranging from 1000 to 4000 $\mu$m, are included on chips B and C1 through C4. The aim has been to provide maximum experimental flexibility by including a wide range of available device dimensions, which permits electrically active areas to span more than seven orders of magnitude. A summary of all devices contained in the MOS mask system is presented in Table I in the form of a device key, listing MOS device, nominal dimension, the chip assignment, and the appropriate probing pad number. Detailed descriptions of each device follow in Subsections 2.1 to 2.5. Dimensional data on all device structures are contained in the pad keys shown in Tables II through V.

### *2.1 Sixfold MOS capacitor group (HEXCAP)*

The design of the lithographic mask system has evolved from a sixfold set of MOS capacitors (HEXCAP) that can be implemented at almost any stage of device processing to provide electrical characterization of dielectric layers.

#### *2.1.1 FOXCAP and GOXCAP*

The field oxide capacitor (FOXCAP) and gate oxide capacitor (GOXCAP) are shown in Fig. 1. For this pair of capacitors, the dimension $L_1$ increases through the sequence 50, 100, 200, 500, 1000, 2000, and 4000 $\mu$m. In all cases the dimension $L_2 = L_1 + 10$ $\mu$m, to conform with relaxed design rules to minimize registration errors (see Section 3.3). All FOXCAP and GOXCAP devices with $L_1 \leq 500$ $\mu$m are contained on the A chip, with peripheral probing pad locations coinciding with the Poon Tester[1] and the Process Monitor[4] chips. To facilitate MOS characterization of thick oxides or deposited dielectrics, a limited number of HEXCAP devices with $L_1$ equal to 1000 and 2000 $\mu$m were assigned to a larger chip B with area equal to that of ten standard Poon chips. The largest FOXCAP and GOXCAP devices on the C1 chips (see Section 3.1.3) are not square. Rectangular GOXCAP dimensions $L_3$ and $L_4$ for the largest devices have been selected so that

$$L_3 L_4 = (4000\ \mu m)^2. \tag{1}$$

The rectangular structures of FOXCAP and GOXCAP are shown in Fig. 16. Specific values for $L_3$ and $L_4$ were selected so that the overall C1 chip dimensions could be adjusted to accommodate the contact metallization test chip (METEST) (see Sections 3.1.4 and 3.2).

In each HEXCAP group, the portions of the polysilicon (POLY) areas that overlay the gate and source and drain (GASAD) areas are

equal. Thus, the capacitors formed over gate oxide ($C_{GOX}$) are equal among all elements of each HEXCAP group except FOXCAP. Furthermore, the total POLY areas are equal for FOXCAP, GOXCAP, and the devices with comb-shaped electrodes (POLYCOMB) to facilitate use with automatic testing programs. Thus, constant parasitic capacitance contributed by the field oxide ($C_{FOX}$) in parallel with $C_{GOX}$ has been maintained among GOXCAP, GOXCOMB, and POLYCOMB (see following Section 2.1.2) for convenience in software development. Detailed dimensional data are contained in the pad keys, Tables II, III, and IV.

It should be clear from Fig. 1 that omission of the gate oxide in GOXCAP results in a structure suitable for ohmic contact, Schottky barrier diode, and p-n junction experiments. For this reason the dimension $L_1$ also decreases through the sequence 20, 15, 10, 7, 5, 4, 3, 2, 1.5, and 1.0 $\mu$m on the A chip. It is not expected, however, that the smallest GOXCAP windows would be routinely resolved by standard photolithographic processes. To resolve the smallest features, the GASAD mask level has been reissued for X-ray lithography. Because the X-ray target is nearly a point source, the finite separation between X-ray mask and the silicon substrate results in a slight magnification of the X-ray image. To compensate for the magnified X-ray image, a small demagnification of all features on the X-ray mask was required to make the X-ray lithographic level compatible with previous or subsequent optical lithographic levels. Alignment in the X-ray exposure facility, however, is done optically. Therefore the spacing between alignment features on the X-ray mask must remain the same as on the optical mask. With these modifications, X-ray lithography can be interleaved with more easily performed photolithographic steps.

The use of the GOXCAP structure to form a guarded Schottky diode is illustrated in Fig. 2, in which a guard ring with width $W$ is diffused into the substrate before GASAD lithography. Guard-ring width options available in the mask set decrease through the sequence 10, 7, 5, 3, 2, and 0 $\mu$m (see Section 4.1). In all cases the guard ring has been centered on the GASAD boundary so that half its width extends into the contacting metal and reduces the effective contact area (see Fig. 2), so that:

$$A_{\text{eff}} = (L_1 - W)^2 \quad (\mu\text{m}^2). \tag{2}$$

For the cases in which $W \geq L_1$, the structure simply reduces to a p-n junction. Square or rectangular features have also been included in the GUARDRING level under the FOXCAP structures to provide the option of fabricating buried channel MOS capacitors[5–8] or to investigate the profiles of various ion implantations, such as those used to control threshold or punchthrough or for depletion loads.

### 2.1.2 GOXCOMB and POLYCOMB

To study peripheral effects or defects, structures with expanded gate-oxide/field-oxide periphery were included as the third HEXCAP element. This structure, abbreviated GOXCOMB, is shown in Fig. 3. On the A chip, the GOXCOMB structures comprise rectangular elements of width $d_1 = 25$ μm, which are spaced $d_2 = 10$ μm apart. The total gate oxide areas of the two GOXCOMB structures on the A chip are $(200\ \mu m)^2$ and $(500\ \mu m)^2$. To further enhance peripheral effects, GOXCOMB structures have been included on the B and C2 chips with $d_1 = 5$ μm and $d_2 = 10$ μm. Because of the decreased filling factor associated with reducing $d_1$ to 5 μm, it was not practical to keep the total gate oxide areas equal to the areas of the associated 1000-, 2000-, and 4000-μm GOXCAP structures; the actual areas are listed in Tables III and IV.

The POLYCOMB structure is similar to GOXCOMB except that the increased perimeter or peripheral expansion occurs at the gate-oxide/polysilicon boundary. The structural detail of POLYCOMB, the fourth HEXCAP element, is shown in Fig. 4. The chip assignments for POLYCOMB are the same as for GOXCOMB except for the 4000-μm structure, which is on the C3 chip. The same values for $d_1$ and $d_2$ apply to both COMB structures.

### 2.1.3 OVLAP and NOVLAP with FIELD PLATE

In some cases it is desirable to minimize parasitic capacitance in an MOS structure, i.e., the parallel capacitance composed of the area in which the gate electrode overlaps field oxide. The last pair of HEXCAP devices has been designed to minimize parasitic capacitance, consistent with the design rules discussed in Section 3.3. The OVLAP capacitor, shown on the left in Fig. 5, has a 5-μm overlap of the gate electrode onto the surrounding field oxide. The NOVLAP capacitor, shown on the right, has a gate electrode that has been retracted 5 μm from the GASAD boundary. The portion of the gate electrode that covers gate oxide in the OVLAP capacitor is equal to the area of the gate electrode in the NOVLAP capacitor. Both OVLAP and NOVLAP must be probed directly, because they are completely surrounded by a field plate that can be used to control the surface potential near the edges of each capacitor.

If a metallic silicide is formed in place of gate oxide, the resulting structure allows investigation of the effects of overlying metallization when excessive metallic penetration at contact window edges is suspected.[9] For these investigations it may be useful to include the GUARDRING option prior to silicide formation.

### 2.2 Sheet resistance group (SADSHEET and POLYSHEET)

Two three-terminal structures on the A chip can be used to obtain sheet resistance data from lines 400 $\mu$m long. Thus, accurate sheet resistance measurements can be made, even though the linewidths may deviate from the coded values because of unknown degrees of overetching or other process variations.

The left side of Fig. 6 shows the structure for measuring polysilicon sheet resistance (POLYSHEET). It consists of two 400-$\mu$m lines in series, but the coded linewidths are different: $W_1 = 5$ $\mu$m and $W_2 = 8$ $\mu$m. After processing, the actual linewidths may differ from the coded linewidths by a constant amount, $\epsilon$. Assume that a positive value for $\epsilon$ corresponds to a linewidth loss from the coded value, $W_i$. If the resistance of each line is measured, it is possible to solve for both the sheet resistance and a constant linewidth loss, $\epsilon$. It can be shown that

$$R_S = \frac{R_1 R_2}{R_1 - R_2} \cdot \frac{W_2 - W_1}{L} = 7.5 \times 10^{-3} \frac{R_1 R_2}{R_1 - R_2} \ (\Omega/\square) \tag{3}$$

and

$$\epsilon = \frac{R_1 W_1 - R_2 W_2}{R_1 - R_2} = \frac{5R_1 - 8R_2}{R_1 - R_2} \quad (\mu\text{m}). \tag{4}$$

A GUARDRING structure is included beneath some of the POLYSHEET lines. If the GUARDRING option were used, for example, to etch channels of various widths in a field oxide, the resulting POLYSHEET structure would provide information on poly-Si linewidths within oxide channels or straddling oxide steps.

Source-and-drain sheet resistance and linewidth variations can be determined from measurements on the structure shown on the right side of Fig. 6. The coded dimensions of the SADSHEET lines are exactly the same as for POLYSHEET, and eqs. (3) and (4) apply.

When the GUARDRING level precedes GASAD, some of the SADSHEET lines are imbedded into the guard-ring diffusion. Such a structure could be useful in determining the sheet resistance of a metallic silicide line for cases in which a low Schottky barrier height between the silicide and the substrate would interfere with electrical measurements.

### 2.3 van der Pauw group (VANDERPAUW)

The four-terminal symmetric structure shown in Fig. 7 has been provided on the A chip to make accurate determinations of polycrystalline silicon (poly-Si) sheet resistance in a way that is independent of the actual shape of the resistive pattern.[10] The poly-Si lines have been extended to the probing pads so that window and metallization lithography is not necessarily required. However, the option to have

overlying metallization on the lines leading to the van der Pauw pattern, with windows to the underlying poly-Si, is available for unusual circumstances in which polysilicon sheet resistance may be very high.

The other VANDERPAUW structures are on the C4 chip, and consist of GUARDRING and GASAD patterns. The combinations POLY/GUARDRING and POLY/GASAD VANDERPAUW patterns are also included on the C4 chip to enable measurements of inversion layer sheet resistance[11] and to investigate CHANSTOP performance.

### *2.4 IGFET group*

It is not anticipated that the IGFET group of devices will be utilized as often as the HEXCAP group of MOS capacitors, because the IGFETs require a minimum of four mask levels (GASAD, POLY, WINDOW, and METAL). For this reason, all IGFETs have been relegated to the B chip that has more available terminals than the A chip, although it may be less convenient for automatic probing.

Most of the IGFETs are included in one group with common sources and gates. The structure of the IGFET with $L = 20$ $\mu$m is shown in Fig. 8. All gates are 100 $\mu$m wide, and the gate lengths $L$ descend through the sequence 20, 15, 10, 8, 6, 5, 4, 3, 2, 1.5, and 1.0 $\mu$m. It is not anticipated, however, that the shortest gates will be resolved with ordinary photolithographic processing. Therefore, the POLY mask level may also be reissued for X-ray lithography. Even with wide variations in processing, the range of gate lengths provides a means to determine the true (electrically active) channel length from a plot of $\beta^{-1}$ versus the coded value for $L$, where $\beta$ is the transconductance of the IGFET.

The GUARDRING option is available on all elements of the IGFET group. The guard ring straddles the GASAD feature on the three sides that are not adjacent to the gate, as shown in Fig. 9. Such a structure may be useful to minimize edge leakage when Schottky barrier sources and drains are investigated.

In some cases it is useful to make C-V (capacitance measured as a function of voltage) measurements of the gate electrode in an active IGFET. But practical IGFETs are generally designed to minimize gate capacitance in order to maximize switching speed, and the true gate capacitance is difficult to separate from parasitic capacitance. Therefore, four large-gate IGFETs have also been included on the B chip with gate dimensions descending through the sequence 500, 300, 200, and 100 $\mu$m square.

### *2.5 Gated diode group (GATODE)*

The measurement of the depleted surface recombination velocity

$s_0$[12] is especially useful in evaluating the effectiveness of a low-temperature anneal to reduce surface state density[13] and to investigate the effects of radiation damage.[14,15] In the determination of $s_0$ it is necessary to directly control the surface potential near an MOS capacitor by means of a third electrode. This option has been made available by means of the gated diode group (GATODE), with dimensions decreasing through the sequence 500, 300, 200, and 100 $\mu$m square. The structure of the 100-$\mu$m gated diode is shown in Fig. 10. Obviously, a nearly equivalent structure could be realized by simply shorting the source to the drain of one of the large area IGFETs. The GATODE structures on the B chip differ from the IGFETs, however, in that the source-and-drain diffusions completely surround the gate electrode except for a 10-$\mu$m tab that connects the gate electrode to the probing pad. The GATODE structures are inverted from the usual gate-controlled diode in the sense that the p-n junction surrounds the gate electrode, whereas, the original gate-controlled diode structure consisted of an MOS capacitor in the form of a ring that surrounded a p-n junction.[16,17] The advantage of the GATODE structure is that better control of minority carrier production is possible when primary interest is centered on the properties of deeply depleted MOS capacitors.[18,19]

### *2.6 Contact metallization test chip (METEST)*

Electromigration studies generally require high current densities, of the order of $10^6$ A/cm$^2$, to achieve accelerated aging at a practical rate.[20] In the vicinity of contact windows, electromigration has been difficult or impossible to study, because the only test structure available has been the 100-window arrays on the Poon Tester A and C chips.[1] At the required current density, the sum of the voltage drops accumulated over a 100-window array often exceeds the breakdown voltage of the p-n junction that exists beneath each pair of windows. The contact metallization test chip D (METEST) has been designed to avoid large accumulated voltage drops by means of a tapped string of metal-to-diffusion windows, as shown in Fig. 11. Each tapped string is composed of series combinations of 1, 2, and 4 contact cells. Structural detail of one such contact cell is shown in Fig. 12 for a window size of 7 $\mu$m. With the D chip, a reliability engineer can select 2, 4, 6, 8, 10, or 14 windows in series, depending upon the particular breakdown characteristics of the structure. Each tapped string has been reproduced for a variety of contact window sizes, decreasing through the sequence 7, 5, 3, 2, 1.5, and 1.0 $\mu$m square. It is not expected, however, that the smallest windows would be routinely resolved by standard photolithographic processes. Therefore, the POLYCON mask level, which contains the contact windows for the METEST structures, has been reissued for X-ray lithography. The X-ray alignment features

have been modified appropriately to make the X-ray lithographic level compatible with prior GASAD and subsequent POLY optical lithographic levels.

There has been a tendency to avoid rectangular contacts with large aspect ratios, i.e., $L/W > 3$. The reason is related to photolithographic exposure problems with very small contact windows, such as $W \leq 2$ $\mu$m. When additional contact area is required, parallel strings of square contact windows are often preferred to large, rectangular contacts. For this reason, the smallest contact windows on the D chip have been repeated in multiples of 4, 6, and 8 parallel windows for the 2-, 1.5-, and 1.0-$\mu$m windows, respectively. Structural detail of a multiple-window contact cell is shown in Fig. 13 for 4-window, 2-$\mu$m contacts. Obviously, the current does not divide evenly among the windows in such a multiple-window structure, but the extra contact windows can be regarded as providing an experimental backup when the first window fails. The multiple window strings also tend to increase continuity probability when working close to the limit of lithographic resolution.

## III. ORGANIZATION

The lithographic mask system for fine-line process development has been organized on the wafer so that the simplest structures with the most convenient dimensions are available together on chip A. The included structures are HEXCAP, SADSHEET, POLYSHEET, and VANDERPAUW (see Section II). Perhaps the most unusual feature of the mask organization has stemmed from the enormous range of device sizes that have been made available to maximize experimental flexibility. Thus, structural dimensions ranging from 1 $\mu$m to 4000 $\mu$m are all present together on the same wafer. Furthermore, the largest areas can be used for direct probing, for evaporated MOS dots, or can be easily cleaved for Auger, SEM, TEM, X-ray, and other analytical investigations. It is the large range of device sizes (4-1/2 orders of magnitude) which has dictated chip designation and wafer layout.

### *3.1 Test chip designation*

#### *3.1.1 Chip A (1600 × 4096 $\mu$m)*

Most of the devices with dimensions ranging between 1.0 and 500 $\mu$m are included on the A chip. A composite view of the POLY and WINDOW levels of the A chip is shown in Fig. 14. Both the dimensions of this chip and the placement of the 36 probing pads have been selected to coincide with the Poon Tester[1] and the Process Monitor[4] chips to facilitate automated probing with existing probe cards.

#### *3.1.2 Chip B (8000 × 8192 $\mu$m)*

The dimensions of the B chip are integral multiples (5 × 2) of the A

chip to facilitate wafer layout (see Section 3.2), and the area is equal to that occupied by ten A chips. A composite view of the POLY, WINDOW, and METAL levels of the B chip is shown in Fig. 15. The size of the B chip has been selected to accommodate HEXCAP groups measuring 1000 and 2000 $\mu$m square, in the case of FOXCAP, GOXCAP, OVLAP, and NOVLAP. The GOXCOMB and POLYCOMB capacitors are nearly square, and have been laid out so that the equivalent areas are equal to the areas of the square capacitors (see Table III). Please note that to provide adequate resolution for illustration in Fig. 15, the width and spacing of the tines in POLYCOMB have been magnified 3X, and the number of tines has been accordingly reduced by a factor of 3 so that the overall dimensions remain unchanged. Accurate dimensional data on POLYCOMB can be measured from Fig. 15 by scaling down detail 3X. Areas and perimeters are listed in Table III. Also the gap between the field plate and the OVLAP and NOVLAP capacitors has been widened 3X. The IGFET arrays and gated diodes were assigned to the B chip for two reasons: (*i*) at least four photolithographic steps are required to realize completed devices, so it is anticipated that these will not be used as frequently as the two-level structures on the A chip; (*ii*) the IGFET and gated diode arrays require 23 additional probing pads that are not available on the A chip. To provide adequate resolution for illustration, the spacing between gates and sources and drains has been increased 3X in Fig. 15. In the gated diodes the space between gates and junctions has also been increased 3X.

#### *3.1.3 Chip C (6400 × 8192 $\mu$m)*

The largest MOS capacitors, with areas measuring $(4000\ \mu m)^2$, had to be allocated to four separate chips. The C1 chip contains FOXCAP and GOXCAP capacitors with areas equal to $(4000\ \mu m)^2$. A composite view of the POLY and WINDOW levels is shown in Fig. 16. The C2 chip contains a rectangular GOXCOMB structure with area somewhat reduced from the rectangular devices on chip C1; the exact coded areas are listed in Table IV. A composite view of the POLY and WINDOW levels is shown in Fig. 17. The C3 chip contains a rectangular POLYCOMB structure with area somewhat reduced from the rectangular devices on chip C1; the exact coded areas are listed in Table IV. A composite view of the POLY and WINDOW levels is shown in Fig. 18. To provide adequate resolution for illustration in Fig. 18, the width and spacing of the tines have been magnified 3X, and the number of tines has been accordingly reduced by a factor of 3 so that the overall dimensions remain unchanged. Accurate dimensional data can be measured from Fig. 18 by scaling down detail 3X. Areas and perimeters are listed in Table IV.

The C4 chip contains both OVLAP and NOVLAP rectangular capacitors with areas measuring $(4000\ \mu m)^2$ and surrounded by a field plate. A composite view of GUARDRING, GASAD, POLY, and WINDOW levels is shown in Fig. 19. For the purpose of illustration the gap between the field plate and the OVLAP and NOVLAP capacitors has been widened 3X in Fig. 19. All C chips measure $6400 \times 8192\ \mu m$. When combined with the D chip (see next section), the overall dimensions of the combination are exactly equal to the dimensions of the B chip or a $2 \times 5$ array of A chips.

#### *3.1.4 Chip D (1600 × 4096 μm) METEST*

A composite view of the POLY and WINDOW levels of the contact metallization test chip D (METEST) is shown in Fig. 20. Both the dimensions and the locations of the 36 probing pads of the METEST chip have been selected to coincide with the Poon Tester[1] and the Process Monitor[4] chips to facilitate automatic probing. It is expected that the tapped strings with 2-, 3-, 5-, and 7-$\mu$m windows will be used most extensively. These strings have been terminated on probing pad numbers 3, 4, 5, 6 (3 $\mu$m), 9, 10, 11, 12 (2 $\mu$m), 21, 22, 23, 24 (7 $\mu$m), and 27, 28, 29, 30 (5 $\mu$m) to coincide with existing metallization probing cards.

Detailed dimensional data for the D chip are listed in Table V. Table V differs from Tables II through IV in many respects, because the tapped strings were not intended to provide capacitance data. There are no GUARDRING features. Entries tabulated under GASAD tub refer to features straddling the indicated pad numbers, although all tubs within each string are connected in parallel after metallization with the POLY level. Entries tabulated under POLYCON window refer to the total cross-sectional area of a single tub input or output. However, current density is not expected to be uniform over any given window and especially among multiple windows. Entries tabulated under POLY are intended to aid in estimating string resistances from the sheet resistance of the metallization layer provided by the POLY pattern. Taps and ties are defined in Fig. 11, and the equivalent numbers of squares straddling each pair of pad numbers are indicated. The equivalent number of squares for the contact areas were not included, because these depend upon the sheet resistance of the underlying tubs.

### *3.2 Wafer layout*

The location of each of the test chips described in the preceding section is shown in Fig. 21. The A chip is the most numerous, totaling 130 and arranged in blocks of 10 to form the cross-shaped pattern coded AX in Fig. 21. The number X, following A, denotes the width of

the guard ring when the GUARDRING (N35) option is selected. The symbol A0 denotes unguarded devices. The arrangement of the A chips, which have been laid out to permit automatic probing with existing facilities, is obviously intended to reveal horizontal and vertical parametric trends on test wafers.

There are only twelve B chips, which contain 1000- and 2000-$\mu$m devices. When the GUARDRING (N35) option is selected, there are only two chips for each guard-ring width, i.e., 2, 3, 5, 7, and 10 $\mu$m. As in the case of the A chip, guard-ring width is represented by X in the notation BX, shown in Fig. 21. The asterisks denote undefined guard-ring diffusions or implantations that cover the entire chip for evaluation of guard-ring performance without a parallel Schottky diode.

There are six C1 and six C4 chips on the test wafer. In each case, three are unguarded and three have 10-$\mu$m guard rings, *viz.* C1-0 and C1-10 in Fig. 21. The C2 and C3 chips contain large GOXCOMB and POLYCOMB structures, respectively. Two are unguarded, *viz.* C2-0, and two have guard rings, *viz.* C2-10, in Fig. 21. In the case of GOXCOMB, the guard-ring width does not permit interdigitating the individual COMB elements, so the guard-ring option provides a buried diffused tub beneath the GASAD structure. As in the B chip, the asterisks denote undefined guard-ring diffusions or implantations.

The contact metallization test chip is denoted D in Fig. 21. There are a total of 40, which have been divided equally among the four quadrants of the wafer.

At the top and bottom and left and right are four alignment patterns that have been designed to permit aligning any mask to any other in any order (see Section 3.4). Also associated with each alignment pattern are two TEM test chips that have been specially designed to facilitate transmission electron microscopic (TEM) analysis.[21] (See Section 3.5.)

### *3.3 Design rules*

The lithographic mask system has been designed specifically for fine-line process development and process control. Since the masks are generally to be used with standard photolithographic processing, it obviously would be inappropriate to interpret data in terms of fine-line design rules. Consequently, most device structures have been designed to tolerate up to 5 $\mu$m in misalignment errors. Figure 22 is an example of such relaxed design rules, showing the source-gate structure of a typical element from the IGFET group (see Section 2.4). The same structure also applies to the junction contacts of the gated diode group (GATODE) (see Section 2.5). In general, all contact windows have a minimum width of 5 $\mu$m, and all overlapping regions are a minimum of 5 $\mu$m.

A number of exceptions exist, however. Most prevalent are the GOXCAP group (see Section 2.1.1), which has been deliberately continued to a minimum size of 1.0 $\mu$m to enable special experiments with nonstandard photolithographic processes or X-ray lithography. A similar philosophy has been applied to the entire contact metallization test chip D (METEST), which has been fully described in Section 2.6.

### *3.4 Alignment features*

It is hoped that maximum flexibility has been achieved by the use of a modified version of the standard Perkin-Elmer projection (PEP) alignment features. These modified PEP (MOPEP) features are shown in Figs. 23a through f and are presented in the anticipated "normal" order or suggested sequences, i.e. GUARDRING, GASAD, POLYCON, POLY, WINDOW, and METAL. The upper set of MOPEP features in each of Figs. 23a through f corresponds to the "normal" processing sequence. Unlike alignment procedures for virtually all device codes, each mask in this lithographic system must be aligned to the immediately preceding level, because levels prior to the one immediately preceding introduce overlapping patterns. But the unique feature of the MOPEP alignment features is that any number of levels can be skipped. For example, it has been anticipated that a popular sequence may be GASAD followed by POLY only. The alignment feature remaining on the test wafer after GASAD lithography is shown in Fig. 23b. Alignment of POLY to GASAD corresponds to a "normal" processing sequence, so the second MOPEP feature in the upper half of Fig. 23d would have to be aligned to the second (right-hand) MOPEP feature in the upper half of Fig. 23b. The left-hand MOPEP feature in Fig. 23b is simply ignored, because the GUARDRING level was omitted.

The lower set of MOPEP alignment features in Figs. 23a through f have been included to enable an "inverted" processing sequence. Such an "inverted" processing sequence might be required for some unique or novel structure that was not originally intended or anticipated. For example, POLY features can be defined on the surface of an unpatterned field oxide. After oxidation, or deposition of an intermediate dielectric layer, it might be necessary to define additional conductive features of either poly-Si or metal directly over the original poly-Si features. This capability is available by using a "GASAD" level with reverse tone (see Table VI), consisting of opaque features within a transparent background, to produce conductive patterns in polysilicon or metal. Alignment is carried out by inserting the central MOPEP feature in the lower half of Fig. 23b into the right-hand MOPEP feature on the lower half of Fig. 23d, which would be the pattern left

on the test wafer after POLY lithography. (Tone reversal is not applied to MOPEP features.)

To be consistent with the relaxed 5-$\mu$m design rules discussed in the preceding section, the right-hand MOPEP feature in the upper halves of Figs. 23a through f are all 25 $\mu$m wide. All of the other MOPEP features in the upper halves of Fig. 23b through e and all MOPEP features in the upper half of Fig. 23f are 20 $\mu$m wide. A similar scheme that provides 2.5-$\mu$m frames for alignment in inverted order applies to the lower halves of Figs. 23a through f. The 2.5-$\mu$m alignment frame has resulted from a compromise that should offset the effects of photolithographic processing variations, but proper alignment does require some judgment on behalf of the alignment operator to optimize registration of sequential mask levels.

### *3.5 TEM test chip*

Sample preparation techniques for transmission electron microscopy (TEM) usually produce sections sufficiently thin over a region that may vary between 40 and 100 $\mu$m. All morphological features essential for process evaluation can be translated into the area for TEM study by a special test pattern 1 mm wide and approximately 6.7 mm long, and with a structural period of 29.5 $\mu$m. The TEM test pattern is shown in Fig. 24, showing gate oxide within regions defined by GASAD, contact windows formed by POLYCON, layers of poly-Si defined by POLY, and subsequent P-glass and metallization levels. Thus all windows, steps, and other peripheral features normally encountered in fine-line process development are reproduced over 200 times within each TEM test chip. Two TEM test chips have been placed symmetrically with respect to each MOPEP alignment feature (see Fig. 21), and no active device areas have been sacrificed. A total of eight TEM test chips have been incorporated into th · lithographic mask system, and the feature boundaries of each TEM test chip are oriented orthogonal to a ⟨100⟩ cleavage plane so that the cross section shown in Fig. 24 can be readily obtained from widely separated areas of the wafer. The TEM test chip shown in Fig. 24 differs from the one published by Sheng and Marcus,[21] partially because the chip in Fig. 24 was designed for a fine-line process that does not involve selective oxidation.

## IV. MASK LEVELS

The six mask levels that comprise the normal tone portion of the lithographic mask system are listed in the upper part of Table VI and are intended to be used with positive photoresist. The suggested sequence reflects the primary purpose for which each level was intended; a few examples are shown in Table VII. Each mask level

contains four full sets of MOPEP alignment features, corresponding to "normal" and "inverted" processing sequences. Thus, it is possible to align any mask level to any other, thereby permitting novel device structures with processing sequences that have not been anticipated. (See Section 3.4 for alignment details.) The three levels that have been issued in reverse tone are shown in the lower part of Table VI. They have been intended for use with negative photoresist, uniform gold metallization, selective oxidation or other special processes.

### *4.1 GUARDRING*

The GUARDRING level would generally be omitted for most MOS processing investigations. In a sense, it may be viewed as being analogous to the isolation tub diffusion that occurs in CMOS processing prior to GASAD. The principal purpose of the guard ring is to provide p-n junctions that straddle the boundaries of Schottky barrier diodes to electrically isolate metallization edges that often obscure barrier characterization. The GUARDRING level is unusual because it comprises a subset of six patterns that provide guard-ring widths of 10, 7, 5, 3, 2, and 0 $\mu$m. The location of each of these subsets is indicated in Fig. 21 by the final hyphened integers X, i.e., C1-X. Each guard ring is located such that it frames each GASAD boundary symmetrically. In the case of the smallest GASAD features, the area enclosed by the larger GUARDRING features vanishes, and a p-n junction is formed, which is useful for evaluating guard-ring performance. The asterisks denote undefined diffused or implanted areas that cover the entire chip. These chips can also be used to characterize the guard rings independently from the other features or to evaluate ion implantation profiles (see Section 2.1.1).

### *4.2 GASAD*

The GASAD level is normally the first level that would be used for MOS process development and monitoring. The principal purpose of the GASAD level is to open up areas in the field oxide in preparation for a possible ion implantation, for threshold control, followed by gate oxidation. If gate oxidation is omitted, however, the GASAD level provides a range of areas for investigations of contact resistance, Schottky barrier diodes, and p-n junctions. Most of the patterns provided by GASAD are square and progressively increase in size through the sequence 1.0, 1.5, 2, 3, 4, 5, 7, 10, 15, 20, 50, 100, 200, 500, 1000, 2000, and 4000 $\mu$m. At 200 $\mu$m and above, comb-like structures (GOXCOMB) are included in the GASAD level for investigation of peripheral effects and defects. The 200- and 500-$\mu$m GOXCOMB structures consist of a series of 25-$\mu$m slots separated by 10 $\mu$m of field oxide (see Fig. 3). All of the slots are interconnected to guarantee

equalization of surface potential. The choice of the relatively large slots assures that all of the MOS capacitors within HEXCAP will have nearly equal gate areas despite typical variations in linewidth owing to processing variables. Obviously, GOXCOMB can be utilized for aggravating edge effects or defects in device structures. In the largest GOXCOMB structures (1000, 2000, and 4000 $\mu$m) the slots have been reduced to 5 $\mu$m, separated by 10 $\mu$m of field oxide, to further increase the aggravation caused by peripheral electric fields and edge-related defects.

It is anticipated that in most MOS process monitoring and development applications it would be possible to use wafers that had been previously patterned using the GASAD mask. Thus, the most important device structures would be complete after only one additional photolithographic step (see POLY, Section 4.4).

### *4.3 POLYCON*

For most MOS monitoring or process development applications the POLYCON level would be omitted. The main reason for including this level has been to provide windows to the underlying GASAD tub diffusions or ion implantations that are required by the metallization test chip D (METEST). However, when investigation of p-n junctions with large areas or extended peripheries is required, the GASAD mask is used to define the diffused or ion-implanted regions. In this case the POLYCON level provides the required contact windows to junctions formed by the GASAD features. Evaluation of p-n junctions thus requires a minimum of three mask levels, because the POLY level must be used for metallization. If it should be necessary to investigate the effects of high-temperature processing after poly-Si deposition, such as oxidations and/or insulating depositions, additional mask levels WINDOW and METAL might be required.

### *4.4 POLY*

It has been anticipated that the combination of GASAD followed by POLY would be the most widely used sequence of mask levels for MOS process development. For this reason, the POLY patterns have been extended to include the probing pads so that the poly-Si can be probed directly. Typical probe-spreading resistance measurements are of the order of 50Ω in a poly-Si film with a sheet resistance of 20 Ω/□, *providing that the probe tips are sufficiently hard and sharp enough to pierce 50Å of native oxide that typically occurs on the surface of $n^+$-poly-Si.* For this purpose tungsten carbide probes are recommended with tip radii of $5 \times 10^{-4}$ cm or less. The use of palladium probes with planar tips $5 \times 10^{-3}$ cm in diameter has been found to be unsatisfactory for probing $n^+$-poly-Si. Unfortunately, many probe

cards designed for automatic probing cannot be used for probing $n^+$-poly-Si directly, because erratic probe contact resistance may range over many orders of magnitude, sometimes exceeding 10 megohms. Regular cleaning and inspection of probe tips are mandatory when probing $n^+$-poly-Si. Ion implantation causes an amorphous layer of semi-insulating material to occur near the surface of $n^+$-poly-Si. Thus, any $n^+$-poly-Si that has been exposed to ion implantation must be annealed at 950°C in $N_2$ for 30 minutes to avoid excessive probe resistance. In automatic probe stations with existing probe cards, the POLY mask level may be used to pattern aluminum, with or without an intervening poly-Si layer, to reduce probe resistance. Alternatively, the WINDOW and METAL mask levels can be used (see next sections).

At 200 $\mu$m and above, comb-like structures (POLYCOMB) are included in the POLY level for investigating edge effects or defects (see Fig. 4). The width and separation of individual elements are the same as for GOXCOMB (see GASAD, Section 4.2).

### *4.5 WINDOW*

Occasionally, it is necessary to investigate changes in device characteristics resulting from oxidations, insulating depositions, or annealing after poly-Si definition. For this purpose the WINDOW level has been provided, which opens 90-$\mu$m square windows over each probing pad. In most cases the poly-Si could then be probed directly at the contact pads without resorting to aluminum deposition and lithography, providing the recommendations contained above in Section 4.4 are followed. In the case of the OVLAP and NOVLAP MOS capacitors surrounded by field plates, the capacitors must be probed directly. For this purpose, the WINDOW level also contains large contacting areas over each capacitor surrounded by a field plate. Occasionally, it may be beneficial to access the van der Pauw pattern with aluminum metallization. Therefore, the WINDOW level also contains four contacts oriented directly over the leads at the edges of the van der Pauw structures to provide conduction to overlying metal lines leading to the probing pads. The WINDOW level is also required for contacts to the sources and drains of IGFETs, the junction terminal of the GATODEs, and to SADSHEET.

### *4.6 METAL*

As in the case of the GUARDRING and POLYCON levels, it is expected that the METAL level could be omitted in most MOS monitoring or process development applications. The principal exceptions include IGFETs and gated diodes, in which structures the re-

quired electrical continuity could not have been provided by the POLY level alone.

In most cases the metal has been excluded from any areas where poly-Si is in contact with gate oxide. The reason for this exclusion stems from experimental evidence that aluminum, sintered into polycrystalline silicon, sometimes deteriorates the dielectric breakdown strength of underlying gate oxides, especially if the gate oxide is very thin (i.e., $\leq$ 250Å). Exception occurs for all of the MOS capacitors surrounded by field plates, which must be probed directly. These OVLAP and NOVLAP capacitors thus provide experimental structures appropriate for cases in which it is necessary to compare the breakdown voltages in MOS capacitors with and without overlying metallization.

## V. APPLICATIONS

Most basic circuit elements utilized by unipolar semiconductor integrated electronics can be easily fabricated with an appropriate subset of the lithographic mask system. These elements fall into five general classifications: MOS capacitors, p-n junctions, contacts, sheet resistors, and IGFETs. The contact class can be further subdivided to include guarded and unguarded Schottky diodes, ohmic contacts, and contact metallization test cells. The sheet resistor class can be subdivided to include polysilicon sheet resistors (POLYSHEET), source and drain sheet resistors (SADSHEET), and van der Pauw patterns in the GUARDRING, GASAD, and POLY levels. The IGFET class also includes gated diodes. These thirteen subdivisions of unipolar device structures are shown in the first column of Table VII. The remaining six columns show the *required* mask levels needed to realize a particular device structure. Other mask levels are generally optional, but some may be required for certain experiments.

At the present time the lithographic mask system is in wide use, and more than fifty experiments have been initiated in the Advanced Large-Scale Integration (LSI) Development Laboratory using one or more levels. References 22 through 26 contain published experiments that have utilized this mask system.

## VI. SUMMARY

Fine-line MOS process characterization, determination of base-line parameters, and new process development can be efficiently carried out using the lithographic mask system. By selecting an appropriate subset of photo- or X-ray lithographic mask levels, most unipolar semiconductor circuit elements can be fabricated in an enormous range of sizes. X-ray and trilevel lithographic processes are used only when

absolutely required, and these can be interleaved with photolithographically defined patterns. Any mask level can be aligned to any other, and any number of mask levels can be skipped. Registration tolerance is 5 $\mu$m for most device structures. Most experimental device structures can be completed and ready for electrical evaluation in a fraction of the time required to fabricate the elements on the Poon Tester chips,[1] which are included within the array of fine-line device chips and require six X-ray lithographic levels to complete.

## VII. ACKNOWLEDGMENTS

The author is indebted to W. T. Lynch for initiating this project and for his continued interest, suggestions, and encouragement. The initial ideas were refined and implemented as a result of numerous discussions with E. N. Fuls, R. A. Kushner, E. I. Povilonis, and N. C. Wittwer. The universal alignment capability, resulting in modified PEP (MO-PEP) features, grew out of discussions with N. C. Wittwer, K. G. Schaffner, and R. Colish. The modification of X-ray alignment features to permit mixing of X-ray and photolithography was done by G. A. Coquin. The design of the metallization test chip (METEST) was carried out in collaboration with A. K. Sinha and S. Vaidya. Discussions with J. R. Brews and G. W. Taylor contributed to the design of the gated diodes and the option of buried channel capacitors. The TEM test chip was contributed by R. B. Marcus. Chip layouts were carried out by A. W. Russo, M. L. Oeser, J. P. Boyle, and M. Wagner of the Engineering Information Department. The wafer array was prepared by S. R. Juice, also of the Engineering Information Department. Mask fabrication was done in the Murray Hill Mask Lab; the cooperation of J. G. Skinner, L. J. Heilos, and other members of the Photomask and Pattern Generation Department is gratefully acknowledged. Final mask inspection was done by D. P. Rosenfeld of the Lithographic Systems Development Department.

## GLOSSARY

| | |
|---|---|
| CHANSTOP | channel stopping implantation or diffusion to avoid inversion of the silicon surface at the Si-$SiO_2$ interface |
| C-V | capacitance measured as a function of voltage |
| FOXCAP | field oxide capacitor |
| GASAD | gate and source and drain feature delineated in the field oxide prior to gate oxidation. Also, the second photolithographic level in the set of fine-line process development masks. |
| GATODE | gated diode, essentially an IGFET (see below) with common source and drain. |
| GOXCAP | gate oxide capacitor |
| GOXCOMB | a gate oxide feature with a comb-shaped structure |
| GUARDRING | electrically guarded structure, fabricated by ion implantation or diffusion, which straddles and surrounds the boundary of a metallization feature, forming a closed ring. |
| HEXCAP | six-fold or hexadic capacitor group |
| IGFET | insulated gate field-effect transistor |
| LSI | large-scale integration |
| METAL | metallization pattern, the final photolithographic level in the set of fine-line process development masks. |
| METEST | metallization test structure consisting of tapped strings with contacts to underlying diffused tubs. |
| MOPEP | modified Perkin Elmer projection alignment features |
| MOS | metal-oxide-semiconductor sandwich structure used |

| | |
|---|---|
| | for electrical characterization of device fabrication processes |
| NOVLAP | conductive pad not overlapping field oxide and forming the top level of a metal-oxide-semiconductor capacitor |
| OVLAP | conductive pad overlapping field oxide and forming the top level of a metal-oxide-semiconductor capacitor |
| PEP | Perkin Elmer projection alignment features |
| POLY | polycrystalline silicon which, when patterned, forms a conductive electrode for electrical tests. Also, an intermediate photolithographic mask level in the set of fine-line process development masks. |
| POLYCOMB | a polycrystalline silicon feature with a comb-shaped structure |
| POLYCON | polycrystalline contact to underlying silicon substrate. Also, an intermediate photolithographic mask level in the set of fine-line process development masks. |
| POLYSHEET | polycrystalline silicon feature for sheet resistance and linewidth loss measurements |
| SADSHEET | structure formed during gate and source and drain (GASAD) lithography to determine source and drain sheet resistance and linewidth loss |
| SEM | scanning electron microscope |
| TEM | transmission electron microscope |
| VANDER-PAUW | a symmetric structure introduced by L. J. van der Pauw[10] to determine the electrical resistivity of thin conductive layers |
| WINDOW | next to the last photolithographic mask level in the set of fine-line process development masks to form source and drain contacts to insulated gate field-effect transistors, junction contacts in gated diodes, and access to polycrystalline silicon features when the poly Si is covered by an intermediate dielectric. |

# A Circuit That Changes the Word Rate of Pulse Code Modulated Signals

By J. C. CANDY and O. J. BENJAMIN

(Manuscript received November 2, 1982)

*In this paper we describe a circuit that accepts pulse code modulated signals sampled at about 8 kHz and resamples them at any desired rate up to 512 kHz. When the sampling satisfies Nyquist's criterion, the distortion introduced is at least 35 dB below the signal level. The circuit uses a digital low-pass filter to interpolate sample values, and it may be integrated as about 2500 gates on a 5 mm$^2$ chip.*

## I. INTRODUCTION

It often is impractical to synchronize all of the clocks of an extensive digital network. Consequently, data will arrive at connections out of synchronism and special circuits are needed to bring them into time with the local clock. For irregular bursts of data, synchronism can be easily obtained using buffer memories, but for continuous streams of data, such methods are useful only for very small discrepancies in clock frequencies. A case of particular interest in telephone networks is the transmission and processing of pulse code modulation (PCM). Changing the word rate of such data can introduce objectionable noise into the signal. We describe a circuit that uses digital filters to contain this noise.

## II. RESAMPLING

We know that when an analog signal, $x(t)$, having spectral density $X(\omega)$ and bandwidth $\omega_0$ is sampled at regular intervals, $\tau$, the spectral density of the sampled signal can be expressed as the sum of images

$$X'(\omega) = \sum_{-\infty}^{\infty} X\left(\omega + \frac{2\pi n}{\tau}\right). \tag{1}$$

When $\omega_0\tau < \pi$, the original signal can be recovered by filtering out the images for $n \neq 0$.

If we were to change the sampling rate[1] by first holding each sample value constant throughout its period and resampling at the new period, $\tau_1 < \pi/\omega_0$, the spectral density of the resampled signal can be expressed as

$$X''(\omega) = \sum_n \sum_k X\left(\omega + \frac{2\pi n}{\tau} + \frac{2\pi k}{\tau_1}\right) H\left(\omega + \frac{2\pi n}{\tau}\right), \tag{2}$$

where

$$H(\omega) = \frac{\sin\left(\frac{\omega\tau}{2}\right)}{\frac{\omega\tau}{2}} = \text{sinc}\,(f\tau). \tag{3}$$

When we try to recover the original signal from $X''(\omega)$ by filtering out the components for $n \neq k \neq 0$, it is contaminated by cross modulation products for which

$$0 < \left(\frac{n}{\tau} + \frac{k}{\tau_1}\right) < f_0 = \frac{\omega_0}{2\pi}. \tag{4}$$

Notice that when $\tau$ and $\tau_1$ are integer multiples of one another, this condition never holds and reflected noise is absent from the baseband.

An obvious means of eliminating in-band cross-modulation products from eq. (2) is to smooth out the high-frequency components of the sampled signal $x'(t)$ before resampling it. This has been accomplished by replacing the sample and hold represented by $H(\omega)$ in eq. (3) by a better low-pass filter that interpolates new sample values from the old ones.[1,2] Another implementation of this method is demodulation with a digital/analog (D/A) converter, analog smoothing, and remodulation with an analog/digital (A/D) converter. The method[1] presented here raises the sample rate to a high multiple of the original rate, smooths the sample values with digital filters, holds the smoothed samples, and resamples them at the desired rate.

## III. A CIRCUIT FOR RESAMPLING 8-kHz PCM

We will describe a circuit for resampling a 3.5-kHz signal that has been pulse code modulated at a nominal 8-kHz rate using 16 bits per word. The new sampling can be at any rate up to 512 kHz and even higher rates can be accommodated by minor modification of the circuits. The technique first raises the sampling rate 16 times to 128 kHz using digital interpolating filters to smooth out all unnecessary images of the signal, leaving only those that are adjacent to the new

rate and its harmonics. The high-frequency code is placed in a holding register from which the output is gated at the desired rate. We will see that the filter action of this hold, sinc $(f/128)$, provides more than 30-dB attenuation of the cross-modulation products that fold into baseband.

Because the complexity of digital filters increases sharply with increasing sampling rate, it pays to raise the rate in stages.[1] Figure 1 illustrates the process. Our first stage raises the sampling rate four times from 8 to 32 kHz, employing a low-pass filter that cuts off sharply to attenuate spectral images between 4 and 28 kHz. The second stage raises the rate to 128 kHz by simple linear interpolation, and the third stage is a holding register. Most of the circuits used originally were

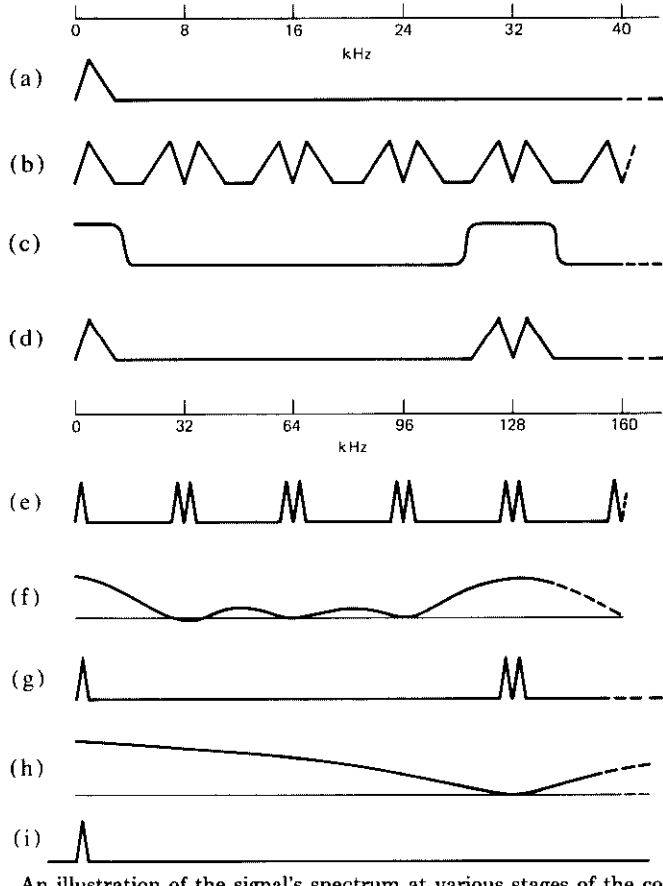

Fig. 1—An illustration of the signal's spectrum at various stages of the conversion: (a) The original signal. (b) The signal sampled at 8 kHz. (c) The response of the low-pass filter. (d) and (e) The output from the low-pass filter. (f) The response of the linear interpolator. (g) The output of the interpolator. (h) The response of the holding circuit. (i) The held signal.

designed to be part of an oversampled coder/decoder (codec).[3] We shall summarize their relevant properties in the following sections.

## IV. THE LOW-PASS FILTER

The low-pass filter shown in Fig. 2 processes data at 32 kilowords per second. Its $z$-transform response is given by

$$F(z) = \frac{1}{32}\frac{1-z^{-4}}{1-z^{-1}} \cdot \frac{1-\frac{5}{4}z^{-1}+z^{-2}}{1-\frac{19}{16}z^{-1}+\frac{31}{64}z^{-2}} \cdot \frac{1-\frac{3}{4}z^{-1}+z^{-2}}{1-\frac{23}{16}z^{-1}+\frac{55}{64}z^{-2}}. \quad (5)$$

Each word of its 8-kHz input signal is repeated four times and fed into two second-order sections. This filter attenuates the images of the signal in the range 4 to 28 kHz by more than 34 dB. Its output is a good approximation of pulse code modulation at 32 kHz. The spectral response of the entire resampler is shown in Fig. 3. The zeros at 4.5 and 6 kHz are introduced by the second-order sections, and those at 8 and 16 kHz by the repetition of input words.

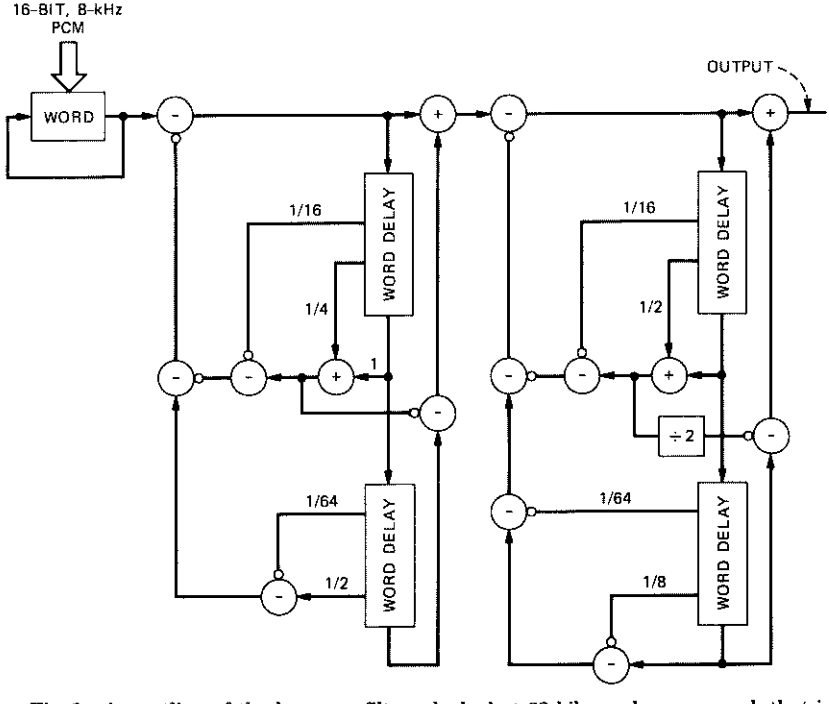

Fig. 2—An outline of the low-pass filter, clocked at 32 kilowords per second, that is used to raise the sampling rate from 8 to 32 kHz.

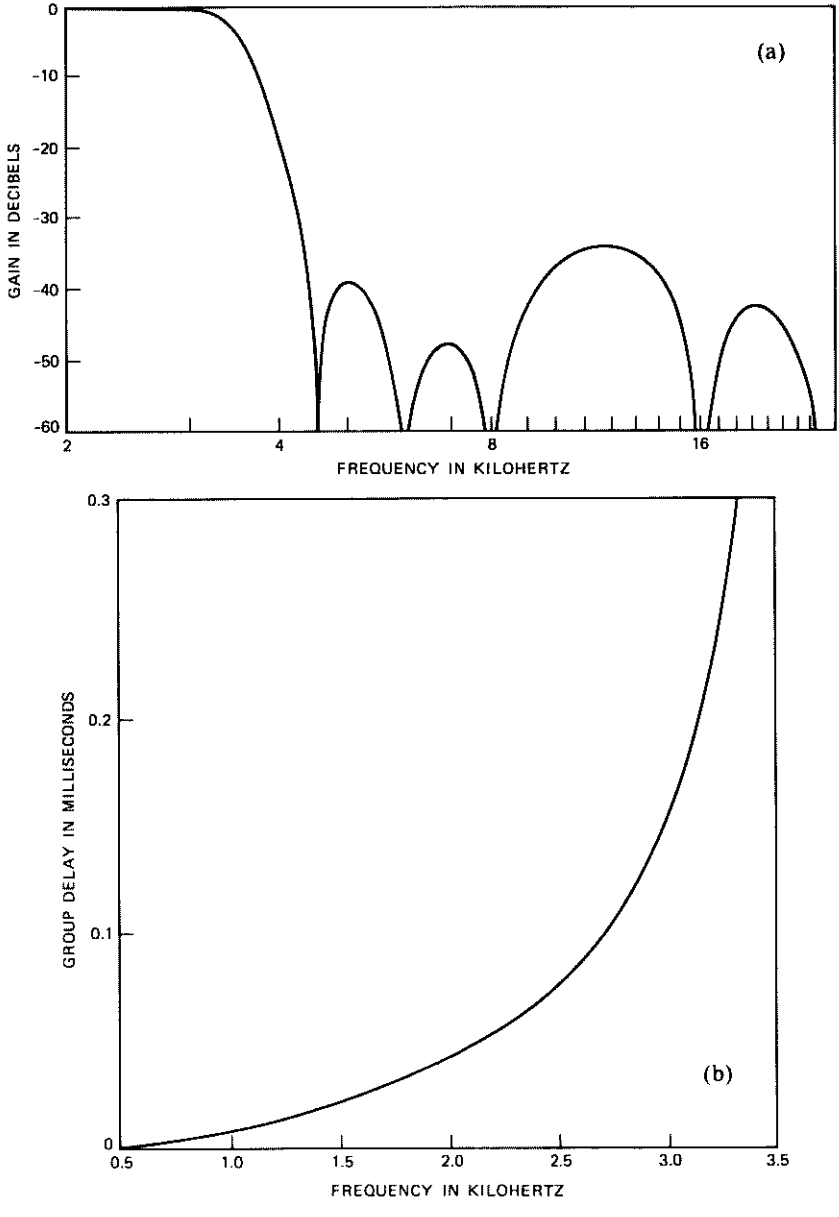

Fig. 3—Spectral response of the resampler. (a) The calculated gain of the cascaded filters used in the resampler. (b) The group delay of the filters.

## V. LINEAR INTERPOLATION

Simple linear interpolation of three sample values increases the sampling rate from 32 to 128 kHz. This process has frequency responses that can be expressed as

$$I(\omega) = \left(\frac{\text{sinc } (f/32)}{\text{sinc } (f/128)}\right)^2. \tag{6}$$

Its attenuation of spectral images in the range 28 to 36, 60 to 68, and 92 to 100 kHz exceeds 40 dB. The small amount of droop introduced into baseband is compensated in the low-pass filter so that the entire circuit has inband gain in the range −0.41 to −0.57 dB. The circuit implementation shown as Fig. 4 is based on the results

$$y(n\tau) = y[(n-1)\tau] + \tfrac{1}{4}\,\Delta x(n\tau)$$

$$\Delta x(n\tau) = x(4n\tau) - x[4(n-1)\tau]$$

and

$$y(4n\tau) = x(4n\tau). \tag{7}$$

After each new input sample enters register $R_1$, the output, held in register $R_2$, increments four times to make its value equal to the input.

## VI. RESAMPLING

Figure 5 shows the circuit that is used to resample the signal at the desired output rate without causing conflict with the internal clock. Here the output from the linear interpolator is loaded into register $R_3$ in time with the internal clock running at 1 MHz. This loading is inhibited by the presence of the output clock, which after a short delay loads $R_4$ from $R_3$. The frequency response associated with the holding action of this circuit may be expressed as

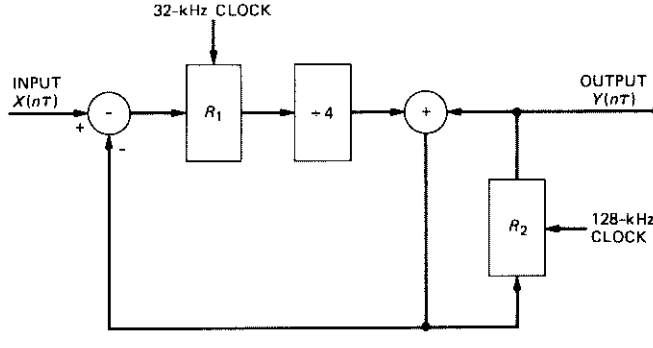

Fig. 4—An outline of the linear interpolator used to raise the sampling rate from 32 to 128 kHz.

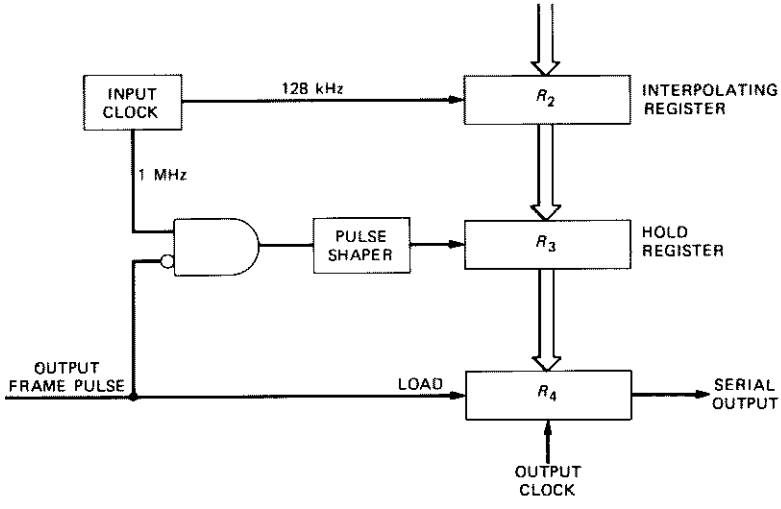

Fig. 5—The circuit used to sample the output. Register $R_2$ is part of the linear interpolator, $R_3$ is loaded from $R_2$ at 1 MHz. An output demand inhibits loading of $R_3$, and then loads $R_4$ from $R_3$.

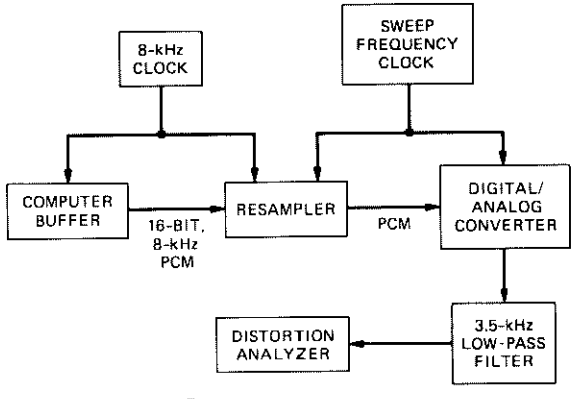

Fig. 6—The test circuit.

$$R(\omega) = \text{sinc}\,(f/128).$$

Images of the signal in the range 124 to 132 kHz are thereby attenuated by more than 30 dB.

## VII. TESTING THE CIRCUIT

A version of the circuit was built of standard digital circuit components and tested in the setup shown in Fig. 6. The net gain of the circuit and its signal-to-noise ratio were measured as the sampling rate was varied continuously from 0 to 256 kHz. For a 1.02-kHz input signal

sampled at 8 kHz, the gain remained constant within ±.05 dB and the signal-to-noise ratio always exceeded 40 dB. Input amplitudes were varied in the range 0 to −60 dB. At lower amplitudes quantization noise inherent in the 16-bit input word was significant.

## VIII. CONCLUDING REMARKS

Experience obtained while designing filters for a version of a codec enables us to estimate that the circuits described here can be implemented on about 5 $mm^2$ of silicon in a standard technology. The performance of the circuit is good enough that imperfections introduced by resampling would be insignificant compared with those normally obtained from $\mu$-255 encoding of the signal.

## IX. ACKNOWLEDGMENT

We thank H. S. McDonald for suggesting this use for our circuits, and J. L. Henry for providing information on the integrated circuit implementation.

## CONTRIBUTORS TO THIS ISSUE

**John Andrews,** B.S., 1958, Houghton College; Ph.D. (Solid State Physics), 1963, Massachusetts Institute of Technology; Research Associate, Massachusetts Institute of Technology, 1963–1966; Bell Laboratories, 1966—. The subject of Mr. Andrews' doctoral thesis was ultrasonic attenuation in superconductors at radio and microwave frequencies. After coming to Bell Laboratories, he worked on laser mixing in nonlinear optical crystals. Next, he investigated ohmic and rectifying metal-semiconductor contacts formed by metallurgical reaction between transition metals and silicon. From 1970 to 1976 he worked with Western Electric engineers at Allentown on silicon integrated circuit manufacture. Since 1976 he has been associated with the Advanced LSI Development Laboratory at Murray Hill, investigating new materials and special processes for fine-line VLSI technology. Senior Member, IEEE; member APS, ECS, and TMS-AIME; associate editor, *Materials Letters.*

**O'Connell J. Benjamin,** B.S.E.E., 1976, Polytechnic Institute of Brooklyn; graduate studies, 1977–1982, Polytechnic Institute of New York; Bell Laboratories, 1973—. Mr. Benjamin has been involved with research in digital MF receivers, voiceband codecs, and, presently, he is working on computer communications.

**G. Samuel Brockway,** B.S.C.E., 1966, University of Miami; M.S.E.M., 1968, Georgia Institute of Technology; Ph.D. (Applied Mechanics), 1972, California Institute of Technology; Bell Laboratories, 1976–1981. Mr. Brockway has worked extensively in such areas of mechanics as elasticity, viscoelasticity, and fracture mechanics, and in the development of plastics for use in fiber optics. He is presently president of Plastics Engineering Consultants.

**James C. Candy,** B.Sc. and Ph.D. (Engineering), University of Wales, Bangor, in 1951 and 1954, respectively; Bell Laboratories, 1961—. From 1954 to 1956 Mr. Candy was with S. Smith and Sons, Guided Weapons Department, Cheltenham, and for the next four years he worked on nuclear instrumentation at the Atomic Energy Research Establishment, Harwell. In 1959 Mr. Candy went to the United States to take up an appointment as a Research Associate at the University of Minnesota, and a year later he joined Bell Laboratories, Holmdel, NJ, where he has investigated digital circuits and the efficient transmission of video signals. He is now concerned with techniques for converting signals between analog and digital formats.

**Stephen E. Levinson,** B.A. (Engineering Sciences), 1966, Harvard; M.S. and Ph.D. (Electrical Engineering), University of Rhode Island, Kingston, Rhode Island, 1972 and 1974, respectively; General Dynamics, 1966–1969; Yale University, 1974–1976; Bell Laboratories, 1976—. From 1966 to 1969, Mr. Levinson was a design engineer at Electric Boat Division of General Dynamics in Groton, Connecticut. From 1974 to 1976, he held a J. Willard Gibbs Instructorship in Computer Science at Yale University. In 1976, he joined the technical staff at Bell Laboratories, where he is pursuing research in the areas of speech recognition and cybernetics. Member, Association for Computing Machinery, Acoustical Society of America, editorial board of Speech Technology; associate editor, IEEE Transactions on Acoustics, Speech and Signal Processing.

**Lawrence R. Rabiner,** S.B. and S.M., 1964, Ph.D. (Electrical Engineering), The Massachusetts Institute of Technology: Bell Laboratories, 1962—. From 1962 through 1964, Mr. Rabiner participated in the cooperative plan in electrical engineering at Bell Laboratories. He worked on digital circuitry, military communications problems, and problems in binaural hearing. Presently, he is engaged in research on speech communications and digital signal processing techniques. He is coauthor of *Theory and Application of Digital Signal Processing* (Prentice-Hall, 1975) and *Digital Processing of Speech Signals* (Prentice-Hall, 1978). Former President, IEEE, ASSP Society; former Associate Editor, ASSP Transactions; former member, Technical Committee on Speech Communication of the Acoustical Society, ASSP Technical Committee on Speech Communication; Member, IEEE Proceedings Editorial Board, Eta Kappa Nu, Sigma Xi, Tau Beta Pi. Fellow, Acoustical Society of America, IEEE.

**Adel A. M. Saleh,** B.Sc. (Electrical Engineering), 1963, University of Alexandria, Alexandria, Egypt; M.S. and Ph.D. (Electrical Engineering) Massachusetts Institute of Technology, Cambridge, MA, 1967 and 1970, respectively; Bell Laboratories, 1970—. From 1963 to 1965 Mr. Saleh worked as an instructor at the University of Alexandria. At Bell Laboratories he is engaged in research on microwave circuits, components, and communication systems. Senior Member, IEEE; member, Sigma Xi.

**Jack Salz,** B.S.E.E., 1955, M.S.E., 1956, and Ph.D., 1961, University of Florida; Bell Laboratories, 1961—. Mr. Salz first worked on remote line concentrators for the electronic switching system. Since 1968 he has supervised a group engaged in theoretical studies in data commu-

nications and is currently a member of the Communications Methods Research Department. During the academic year 1967–68, he was on leave as Professor of Electrical Engineering at the University of Florida. In Spring 1981, he was a visiting lecturer at Stanford University. Member, Sigma Xi.

**Manuel R. Santana,** B.Sc. (Electrical Engineering), 1970, University of Hartford; M.S., (Electrical Engineering), 1971, Georgia Institute of Technology; Bell Laboratories, 1970—. Mr. Santana has worked on the development of multipair cable and in the design, analysis, and testing of lightguide cable. He is presently Supervisor of the Lightguide Cable Group. Member, IEEE, Kappa Mu.

**Man Mohan Sondhi,** B.Sc. (Physics), Honours degree, 1950, Delhi University, Delhi, India, D.I.I.Sc. (Communications Engineering), 1953, Indian Institute of Science, Bangalore, India; M.S., 1955; Ph.D. (Electrical Engineering), 1957, University of Wisconsin, Madison, Wisconsin; Bell Laboratories, 1962—. Before joining Bell Laboratories, Mr. Sondhi worked for a year at the Central Electronics Engineering Research Institute, Pilani, India and taught for a year at the University of Toronto. At Bell Laboratories his research has included work on speech signal processing, echo cancellation, adaptive filtering, modelling of auditory and visual processes, and acoustical inverse problems. From 1971 to 1972 Mr. Sondhi was a guest scientist at the Royal Institute of Technology, Stockholm, Sweden.

# A Long-Wavelength Optical Receiver Using a Short-Channel Si-MOSFET

By K. OGAWA, B. OWEN, and H. J. BOLL

(Manuscript received April 21, 1982)

*Recent improvements in fine-line technology have resulted in silicon metal oxide semiconductor field-effect transistors (MOSFETs) with channel lengths between 0.2 and 0.8 μm. We have measured the low-frequency noise in these transistors and find it to be smaller than that in comparable GaAs-metal Schottky valve field-effect transistors (MESFETs). Theoretical considerations on the FET noise and experimental results at 45 Mb/s indicate that Si-MOSFETs can compete with GaAs-MESFETs in hybrid photoamplifier circuits. As a natural extension, Si-MOSFETs can also be used for the complete monolithic integration of the receiver circuit with the benefits of reliability and improved performance.*

## I. INTRODUCTION

In the absence of high-performance avalanche photodiodes for long-wavelength optical receivers, p-i-n photodiodes with low-noise amplifiers have been used.[1] The amplifiers are designed with ultra-low-noise components to realize high receiver sensitivities. Up until now, GaAs-metal Schottky valve field-effect transistors (MESFETs) were used exclusively as low-noise components at bit rates less than 300 Mb/s.[2,3] We have fabricated a short-channel Si-metal oxide semiconductor field-effect transistor (MOSFET)[4] and used this MOSFET in a hybrid integrated receiver circuit at 45 Mb/s. The receiver's performance is similar to that of a receiver employing a GaAs-MESFET. The use of

Si-MOSFETs creates the opportunity for monolithic integration of the entire front-end amplifier, with the ensuing benefits of circuit reliability and stability.

In the past, Si-FETS were ignored for this application because they were believed to have a lower transconductance than GaAs-FETs of comparable dimensions. This was due to the difference in mobility between the two materials. Recent improvements in fine-line technology have resulted in silicon MOSFETs with short channels from 0.2 to 0.8 $\mu$m. Also, we find that a short-channel Si-FET operating in the saturation region of the electron drift velocity has a transconductance comparable to that of the best GaAs-FET.[5,6] GaAs-FETS exhibit additional noise because of electron scattering in the high electric field of the channel. Since this effect is generally absent in Si-FETs,[7,8] the receiver sensitivity obtained using a Si-MOSFET is now expected to be comparable to or slightly better than that obtained using a GaAs-MESFET.

## II. SILICON SHORT-GATE MOSFET

Table I lists the characteristics of a Si-NMOSFET with a channel length between 0.5 and 0.8 $\mu$m, and for comparison shows the typical characteristics of a GaAs-MESFET with a channel length between 0.5 and 1.0 $\mu$m. The figure of merit, $g_m/C$ of a Si-N-channel metal oxide semiconductor field-effect transistor (NMOSFET) is smaller than that of a GaAs-MESFET when structures with the same dimensions are compared.[6] However, the noise factor, $\Gamma$, of a Si-NMOSFET is smaller than that of the GaAs FET if induced gate noise and its correlation with channel noise are considered.[5,7-9] The mean square of the equivalent input noise current of an FET is given by

$$i_n^2 = 4k\Gamma \frac{\omega^2 (C_{gs} + C_{in})^2}{g_m} \Delta f$$

$$\Gamma = P + \left| \frac{C_{gs}}{C_{in} + C_{gs}} \right|^2 R - 2Q \left| \frac{C_{gs}}{C_{in} + C_{gs}} \right|,$$

where $\Gamma$ is the noise factor, $g_m$ the transconductance, $C_{gs}$ the gate-source capacitance, and $C_{in}$ the input capacitance consisting of the

Table I—Typical Si-NMOSFET characteristics

| | Gate-Source Capacitance (pF) | Transconductance (mS) | Figure of Merit, $g_m/C_{gs}$ (mS/pF) |
|---|---|---|---|
| Si-NMOS | 0.5 to 0.8 | 40 to 50 | 60 to 70 |
| GaAs-MESFET (0.5 to 1.0 $\mu$m) | 0.2 to 0.5 | 25 to 50 | 60 to 140 |

Table II—Noise factor Γ, $P$, $Q$, $R$ for Si-NMOSFET

| | |
|---|---|
| $P$ | 0.763 |
| $Q$ | −0.206 |
| $R$ | 0.245 |
| Typical Γ $C_{gs} = 0.5_{pF} C_{in} = 0.5_{pF}$ | 1.03 |

photodiode capacitance and any parasitic capacitance. $P$ is the noise factor for the channel noise, $R$ is the noise factor for the induced gate noise, and $Q$ is the correlation factor. Table II indicates the values of Γ, $P$, $Q$, and $R$ for a Si-FET with a 0.5-$\mu$m channel length. The noise factor, Γ, for the Si-FET (1.03) is much smaller than the value for a typical GaAs-FET (1.78).

Low-frequency $1/f$ noise in FETs has an important effect on the performance of an optical receiver at low bit rates. We have measured the low-frequency noise of both a Si-NMOSFET and a GaAs FET. The results are shown in Fig. 1. Whereas the low-frequency noise for the GaAs FET does indeed have a $1/f$ dependence, the results show a $f^{-1/2}$ dependence for the Si-NMOSFET. This result has not yet been explained.

The noise measured in Fig. 1 was normalized to the expected channel noise $4kT\Gamma\Delta f/g_m$. The FET transconductance, $g_m$, was 48 mS; the filter bandwidth, $\Delta f$, was 3.1 kHz; and the noise factor, Γ, was 1.03 for

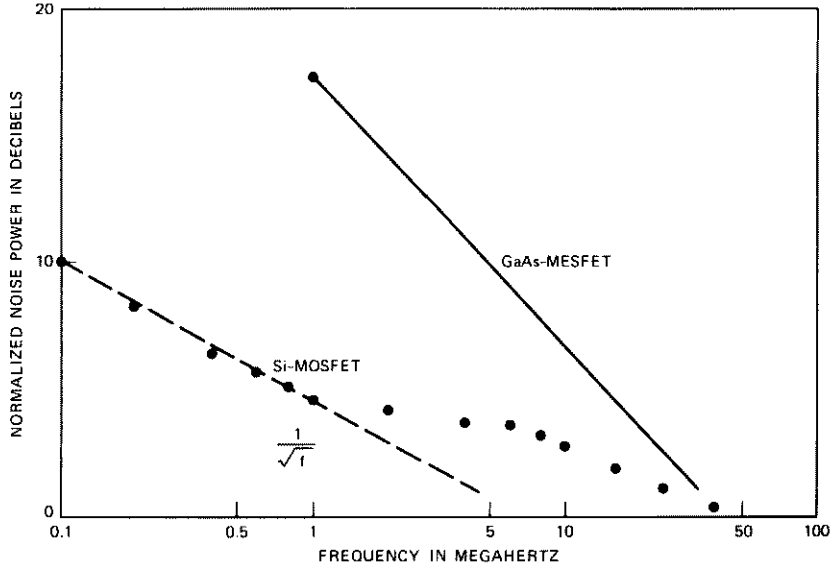

Fig. 1—Low-frequency characteristics of Si-NMOSFET. The dotted points show results measured with a 3.1-kHz filter. The best fit showed by the dashed line has a $f^{-1/2}$ slope. The $1/f$ noise of the GaAs-MESFET is shown (solid line) for comparison.

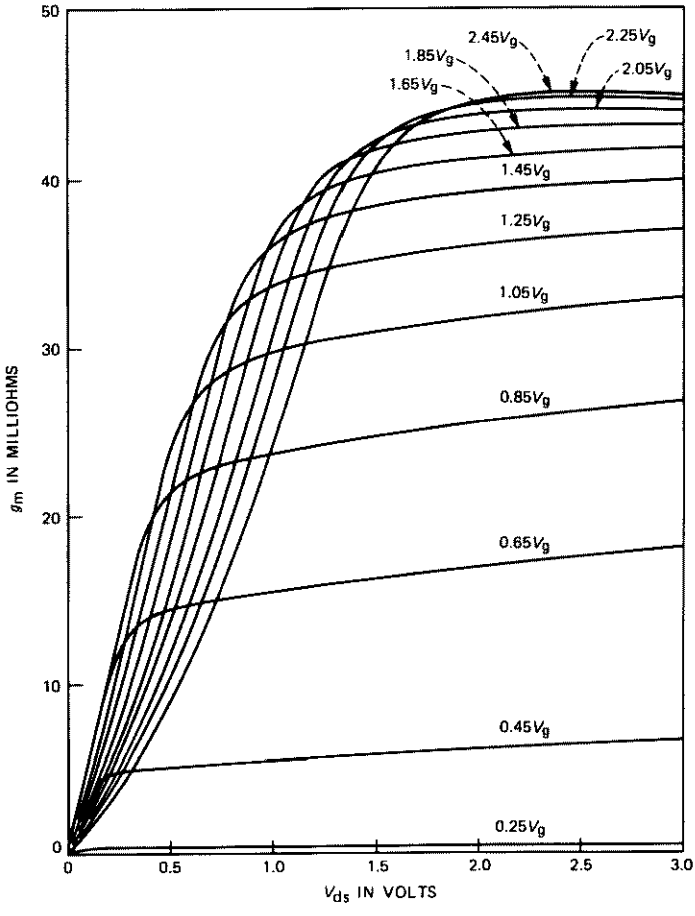

Fig. 2—Transconductance of Si-NMOSFET. Parameters are the gate-source voltage.

the Si-NMOSFET and 1.78 for the GaAs FET. In the Si-NMOSFET, the channel noise exceeded the $4kTT\Delta f/g_m$ value. The excess noise is believed to be thermal noise associated with the large series resistance of the polysilicon gate. This series gate resistance can be reduced by improved fabrication techniques, such as metallizing the gate. From Fig. 1, the noise corner frequency, $f_c$, for the Si-NMOSFET is $\approx$5 MHz. The noise corner frequency for the GaAs FET is $\approx$30 MHz. Therefore, even with the excess noise from the gate resistance, the low-frequency noise contribution of the Si-NMOSFET is clearly smaller than that of the GaAs FET.

Another FET parameter that affects its performance in an optical receiver is gate leakage current. The gate leakage current contributes shot noise at the receiver front end. Again, the Si-NMOSFET is

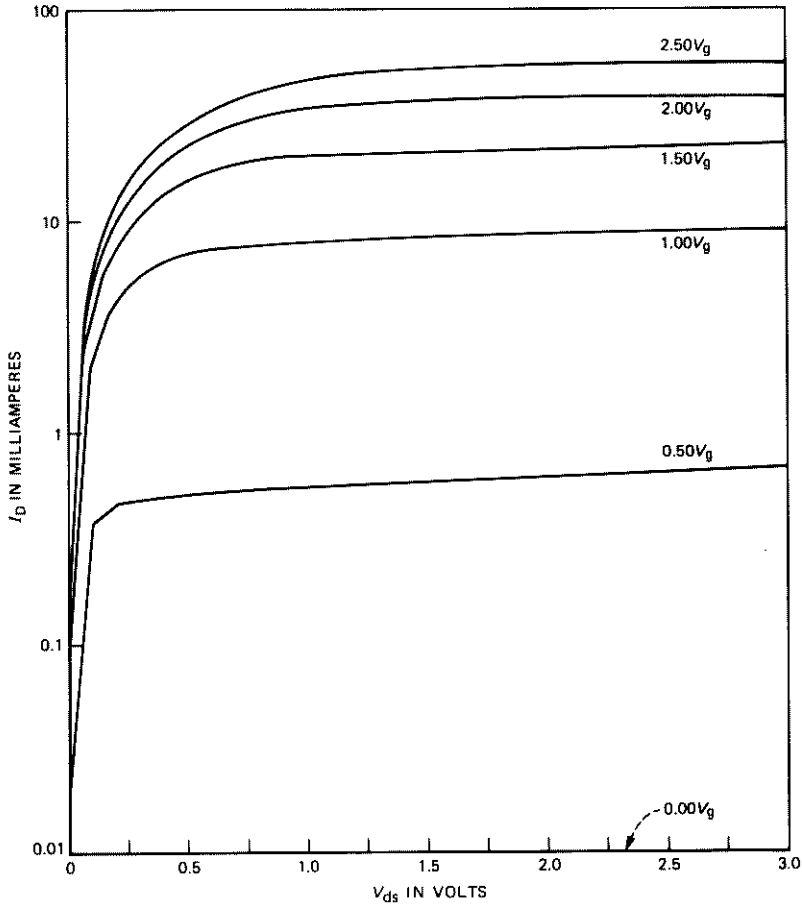

Fig. 3—I-V characteristics of Si-NMOSFET. The parameters are the gate-source voltage.

superior to the GaAs FET. The measured gate leakage current of the GaAs FET is ≈5 nA. The measured gate leakage current of the Si-NMOSFET is ≈10 pA.

Based on these measurements, we have calculated the sensitivity of a 45-Mb/s optical receiver using both a Si-NMOSFET and a GaAs FET. The receiver sensitivity is given by

$$\eta \bar{P} = \left| \frac{h\nu Q}{q} \right| \langle i^2 \rangle_T^{1/2},$$

where the prefactor $(h\nu Q/q)$ is 4.950 W/A at 1.3 μm and at $10^{-7}$ bit error rate; and where the equivalent input noise current, $\langle i^2 \rangle_T$, is given by

$$\langle i^2 \rangle_T = 2qI_L I_2 B$$ Shot noise from the gate leakage current, $I_L$.

$$+ 2qI_D I_2 B$$ Shot noise from the photodiode dark current, $I_D$.

$$+ \frac{4kT}{R_F} I_2 B$$ Thermal noise from the bias resistor, $R_F$.

$$+ \frac{16\pi^2 kTT(C_T^2) I_3 B^3}{g_m}$$ Channel noise in the FET.

$$+ \frac{16\pi^2 kTT(C_T)^2 f_c I_f B^2}{g_m}$$ $1/f$ noise in the FET.

$$+ \langle i^2 \rangle_c$$ Postamplifier noise,

where $B$ is the bit rate, and $I_2$, $I_3$, etc. are Personick integrals associated with the circuit noise. Assuming $R_F$ to be 500 kΩ, and the p-i-n photodiode dark current, $I_D$, at 30 nA, the sensitivity of a 45 Mb/s receiver at $10^{-7}$ bit error rate is −51.3 dBm for a GaAs FET front-end amplifier and −51.8 dBm for a Si-NMOSFET front-end amplifier.

## III. EXPERIMENTS

The Si-NMOSFET used for our experiments was fabricated on a $p$-type substrate (carrier concentration $\approx 2 \times 10^{15}/\text{cm}^3$) with an implanted

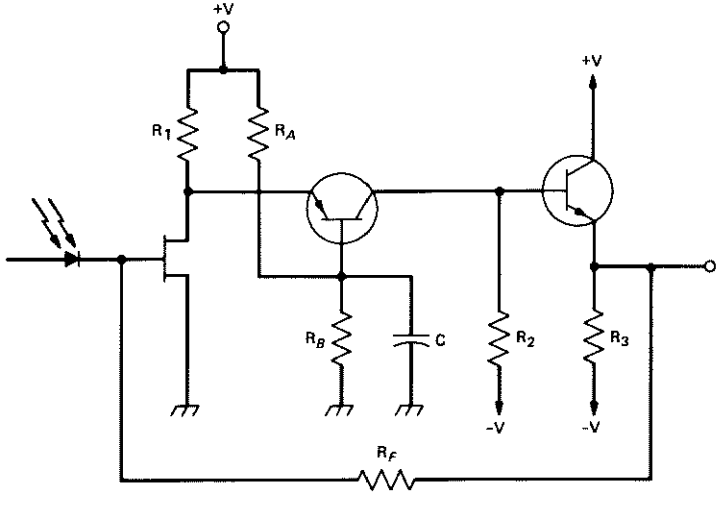

Fig. 4—Front-end amplifier circuit diagram with three active components involved. The first stage with the Si-NMOSFET provides a high input impedance. The second stage p-n-p transistor cascode circuit provides a gain stage and reduces the Miller effect. The last stage is an emitter follower for low output impedance.

$n$-layer (carrier concentration $\approx 5 \times 10^{16}/cm^3$), which had a thickness between 0.5 and 0.6 $\mu$m.[4] The channel width was 500 $\mu$m, and the effective channel length was 0.45 $\mu$m.[5] The gate-source capacitance was 0.5 pF and the transconductance was 45 mS. The gate leakage current was $\approx$10 pA. Figures 2 and 3 show the drain current and transconductance of the Si-NMOSFET versus drain source voltage with different gate voltages.

We have fabricated a transimpedance front-end circuit[3] using an InGaAs p-i-n photodiode with the Si-NMOSFET as the first amplifier stage. The circuit is shown in Fig. 4. The primary gain was achieved in the second stage, which used a p-n-p transistor. The third stage was an emitter-follower circuit using an n-p-n transistor. The feedback

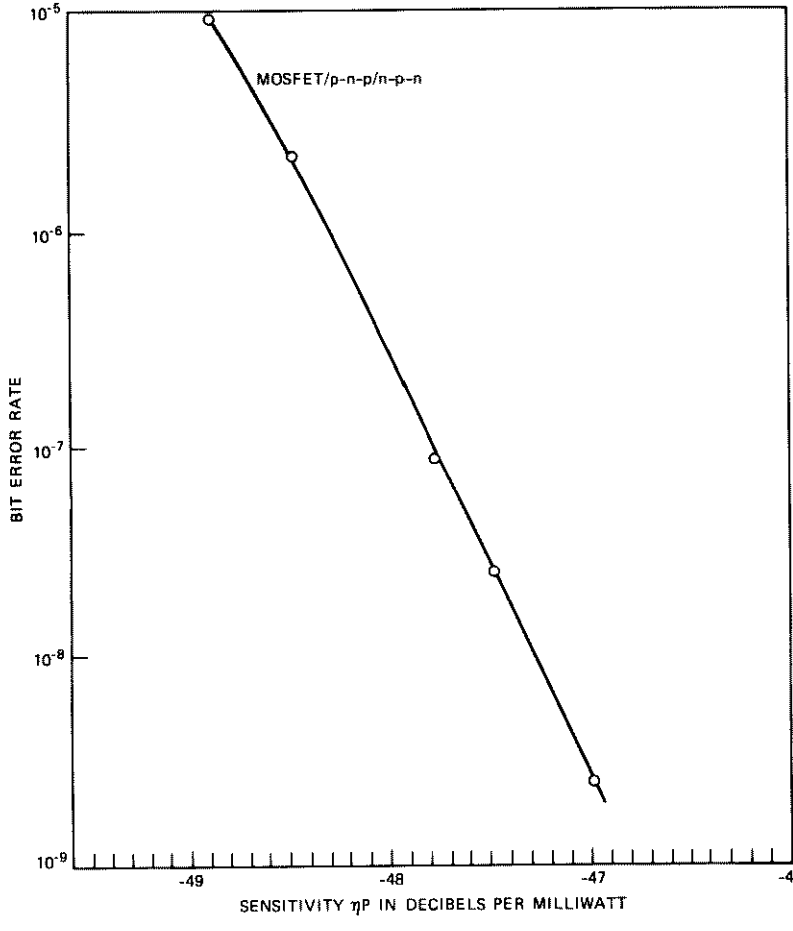

Fig. 5—Error-rate measurement of an InGaAs p-i-n-Si-NMOSFET receiver at 45 Mb/s.

circuit was 500 kΩ. The bit error rate was measured using a 44.7 Mb/s pseudorandom nonreturn to zero (NRZ) optical signal from an InGaAsP LED emitting at 1.3 μm. The receiver circuit was combined with a regenerator circuit and a retiming circuit designed for optical receivers. As shown in Fig. 5, the measured sensitivity at $10^{-7}$ bit error rate was −47.8 dBm (−51.8 dBm theoretical). With a GaAs FET first-amplifier stage, the same receiver circuit had a measured sensitivity of −49.5 dBm (−51.3 dBm theoretical).

## IV. CONCLUSION

Further work is in progress to improve the Si-NMOSFET receiver performance and to integrate the front-end amplifier. The circuit, especially the second stage, is not presently optimized. Also, the Si-NMOSFET has a high series gate resistance because the gate was fabricated with polysilicon. The noise penalty associated with this resistance can be eliminated by metallizing the gate.

In conclusion, theoretical considerations and our first experiments indicate that Si-NMOSFETs can have sensitivity performance comparable to that of GaAs FETs in a 45-Mb/s optical receiver. The natural extension of this result is the complete monolithic integration of the entire receiver circuit using silicon fine-line MOS technology.

# Modal Analysis of Loss and Mode Mixing in Multimode Parabolic Index Splices

By I. A. WHITE and S. C. METTLER

(Manuscript received November 18, 1982)

*In this paper we present an electromagnetic modal theory for characterizing parabolic-index multimode fiber splices with either intrinsic or extrinsic mismatches. The theory agrees with previously published theoretical results for transverse offset using a uniform power distribution. It also agrees with new experimental measurements made with a long, spliced input fiber using a published, theoretical, steady-state modal power distribution. This modal theory predicts, and experiment confirms, a previously unreported periodic fluctuation in splice loss as a function of wavelength for intrinsic parameter mismatch. The analysis also predicts a large degree of mode mixing for transverse offset but negligible mode mixing for parameter mismatch in typical multimode fiber splices.*

## I. INTRODUCTION

Theoretical predictions of splice loss in multimode fibers have been attempted by many researchers (see Ref. 1 for a list). However, these analyses[1–3] do not adequately predict measured splice loss results, and most do not address mode mixing effects, which are important for the prediction of the bandwidth of concatenated lengths of fiber. The best agreement with splice loss measurement data is an empirical model based on geometric optics.[2] However, such an analysis of splice loss provides only a limited description of the effect of splices. Electromagnetic theory, using the coupling coefficients of individual modes, provides a complete treatment of splice loss and mode mixing. The only published electromagnetic theory[3] appears to be in error, since predictions do not approach the well-known correct geometric optics limit for splice loss of fibers with a large normalized frequency, $V$, and a uniform modal power distribution. This paper presents an electromagnetic analysis for splices, which gives single-term expressions for mode

coupling coefficients for the case of either transverse offset or profile parameter mismatch for parabolic-index multimode fibers. These coupling coefficients are used to calculate loss and degree of mode mixing in splices. The results approach the proper geometric optics limit for a uniform modal power distribution. Furthermore, if we compare theoretical and experimental loss to transverse offset results, we can verify a published theoretical "steady-state" power distribution[4] in multimode parabolic-index fibers. Comparing the results of this theory with a measurement of splice loss as a function of transverse offset gives the modal power distribution in a fiber. A wavelength dependence of splice loss for intrinsic parameter mismatch is predicted by this theory and has been experimentally verified. Because splices change the modal power distribution, the power redistribution can cause additional loss as the system evolves towards the steady state in the receiving fiber. In the past[2] this loss has been considered part of the total splice loss, but the improvement of fiber quality has reduced this effect significantly for typical lengths between splices. Because we have ignored the power redistribution effects (after the splice), these theoretical results are only strictly valid for short lengths of fiber after the splice; however, they should remain valid for typical distances between splices.

## II. THEORY

The modal amplitude coupling coefficient, $C[m_1\alpha_1; m_2\alpha_2]$, for mode $m_1\alpha_1$ of the transmitting fiber and mode $m_2\alpha_2$ of the receiving fiber is obtained directly from the theory of excitation of weakly guiding fibers.[5] (The variable $m$ is the radial mode number and $\alpha$ is the azimuthal mode number.)

$$C[m_1\alpha_1; m_2\alpha_2] = \frac{1}{2}\left(\frac{\epsilon_{co}}{\mu}\right)^{1/2} \int \bar{E}_{m_1\alpha_1} \cdot \bar{E}^*_{m_2\alpha_2} dA, \tag{1}$$

where for parabolic-index fibers (using the infinite profile approximation) the electromagnetic modal field, $E_{m_1\alpha_1}$, propagating in the $z$ direction in the fiber core is:

$$\bar{E}_{m_1\alpha_1} = \begin{pmatrix} \hat{x} \\ \hat{y} \end{pmatrix} A_{m_1\alpha_1} t^{\frac{|\alpha_1|}{2}} L_{m_1}^{|\alpha_1|}(t) e^{-\frac{t}{2}} e^{-i(\alpha_1\phi+\beta z)}, \tag{2}$$

where $\hat{x}$ and $\hat{y}$ are the linearly polarized unit field vectors of the mode. $\epsilon_{co}$ and $\mu$ are the permittivity and permeability of the core, respectively, and $\epsilon_{co} = n_{co}^2\epsilon$. Then

$$A_{m_1\alpha_1} = \left[\left(\frac{\mu}{\epsilon_{co}}\right)^{1/2} \frac{V}{\pi a^2} \frac{m_1!}{(m_1 + |\alpha_1|)!}\right]^{1/2}, \tag{3}$$

and

$$\left.\begin{aligned} t &= V\left(\frac{r}{a}\right)^2 \\ \beta^2 &= \left(\frac{2\pi}{\lambda} n_{co}\right)^2 - 2N\frac{V}{a^2} \\ V &= \frac{2\pi}{\lambda} n_{co} a\sqrt{2\Delta}, \end{aligned}\right\} \tag{4}$$

where the principal mode number is $N(= 2m + \alpha + 1)$, and $L_m^{\alpha}(t)$ is an associated Laguerre polynomial. The variable $a$ is the fiber core radius and $\Delta = (n_{co} - n_{cl})/n_{co}$ is the normalized maximum refractive index difference. For weakly guiding fibers the polarization property of the incoming mode is preserved by the splice, as can be seen from eq. (1).

In general we can write:

$$C(m_1\alpha_1; m_2\alpha_2) = K \cdot I(m_1\alpha_1; m_2\alpha_2), \tag{5}$$

where

$$K = \left[\frac{m_1!m_2!}{(m_1 + |\alpha_1|)!(m_2 + |\alpha_2|)!}\right]^{1/2}. \tag{6}$$

$I(m_1\alpha_1; m_2\alpha_2)$ is a function that depends on the type of splice mismatch. Table I shows the expressions for $I(m_1\alpha_1; m_2\alpha_2)$ for the two cases of intrinsic parameter ($V$) mismatch and transverse offset between identical fibers ($r_o$). The derivation of these equations is given in the appendix.

For the parameter mismatch case, the coupling coefficients are a function of the ratio of the normalized frequencies of the two fibers. The hypergeometric function, ${}_2F_1$, is, in this case, a power series in $y^2$ of order $m_1$. Note that because azimuthal symmetry is preserved in the splice, only modes with the same azimuthal mode number couple. In the identical fiber transverse offset case, the coupling coefficients are simple products of Laguerre-Gaussian polynomials with argument proportional to the normalized offset ($r_o/a$). In this case all azimuthal modes have finite coupling coefficients, but, for small offsets, coupling is much stronger for nearest neighbor azimuthal modes.

Assuming a random phase relationship between the modes of the transmitting fiber, the total power coupled into mode $m_2\alpha_2$, $P_{m_2\alpha_2}$, is:

$$P_{m_2\alpha_2} = \sum_{m_1,\alpha_1}^{T} |C(m_1\alpha_1; m_2\alpha_2)|^2 P_{m_1\alpha_1}, \tag{7}$$

and the total splice loss, $\delta_s$, is then:

$$\delta_s = -10 \log \left( \frac{\sum_{m_2,\alpha_2}^{R} P_{m_2\alpha_2}}{\sum_{m_1,\alpha_1}^{T} P_{m_1\alpha_1}} \right) \tag{8}$$

The mode mixing factor, $\Gamma$ (i.e., the fraction of the power that is redistributed into different modes), is:

$$\Gamma = 1 - \frac{\sum_{m_1=m_2,\alpha_1=\alpha_2}^{T} |C(m_1\alpha_1; m_2\alpha_2)|^2 P_{m_1\alpha_1}}{\sum_{m_2,\alpha_2}^{R} P_{m_2\alpha_2}}. \tag{9}$$

The superscripts $R$ and $T$ refer to sums over the bound mode spectra of the receiving and transmitting fibers, respectively.

The range of allowed radial and azimuthal mode numbers, $m$ and $\alpha$, for a fiber with normalized frequency $V$ is:

$$\begin{aligned} m \leqslant m_{\max} &= \mathrm{INT}(V/4) \\ \alpha \leqslant \alpha_{\max} &= \mathrm{INT}(V/2) - 1 \\ N_{\max} &= \mathrm{INT}(V/2), \end{aligned} \tag{10}$$

Table I—Mode coupling functions

| Splice | Parameter of Fiber: Transmitting | Parameter of Fiber: Receiving | $I(m_1\alpha_1; m_2\alpha_2)$ |
|---|---|---|---|
| Parameter Mismatch | | | $= 0$ for $\alpha_1 \neq \alpha_2$ |
| | $a_T$ | $a_R$ | $= \frac{(m_1+m_2+\alpha)!}{m_1!m_2!} \cdot \frac{(1+\epsilon)^{(\alpha+1)/2}}{\left(1+\frac{\epsilon}{2}\right)^{\alpha+1}} \cdot (-1)^{m_1}$ |
| | $\Delta_T$ | $\Delta_R$ | $\cdot y^{-(m_1+m_2)}\, {}_2F_1[-m_2;-m_1;-(m_1+m_2+\alpha);y^2],$ |
| | $V_T$ | $V_R$ | where $y = (2+\epsilon)/\epsilon$ and $\epsilon = \left(\frac{V_R}{\alpha_R^2} \cdot \frac{\alpha_T^2}{V_T}\right) - 1$ |
| Transverse Offset for Identical Fibers | $a$ | $a$ | $= (R_o)^{p/2} e^{-R_o} \cdot \phi(m_1\alpha_1; m_2\alpha_2)$ for $\alpha_1 > 0$, $\alpha_2 < 0$; |
| | $\Delta$ | $\Delta$ | $\phi = L_{m_1}^{\lvert\alpha_2\rvert-\Delta m}(R_o) L_{m_2}^{\lvert\alpha_1\rvert+\Delta m}(R_o)$ for $\alpha_1 > 0$, $\alpha_2 > 0$; |
| | Transverse displacement of the fiber axes $= r_o$ | | $\phi = \frac{(m_2+\alpha_2)!}{m_1!} \cdot (-R_o)^{\Delta m} L_{m_2+\alpha_2}^{p+\Delta m}(R_o) \cdot L_{m_2}^{\Delta m}(R_o),$ where $R_o = \frac{V}{4}\left(\frac{r_o}{a}\right)^2$; $\Delta m = m_1 - m_2$; $p = \lvert\alpha_1 - \alpha_2\rvert$ |

where INT indicates the integer part. It is essential to realize the discrete nature of the bound mode spectra to understand the splice loss predictions for intrinsic parameter ($V$) mismatch. The explicit wavelength dependence of splice loss and mode mixing is demonstrated by the presence of $V$ in the coupling coefficients. However, an implicit wavelength dependence due to the allowed spectrum of bound modes occurs from eq. (10).

## III. RESULTS

Equations (8) and (9) can be used to calculate splice losses and degree of mode mixing for the two cases of parameter mismatch and transverse offset. To validate this analysis, they must be compared with existing theories wherever possible. Most existing results are geometric optics evaluations of splice loss, and the modal power distribution equivalent to any assumed ray distribution is difficult to evaluate in general. However, the ray distribution equivalent to the uniform modal power distribution has been well documented,[6] and comparison of splice loss predictions for this case demonstrates that this analysis is correct. Calculations and experimental results for the effects of different modal power distributions on the mode mixing and loss at a splice are shown in the sections that follow.

### *3.1 Identical fiber transverse offset*

This section presents the results for mode mixing and splice loss associated with transverse offset of the fiber axes for identical fibers.

#### *3.1.1 Splice loss*

Splice loss predictions for transverse offset with a uniform power distribution for several values of the normalized frequency, $V$, are shown in Fig. 1. It is well known that, as $V$ increases, the electromagnetic analysis should asymptotically approach the geometric optics predictions. This is confirmed in Fig. 1. The only other published electromagnetic splice loss theory[3] does not appear to converge to the correct geometric optics limit, e.g., from Fig. 3 of Ref. 3, the splice loss for $0.2a$ offset (for $2a = 50$ $\mu$m) is $\sim$1.0 dB, whereas geometric optics predict a value of 0.8 dB. The small deviation of our results for small offset ($<0.1a$) is believed to be caused by coupling of power to the bound modes of the receiving fiber through the evanescent cladding fields. This effect cannot be predicted using ray optics.

Uniform power distribution results do not agree with realistic splice loss measurements.[2] Figure 2 demonstrates loss versus transverse offset for several power distributions, the Gaussian splice loss model,[2] and experimental data.[8] The experimental data shown were obtained using 0.82-$\mu$m laser excitation of a 7-km input fiber containing about

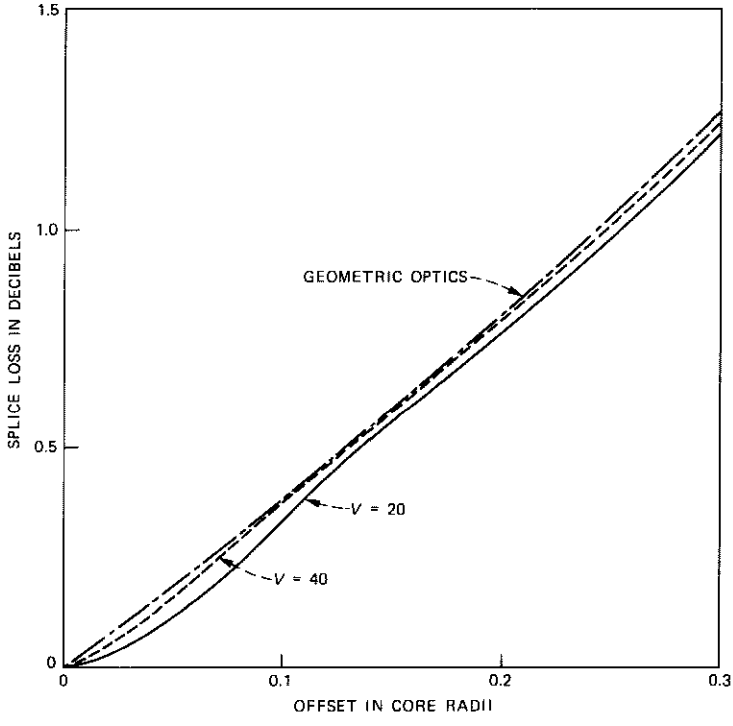

Fig. 1—Splice loss vs. transverse offset with uniform input power.

14 splices into a final splice that was offset in both $x$ and $y$ orthogonal axes. The offset data are in good agreement with previous data and should represent a realistic "steady-state" condition. The theoretical power distribution for steady state due to microbending[4] gives excellent agreement with this data. (A power distribution that has been used to approximate this steady-state distribution is also plotted to show the sensitivity of the loss to the choice of power distribution.) The excellent agreement between the data and this analysis using the steady-state power distribution confirms both the distribution and the splice loss theory. Although this power distribution gives excellent agreement with the data for very long lengths of fiber before the splice, it does not agree as well as the Gaussian model[2] with shorter-length input fiber measurements because the power distribution has not achieved "steady state."

Figure 3 compares experimental data for shorter lengths of input fiber (~1 km) and different excitation conditions[8] with theoretical predictions using both the Gaussian model[2] and various power distributions in this modal analysis. Note that the different excitation conditions significantly affect the splice loss for larger offsets. The

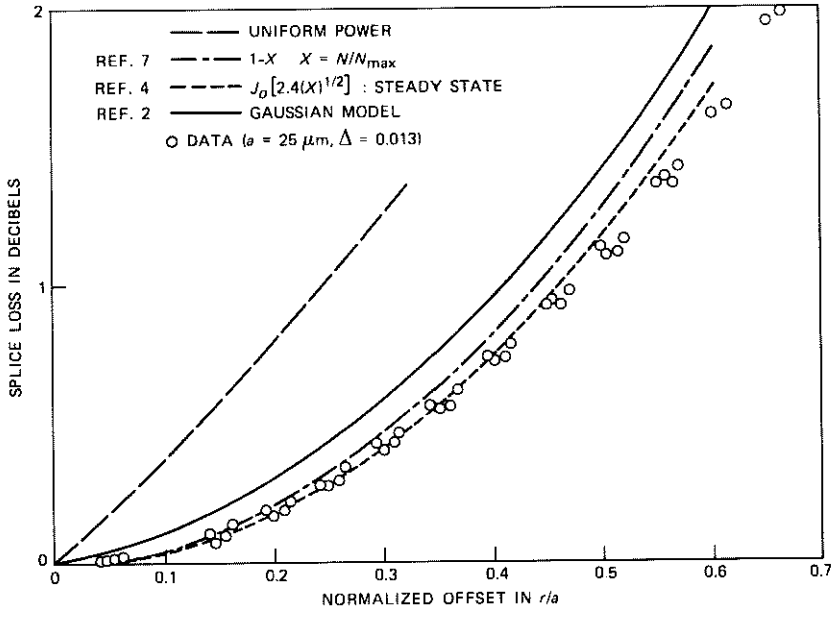

Fig. 2—Loss vs. transverse offset for different modal power distributions.

empirical model of Ref. 2 agrees well with loss measurements for typical offsets expected in practice of 0.1 to 0.2 ($r_o/a$) for both sources and agrees very well over a wider range for the laser source. Modal power distributions for the electromagnetic analysis to describe this situation were empirically chosen so that, for very long fiber lengths, they would degenerate to the steady-state distribution. The simplest choice for a power distribution satisfying this criteria is:

$$P(m_1\alpha_1) = J_o\left[2.405\sqrt{\frac{N}{N_{\max}}}(1 - e^{\eta L})\right]. \tag{11}$$

The choices of $\eta$ shown in Fig. 3 (for $L = 1$ km) demonstrate that excellent agreement between the modal analysis and the splice loss versus transverse offset for the shorter input fiber lengths is possible for both sources. Furthermore, for $\eta = 3$, the results agree with the predictions of the empirical model[2] within 0.03 dB. The theoretically predicted steady-state distribution gives optimistic results for this short length. The existence of a modal power distribution that is in good agreement with the results of Ref. 2 for transverse offset supports the basic assumptions of the empirical model.

### *3.1.2 Mode mixing*

Equation (9) can be used to calculate the amount of power in the

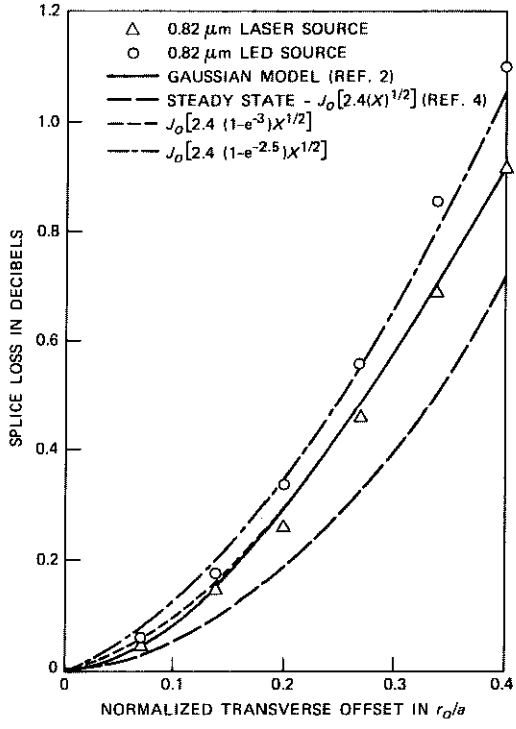

Fig. 3—Splice loss vs. transverse offset for 1-km input fiber.

receiving fiber that has changed propagation mode because of the splice. By changing the summation criteria one can calculate any desired mode mixing factor, such as power coupled within the same principal mode group, nearest neighbor mode groups, etc., where the summation is over all $m_1$, $\alpha_1$ and $m_2$, $\alpha_2$ that differ in principal mode number by $\Delta N$, which is written as:

$$\sum_{2m_2+\alpha_2-2m_1-\alpha_1=\Delta N} \quad \text{for} \quad \Delta N = 0, 1, 2, \cdots . \tag{12}$$

Mode mixing as a function of normalized transverse offset for two different input power distributions is shown in Fig. 4 as the percentage of receiving fiber power that has been redistributed into neighboring mode groups. These differ in principal mode number, $N$, by $\Delta N$ of 0, 1, 2, 3, and 4. ($\Delta N = 0$ represents power coupled within the same degenerate mode group in both transmitting and receiving fibers.) The power distributions used were the uniform and the theoretically predicted power distribution for the steady state for microbending.[4] It is important to note that the percentage of the power-changing propagating mode groups is very high even for small offsets with low splice

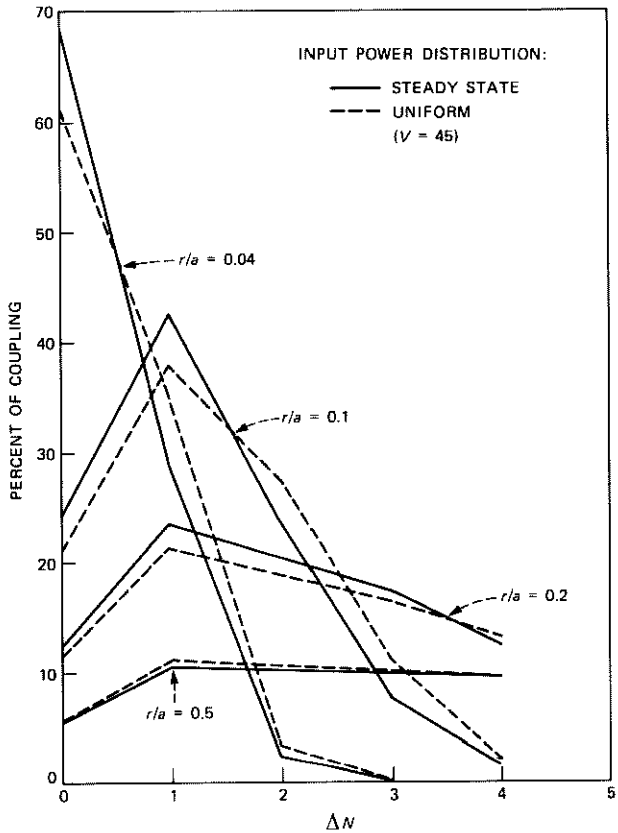

Fig. 4—Power coupling into neighboring mode groups for transverse offset.

loss, i.e., 31 percent for $0.04a$ offset and 0.07 dB splice loss for a $V = 45$ fiber with the steady-state power distribution. Mode mixing is a fairly weak function of the modal power distribution, which indicates that the mode mixing is uniform over all the mode groups as can be seen from the local numerical aperture arguments.[2] As offset increases, the mode mixing changes from being primarily to the nearest neighbor mode groups ($\Delta N = \pm 1$) to being redistributed over a wider range of principal mode groups. The strength of the mode coupling for even small offsets with low splice loss, and the relatively small offsets at which it spreads over many mode groups, are both initially surprising.

### *3.2 Parameter mismatch*

For fibers with no axial offset, the individual mode fields are insensitive to small changes in the $V$ parameter, so that for splices with only slight parameter mismatch, as can be seen in eq. (1), self-coupling

dominates (i.e., mode $m_1\alpha_1$ of the transmitting fiber couples primarily with mode $m_1\alpha_1$ of the receiving fiber). For example, there is less than 3-percent mode mixing for a 5-percent parameter mismatch with uniform modal excitation over the wavelength range of 0.8 to 1.4 $\mu$m. Therefore, splice loss due to parameter mismatch is caused only by this slight field mismatch unless the ranges of the bound mode spectra of the two fibers [eq. (10)] differ, i.e., if the normalized frequencies of the fibers are such that $\Delta N_{\max} \geq 1$. In that case:

$$\Delta N_{\max} = N^T_{\max} - N^R_{\max} \tag{13}$$

or

$$\Delta N_{\max} = \text{INT}\left[\frac{\pi}{\lambda} n_{co}(a_T\sqrt{2\Delta_T})\right] - \text{INT}\left[\frac{\pi}{\lambda} n_{co}(a_r\sqrt{2\Delta_R})\right]. \tag{14}$$

When $\Delta N_{\max}$ is zero, the splice loss is small, as discussed above. However, when $\Delta N_{\max} > 0$, the modes in the highest-order mode group of the transmitting fiber are not bound modes in the receiving fiber. Because self-coupling dominates, most of the power in the highest-order modes couples to leaky/radiation modes in the receiving fiber and is therefore lost. The large degeneracy of the higher-order mode groups [eq. (4)] accentuates this loss. From this discussion we see that parameter mismatch splice loss is caused primarily by the difference between the bound mode volumes of the two fibers, which is a function of the normalized frequencies, $V$. Therefore, both $\Delta$ and radius mismatches can be expressed simply as $V$ mismatch. (An $x$-percent radius mismatch is equivalent to a $2x$-percent $\Delta$ mismatch for small degrees of mismatch.)

Theoretical predictions of splice loss versus normalized parameter mismatch ($\Delta V/V$) for uniform and steay-state input power distributions at 0.82 and 1.3 $\mu$m are shown in Fig. 5. The discontinuities of the splice loss curves are caused by the discreteness of the bound mode spectra, as can be seen from the definition of $\Delta N_{\max}$ in eq. (14). In Fig. 5a this discreteness is most obvious due to the choice of a uniform input power distribution, which accentuates the power in the highest-order mode group. Note that at the longer wavelength the loss is initially higher for a given parameter mismatch because the percentage of the total power that is in the highest-order mode groups is greater than at shorter wavelengths. Each discontinuous increase of splice loss is caused by the stripping of an additional high-order mode group of the input fiber, which does not propagate in the receiving fiber as $\Delta V/V$ increases. The splice loss predicted by geometric optics (which ignores the discreteness of the mode spectra) is also shown.[1] The results for the steady-state power distribution used previously are shown in Fig. 5b displaying similar discontinuous features. However,

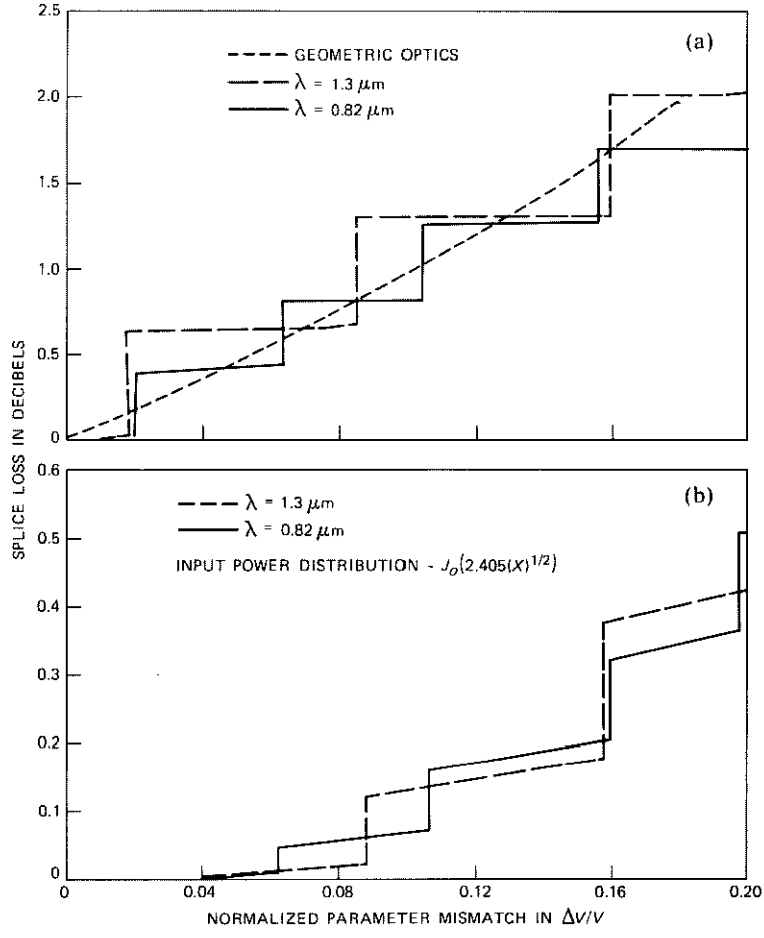

Fig. 5—Splice loss vs. normalized parameter mismatch in $\Delta V/V$ for (a) uniform power distribution and (b) steady-state power distribution.

the decrease in the order of magnitude of the loss allows the observation of the small loss component caused by the slight field mismatch between similar modes of the two fibers. This is reflected in the small slope of the levels. Because the steady-state distribution assumes that there is no power in the highest-order mode group of the transmitting fiber, the first discontinuous change of splice loss of Fig. 5a is negligible in Fig. 5b.

Figure 6 shows the percentage of mode mixing at a splice caused by parameter mismatch for 0.82- and 1.3-μm wavelengths, and the uniform and steady-state power distributions. The substantially higher mode mixing for the uniform power case compared to the steady-state indicates that mode mixing is dominated by the higher-order modes.

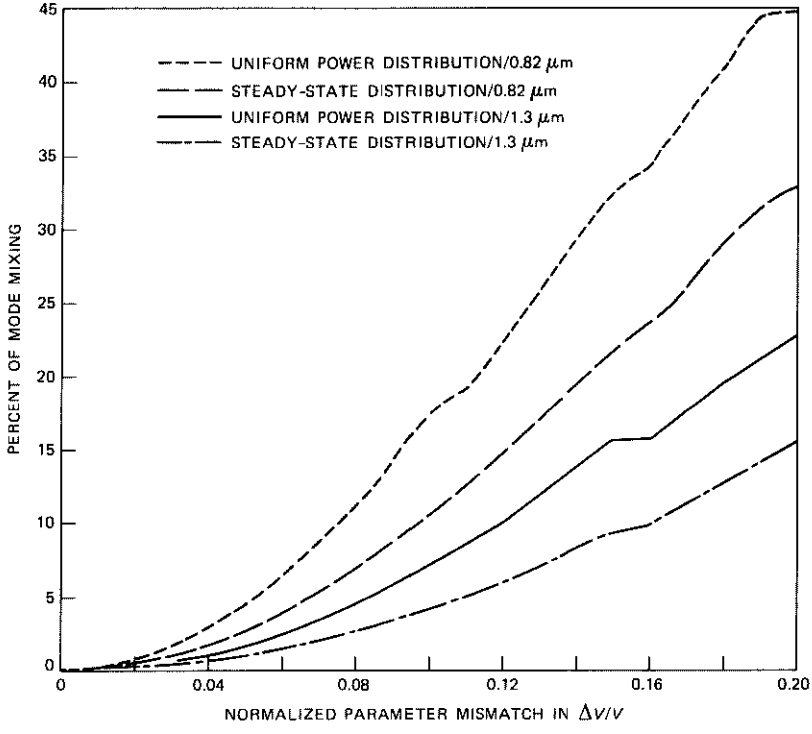

Fig. 6—Percent of mode mixing vs. normalized parameter mismatch.

This contrasts with the transverse offset case shown in Fig. 4, where mode mixing is essentially the same for uniform and steady-state distributions. Reduced mode mixing at longer wavelengths is due to the more diffuse bound mode fields, which result in stronger self coupling between modes. In comparison to the transverse offset case, the degree of mode mixing for the case of parameter mismatch is substantially reduced. Furthermore, a detailed analysis of the mode mixing shows that the coupling is almost completely nearest neighbor coupling ($\Delta N = 1$), e.g., for $\Delta V/V \sim 0.2$, 38 percent of the total 44-percent mode mixed power is coupled to nearest neighbor modes. The deviations from a smoothly increasing function in these curves occur at the transition points of the splice loss curves (see Fig. 5). This is caused by the transition of the highest-order mode group in the receiving fiber from propagating to lossy, removing its contribution to the overall mode mixing.

### *3.3 Wavelength dependence of splice loss for parameter mismatch*

As we can see from eq. (13), for a given degree of parameter mismatch, $\Delta N_{max}$ is also a discontinuous function of wavelength. For

example, if, at some particular wavelength, $V_T$ is 46.1 and $V_R$ is 45.9, $\Delta N_{max}$ is 1 and splice loss is ~0.5 dB. A slight change of wavelength (~1 percent) will cause both $V$'s to simultaneously be greater or less than 46 with $\Delta N_{max} = 0$, and splice loss is ~0.02 dB. Theoretical considerations [eq. (14)] also indicate that the period of the splice loss fluctuations should increase with increasing wavelength because the mode volume is proportional to $1/\lambda$. The magnitude of the fluctuation should also increase with wavelength because the relative amount of power in the highest-order mode group increases as the mode volume decreases. The splice loss wavelength dependence for a parameter mismatch ($\Delta V/V$) of 0.04 and uniform input power distribution is shown in Fig. 7. The magnitude of the splice loss changes considerably over the entire wavelength range. Splice loss calculated from geometric optics for this parameter mismatch case is also shown in Fig. 7 and is approximately the wavelength averaged splice loss as calculated from modal theory. Although the splice loss displays this pathological behavior, the mode mixing remains relatively small and continuous.

Figure 8 gives two further examples of the theoretical splice loss versus wavelength for uniform power excitation and core radius mismatches of 1.0 and 1.5 $\mu$m. For $\Delta a$ of 1.5 $\mu$m, there are ranges of wavelength over which $\Delta N_{max} = 2$, resulting in even larger fluctuations. The choice of a uniform power distribution unrealistically enhances the magnitude of this effect. For example, with the choice of the steady-state distribution, there would be very little power in the highest-order mode group, and therefore this change in loss would be very small, as we can see in Fig. 5b. Splice loss is not expected to vary as abruptly as shown in Figs. 7 and 8, even for a uniform power distribution, because the cladding splits the degeneracy of the highest-order mode group and some modes of this group remain bound even when the group itself, as predicted by the infinite parabolic approxi-

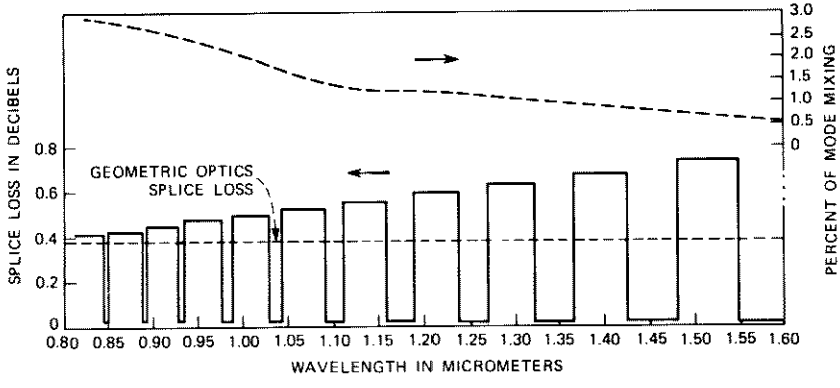

Fig. 7—Splice loss and mode mixing vs. wavelength for $\Delta V/V = 0.04$.

mation, is not bound. This results in a smoothing of the loss versus λ curve, but the periodicity should not be affected. The observation of this effect would further verify this analysis.

### *3.4 Experiment*

The experimental setup shown in Fig. 9 was designed to enhance the power in higher-order mode groups in an attempt to observe the predicted wavelength dependence of splice loss shown in Figs. 7 and 8. A 5 m, 63-μm core, step-index fiber was over-filled and used to excite

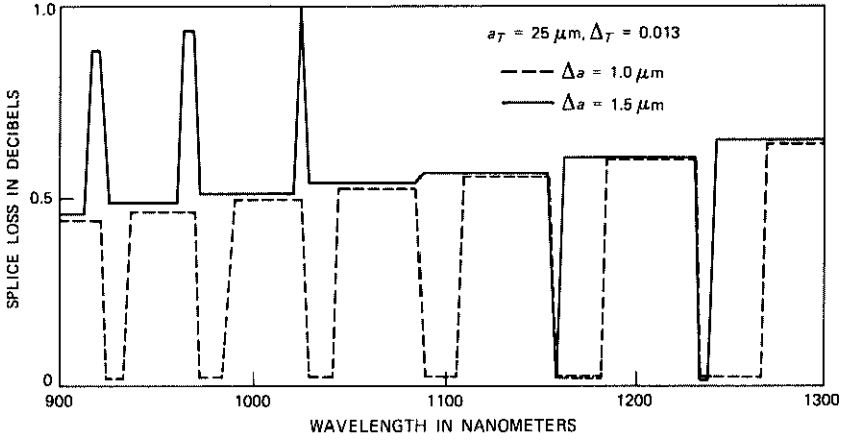

Fig. 8—Theoretical loss vs. wavelength for parameter mismatch.

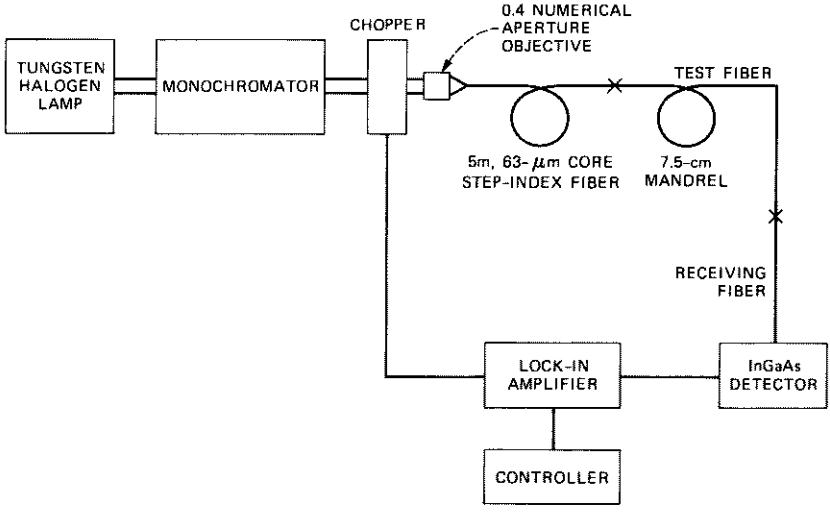

Fig. 9—Splice loss measurement system.

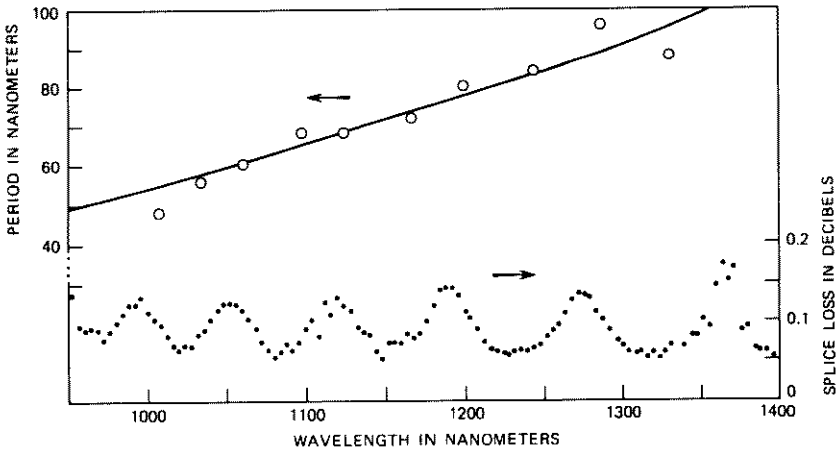

Fig. 10—Measured period and splice loss for parameter mismatch.

the test fiber, which was wound on a 7.5-cm mandrel. A cut-back test determined that approximately 15 m of fiber on this mandrel successfully eliminated leaky modes in the transmitting fiber. This fiber was spliced with micropositioners to a 1 to 2 m length of fiber, which differed in core radius by 1.0 ± 0.2 $\mu$m (but with the same $\Delta$), as determined by refracted near-field measurements. Monochromator resolution was 2 nm and the repeatability of the splice loss measurements was 0.02 dB. As a final check the test fiber was spliced to a length of identical fiber. Maximum splice loss change seen in this case was 0.02 dB, with no discernible wavelength dependence.

The measured wavelength dependence of splice loss and its period are plotted in Fig. 10 for the mismatched fibers. The data show excellent agreement with the period versus wavelength curve obtained from Fig. 8. The increase in maximum amplitude with wavelength seen in Fig. 10 is in qualitative agreement with the theory. Cladding effects (ignored in the infinite parabolic approximation) and only partial success in achieving a uniform power distribution are the probable reasons that the maximum amplitude is less than expected from Fig. 8.

## IV. CONCLUSIONS

In this paper we have presented a modal theory that allows the calculation of mode mixing and loss resulting from parabolic-index multimode fiber splices. The predictions of this model have been confirmed by experiment, including a previously unreported wavelength dependence of splice loss for intrinsic parameter mismatch.

This phenomenon is not expected to be significant for practical "steady-state" system losses but is important for providing insight into the actual loss mechanisms at a splice as well as verifying the validity of the theory. Another effect of this discreteness of the bound mode spectrum has previously been reported for the wavelength dependence of bending loss.[9] The theory also successfully describes splice loss versus transverse offset phenomena and has been used to verify the predicted steady-state power distribution. The analysis provides a basis for understanding mode-mixing effects at splices, which is important for bandwidth studies on concatenated fiber lengths. Splice losses caused by offset or parameter mismatch produce greatly different degrees of intermodal coupling. This implies that the effect of the splice on the bandwidth of a concatenated length is insignificant for the case of small parameter mismatch, but may be significant for transverse offset (due to the strong mode mixing). The sensitivity of the splice loss predictions to the choice of the input power distribution may allow this analysis to provide an evaluation of modal power distributions in fibers from experimental measurements of splice loss versus transverse offset.

The particular case of longitudinal offset has been obtained from a generalization of the parameter mismatch theory but has not been treated here due to its relative unimportance in practical systems. Gloge used geometric optics to show that fiber axis tilt at the splice is equivalent to a transverse offset via the relationship $(r_o/a)^2$ is equal to $\sin^2\theta/2\Delta$, where $\theta$ is the angle between the fiber axes.[10] This equivalence is also valid from the electromagnetic analysis for pure tilt or offset. The modal analysis of combinations of offset (both transverse and longitudinal) with tilt and parameter mismatch (as discussed in Ref. 10) are subjects of continuing work.

## V. ACKNOWLEDGMENTS

We would like to thank D. W. Peckham for providing loss versus transverse offset data; M. J. Saunders for index profile data; and C. M. Miller, P. J. Rich, and R. B. Kummer for helpful discussions.

## APPENDIX

### *Derivation of Modal Coupling Coefficients*

The principal steps in the derivation of the modal coupling coefficients (eq. 1) presented in Table I are shown in this appendix.

#### *A.1 Intrinsic parameter ($V$) mismatch*

In this case both fibers have fields as defined in eq. (2), where the argument of the field, $Z$, is

$$Z_T = V_T(r/a_T)^2 \tag{15}$$

and

$$Z_R = Z_T(1 + \epsilon), \tag{16}$$

where

$$V_T = (2\pi/\lambda) \cdot n_{co} \cdot \sqrt{2\Delta_T} \cdot a_T \tag{17}$$

and

$$\epsilon = \left(\frac{V_R}{a_R^2}\right)\left(\frac{a_T^2}{V_T}\right) - 1, \tag{18}$$

where the normalization expressions $A_{m\alpha}$ also contain $V_T$ and $V_R$.

Examination of the azimuthal integral of eq. (1) shows that, because there is no transverse offset of the fiber axes, azimuthal symmetry is preserved and only modes with the same azimuthal symmetry couple.

Changing the radial integral from an integration over $r$ to one over $Z_T$, we find that it is in the form of a well-documented integral of Laguerre Gaussian functions,[11] giving the expression shown in Table I. The hypergeometric function, ${}_2F_1(-m_2, -m_1, -(m_1 + m_2 + \alpha), y^2)$ is a finite power series in $y^2$ whose order is the lesser of $m_1$ or $m_2$, since both $m_1$ and $m_2$ are integers.

### A.2 Transverse offset—identical fibers

The modal fields to be used in eq. (1) can still be expressed by eq. (2) for both fibers. However, the radial and azimuthal variations of the receiving fiber ($r_R$, $\phi_R$) need to be expressed in terms of the transmitting fiber ($r_T$, $\phi$) and the transverse offset, $r_o$, of the axes. Using

$$r_R^2 = r_T^2 + r_o^2 - 2r_T r_o \cos\phi \tag{19}$$

and the integral relation for Laguerre-Gaussian functions[12]

$$e^{-Z/2}Z^{|\alpha|/2}L_m^{|\alpha|}(Z) = \frac{(-1)^m}{2}\int_o^\infty J_\alpha(\sqrt{xZ})e^{-x/2}x^{|\alpha|/2}L_m^{|\alpha|}(x)dx \tag{20}$$

we can then use the addition theorem for circular cylindrical waves[13] to write the receiving fiber field amplitude $E_R(m, \alpha)$ as

$$E_R(m, \alpha) = \frac{(-1)^m}{2}\sum_{p=-\infty}^{\infty} e^{-i(p+\alpha)\phi} \cdot \int_o^\infty J_p(\sqrt{xZ_o})J_{p+\alpha}(\sqrt{xZ_T})e^{-x/2}x^{|\alpha|/2}L_m^{|\alpha|}(x)dx, \tag{21}$$

where

$$Z_o = V(r_o/a)^2$$
$$Z_T = V(r_T/a)^2. \tag{22}$$

The azimuthal integral of eq. (1), for coupling between mode ($m_1\alpha_1$) of the transmitting fiber and mode ($m_2\alpha_2$) of the receiving fiber, reduces the infinite summation over $p$, introduced by eq. (21), to a single term for

$$p + \alpha_2 = \alpha_1. \tag{23}$$

After a change of variable from $r_T$ to $Z_T$ defined above, the radial integral of eq. (1) can be evaluated by again using eq. (20). (In evaluating this integral it is imperative to realize that the radial field variation of the modes is a function only of the magnitude of the azimuthal mode number, $|\alpha|$.) This evaluation produces two cases, which must be treated separately:

(*i*) $\alpha_1$ and $\alpha_2$—both the same sign

(*ii*) $\alpha_1$ and $\alpha_2$—different sign.

For both cases the final integral over the dummy variable $x$, introduced by the Laguerre-Gaussian integral identity [eq. (20)], can be evaluated by using the relationship[14]

$$L_n^{-\delta}(x) = (-1)^\delta x^\delta \frac{(n-\delta)!}{n!}L_{n-\delta}^\delta(x) \tag{24}$$

to write the integral in the form

$$I = \int_o^\infty y^{p+1} e^{-\alpha y^2} L_m^{p-a}(\alpha y^2) L_n^a(\alpha y^2) J_p(x \cdot y) dy, \tag{25}$$

which is a well-documented integral giving

$$I = (-1)^{m+n}(2\alpha)^{-(p+1)} x^p e^{-x^2/4\alpha} L_m^{a-m+n}(x^2/4\alpha) \cdot L_n^{p-a+m-n}(x^2/4\alpha). \tag{26}$$

In both Refs. 15 and 16, the formula is slightly incorrect due to a reversal of the subscripts of the Laguerre polynomials. The formula of Refs. 15 and 16 is seen to be incorrect by noting that eq. (25) above is a Hankel transform of order $p$, so that, by applying the inverse transform to the result, one should expect to obtain the original function, i.e., the argument of the original Hankel transform. The error persists in Ref. 15 because it used Ref. 16 as its source for this result. The use of this relationship then provides the results in Table I.

# Experimental Results of 20-Mb/s FSK Digital Transmission on 4-GHz (TD) Radio

By Y. Y. WANG

(Manuscript received June 9, 1982)

*This paper presents the results of tests of 20-Mb/s frequency-shift-keying digital transmission on the 4-GHz TD radio system. On the basis of the test results, the performance of the 20-Mb/s system is projected to be satisfactory to support long-haul digital services. The system employs a 20-Mb/s terminal that multiplexes 12 signals at the first level of digital signal hierarchy (DS-1) (1.5 Mb/s) into a 10-Mbaud, 4-level signal to be transmitted by the Bell System standard 4-GHz (TD) FM microwave radio system. The maximum distance of a digital regeneration span in normal operation is limited by the intermodulation noise to approximately 10 typical hops of TD radio. The 20-Mb/s TD radio system uses the standard frequency-diversity protection switching system, which was designed for analog message service. A fundamental system trade-off is, therefore, the choice of switch threshold: long periods of error-free transmission interrupted by infrequent error bursts due to switch transients versus an occasional low background error rate with less frequent switch transients. We concluded that the protection switch threshold of a 1500-message-circuit channel is suitable for 20-Mb/s TD radio channels.*

## I. INTRODUCTION

The growth of *Dataphone** Digital Service[1] (DDS)† and the needs of new services such as *Picturephone*‡ Meeting Service[2] (PMS) require a substantial increase in digital long-haul transmission capacity. The existing long-haul digital facilities, mainly Data-Under-Voice[3] (DUV), are near exhaustion in many areas. Furthermore, some existing frequency modulation (FM) radios will be replaced by the single-sideband

* Service mark of AT&T.
† Acronyms and abbreviations are defined in the Glossary at the back of this paper.
‡ Service mark of AT&T.

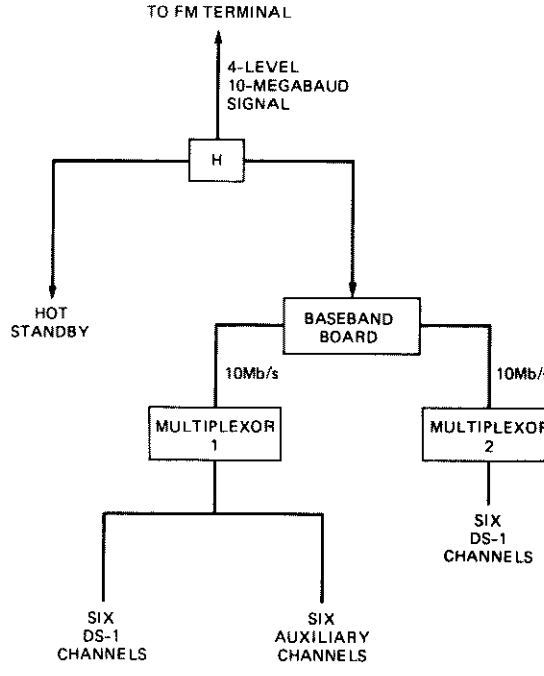

Fig. 1—The 20-Mb/s terminal.

AR-6A[4] radio to increase analog transmission capability. Such replacement reduces the number of DUV channels. New technologies, such as 45-Mb/s transmission on TD radio[5,6] (TD-45A[7,8]) and long-haul digital radio at 4 GHz, will not be available until 1983 and beyond. During the interim, the 20-Mb/s TD system* will be used to provide long-haul digital connectivity.

AT&T Long Lines is deploying an approximately 3000-mile, 20-Mb/s TD network in 1981 and 1982 for DDS application. By the end of 1982, the 20-Mb/s network will have 70 terminals providing 159 digroups. This number of DDS digroups will double the capacity of the 1980 DDS network. The 20-Mb/s terminal has other applications in the Bell System. For example, a portable microwave radio facility can be set up quickly to work with the 20-Mb/s terminals to carry digital services on a temporary basis.

The 20-Mb/s terminal is capable of multiplexing up to 12 asynchronous signals at the first level of digital signal hierarchy (DS-1) into a 9.856-Mbaud, 4-level signal (see Fig. 1). This 4-level signal can be transmitted on the long-haul microwave network using standard FM

* Using the VIDAR DM-12A 20-Mb/s terminal.

terminals and a dedicated 20-MHz bandwidth radio channel suitable for 1500-message-circuit loading. Recommended maximum digital regeneration span is ten TD radio hops (about 250 miles). The existing 100A[9] or 400A[10] protection switch equipment will protect against propagation fading and radio equipment failures.

Following a summary of the test results in Section 2, the test system configuration and the deployment of test equipment are discussed in Section 3. Section 4 records six tests in the absence of multipath fading, e.g., the jitter performance test, fade margin measurements, and the protection switch compatibility test. Section 5 discusses the performance under the multipath fading condition. The projected performance of the 20-Mb/s TD system for DDS and PMS is discussed in Section 6.

Subsequent to these tests, we found that the preferred power level at the input to the Frequency Modulation Transmitter (FMT) could be reduced by 2 dB, from −14.9 dBm to −16.9 dBm. Combined with the use of a narrower band receiver filter, this power reduction improves the adjacent channel interference and the intermodulation noise performance significantly without degrading the performance of the 20-Mb/s channel. The results presented in this report have been adjusted to reflect the reduced drive level and the tighter receiver filters that are being implemented.

## II. SUMMARY

Tests of a 20-Mb/s terminal on a 12-hop, 188-mile TD radio loop were conducted in New Jersey from July to November, 1980. The main results are as follows:

(*i*) It satisfactorily transmitted the digital signal over 12 hops of TD radio without baseband digital regeneration.

(*ii*) The 20-Mb/s terminal showed satisfactory jitter performance.

(*iii*) The system is essentially error-free during normal propagation and operating conditions. System performance as tested in New Jersey is satisfactory for DDS and PMS.

(*iv*) The required cochannel Carrier-to-Interference Ratio (CIR) into a desired 20-Mb/s TD channel is 25 dB at the protection switching point.

(*v*) A switch transient of the 100A frequency-diversity protection switch causes a 6 to 30 millisecond burst of errors. The switch threshold of a 1500-message-circuit channel is suitable for the 20-Mb/s TD channel.

Despite the fact that the protection switch transients will cause transmission errors, the tests confirmed that the use of the 20-Mb/s terminal with the TD radio system can meet long-haul transmission requirements.

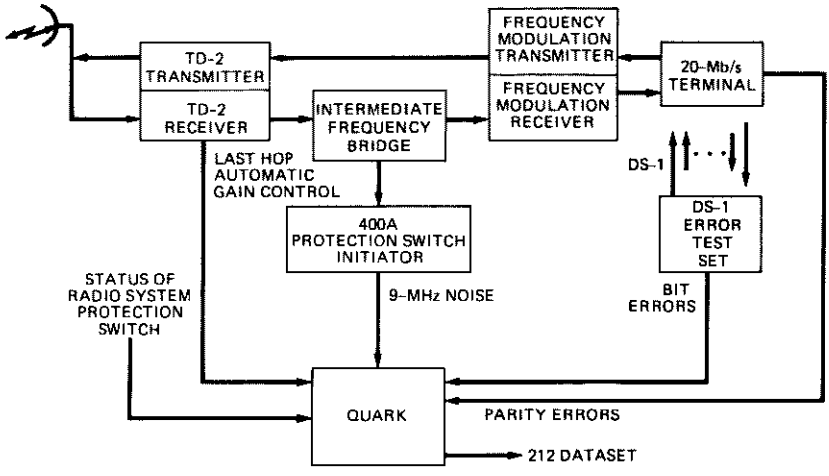

Fig. 2—20-Mb/s TD radio system: test arrangement in Freehold, NJ.

## III. TEST DESCRIPTION

The 20-Mb/s TD radio system under test consists of a 20-Mb/s terminal, a 4A FM terminal, a 12-hop loop of TD-2 radio, and a 100A frequency-diversity protection switch (Section 3.1). Two bit-error-rate test sets (Bowmar), an errored-bit accumulator, a 400A protection switch initiator, and a Quantizer, Analyzer, and Record Keeper (QUARK)[11] were used to monitor and to record the performance statistics (Fig. 2).

### *3.1 System configuration*

The 20-Mb/s terminal multiplexes six even-numbered and six odd-numbered DS-1 (1.544 Mb/s) channels into two 10-Mb/s rails and then encodes the two rails into a 4-level, 10-Mbaud baseband signal. The 4-level, 10-Mbaud baseband signal is connected to an FM terminal that provides Frequency Shift Keying (FSK) modulation and demodulation. The FM terminal is then connected to the TD-2 radio via Intermediate Frequency (IF) cables. The baseband power level at the input to the FMT and the output of the Frequency Modulation Receiver (FMR) were −16.9 dBm and −0.9 dBm, respectively.

The test radio route consisted of two 2-way, 4-GHz radio channels connecting Freehold (FH) and Cherryville (CH), NJ, as shown in Fig. 3. All radio units used in the test were TD-2, retrofitted with solid-state microwave generators. The radio channels are suitable for 1500-message-circuit loading.

### *3.2 Deployment of test equipment*

The switch initiator of a frequency-diversity protection system de-

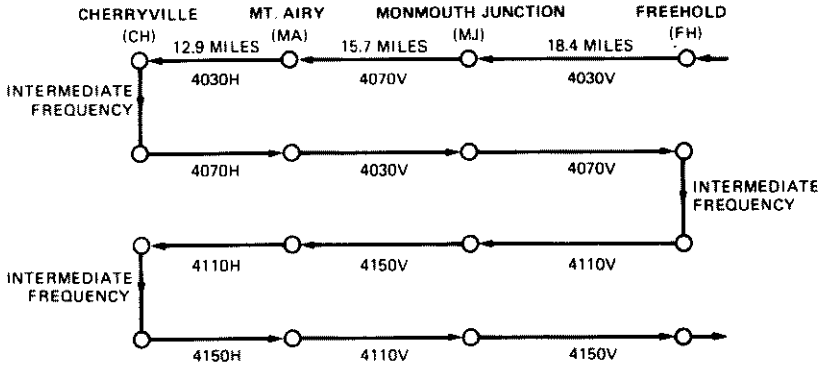

Fig. 3—Frequencies (in megahertz) of TD radio channels for a digital transmission experiment in New Jersey.

tects the noise power in a 1.74-kHz bandwidth centered at 8.9 MHz at the end of a switch section to determine if a working channel needs protection. We therefore installed a 400A protection switch initiator in the receiving IF path to measure the amount of accumulated channel fading over the entire 12-hop route (Fig. 2). For convenience, the power in the 1.74-kHz bandwidth centered at 8.9 MHz will be referred to as the 9-MHz (slot) noise power in the rest of the text.

### *3.3 Data acquisition system*

A QUARK was installed in the Freehold station to record the Automatic Gain Control (AGC) voltage of the last receiving main amplifier and the 9-MHz slot noise of the 12-hop FM radio route, switch activities, errors in two DS-1 channels, and the parity errors in data rail one (9.8 Mb/s, 3672 bits/frame). The statistics of various inputs were accumulated in the QUARK memory. The relationships among DS-1 errors, parity errors, 9-MHz noise, and protection switch activities were studied in terms of statistics of simultaneous events as collected by the QUARK.

## IV. TESTS IN THE ABSENCE OF PROPAGATION FADING

Tests were performed to characterize the system performance under normal operating conditions, as well as under controlled stressing conditions. These tests and their results are described in the following sections.

### *4.1 Baseband spectrum*

Figure 4 shows the received baseband spectra of the 20-Mb/s signal measured at FMR-OUT with and without the 12-hop radio loop. The digital spectrum is down about 15 dB at 6 MHz. The 9-MHz noise

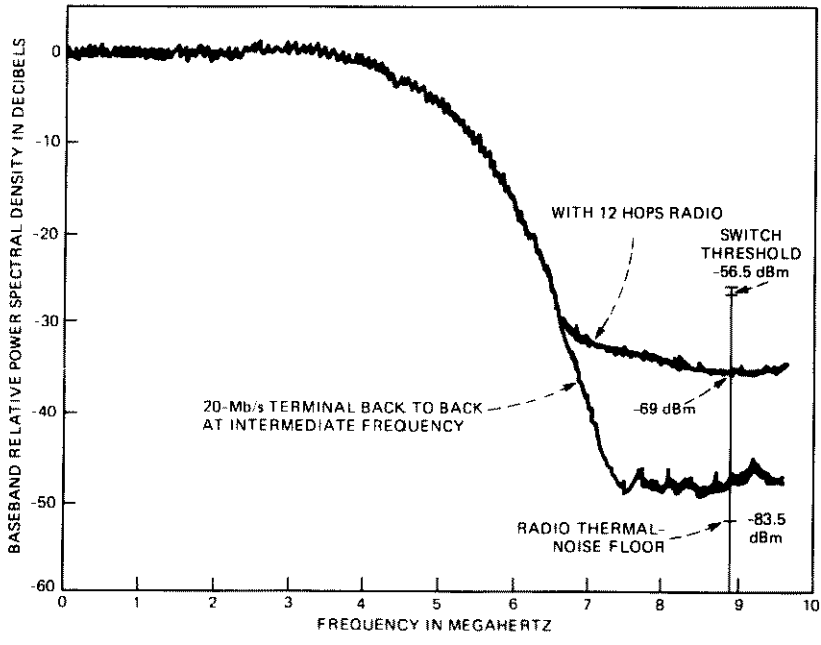

Fig. 4—Baseband spectrum.

power was −69 dBm and −83.5 dBm, with and without the 20-Mb/s modulation, respectively. The 14.5-dB difference represents the 12-hop accumulated intermodulation noise, which dominates the 9-MHz slot noise.

### *4.2 S/N at baseband versus BER at DS-1 level*

Baseband noise was injected before the baseband receiver filter to stress the 20-Mb/s transmission. The main objective was to study the Bit Error Rate (BER) versus baseband signal-to-noise ratio (s/n) relationship.

Figure 5 shows the BER performance of the even- and odd-numbered DS-1 channels of the terminal. The odd-numbered channels perform better than even-numbered channels by 1 dB in s/n for equal BER. This difference is due to the circuit design of the terminal. The 20-Mb/s signal consists of two 10-Mb/s rails. At the terminal receiver, the odd-numbered DS-1 channels are derived from a 10-Mb/s rail, which is decoded from the plus-minus sign decision of the received 10-Mbaud, 4-level signal. The even-numbered DS-1 channels are derived from the other 10-Mb/s rail, which is decoded from the amplitude threshold decision of the received 4-level signal. The plus-minus sign decision is more robust than the amplitude threshold decision by 1 dB

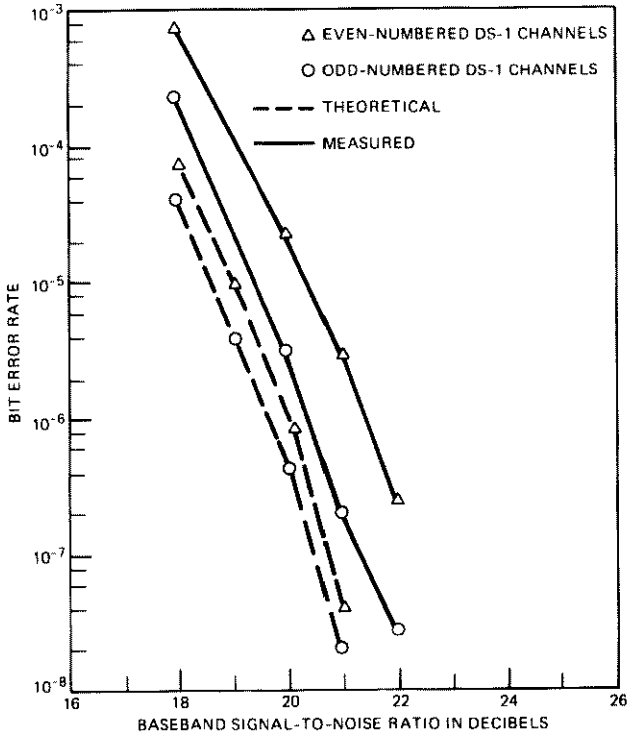

Fig. 5—Bit error rate vs. $s/n_{BB}$ intermediate frequency loopback.

in s/n, as measured, and by 0.5 dB, as theoretically predicted. The theoretical relationship is derived in the appendix. Thus, throughout this study, a discussion of error performance in terms of an even-numbered DS-1 channel implies a conservative (lower) bound on the digital error performance.

Figure 6 shows the measured and calculated BER of the odd-numbered DS-1 channel versus baseband s/n. The 12-hop TD radio degrades the performance of the odd-numbered DS-1 channel by less than 0.5 dB. The effect of 12 hops of TD radio on even-numbered DS-1 channels is practically indiscernible. The maximum regeneration interval (ten TD hops were recommended for the field) is imposed, therefore, by intermodulation noise at the 9-MHz noise slot (Section 4.1), rather than by the digital transmission impairments.

### *4.3 Jitter performance*

Jitter performance of the 20-Mb/s terminal satisfies the requirements of the existing digital network. Under normal operating conditions, the amount of output jitter among DS-1 channels was uniform

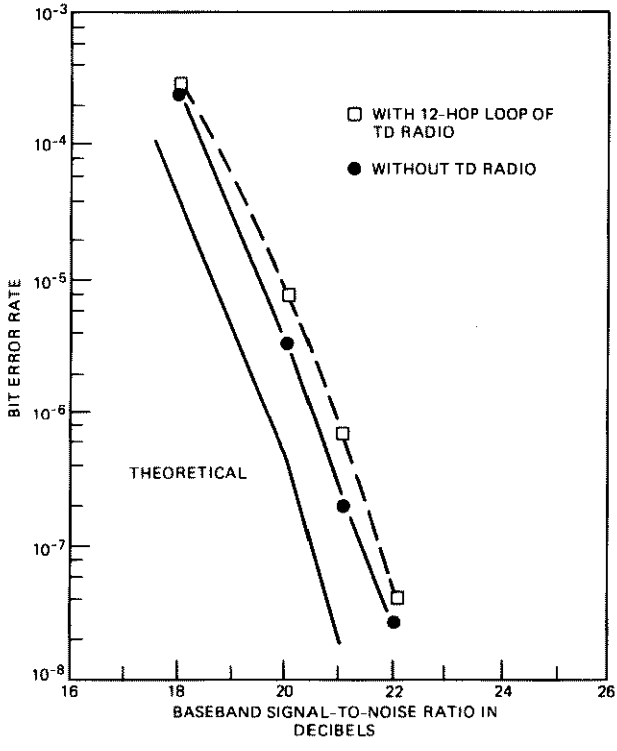

Fig. 6—Bit error rate vs. $s/n_{BB}$ for odd-numbered DS-1 channels.

and comparable to that of the office Quasi-Random-Signal-Source (QRSS), the standard DS-1 signal. In fact, the terminal is effectively a de-jitterizer. The amount of jitter in an output signal was about half that of the input signal, as shown in Table I. Furthermore, digital error performance of two DS-1 channels was compared when the Radio Frequency (RF) signal power was severely attenuated. The channel that took a clean office QRSS as the input consistently made fewer errors than the one that took a jittered source with 11- to 13-percent rms jitter. However, the difference was so small that it was indistinguishable in terms of the fade margin.

#### *4.4 Flat fade margin*

The Bell System microwave radio plant was engineered to have adequate flat fade margins to meet the outage objective of allowing less than 0.01-percent outage for all causes over one-way, 4000-mile transmission. The outage of a digital system comprises the time when the one-second-averaged BER exceeds $1 \times 10^{-3}$. This objective need

Table I—Jitter performance

| | Input to the 20-Mb/s Terminal | | Output of the 20-Mb/s Terminal | |
|---|---|---|---|---|
| | Percent of Jitter (rms) | Percent of Jitter (Peak to Peak) | Percent of Jitter (rms) | Percent of Jitter (Peak to Peak) |
| 1 loop* | 13 to 14 | 60 to 75 | 5 to 6 | 25 to 30 |
| 2 loops | 9 to 11 | 50 to 65 | 4 to 5 | 15 to 25 |
| 3 loops | 14 to 16 | 75 to 120 | 5 to 7 | 25 to 40 |
| 4 loops | 15 to 18 | 90 to 130 | 7 to 9 | 35 to 50 |

* Each loop consists of two complete M13 passes and four hops of digital radio.

Table II—Flat fade margin

| Radio Hop | $F_s$ (dB) | $F_d$ (dB) | $F_d$-$F_s$ |
|---|---|---|---|
| FH-MJ | 43.0 | 43.0 | 0 |
| MJ-MA | 39.3 | 42.7 | 3.4 |
| MA-CH | 44.0 | 46.0 | 2.0 |
| CH-MA | 45.0 | 42.8 | −2.2 |
| MA-MJ | 41.5 | 42.5 | 1.0 |
| MJ-FH | 41.5 | 40.0 | −1.5 |
| FH-MJ | 39.5 | 41.5 | 2.0 |
| MJ-MA | 39.5 | 42.8 | 3.3 |
| MA-CH | 40.5 | 44.0 | 3.5 |
| CH-MA | 40.0 | 42.3 | 2.2 |
| MA-MJ | 37.8 | 39.5 | 1.7 |
| MJ-FH | 38.0 | 40.0 | 2.0 |

$F_s$ = switch point fade margin.
$F_d$ = fade margin to $10^{-6}$ BER.

not be met on a per-hop basis, because of the existence of severe interference conditions at some junction radio stations, as long as the prorated objective on a per switch section basis was satisfied.

This test measured the required amount of RF attenuation at each radio transmitter to reach the protection switch threshold, which is −56.5 dBm noise power at the 9-MHz slot. This test showed that the fade margin against a BER of $1 \times 10^{-3}$ always exceeded the switch point fade margin, indicating that the 20-Mb/s TD system can be engineered to meet the facility outage objective. In fact, even the margin against a BER of $1 \times 10^{-6}$ was generally found greater than the corresponding switch point fade margin. The $10^{-6}$ margin is of interest because the number of seconds at a BER of $1 \times 10^{-6}$ at the DS-1 level is an estimate of the number of errored seconds (ES), which is an often referenced service performance parameter.

Table II summarizes the measured switch point fade margins and the $10^{-6}$ margins of the test system. There were two hops where the BER could exceed $1 \times 10^{-6}$ before the radio channel would request protection. Since this condition is expected at a few junction stations of the network and we wanted to have a "typical" TD route to conduct this test, no effort was invested to identify the cause and eliminate the situation.

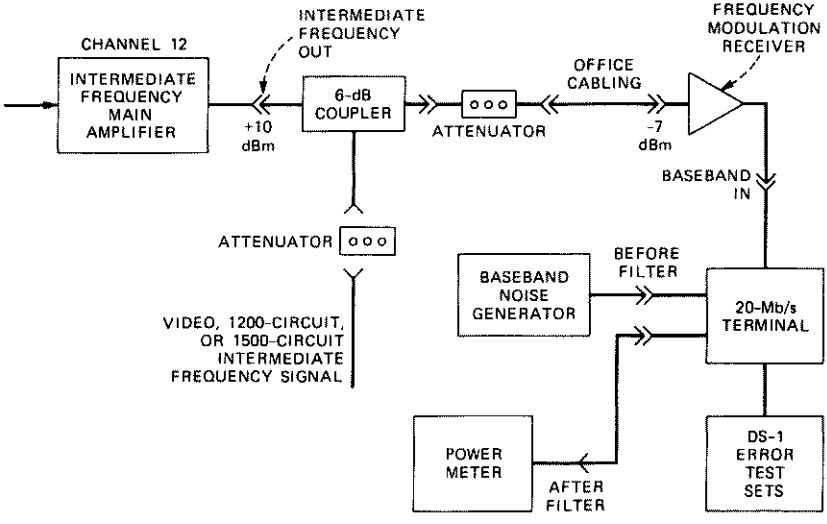

Fig. 7—CIR vs. s/n test setup.

### *4.5 Effect of cochannel interference*

To study the impact of severe cochannel interference on the 20-Mb/s TD channel, an interfering signal was injected at IF. Three kinds of interference signals [i.e., 1200-circuit message, 1500-circuit message, and video (color bar)] were used. The test setup is illustrated in Fig. 7. Figure 8 shows the results for a fixed BER of $1 \times 10^{-6}$. The color-bar video signal was observed to be the most interfering; the 1500-circuit message was the least interfering among the three. This is due to the higher concentration of spectral energy near the carrier in certain signals. The baseband filter does not reduce this type of signal appreciably.

At the protection switch initiation point, the s/n versus CIR relationship was also measured, as shown in Fig. 8. In the region where the faded CIR exceeds 25 dB, as the s/n decreases, a protection switch will be initiated before BER degrades to $1 \times 10^{-6}$. However, if the faded CIR were less than 25 dB, thermal noise in the radio channel could cause BER to exceed $1 \times 10^{-6}$ before the switch point. Therefore, severe cochannel interference reduces the effectiveness of the protection switch and degrades the digital error performance.

### *4.6 Switch system compatibility*

For this portion of the test only, a two-way radio channel from Freehold to Cherryville was included in the 100A switching system between these locations. The connection thus had two one-way switch

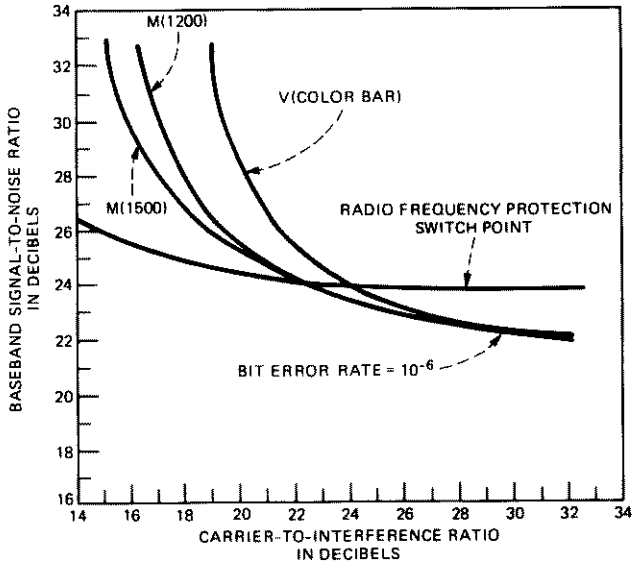

Fig. 8—CIR vs. $s/n_{BB}$ for even-numbered DS-1 channels.

sections, each consisting of three hops of TD radio. Test results include:

(*i*) A switch cycle (to and back from the protection channel) consists of two transients, i.e., two interruptions in data transmission. More than one switch cycle in a second is possible, and the time span from initial loss of signal to the resynchronization of the receiving part of the 20-Mb/s terminal is approximately 30 milliseconds.

(*ii*) No special modification to the 100A switch equipment is necessary. The frequency-diversity protection switch is compatible with the 20-Mb/s TD radio system.

## V. PERFORMANCE UNDER MULTIPATH FADING CONDITION

### *5.1 Amount of multipath fading activity*

During the period from July 10, 1980 to August 13, 1980, the impact of multipath fading over the test route was studied. Figure 9 shows the statistics of the 9-MHz slot noise during this period. The measured distribution of 9-MHz noise displayed the inverse slope of 10 dB per decade of probability (the $L^2$ law[12]). This slope is a well-known characteristic of multipath fading for unprotected radio. The number of events was greater than the number of seconds when the 9-MHz noise exceeded a given abscissa. This observation suggests that multiple switch requests could occur in a second. A switch transient causes errors, and, therefore, frequency-diversity protection is expected to

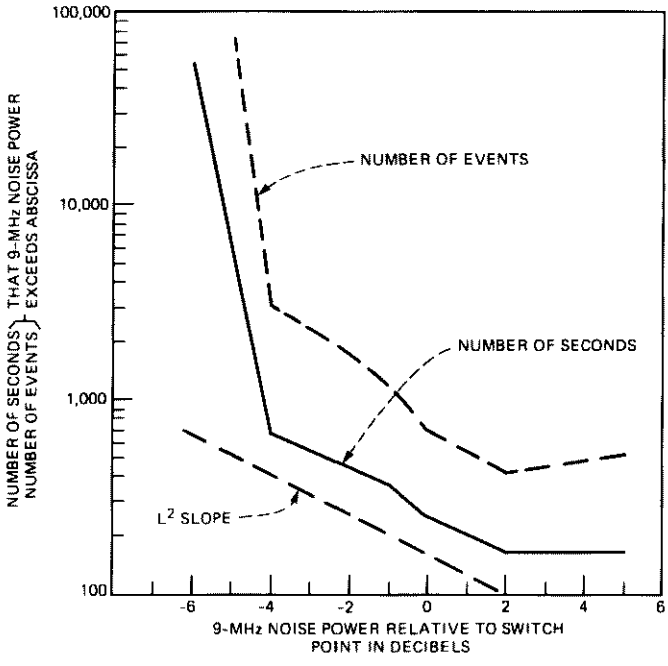

Fig. 9—Distribution of time and events of 9-MHz noise power. The time period monitored was July 10, 1980 through August 13, 1980.

offer limited reduction in the number of errored seconds during multipath fading periods.

The fading statistics of a single hop from Monmouth Junction (MJ) to Freehold are shown in Fig. 10. The solid curve in Fig. 10 also has an inverse slope of 10 dB per decade of probability. The engineering model[12] predicted 166 seconds below 30 dB for this hop during a heavy fading month. We recorded 115 seconds, which is about two thirds of a heavy fading month. Hence, we did experience a fair amount of multipath fading during the test.

### *5.2 Digital error performance*

The measured distribution of BER of an even-numbered DS-1 channel is shown in Fig. 11. There were 432 errored seconds (ES); 263 of them have BER exceeding $10^{-3}$. The BER statistics for simultaneous errored seconds of even-numbered and odd-numbered DS-1 channels were also plotted in Fig. 11. They differ in the number of low-BER ES, as expected (see Section 4.2 and the appendix). The number of ES in even-numbered DS-1 channels is approximately 25 percent more than the ES in odd-numbered DS-1 channels.

The data format of the terminal multiplexor contains one parity bit

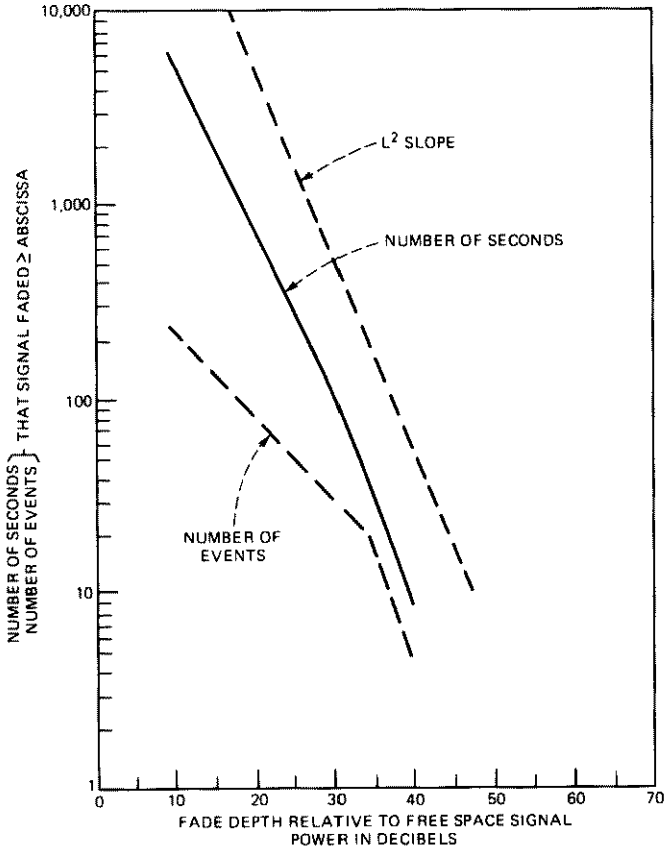

Fig. 10—Distribution of time and events of received signal power. The time period monitored was July 10, 1980 through August 13, 1980.

in a 3672-bit frame. Fault-detection algorithms internal to the terminal and a real-time error-performance monitoring plan to be used by the AT&T Long Lines operations personnel depend on the detection of the parity violations. The distribution of parity violations in a 9.8-Mb/s rail (which feeds six DS-1 channels) can be found in Fig. 12. Those parity violation seconds occurring simultaneously with the ES for the information bits of one even-numbered DS-1 channel are also plotted in Fig. 12. The difference between the two was found to be insignificant. The parity violation seconds offers an effective representation of the real DS-1 ES.

### *5.3 Relationship between digital errors and 9-MHz noise*

Figure 13 shows the distribution of BER of an even-numbered DS-1 channel and the portion of the errored seconds with 9-MHz noise

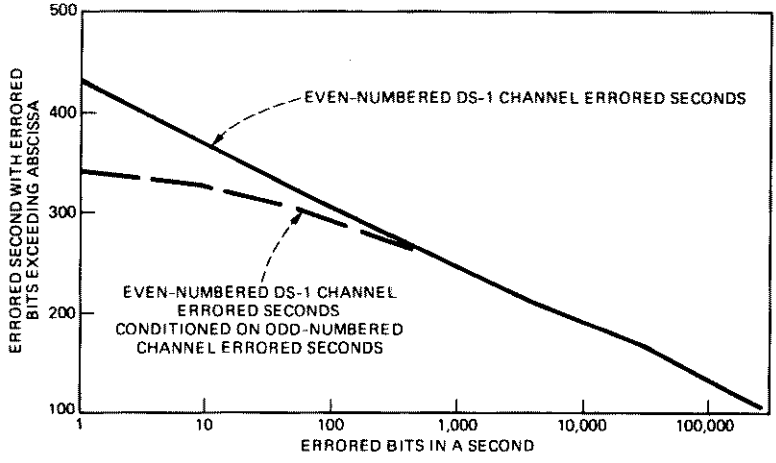

Fig. 11—DS-1 errored-second statistics for the time period July 10, 1980 through August 13, 1980.

exceeding switching point from August 14, 1980 to September 20, 1980. About 10 percent of the errored seconds occurred before the 9-MHz noise reached the switching threshold. All ES with more than 100 errors occurred at the same time the 9-MHz noise exceeded the switch point. Thus, these errored seconds are likely to be accompanied by switch activities in the plant environment.

### *5.4 Impact of frequency-diversity protection*

Based on the assumption that the protection channel is always available for error-free transmission, this section will show that:

(*i*) The switching threshold of a 1500-message-circuit loaded channel is suitable for a 20-Mb/s TD channel, and

(*ii*) During multipath fading periods, the protection switch would have offered little improvement in terms of ES reduction owing to the frequent switching activities.

Under the assumption of perfect frequency-diversity protection, those errored seconds that occurred while the 9-MHz noise exceeded the switching threshold would have been prevented. The exception would be those seconds in which the 9-MHz noise passes through the switching threshold. This is because the actual switch transfer causes an errored second. Based on the observation that a switch cycle could be completed within a second (Sections 4.6 and 5.1), we estimate the number of seconds containing switching activities by the number of seconds in which the maximum value of the measured 9-MHz noise in a second exceeded the switching threshold. Hence, if the test route had been frequency-diversity protected, we would have $X$ ES, where

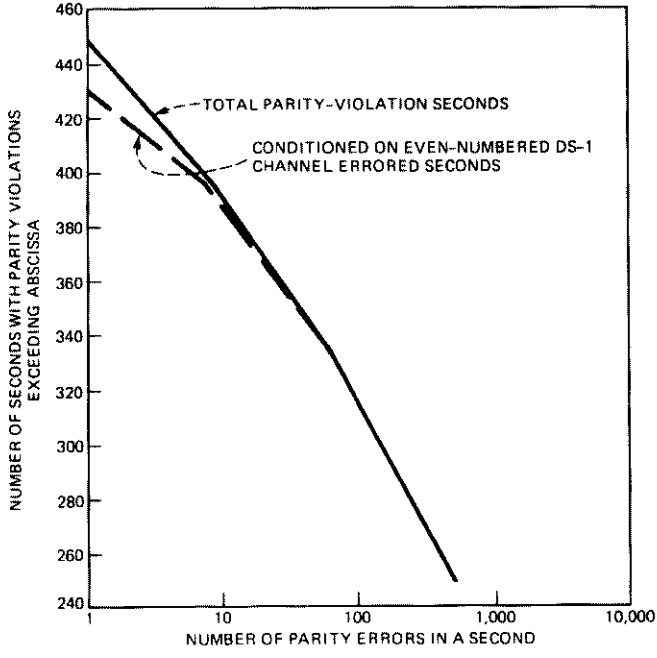

Fig. 12—Parity-violation-second statistics for the time period July 10, 1980 through August 13, 1980.

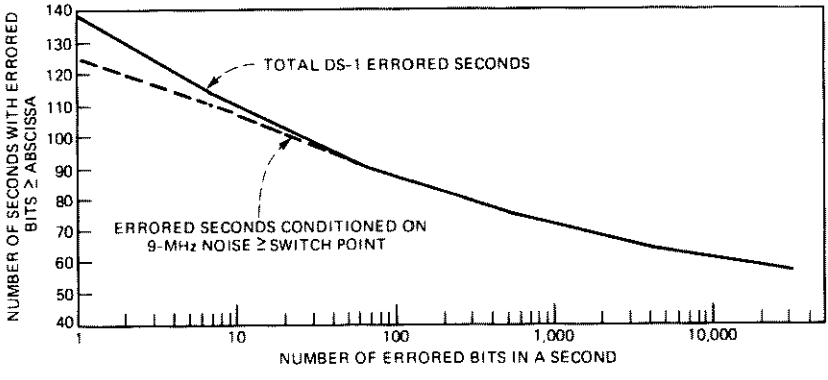

Fig. 13—DS-1 errored-second statistics for the time period August 14, 1980 through September 20, 1980.

$X$(at a given threshold) =

(Total ES) − (ES conditioned on 9-MHz noise power ≥ threshold)

+ (number of seconds with maximum 9-MHz noise power

≥ threshold).

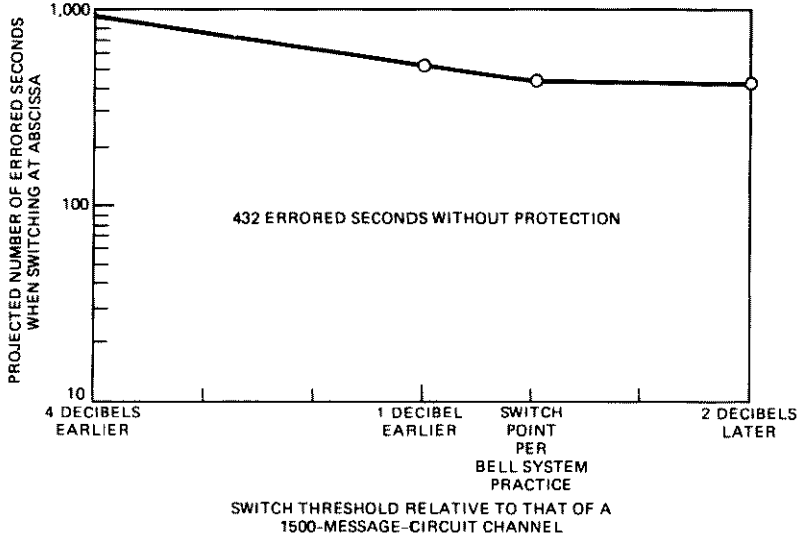

Fig. 14—Sensitivity of switch threshold to errored-second performance projection based on data collected July 10, 1980 through August 13, 1980.

Figure 14 shows the projected number of ES as a function of switching threshold. The projected number of ES decreases as the switch threshold decreases until the switch threshold reaches the level of a 1500-message-circuit loaded channel. Since the 20-Mb/s channel will coexist with 1500-message-circuit loaded channels in the plant, it is desirable from operations and maintenance considerations to use the switch threshold of a 1500-message-circuit loaded channel for a 20-Mb/s TD channel.

## VI. PERFORMANCE PROJECTION FOR DDS AND PMS

A properly engineered 20-Mb/s TD system can meet the long-haul outage and quality objectives for DDS and PMS. The long-haul outage objective[13,14] for DDS or PMS is the same as that for Message Telecommunications Service (MTS). Engineering guidelines for TD radio were developed to meet the MTS outage objective and, therefore, those for DDS and PMS as well.

The following demonstrates the ability of the 20-Mb/s TD system to meet the long-haul quality objectives for DDS and PMS.

### *6.1 Meeting the DDS quality objective*

#### *6.1.1 The DDS quality objective*

The quality objective of the DDS transmission design requires 99.5-percent error-free-seconds at DS-0 (56-kb/s rate) for 4000-mile, one-

way, end-to-end transmission. The test results showed that 90 percent of the errored seconds would be associated with switch transients, which cause errors in all 23 DS-0 channels of a DS-1 signal. We, therefore, assume as a worst case that the DDS quality objective for the 20-Mb/s TD system is the same at DS-0 and DS-1 levels. The objective is thus to have less than 0.5-percent ES for a one-way, 4000-mile transmission.

#### *6.1.2 Generalized performance projection*

The majority (ninety percent in this test) of ES of a properly engineered 20-Mb/s TD radio system are expected to be caused by protection switch transients. Therefore, to project the performance of a 20-Mb/s TD system, the statistics of switch activities in a 4000-mile TD route must be considered.

Every switch system (e.g., 100A, 400A) has a switch register that counts the number of automatic switch completions. Any manually forced protection switches for routine maintenance are not included in these counts. AT&T Long Lines records the number of switches on a weekly basis. These records of switch completions from June 16, 1979 through June 7, 1980 on five TD routes (New York City to Boston, New York City to Philadelphia, Philadelphia to Silver Spring, Pittsburg to Silver Spring, and Chicago to Kalamazoo) suggest that there are 13,500 switch completions per year for an average one-way radio channel for multipath fading protection in a 4000-mile TD radio system. There could be two errored seconds associated with a switch cycle; therefore, 27,000 ES due to multipath fading are expected annually.

The one-year switch register data also revealed that, in addition to the switchings due to multipath fading, there were protection switches, called the background switch activities, which were attributed to craft activities, hardware problems, and other causes. These background switches are of a transient nature. A switch cycle lasts much less than a second. According to the same database, this type of switch amounted to 0.03 switch completion per mile per week per channel on average. Thus, we project 6240 ES due to background switches.

Table III summarizes the projected number of ES in a year due to all causes. The total number of ES is 34,078 which is 0.11 percent of a year. This projection compares favorably with the objective of 0.5 percent and shows that the 20-Mb/s TD system performance is satisfactory for DDS.

### *6.2 Meeting the PMS quality objective*

We have observed essentially error-free performance without fading. Multipath fading seldom occurs during an 8 am to 9 pm business day,[12]

Table III—Projection of errored seconds caused by switching in a one-way, 4000-mile TD route in a year

| Cause | Errored seconds |
|---|---|
| FMT or 20-Mb/s terminal failure | 18 |
| Routine maintenance | 720 |
| Radio failure | 100 |
| Background switch activity | 6240 |
| Multipath fading | 27,000 |
| Total | 34,078 |
| | =0.11 percent/year |

when most PMS calls will take place. Therefore, based on the rate of background switches, as discussed in the previous section, we project that the 20-Mb/s system performance is satisfactory for PMS.

## VII. ACKNOWLEDGMENT

Many colleagues at Bell Laboratories and AT&T Long Lines offered their prompt assistance at every stage of this project. I am particularly grateful to L. A. Dietrich and S. H. Lin for their participation and technical guidance throughout the project. The QUARK was designed by T. G. Szekeres and G. A. Zimmerman.

## APPENDIX

### *Predicted Error Performance With Ideal Channel Plus Gaussian Noise*

This appendix approximates a set of relationships between a 1-second bit error rate at DS-1 level and the baseband signal-to-noise ratio based on our understanding of the 20-Mb/s terminal and an idealized FM channel with Gaussian noise.

There are two multiplexor units in the main/working portion of a terminal. The number 1 multiplexor unit accepts data from the six odd-numbered DS-1 channels plus the six auxiliary (AUX) channels. The number 2 multiplexor unit accepts data from six even-numbered DS-1 channels. Each multiplexor combines its inputs into a single data-bit stream of 9.856 MHz. These two bit streams form binary groups: the first digit in the binary group is taken from the number 1 multiplexor, the second from the number 2 multiplexor. These binary groups are Gray coded and are then converted into a single 4-level signal. It has been verified in the laboratory that the four levels at the transmitter output are indeed equally spaced.

The decoder at the terminal receiver performs the inverse operation. The probabilities of error for even- and odd-numbered DS-1 channels separately can be derived in a manner similar to the analysis of Lucky[15] and others under the following assumptions:

1. The amplitudes of the four symbols are equally likely to assume any of the four equally spaced values $\pm d$ and $\pm 3d$. Symbols occurring at different times are independent.

2. The bit error performance of the terminal depends on s/n but is insensitive to the spectral shape of noise. (This has been verified in the laboratory.) We assume that the additive noise is Gaussian.

3. The pulse shaping $X(w)$ is raised cosine with 50 percent roll-off:

$$X(w) = \begin{cases} T & 0 \leq w \leq \dfrac{\pi}{2T} \\ \dfrac{T}{2}(1 + \sin wT) & \dfrac{\pi}{2T} \leq w \leq \dfrac{3\pi}{2T}, \end{cases}$$

where $T$ is the baud interval.

The terminal puts all pulse shaping at the transmitter. Therefore, the signal power input to the FM channel is:

$$p_s = \frac{\overline{a^2}}{2\pi T} \int_{-\infty}^{\infty} |X(w)|^2 dw$$

$$= \frac{35}{8} d^2,$$

where $\overline{a^2}$ is the average symbol power, $\overline{a^2} = 5d^2$.

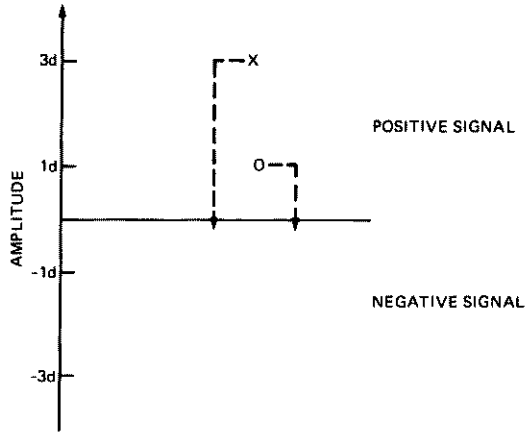

Fig. 15—Error occurrence in an odd-numbered DS-1 channel.

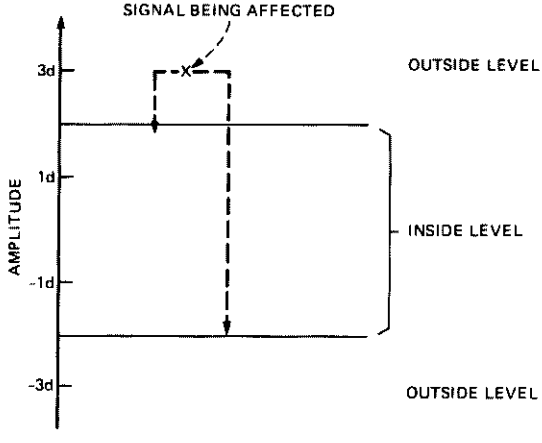

Fig. 16—Error occurrence of an outside-level signal in an even-numbered DS-1 channel.

The receiver detects the signal levels and places slicing levels at 0 and $\pm 2d$. An error occurs when the noise at a sampling time pushes the received signal amplitude (voltage) across the slicing levels. The slicing level drift due to noise is assumed insignificant. The probability of a signal being at one of the outside two levels equals that of being at one of the inside two levels. A signal at the outside level, or inside level, can only cross the zero level in one direction when the noise voltage $|y|$ exceeds $3d$ or $d$, respectively, as illustrated in Fig. 15. Therefore, the probability of error for an odd-numbered channel is:

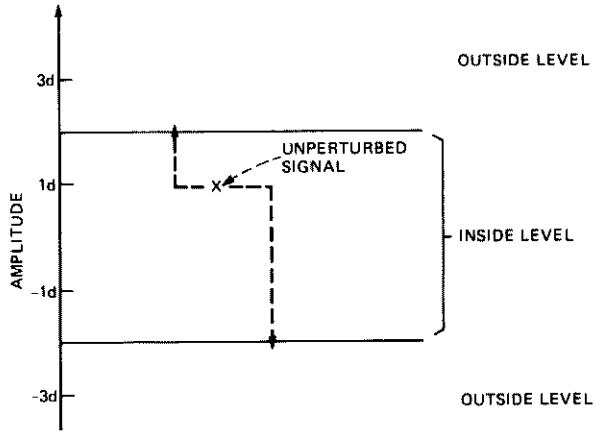

Fig. 17—Error occurrence of an inside-level signal in an even-numbered DS-1 channel.

$$p^{\text{odd}} = \tfrac{1}{2} \cdot \tfrac{1}{2}p(|y| > 3d) + \tfrac{1}{2} \cdot \tfrac{1}{2}p(|y| > d), \tag{1}$$

where $p(|y| > d)$ represents the probability of noise voltage exceeding $d$.

The probability of error for an even-numbered channel, $p^{\text{even}}$, can be derived similarly. The probability of a signal in the outside state is ½. For that signal to be in error, the noise in one direction only with a magnitude $|y|$,

$$5d > |y| > d$$

is required, as illustrated in Fig. 16. The probability of a signal in an inside level crossing a $\pm 2d$ slicing level is $p(|y| > d) - \tfrac{1}{2}p(3d > |y| > d)$, as shown in Fig. 17. Therefore,

$$\begin{aligned} p^{\text{even}} &= \tfrac{1}{4}p(5d > |y| > d) \\ &\quad + \tfrac{1}{2}p(|y| > d) - \tfrac{1}{4}p(3d > |y| > d) \\ &= \tfrac{1}{4}p(|y| > d) - \tfrac{1}{4}p(|y| > 5d) \\ &\quad + \tfrac{1}{2}p(|y| > d) \\ &\quad - \tfrac{1}{4}p(|y| > d) + \tfrac{1}{4}p(|y| > 3d) \\ &= \tfrac{1}{2}p(|y| > d) + \tfrac{1}{4}p(|y| > 3d) \\ &\quad - \tfrac{1}{4}p(|y| > 5d). \end{aligned} \tag{2}$$

This probability is easily computed since the noise at the receiver input is assumed Gaussian. The probability of noise voltage exceeding

$d$ is conveniently expressed in terms of the normal probability integral, $p(|y| > d) = 2Q\left(\frac{d}{\sigma}\right)$, where

$$Q(x) = \frac{1}{\sqrt{2\pi}} \int_x^\infty e^{-t^2/2}\, dt$$

and $\sigma$ is the root-mean-square (rms) noise voltage.

The signal to noise power ratio, $p_s/p_N$, can be expressed as

$$\frac{p_s}{p_N} = \frac{35d^2}{8\sigma^2}.$$

Hence, eqs. (1) and (2) become

$$p^{\text{odd}} = \frac{1}{2}\left\{Q\left[3\left(\frac{8X}{35}\right)^{1/2}\right] + Q\left[\left(\frac{8X}{35}\right)^{1/2}\right]\right\}$$

$$p^{\text{even}} = \frac{1}{2} Q\left[\left(\frac{8X}{35}\right)^{1/2}\right]\left\{1 - 2Q\left[5\left(\frac{8X}{35}\right)^{1/2}\right]\right\} + Q\left[\left(\frac{8X}{35}\right)^{1/2}\right] - \frac{1}{2} Q\left[\left(\frac{8X}{35}\right)^{1/2}\right]\left\{1 - 2Q\left[3\left(\frac{8X}{35}\right)^{1/2}\right]\right\},$$

where $X = \frac{p_s}{p_N}$.

A digital computer was used to compute the probabilities of error as a function of the baseband signal-to-noise ratio. Results are discussed in Section 4.2.

# An Experimental Broadband Imaging Feed

By T. S. CHU and R. W. ENGLAND*

(Manuscript received November 8, 1982)

*Imaging with Fresnel diffraction taken into account is applied to the design of a broadband narrow pattern feed. This feed is not only a basic building block of an imaging beam waveguide, but also essential for an offset reflector antenna of large effective F/D ratio. Furthermore, it can be used as a constant beamwidth radiometer antenna for multifrequency remote sensing. We have built and tested a practical example that consists of an offset ellipsoidal reflector and a corrugated horn. Measured amplitude and phase patterns agree with calculated results, which include truncation effects. Systematic design procedures are obtained for a given feed horn and the required reflector illumination. Necessary and sufficient conditions of the thin lens model are translated into design parameters of an offset ellipsoidal reflector with projected circular aperture. Geometrical relations of the offset ellipsoid and calculations of radiation patterns are described in the appendices.*

## I. INTRODUCTION

The successful performance of an offset dual-reflector antenna often depends upon illumination by a broadband feed with a narrow feed pattern.[1] For example, a broadband corrugated horn with the required pattern could be used, but it would be excessively long for most practical applications. Good illumination can also be achieved by a narrowband offset launcher,[2] which is essentially an offset reflector fed by a relatively short feed horn. Excellent 19/28.5 GHz dual-frequency performance was demonstrated by the Crawford Hill 7-meter antenna using a quasi-optical frequency diplexer to combine two narrowband offset launchers.[1] However, this approach is not usually cost effective, especially for lower frequency systems. In this paper we present design

* Now at AT&T Long Lines.

procedures for *broadband* offset launchers and comparisons between calculated and measured patterns of both amplitude and phase. These feeds represent a considerable simplification of the hardware, and thus improve the prospect for system application of offset dual-reflector antennas.

The following analysis will assume the thin lens approximation for an imaging offset reflector. It will also make use of the frequency insensitivity of the field distribution in the aperture of a corrugated horn.[3,4] The principles of imaging have been discussed previously in connection with frequency-independent far-field beamwidths,[5] and the laws of geometrical optics have been used for the design of imaging reflector arrangements.[6] However, broadband feed illumination for reflector antennas needs not only constant beamwidth, but also constant phase center. The condition for satisfying the latter requirement is obtained in this paper by an interpretation of the additional phase shift[7] due to Fresnel diffraction. The imaging laws of geometrical optics are thus modified to provide a theoretically frequency-independent design of offset-launcher feeds. However, the practical bandwidth will be limited by the corrugated horn and truncation effects. These effects will be examined by numerical calculations and experimental measurements.

The imaging feed discussed here has important potential for application in radio communication and other scientific explorations. Furthermore, the basic properties of single-stage imaging are of vital interest in the design of multistage-imaging beam waveguides.[8] One notes the difficulty of performing pattern measurements of a bulky beam waveguide assembly. Both single- and double-stage imaging are also special cases of a proposed technique[9] for broadband astigmatic compensation in which the image of a corrugated horn through two astigmatic lenses can be designed to produce a specified astigmatic illumination.

Section II will discuss the imaging feed within thin lens approximation. Section III will describe how to translate the design parameters from the thin lens model to a practical offset ellipsoidal reflector with the required projected circular aperture. Section IV will give comparisons between calculated and measured data for both amplitude and phase patterns of an experimental broadband imaging feed. Geometrical relations of an offset ellipsoid and a calculation of radiation patterns will be given in Appendices A and B, respectively.

## II. THIN LENS MODEL

It is well known that the aperture distribution of a corrugated horn with radius $a_0$ is the Bessel function $J_0\ (\alpha\rho/a_0)$.[3,4] The edge field vanishes when $\alpha = 2.405$. This normally occurs at the design frequency

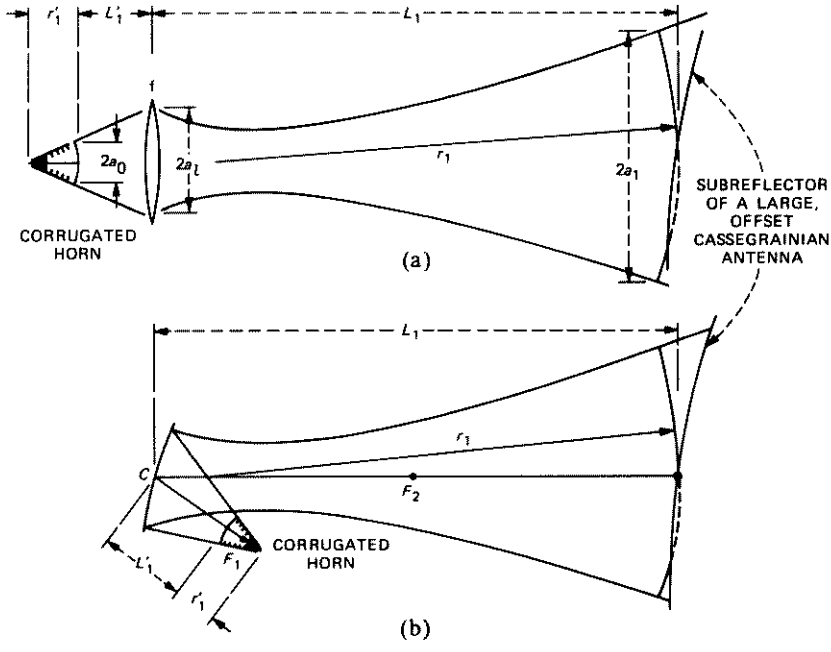

Fig. 1—Sketch of a broadband imaging feed. (a) Thin lens approximation. (b) Offset ellipsoidal reflector.

for resonant corrugations. However, $\alpha$ remains close to the above optimum value over a broad bandwidth if the aperture diameter is about five wavelengths or greater. If a magnified image of the corrugated-horn-aperture distribution is used to illuminate a reflector antenna, the illumination is expected to be a truncated Bessel function. For a specified reflector edge taper of $T$(in dB), the radius $a_r$ of the illumination circle at the reflector aperture should have a value satisfying

$$20 \log_{10} J_o(\alpha a_r / a_1) = -T, \tag{1}$$

where $a_1 = Ma_0$ is the magnified corrugated-horn-aperture radius. The magnification is given by

$$M = \frac{L_1}{L_1'}, \tag{2}$$

where $L_1$ *and* $L_1'$ are the distances of the illuminated reflector and the corrugated horn from the imaging lens, respectively, as shown in Fig. 1.

Now the focal length, $f$, of the imaging lens should obey the thin

lens formula:

$$\frac{1}{f}=\frac{1}{L_1}+\frac{L}{L_1'}. \tag{3}$$

Furthermore, the image-illumination phase-front radius of curvature $r_1$ can be expressed in terms of the feed-horn-aperture phase-front radius of curvature $r_1'$ as

$$\frac{1}{r_1}=\frac{1}{L_1}\left[1+\frac{L_1'}{L_1}\left(1+\frac{L'_1}{r_1'}\right)\right]. \tag{4}$$

Equation (4), which is the same as the relation for Gaussian beam imaging,[8,9] is essentially an alternative form of eq. (7) in Ref. 7. This equation represents the additional phase shift due to Fresnel diffraction.

Equation (4) shows that $r_1$ will be always less than $L_1$ if all parameters on the right side are positive. $r_1$ may become greater than $L_1$ for negative $r_1'$. One notes that $r_1'$ is always positive for any corrugated-feed horn unless modified by another lens or offset reflector. To obtain some feeling about the required physical spacings for a given pair of specified illumination and feed horn, normalized $L_1$ (with respect to $r_1$) has been plotted from eq. (4) versus normalized $L_1'$ (with respect to $r_1'$) for several ratios of $L_1'/L_1$ in Fig. 2. For a given pair of specified illumination and corrugated horn, i.e., $L_1'/L_1$, $r_1$ and $r_1'$ specified, it is also convenient to rearrange eq. (4), as follows:

$$\frac{L_1}{r_1}=\frac{1+\dfrac{L_1'}{L_1}}{1-\left(\dfrac{L_1'}{L_1}\right)^2\dfrac{r_1}{r_1'}}. \tag{5}$$

It is of interest to note a few special cases of eq. (4). The near-field gregorian configuration[6] corresponds to $r_1'=\infty$ in eq. (4). J. A. Arnaud's confocal feed reflector arrangement[10] is also a special case in which $r_1'=-L_1'$ and $r_1=L_1$. However, Arnaud assumed both constant beamwidth and constant phase center for the corrugated horn to obtain a frequency-independent aperture distribution at his first reflector.

If the radiation from a corrugated horn is approximated by a Gaussian beam, the $1/e^*$ beam radius at the horn aperture has been shown[5] to be $w_1'=0.64a_o$, where $a_o$ is the horn-aperture radius. Then

* Here $e=2.71828$, whereas $e$ represents eccentricity of a conic in the next section and appendices.

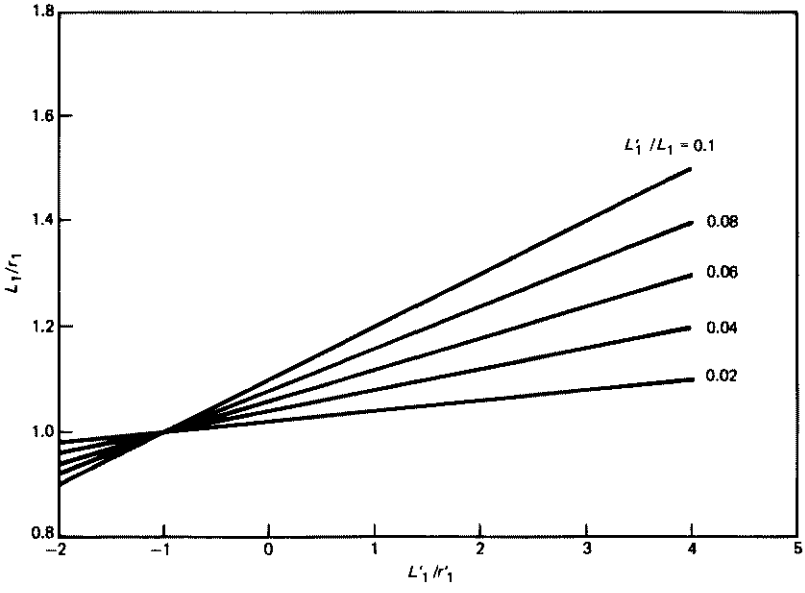

Fig. 2—Relation between image and object phase curvatures for various ratios of $L_1'/L_1$.

the Gaussian beam radius $w_2$ at the imaging lens can be found from[11]

$$w_2 = w_1' \sqrt{\left(\frac{L_1'}{r_1'} + 1\right)^2 + \left(\frac{\lambda L_1'}{\pi w_1'^2}\right)^2}. \tag{6}$$

The lens diameter should be 3.04 times the Gaussian beam radius $w_2$ for a truncation edge taper of $-20$ *dB*.

## III. OFFSET ELLIPSOIDAL REFLECTOR WITH PROJECTED CIRCULAR APERTURE

In practice, the thin lens will be approximated by an offset ellipsoidal reflector, as shown in Fig. 1(b). The distances from the center of the reflector to the two foci, $F_1$ and $F_2$, are, respectively, the incident and reflected phase-front radii of curvature. The incident phase-front radius of curvature can be obtained from the Gaussian beam propagation formula[11]

$$R_1 = L_1 \Bigg/ \left[ 1 - \frac{\dfrac{L_1'}{r_1'} + 1}{\left(\dfrac{L_1'}{r_1'} + 1\right)^2 + \left(\dfrac{\lambda L_1}{\pi w_1'^2}\right)^2} \right]. \tag{7}$$

If the offset ellipsoid is in the far zone of the horn, $R_1$ becomes the distance $CF_1$ from the phase center of the horn to the center of the reflector. The thin lens formula yields $R_2 = CF_2$, the reflected phase-front radius of curvature

$$\frac{1}{R_1} + \frac{1}{R_2} = \frac{1}{f}. \tag{8}$$

The frequency-dependent $R_1$ and $R_2$ are often not the same as $L_1$ and $L_1'$ in eq. (3). The equivalent focal length $f$ is identical to that in eq. (3). It has been shown[8] that the second-order terms of the offset ellipsoidal surface are only functions of $f$ and the angle of incidence, whereas the third-order terms are also dependent upon $R_1$ and $R_2$.

The design of an offset ellipsoidal reflector with oversized aperture of rectangular shape was discussed in Ref. 8. Since corrugated feed horns and required reflector illuminations are often of circular shape, we shall now describe the design of offset ellipsoidal reflectors with projected circular apertures.

The intersection of an ellipsoid and a circular cone subtended at one focus is a plane ellipse subtended by another circular cone at the other focus[1] (see Appendix A for proof and other geometrical relations). However, the two circular cone axes do not intersect the ellipsoid at the same point. In an ideal approximation of the thin lens by an offset ellipsoidal reflector, one would like to have both beam axes of the incident and reflected beams intersect the ellipsoid at the center of the offset reflector. This condition can be approximately realized by locating the intersection of $R_1$ and $R_2$ midway between the intersections 0 and 0′ of two circular cone axes with the ellipsoid, as shown in Fig. 3, i.e.,

$$R_1(\theta_{p1} - \theta_o) = R_2(\theta_o' - \theta_{p2}), \tag{9}$$

where

$$\frac{\sin \theta_{p1}}{\sin 2\theta_i} = \frac{R_2}{\sqrt{R_1^2 + R_2^2 - 2R_1R_2\cos 2\theta_i}} \tag{10}$$

and

$$\frac{\sin \theta_{p2}}{\sin 2\theta_i} = \frac{R_1}{\sqrt{R_1^2 + R_2^2 - 2R_1R_2\cos 2\theta_i}}. \tag{11}$$

$\theta_o$ and $\theta_o'$ are defined in Appendix A. We also need the expressions for the eccentricity, $e$, and the distance, $f_o$, between the vertex and the near focus:

$$f_o = \frac{|R_1 + R_2| - \sqrt{R_1^2 + R_2^2 - 2R_1R_2\cos 2\theta_i}}{2} \tag{12}$$

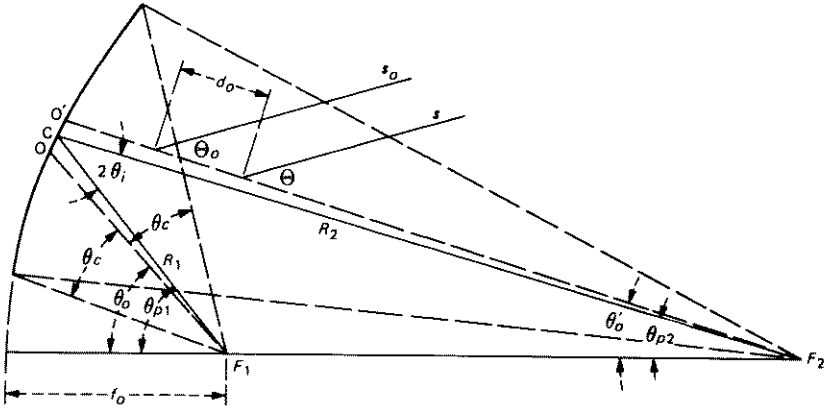

Fig. 3—Schematic diagram of an offset ellipsoidal reflector.

$$e = 1 - \frac{2f_o}{|R_1 + R_2|}. \tag{13}$$

Now the minor radius of the plane ellipse in eq. (23) should be equal to the radius of the projected circular aperture in the beam direction. (i.e., the thin lens aperture radius)

$$\rho_{\text{major}}\sqrt{1 - e^2\sin^2\theta_{po}} = a_l. \tag{14}$$

Substituting eqs. (20) and (22) into eq. (14), we obtain

$$e^2\cos^2\theta_o + 2e\cos\theta_c\cos\theta_o + 1 - \sin^2\theta_c\left[e^2 + \frac{(1+e)^2f^2}{a_l^2}\right] = 0. \tag{15}$$

When we are given an angle of incidence, $\theta_i$, and a pair of radii of curvature, $R_1$ and $R_2$, eqs. (9) and (15) can be solved simultaneously for numerical values of $\theta_o$ *and* $\theta_c$. These parameters completely determine both the shape and size of the ellipsoid.

## IV. NUMERICAL AND MEASURED RESULTS

To demonstrate practical feasibility of the proposed imaging feed design, we have built and tested an experimental broadband offset launcher. This feed was designed to provide the illumination required for the hyperboloidal subreflector of the Crawford Hill 7-meter offset cassegrainian antenna.

Following the method of Section II, we obtain parameters for the thin lens model of this experimental feed, as listed in Table I. Using the procedures described in Section III, we translated the lens parameters into dimensions of an offset ellipsoid, as shown in the schematic diagram of Fig. 3. A design frequency of 22 GHz was used in eqs. (7) and (8) to find $R_1$ and $R_2$, as shown in Table II.

Table I—Design parameters of the thin lens model for a broadband imaging feed (all lengths are in cm.)

| | |
|---|---|
| Required −15 dB illumination circle radius | 47.5 |
| Required phase-front radius of curvature | 535.9 |
| Frequency band (GHz) | 19/28.5 |
| Corrugated horn aperture radius, $a_0$ | 3.8 |
| Horn apex to aperture distance, $r_1'$ | 15.9 |
| Horn aperture to imaging lens distance, $L_1'$ | 47.5 |
| Imaging lens to subreflector distance, $L_1$ | 684.6 |
| Lens focal length, $f$ | 44.5 |
| Lens radius (truncation edge taper $\approx$ 20 $dB$) | 21 |
| Lens to phase-center distance, $\Delta$ | 148.7 |

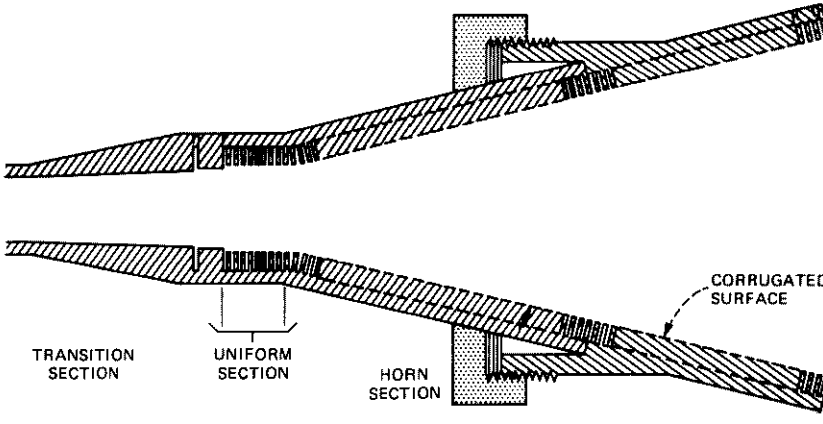

Fig. 4—Corrugated horn geometry.

A sketch of the corrugated horn is shown in Fig. 4. The corrugation depth is about a quarter wavelength at 18 GHz. The steps between smooth and corrugated sections help impedance matching because the desirable $HE_{11}$ mode in the corrugated guide is concentrated toward the center of the cross section. The return loss of the horn is better than 20 dB for frequencies above 16 GHz. The E- and H-plane beamwidths are nearly identical to each other from 16 to 30 GHz.

Figure 5 shows a photograph of the combination of offset ellipsoidal reflector and corrugated horn. Amplitude and phase patterns have been measured in both the offset plane and the transverse plane orthogonal to the offset. Since the phase center is located about 1.5 m from the center of the offset ellipsoid, physical rotation around the phase center would cause problems of mechanical unbalance. Therefore, the center of rotation in the pattern measurements is located midway between the ellipsoid and the phase center. The measured data can be transformed into measured patterns around the phase center by the relations between the angles of rotation and between the path lengths.

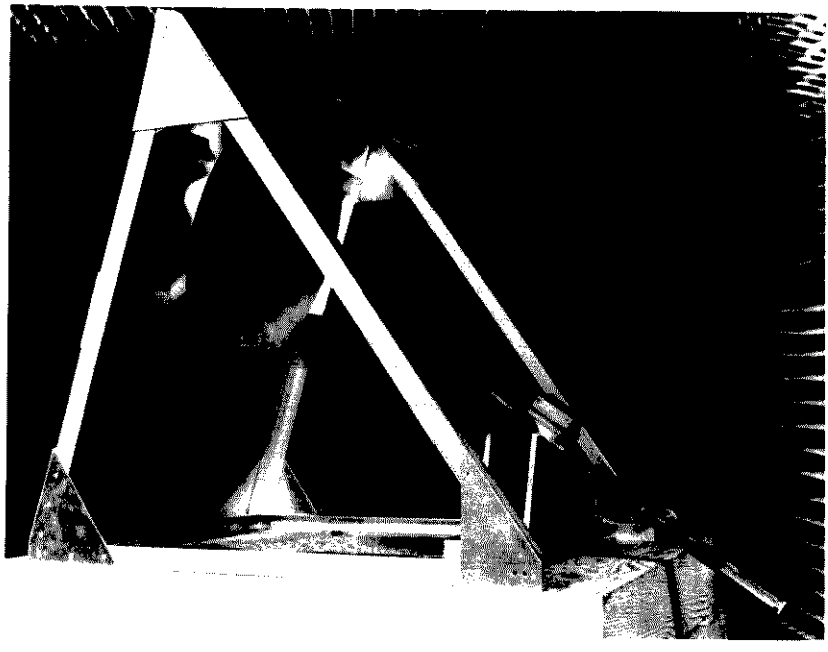

Fig. 5—Experimental broadband imaging feed.

Table II—Design parameters of the offset ellipsoidal reflector (all lengths are in cm.)

| | |
|---|---|
| Incident phase-front radius of curvature $R_1$ | 54.36 |
| Reflected phase-front radius of curvature $R_2$ | 244.22 |
| Angle of incidence, $\theta_i$ | 17° |
| Angle between incident center ray and major ellipsoidal axis, $\theta_{p1}$ | 42.68° |
| Angle between reflected center ray and major ellipsoidal axis, $\theta_{p2}$ | 8.68° |
| Offset angle, $\theta_o$ | 41.87° |
| Half-cone angle, $\theta_c$ | 22.09° |
| Offset angle at the distant focus, $\theta_o'$ | 8.86° |
| Vertex to near focus distance, $f_o$ | 48.56 |
| Eccentricity, $e$ | 0.67475 |
| Semi-major-axis of plane ellipse, $\rho_{major}$ | 21.98 |
| Semi-minor-axis of plane ellipse, $\rho_{minor}$ | 21 |
| Semi-major-axis of ellipsoid, $a$ | 149.29 |
| Semi-minor-axis of ellipsoid, $b$ | 110.18 |

The two equations below

$$\sin \Theta = \frac{s_o}{s} \sin \Theta_o \tag{16}$$

$$s = \sqrt{s_o^2 + d_o^2 - 2s_o d_o \cos \Theta_o} \tag{17}$$

are similar to eqs. (32) and (31). The parameters are explained in Fig. 3. The angular conversion of eq. (16) will be required in both

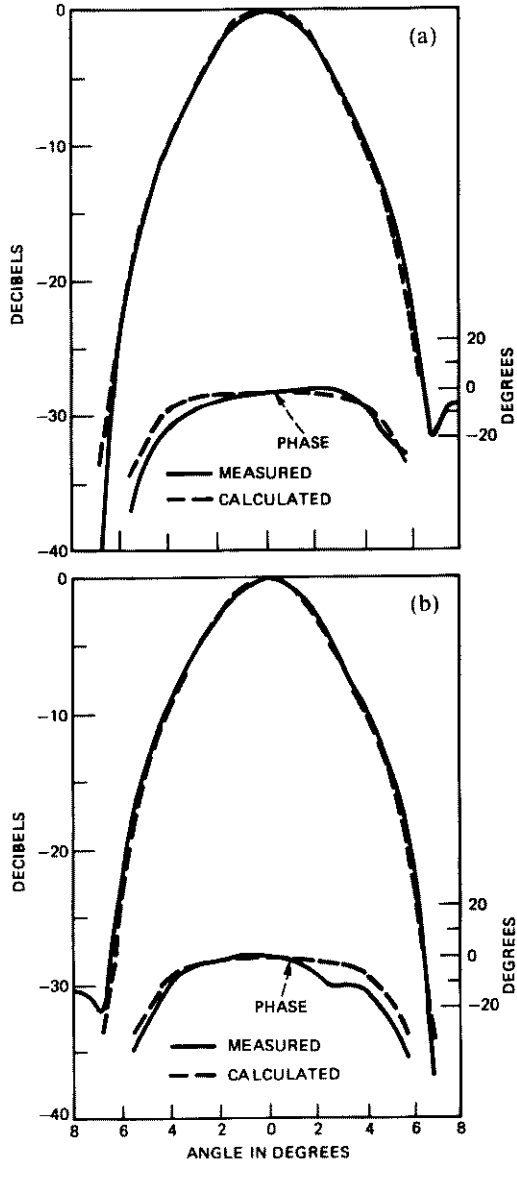

Fig. 6—19-GHz radiation pattern of transverse polarization (transverse perpendicular to offset) in (a) offset plane and (b) transverse plane.

amplitude- and phase-pattern transformations, whereas another factor of $(s + d_o - s_o)$ will be also added to the measured phase pattern.

To ensure reliable phase data, all pattern measurements were made in the azimuthal plane where a rotary joint can be used for avoiding

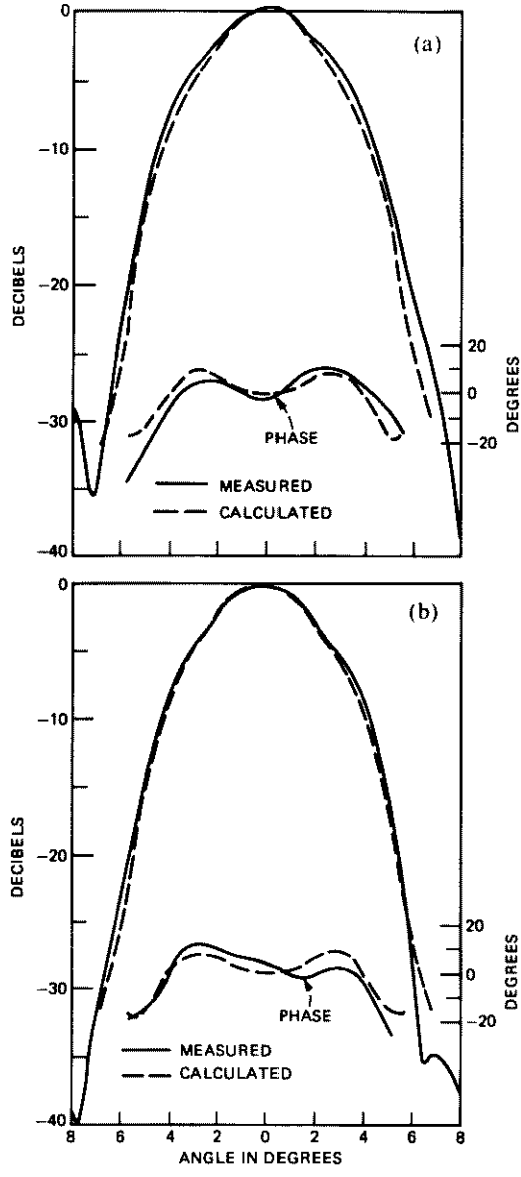

Fig. 7—23-GHz radiation pattern of transverse polarization (transverse perpendicular to offset) in (a) offset plane and (b) transverse plane.

cable motion during rotation of the turntable. Care was taken in keeping the same center of rotation by flipping over the feed assembly between measuring the transverse plane and offset plane cuts.

Calculations of radiation patterns are described in Appendix B. Both

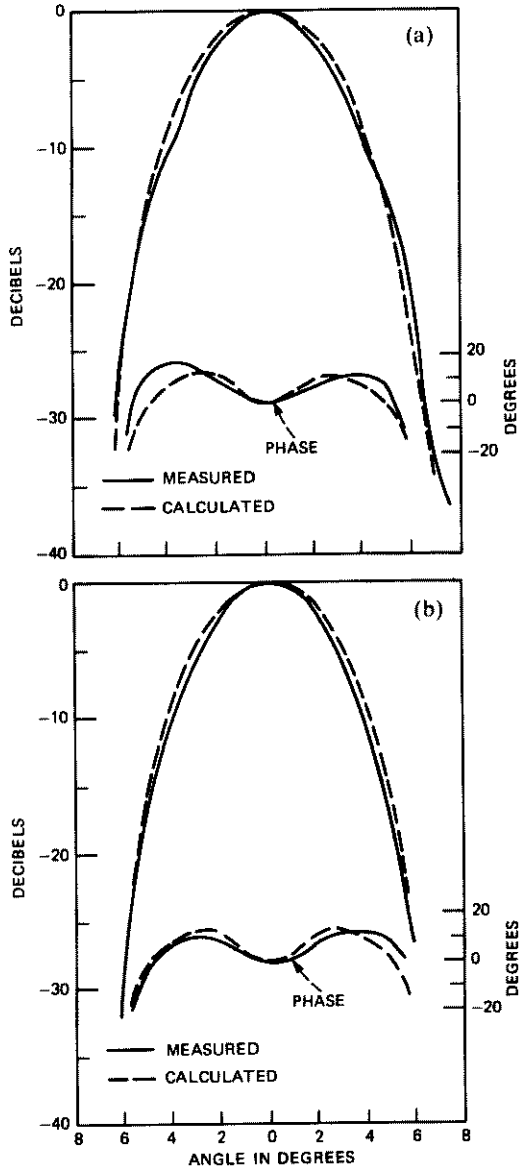

Fig. 8—28-GHz radiation pattern of transverse polarization (transverse perpendicular to offset) in (a) offset plane and (b) transverse plane.

measured and calculated patterns around the phase center are shown in Figs. 6, 7, and 8 for 19, 23, and 28 GHz, respectively. Comparisons between measured and calculated data show generally good agreement for both amplitude and phase patterns. An ideal imaging feed would

have a frequency-independent amplitude pattern of −15 dB taper at 5 degrees and a straight-line phase pattern that represents an exact spherical wave originating from a point source at the phase center. Deviations from these ideal patterns can be attributed to the imperfection of the paraxial approximation and to the truncation effect. Measured patterns also include the effect of deviation of the corrugated-horn-aperture field from the theoretical model. Figures 6 through 8 show that 28-GHz measured pattern widths are slightly narrower than those of 19 GHz. Phase deviations remain less than 20 degrees. These results are very similar to those of a long broadband corrugated horn designed for constant beamwidth feed.

The patterns in Figs. 6 through 8 were measured with the polarization transverse to the offset plane. Measurements with the polarization parallel to the offset plane showed similar patterns. Cross-polarized pattern measurements showed a maximum cross polarization of −26 dB, which is what would be expected from the offset geometry.[12]

## V. DISCUSSIONS

Theoretical and experimental studies have demonstrated the feasibility of a broadband imaging feed using the combination of an offset ellipsoid and a corrugated horn. This feed is also important for serving as a basic building block of the imaging beam waveguide.

Since a broadband feed design will avoid the need of quasi-optical frequency diplexing, a much simpler, cost-effective feed system can be built to achieve performance similar to that of the 19/28.5 GHz feed of the Crawford-Hill 7-meter antenna.

The application of imaging of a corrugated horn by an offset ellipsoidal reflector is certainly not limited to broadband narrow feed patterns for large ground station antennas. For example, Dragone suggests[13] its application to terrestrial microwave repeater antennas. Furthermore, it can be used as a constant beamwidth radiometer antenna for multifrequency remote sensing.

## APPENDIX A

### *Geometry of Offset Ellipsoids*

The geometrical properties of offset ellipsoids can be generalized from those[14] of offset paraboloids. The following formulas are derived by lengthy but straightforward algebra. The intersection of an offset ellipsoid and a circular cone subtended at the focus is a plane ellipse, which is subtended by another circular cone at the other (distant) focus. This property was indicated in Ref. 1, and also observed later in Ref. 15.

Let us define the ellipsoid in Figure 9 by

$$r = \frac{(1 + e) f_o}{1 + e \cos \theta_p}, \tag{18}$$

where the eccentricity, $e$, is less than unity. $f_o$ is the distance between the origin in $X_p Y_p Z_p$ coordinates and the vertex, and $\theta_p$ is the polar angle with respect to the $Z_p$ axis. We first find the intersection between the ellipsoid and the $x_o y_o$ plane, which is perpendicular to $x_p z_p$ plane, located at a distance $r_o$ from the origin, and its normal makes an angle $\theta_{po}$ with the $Z_p$ axis:

$$(1 - e^2 \sin^2 \theta_{po}) \left\{ x_o - \frac{e(\sin \theta_{po})}{1 - e^2 \sin^2 \theta_{po}} [(1 + e) f_o - e r_o \cos \theta_{po}] \right\}^2 + y_o^2 = \frac{[e r_o \cos \theta_{po} - (1 + e) f_o]^2}{1 - e^2 \sin^2 \theta_{po}} - r_o^2. \tag{19}$$

Next, the following expressions are found for $\theta_{po}$ and $r_o$:

$$\theta_{po} = \sin^{-1} \left( \frac{\sin \theta_o}{\sqrt{1 + 2e \cos \theta_o \cos \theta_c + e^2 \cos^2 \theta_c}} \right) \tag{20}$$

$$r_o = \frac{(1 + e) f_o \cos \theta_c}{\sqrt{1 + 2e \cos \theta_o \cos \theta_c + e^2 \cos^2 \theta_c}}, \tag{21}$$

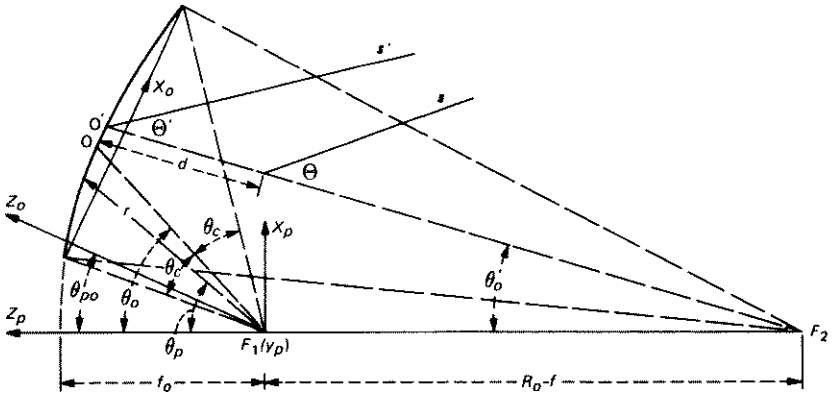

Fig. 9—Geometry of an offset ellipsoid subtended by circular cones at two foci.

where $\theta_o + \theta_c$ and $\theta_o - \theta_c$ are the polar angles of the top and bottom edges of the offset ellipsoid in the $x_p z_p$ plane. Now it can be shown that the intersection of the $x_o y_o$ plane with the circular cone, which has its axis oriented at $\theta_p = \theta_o$ and a half cone angle of $\theta_c$, is the same ellipse as represented by eq. (19).

The major and minor radii of the ellipse are

$$\rho_{\text{major}} = \frac{(1+e) f_o \sin\theta_c \sqrt{1 + 2e\cos\theta_o \cos\theta_c + e^2\cos^2\theta_c}}{1 + 2e\cos\theta_o\cos\theta_c + e^2\cos^2\theta_c - e^2\sin^2\theta_o} \tag{22}$$

$$\rho_{\text{minor}} = \rho_{\text{major}} \sqrt{1 - e^2\sin^2\theta_{po}}. \tag{23}$$

When $e = 1$, the above equations are reduced to those of Appendix A in Ref. 14. One notes an error in eq. (50) for the plane ellipse in Ref. 14, i.e., missing a term $(r_o \tan\theta_{po})$ in the bracket on the left-hand side of that equation.

The axis of the circular cone subtended at the second (distant) focus is oriented with respect to the major axis of the ellipsoid at

$$\theta'_o = \frac{1}{2}\left\{\sin^{-1}\left[\frac{r_2}{R_o + f_o - r_2}\sin(\theta_o + \theta_c)\right] + \sin^{-1}\left[\frac{r_1}{R_o + f_o - r_1}\sin(\theta_o - \theta_c)\right]\right\}, \tag{24}$$

where

$$r_{1,2} = \frac{(1+e) f_o}{1 + e\cos(\theta_o \mp \theta_c)} \tag{25}$$

are the radial distances from the (near) focus to the termini of the major axis of the ellipse represented by eq. (19) and

$$R_o = f_o\left(\frac{1+e}{1-e}\right) \tag{26}$$

is the distance from the vertex to the second focus.

## APPENDIX B

### *Calculation of Radiation Pattern*

In this appendix we shall calculate the radiation pattern of an offset ellipsoid illuminated by a corrugated feed horn. The numerical integration of the diffraction integral accomplishes computer simulation of the hardware.

When an ellipsoid is illuminated by a feed located at the near focus, the geometrical optic rays reflected from the ellipsoid are expected to converge toward the distant focus. Although the diffraction effect will take place before reaching that second focus, the ray approximation should be valid in the vicinity of the ellipsoid. To find the radiation from the ellipsoid, we will employ a spherical wave field in an equivalent plane aperture that is perpendicular to the axis of, and subtended by, the cone of reflected rays, and passes through the point, O′, of intersection of the centric reflected ray with the ellipsoid. The radius of curvature of the spherical wave is the distance, $R'_o$, from the distant focus to the point O′.

$$R'_o = \frac{(1+e)f_o}{1 - e\cos\theta'_o} \tag{27}$$

The transverse cartesian coordinates in the plane aperture are

$$\begin{cases} x = R(\cos\theta_o\sin\theta\cos\phi + \sin\theta_o\cos\theta)\cos\theta'_o \\ \qquad - [R(-\sin\theta_o\sin\theta\cos\phi + \cos\theta_o\cos\theta) + R_o - f]\sin\theta'_o \\ y = R\sin\theta\sin\phi, \end{cases} \tag{28}$$

where

$$R = \frac{(1+e)f_o}{1 + e(\cos\theta_o\cos\theta - \sin\theta\sin\theta_o\cos\phi)} \tag{29}$$

is the position radius from the focus to the ellipsoid. $\theta$ and $\phi$ are the standard spherical coordinates with the polar axis $F_1O$ along the axis of the circular cone subtended at the near focus, as shown in Fig. 9.

Using a small angle scalar approximation, we can determine the radiation of the offset ellipsoid as

$$E = \frac{je^{-jk(s+d)}}{\lambda(s+d)}\int\frac{F}{R}\exp\left\{jk\left[x\sin\Theta'\cos\Phi + y\sin\Theta'\sin\Phi + \frac{x^2+y^2}{2R'_o} - \frac{x^2+y^2}{2(s+d)} + (s+d-s')\right]\right\}dA, \tag{30}$$

where $F$ is the feed pattern, which will be described later. The term $(x^2 + y^2)/2(s + d)$ is a phase correction needed for the Fresnel region in which the Cassegrainian subreflector is located. The factor $(s + d - s')$ is added to give a phase pattern with respect to the phase center, which is located at a distance $d$ in front of the ellipsoid. $s$ is the distance between the phase center and the field point, and $s'$ is the distance between the point O', which is the effective center of the ellipsoid aperture, and the field point

$$s' = \sqrt{s^2 + d^2 + 2sd \cos \Theta}. \tag{31}$$

The angle $\Theta'$, between $s'$ and the cone axis $O'F_2$, is related by the sine law to the angle $\Theta$ between $s$ and the cone axis, as shown below:

$$\sin \Theta' = \frac{s}{s'} \sin \Theta. \tag{32}$$

$\phi$ is the azimuth coordinate of the field point. The surface element $dA$ is

$$dA = \frac{R^2 \sin \theta d\theta d\phi}{\cos \theta_i} \cos \theta_r, \tag{33}$$

where $\theta_i$ is the angle of incidence between the incident ray and the unit vector normal to the ellipsoidal surface, and $\theta_r$ is the angle between this unit normal and the beam axis. Since the ellipsoids under consideration are only slight perturbations of paraboloids, $\cos \theta_i \approx \cos \theta_r$. Noting the symmetry of the aperture field, eq. (30) becomes

$$E = \frac{je^{-jk(s+d)}}{\lambda(s + d)} \int_o^{\pi} \int_o^{\theta_c} F \exp jk \left[ x \sin \Theta' \cos \Phi + \frac{x^2 + y^2}{2R'_o} - \frac{x^2 + y^2}{2(s + d)} + (s + d - s') \right] \cos[ky \sin \Theta' \sin \Phi] R \sin \theta d\theta d\phi. \tag{34}$$

The feed pattern of a corrugated horn is given by

$$F(\Theta') = \int_0^1 J_o(\alpha r) J_o \left( ka \sin \theta' \frac{R}{R'} r \right) e^{-jk\left[ ar \tan \frac{\beta}{2} + \frac{(ar)^2}{2R'} + \ell(1 - \cos \theta') \right]} r dr, \tag{35}$$

where $a$ is the aperture radius, $\beta$ is the half cone angle of the horn, $\alpha = 2.405$ for frequencies close to the resonance of the corrugated depth, $r$ is the normalized radial coordinate of the horn aperture, and $\sin \theta'$ is multiplied by $R/R'$ because $\theta'$ is referred to the ellipsoid focus (the phase center of the horn), which is located at a distance $\ell$ behind the horn aperture. $R'$ is the distance from the center of the horn aperture to a point on the ellipsoid:

$$R' = \sqrt{R^2 + \ell^2 - 2R\ell \cos \theta'}. \tag{36}$$

The first term $kar^2\tan(\beta/2)$ in the exponential bracket of eq. (35) is the phase deviation in the horn aperture, the second term is a phase correction in the Fresnel region, and the third term is added to give a phase pattern with respect to the horn phase center (ellipsoidal focus) instead of the horn aperture.

To compensate for the difference in length between the radii from the focus toward the top and bottom edges of the offset ellipsoid, the axis of the feed horn is offset by an angle $\theta_1$ from the axis of the circular cone subtended by the ellipsoid at the focus. $\theta'$ can be expressed in terms of the angular coordinates $(\theta, \phi)$ of the offset ellipsoid:

$$\cos\theta' = \cos\theta\cos\theta_1 + \sin\theta\sin\theta_1\cos\phi. \tag{37}$$

$\theta_1 = 1.6$ degrees is used in the calculated patterns of Figs. 6, 7, and 8.

# An M/G/1 Queue With a Hybrid Discipline

By B. T. DOSHI

(Manuscript received October 27, 1982)

*In this paper we analyze the delay in a single-server queue in which the server, when it becomes free, selects for the next service the oldest customer with current delay smaller than T. If no such customer is present, then it selects the youngest customer with the current delay in excess of T. This service discipline is desirable in applications where the success or failure of a service depends on the delay in providing the service. Telephone call processing and steel rolling are two of these applications. We obtain the delay distribution for this service discipline using a combination of level-crossing arguments and renewal theory, and compare this performance with that of the last-in-first-out discipline with respect to the throughput of successfully served customers.*

## I. INTRODUCTION

The following situation is common in telephone call processing or data-processing systems. When a customer requests service, an entry is made in the queue that is serviced by a processor. The processor serves the queue of entries according to some specified service discipline. When an entry is served, the corresponding customer is notified of the completion of the service. The customer, however, does not wait forever for the completion of the service. At some random time, $R$, after its arrival, the customer will renege if service is not completed. The associated entry remains in the queue, and the server does not know that the customer has reneged until after it completes the service and attempts to notify the customer. Such a service is wasted. The customer may make the situation worse by reattempts at getting the desired service, thereby increasing the load on the server. It is therefore necessary to keep the proportion of reneging customers as small as possible. This can be done by selecting an appropriate discipline.

In this paper we study a specific model of the above situation. In

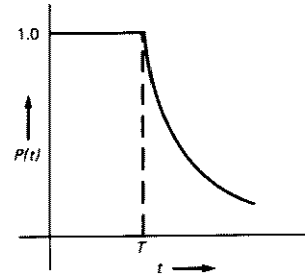

Fig. 1—Customer behavior function 1.

particular, we have a single-server queue with Poisson arrivals at rate $\lambda > 0$.

Let $G$ be the distribution of the service time. Let $\bar{P}(t)$ be the probability that the customer does not renege before time $t$. We may think of $\bar{P}(t)$ as the expected reward obtained by completing the service of a customer at $t$ time units after its arrival. With this general interpretation $\bar{P}(t)$ need not be restricted to be between 0 and 1. Let

$$P(t) = \int_{0^-}^{\infty} \bar{P}(t + y)dG(y) \tag{1}$$

for $0 \leq t < \infty$. Then $P(t)$ is the expected reward from a customer whose *waiting time* (excluding the service time) is $t$. Let $W_\pi$ be the distribution of the waiting time under the specified service discipline, $\pi$. Then the expected reward from an arbitrary customer is

$$V_\pi = \int_{0^-}^{\infty} P(t)dW_\pi(t). \tag{2}$$

We want to select a service discipline that maximizes $V_\pi$. It was shown in Doshi and Lipper[1] that if $P(t)$ is convex (respectively, concave), then the last-in-first-out (LIFO) [respectively, first-in-first-out (FIFO)] discipline is optimal. More realistic functions $P(t)$, however, are of the forms given in Figs. 1 and 2.

For such functions, $P(t)$, an optimal service discipline, is not known. However, our results for concave and convex $P(t)$ indicate that a hybrid discipline may provide better performance than either the FIFO or the LIFO discipline does. In this hybrid discipline the server, when it completes a service, first looks at the customers with the current waiting time less than $T$ and selects the oldest waiting customer for the next service. If no such customer is waiting, then the server looks at the customers with the current waiting time in excess of $T$ and selects the youngest customer. Note that this hybrid discipline includes FIFO ($T = \infty$) and LIFO ($T = 0$) as special cases. Since $P(t)$

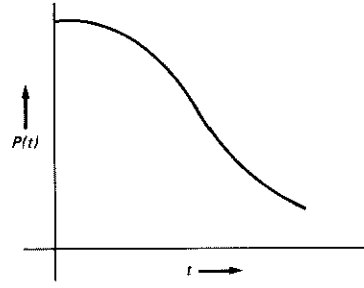

Fig. 2—Customer behavior function 2.

is assumed to be given, we only need $W_\pi(t)$, $0 \leq t < \infty$, for this hybrid discipline $\pi$, to calculate $V_\pi$. In this paper we obtain $W_\pi$ for general service time distribution. We do this in three steps. First we describe another queueing system for which the distribution of the waiting time is the same as for the original system. Moreover, for this equivalent queueing system the distribution of the waiting time can easily be expressed in terms of the distribution, $F(x)$, of the work in a subsystem. We then use level-crossing arguments to derive an integral equation satisfied by $f(x) = F'(x)$. Finally, we use some results from renewal theory to solve this integral equation.

Some comments about the model are in order before we proceed to give an outline of the rest of this paper. Models similar to the one studied here can be useful in a variety of other applications. Some of these are the management of steel-rolling operation and the management of blood bank. Also, in many applications the customers do not necessarily renege. They simply take actions (start to dial, become cold, etc.) which make any subsequent service worthless.

This paper is organized as follows: In Section II we formally define the queueing system under consideration. We describe an equivalent queueing system in Section III. There we also show the relationship between the distributions of the waiting time in the original system and of the work in a subsystem of the equivalent queueing system. In Section IV we derive an integral equation for the steady-state density of the work in the subsystem. We give the solution of this integral equation in Section V. There we also derive the steady-state distribution of the waiting time in the original system. Finally, we give some numerical results in Section VI.

## II. MODEL

The queueing system and the hybrid service discipline discussed in Section I can be formally described as follows: We have a queueing system with a single server and two queues, Q1 and Q2. Customers in

Q1 have a nonpreemptive priority over those in Q2. The order of service is first-in-first-out (FIFO) in Q1 and last-in-first-out (LIFO) in Q2. Customers arrive according to a Poisson process at rate $\lambda > 0$. On arrival the customer is put in Q1. If its service has not started within $T$ seconds after its arrival, then at that time it is transferred to Q2. The service times of the customers are independent and identically distributed with distribution function $G$ with continuous density $g$.

Let $\mu_K$ denote the $K$th moment of the service time and let $\rho = \lambda\mu_1$. Assume that the waiting-time process is in the steady state. Let $W$ denote the distribution function of the waiting time seen by an arbitrary customer. Since $G$ has a continuous density, $W$ is differentiable on $(0, \infty)$. Let

$$w(x) = W'(x) \qquad 0 < x < \infty.$$

We are interested in obtaining an expression for $W(x)$ or, equivalently, for $W(0)$ and $w(x)$, $0 < x < \infty$.

## III. AN EQUIVALENT QUEUEING SYSTEM

We now describe a queueing system that is equivalent to the one described in Section II as far as the waiting times of the customers are concerned. However, the number of customers in Q1 and Q2 at a given time may be different in the two systems.

Consider the subsystem consisting of the server and Q1. Let $X_t$ denote the work, at time $t$, in this subsystem. Thus, $X_t$ is the sum of the remaining service time of the customer, if any, being served and the service times of all the customers in Q1. If a customer arriving at time $t$ finds $X_t \leq T$, then it joins Q1; otherwise it joins Q2. Recall that Q1 has a nonpreemptive priority over Q2 and that Q1 is served FIFO and Q2 is served LIFO. A little reflection shows that the waiting time of a customer is the same in this system as in the one described in Section II.

We now relate the waiting-time distribution, $W$, to the steady-state distribution, $F$, of the work, $X$, in the subsystem consisting of the server and Q1. If an arriving customer sees $X \leq T$, then its waiting time will be $X$ because the service in Q1 is FIFO and because Q1 has a nonpreemptive priority over Q2. Thus,

$$W(x) = F(x) \qquad 0 \leq x \leq T. \tag{3}$$

In particular,

$$W(0) = F(0), \tag{4}$$

and

$$w(x) = f(x) = F'(x) \qquad 0 < x < T. \tag{5}$$

If an arriving customer sees $X > T$, then it joins Q2. Since Q1 has priority over Q2 and since Q2 is served LIFO, this customer has to wait for the duration of a busy period in the M/G/1 queue with initial work, $X$. Let $B_y$ denote the distribution of the busy period in the M/G/1 queue started by initial work, $y$. Since $G$ has a continuous density,

$$b_y(x) = B'_y(x) \tag{6}$$

exists for all $x > y$. Then

$$w(x) = \int_T^x f(y) b_y(x) d(y) \qquad x > T. \tag{7}$$

Thus, it is sufficient to find the distribution of $X$.

## IV. INTEGRAL EQUATION FOR $f(x)$

We now use level-crossing arguments (see Ref. 2) to derive an integral equation for $f$. Figure 3 shows a typical sample function for the process $\{X_t\}$. Assume that at time 0 the queues are empty, the server is idle, and a customer arrives and enters service. If $X_t > 0$, then it decreases at unit rate as in a M/G/1 queue. Symbols o represent arrivals which see $X_t \leq T$ and join the subsystem, thus increasing $X_t$ by a service time. A symbol in the shape of a dot (●) represents arrivals that see $X_t > T$, and join Q2 without affecting $X_t$ on their arrival. When $X_t$ reaches zero, two things can happen: Q2 is empty and the server remains idle until the next arrival, or Q2 is nonempty and a customer from Q2 enters service, thus increasing $X_t$ by its service time. Such arrivals from Q2 into the server are denoted by a symbol in the shape of a square (■).

The stochastic process $\{X_t\}$ is not Markovian because what happens

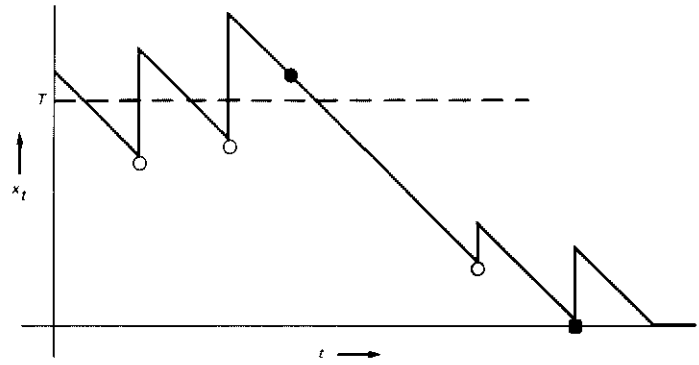

Fig. 3—Typical sample function for the process $\{X_t\}$.

when $X_t$ reaches zero depends on the past. On the other hand, the vector-valued process $\{(X_t, N_t)\}$, where $N_t$ is the number in Q2 at time $t$, is a Markov process. We can derive the steady-state distribution of $(X_t, N_t)$ using the standard results and use that to obtain the marginal steady-state distribution of $X$. We, however, use a simpler approach here. Recall that $\mu_2 < \infty$. Consider the following two cases:

(*i*) $\rho < 1$. In this case the process $\{X_t\}$ is regenerative and with the regeneration points corresponding to the external arrivals that make an idle server busy. Denote this event by E. Then E is a positive recurrent, regenerative event.

(*ii*) $\rho \geq 1$. In this case the queue length in Q2 grows without bound and, in the steady state, can be assumed to be $\infty$. Thus, a customer is removed from Q2 to enter service every time $X_t$ reaches 0. This event, E′, is then positive recurrent.

Standard regenerative arguments now show that $\{X_t\}$ has a steady-state distribution and that

$$X_t \xrightarrow{D} X,$$

where the distribution of $X$ is the steady-state distribution of $\{X_t\}$. Moreover, for any $x$, $0 < x < \infty$, the steady-state rate, $D(x)$, at which $X_t$ crosses $x$ from above, equals the rate $U(x)$, at which $X_t$ jumps from below $x$ to above $x$. We now express $D(x)$ and $U(x)$ in terms of $f(x)$ and get the desired integral equation by equating these expressions.

$X_t$ decreases at unit rate until an arrival occurs or until $X_t = 0$. Thus, during every downcrossing of level $x$, the $\{X_t\}$ process spends $dx$ units of time in the interval $(x - dx, x)$. Hence,

$$D(x) = f(x) \qquad 0 < x < \infty. \tag{8}$$

Before deriving an expression for $U(x)$ we introduce some notation. Let $p$ denote the rate at which $X_t$ jumps from 0 to some positive value. These jumps may be due to either external arrivals coming to an idle system or to customers from Q2 moving to the server. Also, let $\bar{G}$ denote the complementary service time distribution defined by

$$\bar{G}(x) = 1 - G(x) \qquad 0 \leq x < \infty. \tag{9}$$

Assume that $G(0) = 0$, $\bar{G}(0) = 1$. Then, for $x \leq T$

$$U(x) = \lambda \int_0^x f(y)\bar{G}(x - y)dy + p\bar{G}(x). \tag{10}$$

Since an external arrival causes a jump in $X_t$ only when $X_t \leq T$, we have, for $x > T$,

$$U(x) = \lambda \int_0^T f(y)\bar{G}(x - y)dy + p\bar{G}(x). \tag{11}$$

Thus,

$$U(x) = \lambda \int_0^{T \wedge x} f(y)\bar{G}(x-y)dy + p\bar{G}(x) \qquad 0 < x < \infty. \tag{12}$$

Let

$$f(0) = \lim_{x \downarrow 0} f(x). \tag{13}$$

Then $f(0)$ is the rate at which $\{X_t\}$ hits level zero. In the steady state, this must equal the rate at which $\{X_t\}$ jumps from 0 to some positive value. Thus

$$p = f(0). \tag{14}$$

We now have for $0 < \rho < \infty$, $0 < x < \infty$,

$$\begin{aligned} f(x) &= D(x) \\ &= U(x) \\ &= \lambda \int_0^{x \wedge T} f(y)\bar{G}(x-y)dy + f(0)\bar{G}(x). \end{aligned} \tag{15}$$

Let

$$q = \frac{f(0)}{\lambda}.$$

Then

$$f(x) = \lambda \int_0^{x \wedge T} f(y)\bar{G}(x-y)dy + q\lambda\bar{G}(x). \tag{16}$$

This is the desired integral equation for $f$. The additional conditions needed to solve this completely depend on whether $\rho < 1$ or $\rho \geq 1$.

First consider the case where $\rho < 1$. Let $P_2$ be the probability that an arriving customer sees $X_t > T$ and joins Q2. Since, for $\rho < 1$, every arriving customer is eventually served, the rate at which customers enter the server from Q2 is $\lambda P_2$. Also, the rate of arrivals coming to an empty system is $\lambda F(0)$. Thus,

$$q = \frac{f(0)}{\lambda} = \frac{\lambda[F(0) + P_2]}{\lambda} = F(0) + P_2. \tag{17}$$

Also,

$$P_2 = \int_T^{\infty} f(x)dx, \tag{18}$$

and

$$F(0) + \int_0^\infty f(x)dx = 1. \tag{19}$$

For $\rho \geq 1$, Q2 is always nonempty in steady state. Hence $F(0) = 0$,

$$q = \frac{f(0)}{\lambda}, \tag{20}$$

and

$$\int_0^\infty f(x)dx = 1. \tag{21}$$

Equation (16), together with either conditions [eqs. (17) to (19) or 20], characterizes $f$ completely. We solve this equation in the next section.

## V. SOLUTION OF THE INTEGRAL EQUATION

We now solve eq. (15) to obtain an expression for $f(x)$. For $0 < x < \infty$, let

$$h(x) = \lambda \bar{G}(x) \tag{22}$$

and let $m(x)$ be the renewal density function for $h(x)$. Then $m(x)$ satisfies (see Ref. 3):

$$m(x) = h(x) + \int_0^x h(x - y)m(y)dy. \tag{23}$$

Equation (15) can now be rewritten as

$$f(x) = qh(x) + \int_0^x f(x - y)h(y)dy \qquad (0 < x < T), \tag{24}$$

and

$$f(x) = qh(x) + \int_0^T f(y)h(x - y)dy \qquad T \leq x < \infty. \tag{25}$$

Equation (24) is a renewal equation and its solution is given by

$$\begin{aligned} f(x) &= qh(x) + q\int_0^x h(x - y)m(y)dy \\ &= q\left[h(x) + \int_0^x h(x - y)m(y)dy\right] \\ &= qm(x), \end{aligned} \tag{26}$$

where the last equality follows from (23). Note that $0 < h(x) < \infty$, and

$$\int_0^\infty h(x)dx = \lambda\mu_1 = \rho.$$

Thus, $h$ is like a probability density with total mass, $\rho$. The function $m(x)$ is well defined for any finite $x$ irrespective of the value of $\rho$, $0 < \rho < \infty$. To obtain an expression for $f(x)$, $x \geq T$, we note that the right-hand side of (25) involves $f(y)$ for $y$ only in the interval $(0, T)$, which we have obtained in (26). Thus, replacing $f(y)$ on the right-hand side of (25) by $qm(y)$, we get

$$f(x) = \left[ qh(x) + \int_0^T qm(y)h(x-y)dy \right]$$

$$= q\left[ h(x) + \int_0^T h(x-y)m(y)dy \right] \qquad x \geq T. \tag{27}$$

We now use conditions (17) through (19) or (20) through (21) to evaluate $q$ and thus completely characterize $f$. First, consider the case $\rho < 1$. We have

$$q = F(0) + P_2, \tag{28}$$

and

$$F(0) + q\int_0^T m(x)dx + P_2 = 1. \tag{29}$$

Also, equating the rate of customers coming to the system with the rate of customers leaving the system, we get

$$\lambda = \frac{1}{\mu_1}[1 - F(0)],$$

or

$$F(0) = 1 - \rho. \tag{30}$$

We can now solve (28) through (30) for $q$ and $P_2$ to get

$$P_2 = \frac{\rho - (1-\rho)\displaystyle\int_0^T m(x)dx}{1 + \displaystyle\int_0^T m(x)dx},$$

and

$$q = F(0) + P_2 = \frac{1}{1 + \int_0^T m(x)dx}.$$

Thus,

$$F(0) = 1 - \rho \tag{31}$$

$$f(x) = \frac{m(x)}{1 + \int_0^T m(x)dx} \qquad x < T \tag{32}$$

$$= \frac{h(x) + \int_{y=0}^{T} h(x-y)m(y)dy}{1 + \int_0^T m(x)dx} \qquad x \geq T. \tag{33}$$

Next, consider the case where $\rho \geq 1$. Here,

$$q = \frac{f(0)}{\lambda},$$

and

$$\int_0^T f(x)dx + \int_T^\infty f(x)dx = 1.$$

Thus,

$$f(0)\left\{\int_0^T m(x)dx + \rho\left[1 + \int_0^T m(x)dx\right] - \int_0^T m(x)dx\right\} = 1,$$

or

$$f(0) = \frac{1}{\rho\left[1 + \int_0^T m(x)dx\right]}, \tag{34}$$

$$f(x) = \frac{m(x)}{\rho\left[1 + \int_0^T m(x)dx\right]} \qquad x < T, \tag{35}$$

and

$$f(x) = \frac{h(x) + \int_0^T h(x-y)m(y)dy}{\rho\left[1 + \int_0^T m(x)dx\right]} \qquad x \geq T. \tag{36}$$

We now consider a special case where $\bar{G}(x) = e^{-\mu x}$, $\mu = 1/\mu_1$. Then,

$$h(x) = \lambda e^{-\mu x} \qquad 0 < x < \infty,$$

$$m(x) = \lambda e^{(\lambda-\mu)x} \qquad 0 < x < \infty,$$

$$1 + \int_0^T m(x)dx = \frac{1}{(1-\rho)}[1 - \rho e^{-\mu(1-\rho)T}],$$

and, for $x \geq T$,

$$\begin{aligned} h(x) + \int_0^T h(x-y)m(y)dy &= \lambda e^{-\mu x} + \lambda^2 \int_0^T e^{-\mu(x-y)} e^{-(\mu-\lambda)y} dy \\ &= \lambda e^{-\mu x} + \lambda^2 e^{-\mu x} \int_0^T e^{+\lambda y} dy \\ &= \lambda e^{-\mu x + \lambda T}. \end{aligned}$$

Thus, for $\rho < 1$

$$F(0) = 1 - \rho$$

$$f(x) = \frac{1-\rho}{1 - \rho e^{-\mu(1-\rho)T}} e^{-\mu(1-\rho)x} \qquad x < T,$$

and

$$f(x) = \frac{1-\rho}{1 - \rho e^{-\mu(1-\rho)T}} e^{-\mu x + \lambda T} \qquad x \geq T.$$

For $\rho \geq 1$

$$F(0) = 0,$$

$$f(x) = \frac{1-\rho}{\rho[1 - \rho e^{\mu(\rho-1)T}]} e^{\mu(\rho-1)x} \qquad x < T,$$

and

$$f(x) = \frac{1-\rho}{\rho[1-\rho e^{\mu(\rho-1)T}]} e^{-\mu x+\lambda T} \qquad x \geq T.$$

## VI. WAITING-TIME DISTRIBUTION

We now use the results of Section V to obtain an expression for the waiting-time distribution and its Laplace Stieltjes Transform. From eqs. (4), (5) and (6) we get

$$W(0) = F(0) = \begin{cases} 1-\rho & \rho < 1 \\ 0 & \rho \geq 1, \end{cases} \tag{37}$$

$$w(x) = f(x) = \begin{cases} \dfrac{m(x)}{\left[1 + \displaystyle\int_0^T m(x)dx\right]} & \rho < 1 \\ \dfrac{m(x)}{\rho\left[1 + \displaystyle\int_0^T m(x)dx\right]} & \rho \geq 1, \end{cases} \tag{38}$$

and

$$w(x) = \begin{cases} \dfrac{\displaystyle\int_T^x \left[h(y) + \int_0^T h(y-z)m(z)dz\right] b_y(x)dy}{1 + \displaystyle\int_0^T m(x)dx} & \rho < 1 \\ \dfrac{\displaystyle\int_T^x \left[h(y) + \int_0^y h(y-z)m(z)dz\right] b_y(x)dy}{\rho\left[1 + \displaystyle\int_0^T m(x)dx\right]} & \rho \geq 1. \end{cases} \tag{39}$$

Let

$$W^*(\theta) = E[e^{-\theta W}] = W(0) + \int_0^\infty e^{-\theta x} w(x)dx \qquad \text{Re } \theta > 0. \tag{40}$$

Also, for Re $\theta > 0$ let

$$g^*(\theta) = \int_0^\infty e^{-\theta x} g(x)dx \tag{41}$$

$$h^*(\theta) = \int_0^\infty e^{-\theta x} h(x)dx$$

$$= \frac{\lambda[1 - g^*(\theta)]}{\theta}, \tag{42}$$

and

$$m^*(\theta) = \int_0^\infty e^{-\theta x} m(x)dx$$

$$= \frac{h^*(\theta)}{1 - h^*(\theta)}$$

$$= \frac{\lambda[1 - g^*(\theta)]}{\theta - \lambda[1 - g^*(\theta)]}. \tag{43}$$

Let $B^*(\theta)$ be the Laplace Stieltjes Transform of the ordinary busy period in an M/G/1 queue with the arrival rate $\lambda > 0$ and the service distribution, $G$. Then $B^*$ satisfies

$$B^*(\theta) = g^*\{\theta + \lambda[1 - B^*(\theta)]\}. \tag{44}$$

Also, let $B_y^*(\theta)$ be the Laplace Stieltjes Transform of $B_y$. Then

$$B_y^*(\theta) = e^{-y\{\theta + \lambda[1 - B^*(\theta)]\}}. \tag{45}$$

We now express $W^*(\theta)$ in terms of $m$, $m^*$ and $B^*$. First, consider the case $\rho < 1$, where

$$W^*(\theta) = 1 - \rho + \frac{1}{1 + \int_0^T m(x)dx} \left\{ \int_0^T e^{-\theta x} m(x)dx \right.$$

$$\left. + \int_T^\infty e^{-\theta x} \int_{y=T}^x \left[ h(y) + \int_0^T h(y - z)m(z)dz \right] b_y(x)dydx \right\}$$

$$= 1 - \rho + \frac{1}{1 + \int_0^T m(x)dx} \left( \int_0^T e^{-\theta x} m(x)dx \right.$$

$$\left. + \frac{\theta}{\theta + \lambda[1 - B^*(\theta)]} \int_T^\infty e^{-\{\theta + \lambda[1 - B^*(\theta)]\}x} m(x)dx \right). \tag{46}$$

For $\rho > 1$,

$$W^*(\theta) = \frac{1}{\rho\left[1 + \int_0^T m(x)dx\right]}\left\{\int_0^T e^{-\theta x}m(x)dx + \frac{\theta}{\theta + \lambda[1 - B^*(\theta)]}\int_T^\infty e^{-[\theta+\lambda(1-B^*(\theta))]x}m(x)dx\right\}. \quad (47)$$

### 6.1 Mean value of the waiting time

Let $\bar{W}$ denote the mean value of the waiting time. For $\rho < 1$, every customer is eventually served. Hence, $\bar{W}$ is the average over all the customers. For $\rho > 1$, some of the arriving customers do not get served and, in this case, $\bar{W}$ is the average waiting time of those who do get served. In the first case,

$$\bar{W} = -W^{*\prime}(0^+),$$

and for the second case,

$$\bar{W} = \frac{-W^{*\prime}(0^+)}{W^*(0^+)}.$$

For $\rho < 1$, all customers are served and the order of service does not affect the mean waiting time. Thus, in this case the mean waiting time is the same as that for an M/G/1 queue with the FIFO discipline. That is,

$$\bar{W} = \frac{\lambda\mu_2}{2(1-\rho)}. \quad (48)$$

For $\rho > 1$, the busy period distribution is defective. Let

$$b_o = P\{\text{Busy period} < \infty\}.$$

Then $b_o$ is the unique solution in (0, 1) of

$$B^*(0^+) = b_o = g^*[\lambda(1 - b_o)]. \quad (49)$$

Also,

$$B^{*\prime}(0^+) = \frac{g^{*\prime}[\lambda(1-b_o)]}{1 + \lambda g^{*\prime}[\lambda(1-b_o)]} \quad (50)$$

and

$$B^{*\prime\prime}(0^+) = \frac{g^{*\prime\prime}[\lambda(1-b_o)]}{\{1 + \lambda g^{*\prime}[\lambda(1-b_o)]\}^3}. \quad (51)$$

Now, from eq. (47), we get

$$W^*(0^+) = \frac{1}{\rho\left[1 + \int_0^T m(x)dx\right]}$$

$$\cdot\left[\int_0^T m(x)dx + \frac{1}{\lambda(1-b_o)} \lim_{\theta\to 0^+} \int_T^\infty \theta e^{-\{\theta+\lambda[1-B^*(\theta)]\}x} m(x)dx\right]$$

$$= \frac{1}{\rho\left[1 + \int_0^T m(x)dx\right]}\left[\int_0^T m(x)dx + 1\right]$$

$$= \frac{1}{\rho} \tag{52}$$

and

$$-W^{*\prime}(0^+) = \frac{1}{\rho\left[1 + \int_0^T m(x)dx\right]}$$

$$\cdot\left\{\int_0^T xm(x)dx + \frac{1}{\lambda(1-b_o)}\left[1 + \int_0^T m(x)dx\right]\right\}$$

$$= \frac{1}{\rho}\left[\frac{\int_0^T xm(x)dx}{1 + \int_0^T m(x)dx} + \frac{1}{\lambda(1-b_o)}\right]. \tag{53}$$

From (52) and (53) we have

$$\bar{W} = \frac{-W^{*\prime}(0^+)}{W^*(0^+)} = \frac{\int_0^T xm(x)dx}{1 + \int_0^T m(x)dx} + \frac{1}{\lambda(1-b_o)}. \tag{54}$$

Equation (54) shows that the mean waiting time of the customers who get served is minimized by the LIFO discipline ($T = 0$).

## VII. NUMERICAL RESULTS

In this section we present some numerical results. Instead of calcu-

lating the waiting-time distribution, we calculate the quantity of interest, namely

$$V = \int_{0^-}^{\infty} P(t)dW(t)$$

for a specific $P$. Let

$$P(t) = \begin{cases} 1 & t \le T \\ e^{-\sigma(t-T)} & t > T. \end{cases} \tag{55}$$

We now evaluate $V$ for the hybrid discipline with parameter $T$ and also for the LIFO discipline. For the hybrid discipline we have

$$\begin{aligned} V_T = q \cdot \Bigg[ & \int_0^T m(x)dx + e^{\sigma T} m^*\{\sigma + \lambda[1 - B^*(\sigma)]\} \\ & \cdot (1 + h^*\{\sigma + \lambda[1 - B^*(\sigma)]\}) \\ & - e^{\sigma T}(1 + h^*\{\sigma + \lambda[1 - B^*(\sigma)]\}) \\ & \cdot \int_0^T m(y) e^{-y(\sigma+\lambda)[1-B^*(\sigma)]} dy \Bigg], \end{aligned} \tag{56}$$

where

$$q = \begin{cases} \dfrac{1}{1 + \displaystyle\int_0^T m(x)dx} & \rho < 1 \qquad (57) \\[2ex] \dfrac{1}{\rho\left[1 + \displaystyle\int_0^T m(x)dx\right]} & \rho > 1. \qquad (58) \end{cases}$$

We need some more notation before writing an expression for $V_L$. Let $b_{\mathrm{FR}}(\cdot)$ denote the density function for the busy period started by the forward recurrence time of the service time. Thus,

$$b_{\mathrm{FR}}(x) = \int_0^x b_y(x) \frac{1 - G(y)}{\mu_1} dy. \tag{59}$$

Then, for $\rho < 1$,

$$\begin{aligned} V_L &= 1 - \rho + \rho \int_0^T b_{\mathrm{FR}}(x) + \rho e^{\sigma T} \int_T^{\infty} e^{-\sigma x} b_{\mathrm{FR}}(x)dx \\ &= 1 - \rho + \rho \left[ \int_0^T b_{\mathrm{FR}}(x)dx - e^{\sigma T} \int_0^T e^{-\sigma x} b_{\mathrm{FR}}(x)dx \right] \\ &\quad + e^{\sigma T} \frac{\lambda[1 - B^*(\sigma)]}{\sigma + \lambda[1 - B^*(\sigma)]}, \end{aligned} \tag{60}$$

and, for $\rho > 1$,

$$V_L = \int_0^T b_{FR}(x)dx - e^{\sigma T}\int_0^T e^{-\sigma x}b_{FR}(x)dx + \frac{1 - B^*(\sigma)}{\mu_1\{\sigma + \lambda[1 - B^*(\sigma)]\}}. \tag{61}$$

For numerical calculations we considered all integrals in eqs. (56) through (58) and (60) through (61) as functions of $T$, obtained their Laplace transforms, and inverted the transform at the specified value of $T$ using the inversion method of D. Jagerman.[3] Thus, let

$$R_1(t) = \int_0^t m(x)dx,$$

$$R_2(t) = \int_0^t m(x)e^{-x(\sigma+\lambda[1-B^*(\sigma)])}dx,$$

$$R_3(t) = \int_0^t b_{FR}(x)dx,$$

and

$$R_4(t) = \int_0^t e^{-\sigma x}b_{FR}(x)dx.$$

Also, for $i = 1, 2, 3, 4$, and $\theta$ in the appropriate domain, let

$$R_i^*(\theta) = \int_0^\infty e^{-\theta t}R_i(t)dt.$$

Then

$$R_1^*(\theta) = \frac{m^*(\theta)}{\theta},$$

$$R_2^*(\theta) = \frac{m^*\{\theta + \sigma + \lambda[1 - B^*(\sigma)]\}}{\theta},$$

$$R_3^*(\theta) = \frac{1 - B^*(\theta)}{\theta\{\theta + \lambda[1 - B^*(\theta)]\}},$$

and

$$R_4^*(\theta) = \frac{1 - B^*(\theta + \sigma)}{\sigma + \theta + \lambda[1 - B^*(\theta + \sigma)]}.$$

For numerical examples we had the service time distribution gamma with mean 1 and variance $1/K$. We used two different values of $K$, $K = 1$ (exponential distribution), and $K = 10$. We used two different

values of $T$, 1 and 3. Finally, we used two values of $\sigma$, 2.0 and 0.15. These give us eight parameter sets. The values of $V_T$ and $V_L$ as functions of the load $\lambda = \rho$ are given in Figs. 4 through 11. From these figures we observe:

(*i*) For both service disciplines, the throughput of good calls is larger for larger $T$, smaller $\sigma$, and larger $K$. The behavior of the throughput with respect to $T$ and $\sigma$ is obvious. Larger $K$ implies smaller variability in the service time, thus reducing the probability of a customer getting served after a long wait. This, in turn, results in a higher throughput.

(*ii*) For the assumed customer behavior, the hybrid discipline always provides higher throughput than the LIFO discipline does. The difference is larger for larger $T$, larger $\sigma$, and larger $K$.

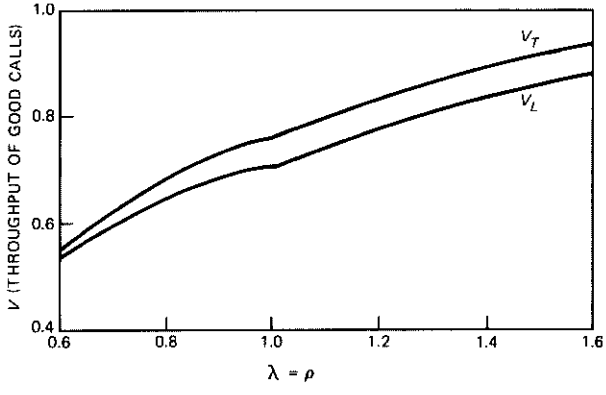

Fig. 4—The values $V_T$ and $V_L$ as functions of the load $\lambda = \rho$ for $T = 3.0$, $\sigma = 2.0$, and $K = 1$.

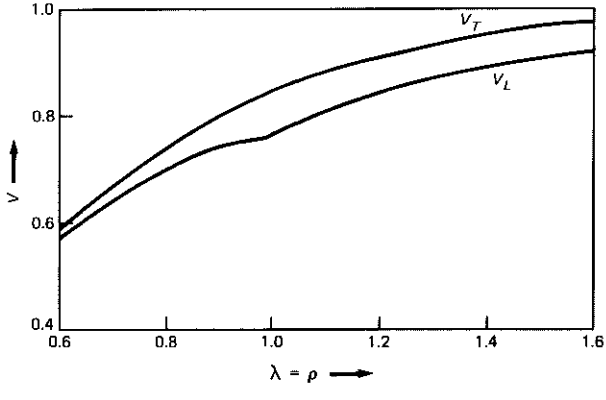

Fig. 5—The values $V_T$ and $V_L$ as functions of the load $\lambda = \rho$ for $T = 3.0$, $\sigma = 2.0$, and $K = 10$.

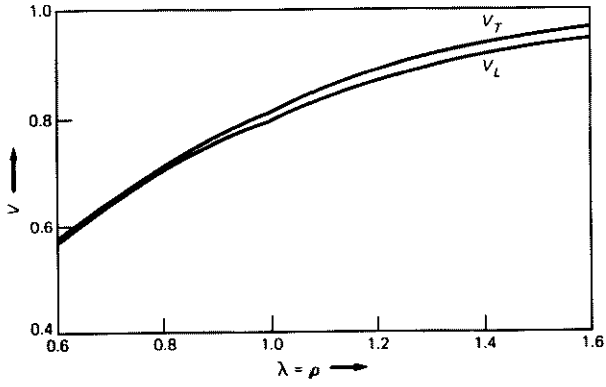

Fig. 6—The values $V_T$ and $V_L$ as functions of the load $\lambda = \rho$ for $T = 3.0$, $\sigma = 0.15$, and $K = 1$.

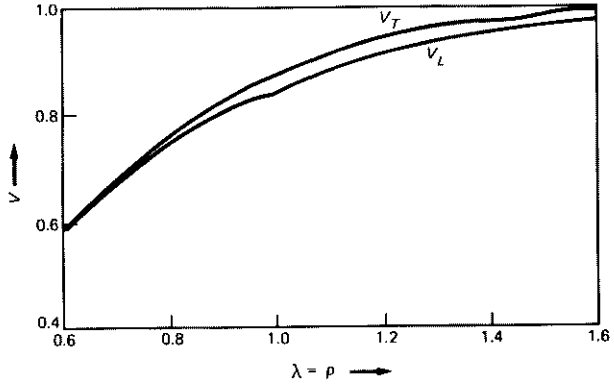

Fig. 7—The values $V_T$ and $V_L$ as functions of the load $\lambda = \rho$ for $T = 3.0$, $\sigma = 0.15$, and $K = 10$.

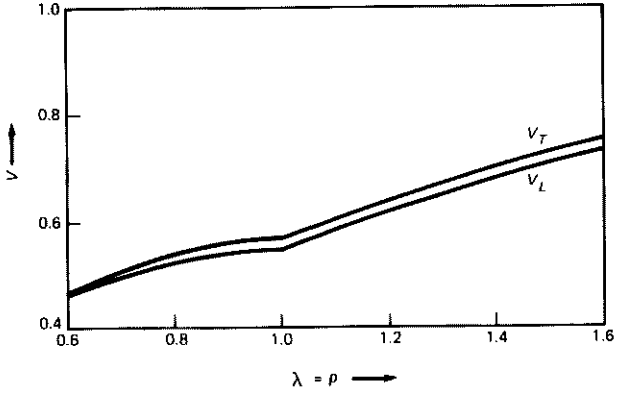

Fig. 8—The values $V_T$ and $V_L$ as functions of the load $\lambda = \rho$ for $T = 1.0$, $\sigma = 2.0$, and $K = 1$.

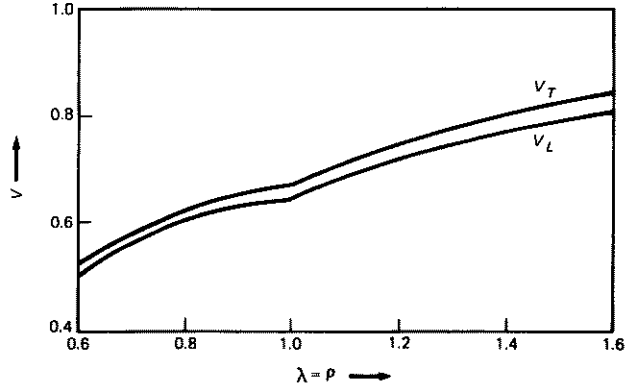

Fig. 9—The values $V_T$ and $V_L$ as functions of the load $\lambda = \rho$ for $T = 1.0$, $\sigma = 2.0$, and $K = 10$.

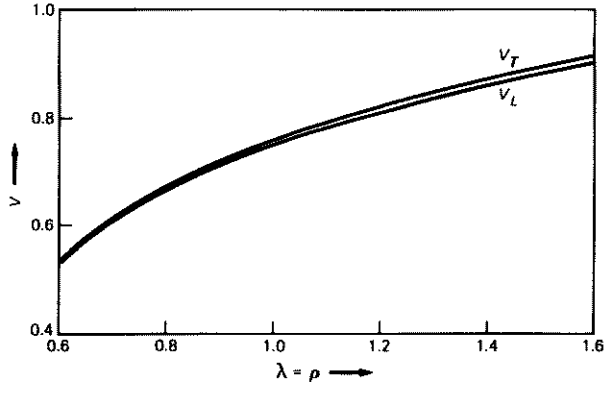

Fig. 10—The values $V_T$ and $V_L$ as functions of the load $\lambda = \rho$ for $T = 1.0$, $\sigma = 0.15$, and $K = 1$.

Of course, our knowledge of the customer behavior may be more or less accurate, depending on the application. An issue of interest then is the sensitivity of the throughput to the assumed customer behavior. This was studied for a special case ($K = 1$) in Ref. 1. The analysis in this paper can be used to answer such issues for more general service time distributions. Qualitatively, however, the conclusions will remain the same: the last-in-first-out (LIFO) discipline is robust with respect to the knowledge of customer behavior. The hybrid discipline, on the other hand, is very sensitive to the customer behavior and should be used only when the customer behavior is adequately known and does not change in time, or when the parameters of the customer behavior can be estimated and used to change the control parameters dynamically.

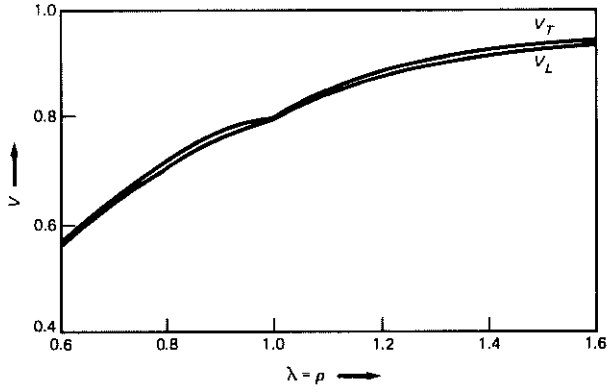

Fig. 11—The values $V_T$ and $V_L$ as functions of the load $\lambda = \rho$ for $T = 1.0$, $\sigma = 0.15$, and $K = 10$.

# Off-Line Quality Control in Integrated Circuit Fabrication Using Experimental Design

By M. S. PHADKE, R. N. KACKAR, D. V. SPEENEY, and M. J. GRIECO

(Manuscript received March 25, 1982)

*In this paper we describe the off-line quality control method and its application in optimizing the process for forming contact windows in 3.5-μm complementary metal-oxide semiconductor circuits. The off-line quality control method is a systematic method of optimizing production processes and product designs. It is widely used in Japan to produce high-quality products at low cost. The key steps of off-line quality control are: (i) Identify important process factors that can be manipulated and their potential working levels; (ii) perform fractional factorial experiments on the process using orthogonal array designs; (iii) analyze the resulting data to determine the optimum operating levels of the factors (both the process mean and the process variance are considered in this analysis; (iv) conduct an additional experiment to verify that the new factor levels indeed improve the quality control.*

## I. INTRODUCTION AND SUMMARY

This paper describes and illustrates the off-line quality control method, which is a systematic method of optimizing a production process. It also documents our efforts to optimize the process for forming contact windows in 3.5-μm technology complementary metal-oxide semiconductor (CMOS) circuits fabricated in the Murray Hill Integrated Circuit Design Capability Laboratory (MH ICDCL). Here, by optimization we mean minimizing the process variance while keeping the process mean on target.

A typical very large scale integrated circuit (IC) chip has thousands of contact windows (e.g., a *BELLMAC**-32 microprocessor chip has

* Trademark of Bell Laboratories.

250,000 windows on an approximately 1.5-cm$^2$ area), most of which are not redundant. It is critically important to produce windows of size very near the target dimension. (In this paper windows mean contact windows.) Windows that are not open or are too small result in loss of contact to the devices, while excessively large windows lead to shorted device features. The application of the off-line quality control method has reduced the variance of the window size by a factor of four. Also, it has substantially reduced the processing time required for the window-forming step.

This study was inspired by Professor Genichi Taguchi's visit to the Quality Theory and Systems Group in the Quality Assurance Center at Bell Laboratories during the months of August, September, and October, 1980. Professor Taguchi, director of the Japanese Academy of Quality and a recipient of the Deming award, has developed the method of off-line quality control during the last three decades. It is used routinely by many leading Japanese industries to produce high-quality products at low cost. An overview of Professor Taguchi's off-line and on-line quality control methods is given in Taguchi,[1] and Kackar and Phadke.[2] This paper documents the results of the first application of Professor Taguchi's off-line quality control method in Bell Laboratories.

The distinctive features of the off-line quality control method are experimental design using orthogonal arrays and the analysis of signal-to-noise ratios (s/n). The orthogonal array designs provide an economical way of simultaneously studying the effects of many production factors on the process mean and variance. Orthogonal array designs are fractional factorial designs with the orthogonality property defined in Section IV. The s/n is a measure of the process variability. According to Professor Taguchi,[3] by optimizing the process with respect to the s/n, we ensure that the resulting optimum process conditions are robust or stable, meaning that they have the minimum process variation.

The outline of this paper is as follows: Section II gives a brief description of the window-forming process, which is a critical step in IC fabrication. The window-forming process is generally considered to be one of the most difficult steps in terms of reproducing and obtaining uniform-size windows. Nine key process factors were identified and their potential operating levels were determined. A description of the factors and their levels is given in Section III. The total number of possible factor-level combinations is about six thousand.

The aim of the off-line quality control method is to determine a factor-level combination that gives the least variance for the window size while keeping the mean on target. To determine such a factor-level combination we performed eighteen experiments using the $L_{18}$

orthogonal array. The experimental setup is given in Section IV. These eighteen experiments correspond to eighteen factor-level combinations among the possible six thousand combinations. For each experiment, measurements were taken on the line width and the window-size control features. The resulting data were analyzed to determine the optimum factor-level combination. The measurements and the data analysis are presented in Sections V through IX.

The optimum factor levels, inferred from the data analysis, were subsequently used in fabricating the *BELLMAC*-32 microprocessor, the *BELLMAC*-4 microcomputer, and some other chips in the Murray Hill ICDCL. The experience of using these conditions is discussed in Section X.

The experiment was designed and preliminary analysis of the experimental data was performed under Professor Taguchi's guidance and collaboration.

## II. THE WINDOW-FORMING PROCESS

Fabrication of integrated circuits is a complex, lengthy process.[4] Window forming is one of the more critical steps in fabricating state of the art CMOS integrated circuits. It comes after field and gate oxides are grown; polysilicon lines have been formed; and the gate, source, and drain areas are defined by the process of doping. Figure 1 shows the windows in a cross section of a wafer. A window is a hole of about 3.5 $\mu$m diameter etched through an oxide layer of about 2 $\mu$m thickness. The purpose of the windows is to facilitate the interconnections between the gates, sources, and drains. For this reason these windows are called contact windows.

The process of forming windows through the oxide layers involves photolithography. First the *P*-glass surface is prepared by depositing

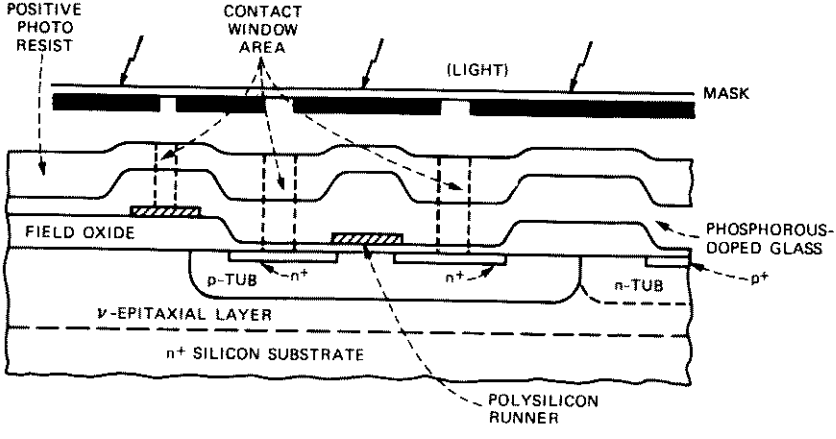

Fig. 1—Cross section of a wafer.

undoped oxide on it and prebaking it. The window-forming process is described below.

(*i*) Apply Photoresist: A wetting agent is sprayed on the wafer to promote adhesion of photoresist to the oxide surface. Then an appropriate photoresist is applied on the wafer and the wafer is rotated at high speed so that the photoresist spreads uniformly.

(*ii*) Bake: The wafer is baked to dry the photoresist layer. The thickness of the photoresist layer at this stage is about 1.3 to 1.4 $\mu$m.

(*iii*) Expose: The photoresist-coated wafer is exposed to ultraviolet radiation through a mask. The windows to be printed appear as clear areas on the mask. In addition to the windows, which are parts of the desired circuits, the mask has some test patterns. Light passes through these areas and causes the photoresist in the window areas and the test pattern areas to become soluble in an appropriate solvent (developer). The areas of the photoresist where light does not strike remain insoluble.

(*iv*) Develop: The exposed wafer is dipped in the developer, which dissolves only the exposed areas. In properly printed windows, the exposed photoresist is removed completely and the oxide surface is revealed.

(*v*) Plasma Etch: The wafers are placed in a high-vacuum chamber wherein a plasma is established. The plasma etches the exposed oxide areas faster than it etches the photoresist. So at the places where the windows are printed, windows are cut through the oxide layers down to the silicon surface.

(*vi*) Remove Photoresist: The remaining photoresist is now removed with the help of oxygen plasma and wet chemicals.

In the formation of the final contact windows there are additional steps: (*vii*) removal of cap-oxide, (*viii*) oxidation of the contact area to prevent diffusion of phosphorus in the subsequent step, (*ix*) reflow of the *P*-glass to round the window corners, (*x*) hydrogen annealing, and (*xi*) pre-metal wet-etching to remove any remaining oxides from the contact window areas.

At the time we started this study, the target window size at step 6 was considered to be 3.0 $\mu$m. The final target window size (after step *xi*) was 3.5 $\mu$m.

## III. SELECTION OF FACTORS AND FACTOR LEVELS

For the present study only the steps numbered (*i*) through (*v*) were chosen for optimization. Discussions with process engineers led to the selection of the following nine factors for controlling the window size. The factors are shown next to the appropriate fabrication steps.

(*i*) Apply Photoresist: Photoresist viscosity ($B$) and spin speed ($C$).

(*ii*) Bake: Bake temperature (*D*) and bake time (*E*).

(*iii*) Expose: Mask dimension (*A*), aperture (*F*), and exposure time (*G*).

(*iv*) Develop: Developing time (*H*).

(*v*) Plasma etch: Etch time (*I*).

No factor was chosen corresponding to the photoresist removal step because it does not affect the window size.

The standard operating levels of the nine factors are given in Table I. Under these conditions, which prevailed in September 1980, the contact windows varied substantially in size and on many occasions even failed to print and open. Figure 2 shows a typical photograph of the programmed logic array (PLA) area of a microcomputer chip. The wide variation in window size and the presence of unopened windows is obvious from the figure.

The principle of off-line quality control is to systematically investigate various possible levels for these factors with an aim of obtaining uniform-size windows.

In the window-forming experiment a number of alternate levels were considered for each of the nine factors. These levels are also listed in Table I. Six of these factors have three levels each. Three of the factors have only two levels.

Table I—Test levels

| Label | Factors Name | Levels | | |
|---|---|---|---|---|
| | | | Standard Levels | |
| A | Mask Dimension (μm) | | 2 | 2.5 |
| B | Viscosity | | 204 | 206 |
| C | Spin Speed (rpm) | Low | Normal | High |
| D | Bake Temperature (°C) | 90 | 105 | |
| E | Bake Time (min) | 20 | 30 | 40 |
| F | Aperture | 1 | 2 | 3 |
| G | Exposure Time | 20% Over | Normal | 20% Under |
| H | Developing Time (s) | 30 | 45 | 60 |
| I | Plasma Etch Time (min) | 14.5 | 13.2 | 15.8 |

Dependence of spin speed on viscosity

| | | Spin Speed (rpm) | | |
|---|---|---|---|---|
| | | Low | Normal | High |
| Viscosity | 204 | 2000 | 3000 | 4000 |
| | 206 | 3000 | 4000 | 5000 |

Dependence of exposure on aperture

| | | Exposure (PEP-Setting) | | |
|---|---|---|---|---|
| | | 20% Over | Normal | 20% Under |
| Aperture | 1 | 96 | 120 | 144 |
| | 2 | 72 | 90 | 108 |
| | 3 | 40 | 50 | 60 |

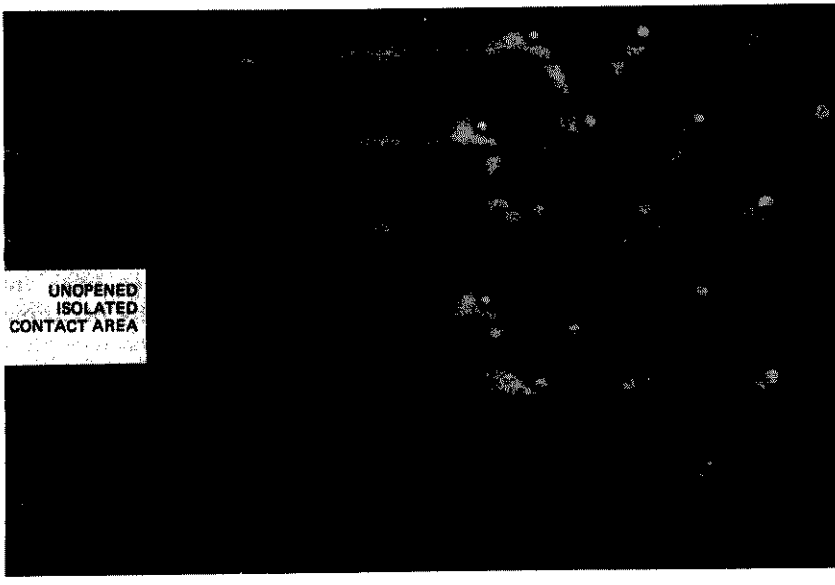

Fig. 2—Example of nonuniform contact window sizes and an isolated, unopened contact window. Both are typical results obtained in August 1980, for the PLA area of microprocessor and microcomputer chips. The contact windows are round shaped.

The levels of spin speed are tied to the levels of viscosity. For the 204 photoresist viscosity the low, normal, and high spin speeds mean 2000 rpm, 3000 rpm, and 4000 rpm, respectively. For the 206 photoresist viscosity the spin speed levels are 3000 rpm, 4000 rpm, and 5000 rpm. Likewise, the exposure setting depends on the aperture. These relationships are also shown in Table I.

## IV. THE ORTHOGONAL ARRAY EXPERIMENT

The full factorial experiment to explore all possible factor-level combinations would require $3^6 \times 2^3 = 5832$ experiments. Considering the cost of material, the time, and the availability of facilities, the full factorial experiment is prohibitively large. Also from statistical considerations it is unnecessary to perform the full factorial experiment because processes can usually be adequately characterized by a relatively few parameters.

The fractional factorial design used for this study is given in Table II. It is the $L_{18}$ orthogonal array design consisting of 18 experiments taken from Taguchi and Wu.[3] The rows of the array represent runs while the columns represent the factors. Here we treat $BD$ as a joint factor with the levels 1, 2, and 3 representing the combinations $B_1D_1$, $B_2D_1$, and $B_1D_2$, respectively. This is done so that we can study all the

Table II—The $L_{18}$ orthogonal array

| Experiment Number | Column Number & Factor | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | 1 A | 2 BD | 3 C | 4 E | 5 F | 6 G | 7 H | 8 I |
| 1 | 1 | 1 | 1 | 1 | 1 | 1 | 1 | 1 |
| 2 | 1 | 1 | 2 | 2 | 2 | 2 | 2 | 2 |
| 3 | 1 | 1 | 3 | 3 | 3 | 3 | 3 | 3 |
| 4 | 1 | 2 | 1 | 1 | 2 | 2 | 3 | 3 |
| 5 | 1 | 2 | 2 | 2 | 3 | 3 | 1 | 1 |
| 6 | 1 | 2 | 3 | 3 | 1 | 1 | 2 | 2 |
| 7 | 1 | 3 | 1 | 2 | 1 | 3 | 2 | 3 |
| 8 | 1 | 3 | 2 | 3 | 2 | 1 | 3 | 1 |
| 9 | 1 | 3 | 3 | 1 | 3 | 2 | 1 | 2 |
| 10 | 2 | 1 | 1 | 3 | 3 | 2 | 2 | 1 |
| 11 | 2 | 1 | 2 | 1 | 1 | 3 | 3 | 2 |
| 12 | 2 | 1 | 3 | 2 | 2 | 1 | 1 | 3 |
| 13 | 2 | 2 | 1 | 2 | 3 | 1 | 3 | 2 |
| 14 | 2 | 2 | 2 | 3 | 1 | 2 | 1 | 3 |
| 15 | 2 | 2 | 3 | 1 | 2 | 3 | 2 | 1 |
| 16 | 2 | 3 | 1 | 3 | 2 | 3 | 1 | 2 |
| 17 | 2 | 3 | 2 | 1 | 3 | 1 | 2 | 3 |
| 18 | 2 | 3 | 3 | 2 | 1 | 2 | 3 | 1 |

nine factors with the $L_{18}$ orthogonal array. Thus, experiment 2 would be run under level 1 of factors *A*, *B*, and *D*, and level 2 of the remaining factors. In terms of the actual settings, these conditions are: 2-$\mu$m mask dimension, 204 viscosity, 90°C bake temperature, 3000-rpm spin speed, bake time of 30 minutes, aperture 2, exposure PEP setting 90, 45-second developing time, and 13.2 minutes of plasma etch. The other rows are interpreted similarly.

Here are some of the properties and considerations of this design:

(*i*) This is a main-effects-only design; i.e., the response is approximated by a separable function. A function of many independent variables is called separable if it can be written as a sum of functions where each component function is a function of only one independent variable.

(*ii*) For estimating the main effects there are two degrees of freedom associated with each three-level factor, one degree of freedom for each two-level factor, and one degree of freedom with the overall mean. We need at least one experiment for every degree of freedom. Thus, the minimum number of experiments needed is $2 \times 6 + 1 \times 3 + 1 = 16$. Our design has 18 experiments. A single-factor-by-single-factor experiment would need only 16 experiments, two fewer than 18. But such an experiment would yield far less precise information compared with the orthogonal array experiment.[3,5]

(*iii*) The columns of the array are pairwise orthogonal. That is, in every pair of columns, all combinations of levels occur and they occur an equal number of times.

(*iv*) Consequently, the estimates of the main effects of all factors

as shown in Table II and their associated sums of squares are independent under the assumption of normality and equality of error variance. So the significance tests for these factors are independent. Though $BD$ is treated as a joint factor, the main effects and sums of squares of $B$ and $D$ can be estimated separately under the assumption of no interaction. In general, these estimates would be correlated with each other. However, these estimates are not correlated with those for any of the other seven factors.

(*v*) The estimates of the main effects can be used to predict the response for any combination of the parameter levels. A desirable feature of this design is that the variance of the prediction error is the same for all parameter-level combinations covered by the full factorial design.

(*vi*) It is known that the main-effect-only models are liable to give misleading conclusions in the presence of interactions. However, in the beginning stages of this study the interactions are assumed to be negligible. If we wished to study all two-factor interactions, with no more than 18 experiments we would have enough degrees of freedom for studying only two three-level factors, or five two-level factors! That would mean in the present study we would have to eliminate half of the process factors without any experimental evidence. Alternately, if we wished to study all the nine process factors and their two-factor interactions, we would need at least 109 experiments! Orthogonal array designs can, of course, be used to study interactions.[3]

(*vii*) Optimum conditions obtained from such an experiment have to be verified with an additional experiment. This is done to safeguard us against the potential adverse effects of ignoring the interactions among the manipulatable factors.

In conducting experiments of this kind, it is common for some wafers to get damaged or broken. Also, the wafer-to-wafer variability of window sizes is typically large. So we decided to run each experiment with two wafers.

#### *4.1 Analysis of variance*

Data collected from such experiments are analyzed by a method called analysis of variance (ANOVA).[6] The purpose of ANOVA is to separate the total variability of the data, which is measured by the sum of the squared deviations from the mean value, into contributions by each of the factors and the error. This is analogous to the use of Parseval's theorem to separate the signal strength into contributions by the various harmonics.[3] To see which of the factors have a significant effect, $F$-tests are performed. In performing the standard $F$-test we assume that the errors are normally distributed with equal variance and are independent. The results of the $F$-test are indicated by the significance level. When we say that a factor is significant at 5-percent

level we mean that there is 5 percent or less chance that, if we change the level of the factor, the response will remain the same. If the $F$-test indicates that a factor is not significant at the 5-percent level it means that, if we change the level of that factor, there is more than a 5-percent chance that the response will remain the same.

The levels of factors which are identified as significant are then set to obtain the best response. The levels of the other factors can be set at any levels within the experimental range. We choose to leave them at the starting levels.

If the assumptions of the $F$-test are not completely satisfied, the quoted significances are not accurate. However, the standard $F$-test is relatively insensitive to deviations from the assumptions used in its derivation. Thus, for making engineering decisions about which factor levels to change, the accuracy of the significance level is an adequate guide. In this paper we will use the standard $F$-test even though some of the assumptions are not strictly satisfied.

## V. QUALITY MEASURES

The window size is the relevant quality measure for this experiment. The existing equipment does not give reproducible measurements of the sizes of windows in the functional circuits on a chip. This is because of the small size of these windows and their close proximity to one another. Therefore, test patterns—a line-width pattern and a window pattern—are provided in the upper left-hand corner of each chip. The following measurements were made on these test patterns to indicate the quality.

(*i*) Line width after step (*iv*), called the pre-etch line width or photo-line width.

(*ii*) Line width after step (*vi*), called the post-etch line width.

(*iii*) Size of the window test pattern after step (*vi*), called the post-etch window size.

Five chips were selected from each wafer for making the above measurements. These chips correspond to specific locations on a wafer—top, bottom, left, right, and center.

All three quality measures are considered to be good indicators of the size of the functional windows. However, between the geometries of the window-size pattern and the line-width pattern, the geometry of the window-size pattern is closer to the geometry of the functional windows. So, among the three quality measures, the post-etch window size may be expected to be better correlated with the size of the functional windows.

## VI. EXPERIMENTAL DATA

Only thirty-four wafers were available for experimentation. So experiments 15 and 18 were arbitrarily assigned only one wafer each. One

Table III—Experimental data

| 18 | — | — | — | — | — | No wafer |

of the wafers assigned to experiment 5 broke in handling. So experiments 5, 15, and 18 have only one wafer.

The experimental data are shown in Table III.

The data arising from such experiments can be classified as two types—continuous data and categorical data. Here, the pre-etch and the post-etch line-width data are of the continuous type. The post-etch window size data are mixed categorical-continuous type, because some windows are open while some are not. The two types of data are analyzed somewhat differently, as we explain the following two sections.

## VII. ANALYSIS OF THE LINE-WIDTH DATA

Both the pre-etch and the post-etch line widths are continuous variables. For each of these variables the statistics of interest are the

mean and the standard deviation. The objective of our data analysis is to determine the factor-level combination such that the standard deviation is minimum while keeping the mean on target. We will call this the optimum factor-level combination. Professor Taguchi's method for obtaining the optimum combination is given next.

### *7.1 Single response variable*

Let us first consider the case where there is only one response variable. Instead of working with the mean and the standard deviation, it is preferable to work with the transformed variables—the mean and the signal-to-noise ratio (s/n). The s/n is defined as

$$\text{s/n} = \log_{10}\left(\frac{\text{Mean}}{\text{Standard Deviation}}\right)$$

$$= -\log_{10}(\text{coefficient of variation}).$$

* WNO—Window not open.

In terms of the transformed variables, the optimization problem is to determine the optimum factor levels such that the s/n is maximum while keeping the mean on target. This problem can be solved in two stages:

(*i*) Determine which factors have a significant effect on the s/n. This is done through the analysis of variance (ANOVA) of the s/n. These factors are called the *control factors*, implying that they control the process variability. For each control factor we choose the level with the highest s/n as the optimum level. Thus the overall s/n is maximized.

(*ii*) Select a factor that has the smallest effect on the s/n among all factors that have a significant effect on the mean. Such a factor is called a *signal factor*. Ideally, the signal factor should have no effect

on the s/n. Choose the levels of the remaining factors (factors that are neither control factors nor signal factors) to be the nominal levels prior to the optimization experiment. Then set the level of the signal factor so that the mean response is on target.

In practice, the following two aspects should also be considered in selecting the signal factor: (*i*) If possible, the relationship between the mean response and the levels of the signal factor should be linear, and (*ii*) It should be convenient to change the signal factor during production. These aspects are important from the on-line quality control considerations. The signal factor can be used during manufacturing to adjust the mean response.[1-3]

Why do we work in terms of the s/n ratio rather than the standard deviation? Frequently, as the mean decreases, the standard deviation also decreases and vice versa. In such cases, if we work in terms of the standard deviation, the optimization cannot be done in two steps; i.e., we cannot minimize the standard deviation first and then bring the mean on target.

Through many applications, Professor Taguchi has empirically found that the two-stage optimization procedure involving the s/n indeed gives the parameter-level combination where the standard deviation is minimum, while keeping the mean on target. This implies that the engineering systems behave in such a way that the manipulatable production factors can be divided into three categories:

(*i*) Control factors, which affect process variability as measured by the s/n

(*ii*) Signal factors, which do not influence (or have negligible effect on) the s/n but have a significant effect on the mean

(*iii*) Factors that do not affect the s/n or the process mean.

The two-stage procedure also has an advantage over a procedure that directly minimizes the mean square error from the target mean value. In practice, the target mean value may change during the process development. The advantage of the two-stage procedure is that for any target mean value (of course, within reasonable bounds) the new optimum factor-level combination is obtained by suitably adjusting the level of only the signal factor. This is so because in step (*i*) of the algorithm the coefficient of variation is minimized for every mean target value.

### *7.2 Multiple response variables*

Now let us consider the case where there are two or more response variables. In such cases, engineering judgment may have to be used to resolve the conflict if different response variables suggest different levels for any one factor. The modified two-stage procedure is as follows:

(*i*) Separately determine control factors and their optimum levels corresponding to each response variable. If there is a conflict between the optimum levels suggested by the different response variables, use engineering judgment to resolve the conflict.

(*ii*) Select a factor that has the smallest effect (preferably no effect) on the signal-to-noise ratios for all the response variables but has a significant effect on the mean levels. This is the signal factor. Set the levels of the remaining factors, which affect neither the mean nor the s/n, at the nominal levels prior to the optimization experiment. Then set the level of the signal factor so that the mean responses are on target. Once again engineering judgment may have to be used to resolve any conflicts that arise.

The selection of the control factors, signal factor, and their optimum levels for the present application will be discussed in Section IX. The remaining portions of Sections VII and VIII contain the data analysis that forms the basis for selecting the optimum factor levels.

### *7.3 Pre-etch line width*

Mean, standard deviation, and s/n were calculated for each of the eighteen experiments. For those experiments with two wafers, ten data points were used in these calculations. When there was only one wafer, five data points were used. These results are shown in Table IV. The presence of unequal sample sizes has been ignored in the subsequent analysis. Let $\bar{x}_i$ and $\eta_i$ denote the mean and the s/n for the $i$th experiment.

Table IV—Pre-etch line-width data

| Experiment Number | Mean Line Width, $\bar{x}$ ($\mu$m) | Standard Deviation of Line Width, $s$ ($\mu$m) | s/n $\eta = \log(\bar{x}/s)$ |
|---|---|---|---|
| 1 | 2.500 | 0.0827 | 1.4803 |
| 2 | 2.684 | 0.1196 | 1.3512 |
| 3 | 2.660 | 0.1722 | 1.1889 |
| 4 | 1.962 | 0.1696 | 1.0632 |
| 5 | 1.870 | 0.1168 | 1.2043 |
| 6 | 2.584 | 0.1106 | 1.3686 |
| 7 | 2.032 | 0.0718 | 1.4520 |
| 8 | 3.267 | 0.2101 | 1.1917 |
| 9 | 2.829 | 0.1516 | 1.2709 |
| 10 | 2.660 | 0.1912 | 1.1434 |
| 11 | 3.166 | 0.0674 | 1.6721 |
| 12 | 3.323 | 0.1274 | 1.4165 |
| 13 | 2.576 | 0.0850 | 1.4815 |
| 14 | 2.308 | 0.0964 | 1.3788 |
| 15 | 2.464 | 0.0385 | 1.8065 |
| 16 | 2.667 | 0.0706 | 1.5775 |
| 17 | 3.156 | 0.1569 | 1.3036 |
| 18 | 3.494 | 0.0473 | 1.8692 |

By computing a single mean $\bar{x}_i$ and a single variance $s_i^2$ (needed for computing $\eta_i$) from the two wafers of each experiment $i$, we pool together the between wafer and the within wafer variance. That is,

$$E(s_i^2) = (\text{Between wafer variance for experiment } i) \times \tfrac{5}{6} + (\text{Within wafer variance for experiment } i).$$

Thus, when we maximize $\eta$, we minimize the sum of the between-wafer and the within-wafer variances of the line width, which is the response of interest to us. There can be situations when one wants to separately estimate the effects of the factor levels on the between-wafer and within-wafer variances. In those cases, one would compute the s/n and the mean line width for each individual wafer.

In the analysis of the pre-etch and the post-etch line widths, we compute the $\bar{x}_i$ and the $s_i^2$ for each experiment by pooling the data from both wafers used in that experiment. A relative measure of the between-wafer and within-wafer variance is obtained in Section VIII, while the post-etch window-size data is being analyzed.

#### *7.3.1 Analysis of s/n*

The estimates of the average s/n for all factor levels are given in Table V. The average for the first level of factor A is the average of the nine experiments (experiments 1 through 9), which were conducted with level 1 of the factor A. Likewise, the average for the second level of factor A is the mean of experiments 10 through 18, which were conducted with level 2 of the factor A. Let us denote these average effects of $A_1$ and $A_2$ by $m_{A_1}$ and $m_{A_2}$, respectively. Here $m_{A_1} = 1.2857$ and $m_{A_2} = 1.5166$. The other entries of Table V were calculated similarly.

The average signal-to-noise ratios for every level of the eight factors are graphically shown in Fig. 3. Qualitatively speaking, the mask dimension and the aperture cause a large variation in the s/n. The

Table V—Pre-etch line width for average s/n

| | Factor | Average s/n Level 1 | Level 2 | Level 3 |
|---|---|---|---|---|
| A | Mask Dimension | 1.2857 | 1.5166 | |
| BD | Viscosity Bake Temperature | ($B_1D_1$) 1.3754 | ($B_2D_1$) 1.3838 | ($B_1D_2$) 1.4442 |
| B | Viscosity | 1.4098 | 1.3838 | |
| D | Bake Temperature | 1.3796 | 1.4442 | |
| C | Spin Speed | 1.3663 | 1.3503 | 1.4868 |
| E | Bake Time | 1.4328 | 1.4625 | 1.3082 |
| F | Aperture | 1.5368 | 1.4011 | 1.2654 |
| G | Exposure Time | 1.3737 | 1.3461 | 1.4836 |
| H | Developing Time | 1.3881 | 1.4042 | 1.4111 |

Overall average s/n = 1.4011.

developing time and the viscosity cause a small change in the s/n. The effect of the other factors is in between.

For three-level factors, Fig. 3 can also be used to judge the linearity of the effect of the factors. If the difference between levels 1 and 2, and levels 2 and 3 is equal and these levels appear in proper order (1, 2, 3, or 3, 2, 1), then the effect of that factor is linear. If either the differences are unequal or the order is mixed up, then the effect is not linear. For example, the aperture has approximately linear response while the bake time has a nonlinear response.

We shall perform a formal analysis of variance (ANOVA) to identify statistically significant factors. The analysis of variance of general linear models is widely known in literature, see e.g., Searle[7] and Hicks.[6] Simple ANOVA methods for orthogonal array experiments are described in Taguchi and Wu.[3] The linear model used in analyzing this data is:

$$y_i = \mu + x_i + e_i, \tag{1}$$

where

$i = 1, \cdots, 18$ is the experiment number.

$\mu$ is the overall mean.

$x_i$ is the fixed effect of the factor-level combination used in experiment $i$. Here we consider only the main effect for each of the factors. Thus it represents the sum of the effects of the eight factors.

$e_i$ is the random error for experiment $i$.

$y_i$ is the s/n for experiment $i$.

To clarify the meaning of the term $x_i$, let us consider experiment 1, which was run at level 1 of each of the eight factors A through H. Note that the factor I is irrelevant for studying the pre-etch line width. So $x_1$ is the sum of the main effects associated with the first level of each of the factors A through H.

The sum of squares and the mean squares for the eight factors are tabulated in Table VIa. The computations are illustrated in Appendix A.

The expected mean squares are also shown in Table VIa. See Refs. 6 and 7 for the computation of expected mean squares, which are used in forming appropriate F-tests. The error variance, i.e., variance of $e_i$, is denoted by $\sigma^2$. The variability due to the factors A through H is denoted by $\phi$ with an appropriate subscript.

In Table VIa we see that the mean sum of squares for factors BD, C, G, and H are smaller than the mean error sum of squares. So a new ANOVA table, Table VIb, was formed by pooling the sum of squares of these factors with the error sum of squares. The linear model underlying the ANOVA Table VIb is the same as Eq. (1), except that

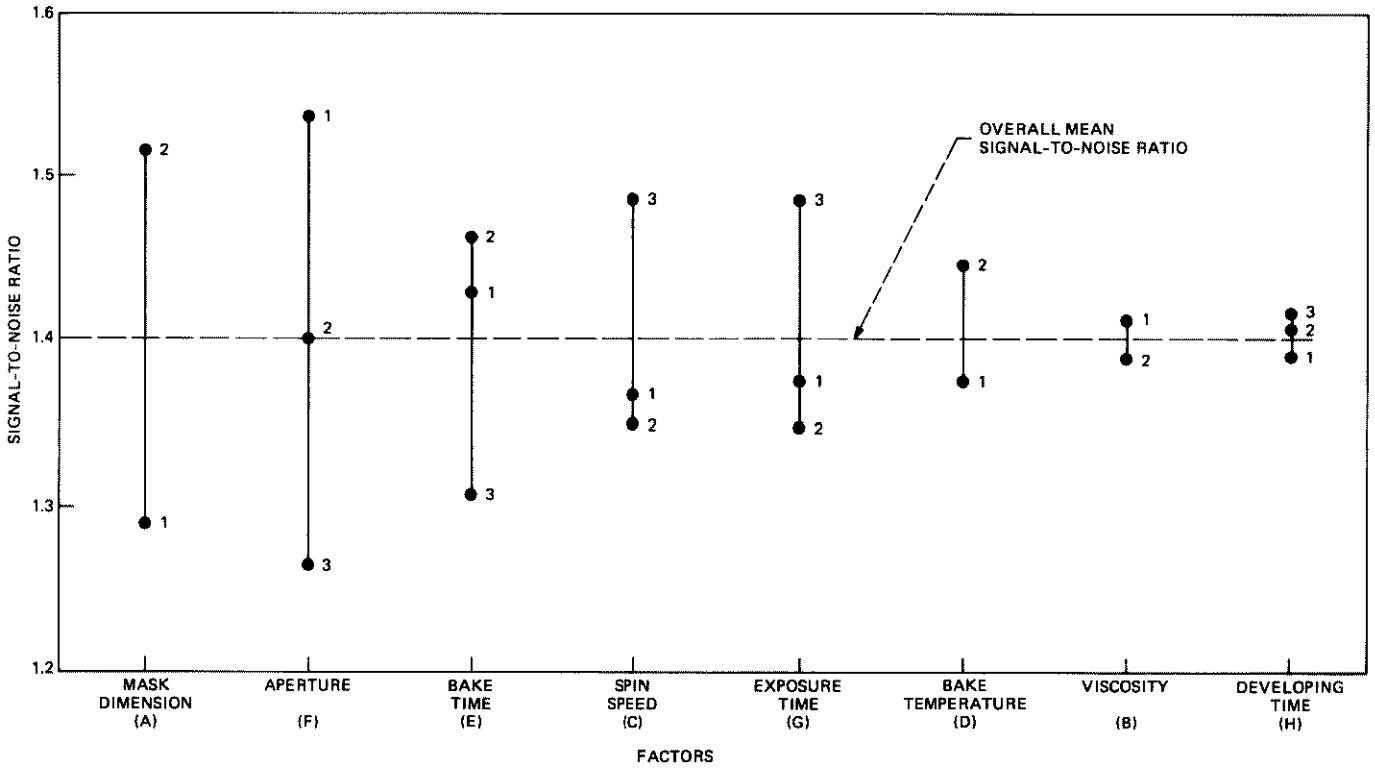

Fig. 3—Signal-to-noise ratios for pre-etch line width. The average s/n for each factor level is indicated by a dot. The number next to the dot indicates the factor level.

now $x_i$ stands for the sum of the main effects of only A, E, and F. The F ratios, computed by dividing the factor mean square by the error mean square, are also shown in Table VIb. Factors A and F are significant using F-table values for the 5-percent significance level. So the mask dimension and the aperture are the control factors.

In performing the analysis of variance, we have tacitly assumed that the response for each experiment, here the s/n, has a normal distribution with constant variance. We are presently investigating the distributional properties of the s/n and their impact on the analysis of variance. In this paper we treat the significance levels as approximate.

The engineering significance of a statistically significant factor can be measured in terms of the percent contribution, a measure introduced by Taguchi.[3] The percent contribution is equal to the percent of the total sum of squares explained by that factor after an appropriate estimate of the error sum of squares has been removed from it. The larger the percent contribution, the more can be expected to be achieved by changing the level of that factor. Computation of the percent contribution is illustrated in Appendix B, and the results are shown in Table VIb.

From Table VIb we see that both the factors A (mask dimension) and F (aperture) contribute in excess of 20 percent each to the total

Table VI—Pre-etch line width

(a) ANOVA for s/n

| | Source | Degrees of Freedom | Sum of Squares | Mean Square | Expected Mean Square |
|---|---|---|---|---|---|
| A | Mask Dimension | 1 | 0.2399 | 0.2399 | $\sigma^2 + \phi_A$ |
| BD | Viscosity Bake Temperature | 2 | 0.0169 | 0.0085 | $\sigma^2 + \phi_{BD}$ |
| C | Spin Speed | 2 | 0.0668 | 0.0334 | $\sigma^2 + \phi_C$ |
| E | Bake Time | 2 | 0.0804 | 0.0402 | $\sigma^2 + \phi_E$ |
| F | Aperture | 2 | 0.2210 | 0.1105 | $\sigma^2 + \phi_F$ |
| G | Exposure Time | 2 | 0.0634 | 0.0317 | $\sigma^2 + \phi_G$ |
| H | Developing Time | 2 | 0.0017 | 0.0009 | $\sigma^2 + \phi_H$ |
| Error | | 4 | 0.1522 | 0.0381 | $\sigma^2$ |
| Total | | 17 | 0.8423 | | |

(b) Pooled ANOVA for s/n

| | Source | Degrees of Freedom | Sum of Squares | Mean Square | F | Percent Contribution |
|---|---|---|---|---|---|---|
| A | Mask Dimension | 1 | 0.2399 | 0.2399 | 9.56* | 25.5 |
| E | Bake Time | 2 | 0.0804 | 0.0402 | 1.60 | 3.6 |
| F | Aperture | 2 | 0.2210 | 0.1105 | 4.40* | 20.3 |
| Error | | 12 | 0.3010 | 0.0251 | | 50.6 |
| Total | | 17 | 0.8423 | | | 100.00 |

$F_{1,12}(0.95) = 4.75$.
$F_{2,12}(0.95) = 3.89$.
* Factors significant at 95-percent confidence level.

sum of squares. So the factors A and F are not only statistically significant, they have a sizable influence on the s/n. These results are consistent with Fig. 3. They will be used in Section IX for selecting the control factors.

#### *7.3.2 Analysis of the means*

Now we analyze the mean pre-etch line widths, $\bar{x}_i$ values, to find a signal factor.

The estimates of the mean line widths for all factor levels are given in Table VII. These estimates are graphically shown in Fig. 4. It is apparent that the levels of viscosity, mask dimension, and spin speed cause a relatively large change in the mean line width. Developing time and aperture have a small effect on the line width. The remaining two factors have an intermediate effect.

The linear model used to analyze this data is the same as eq. (1), except that now $y_i$ stands for the mean pre-etch line width rather than the s/n.

The original and the pooled ANOVA tables for the mean pre-etch line width are given in Tables VIIIa and b, respectively. Because the design is not orthogonal with respect to the factors B and D, we need a special method, described in Appendix C, to separate $S_{BD}$ into $S_B$ and $S_D$.

It is clear from Table VIIIb that the mask dimension (A), viscosity (B), and spin speed (C) have a statistically significant effect on the mean pre-etch line width. Also, these factors together contribute more than 70 percent to the total sum of squares. These results will be used in Section IX for selecting the signal factor.

### *7.4 Post-etch line width*

The analysis of the post-etch line-width data is similar to the analysis of the pre-etch line-width data. The mean, the standard deviation, and the s/n for each experiment are shown in Table IX.

Table VII—Pre-etch line width for the mean line width

| | Factor | Mean Line Width (μm) Level 1 | Level 2 | Level 3 |
|---|---|---|---|---|
| A | Mask Dimension | 2.39 | 2.87 | |
| BD | Viscosity Bake Temperature | ($B_1D_1$) 2.83 | ($B_2D_1$) 2.31 | ($B_1D_2$) 2.74 |
| B | Viscosity | 2.79 | 2.31 | |
| D | Bake Temperature | 2.57 | 2.74 | |
| C | Spin Speed | 2.40 | 2.59 | 2.89 |
| E | Bake Time | 2.68 | 2.68 | 2.53 |
| F | Aperture | 2.68 | 2.56 | 2.64 |
| G | Exposure Time | 2.74 | 2.66 | 2.49 |
| H | Developing Time | 2.60 | 2.60 | 2.69 |

Overall mean line width = 2.63 μm.

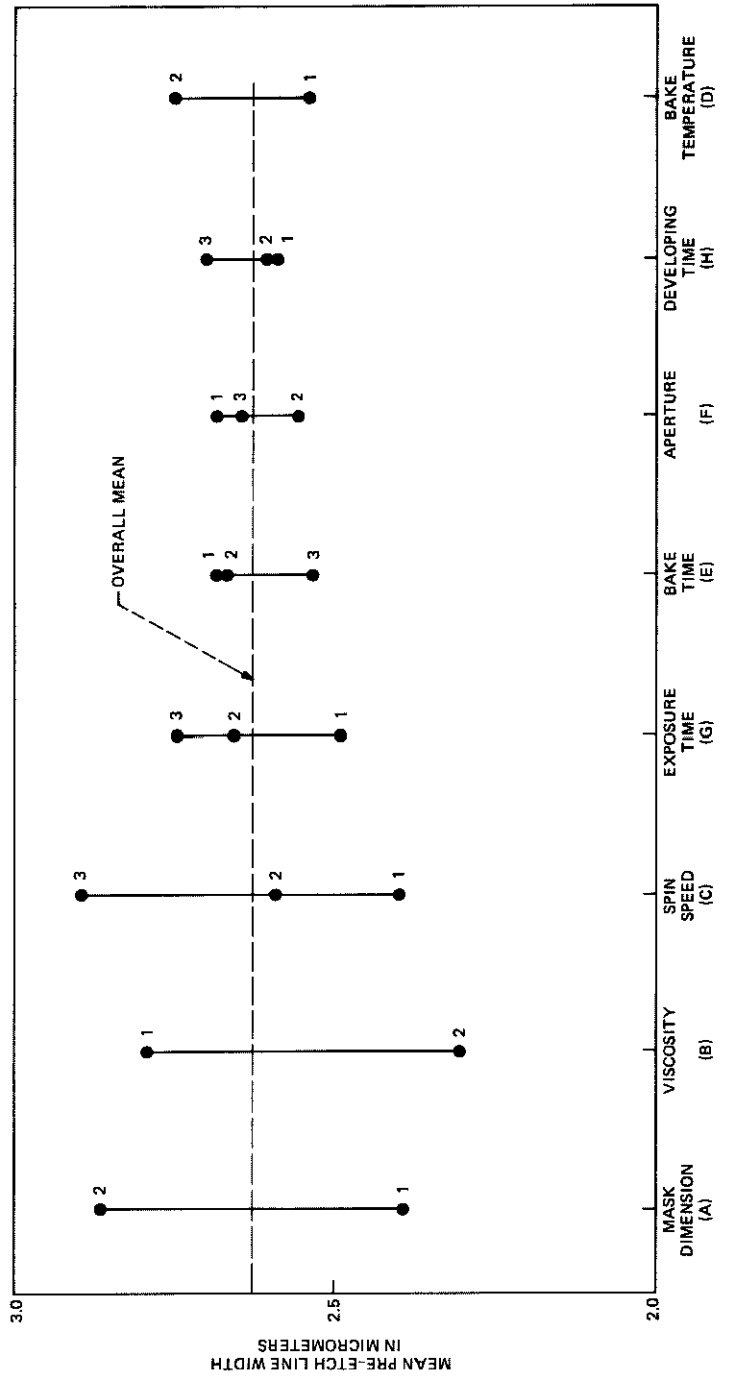

Fig. 4—Mean pre-etch line width. The mean line width for each factor level is indicated by a dot. The number next to each dot indicates the factor level.

Table VIII—Pre-etch line width

(a) ANOVA for mean line width

| | Source | Degrees of Freedom | Sum of Squares | Mean Square | Expected Mean Square |
|---|---|---|---|---|---|
| A | Mask Dimension | 1 | 1.05 | 1.050 | $\sigma^2 + \phi_A$ |
| BD | Viscosity Bake Temperature | 2 | 0.95 | 0.475 | $\sigma^2 + \phi_{BD}$ |
| C | Spin Speed | 2 | 0.73 | 0.365 | $\sigma^2 + \phi_C$ |
| E | Bake Time | 2 | 0.10 | 0.050 | $\sigma^2 + \phi_E$ |

| H | Developing Time | 2 | 0.04 | 0.020 | $\sigma^2 + \phi_H$ |
| Error | | 4 | 0.26 | 0.065 | $\sigma^2$ |
| Total | | 17 | 3.37 | | |

(b) Pooled ANOVA for mean line width

| | Source | Degrees of Freedom | Sum of Squares | Mean Square | F | Contribution Percent |
|---|---|---|---|---|---|---|
| A | Mask Dimension | 1 | 1.05 | 1.050 | 19.81* | 29.6 |
| B | Viscosity | 1 | 0.83 | 0.834 | 15.74* | 22.6 |
| C | Spin Speed | 2 | 0.73 | 0.365 | 6.89* | 18.5 |
| G | Exposure Time | 2 | 0.19 | 0.095 | 1.79 | 2.5 |
| Error | | 11 | 0.58 | 0.053 | | 26.8 |
| Total | | 17 | 3.37 | | | 100.0 |

$F_{1,11}(0.95) = 4.84$.
$F_{2,11}(0.95) = 3.98$.
* Factors significant at 95-percent confidence level.

Table IX—Post-etch line-width data

| Experiment Number | Mean Line Width, $\bar{x}$ ($\mu$m) | Standard Deviation of Line Width $s$ ($\mu$m) | s/n $\eta = \log(\bar{x}/s)$ |
|---|---|---|---|
| 1 | 2.84 | 0.11 | 1.42 |
| 2 | 3.14 | 0.063 | 1.70 |
| 3 | 3.65 | 0.15 | 1.40 |
| 4 | 2.57 | 0.20 | 1.11 |
| 5 | 1.72 | 0.40 | 0.63 |
| 6 | 3.12 | 0.27 | 1.07 |
| 7 | 2.62 | 0.19 | 1.14 |
| 8 | 4.10 | 0.18 | 1.37 |
| 9 | 3.55 | 0.26 | 1.13 |
| 10 | 3.31 | 0.35 | 0.98 |
| 11 | 3.60 | 0.38 | 0.98 |
| 12 | 4.17 | 0.27 | 1.18 |
| 13 | 3.10 | 0.16 | 1.29 |
| 14 | 3.14 | 0.16 | 1.29 |
| 15 | 2.55 | 0.21 | 1.09 |
| 16 | 2.81 | 0.37 | 0.88 |
| 17 | 3.78 | 0.22 | 1.23 |
| 18 | 4.34 | 0.078 | 1.75 |

The average s/n and the mean line width for each factor level are shown in Tables Xa and b, respectively.

The linear model (1) was again used to analyze the post-etch line-width data. The ANOVA for the signal-to-noise ratios, Table XIa, indicates that none of the nine process factors has a significant effect (approximately 5-percent level) on the s/n for the post-etch line width. The pooled ANOVA for the mean post-etch line widths is shown in Table XIb. It is obvious from the table that the viscosity, exposure, spin speed, mask dimension, and developing time have significant effects (5-percent level) on the mean line width. The contribution of these factors to the total sum of squares exceeds 90 percent. The mean line width for each factor level is shown graphically in Fig. 5.

## VIII. ANALYSIS OF POST-ETCH WINDOW-SIZE DATA

Some windows are printed and open while the others are not. Thus the window-size data are mixed categorical-continuous in nature. Analysis of such data is done by converting all the data to the categorical type and then using the 'accumulation analysis' method, which is

Table X—Post-etch line width

(a) Average signal-to-noise ratios

| | Factor | Average s/n Level 1 | Level 2 | Level 3 |
|---|---|---|---|---|
| A | Mask Dimension | 1.22 | 1.19 | |
| BD | Viscosity Bake Temperature | ($B_1D_1$) 1.28 | ($B_2D_1$) 1.08 | ($B_1D_2$) 1.25 |
| B | Viscosity | 1.27 | 1.08 | |

| E | Bake Time | 3.15 | 3.18 | 3.35 |
| F | Aperture | 3.28 | 3.22 | 3.18 |
| G | Exposure Time | 3.52 | 3.34 | 2.83 |
| H | Developing Time | 3.04 | 3.09 | 3.56 |
| I | Etch Time | 3.14 | 3.22 | 3.32 |

Overall mean line width = 3.23 μm.

described by Taguchi in Refs. 3 and 8. Factors that are found significant in this analysis are control factors.

The window sizes were divided into the following five categories:

| Category | Description (micrometers) |
|---|---|
| I | Window not open or not printed |
| II | (0, 2.25) |
| III | [2.25, 2.75) |
| IV | [2.75, 3.25] |
| V | (3.25, ∞) |

Note that these categories are ordered with respect to window size. The target window size at the end of step (*vi*) was 3 μm. Thus category IV is the most desired category, while category I is the least desired category. Table XII summarizes the data for each of the experiments by categories. To simplify our analysis, we shall presume that a missing wafer has the same readings as the observed wafer for that experiment. This is reflected in Table XII, where we show the combined readings for the two wafers of each experiment.

Table XI—Post-etch line width

a) ANOVA for s/n

| | Source | Degrees of Freedom | Sum of Squares | Mean Square | F |
|---|---|---|---|---|---|
| A | Mask Dimension | 1 | 0.005 | 0.005 | 0.02 |

Table XIII gives the frequency distribution corresponding to each level of each factor. To obtain the frequency distribution for a specific level of a specific factor, we summed the frequencies of all the experiments that were conducted with that particular level of that particular factor. For example, the frequency distribution for the first level of factor C (low spin speed) was obtained by summing the frequency distributions of experiments with serial numbers 1, 4, 7, 10, 13, and 16. These six experiments were conducted with level 1 of factor C.

The frequency distributions of Table XIII are graphically displayed by star plots in Fig. 6. From this figure and the table it is apparent that a change in the level of viscosity, spin speed, or mask dimension causes a noticeable change in the frequency distribution. A change in the level of etch time, bake time, or bake temperature seems to have only a small effect on the frequency distribution. The effects of the other factors are intermediate.

We now determine which factors have a significant effect on the frequency distribution of the window sizes. The standard chi-square test for multinomial distributions is not appropriate here because the categories are ordered. The accumulation analysis method has an intuitive appeal and has been empirically found by Professor Taguchi to be effective in analyzing ordered categorical data. The method consists of the following three steps:

(*i*) Compute the cumulative frequencies. Table XIII shows the cumulative frequencies for all factor levels. The cumulative categories are denoted with parentheses. Thus (III) means sum of categories I,

Table XIII—Post-etch window-size data—frequencies by factor level

| | Frequencies | | | | | Cumulative Frequencies | | | | |

| Totals | 86 | 16 | 23 | 35 | 20 | 86 | 102 | 125 | 160 | 180 |

II, and III. Note that the cumulative category (V) is the same as the total number of window readings for the particular factor level.

(*ii*) Perform "binary data" ANOVA[7] on each cumulative category except the last category, viz. (V). Note that a certain approximation is involved in the significance levels suggested by this ANOVA because the observations are not normally distributed.

(*iii*) Assign weights to each cumulative category. These weights are inversely proportional to the Bernoulli trial variance. Let $cum_c$ be the total number of windows in the cumulative category, $c$, as given in the bottom row of Table XIII. Then the weight for that category is:

$$W_c = \frac{1}{\frac{cum_c}{180} \times \left(1 - \frac{cum_c}{180}\right)} = \frac{180^2}{cum_c(180 - cum_c)}.$$

These weights are shown in Appendix D for each category.

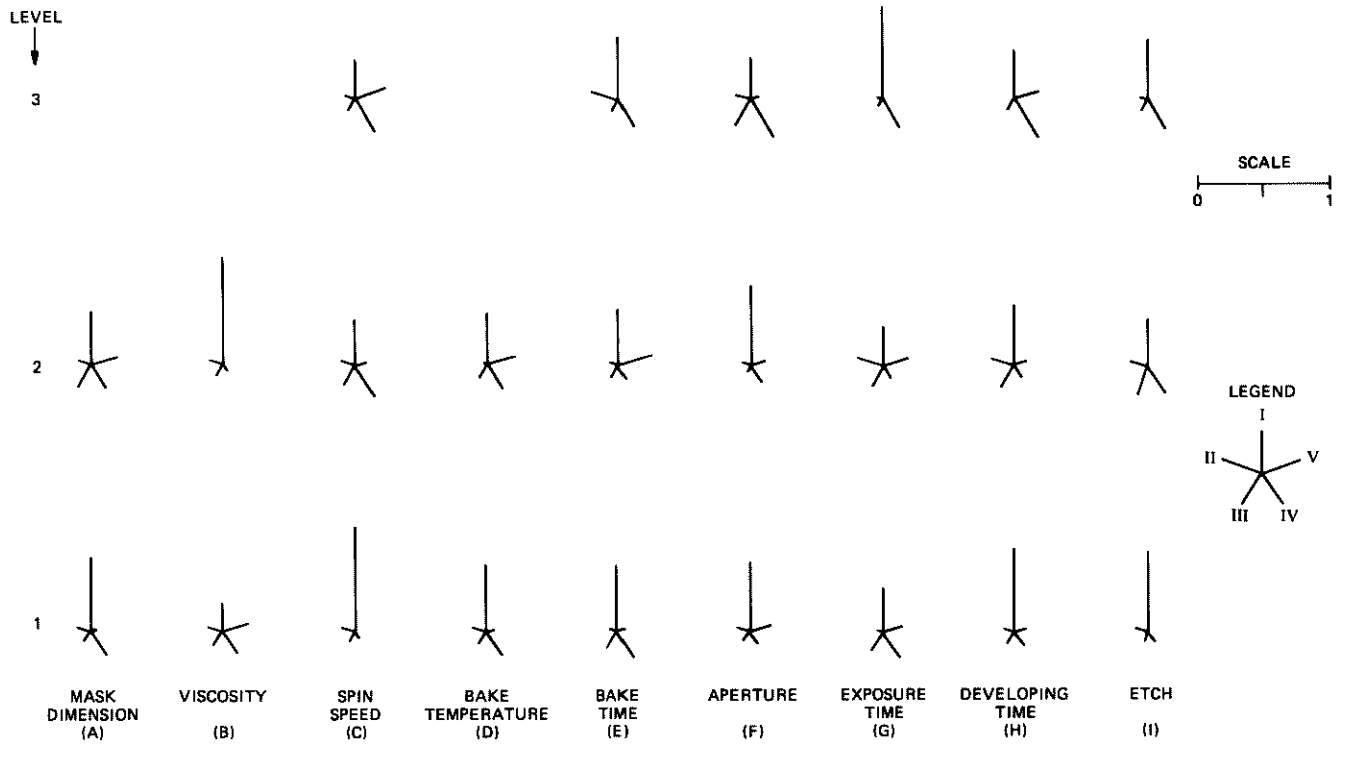

Fig. 6—Post-etch window size. The star gives the frequency distribution for each factor level.

Then for each factor and for each error term the accumulated sum of squares is taken to be equal to the weighted sum of the sum of squares for all cumulative categories.

The intuitive appeal for accumulation analysis is that by taking cumulative frequencies we preserve the order of the categories. By giving weights inversely proportional to the sampling errors in each cumulative category, we make the procedure more sensitive to a change in the variance. The difficulty is that the frequencies of the cumulative categories are correlated. So the true level of significance of the F-test may be somewhat different from that indicated by the F table. More work is needed to understand the statistical properties of the accumulation analysis.

Table XIV gives the final ANOVA with accumulated sum of squares. The computations are illustrated in Appendix D. For each cumulative category, the following nested, mixed linear model was used in performing the ANOVA:

$$y_{ijk} = \mu + x_i + e_{1ij} + e_{2ijk}, \tag{2}$$

where

$i$ = 1, ⋯, 18 stands for the experiment.
$j$ = 1, 2 stands for wafer within the experiment.
$k$ = 1, ⋯, 5 stands for replicate or position within wafer within the experiment.
$\mu$ is the overall mean.
$x_i$ is the fixed effect of the factor-level combination used in experiment $i$. Here we consider only the main effect for each of the factors. See the discussion of model (1) in Section 7.3 for more details of the interpretation of $x_i$.
$e_{1ij}$ is the random effect for wafer $j$ within experiment $i$.
$e_{2ijk}$ is the random error for replicate $k$ within wafer $j$ within experiment $i$.
$y_{ijk}$ is the observation for replicate $k$ in wafer $j$ in experiment $i$. $y_{ijk}$ takes a value 1 if the window size belongs to the particular category. Otherwise, the value is zero.

The expected mean squares for this ANOVA model are also shown in Table XIV. The variances of $e_1$ and $e_2$ are denoted by $\sigma_1^2$ and $\sigma_2^2$, respectively. The effects of the factors A through I are denoted by $\phi$ with an appropriate subscript. The effect of lack of fit is denoted by $\phi_\ell$. We assume that the random variables $e_{1ij}$ and $e_{2ijk}$ are independent for all values of $i, j$ and $k$. The degrees of freedom shown in Table XIV have been adjusted for the fact that three experiments have only one wafer each.

For testing the significance of the effect of error between wafers within experiments, the relevant denominator sum of squares is the

Table XIV—Post-etch window size

ANOVA for accumulation analysis

| Source | Degrees of Freedom | Sum of Squares | Mean Square | F | (Expected Mean Square) + $\bar{W}$ |
|---|---|---|---|---|---|
| A Mask Dimension | 4 | 26.64 | 6.66 | 2.67* | $\sigma_2^2 + 5\sigma_1^2 + \phi_A$ |
| BD Viscosity-Bake Temperature | 8 | 112.31 | 14.04 | 5.64* | $\sigma_2^2 + 5\sigma_1^2 + \phi_{BD}$ |
| C Spin Speed | 8 | 125.52 | 15.69 | 6.30* | $\sigma_2^2 + 5\sigma_1^2 + \phi_C$ |
| E Bake Time | 8 | 36.96 | 4.62 | 1.86 | $\sigma_2^2 + 5\sigma_1^2 + \phi_E$ |

| G Exposure Time | 8 | 42.28 | 5.29 | 2.12* | $\sigma_2^2 + 5\sigma_1^2 + \phi_G$ |
| H Developing Time | 8 | 45.57 | 5.70 | 2.29* | $\sigma_2^2 + 5\sigma_1^2 + \phi_H$ |
| I Etch Time | 8 | 23.80 | 2.98 | 1.20 | $\sigma_2^2 + 5\sigma_1^2 + \phi_I$ |
| Lack of Fit | 8 | 17.25 | 2.16 | 0.87 | $\sigma_2^2 + 5\sigma_1^2 + \phi_I$ |
| Error Between Wafers Within Experiment | 60 | 149.33 | 2.49 | 11.69* | $\sigma_2^2 + 5\sigma_1^2$ |
| Error Between Replicates Within Wafers Within Experiment | 528 | 112.45 | 0.21 | | $\sigma_2^2$ |
| Total | 656 | 720.00 | | | |

$\bar{W} = (W_{(I)} + W_{(II)} + W_{(III)} + W_{(IV)})/4$.
$F_{4,60}(0.95) = 2.53$, $F_{8,60}(0.95) = 2.10$, $F_{60,528}(0.95) = 1.32$.

(b) Separation of $S_{BD}$

| Source | Degrees of Freedom | Sum of Squares | Mean Square | F |
|---|---|---|---|---|
| B Viscosity | 4 | 87.38 | 21.85 | 8.78* |
| D Bake Temperature | 4 | 6.55 | 1.64 | 0.66 |

* Factors significant at 95-percent confidence level.

estimate of $\sigma_2^2$. The corresponding F value is 11.69, which is significant far beyond the nominal 5-percent level. To test for the lack of fit of the main-effects-only model, the appropriate denominator is the estimate $\sigma_2^2 + 5\sigma_1^2$. The corresponding F ratio is 0.87. This indicates that the main-effects-only model adequately describes the observed data relative to the random errors between wafers. For testing the significance of the process factors, the denominator mean square is again the estimate of $\sigma_2^2 + 5\sigma_1^2$. We see that the mask dimension, viscosity, spin speed, exposure time, and developing time have a significant effect (approximately 5-percent level) on the window size. The effects of the other factors are not significant.

## IX. SELECTION OF OPTIMUM FACTOR LEVELS

The following table summarizes the significant results of the analyses performed in Sections VII and VIII. In each category, the factors are arranged in descending order according to the F value.

Significant effect on s/n:

Pre-etch line width: A, F
Post-etch line width: None
Significant effect on mean:
Pre-etch line width: A, B, C
Post-etch line width: B, G, C, A, H
Significant factors identified by accumulation analysis:
Post-etch window size: B, C, A, H, G

Factors that have a significant effect on the s/n and the factors identified to be significant by the accumulation analysis are all control factors. Setting their levels equal to optimum levels minimizes the process variability. Here the control factors are A, F, B, C, H, and G.

To keep the process mean on target we use a signal factor. Ideally, the signal factor should have a significant effect on the mean, but should have no effect on the s/n. Then changing the level of the signal factor would affect only the mean. In practice, a small effect on the s/n may have to be tolerated.

Among the factors (A, B, C, G, and H) that have a significant effect on the mean, factors A, B, and C are relatively strong control factors as measured by the F statistics for the accumulation analysis and the ANOVA for pre-etch line-width s/n. Also, these factors are relatively difficult to change during production. So A, B, and C are not suitable as signal factor. Between the remaining two factors, G and H, G has greater effect on the mean and also shows as a less significant factor in accumulation analysis. So exposure time was assigned to be the signal factor.

The optimum levels for the control factors were selected as follows. The mask dimension (A) and the aperture (F) have a significant effect on the s/n for pre-etch line width. From Table V we see that the 2.5-$\mu$m mask (level 2) has a higher s/n than the 2.0-$\mu$m mask. Hence 2.5 $\mu$m was chosen to be the optimum mask dimension. Also, aperture 1 (level 1) has the highest s/n among the three apertures studied. However, because of the past experience, aperture 2 was chosen to be the preferred level.

The accumulation analysis of the post-etch window-size data indicated that the viscosity, spin speed, mask dimension, developing time, and exposure have statistically significant effects on the frequency distribution. The optimum levels of these factors can be determined from Table XIII and Fig. 6 to be those that have the smallest fraction of windows not open (category I) and the largest fraction of windows in the range $3.0 \pm 0.25$ $\mu$m (category IV). Because it is more critical to have all the windows open, when there was a conflict we took the requirement on category I to be the dominant requirement. The optimum levels are: 2.5-$\mu$m mask dimension, viscosity 204, 4000-rpm spin speed, 60-second developing time, and normal exposure.

Table XV—Optimum factor levels

| Label | Factors Name | Standard Levels | Optimum Levels |
|---|---|---|---|
| A | Mask Dimension (μm) | 2.0 | 2.5 |
| B | Viscosity | 204 | 204 |
| C | Spin Speed (rpm) | 3000 | 4000 |
| D | Bake Temperature (°C) | 105 | 105 |
| E | Bake Time (min) | 30 | 30 |
| F | Aperture | 2 | 2 |
| G | Exposure (PEP setting) | Normal | Normal |
| H | Developing Time (s) | 45 | 60 |
| I | Plasma Etch Time (min) | 13.2 | 13.2 |

Table XV shows side by side the optimum factor levels and the standard levels as of September 1980. Note that our experiment has indicated that the mask dimension be changed from 2.0 μm to 2.5 μm, spin speed from 3000 rpm to 4000 rpm, and developing time from 45 seconds to 60 seconds. The exposure time is to be adjusted to get the correct mean value of the line width and the window size. The levels of the other factors, which remain unchanged, have been confirmed to be optimum to start with.

In deriving the optimum conditions we have conducted a highly fractionated factorial experiment and have considered only the main effects of the factors. The interactions between the factors have been ignored. If the interactions are strong compared to the main effects, then there is a possibility that the optimum conditions thus derived would not improve the process. So experiments have to be conducted to verify the optimum conditions. The verification was done in conjunction with the implementation, which is described next.

## X. IMPLEMENTATION AND THE BENEFITS OF THE OPTIMUM LEVELS

We started to use the optimum process conditions given in Table XV in the Integrated Circuits Design Capability Laboratory in January 1981. In the beginning the exposure was set at 90, which is the normal setting given in Table I. We observed that the final window at the end of step ($xi$) was much larger than the target size of 3.5 μm. Through successive experiments, we reduced the exposure time until the mean final window size came to about 3.5 μm. The corresponding exposure setting is 140. Since then the process has been run at these conditions. The benefits of running the process at these conditions are:

($i$) The pre-etch line width is routinely used as a process quality indicator. Before September 1980 the standard deviation of this indicator was 0.29 μm on a base line chip (DSO chip). With the optimum process parameters, that standard deviation has come down to 0.14 μm. This is a two-fold reduction in standard deviation, or a four-fold reduction in variance. This is evidenced by Fig. 7, which shows a

typical photograph of the PLA area of a *BELLMAC*-32 microprocessor chip fabricated by the new process. Note that windows in Fig. 7 are much more uniform in size compared to the windows in Fig. 2. Also, all windows are printed and open in Fig. 7.

(*ii*) After the final step of window forming, i.e., after step (*xi*), the windows are visually examined on a routine basis. Analysis of the quality control data on the DSO chip, which has an area of approximately 0.19 $cm^2$, showed that prior to September 1980 about 0.12 window per chip was either not open or not printed (i.e., approximately one incidence of window not open or not printed was found in eight chips). With the new process only 0.04 window per chip is not open or printed (i.e., approximately one incidence of window not open or printed is found in twenty-five chips). This is a three-fold reduction in defect density due to unopened windows.

(*iii*) Observing these improvements over several weeks, the process engineers gained a confidence in the stability and robustness of the new process parameters. So they eliminated a number of in-process checks. As a result the overall time spent by the wafers in window photolithography has been reduced by a factor of two.

The optimum parameter levels were first used in the Integrated Circuit Device Capability Laboratory with only a few codes of ICs. Subsequently, these parameter levels were used with all codes of 3.5-$\mu$m technology chips, including *BELLMAC*-4 microcomputer and *BELLMAC*-32 microprocessor chips. The mask dimension change from 2.0 to 2.5 $\mu$m is now a standard for 3.5-$\mu$m CMOS technology.

## XI. DISCUSSION AND FUTURE WORK

The off-line quality control method is an efficient method of improving the quality and the yield of a production process. The method has a great deal of similarity with the response surface method[9] and the evolutionary operations method,[10] which are commonly known in statistical literature in this country. Both the response surface and the evolutionary operations methods are used to maximize the yield of a production process and they both make use of the experimental design techniques. The main difference is that in the off-line quality control method the process variability that has a great impact on the product quality is the objective function. In the response surface and evolutionary operations methods, the process variability is generally not considered. Thus, intuitively, the optimum levels derived by using the off-line quality control method can be expected to be more robust, stable, and dependable.

In the response surface method one typically uses a relatively large fraction of the factorial experiment. However, in off-line quality control usually a very small fraction is chosen. Another difference is that in

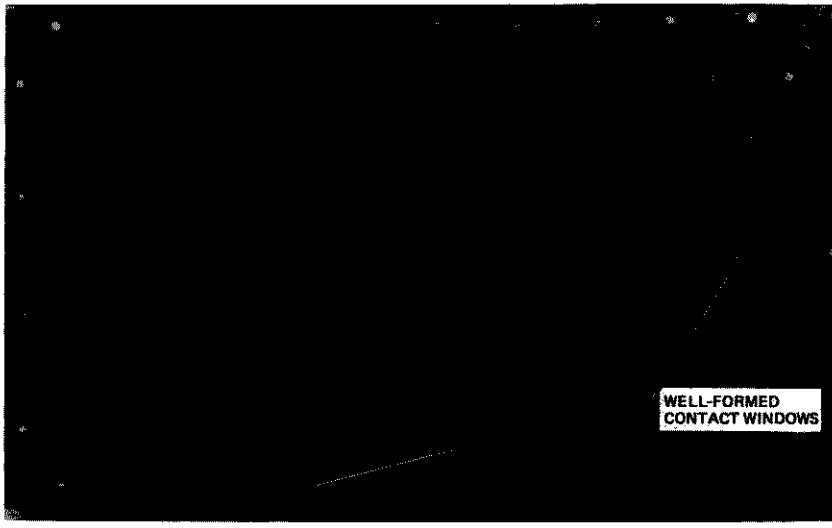

Fig. 7—Typical results for contact windows in PLA area (January through March, 1981) using parameters derived from this experiment. The contact windows are round shaped.

the response surface method the objective function is considered to be a continuous function approximated by a low-order polynomial. In off-line quality control, we can simultaneously study both the continuous and discrete factors.

Our application of the off-line quality control method to the window-cutting process in the Murray Hill 3.5-$\mu$m CMOS technology, as seen from the earlier sections, has resulted in improved control of window size, lower incidence of unopened windows, and reduced time for window photolithography. Presently, we have undertaken to optimize two more steps in IC fabrication. Those steps are polysilicon patterning and aluminum patterning. Both these processes, like the window-cutting process, involve photolithography and are among the more critical processes of IC fabrication. We think that the method has a great potential and would like to see applications in various parts of Bell Laboratories and Western Electric Company.

## XII. ACKNOWLEDGMENTS

The authors acknowledge with gratitude the support and the encouragement given by R. L. Chaddha, R. Edwards, J. V. Dalton, A. B. Hoadley, and G. R. Weber. R. G. Brandes, K. J. Orlowski, and members of the IC Process Operations Group provided valuable help in conducting the experiments. We also thank Ramon Leon for helpful discussions on the graphical representation of the data and I. J. Terpenning for helpful comments on an earlier draft of this paper. The

original manuscript was carefully prepared by Jill Cooper on the *UNIX** operating system.

## APPENDIX A

### *Computation of the Sum of Squares—Analysis of the Signal-to-Noise Ratio for Pre-Etch*

The computations of the sum of squares tabulated in Table VIa are illustrated below.

$$S_m = \text{Correction Factor}$$

$$= \frac{\left(\sum_{i=1}^{18} \eta_i\right)^2}{18} = \frac{(25.2202)^2}{18} = 35.3366$$

$$S_A = \text{Sum of squares for factor A}$$

$$= \frac{(9m_{A_1})^2 + (9m_{A_2})^2}{9} - S_m$$

$$= \frac{(11.5711)^2 + (13.6491)^2}{9} - 35.3366$$

$$= 0.2399 \qquad (d.f. = 1)$$

$$S_C = \frac{(6m_{C_1})^2 + (6m_{C_2})^2 + (6m_{C_3})^2}{6} - S_m$$

* Trademark of Bell Laboratories.

$$= \frac{(8.1979)^2 + (8.1017)^2 + (8.9206)^2}{6} - S_m$$

$$= 0.0668 \qquad (d.f. = 2).$$

Sums of squares for the factors E, F, G, and H were calculated similarly. The combined sum of squares due to B and D is given by

$$S_{BD} = \text{Sum of squares for the column BD}$$

$$= \frac{(6m_{B_1D_1})^2 + (6m_{B_1D_2})^2 + (6m_{B_2D_1})^2}{6} - S_m$$

$$= \frac{(8.2524)^2 + (8.6649)^2 + (8.3029)^2}{6} - 35.3366$$

$$= 0.0169 \qquad (d.f. = 2).$$

The total sum of squares is

$$S_T = \sum_{i=1}^{18} \eta_i^2 - S_m = 0.8423. \qquad (d.f. = 17).$$

The error sum of squares is calculated by subtraction.

$$S_e = S_T - (S_A + S_{BD} + S_C + S_E + S_F + S_G + S_H)$$

$$= 0.1522 \qquad (d.f. = 4).$$

Here we do not compute the sum of squares due to factor I (etch time), because it has no influence on the pre-etch line width.

## APPENDIX B

### *Computation of the Percent Contribution—Analysis of the Signal-to-Noise Ratio for Pre-Etch Line Width*

The computation of the percent contribution is explained below. The contribution of factor A to the total sum of squares

$$= S_A - (d.f. \text{ of A})(\text{error mean square}).$$

Hence, the percent contribution for factor A

$$= \frac{S_A - (\text{d.f. of A})(\text{error mean square})}{\text{total sum of squares}} \times 100$$

$$= \frac{0.2399 - 0.0251}{0.8423} \times 100 = 25.5\%.$$

The percent contributions of E and F are determined similarly. Now consider, the contribution of error to the total sum of squares:

$$= S_e + (\text{total } d.f. \text{ for factors})(\text{error mean square}).$$

Hence, the percent contribution for error

$$= \frac{S_e + (\text{total } d.f. \text{ for factors})(\text{error mean square})}{\text{total sum of squares}} \times 100$$

$$= \frac{0.3010 + 5 \times 0.0251}{0.8423} \times 100 = 50.6\%.$$

## APPENDIX C

### *Separation of $S_{BD}$ into $S_B$ and $S_D$—Analysis of the Mean Pre-Etch Line Width*

The sum of squares, $S_{BD}$, can be decomposed in the following two ways[11] to obtain the contributions of the factors B and D:

$$S_{BD} = S'_{B(D)} + S'_D$$

and

$$S_{BD} = S'_{D(B)} + S'_B.$$

Here $S'_{B(D)}$ is the sum of squares due to B, assuming D has no effect; $S'_D$ is the sum of squares due to D after eliminating the effect of B. The terms $S'_{D(B)}$ and $S'_B$ are interpreted similarly. We have

$$S'_{B(D)} = \frac{(6m_{B_1D_1} + 6m_{B_1D_2} - 12m_{B_2D_1})^2}{(1^2 + 1^2 + 2^2) \times 6} = 0.903 \qquad (d.f. = 1)$$

$$S'_D = S_{BD} - S'_{B(D)} = 0.047 \qquad (d.f. = 1).$$

Similarly,

$$S'_{D(B)} = \frac{(6m_{B_1D_1} + 6m_{B_2D_1} - 12m_{B_1D_2})^2}{(1^1 + 1^2 + 2^2) \times 6} = 0.116 \qquad (d.f. = 1)$$

$$S'_B = S_{BD} - S'_{D(B)} = 0.834 \qquad (d.f. = 1).$$

For testing the significance of the factors B and D we use $S'_B$ and $S'_D$, respectively. Note that $S'_B$ and $S'_D$ do not add up to $S_{BD}$, which is to be expected because the design is not orthogonal with respect to the factors B and D.

## APPENDIX D

### *Computation of the Sum of Squares for Accumulation Analysis—Analysis of Post-Etch Window Size*

The weights for the cumulative categories (I), (II), (III), and (IV) are given below. The frequencies of the bottom line of Table XIII are used in computing these weights. Therefore:

$$W_{(I)} = \frac{1}{\frac{86}{180} \times \frac{180 - 86}{180}} = 4.008$$

$$W_{(II)} = \frac{180^2}{102 \times (180 - 102)} = 4.072$$

$$W_{(III)} = \frac{180^2}{125 \times (180 - 125)} = 4.713$$

$$W_{(IV)} = \frac{180^2}{160 \times (180 - 160)} = 10.125.$$

Computation of the sum of squares tabulated in Table XIV are illustrated below:

$$S_A = W_{(I)} \times \left(\frac{51^2 + 35^2}{90} - \frac{86^2}{180}\right) + W_{(II)} \times \left(\frac{58^2 + 44^2}{90} - \frac{102^2}{180}\right)$$
$$+ W_{(III)} \times \left(\frac{67^2 + 58^2}{90} - \frac{125^2}{180}\right) + W_{(IV)} \times \left(\frac{88^2 + 72^2}{90} - \frac{160^2}{180}\right)$$
$$= 26.64,$$

and

$$S_C = W_{(I)} \times \left(\frac{47^2 + 22^2 + 17^2}{60} - \frac{86^2}{180}\right)$$
$$+ W_{(II)} \times \left(\frac{52^2 + 29^2 + 21^2}{60} - \frac{102^2}{180}\right)$$
$$+ W_{(III)} \times \left(\frac{58^2 + 39^2 + 28^2}{60} - \frac{125^2}{180}\right)$$
$$+ W_{(IV)} \times \left(\frac{60^2 + 55^2 + 45^2}{60} - \frac{160^2}{180}\right)$$
$$= 125.52.$$

# The Effects of Selected Signal Processing Techniques on the Performance of a Filter-Bank-Based Isolated Word Recognizer

By B. A. DAUTRICH, L. R. RABINER, and T. B. MARTIN

(Manuscript received December 3, 1982)

*To implement an isolated word recognizer based on filter bank techniques, decisions must be made as to how to condition the speech signal prior to the filter bank analysis (preprocessing), how to condition the feature vector at the output of the filter bank analysis (postprocessing), and how to perform the time alignment in the pattern comparison between an unknown test pattern and previously stored reference patterns (registration and distance computation). In the past most designers of such word recognition systems made arbitrary choices about how the various signal processing operations were to be carried out. This paper presents results of a systematic study of the effects of selected signal processing techniques on the performance of a filter bank isolated word recognizer using telephone-quality speech. In particular, the filter bank analyzer was a 13-channel, critical-band-spaced filter bank with excellent time resolution (impulse response durations of from 3 to 30 ms) and poor frequency selectivity (highly overlapping filters with ratios of center frequency to 3-dB bandwidth of about 8 for each band). Among the signal processing techniques studied were: preemphasis of the speech signal; time and frequency smoothing of the filter bank outputs; thresholding, quantization, and normalization of the feature vector; principal components analysis of the feature vector; local and global distance computations for use in the time alignment procedure; and noise analysis in both training and testing. Each of the signal processing techniques was studied individually; hence no tests were run in which several of the techniques were used together. Results showed that some fairly simple signal processing operations provided the best overall performance in the noise-free case; in noisy conditions performance degraded significantly for signal-to-noise ratios less than about 24 dB.*

## I. INTRODUCTION

To implement an isolated word recognizer based on a filter analysis, decisions must be made as to how to preprocess the speech signal prior to the filter bank analysis, how to postprocess the feature vectors obtained at the output of the filter bank analysis, and how to perform the time alignment and distance computation in the pattern comparison between an unknown test pattern and previously stored reference patterns. Often such decisions are made arbitrarily based on experience, heuristic procedures, or sometimes a few brief tests with the system. To our knowledge no one has attempted to systematically examine the effects of various signal processing techniques on the performance (as measured in word error rate) of a filter-bank-isolated word recognizer. This paper provides such a comparison by examining several of the most popular signal processing techniques and showing how they affect the performance of a particular filter bank word recognizer using telephone-quality speech.[1]

There are two inherent problems with any study that attempts to find the best signal processing techniques for a system via experimental means. The first is that the results presented are highly dependent on the signal processing techniques that were studied. Hence, the "optimal" way of processing the signal may not even have been investigated (due to lack of knowledge, etc). With our limited knowledge we know of no way to avoid this difficulty. The second problem is that, of necessity, each of the various signal processing techniques is studied independently of any other (thereby tacitly assuming independence of the various methods). Hence, any interactions between the techniques studied will go unnoticed. Again, we know of no practical way of studying the interactions between signal processing operations; the processing, assuming independence of operations, took about four full months on a modern minicomputer system!

The results to be presented in this paper are an extension of a previous study[1] that examined different filter bank structures and compared their performance to that of a conventional linear predictive coefficient (LPC) word recognizer.[2,3] The key results of this earlier work were:

(*i*) The best performance in word recognition tests was achieved by both a 13-channel, critical-band-spaced filter bank, and a 15-channel, uniformly spaced filter bank. Both filter banks had composite frequency responses without gaps at the band edges. The 13-channel filter bank had highly overlapping filters; the 15-channel filter bank had filters with almost no overlap.

(*ii*) There were significant performance differences between talkers (especially female as opposed to male talkers).

(*iii*) Performance of the LPC and the best filter bank recognizers were comparable for a simple vocabulary of the 10 digits using telephone-quality speech (with no extra noise degradation) over a dialed-up telephone line using a local private branch exchange (PBX).

(*iv*) Performance of the LPC recognizer was superior to that of the best filter-bank recognizers for a complex vocabulary of the alphabet, digits, and three command words, again using telephone-quality speech.

A key question arising from these results was whether any of the proposed signal-processing techniques for the filter bank system could bring up the performance to that of the LPC system for the complex alpha-digits vocabulary. Unfortunately, we will see that none of the proposed methods was able to significantly improve filter-bank performance. (However, some were able to keep performance the same while reducing required storage.)

Two other implementational aspects of word recognizers were studied. The first involves the use of the normalize-and-warp procedure proposed by Myers et al.[4] In this procedure a fixed-length pattern is created for both test and reference patterns prior to time alignment. In this manner the largest warping area is obtained, and the computational aspects of implementing the time-warping procedure are greatly simplified. Instead of considering just the word average length for warping, we studied the effects (for both the filter bank and LPC systems) of warping to prespecified lengths of various amounts. It was found that a large amount of compression could be made before system performance degraded by a significant amount.

The second implementational aspect studied was the effects of additive noise on the performance of both the LPC and filter bank recognizers. We considered cases in which both the training and testing occurred in the noisy background, and when only the testing occurred in the noisy background. It was found that far superior performance was obtained, at all signal-to-noise ratios, when both training and testing occurred in the noisy background. Furthermore, performance of both types of recognizers degraded for signal-to-noise ratios less than or equal to 24 dB. Also, for signal-to-noise ratios greater than 6 dB, the LPC recognizer outperformed the filter bank recognizer.

An overview of the work presented in this paper is as follows. In Section II we review the general implementation of the filter bank isolated word recognizer. In Section III we discuss the signal processing methods that were studied in conjunction with the filter bank. In Section IV we discuss the noise studies. In Section V we describe the experiments performed and give word error rates for the various tests. Finally, a discussion of the results is given in Section VI.

## II. THE FILTER-BANK-ISOLATED WORD RECOGNIZER

Figure 1 shows a block diagram of the overall filter bank word recognizer. The input speech signal is recorded off a dialed-up telephone line, band-limited to 3200 Hz, and digitized at a 6.67-kHz rate. The digitized speech signal, $s(n)$, is first sent to a preprocessor to condition the signal for the filter bank analyzer. Preprocessing is basically a spectra-shaping operation (e.g., linear filtering) for increased immunity to finite word-length processing in the remainder of the system.[5] The preprocessed signal, $\hat{s}(n)$, is then sent to a filter bank analyzer whose structure is shown in Fig. 2. The filter bank contains a set of $Q$ parallel bandpass filters that cover the speech band of

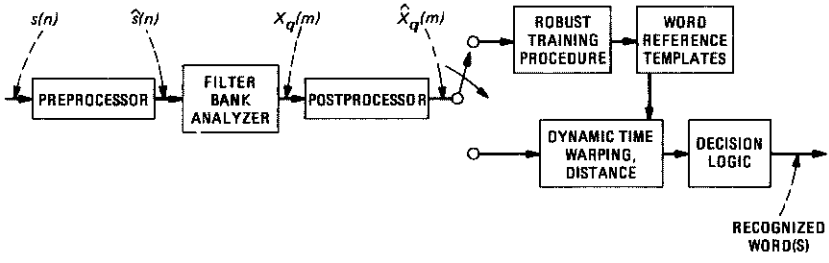

Fig. 1—Filter bank word recognizer with both preprocessing and postprocessing operations.

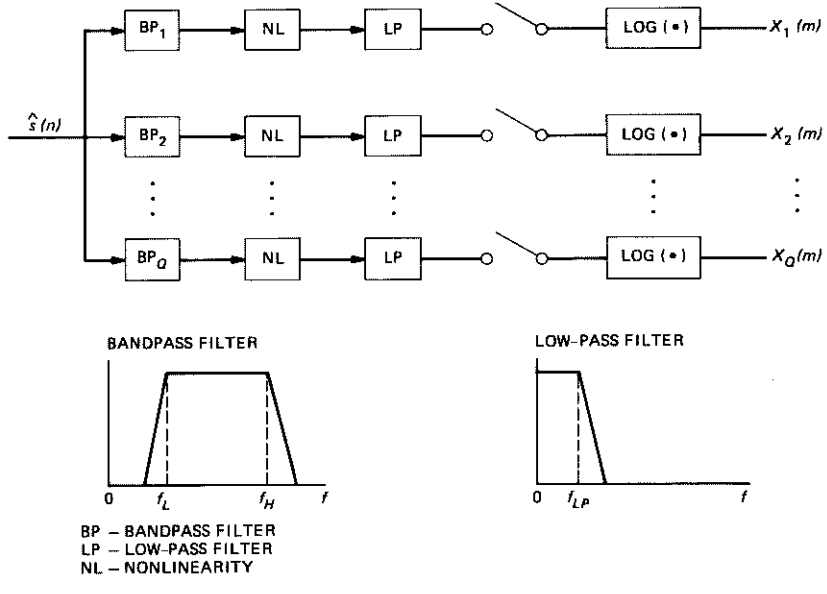

Fig. 2—Structure of filter bank analyzer.

interest (100 to 3200 Hz for telephone speech). Each bandpass filter is followed by a nonlinearity (NL), a low-pass (LP) filter, a sampler, and a logarithmic compressor. The output of the filter bank at time $m$ is a vector

$$X(m) = [X_1(m), X_2(m), \cdots, X_Q(m)], \tag{1}$$

whose components $X_i(m)$ represent the energy in the speech signal in channel $i$ at time $m$.

In our previous work[1] we studied the effects of different types of filter banks on recognizer performance and found that the highest accuracy was obtained with two types of filter banks, namely:

(*i*) A 13-channel, critical-band-spaced filter bank with higher overlapping channels. This filter bank had excellent time resolution (on the order of 10 ms) but poor frequency resolution.

(*ii*) A 15-channel, uniformly spaced filter bank with essentially no overlap between channels. This filter had poor time resolution but excellent frequency resolution. The composite spectrum of this filter bank was flat to within fractions of a dB.

Both of these filter banks used a magnitude nonlinearity and a 3-pole, Bessel, low-pass filter with a 30-Hz cutoff frequency. The sampling rate of the output feature vector was 67 Hz—i.e., adjacent feature estimates were spaced 15 ms in time.

The output of the filter bank was sent to a postprocessor, which performed one or more of the following operations:

(*i*) Time smoothing of feature vectors
(*ii*) Frequency smoothing of channels within a feature vector
(*iii*) Normalization of the feature vector
(*iv*) Thresholding and/or quantization of the feature vector
(*v*) Principal components analysis of the feature vector.

The output of the postprocessor was the input pattern to either the training mode (a robust training procedure[6]), or to the testing mode. In the training mode a set of word reference templates were created based on consistent matches of tokens of a word to previously analyzed tokens of the same word. In the testing mode the test pattern, $T$, consisting of the sequence of feature vectors

$$\mathbf{T} = \{\hat{X}(1), \hat{X}(2), \cdots, \hat{X}(M)\} \tag{2}$$

was compared to the reference pattern, $R^i$, for the $i$th vocabulary word using a dynamic time-warping alignment procedure.[2] For the $i$th reference pattern, a total average distance, $D_i$, between it and the test pattern was computed, and simple decision logic was used to make the word choice for recognition.

To implement the word recognizer of Fig. 1, one has to choose the types of processing to go into the preprocessor, the filter bank analyzer,

the postprocessor, and the dynamic time-warping algorithm. Based on the earlier study[1] we limited the filter bank to the 13-channel critical-band filter bank. However, for each of the remaining signal-processing blocks we tried to choose one or more possibilities and then did experiments to evaluate its usefulness to the overall word recognizer. We discuss our choices in detail in Section III. In addition we chose to study the effects of both noise addition and length quantization of both reference and test patterns on overall performance. These experiments are described in Section IV.

## III. SIGNAL PROCESSING CHOICES IN THE RECOGNIZER

### 3.1 Preprocessor

The function of the preprocessor is to spectrally shape the speech signal to achieve some desired gross spectral shape. The most common form of preprocessing is simple preemphasis, which is used to compensate the inherent 6-dB per octave falloff in the speech spectrum. In such a case a simple first-order network of the form

$$H(z) = 1 - \alpha z^{-1} \tag{3}$$

has been found adequate[3] for recognition purposes. Thus, the difference equation relating $\hat{s}(n)$ to $s(n)$ is of the form

$$\hat{s}(n) = s(n) - \alpha s(n-1), \tag{4}$$

where a value of $\alpha = 0.95$ has been used previously.

### 3.2 Postprocessing

We denote the output of the $q$th channel of the filter bank at frame $m$ as $X_q(m)$, $m = 1, 2, \cdots, M$, $q = 1, 2, \cdots, Q$. All of the postprocessing operations can be expressed in terms of signal processing on $X_q(m)$ to give the signal $\hat{X}_q(m)$. We have considered the operations in Sections 3.2.1 through 3.2.5.

#### 3.2.1 Thresholding and energy normalization

The purpose of channel thresholding is to clamp low-level noise signals from channels at times when essentially no speech signal is present. This is done by applying a threshold so that channel signals below threshold are clamped at the threshold value. In this way much less sensitivity to background noise is achieved. In particular, this is achieved by determining $X_q^{\text{MAX}}$, the peak signal level for the $q$th channel, for each word as:

$$X_q^{\text{MAX}} = \max_{1 \le m \le M} [X_q(m)]. \tag{5}$$

Then the threshold for the $q$th channel is set at

$$T_q^* = X_q^{\text{MAX}} - T^*, \tag{6}$$

where $T^*$ is a parameter of the recognition system. A typical range of $T^*$ is from 30 to 50 (dB).[1] The thresholded channel signal is then given as

$$\hat{X}_q(m) = \max[X_q(m), T_q^*] \tag{7}$$

for all $q$ and $m$.

The purpose of frame energy normalization is to compensate for variations in speech level from utterance to utterance. We have considered two distinct normalization methods, which we call average and peak normalization. For average normalization we calculate the frame average, $\bar{X}(m)$, as

$$\bar{X}(m) = \frac{1}{Q} \sum_{q=1}^{Q} X_q(m), \tag{8}$$

and for peak normalization we calculate the peak as

$$\bar{X}(m) = \max_{1 \le q \le Q} [X_q(m)]. \tag{9}$$

The energy-normalized feature vector is then given as†

$$\hat{X}_q(m) = X_q(m) - \hat{X}(m). \tag{10}$$

It can readily be shown that both peak and average normalization have the property that if a feature set $T$ is derived from the speech signal $s(n)$, then the feature set $T'$ derived from

$$s'(n) = \gamma s(n) \tag{11}$$

will be identical to $T$ after the normalization of eq. (10) is carried out. Hence, gain variations are normalized out of the processing as desired.

#### *3.2.2 Time smoothing of feature vectors*

The purpose of time smoothing of feature vectors is to reduce the variability in channel outputs by averaging adjacent time frames. The cost of such smoothing is a decrease in time resolution achieved by the recognizer. If we assume that $M^*$ adjacent frames are to be overlapped and smoothed, then time smoothing can be expressed as

$$\hat{X}_q(m) = \frac{1}{M^*} \sum_{\hat{m}=m-M^*+1}^{m} X_q(\hat{m}), \qquad m = M^*, \cdots, M. \tag{12}$$

† The reader is reminded that the channel signals are logarithmically encoded. Hence, normalization takes the form of subtraction.

It should be noted that the first $(M^* - 1)$ frames are eliminated and are used as initial conditions for the smoothing.

#### 3.2.3 Frequency smoothing of channel outputs

As in time smoothing, the purpose of frequency smoothing is to reduce the variability in channel outputs by averaging adjacent channels for a given time frame. Again, the cost of this smoothing is a loss in frequency resolution. If we assume that $Q^*$ adjacent channels are to be overlapped and smoothed, then frequency smoothing can be expressed as

$$\hat{X}_q(m) = \frac{1}{Q^*} \sum_{\hat{q}=q-Q^*+1}^{q} X_{\hat{q}}(m), \qquad q = Q^*, \cdots, Q. \tag{13}$$

It should again be noted that the first $(Q^* - 1)$ channels are eliminated and are used as initial conditions for the smoothing.

#### 3.2.4 Quantization of channel outputs

The purpose of quantizing the channel outputs is to reduce the storage requirements of the recognizer both for reference patterns and for the test pattern. If we use a $B$-bit quantizer, and we assume the channel signals are in the range $[0, -T^*]$ because of the thresholding and energy normalization operations, then with a uniform quantizer we have a quantization width of

$$\Delta E = \frac{T^*}{2^B} \tag{14}$$

and we can express the quantized output signal as

$$\hat{X}_q(m) = \lfloor X_q(m)/\Delta E \rfloor \cdot \Delta E, \tag{15}$$

where $\lfloor x \rfloor$ is the greatest integer less than $x$, and it is assumed that $\hat{X}_q(m)$ is already thresholded and energy normalized.

#### 3.2.5 Principal components analysis

The last form of postprocessing that we considered was a principal components analysis[7] in which the $Q$-dimensional filter bank feature vector is transformed into a new $P$-dimensional feature vector, where $P < Q$, such that all the important information in the original vector is retained. The purpose of reducing the feature dimensionality is to reduce the required storage for reference and test patterns. This method has also been used by Pols[7] to recognize vowels with good success.

The way in which the principal components analysis was performed was as follows. The first step is to collect a large number of filter bank

feature vectors and to compute the covariance matrix, $\Lambda$, between dimensions as

$$\Lambda_{ij} = \frac{\sum_{\cdot} [X_i(\cdot) - \bar{X}_i(\cdot)][X_j(\cdot) - \bar{X}_j(\cdot)]}{\left\{\sum_{\cdot} [X_i(\cdot) - \bar{X}_i(\cdot)]^2 \sum_{\cdot} [X_j(\cdot) - \bar{X}_j(\cdot)]^2\right\}^{1/2}}, \tag{16}$$

where the summation is over the training set of feature vectors. The principal components analysis then determines a new dimension, which is a linear combination of the original $Q$ dimensions, that contains as much of the total variance as possible. Then a second new dimension is determined such that it is orthogonal to the first new dimension and contains as much of the remaining variance as possible. This new dimension is again a linear combination of the $Q$ old dimensions. This process is continued until we have $P$ new orthogonal dimensions, all of which are linear combinations of the original $Q$ dimensions. Hence, if we denote the transformed set as $\hat{X}_{\hat{q}}(m)$, the transformation to the new dimensions is of the form

$$\hat{X}_{\hat{q}}(m) = \sum_{q=1}^{Q} \beta_{\hat{q}}(q) X_q(m), \qquad \hat{q} = 1, 2, \cdots, P, \tag{17}$$

where $\beta_{\hat{q}}(q)$ is the coefficient vector for dimension $\hat{q}$.

The resulting $P$-dimensional space of the principal components analysis contains as much of the total variance of the original space as is possible in $P$ dimensions. The new space is obtained formally by doing an eigenvector analysis of the original covariance matrix, $\Lambda$. The resulting eigenvectors are the coefficient vectors for the transformation of eq. (17).

### 3.3 *Dynamic time-warping considerations*

Once the feature vectors have been obtained, the recognizer must compare the unknown test pattern, $T$, to each word reference pattern, $R_i$, $i = 1, 2, \cdots, V$, for a $V$-word vocabulary. For this comparison the technique of dynamic time warping (DTW) is used.[2,8,9] If we denote the test pattern, $T$, as

$$T = \{T(1), T(2), \cdots, T(M)\} \tag{18}$$

and the $i$th reference, $R_i$, as

$$R^i = \{R^i(1), R^i(2), \cdots, R^i(N_i)\}, \tag{19}$$

then the DTW algorithm determines a warping path

$$n = w(m) \tag{20}$$

such that the total distance, $D(T, R^i)$, defined as

$$D(T, R^i) = \frac{1}{M} \sum_{m=1}^{M} d\{T(m), R^i[w(m)]\} \tag{21}$$

is minimized, where $d(T, R^i)$ is the local distance between test and reference frames.

We have considered several variations on the conventional DTW algorithm. First we have modified the global distance of eq. (21) to include a time weighting of the form

$$\hat{D}(T, R^i) = \frac{\sum_{m=1}^{M} W^T(m) d\{T(m), R^i[w(m)]\}}{\sum_{m=1}^{M} W^T(m)}, \tag{22}$$

where $W^T(m)$ is the weight applied to the local distance at frame $m$. It should be noted that in eq. (22) the weight is a function of only the test pattern, $T$.

We have also considered a variety of types of local distance calculations of the form

$$d(T, R) = \frac{\left\{ \sum_{q=1}^{Q} (W_q^T)^p [|\, T(q) - R(q) \,|^p] \right\}^{\frac{1}{p}}}{\left[ \sum_{q=1}^{Q} (W_q^T)^p \right]^{\frac{1}{p}}}, \tag{23}$$

where $W_q^T$ is a frequency weighting curve dependent only on the test pattern, $T$, and $p$ is the distance power for emphasizing the frequency variations. Typical values for $p$ are 1 (magnitude distance), 2 (squared distance), and 1/2 (square root distance). Again, it should be noted that the frequency weight of eq. (22) is only a function of the test frame.

An alternative form of distance weighting was suggested by Silverman and Dixon[10] and is of the form

$$d(T, R) = \frac{1}{Q} \sum_{q=1}^{Q} |\, T(q) - R(q) - f(|\, \bar{T} - \bar{R} \,|) \,|, \tag{24}$$

where

$$f(y) = 1 - \frac{y}{y^{\mathrm{MAX}}} \tag{25}$$

and $y^{\mathrm{MAX}}$ is the largest value that $y$ can attain. The form of eq. (24) is similar to that of the average normalization [eq. (8)] discussed earlier in that the means of $T$ and $R$ (over channels) are essentially subtracted

from each $T(q)$ and $R(q)$ component. However, this is only the case when $|\bar{T} - \bar{R}| \approx 0$, in which case $f(|\bar{T} - \bar{R}|) \approx 1$. For cases in which $|\bar{T} - \bar{R}|$ is large (i.e., close to the maximum difference of $T^*$), then $f(|\bar{T} - \bar{R}|) \approx 0$ and no mean correction is used. Thus, the weighting of eq. (24) places extra emphasis on regions of high average energy difference, and less emphasis on regions of low average energy difference. We denote the distance measure of eq. (24) as the Silverman-Dixon (SD) distance measure.

The last variation on the conventional DTW algorithm that we have investigated is the relaxation of the endpoint constraints on the warping path. Normally we use the simple constraints that

$$w(1) = 1 \qquad \text{Initial Point} \tag{26a}$$

$$w(M) = N_i \qquad \text{Final Point,} \tag{26b}$$

i.e., the first test frame is mapped to the first reference frame and the last test frame is mapped to the last reference frame. We have considered relaxation of both endpoint constraints of eq. (26) to the form

$$1 \le w(M_B) \le \delta_{\text{BEG}}, \qquad 1 \le M_B \le \delta_{\text{BEG}} \tag{27a}$$

$$N_i - \delta_{\text{END}} \le w(M_E) \le N_i, \qquad M - \delta_{\text{END}} \le M_E \le M. \tag{27b}$$

The new endpoint constraints say that the warping path can begin anywhere within a square of size $\delta_{\text{BEG}} \times \delta_{\text{BEG}}$ at the origin of the test-reference plane, and end anywhere with a square of size $\delta_{\text{END}} \times \delta_{\text{END}}$ at the upper right-hand corner of the test-reference plane. This situation is depicted in Fig. 3. By using local path constraints, which keep the slope of the warping path greater than 1/2 and less than 2, the warping path becomes constrained to lie within the shaded area of the test-reference plane.

### *3.4 The normalize-and-warp procedure*

The conventional DTW algorithm works quite well for most cases of interest. However, in cases when the length of the test pattern, $M$, is significantly different from the length of a reference pattern, $N$, then the region in the test-reference plane in which the warping path can lie often becomes very small. To handle such cases the normalize-and-warp procedure was devised,[4] and it basically consists of linearly prenormalizing both the test and reference patterns to a fixed length, $\hat{N}$, and then performing the DTW on these equal length patterns. In this manner the area in the test-reference plane in which the warping path can lie is maximized; hence we have the best chance of finding a good time-alignment path.

The normalize-and-warp procedure has been successfully used in a number of tests with an LPC recognizer[4,11-13] with very good results.

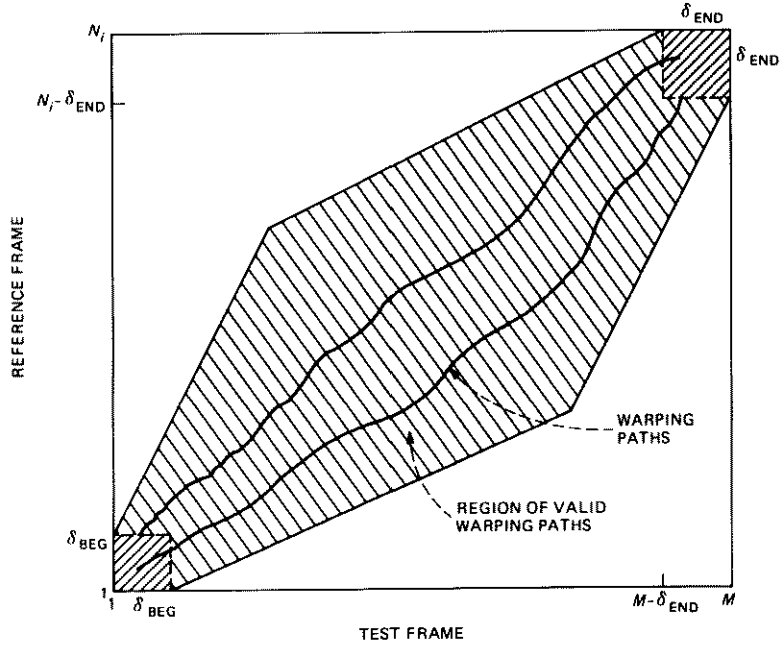

Fig. 3—The allowable warping region in the "test-reference" plane when the warping path has a beginning region of size $\delta_{BEG} \times \delta_{BEG}$ and an ending region of size $\delta_{END} \times \delta_{END}$.

For all these systems the fixed length to which all patterns were warped was the average duration of all words in the vocabulary. In this study we consider use of the normalize-and-warp procedure with the fixed length parameter a free variable.

### *3.5 Summary of signal processing choices*

In this section we have enumerated a number of ways of implementing the signal processing of a filter bank isolated word recognizer. These factors include

(*i*) Spectral preemphasis
(*ii*) Thresholding of channel signals
(*iii*) Energy normalization of channel signals
(*iv*) Time smoothing of feature vectors
(*v*) Frequency smoothing of channel outputs
(*vi*) Quantization of channel signals
(*vii*) Principal components analysis
(*viii*) Time weighting of local DTW distances
(*ix*) Frequency weighting of channel signals in DTW computation
(*x*) Local distance metric for DTW computation
(*xi*) Loosened endpoint constraints in DTW computation

(*xii*) Use of the normalize-and-warp procedure for DTW computation.

In Section V we give the actual choices that were studied for each of the above factors. First, however, we describe the tests of the noise immunity of both filter bank and LPC word recognizers.

## IV. NOISE STUDIES WITH THE ISOLATED WORD RECOGNIZER

Almost all tests of isolated word recognizers are made in a laboratory environment with a high signal-to-noise ratio on the recordings (e.g., greater than 35 dB is typical). There are a wide variety of applications (namely those of the military) in which the word recognizer is required to operate in noisy environments [e.g., signal-to-noise ratios (s/n) around 0 to 20 dB]. Thus, an important consideration in the evaluation of an isolated word recognizer is how the performance degrades as the background goes from laboratory conditions to highly noisy conditions.

When a word recognizer must operate in high-background-noise environments, an important issue arises, namely, whether it is better to train the system in a noise-free environment (and test in the noisy background), or to train and test in the noisy background. We have attempted to study these questions by artificially adding uncorrelated, zero mean, white noise to the speech signals at a specified signal-to-noise ratio, and then performing the required word recognition tests on both the filter bank and LPC word recognizers. A discussion of the test conditions and the results is given in the next section.

When one is concerned with using a word recognizer in an environment with a poor signal-to-noise ratio, another important consideration is whether one would "cancel" any of the noise by using a noise spectral estimation technique and subtracting the noise spectrum out. These techniques have been investigated in the context of voice coding[14-16] and have achieved various degrees of success. For sufficiently stationary noise backgrounds it seems reasonable to expect that a high degree of noise cancellation could be obtained. For such cases it would be of interest to understand how such noise cancellation algorithms work in the context of word recognition.

## V. EXPERIMENTAL RESULTS ON ISOLATED WORD RECOGNITION

To evaluate the effects on performance (word error rate) of each of the recognition system factors of Sections III and IV, a series of tests were run with the following specifications:

| | | |
|---|---|---|
| Vocabulary | — | 39 word alpha-digits |
| Number of talkers | — | 2 male, 2 female |
| Training | — | 7 replications for each word |
| Testing | — | 10 replications for each word. |

Table I—Word error rates for filter bank and LPC word recognizers

| Talker | Candidate Position 1 | 2 | 3 | 4 | 5 |
|---|---|---|---|---|---|
| (a) Rates for baseline filter bank recognizer as a function of talker and candidate position | | | | | |
| 1 (Male) | 9.0 | 4.1 | 0.5 | 0.5 | 0.0 |
| 2 (Male) | 5.4 | 2.3 | 1.0 | 0.5 | 0.3 |
| 3 (Female) | 13.1 | 2.8 | 0.5 | 0.3 | 0.3 |
| 4 (Female) | 18.7 | 8.5 | 4.4 | 2.1 | 1.3 |
| Average | 11.6 | 4.4 | 1.6 | 0.9 | 0.5 |
| (b) Rates for LPC recognizer as a function of talker and candidate position | | | | | |
| 1 (Male) | 5.1 | 0.5 | 0.0 | 0.0 | 0.0 |
| 2 (Male) | 4.1 | 2.3 | 0.8 | 0.3 | 0.3 |
| 3 (Female) | 10.3 | 2.3 | 1.3 | 1.0 | 0.5 |
| 4 (Female) | 11.8 | 6.7 | 3.3 | 1.3 | 0.8 |
| Average | 7.8 | 3.0 | 1.4 | 0.7 | 0.4 |

All recordings were made over dialed-up telephone lines, and the test and training replications were obtained in different recording sessions. The speaker-dependent training used the robust training method[6] to give a single reference pattern for each vocabulary word.

The filter bank used was the 13-channel, critical-band spacing system that gave essentially the best performance in earlier tests.[1] A "baseline" filter bank recognizer was defined that had the following signal processing options:

(*i*) No preemphasis—$\alpha = 0$.

(*ii*) Channel thresholding at $T^* = 50$ dB below the peak in each channel.

(*iii*) Average energy normalization.

(*iv*) No time smoothing—$M^* = 1$.

(*v*) No frequency smoothing—$Q^* = 1$.

(*vi*) No quantization of channel signals (i.e., floating point accuracy)—$B = \infty$.

(*vii*) No principal components analysis.

(*viii*) Uniform time weighting of local distances—$W^T(m) = 1$, all $m$.

(*ix*) Uniform frequency weighting of local distances—$W_q^T = 1$, all $q$.

(*x*) Magnitude local distance—$p = 1$.

(*xi*) No opening up of DTW endpoint regions—$\delta_{\text{BEG}} = \delta_{\text{END}} = 1$.

(*xii*) No length prenormalization prior to the DTW.

(*xiii*) No additive noise—s/n(*Test*) = s/n(*Train*) = $\infty$.

The performance results of this baseline system are given in Table Ia and are shown plotted in Fig. 4a. Both the table and the figure show the word error rate as a function of candidate position for all four

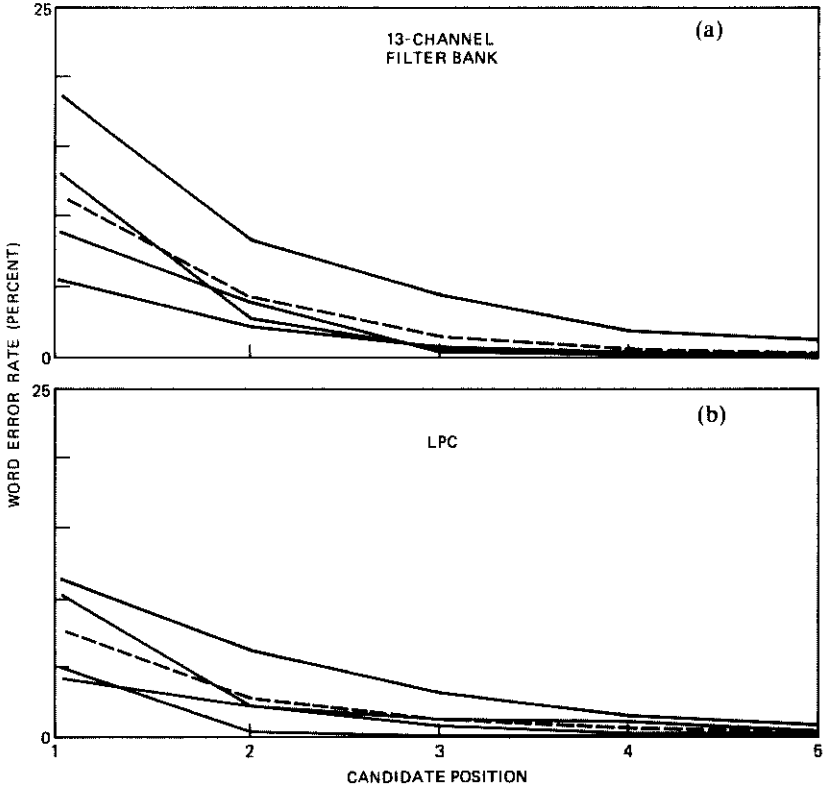

Fig. 4—Plots of word error rate versus candidate position for each of the four talkers and the average for (a) the baseline 13-channel filter bank system, and (b) the LPC word recognizer.

talkers (the solid curves in Fig. 4a) and the average (the dashed curve). These results show an average error rate of 11.6 percent in the top candidate position, with a high degree of variability in error rate across talkers. For comparison purposes, Table Ib and Fig. 4b show similar results on the LPC word recognizer. The average error rate for the top candidate position is about 4 percent lower for the LPC recognizer than for the 13-channel filter bank recognizer. Again we see a fair degree of variability in error rate scores across talkers for the LPC recognizer.

In the following sections we present results of tests designed to measure changes in performance of the filter bank recognizer as the factors noted above are varied. As discussed earlier we have been forced to use the expedient of only varying one parameter at a time; hence all information about interactions between two or more parameters is unavailable.

### 5.1 Effects of simple preemphasis

Only one value of the preemphasis constant, $\alpha$, was studied, namely, $\alpha = 0.95$. This is the value used in previous work on the LPC recognizer.[3] The results of recognition with the use of the preemphasis network are given in Table IIa (only results for top candidate position are included). It can be seen by comparing these results to those of the baseline system that a small improvement in average accuracy was obtained. This improvement was not statistically significant at the 0.9 confidence level.

### 5.2 Effect of clipping threshold

The values studied for the clipping threshold were $T^* = 40$ and $T^* = 30$ (dB). The resulting recognition scores are given in Table IIb for the top candidate position. The results for $T^* = 40$ are comparable to those for $T^* = 50$ in the baseline system, whereas for $T^* = 30$ a significant loss (2.4 percent) in word accuracy is obtained. Hence, a 30-dB range is deleterious to the channel signals in that useful recognition information is lost by clamping the signals at too high a level.

### 5.3 Effects of peak energy normalization

The results of using peak (rather than average) energy normalization of the channel signals are given in Table IIc.† The results show a large increase in word error rate for all talkers, thereby indicating a lack of stability of the peak in each frame and therefore its inappropriateness to be used as an energy normalization aid.

### 5.4 Effects of time smoothing

The value used for the smoothing duration, $M^*$, were 2 and 3 (frames). The recognition results for this condition are given in Table IId for the top candidate position. For $M^* = 2$ an insignificant increase in average error rate occurred, while for $M^* = 3$ there was a very significant increase in error rate. The results show that time smoothing produced far worse scores for female talkers (3 and 4) than for male talkers (1 and 2). This was undoubtedly due to the high variability in channel signals for the females (due to the high pitch frequency), which often led to smearing a "good" frame with a "bad" adjacent frame. The results indicate that time smoothing should not be done.

### 5.5 Effects of frequency smoothing

The results of smoothing across $Q^* = 2$ adjacent frequency channels are given in Table IIe. It can be seen that a uniform increase of about

† Recall that average normalization is one of the standard options used in the recognizer.

Table II—Word error rates for several signal processing techniques in the filter bank recognizer

| | Talker | | | | |
|---|---|---|---|---|---|
| (a) Rate with preemphasis ($\alpha = 0.95$) | | | | | |
| $\alpha$ | 1 | 2 | 3 | 4 | Average |
| 0.95 | 7.7 | 7.7 | 11.8 | 17.4 | 11.2 |
| (b) Rates as a function of threshold parameter, $T^*$ (dB) | | | | | |
| $T^*$ | 1 | 2 | 3 | 4 | Average |
| 40 | 8.7 | 6.9 | 13.3 | 17.4 | 11.6 |
| 30 | 9.5 | 8.5 | 17.2 | 21.0 | 14.0 |
| (c) Rates for peak energy normalization | | | | | |
| Method | 1 | 2 | 3 | 4 | Average |
| Peak | 23.1 | 19.5 | 14.4 | 40.5 | 24.4 |
| (d) Rates as a function of number of frames over which smoothing occurred, $M^*$ | | | | | |
| $M^*$ | 1 | 2 | 3 | 4 | Average |
| 2 | 7.9 | 5.6 | 13.1 | 21.3 | 12.0 |
| 3 | 7.7 | 5.6 | 26.9 | 29.7 | 17.5 |
| (e) Rates as a function of number of frequency channels over which smoothing occurred, $Q^*$ | | | | | |
| $Q^*$ | 1 | 2 | 3 | 4 | Average |
| 2 | 12.6 | 7.4 | 15.4 | 20.5 | 14.0 |
| (f) Rates as a function of $B$, the number of bits used to quantize the channel signals | | | | | |
| $B$ | 1 | 2 | 3 | 4 | Average |
| 6 | 6.7 | 5.6 | 14.4 | 17.4 | 11.0 |
| 4 | 11.3 | 7.2 | 16.9 | 18.7 | 13.5 |
| (g) Rates as a function of $P$, the dimensionality of the principal components analysis | | | | | |
| $P$ | 1 | 2 | 3 | 4 | Average |
| 12 | 11.3 | 9.9 | 25.1 | 29.5 | 18.7 |
| 6 | 11.3 | | | | |
| 4 | 11.5 | | | | |
| 2 | 18.7 | | | | |
| (h) Rates using a nonuniform time weighting in the DTW algorithm | | | | | |
| | 1 | 2 | 3 | 4 | Average |
| | 9.2 | 6.5 | 14.5 | 19.5 | 12.4 |
| (i) Rates using a nonuniform frequency weighting in the DTW algorithm | | | | | |
| Weight | 1 | 2 | 3 | 4 | Average |
| Fig. 5 | 8.7 | 8.7 | 16.2 | 21.3 | 13.7 |
| SD | 8.2 | 7.4 | 16.4 | 17.4 | 12.4 |
| (j) Rates as a function of $p$, the power in the local distance computation | | | | | |
| $p$ | 1 | 2 | 3 | 4 | Average |
| 2 | 12.3 | 7.1 | 21.4 | 23.1 | 16.0 |
| ½ | 10.0 | 6.2 | 13.1 | 20.8 | 12.5 |

(k) Rates as a function of the opening region parameters $\delta_{BEG}$ and $\delta_{END}$ of the DTW algorithm

| $\delta_{BEG}$ | $\delta_{END}$ | Region | 1 | 2 | 3 | 4 | Average |
|---|---|---|---|---|---|---|---|
| 2 | 0 | Square | 8.7 | 5.6 | 13.1 | 22.3 | 12.4 |
| 0 | 4 | Square | 7.9 | 5.4 | 13.8 | 21.5 | 12.2 |
| 2 | 4 | Square | 8.5 | 5.6 | 14.4 | 22.8 | 12.8 |
| 2 | 4 | Line | 8.9 | 6.2 | 24.6 | 22.1 | 15.5 |

2.5 percent in word error rate is obtained for all four talkers. Thus we conclude that smoothing across channels leads to a loss in information for recognition and therefore should not be used.

### 5.6 Quantization of channel signals

The results on channel signal quantization are presented in Table IIf. It can be seen that quantization of the channel signals to 6 bits actually decreases the average error rate by 0.6 percent; however, a further reduction to 4 bits leads to a 1.9-percent increase in error rate over the baseline system. Hence the results indicate that 6-bit quantization is adequate for the channel signals.

### 5.7 Results using principal components analysis

The results obtained using the principal components analysis for a single talker are presented in Table IIg. It can be seen that for $P = 12$ a 7.1-percent increase in average error rate is obtained; however, small increases in error rate were attained for reductions in $P$ down to 4. In fact, for talker 1 the word error rate increased by 0.2 percent in going from 12 to 4 principal components.

An explanation of why the $P = 12$ principal components analysis led to such large increases in error rate is as follows. The transformation of the feature vector used in the principal components analysis has the property that it is invariant to a quadratic distance measure. The distance measure used in the baseline system was an absolute value distance; hence a significant decrease in accuracy resulted. We will show in Section 5.10 that using a quadratic distance measure gave much worse recognition accuracy than the absolute distance. Thus it would appear that the principal components analysis is not a useful tool, at least for this particular filter bank word recognizer.

### 5.8 Results using time weighting in the global distance for DTW

The results using nonuniform time weighting in the DTW global distance calculation are given in Table IIh. The actual weighting function, $W^T$, was a function only of the energy in the test pattern, of the type shown in Fig. 5. The test energy, $E^T$, was estimated as the sum of the individual channel energies. A high correlation ($\approx$0.94) was measured between this estimate of test energy, and the actual test energy (as computed from the raw speech samples). For frames in which the test energy was within 20 dB of the peak energy (suitably normalized to 0 dB), the frame weight was 1.0; for frames with $E_T$ less than 40 dB below the peak, the weight was set to 0.01; a linear interpolation of the weight was used for frames with $-40 \leq E_T \leq -20$ dB.

The results in Table IIh show a small increase in word error rate for

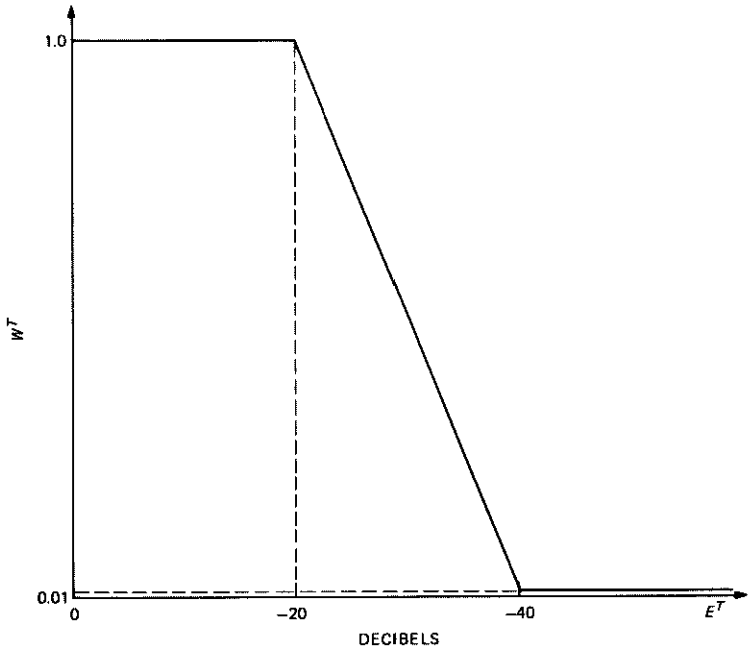

Fig. 5—The nonlinear weighting function, $W^T$, on the local distance as determined from the test energy, $E^T$, estimated from the sum of channel outputs.

*each* talker. Hence we conclude that the addition of time weighting (of the form of Fig. 5) in the DTW distance calculation is unnecessary.

### *5.9 Results using frequency weighting in the local distance for DTW*

The results of using a nonuniform frequency weighting for local distances in the DTW algorithm are shown in Table IIi. The frequency-weighting characteristic was identical to the time-weighting characteristic of Fig. 5, except that the abscissa was the individual channel energy (relative to the peak channel energy for the word) and the ordinate was frequency weight $W_q$. It can be seen from Table IIi that a 2.1-percent increase in average word error rate is obtained using the nonuniform frequency weighting. Hence we again conclude that such weighting should not be used for this particular filter bank recognizer.

The results of using the SD weighting proposed by Silverman and Dixon (based on both reference and test frame energies) are also shown in Table IIi. Although the average word error rate is lower than for the nonuniform weighting of Fig. 5, it is still about 0.8 percent higher than obtained using simple uniform weights.

### 5.10 Effects of different local distance computations

The results of using different local distance computations in the DTW algorithm are given in Table IIj. Values for $p$ of 2 (squared distance) and 1/2 (square root distance) were considered. It can be seen that for $p = 2$ a 4.4-percent increase in average word error rate is obtained; for $p = 1/2$ the increase in average word error rate is 0.9 percent. These results indicate that the magnitude distance ($p = 1$) is the best compromise between giving extra weight to very different channel energies ($p = 2$) and giving a small weight to very different channel energies ($p = 1/2$).

### 5.11 Results of opening up the DTW starting and ending regions

The results of opening up the beginning and/or ending region of the DTW speech regions are given in Table IIk. Results are given for an initial or final square search region, as well as for an initial or final line search region (i.e., the path had to begin or end at the first or last frame of *either* the test or reference; it could not begin or end at a noninitial or nonfinal frame of *both*). It can be seen that all the cases studied led to a small (for square regions) or a large (for the line region) increase in average word error rate. This result is anticipated from previous results, which have shown that opening up the DTW search region consistently aids false matches (reference and test different) as much or more than true matches (reference and test the same).[3,4,17]

### 5.12 Results using length normalization prior to DTW

The results of using fixed-length word normalization prior to the DTW (the normalize-and-warp procedure) are given in Table III and Fig. 6. Table IIIa and Fig. 6a show results for the 13-channel filter bank and Table IIIb and Fig. 6b show results for the LPC-based recognizer. The results show that for a broad range of warping lengths (from 20 to 45 frames) the average word accuracy does not change significantly. Significant degradation in performance is obtained only for the shortest warping lengths considered (i.e., 10 and 15 frames). Hence the results indicate that the normalize-and-warp procedure is suitable for a sizeable range of warping lengths so long as the length used does not become too small.

### 5.13 Results on noise studies

The results of the noise studies are given in Table IV and plotted in Fig. 7. Results are given for three cases:

(*i*) Signal-to-noise ratio (s/n)(Test) = s/n(Train), where s/n varied from $\infty$ down to 0 dB (Table IVa, Fig. 7a).

Table III—Word error rates for the normalize-and-warp procedure applied to both the filter bank and LPC word recognizers

| | | Length of Reference and Test | | | | | |
|---|---|---|---|---|---|---|---|
| (a) Rates as a function of warping length of reference and test prior to DTW for the 13-channel recognizer | | | | | | | |
| Talker | Variable | 40 | 30 | 25 | 20 | 15 | 10 |
| 1 | 9.0 | 8.7 | 9.5 | 8.7 | 8.7 | 10.3 | 12.6 |
| 2 | 5.4 | 5.6 | 5.4 | 5.9 | 5.6 | 6.9 | 11.5 |
| 3 | 13.1 | 13.1 | 14.6 | 14.1 | 14.6 | 15.4 | 19.5 |
| 4 | 18.7 | 21.8 | 20.8 | 21.8 | 20.8 | 22.8 | 23.3 |
| Average | 11.6 | 13.1 | 12.6 | 12.6 | 12.7 | 13.9 | 16.7 |

| (b) Rates as a function of warping length of reference and test prior to DTW for the LPC-based recognizer | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| Talker | Variable | 45 | 40 | 35 | 30 | 25 | 20 | 15 | 10 |
| 1 | 5.1 | 4.9 | 6.2 | 4.6 | 4.6 | 5.1 | 4.9 | 8.5 | 11.8 |
| 2 | 4.1 | 4.6 | 3.8 | 4.9 | 5.1 | 4.9 | 5.6 | 6.9 | 7.4 |
| 3 | 10.3 | 8.2 | 9.0 | 7.9 | 8.5 | 10.0 | 10.5 | 12.6 | 12.8 |
| 4 | 11.8 | 11.3 | 12.1 | 12.6 | 11.5 | 12.6 | 12.8 | 14.1 | 20.0 |
| Average | 7.8 | 7.3 | 7.8 | 7.5 | 7.4 | 8.2 | 8.5 | 10.5 | 13.0 |

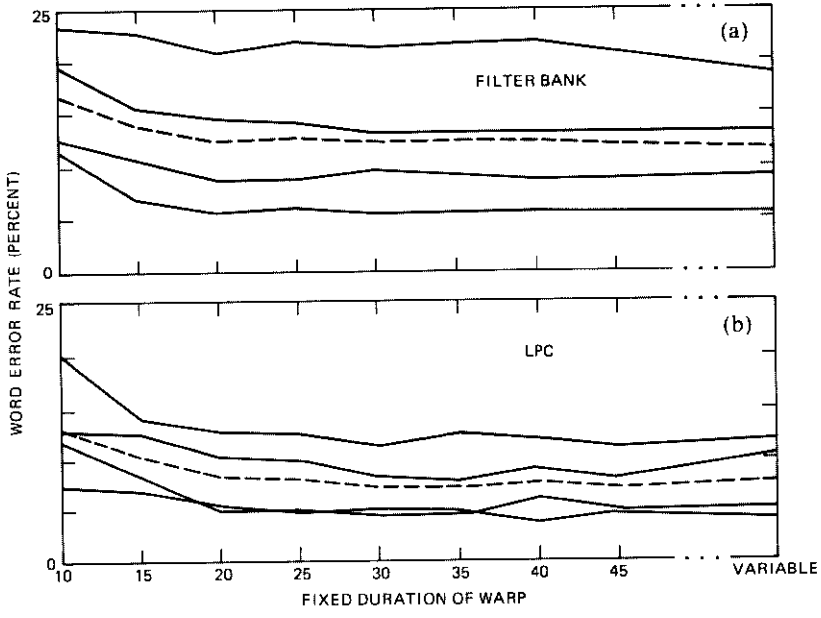

Fig. 6—Plots of word error rate versus fixed frame duration for linear prewarp prior to DTW alignment for (a) the filter bank system, and (b) the LPC system.

(*ii*) s/n(Train) = ∞, s/n(Test) variable from ∞ down to 0 dB (Table IVb, Fig. 7b).

(*iii*) s/n(Test) = 18 dB, s/n(Train) variable from ∞ down to 0 dB (Table IVc, Fig. 7c).

The first case represents the situation when both training and testing

Table IV—Word error rates for noise studies

| | s/n (dB) | | | | | | |
|---|---|---|---|---|---|---|---|
| (a) Rates for filter bank (FB) and LPC word recognizers as a function of s/n for case when noise added to both test and reference signals | | | | | | | |
| System | ∞ | 30 | 24 | 18 | 12 | 6 | 0 |
| FB | 9.0 | 9.5 | 11.0 | 13.1 | 13.6 | 16.7 | 21.0 |
| LPC | 5.1 | 3.8 | 6.2 | 7.4 | 11.3 | 16.7 | 23.6 |
| (b) Rates for filter bank (FB) and LPC word recognizers as a function of s/n for the case when noise added to test only—i.e., s/n of reference for training was ∞ | | | | | | | |
| System | ∞ | 30 | 24 | 18 | 12 | 6 | 0 |
| FB | 9.0 | 14.4 | 17.3 | 32.6 | 61.0 | 82.3 | 92.3 |
| LPC | 5.1 | 10.0 | 17.4 | 37.2 | 65.1 | 76.9 | 90.8 |
| (c) Rates for filter bank (FB) and LPC word recognizers as a function of s/n for case when noise added to reference at variable s/n, and with test s/n set to 18 dB | | | | | | | |
| System | ∞ | 30 | 24 | 18 | 12 | 6 | 0 |
| FB | 32.6 | 12.3 | 11.8 | 13.1 | 14.1 | 18.5 | 89.5 |
| LPC | 37.2 | 10.3 | 7.2 | 7.4 | 10.0 | 17.2 | 31.5 |
| (d) Rates for filter bank (FB) and filter bank with noise removal (FB/NR) for case when noise added to reference at variable s/n, and with test s/n set to 18 dB | | | | | | | |
| System | ∞ | 30 | 24 | 18 | 12 | 6 | 0 |
| FB | 32.6 | 12.3 | 11.8 | 13.1 | 14.1 | 18.5 | 89.5 |
| FB/NR | 26.2 | 12.6 | 11.8 | 13.1 | 14.4 | 18.7 | 28.2 |

of the word recognizer are done in the same noisy background; case (*ii*) represents the situation when there is "clean" training (no noise) but the test words are spoken in the noisy background; case (*iii*) represents the situation when there is noise in both training and testing; however there may be a mismatch in s/n.

The results in Table IV and Fig. 7 show that:

(*i*) For case (*i*), the LPC system performs as well as or better than the filter bank (FB) system for s/n $\geq$ 6 dB. The filter bank (FB) system outperformed the LPC system only at a 0 dB s/n.

(*ii*) For case (*i*), there was little degradation in performance down to s/n's of close to 24 dB for either the FB or LPC recognizer.

(*iii*) For case (*ii*) the performance of both the FB and LPC recognizers was significantly worse at all s/n's than for case (*i*). Hence we see that using clean training data with noisy test data leads to badly degraded system performance for s/n $\leq$ 30 dB.

(*iv*) For case (*iii*) the results indicate that when s/n(Test) and s/n(Train) differ by as little as 6 dB (or more) degraded performance results.

The results of Table IV and Fig. 7 indicate that it is mandatory that both the training (reference) and testing data be obtained in the same background noise conditions for best word recognition performance.

A test was also conducted on the filter bank recognizer to determine whether the effects of additive (background) noise could be lessened by subtracting out an (estimated) average noise spectrum prior to recognition. A one-second average was calculated for each channel

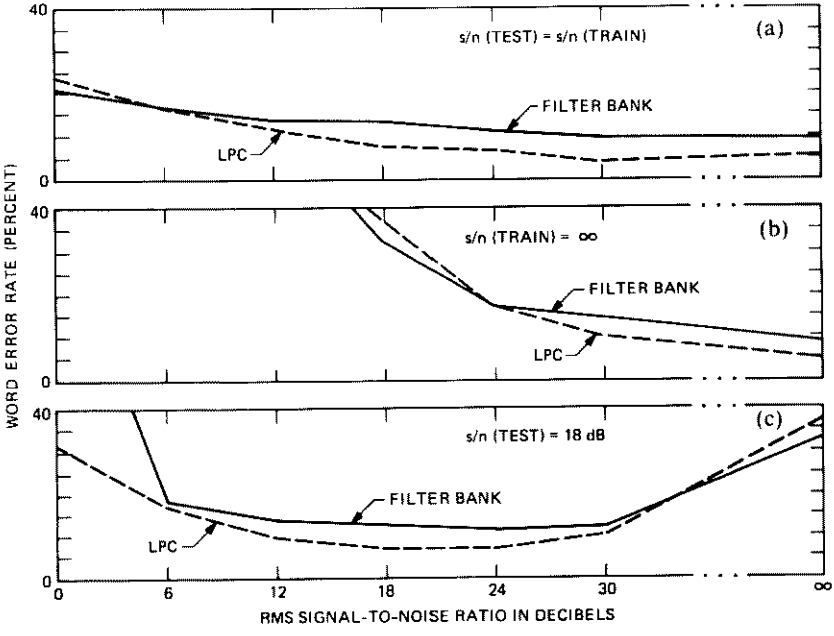

Fig. 7—Plots of word error rate (for a single talker) versus signal-to-noise ratio for both the LPC and filter bank recognizers for, (a) s/n(Test) = s/n(Train); (b) s/n(Train) = ∞, s/n(Test) variable; and (c) s/n(Test) = 18 dB, s/n(Train) variable.

signal of the filter bank when only the additive white noise was present at the input. Each of these 13-channel average noise values was then subtracted from the corresponding channel signal to form a new channel signal, which was used in the recognition processing. For these tests the signal-to-noise ratio for the test data was held constant at 18 dB, and the noise level in the reference data was varied to give signal-to-noise ratios between 0 dB and ∞.

The results of this experiment are given in Table IVd. These results show that the effects of this simple noise-cancelling arrangement are to broaden the range of signal-to-noise ratios over which the filter bank recognizer can operate. It can be seen that recognizer performance is not changed significantly between 30-dB and 6-dB signal-to-noise ratios from that obtained without the noise cancellation. However, for signal-to-noise ratios of ∞ and 0 dB, a considerable reduction of error rate is obtained with the noise cancellation method. The conclusion from this test is that noise cancelling is useful for reducing the effects of variations in noise level between reference and test data.

## VI. DISCUSSION AND CONCLUSIONS

The results presented in Section V lead to the following conclusions:

(*i*) Essentially none of the proposed signal processing techniques

for use in the filter bank word recognizer led to an improvement in performance of the system (i.e., reduced word error rate). At best any single technique led to a small (insignificant) increase or decrease in word error rate; at worst it led to a significant increase in word error rate.

(*ii*) The filter bank coefficients (for telephone inputs) needed only about 6 uniform bits for a representation with no increase in word error rate. Hence, the storage requirements on the $Q = 13$ channel recognizer were about 78 bits per frame using this 6-bit coding scheme.

(*iii*) The normalize-and-warp procedure was an effective method for reducing storage and processing requirements in the DTW computation in that fixed duration linear prewarps of size as small as 20 frames per word did not increase word error rate significantly for either the LPC or FB recognizers.

(*iv*) The best strategy for using a word recognizer in a noisy background was to both train and test the recognizer in the same noise background.

(*v*) The LPC word recognizer gave error rates the same or lower than the FB word recognizer for s/n $\geq$ 6 dB.

Our initial goal was to find signal processing techniques to enhance the performance of the FB word recognizer so as to come closer to that of an existing LPC word recognizer. Our results indicate that we have not succeeded in attaining this goal. Hence our main question is whether we failed because we tried the wrong things, or because there is no way of doing consistently better with the FB limitations. There is no simple answer to this question. Perhaps our best response is that we tried a wide range of techniques that encompassed those methods previously proposed and studied in other FB recognizers. The lack of any significant improvement in performance for any of the proposed techniques indicates to us that perhaps the only way to improve accuracy is by some heuristic based on linguistic knowledge of the vocabulary words. We have meticulously avoided such techniques as they change the nature of the recognizer from a vocabulary-independent system to one that depends on the specific words to be recognized.

Another possible objection to the conclusions as drawn from the results given in Section V is that we studied each proposed signal processing technique independently. As such we avoided interactions between techniques that could have led to improved accuracy. Again we iterate our speculation that since no individual technique led to a real performance improvement, we are skeptical that combinations of techniques would lead to real improvements. Of course we have no concrete evidence that this is indeed the case.

Our noise analysis results dispel the common notion that LPC recognizers "fall apart" in noisy backgrounds while FB recognizers

degrade gracefully. Our results show that with proper training the LPC system outperforms the FB system at all reasonable signal-to-noise ratios.

Finally, the noise results show that training and testing should *always* be done in the same acoustic backgrounds. If there are gross differences in acoustic backgrounds, significant degradation in performance results.

## VII. SUMMARY

We have presented results of a study to measure the effects of selected signal processing techniques on the performance of a filter bank word recognizer. We have shown that a fairly simple set of signal processing techniques led to the best overall performance of the word recognizer in the noise-free case. In noisy conditions the performance of the recognizer degraded significantly for signal-to-noise less than about 24 dB.

## CONTRIBUTORS TO THIS ISSUE

**Harry J. Boll,** B.S., M.S., Ph.D. (Electrical Engineering), University of Minnesota, Minneapolis, in 1956, 1958, and 1962, respectively; Bell Laboratories, 1962—. After completing graduate work in secondary electron emission, he joined Bell Laboratories, Murray Hill, NJ, where he has worked in the general area of semiconductor devices and integrated circuits. He is presently a Group Supervisor in the Advanced Large-Scale Integration Development Laboratory, where his duties include very large-scale integrated logic design. Fellow, IEEE; member, Eta Kappa Nu, Tau Beta Pi. He received a Bell Laboratories Fellowship award for his work in custom integrated circuits.

**Ta-Shing Chu,** B.S., 1955, National Taiwan University; M.S., 1957, and Ph.D., 1960, Ohio State University; Research Associate, Courant Institute of Mathematical Sciences, New York University, 1961–1963; Bell Laboratories, 1963—. Mr. Chu has been engaged in research on microwave antennas and wave propagation for satellite communication and terrestrial radio systems. His work included surface wave diffraction, precision gain standard, propagation through precipitation, dual-polarization radio transmission, and the Crawford Hill 7-meter offset millimeter wave antenna. Fellow, IEEE; Member, International Scientific Radio Union, Sigma Xi, Pi Mu Epsilon.

**Bruce A. Dautrich,** B.S. (Electrical Engineering), 1980, Pennsylvania State University; M.S. (Electrical Engineering), 1981, Purdue University; Bell Laboratories, 1980—. Mr. Dautrich has been engaged in speech communication research and development and is presently concentrating on problems of speech recognition. Member Eta Kappa Nu, Tau Beta Pi, Phi Kappa Phi.

**Bharat T. Doshi,** B. Tech (Mechanical Engineering), 1970, I.I.T., Bombay; Ph.D. (Operations Research), 1974, Cornell University; Bell Laboratories, 1979—. Before joining Bell Laboratories Mr. Doshi was an Assistant Professor at Rutgers University. At Bell Laboratories his technical work has included modeling and analysis of processor schedules and overload controls. His research interests include queueing theory applied to performance analysis of computer and communication systems. Member, IEEE, ORSA; Associate Editor, OR Letters.

**Robert W. England,** B.S., 1973, Capitol Institute of Technology; Bell Laboratories, 1973–1981; AT&T Long Lines, 1981—. At Bell Laboratories, Mr. England worked on microwave antennas for satellite

communication. He was involved in the measurement of the Crawford Hill 7-meter antenna and the development of an earth station receiver for the ATS-6 satellite. Since coming to Long Lines, Mr. England has been Senior Engineer on Long Lines' new coaxial cable transmission system.

**Michael J. Grieco,** B.S. (Chemistry), 1966, Rutgers University, New Brunswick, NJ; Bell Laboratories, 1961–68, 1972—. Mr. Grieco has worked in many aspects of semiconductor processing such as photolitography, etching, C.V.D., and wafer cleaning. He has been involved in photolithographic process engineering for the *BELLMAC**-8, -4, and most recently the *BELLMAC*-32 microprocessor. This process engineering work is being continued in 1-$\mu$m MOS device technology.

**Raghu N. Kackar,** B.Sc. (Mathematics, Physics, Chemistry), 1970, University of Delhi; M. Stat., 1972, Agra University; M.S. (Statistics), 1974, University of Guelph; Ph.D. (Statistics), 1979, Iowa State University; Bell Laboratories, 1980—. Mr. Kackar is applying new methods for total quality control to enhance quality and productivity of several production lines. At present his primary emphasis is on development and application of the technique of designed experiments. Member, ASA, ASQC.

**Thomas B. Martin,** B.S.E.E., 1957, University of Notre Dame; M.S.E.E., Ph.D., University of Pennsylvania, 1960 and 1970, respectively. In 1970 he co-founded Threshold Technology Inc., which developed the first practical automatic speech recognition systems to be used in industry. In March 1982, he joined Bell Laboratories and has continued to work in speech recognition.

**Stephen C. Mettler,** B.S., 1962, U.S.A.F. Academy; M.S. (Physics), 1972, and Ph.D. (M.E.), 1976, Purdue University; Bell Laboratories, 1976—. Mr. Mettler is presently engaged in research on optical fiber components and splicing. Member, OSA.

**Kinichiro Ogawa,** B.S.E.E., 1966, M.S.E.E., 1968, University of Tokyo, D.Sc. (Electrical Engineering), Washington University; Nippon Telegraph & Telephone Public Corporation, 1968–1976; Bell Laboratories, 1976—. At N.T.T., Mr. Ogawa worked on long-haul analog coaxial cable systems and on video transmission. He also worked on

* Trademark of Bell Laboratories

the development of pulse-code modulated/frequency division multiplex digital systems. At Bell Laboratories, he has been involved in research on optical data links and digital lightwave systems. Member, IEEE, Optical Society of America, IECE of Japan.

**Brian Owen,** B.Sc., 1963; Ph.D., 1967 (Electrical Engineering), Birmingham University, England; Bell Laboratories, 1968—. Mr. Owen is a Member of the Technical Staff in the Lightwave Subsystems Department at Allentown. From 1968 to 1977 he was involved in the design of microwave and millimeter-wave components. Since 1977 he has been involved in photonics working primarily on optical receivers.

**Madhav Phadke,** B. Tech, 1969 (Mechanical Engineering), Indian Institute of Technology, Bombay; M.S., 1972 (Statistics), and Ph.D., 1973 (Mechanical Engineering), University of Wisconsin, Madison; Bell Laboratories, 1977—. Prior to joining Bell Laboratories, Mr. Phadke worked as a Research Associate in the Statistics Department of the University of Wisconsin and as a Visiting Scientist at the IBM Watson Research Center. He has published articles in professional journals covering topics in quality assurance, design of experiments, process control, system identification, time series analysis, mechanical design, and air pollution data analysis. His current interests are in the applications of Japanese methods of quality control and productivity improvement in design, development, and manufacturing of products. Member, Phi Kappa Phi, Sigma Xi, American Statistical Association, the American Society for Quality Control.

**Lawrence R. Rabiner,** S.B. and S.M., 1964, Ph.D. (Electrical Engineering), The Massachusetts Institute of Technology; Bell Laboratories, 1962—. From 1962 through 1964, Mr. Rabiner participated in the cooperative plan in electrical engineering at Bell Laboratories. He worked on digital circuitry, military communications problems, and problems in binaural hearing. Presently, he is engaged in research on speech communications and digital signal processing techniques. He is coauthor of *Theory and Application of Digital Signal Processing* (Prentice-Hall, 1975), *Digital Processing of Speech Signals* (Prentice-Hall, 1978), and *Multirate Digital Signal Processing* (Prentice Hall, 1983). Former President, IEEE, ASSP Society; former Associate Editor, ASSP Transactions; former member, Technical Committee on Speech Communication of the Acoustical Society, ASSP Technical Committee on Speech Communication; Member, IEEE Proceedings Editorial Board, Eta Kappa Nu, Sigma Xi, Tau Beta Pi. Fellow, Acoustical Society of America, IEEE.

**Donald V. Speeney,** Assoc. in Technology (Electronics), 1960, Temple University; Bell Laboratories, 1960—. Since joining Bell Laboratories, Mr. Speeney has worked in the area of semiconductor device technology development and device physics. This includes work on the discrete components of germanium, silicon, and gallium arsenide, as well as CMOS microcomputer and microprocessor integrated circuits. More recently, he has been working on processes and technology for producing silicon integrated circuits.

**York Y. Wang,** B.S. (Physics), 1970, Chung-Yuan Christian College, Taiwan; M.S. (Physics), 1972, and Ph.D. (Physics), 1976, University of Missouri at Columbia; Jet Propulsion Laboratory, 1975–1977, Bell Laboratories, 1977—. At Jet Propulsion Laboratory, Mr. Wang worked on Viking and Voyager Projects as a mission planner. At Bell Laboratories, he has been involved in microwave radio propagation studies, space diversity signal combining techniques, digital microwave radio systems performance and applications, digitization of analog microwave radio systems, and advanced network services planning. Member, IEEE, Sigma Xi.

**Ian A. White,** B.Sc. (Hon.) (Physics), 1974, University of Queensland, Australia; Ph.D. (Applied Mathematics), 1977, Australian National University; Bell Laboratories, 1979—. From 1977 to 1979 Mr. White did post-doctoral research in the theory of fiber and integrated optics at the Optical Sciences Center, University of Arizona at Tucson. Since 1979 he has been with Bell Laboratories, Norcross, Georgia, where he is a member of the Exploratory Components and Media Studies Group.

# On the Start-Up Problem in Digital Echo Cancelers

By J. SALZ*

(Manuscript received October 5, 1982)

Digital echo cancellation techniques make it possible to realize efficient full-duplex data transmission over a single loop. The purpose of this paper is to elucidate the solution to the start-up problem in these devices and to present a new, fast, and simple tap-adjustment procedure. The theory indicates that a modified stochastic gradient tap-adjustment algorithm, using pseudorandom input data sequences for the initial training period, converges in $N$ steps, where $N$ is the total number of canceler taps, and that this is the fastest possible convergence time.

## I. INTRODUCTION

Two-way voice communication over a single loop is made possible by the use of a hybrid bridge. However, the suppression of echoes by fixed hybrids is insufficient to support full-duplex data transmission, and therefore makes adaptive data echo cancelers necessary.

In two-way data communications, transmitted data "echoes" back to the near-end receiver after being reflected and dispersed through an unknown return path. So, if one assumes that the echo path is linear, the estimation of its overall impulse response is sufficient to allow the synthesis of one's own echo signal. This synthesized version is subtracted from the received signal, which then makes it possible for the receiver to extract the data intended for it.

The impulse response of the echo channel (local transmitter output to local receiver input) can be measured in several ways. An obvious way to do this is to transmit a single impulse and measure the echo. However, among other defects of this procedure, the average power would be very low and the resulting signal-to-noise ratio (s/n) would be inadequate. If a pseudorandom sequence (+1 or −1) is transmitted instead, the average power would be much greater and would be essentially constant on the line, more nearly representing a true data signal. The latter is the preferable approach.

Digital data echo cancelers operate in two modes. In the acquisition mode, or start-up, the impulse response of the echo path is measured. This is best accomplished, as we shall see, with the use of fixed data sequences. Since, during this period, no information is conveyed to the far-end, the time allotted for this purpose should be as short as possible. Although it is conceptually possible to start an echo canceler either blind or with random data, the convergence of the taps, or the reliable measurements of the impulse response, are known to require a long time. In the subsequent mode, or during actual data transmission, a tracking algorithm is initiated whose function is to update the measurements when slight changes occur in the impulse response. We focus on the more critical start-up algorithm.

From an operational point of view, it is desirable to implement these algorithms in a recursive fashion, or in a closed-loop manner. This means that the canceler tap coefficients, which represent the sampled impulse response, are updated in response to a measured error between the actual impulse response and the one estimated at any particular instant. Conventional gradient adjustment algorithms, even with fixed data sequences, are known to converge very slowly.

This research was motivated by the need for a theory capable of explaining the behavior of tap-adjustment algorithms. During the course of this investigation a modified stochastic gradient algorithm that is simple to implement and converges in the theoretically smallest number of steps was discovered.

## II. PROBLEM FORMULATION

Figure 1 shows a full-duplex data modem employing a digital echo canceler. We are concerned with the sampled signal values

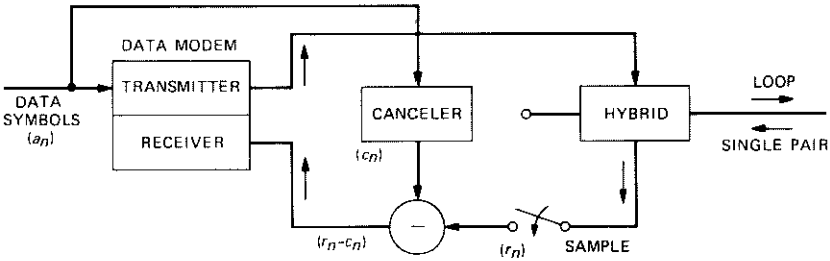

Fig. 1—Digital data canceler.

$$r_n = \sum_{k=-\infty}^{\infty} h_k a_{n-k} + \nu_n, \tag{1}$$

where the $a_n$'s are the transmitted data symbols that echo back to the receiver, the $h_n$'s are the overall impulse response values of the echo path, and the $\nu_n$'s are the desired received signal values plus noise. The object of the canceler is to synthesize signal values, $c_n$, which are estimates of $\sum_k h_k a_{n-k}$ and subtract them from the $r_n$'s. The receiver then proceeds to process the difference signal values, $r_n - c_n$, to extract the data intended for it.

The fundamental problem is to devise procedures for estimating the $h_n$'s from observations of the $r_n$'s, while treating the $\nu_n$'s as undesirable noise. Practically, it must be assumed that only a finite number, $N$, of the $h_n$'s can be estimated, and so we express (1) compactly as

$$r_n = H^t A_n + \nu_n, \tag{2}$$

where $H$ and $A_n$ are finite dimensional column vectors,*

$$H = \begin{pmatrix} h_N \\ \vdots \\ h_1 \end{pmatrix}, \quad \text{and} \quad A_n = \begin{pmatrix} a_{n-N} \\ \vdots \\ a_{n-1} \end{pmatrix},$$

and where $(\,)^t$ indicates the transpose of a matrix.

In the absence of precise statistical knowledge of the $\nu_n$'s and $H$, a natural procedure for choosing an estimator of $H$ is to minimize the sum of squared errors from time 1 to time $l$

$$\epsilon_l = \sum_{n=1}^{l} (r_n - \hat{H}^t A_n)^2.$$

This is a standard problem and the solution is immediate. It involves the solution of a set of linear equations

$$Z_l \hat{H}_l = U_l \tag{3}$$

* We deal with a baseband model for notational convenience. By using complex numbers throughout, the treatment generalizes to passband models.

for the best estimator at time $l$, $\hat{H}_l$.

In (3)
$$U_l = \sum_{n=1}^{l} A_n r_n$$

and
$$Z_l = \sum_{n=1}^{l} A_n A_n^t.$$

In applications it is usually desirable to solve these equations recursively with a minimum computational effort and to assure rapid convergence to the actual $H$. Our attention in the next sections is directed toward these aims. However, before dealing with our main subject we wish first to examine some asymptotic behaviors of the standard solution.

### *2.1 Random input data*

In some applications, echo cancelers must start blind, i.e., from random data. This is the case in echo cancelers used to suppress speech. However, in full-duplex data communications, a preamble word, or words, can be sent first to assure rapid convergence. To emphasize these differences we examine the behavior of the estimator with random data first, where one has no choice in the selection of the starting sequences. So, consider random data such that the $a_n$'s assume $\pm 1$ independently with equal probability and examine the limit as $l \to \infty$. It is found that

$$\begin{aligned} U_l &\to lE\{A_n r_n\} \\ &= lE\{A_n A_n^t\} H, \\ Z_l &\to lE\{A_n A_n^t\} = lI, \end{aligned}$$

and, consequently,

$$Z_l^{-1} U_l \to H. \tag{4}$$

In the above we made use of the fact that the $\nu_n$'s and $A_n$'s are naturally independent. We assumed that these sequences are ergodic and so replaced time averages with mathematical expectations, $E\{\cdot\}$. This then demonstrates that if one is willing to wait forever, it is conceptually possible to determine $H$ exactly—not a terribly startling result.

While the asymptotic behavior is easy to deduce, the statistical behavior of the estimator for finite $l$ is difficult to glean. One immediately encounters an unsolved mathematical problem that involves the conditions on the random sequences that would guarantee the existence of the inverse matrix $Z_l^{-1}$. Clearly, $l$ has to be greater than $N$ for the inverse to even have a chance to exist, and for those

Likewise, the vector

$$U_l = \sum_{n=1}^{l} A_n r_n = U_{l-1} + A_l r_l. \tag{13}$$

Now, applying the matrix inversion lemma[2] to (12), and assuming that the inverses exist, we find that

$$Z_l^{-1} = Z_{l-1}^{-1} - \frac{Z_{l-1}^{-1} A_l A_l^t Z_{l-1}^{-1}}{1 + A_l^t Z_{l-1}^{-1} A_l}. \tag{14}$$

This is the key equation and, in conjunction with (13), makes it possible to claim (11). We note that the algorithm expressed in (13) is computationally complicated since it requires the calculation of a matrix recursion, (14), and multiplication of matrices by vectors at each iteration. For large $N$ this becomes infeasible and simpler procedures are therefore sought. However, before proposing a simpler algorithm we need to review some properties of pseudorandom sequences.

The pseudorandom data sequences that are the inputs to the canceler during the start-up period derive from the binary sequences

$$X = x_1 x_2 x_3 x_4 \cdots$$

($x_i = 0$, or 1). The $n$th digit is computed from certain of the earlier digits by means of the recurrence relation

$$x_n = x_{n-c} + x_{n-b} \bmod 2,$$

where $c$ and $b$ are integers, $0 < c < b$. The actual data sequences $\{a_n\}$ that are applied to the canceler are the $x_n$'s with "0" replaced by "−1".

Returning now to the sequence $X$, we remark that in spite of the fact that $x_n$ is completely determined by the digits that precede it, the sequence $X$ resembles in some respects a completely random sequence. The calculation of the sequence $X$ is carried out in a shift register working in a closed loop and a mod 2 adder. It turned out that for special choices of $c$ and $b$ the sequence $X$ is periodic with period $2^b - 1$.[2]

In our application, we will make use of the following known properties of the sequences

$$1)\ A_n^t A_m = \sum_{i=1}^{N} a_{n-i} a_{m-i} = \begin{cases} N, & n = m \\ -1, & n \neq m \end{cases}$$

$$2)\ Q^t A_n = 1, \quad \text{for} \quad n = 1, \cdots, N$$

$$Q = \begin{bmatrix} 1 \\ 1 \\ 1 \\ 1 \\ 1 \end{bmatrix}_1^N,$$

the all "1" vector

$$3)\ A_{n+N} = A_n, \text{ periodicity.}$$

Data sequences possessing properties 1 through 3 are also referred to as pseudorandom sequences. As a consequence of these properties, it is easy to verify the following:
Property (a):

$$Z_N = \sum_{n=1}^{N} A_n A_n^t$$

$$= (N+1)I - QQ^t, \ N \text{ x } N \text{ matrix,}$$

where $I$ is the identity matrix. This decomposition is possible since the $ij$th element of the matrix $Z_N$, $(Z_N)_{ij} = N$ for $i = j$ and $-1$ on the off-diagonals. This can readily be seen from property 1.
Property (b): The inverse matrix

$$Z_N^{-1} = \frac{1}{N+1}(I + QQ^t).$$

This can be derived from the matrix inversion lemma or verified by actually computing $Z_N Z_N^{-1} = I$.
Property (c): The set of vectors

$$B_n = Z_N^{-1} A_n, \ n = 1 \cdots N$$

are orthonormal to the vectors $A_n$, $n = 1, \cdots N$. This is a crucial property to what follows, so we prove that

$$A_m^t Z_N^{-1} A_n = \frac{A_m^t}{N+1}(I + QQ^t)A_n$$

$$= \frac{A_m^t A_n + (A_m^t Q)(Q^t A_n)}{N+1} = \begin{cases} 0, & n \neq m \\ 1, & n = m. \end{cases}$$

These properties suggest an approach to a simple and rapidly converging tap-adjustment algorithm.

The key to the simplification of the algorithm, (11), is the recognition that $Z_l^{-1}$ for $l < N$ does not exist, and so it is not possible to start the algorithm at $l = 1$. The basic idea is to replace $Z_l$ by $Z_N$ and thus obtain the simpler algorithm

$$\hat{H}_{n+1} = \hat{H}_n - Z_N^{-1} A_n e_n, \tag{15}$$

where the error at time $n$ is again

$$e_n = A_n^t \hat{H}_n - r_n$$

$$= A_n^t(\hat{H}_n - H) - v_n.$$

Note that this is a measurable quantity at each iteration and $A_n e_n$ is just the gradient of the instantaneous squared error.

The algorithm expressed in (15) is remarkably simple since

$$Z_N^{-1} A_n = \frac{1}{N+1} (I + QQ^t) A_n$$

$$= \frac{1}{N+1} (A_n + Q),$$

which follows from the definition of $Z_N$ and property (b). Inserting this into (15) we obtain

$$\hat{H}_{n+1} = \hat{H}_n - \frac{1}{N+1} (A_n + Q) e_n. \tag{16}$$

This form is immediately recognized as a slightly modified stochastic gradient algorithm with step size equal to $1/N + 1$ and the gradient vector, $A_n$, replaced by $A_n + Q$. It is nothing more than the original vector, $A_n$, in which $a_n$'s equal to $-1$ are replaced by zero and $a_n = 1$ is replaced by $a_n = 2$. We wish to acknowledge that during the course of the development of this theory C. W. Farrow anticipated the form of this algorithm.

It now remains to demonstrate that (16) indeed converges "fast", by which we mean that it converges in $N$ steps. Toward this end, define the error vector

$$\epsilon_n = \hat{H}_n - H,$$

and rewrite (16) in the form,

$$\begin{aligned} \epsilon_{n+1} &= \epsilon_n - Z_N^{-1} A_n (A_n^t \epsilon_n - \nu_n) \\ &= (I - B_n A_n^t) \epsilon_n + B_n \nu_n. \end{aligned} \tag{17}$$

Iterating (17) yields explicitly

$$\epsilon_{n+1} = \prod_{k=1}^{n} (I - B_k A_k^t) \epsilon_1 + \sum_{k=1}^{n} \prod_{j=k}^{n-1} (I - B_{j+1} A_{j+1}^t) B_k \nu_k. \tag{18}$$

This is the general solution but because of property (c), which states that $A_n^t B_{n-1} = 0$, we get a much simpler solution, which is the chief reason for the rapid convergence, namely,

$$\epsilon_{n+1} = \left(I - \sum_{k=1}^{n} B_k A_k^t\right) \epsilon_1 + \sum_{k=1}^{n} B_k \nu_k$$

$$= \left[I - Z_N^{-1}\left(\sum_{k=1}^{n} A_k A_k^t\right)\right] \epsilon_1 + Z_N^{-1}\left(\sum_{k=1}^{n} A_k \nu_k\right). \tag{19}$$

This simple form results because the product of the matrices in (18) reduces to

$$\prod_{k=1}^{n} (I - B_k A_k^t)\epsilon_1$$

$$= (I - B_1 A_1^t)(I - B_2 A_2^t) \cdots (I - B_n A_n^t)\epsilon_1$$

$$= [(I - B_1 A_1^t)(I - B_2 A_2^t) \cdots -B_n A_n^t]\epsilon_1$$

$$= \left[I - \sum_{k=1}^{n} B_k A_k^t\right] \epsilon_1.$$

The evolution of the error vector $\epsilon_n$ is guided by two components, the transient

$$\tau_n = \left[I - Z_N^{-1}\left(\sum_{k=1}^{n} A_k A_k^t\right)\right] \epsilon_1, \tag{20}$$

and the steady-state component

$$S_n = Z_N^{-1}\left(\sum_{k=1}^{n} A_k \nu_k\right). \tag{21}$$

A most crucial property of the transient solution is that at $n = N$, $\tau_n$ vanishes, and this is the reason for claiming "fast" convergence. Clearly, the transient solution cannot vanish before this time since the inverse doesn't even exist, and therefore we claim the algorithm convergence in the least possible number of steps. This most important property of the algorithm can be seen from (20), since

$$\tau_N = (I - Z_N^{-1} Z_N)\epsilon_1 = 0.$$

Consequently, the error vector at time $N + 1$ consist only of measurement noise, or the steady-state component

$$\epsilon_{N+1} = Z_N^{-1} \left( \sum_{k=1}^{N} A_k \nu_k \right). \tag{22}$$

We have thus demonstrated that the algorithm converges to the true solution in $N$ steps since the transient vanishes at the end of the $N$th iteration and, from that time on, the taps fluctuate around the true value due to measurement noise, $\nu_n$, alone. The variance of the tap fluctuations can be calculated from the variance matrix

$$\begin{aligned} \rho_N &= E\{\epsilon_{N+1}\epsilon_{N+1}^t\} \\ &= Z_N^{-1} \left( \sum_{k,k'=1}^{N} A_k A_{k'}^t E\{\nu_k \nu_{k'}\} \right) Z_N^{-1} \\ &= \sigma^2 Z_N^{-1} = \frac{\sigma^2}{N+1} (I + QQ^t), \end{aligned} \tag{23}$$

where again we assumed that the $\nu_k$'s are identically and independently distributed. The error variance, $\sigma_H^2$, is therefore,

$$\begin{aligned} \sigma_H^2 &= \sigma^2 \text{ Trace } Z_N^{-1} \\ &= \frac{\sigma^2}{N+1} \text{Trace}[I + QQ^t] \\ &= \sigma^2 \frac{2N}{N+1}. \end{aligned} \tag{24}$$

This is precisely the value we obtained from solving the set of linear equations, (3), with pseudorandom input sequences. Thus, iterating $N$ times provides the solution in a simple fashion.

It may turn out in applications that the value of variance obtained in $N$ iterations is not sufficiently small. As seems reasonable, the noise variance can be reduced to any desired value by repeating the pseudorandom sequence of length $N$. To see this, consider a slightly modified tap-adjustment algorithm

$$H_{n+1} = H_n - \alpha Z_N^{-1} A_n e_n, \tag{25}$$

where now the scaler, $\alpha$, is a fixed step size yet to be determined. Proceeding as before, the recursion for the tap error $\epsilon_n = H_n - H$ now becomes

$$\epsilon_{n+1} = (I - \alpha B_n A_n)\epsilon_n + \alpha B_n \nu_n, \tag{26}$$

with the concomitant solution

$$\epsilon_{n+1} = \left[I - \alpha Z_N^{-1}\left(\sum_{k=1}^{n} A_k A_k^t\right)\right]\epsilon_1 + \alpha Z_N^{-1}\left(\sum_{k=1}^{n} A_k \nu_k\right). \tag{27}$$

Again, examine the solution at $n = pN + 1$, where $p$ is a positive integer, to obtain

$$\epsilon_{pN+1} = \left[I - \alpha Z_N^{-1}\left(\sum_{k=1}^{pN} A_k A_k^t\right)\right]\epsilon_1 + \alpha Z_N^{-1}\left(\sum_{k=1}^{pN} A_k \nu_k\right). \tag{28}$$

Since $A_n$ is periodic with period $N$ (property 3), we conclude that

$$\epsilon_{pN+1} = (1 - \alpha p)\epsilon_1 + \alpha Z_N^{-1}\left(\sum_{k=1}^{pN} A_k \nu_k\right), \tag{29}$$

and so we see that the transient component can be made to vanish when $\alpha = 1/p$. A straightforward calculation indicates that with this choice of $\alpha$ the variance is

$$\sigma_H^2 = \frac{2N}{p(N+1)}\,\sigma^2, \tag{30}$$

indicating a reduction by a factor of $p$—the number of times the pseudorandom sequence is repeated.

# Sample Reduction and Subsequent Adaptive Interpolation of Speech Signals

By R. STEELE* and F. BENJAMIN†

(Manuscript received December 15, 1982)

In this paper we investigate the effect of rejecting every $n$th speech sample and replacing it by means of adaptive interpolation. The interpolation procedure attempts to minimize the mean square interpolation error by recomputing the autocorrelation function of the speech sequence every $W$ samples. We describe three methods of computing the correlation function. An iterative procedure is evaluated for estimating the correlation function of a speech sequence whose every $n$th sample has been discarded. For speech bandlimited to 3.2 kHz, sampled at 8 kHz, and $n = 4$, $W = 256$, the gain in signal-to-noise ratio (s/n) achieved by adaptive interpolation compared to nearest neighbor average interpolation was 14 and 8 dB, depending on whether the correlation function was computed from the original speech, or by using the iterative procedure, respectively. The effect of varying $n$ from 2 to 6 was also investigated. Finally, we applied the interpolation procedures to 8-bit $\mu$-law pulse code modulation (PCM), $\mu = 255$, reducing 64 kb/s transmission to 48 kb/s by rejecting one PCM word in four. The recovered speech after interpolation had a s/n that approximated that of conventional 56 kb/s $\mu$-law PCM speech.

## I. INTRODUCTION

Sampling of speech signals is usually performed at a rate high enough to prevent objectionable aliasing. Thus a speech signal whose bandwidth extends from 0.3 to 3.3 kHz is typically sampled at 8 kHz. After the speech signal has been sampled, the subsequent processing

of the samples depends on the application. In digital encoding the samples are converted into a digital (usually binary) sequence. Clearly, the lower the sampling rate the lower the bit rate of the digitally encoded speech, and the smaller the required channel capacity. There are numerous techniques for bit-rate reduction that have been compiled and categorized.[1,2] Our intention here is to dwell on a specific subset of bit-rate reduction, namely that arising from discarding speech samples at the transmitter or at a node in a network, and replacing them at the receiver by interpolation. The impetus for this approach arose from two unrelated interests, analog speech scramblers and bit-rate reduction in $\mu$-law pulse code modulation (PCM). Scramblers that offer a reasonable amount of security, such as modulo masking scramblers, expand the bandwidth to half the sampling rate. Thus, operating on 8-kHz sampled speech, we wanted to reduce the sampling rate by discarding every fourth sample such that, after scrambling, the bandwidth would be 3 kHz, i.e., confined to the bandwidth of telephonic speech. The descrambled samples at the receiver would be brought back to the original 8-kHz rate by interpolating the missing samples. In the case of $\mu$-law PCM our interest was to discard a percentage (typically 25 percent) of the words representing encoded speech, enabling other data to have a free ride. At the receiver the data would be removed and the missing speech samples recovered by interpolation.

Interpolation ideas are part of everyday life; we are always filling in the gaps in our perception by interpolation, extrapolation, and prediction. We will avoid the luxury of philosophizing, and briefly review some of the interesting aspects of interpolation that are related to speech encoding. Mathews,[3] in an attempt to make significant reductions in the sampling rate of speech, considered extremal encoding. With this technique the amplitudes of the speech signal at its extremes and the time intervals between these extremes are transmitted in an encoded format. At the receiver the extremes can be widely separated, and the interpolation of the missing samples can be thought of as curve fitting, i.e., passing a quadratic function through the extreme sample and two nearest received samples. In the 1960's there was considerable interest in interpolation, which Kortman[4] defined as "the process of after-the-fact polynomial curve fitting to eliminate redundant data samples." The interpolators[4–6] tended to be concerned with zero-order, first-order, and fan interpolators, and were closely related to aperture predictors.[4–7] Andrews et al.[6] considered straight-line optimum, optimum interpolation filter, $(\sin x)/x$, Lagrange, and Fourier reconstruction interpolators. The use of piecewise polynomials, called splines, have been extensively investigated (see Ref. 8 and its bibliography). More recently, there have been a spate of publications[9] on

digital speech interpolation, although the interpolation there was mainly concerned with Time Assignment Speech Interpolation (TASI)-type systems. Interpolation techniques have also been applied to reduce distortion in packet switching of speech when a packet is lost or discarded.[10] For an understanding of the existing low-pass filtering procedures of interpolation and decimation of digital signals, the reader is directed to the in-depth review presented by Crochiere and Rabiner.[11]

Having commented on some of the existing interpolation methods let us now proceed to the issues to be addressed here. Consider the situation of being presented with the speech samples, or say $\mu$-law PCM words, at some point in a communications network, together with a system control demand to eliminate $J$ samples (or words) per $W$ samples (or words). This could happen, for example, if there were a sudden increase in traffic. Rejection of these $J$ samples might precipitate unacceptable degradation in the recovered speech unless we introduced at the receiver replacement samples that closely approximate those samples rejected. We must therefore decide at the outset on the means of reinserting the $J$ samples, for example, by prediction or interpolation, using those samples not discarded. Having replaced the missing samples, we need to establish criteria for judging the quality of the recovered speech signal. Is a single criterion such as mean square error sufficient, or is a combination of objective and subjective measures required? Coupled with the issues of reinsertion and quality are the criteria of how to select which $J$ samples are to be rejected in every $W$ samples. Should we determine if speech is present as distinct from silence, and if so, whether it is voiced or unvoiced? Is it better to reject small groups of samples (e.g., in silence periods), leaving clusters of samples intact because rejection followed by subsequent interpolation of one of these samples might cause significant speech degradation, or should we always endeavor to retain samples on either side of a rejected sample, and so on?

Clearly, the choices are legion, and faced with this situation we have imposed a set of guidelines that are not concerned with what the samples (or words) represent in the speech signal. For example, we make no attempt to recognize if the talker is male or female, whether the speech is voiced or unvoiced, or in transition, and so on. Instead, we simply reject samples on a periodic basis, and reinsert them at their destination by means of adaptive interpolation. By making the interpolation adaptive we take cognizance of the local statistics of the speech signal, specifically, the utilization of the signal's correlative properties. This is the only characteristic of the speech signal that is exploited. Our approach is, therefore, oriented to ease implementation rather than to squeeze the maximum advantage from the properties

of speech. Indeed, the method is applicable to other types of analog signals (e.g., modem-generated data signals), provided the signals possess correlative properties that are capable of exploitation in the interpolation processes. Our strategy is as follows:

1. Discard samples on a periodic basis, with no two consecutive samples being rejected.
2. Process blocks of $W$ samples at a time.
3. Exploit the local statistics of the speech samples by determining their correlation function over each block. Approximate methods for determining the correlation function are required when the sequence has had $J$ of its $W$ samples rejected.
4. Apply adaptive interpolation.
5. Employ quality criteria based on the minimization of the mean square error, justified by the prior knowledge that the mean square error values achieved will conform to perceptual standards based on informal listening tests.

Having introduced the notion of sample or word rejection to reduce the baud or bit rate, and an outline of how to discard the samples or words and reintroduce them at their destination, we will now formulate the problem and its solution in detail.

## II. THE PROBLEM

Consider a speech signal $x(t)$, bandlimited to $f_c H_z$ and sampled at $f_s H_z$ to yield the sequence $\{x_k\}$, where $f_s$ satisfies

$$f_s \geq 2f_c. \tag{1}$$

This sequence $\{x_k\}$ could be encoded into binary words, or we could be given binary words at a node in the network. In such situations our description of the problem would be in data words. However, for ease of explanation we will confine our discussion to operations on samples unless otherwise stated.

To reduce the number of samples per second in $\{x_k\}$, we discard every $n$th sample. This is achieved by clocking the speech samples into a gear-down changing buffer under the auspices of a clock operating at $f_s$ samples per second, such that, after every $n$ samples are inserted into the buffer, the clock is inhibited for one clock period. The arrangement is shown in Fig. 1. The samples are clocked out of the buffer at a rate

$$F_s < 2f_c \tag{2}$$

to yield a sequence $\{y_k\}$ whose components are uniformly spaced in time by $1/F_s$. Figure 2 shows $\{x_k\}$ and $\{y_k\}$ for arbitrary segments of sampled speech. Observe that $\{y_k\}$ has its parameter $F_s$ related to $f_s$ by

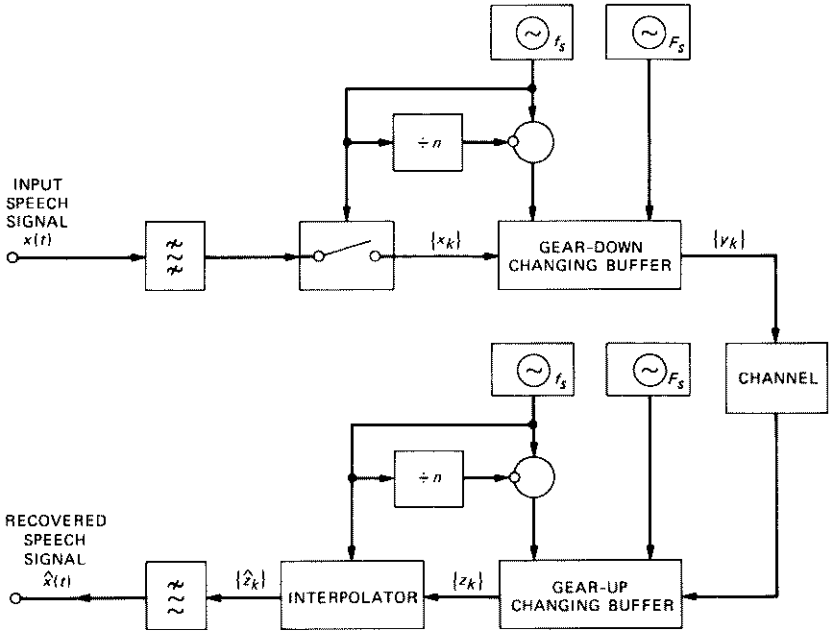

Fig. 1—Arrangement for decreasing the sample rate.

$$F_s = \left(\frac{n-1}{n}\right) f_s. \tag{3}$$

Suppose $\{y_k\}$ with its symbol rate lower than $\{x_k\}$ is transmitted over an ideal channel. Let us further assume that the receiver is able to return the samples in $\{y_k\}$ to the relative time positions they occupied in the original speech sequence $\{x_k\}$ using the gear-up changing buffer shown in Fig. 1. This newly formed sequence, $\{z_k\}$, generated at a rate $1/f_s$, has one out of every $n$ samples absent owing to the sample reduction process at the transmitter. A small, arbitrary segment of this sequence $\{z_k\}$, corresponding to a particular $\{x_k\}$ and $\{y_k\}$, is displayed in Fig. 2. Our problem is to replace those samples rejected at the transmitter with substitutes of acceptable accuracy whose generation is not excessively complex. The approach employed is adaptive interpolation.

## III. ADAPTIVE INTERPOLATION

The speech sequence $\{z_k\}$ is divided into sequential blocks having $W$ sample positions spaced $1/f_s$ seconds apart. The sequence $\{z_k\}$ is therefore composed of $W$ samples from $\{x_k\}$ with every $n$th sample absent. Our purpose is to interpolate the missing samples to produce

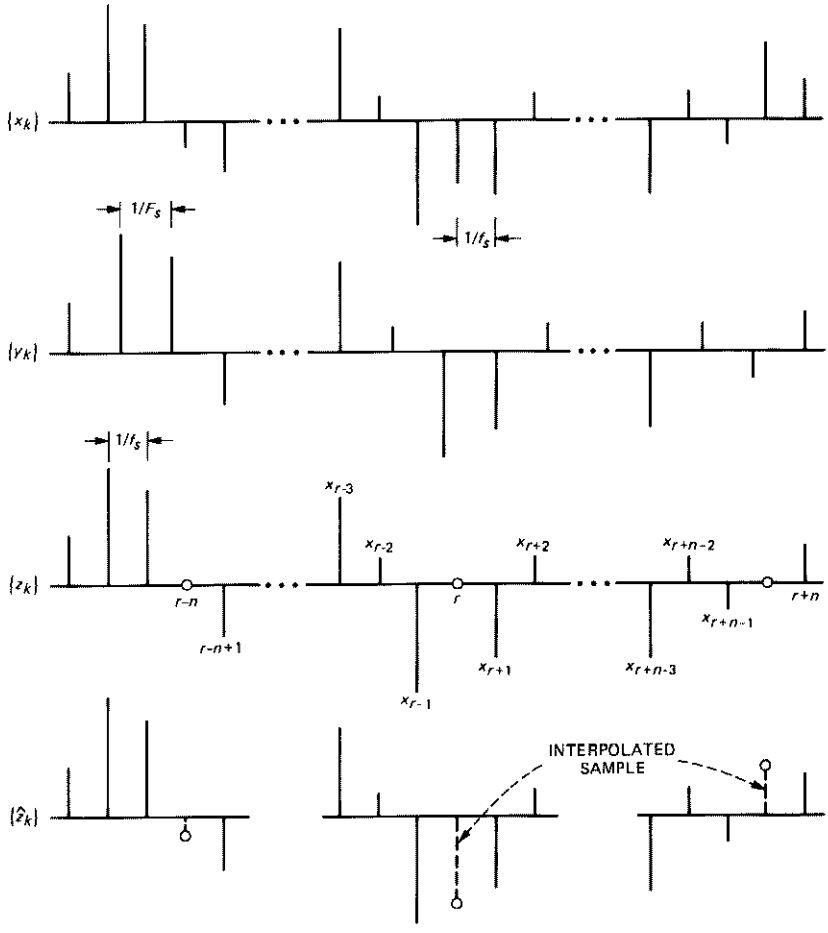

Fig. 2—Sampled sequences for arbitrary segment of speech; $\{x_k\}$ is the original speech sequence; $\{y_k\}$ is the sequence after sample reduction and gearing changing; $\{z\}$ is $\{x_k\}$ with every $n$th sample absent; $\{\hat{z}\}$ is the recovered speech sequence.

a sequence for the first block having components

$$x_1, \cdots, x_{n-1}, \hat{z}_n, x_{n+1}, \cdots, x_{W-2}, x_{W-1}\hat{z}_W,$$

where

$$\hat{z}_r; \qquad r = n, 2n, \cdots, W - n, W$$

are the interpolated samples. When interpolating each speech sample, we will use $\lambda$ past and $\lambda$ previous samples, and restrict $\lambda$ to be

$$\lambda \leq n - 1. \tag{4}$$

Thus, a missing sample at the $r$th sampling instant (see Fig. 2) is

formed by interpolation according to

$$\hat{z}_r = \sum_{i=-\lambda}^{-1} a_i x_{r+i} + \sum_{i=1}^{\lambda} a_i x_{r+i}, \tag{5}$$

where $a_i$ are the interpolation parameters. Equation (5) may be written as

$$\hat{z}_r = \sum_{i=-\lambda}^{\lambda} a_i x_{r+i}, \tag{6}$$

where $a_0 = 0$. The interpolation error of the $r$th sample is

$$e_r = x_r - \hat{z}_r \tag{7}$$

and the square of this error is

$$\begin{aligned} e_r^2 &= x_r^2 - 2x_r \sum_{i=-\lambda}^{\lambda} a_i x_{r+i} + \left( \sum_{i=-\lambda}^{\lambda} a_i x_{r+i} \right)^2 \\ &= x_r^2 - 2x_r \sum_{i=-\lambda}^{\lambda} a_i x_{r+i} + \sum_{i=-\lambda}^{\lambda} a_i^2 x_{r+i}^2 + 2 \sum_{i=-\lambda}^{\lambda} \sum_{j=-\lambda}^{\lambda} a_i x_{r+i} a_j x_{r+j} \end{aligned} \tag{8}$$

with $i \neq j$ and $j > i$. To determine the interpolation parameters we proceed as follows. The square of the error is summed over the block of samples

$$\begin{aligned} E_r^2 = \sum_{r=n}^{W} e_r^2 = \sum_{r=n}^{W} x_r^2 - 2 \sum_{r=n}^{W} \left\{ x_r \sum_{i=-\lambda}^{\lambda} a_i x_{r+i} \right\} \\ + \sum_{r=n}^{W} \sum_{i=-\lambda}^{\lambda} a_i^2 x_{r+i}^2 + 2 \sum_{r=n}^{W} \sum_{i=-\lambda}^{\lambda} \sum_{j=-\lambda}^{\lambda} a_i x_{r+i} a_j x_{r+j}, \end{aligned} \tag{9}$$

where $r = n, 2n, \cdots, W$. To select coefficients that minimize this summation, we partially differentiate $E_r^2$ with respect to each of the coefficients and set the result to zero. After rearranging the equations we have

$$\sum_{r=n}^{W} x_r x_{r+j} = \sum_{i=-\lambda}^{\lambda} \sum_{r=n}^{W} a_i x_{r+i} x_{r+j}, \tag{10}$$

where

$$\begin{aligned} j &= \pm 1, \pm 2, \cdots, \pm\lambda \\ i &= -\lambda, -\lambda + 1, \cdots, \lambda \\ r &= n, 2n, \cdots, W - n, W \\ W &\geq 2n. \end{aligned}$$

The interpolation coefficients in eq. (10) can be represented in vector form as

$$\alpha = A^{-1}C, \tag{11}$$

where

$$\alpha = [a_{-\lambda}, a_{-\lambda+1}, \cdots, a_{-1}, a_1, \cdots, a_{\lambda-1}, a_\lambda]^T, \tag{12}$$

$$C = [R(0, -\lambda), R(0, -\lambda + 1), \cdots, R(0, -1), R(0, 1), \cdots, R(0, \lambda - 1), R(0, \lambda)]^T, \tag{13}$$

and the superscripts $-1$ and $T$ represent inverse and transpose operations, respectively. The rectangular matrix $A$ is of order $2\lambda$, and its elements are presented in Table I. The concentric dotted enclosures, commencing with the inner one, refer to the $A$ matrix for $\lambda = 1, 2, 3, \cdots$. The elements are given by

$$R(k, j) = \frac{\sum_{r=n}^{W} x_{r+k}x_{r+j}}{\sum_{r=n}^{W} x_{r+j}^2}$$

$$k = \pm 1, \pm 2, \cdots, \pm\lambda$$

$$j = \pm 1, \pm 2, \cdots, \pm\lambda$$

$$r = n, 2n, \cdots, W, \tag{14}$$

and $R(k, j)$ will be referred to as the correlation function $R(k, j)$. The vector $C$ has elements $R(0, j)$, i.e., the elements are given by eq. (13) with $k$ always zero.

As an example of the application of eq. (11), consider the case of $W = 32$, $n = 4$, $\lambda = 2$, whence

$$\begin{bmatrix} a_{-2} \\ a_{-1} \\ a_1 \\ a_2 \end{bmatrix} = \begin{bmatrix} 1 & R(-1, -2) & R(1, -2) & R(2, -2) \\ R(-2, -1) & 1 & R(1, -1) & R(2, -1) \\ R(-2, 1) & R(-1, 1) & 1 & R(2, 1) \\ R(-2, 2) & R(-1, 2) & R(1, 2) & 1 \end{bmatrix}^{-1} \begin{bmatrix} R(0, -2) \\ R(0, -1) \\ R(0, 1) \\ R(0, 2) \end{bmatrix} \tag{15}$$

and eq. (14) becomes for the $A$ and $C$ matrices

$$R(k, j) = \frac{\sum_{r=4}^{32} x_{r+k}x_{r+j}}{\sum_{r=4}^{32} x_{r+j}^2}; \quad \begin{array}{l} k = 0, \pm 1, \pm 2 \\ j = \pm 1, \pm 2 \\ r = 4, 8, 12, 16, 20, 24, 28, 32 \end{array}$$

Table I—The $A$ matrix

When $r = 32$ and $|k|$ or $|j| \geq 1$, samples are used that reside in the subsequent block.

When the block size $W$ is large, typically in excess of 256 samples, the computations required to solve eq. (11) can be reduced at the expense of a small increase in interpolation noise power. This is accomplished by replacing $R(k, j)$ of eq. (14) by the correlation function

$$R(\tau) = \frac{(W-\tau)\sum_{i=1}^{W-\tau} x_i x_{i+\tau} - \left(\sum_{i=1}^{W-\tau} x_i\right)\left(\sum_{i=1}^{W-\tau} x_{i+\tau}\right)}{\left\{\left[(W-\tau)\sum_{i=1}^{W-\tau} x_i^2 - \left(\sum_{i=1}^{W-\tau} x_i\right)^2\right] \cdot \left[(W-\tau)\sum_{i=1}^{W-\tau} x_{i+\tau}^2 - \left(\sum_{i=1}^{W-\tau} x_{i+\tau}\right)^2\right]\right\}^{1/2}}, \tag{16}$$

where

$$\tau = |k - j| \tag{17}$$

and $k$ and $j$ have values prescribed in eq. (14). For a further small increase in interpolation noise, which typically reduces the recovered signal-to-noise ratio (s/n) by a couple of decibels compared to when eq. (16) is used, $R(\tau)$ can be simplified to

$$R(\tau) = \frac{\sum_{r=1}^{W-\tau} x_r x_{r+\tau}}{\sum_{r=1}^{W} x_r^2}, \tag{18}$$

where $r$ is integer-valued. Observe that, in computing the interpolation coefficients with the aid of eqs. (16) or (18), only $\lambda$ values need be determined as

$$a_{-p} = a_p; \qquad p = 1, 2, \cdots, \lambda. \tag{19}$$

By contrast, when $R(k, j)$ is used in preference to $R(\tau)$, eq. (19) does not apply and $2\lambda$ coefficients must be computed.

Thus, provided we can compute $R(k, j)$ or $R(\tau)$, over a duration of $W/f_s$, where $W$ is the block length, we can determine the interpolation parameters contained in the vector $\alpha$. Employing eq. (5) we can estimate the missing samples by means of interpolation. The mean squared error between $\{x_k\}$, and the recovered sequence $\{\hat{z}_k\}$ containing the interpolated samples (see the example shown in Fig. 2), is approximately minimized, provided $W$ is sufficiently large. Practical values of $W$ are determined in Section VI.

## IV. INTERPOLATION PARAMETERS DERIVED FROM THE INPUT DATA

The interpolation parameters are computed by first finding the correlation function $R(\theta)$, where $\theta$ is $k$, $j$, or $\tau$. Equation (14) shows $R(\theta)$ as dependent on the input sequence $\{x_k\}$. Clearly, as $\{x_k\}$ is only known at the transmitter, it follows that the interpolation vector $\alpha$ must be computed at the transmitter and multiplexed with the slowed-down speech samples $\{y_k\}$. Consequently,

$$Y = \left(\frac{n-1}{n}\right) W + \nu \tag{20}$$

samples are transmitted every $W/f_s$ seconds, where $Y$ is composed of $W(n-1)/n$ speech samples and $\nu$ interpolation parameter samples. The value of $\nu$ is $\lambda$ or $2\lambda$, depending on whether $\theta$ is $\tau$ or $k$, $j$, respectively. This means that $F_s$ of eq. (3) is modified to

$$F_s' = F_s + \frac{\nu}{W} f_s. \tag{21}$$

For example, if $f_s = 8$ kHz, $n = 4$, $F_s = 6$ kHz, $W = 256$, $\lambda = 3$, $\theta = \tau$, then $F_s' = 6.093$ kHz. We also observe from eq. (20) that three interpolation samples are sent for every 192 speech samples. The values of $\lambda$ and $W$ as a function of s/n are present in Section VI.

## V. INTERPOLATION PARAMETERS DERIVED FROM THE RECEIVED DATA

The receiver produces the sequence $\{z_k\}$ whose samples are spaced apart by $1/f_s$, and in every $n$th sample position one sample is missing, as shown in Fig. 2. The receiver has the task of estimating the interpolation coefficients from $\{z_k\}$, and must therefore commence by calculating the correlation function $R(\tau)$ without the full knowledge of the original speech sequence $\{x_k\}$. In this situation we proceed as follows. The missing samples are found as an average of adjacent speech samples

$$\bar{x}_r = (x_{r-1} + x_{r+1})/2 \tag{22}$$

until a sequence $\{\bar{z}_k\}$ consisting of $W(n-1)/n$ original speech samples and $W/n$ interpolated samples is formed, where each sample is equally spaced from its neighbor by $1/f_s$ seconds. This sequence corresponds to a recovered speech signal that has considerable distortion, particularly for female speakers. Instead of accepting $\{\bar{z}_k\}$ as the recovered speech sequence, we use it solely for the purpose of computing $R(\tau)$, and hence the vector $\alpha$ containing $a_{-1}$ and $a_1$. We now remove the samples introduced by eq. (22) and replace them by using adaptive interpolation based on the two nearest neighbors, viz:

$$ {}_2x_r = a_{-1}x_{r-1} + a_1 x_{r+1}, \tag{23} $$

where $a_{-1}$ and $a_1$ are found using eq. (11) with $R(k, j)$ replaced by $R(\tau)$ of eq. (18). The new recovered speech sequence $\{{}_2z_k\}$ has interpolated samples formed according to eq. (23), and in general contains less distortion than $\{\tilde{z}_k\}$. However, we can further reduce the distortion. The function $R(\tau)$ is again computed, this time from $\{{}_2z_k\}$. The interpolated samples in $\{{}_2z_k\}$, derived with the aid of eq. (23), are rejected and replaced by

$$ {}_4x_r = a_{-2}x_{r-2} + a_{-1}x_{r-1} + a_1 x_{r+1} + a x_{r+2} \tag{24} $$

to yield the speech sequence $\{{}_4z_k\}$. The correlation function $R(\tau)$ of sequence $\{{}_4z_k\}$ is found, and those interpolated samples previously formulated with the aid of eq. (24) are exchanged for

$$ {}_6x_r = \sum_{i=-3}^{3} a_i x_{r-i}, \qquad a_0 = 0. \tag{25} $$

This process of using two more samples per iteration in the interpolation procedure continues until the limits of the summation in eq. (25) become $n - 1$, when the final recovered speech sequence $\{\hat{z}_k\}$ is obtained. It should be noted that more than $2(n - 1)$ samples can be used in each interpolation process, but the improvement in interpolation accuracy results in a significant increase in complexity.

Often it is sufficient to produce the sequence $\{\tilde{z}_k\}$, compute $R(\tau)$ from $\{\tilde{z}_k\}$, remove the samples formed by averaging the adjacent two samples, and with the aid of $\lambda \leq n - 1$ samples on either side of each discarded sample, insert the missing samples by adaptive interpolation. When this process is adopted, it will be referred to as $\lambda$-interpolation. However, when the same $\lambda$ samples are used in the interpolation process, and the iteration procedure of eqs. (22) to (25) activated, we will refer to this interpolation scheme as $\lambda$-with-iteration.

Observe that $R(\tau)$ is used in the $\lambda$-with-iteration scheme. If $R(k, j)$ is employed instead of $R(\tau)$, the final interpolation is not better than that of the sample used to approximate $x_r$. For example, if we replaced $x_r$ by $\tilde{x}_r$, the iterative algorithm would merely attempt to minimize the error power between the $\tilde{x}_r$ samples and the interpolated samples. Unlike the application of $R(k, j)$, the $R(\tau)$ function does not enable an exact minimization of interpolation error power to be achieved at the transmitter. However, it transpires that by computing $R(\tau)$ at the receiver, and using the iterative procedure to interpolate the missing samples, the interpolation noise is significantly reduced (see Section 6.2).

## VI. RESULTS

The speech signal used in our experiments consisted of two con-

catenated sentences, "Live wires should be kept covered," and "To reach the end he needs much courage." These were spoken by a male and female, respectively. The signal was bandlimited from 0.3 to 3.2 kHz and sampled at 8 kHz to give the input speech sequence $\{x_k\}$. This sequence is displayed in Fig. 3, together with its spectrogram, where the higher frequencies have been preemphasized.

### *6.1 Interpolation parameters generated from the original speech*

The gear-down changing procedure was invoked (see Figs. 1 and 2) whereby the sampling rate of 8 kHz was decreased to a uniform $F_s$-kHz rate by rejecting every $n$th sample, and adjusting the sample spacing to provide the output sequence $\{y_k\}$. This sequence was assumed to be transmitted through an ideal channel, and after passing through the receiver's gear-up changing buffer the sequence $\{z_k\}$ was formed. The sequence $\{z_k\}$ had a symbol rate of 8 kHz, with every $n$th sample absent. The absentee samples rejected at the transmitter were then formulated according to eq. (6). The interpolation parameters $a_i$ were found with the aid of eq. (11), which used correlation functions $R(k, j)$ related to the input speech sequence $\{x_k\}$. Thus, in our first experiment we were concerned with how successfully we could discard every $n$th sample in $\{x_k\}$, and replace the discarded samples using interpolation parameters based on $\{x_k\}$.

We used as a performance criterion segmental signal-to-noise ratio[12] (SEG-s/n), computed using the input sequence $\{x_k\}$, and the error sequence $\{e_k\}$ whose components are given by eq. (7). In our initial experiment the variation of SEG-s/n as a function of block size $W$ was found using practical values of $W$ extending from 64 to 1024, and $n = 4$. This value of $n$ is a compromise between providing adequate SEG-s/n and a reasonable reduction in the number of transmitted samples. Applying the correlation function $R(k, j)$ in the determination of the interpolation parameters, we obtained the solid curves in Fig. 4. Curves a, b, and c apply for the case of $\lambda = 3$, 2, and 1, respectively. Curve d is the SEG-s/n when the interpolation was performed using the average of adjacent samples. Increasing $\lambda$ to $n - 1$, i.e., to 3, resulted in an increase in SEG-s/n compared to lower values of $\lambda$, and for a block size of 256 and $\lambda = 3$, a gain of 13.7 dB in SEG-s/n was obtained compared to the simple interpolation averaging method of eq. (22). When the correlation function $R(\tau)$ of eq. (18) was employed to compute the interpolation parameters, curves e, f, and g were obtained corresponding to $\lambda = 3$, 2, and 1, respectively. The improvement in SEG-s/n derived from employing $R(k, j)$ rather than $R(\tau)$ increased with increasing $\lambda$, being 0.1, 1, and 3 dB for $\lambda = 1$, 2, and 3, respectively, and with $W = 256$.

As a means of providing further insight into the performance of the

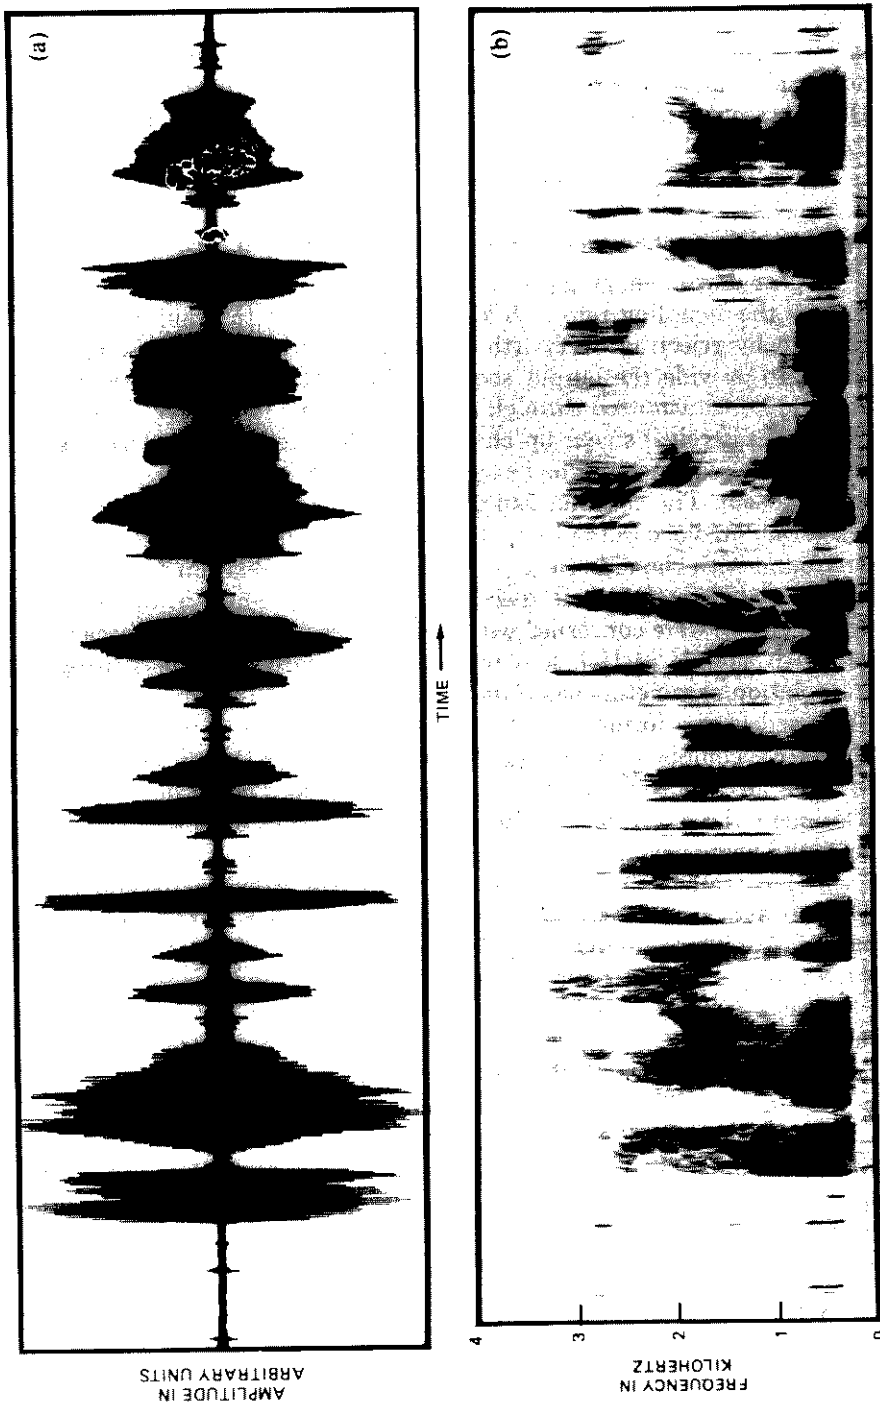

Fig. 3—(a) Input speech sequence $\{x_k\}$ and (b) its preemphasized spectrogram.

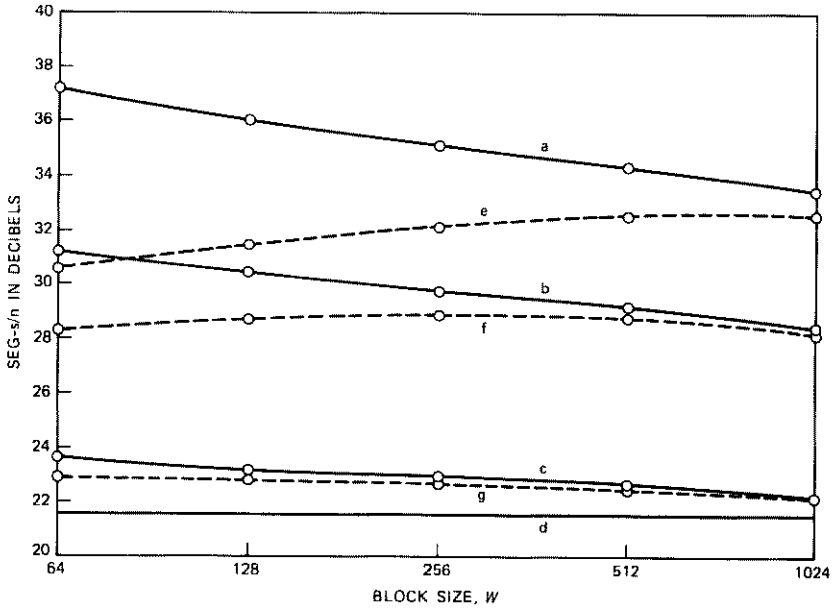

Fig. 4—SEG-s/n versus block size $W$. Curves a, b, and c apply for $\lambda = 3$, 2, and 1; and $\hat{R}(k, j)$ was used in calculating the interpolation parameters. Curve d relates to interpolation using nearest neighbor averaging. Curves e, f, and g apply for $\lambda = 3$, 2, and 1; and $R(\tau)$, given by eq. (18), was used in calculating the interpolation parameters.

interpolation system, we show in Fig. 5 the variation of the s/n of each block in the speech signal as a function of successive blocks for $W = 256$, $n = 4$. The average of these s/n values constitutes the SEG-s/n points in Fig. 4 for $W = 256$. As expected, we found that the s/n in every block was greater, if only by an infinitesimal amount, when more samples were used in the interpolation process, i.e., when larger values of $\lambda$ were employed. Interpolation by adjacent sample averaging always provided the lowest s/n. In some blocks the advantage of using $\lambda = 3$ compared to $\lambda = 2$, $\lambda = 1$, and nearest neighbor averaging, provided s/n gains as large as 13, 31, and 33 dB, respectively.

Returning to Fig. 4, the SEG-s/n of over 35 dB, $\lambda = 3$, was found to be approximately 3 dB greater than the coventional s/n computed by measuring the mean square values of the components in $\{x_k\}$ and $\{e_k\}$ over the entire speech input signal. Our SEG-s/n measurements therefore indicate that the recovered speech is similar to toll quality speech.[2] Informal listening experiences for the recovered speech sequence $\{\hat{z}_k\}$ when $\lambda = 3$, $W = 256$, tended to confirm the SEG-s/n findings that the quality of the recovered speech sequence $\{\hat{z}_k\}$ was judged to be very similar to that of the original bandlimited sequence $\{x_k\}$. We observed that although the distortion in $\{\hat{z}_k\}$ for $\lambda = 1$ was

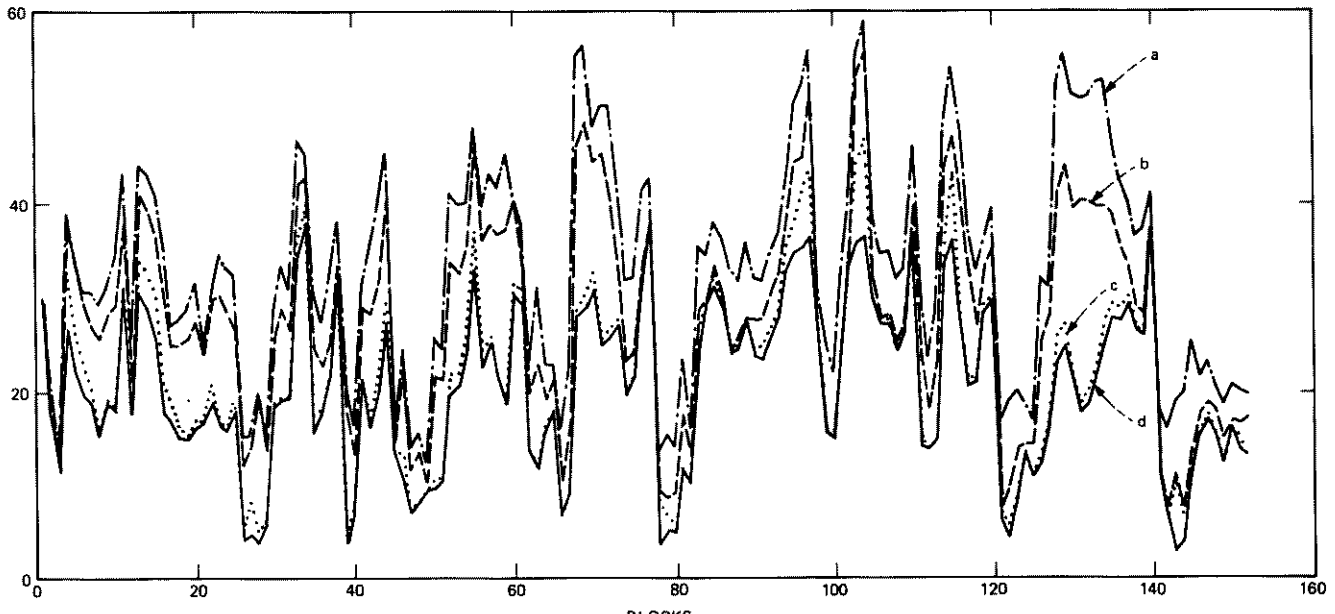

Fig. 5—Variation of block s/n as a function of block number, $W = 256$, $n = 4$. Interpolation procedure used (a) $\lambda = 3$, (b) $\lambda = 2$, (c) $\lambda = 1$, and (d) nearest neighbor averaging.

annoying, by making $\lambda = 2$ the interpolation noise was barely noticeable.

In Section III we present different expressions for the correlation function $R(\theta)$, namely eq. (14), where $\theta = k, j$, and eqs. (16) or (18) having $\theta = \tau$. The SEG-s/n and block s/n values shown in Figs. 4 and 5 were determined using $\theta = k, j$. We now demonstrate the loss in SEG-s/n due to using $\theta = \tau$ compared to when $\theta = k, j$ as a function of $W$, for the conditions of $n = 4$ and $\lambda = 3$. It will be recalled that $\theta = k, j$ enables the interpolation samples to be formulated that minimize $E_r^2$ over a block of $W$ samples. When $\theta = \tau$ a low but not minimum value of $E_r^2$ is produced over the working range of $W$. The application of eq. (16) gives a more accurate measure of $R(\tau)$ than the simpler expression of eq. (18). Figure 6 shows the variation of SEG-s/n with block size when $R(\theta)$ is computed using eqs. (14), (16), and (18), $n = 4$, $\lambda = 3$. When $R(k, j)$ was used, the effect of increasing $W$ was to decrease the SEG-s/n. This is to be expected because the interpolation parameters are fixed for a block, and we may think of a large block as composed of many smaller blocks, each with its optimum interpolation parameters. Thus, if one set of parameters is selected for the large block, these parameters are inevitably suboptimum for the smaller subblocks, and hence the SEG-s/n is lower for the larger

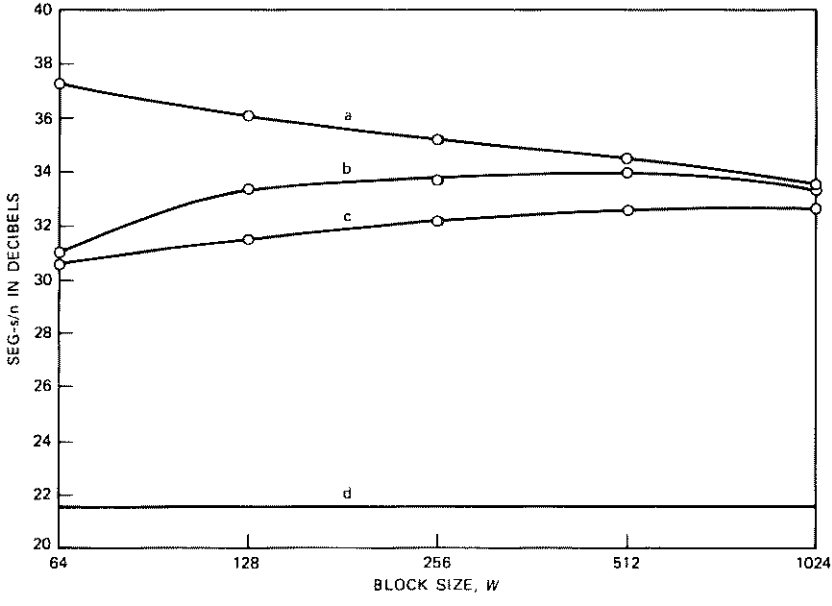

Fig. 6—Variation of SEG-s/n versus block size $W$ for $\lambda = 3$, $n = 4$. The correlation function was computed for curves a, b, and c using eqs. (12), (16), and (18), respectively. Curve d applies to nearest neighbor averaging.

blocks. By contrast the SEG-s/n determined using $R(\tau)$ deteriorates with decreasing $W$. Now $R(\tau)$ is the conventional correlation function that assumes the speech signal to have stationary statistics. For the larger block sizes shown in Fig. 6, local statistical departures from stationarity tend to be smoothed by the $R(\tau)$ equations, but at low values of $W$ a considerable number of interpolation errors occur in some blocks to yield a low SEG-s/n. When $W = 1024$ the SEG-s/n values computed using the different $R(\theta)$ expressions are very similar. We do not plot curves for $W < 64$ as the side information to transmit the interpolation parameters is unacceptably high [see eq. (20)], and for $W > 1024$ the delay is excessive (>250 ms). Thus, by using $R(k, j)$ we obtain higher and better interpolation performance compared with employing the conventional $R(\tau)$, but the computational complexity is greater.

### 6.2 *Interpolation parameters generated from the received sequence*

Having concluded that every fourth speech sample can be discarded and replaced by an interpolated sample to yield speech with negligible perceptual degradation, we next considered the performance of our scheme when the interpolation parameters were derived from the received data. The problem in this case was how to obtain a reliable estimate of the autocorrelation function $R(\tau)$. The procedures described in Section V for determining $R(\tau)$, and thence the interpolation parameters, were tried, and the variation of SEG-s/n with block size

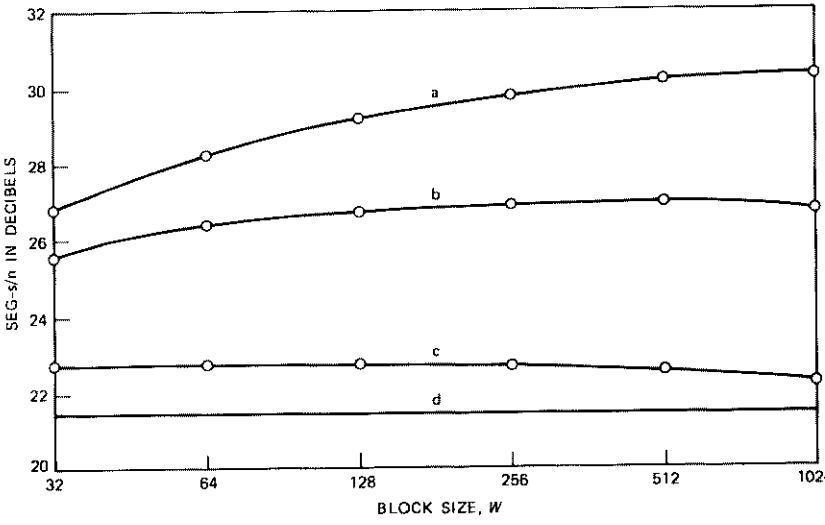

Fig. 7—SEG-s/n versus block size for interpolation parameters derived from the received sequence. Curves a, b, c, and d apply for λ-with-iteration, λ = 3; λ-interpolation, λ = 3; λ-interpolation, λ = 1; and average of adjacent sample interpolation, respectively.

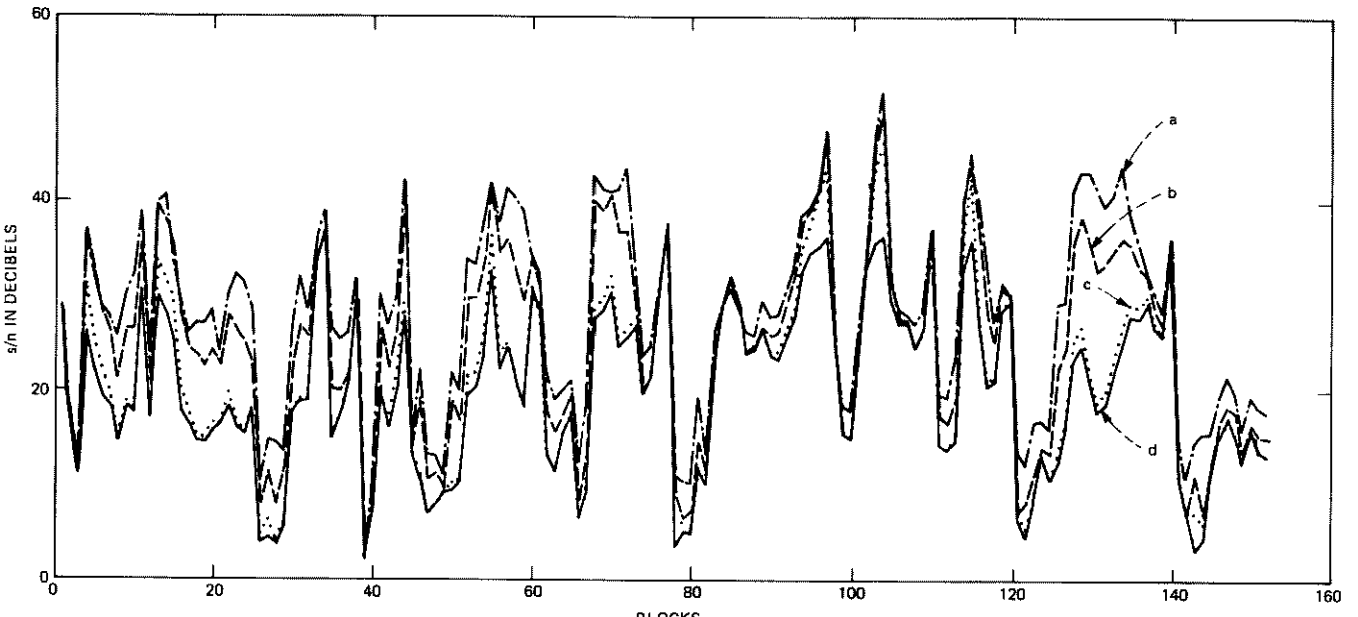

Fig. 8—Variation of block s/n versus block number for the iterative interpolation procedure, $W = 256$, $n = 4$. Curves a, b, c, and d apply for $\lambda = 3$, 2, 1, and nearest neighbor averaging, respectively.

$W$ found for different values of $\lambda$. Curve d in Fig. 7 shows that a SEG-s/n of 21.5 dB was obtained when the interpolation process used nearest neighbor averaging, and was employed as a reference level. When the nearest neighbor interpolation was made adaptive, eq. (23) was used for which $\lambda = 1$, and curve c obtained. By using the iteration procedure where the interpolation was made according to eq. (25), $\lambda = 3$, a s/n $> 30$ dB was achieved for $N = 512$ (see curve a).

Also shown in Fig. 7 is curve b, which was obtained by formulating the sequence $\{\hat{z}_k\}$ based on first computing $\{\bar{z}_k\}$ according to eq. (22), formulating $R(\tau)$, and then removing samples $\bar{z}_r$ and replacing them with interpolated samples derived by using $\lambda = 3$. Thus, in this $\lambda$-interpolation method we do not progress from the average sequence to those derived with $\lambda = 1$ and 2, but proceed directly from the average sequence to compute the parameters with $\lambda = 3$. The result is a s/n of 27 dB for $W = 256$ to 1024, a 3-dB reduction compared to the $\lambda$-with-iteration ($\lambda = 3$) case, and a diminution in complexity. Informal listening experiences showed that the $\lambda$-interpolation and $\lambda$-with-iteration schemes, both with $\lambda = 3$, produced speech whose impairments were barely perceptible.

The variation of block s/n with block number for the iterative interpolation procedure is displayed in Fig. 8, $n = 4$, $W = 256$. The average values of these block s/n's give the segmental s/n in Fig. 7 for $W = 256$. Close inspection of the curves in Fig. 8 reveal that progressive iteration does not always give the highest block s/n. However, $\lambda$-with-iteration, $\lambda = 3$, achieved the highest s/n for most blocks with gains up to 25 dB compared to nearest neighbor averaging interpolation.

In Fig. 9, the variation of block s/n with block number is displayed for the $\lambda = 3$ condition, $n = 4$, $W = 256$. Curves a and b are those previously displayed in Figs. 5a and 8a, and refer to interpolation parameters computed from the original speech sequence, and by $\lambda$-with-iteration procedure, respectively. Curve c applies for the $\lambda$-interpolation method, while curve d corresponds to nearest neighbor averaging interpolation, and is included as a reference level. The curves in Fig. 9 illustrate that by deriving the interpolation parameters from the original speech instead of from the received data, the large dips in block s/n are mitigated.

#### *6.2.1 Interpolation errors*

We will now consider the interpolation error sequences and their spectra when the interpolation parameters are generated from the received sequence $\{z_k\}$. To illustrate the error performance we selected an arbitrary segment of our input speech signal (see Fig. 3) that had high-level and low-level voiced speech, and unvoiced speech. The speech segment and its spectrogram are displayed in Fig. 10. As before,

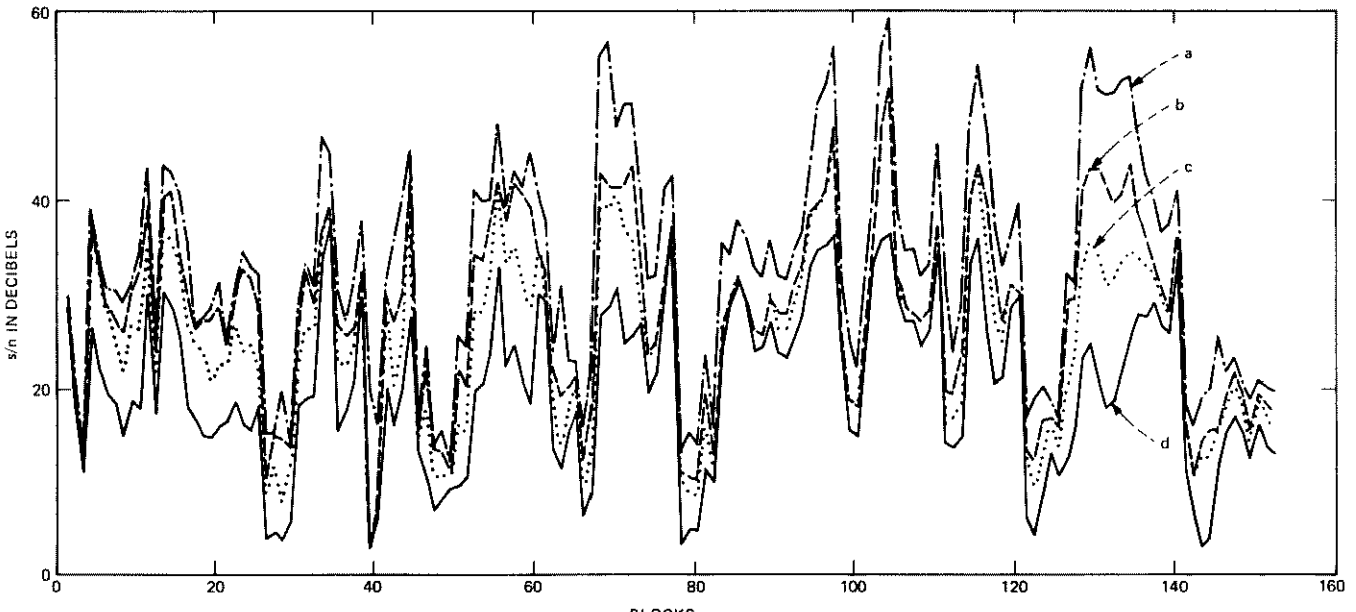

Fig. 9—Variation of block s/n as a function of block number for the $\lambda = 3$ condition, $W = 256$, $n = 4$. Curves a, b, c, and d are for interpolation parameters computed from original speech, $\lambda$-with-iteration, $\lambda$-interpolation, and nearest neighbor averaging, respectively.

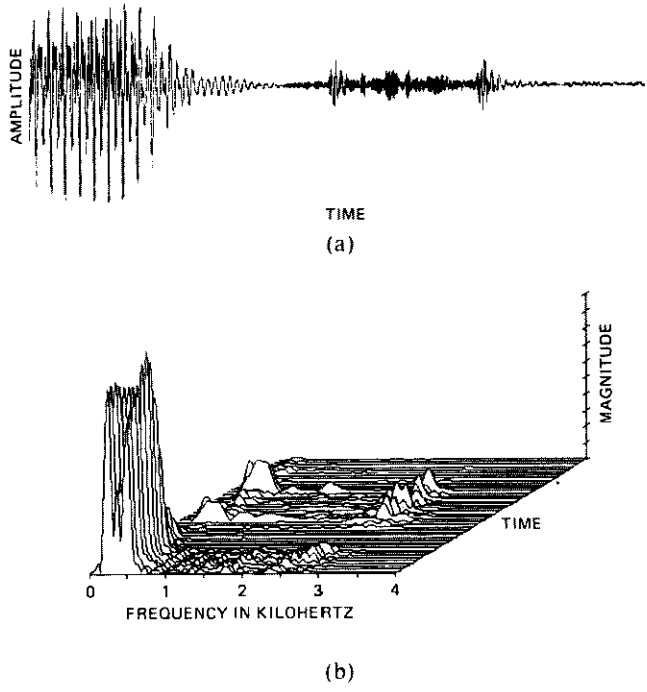

Fig. 10—Speech segment: (a) time waveform, and (b) spectrogram.

every fourth sample in the segment was removed and replaced by a sample produced by interpolation from neighboring samples, where the interpolation parameters were derived from the received data as described in Section V. We avoid displaying the spectrograms of the recovered speech segments associated with the four interpolation conditions used in Fig. 7 because of their similarity. Instead we show in Fig. 11a, b, c, and d the error signals determined as the difference between the input speech segment shown in Fig. 10a and the recovered waveforms produced using interpolation methods of: average of adjacent samples; λ-interpolation with $\lambda = 1$ and 3; λ-with-iteration, $\lambda = 3$; respectively. The error signals in Fig. 11 are small for the low-level highly correlated voiced speech section, and are much greater in the high-level voiced section and for the unvoiced speech. The block s/n values for the speech signal in Fig. 10a are therefore higher for the voiced speech than for the unvoiced speech. Inspection of Fig. 11 shows that the smallest error signal amplitudes generally occurred when the interpolation procedure used three samples on either side of each missing sample. For this segment of speech the advantage of using the full iteration procedure is small compared to $\lambda = 3$, no

(e)

Fig. 11 (e)—Error waveforms and their spectrograms. The error waveforms in a, b, c, and d are the difference between the input speech segment of Fig. 10a and the recovered signals formulated using the interpolation method of: average of adjacent samples, λ-interpolation, $\lambda = 1$, $\lambda = 3$, and λ-with-iteration, $\lambda = 3$, respectively, $W = 256$. The waveform in e shows the effect of $\mu$-law PCM encoding the speech samples prior to interpolation, λ-with-iteration, $\lambda = 3$, $W = 256$.

iteration. The spectrograms of the error signals are displayed above these signals in Fig. 11.

As the error sequence $\{e_k\}$ is the difference between the original speech sequence $\{x_k\}$ and the recovered speech sequence $\{\hat{z}_k\}$, it is composed of $n - 1 = 3$ components of zero magnitude followed by a nonzero component due to the interpolation error. The components in the original and recovered speech sequences occur at a rate $f_s = 8$ kHz, while the components in $\{e_k\}$ are generated at $f_s/n = 2$ kHz in Fig. 11. Close examination of the error spectra in this figure shows a symmetry about 2 kHz over the range dc to 4 kHz, and further symmetries about 1 kHz and 3 kHz for the frequency ranges of dc to 2 kHz, and 2 kHz to 4 kHz, respectively.

The noise components above 3.3 kHz were removed by the output filter shown in Fig. 1. When this was done the improvement in speech quality was minimal, as can be anticipated from the spectrograms of Fig. 11. Also the SEG-s/n values shown in Fig. 7 were only increased by a fraction of a decibel.

Figures 12a through d show the error spectrograms obtained when

the interpolation procedure used adjacent sample averaging, λ-interpolation with $\lambda = 1$, $\lambda = 3$, and λ-with-iteration, $\lambda = 3$ for the entire speech signal of Fig. 3. The spectrograms are not preemphasized. The effect of using $\lambda = 3$ compared to $\lambda = 1$ is to alter the nature of the noise spectrum, increasing its tendency to be more random. When we connected the error signal appertaining to the interpolation procedure having $\lambda = 3$ to a pair of earphones, it was found to be unintelligible and noise-like. With adjacent sample averaging the error signal was significantly more correlated with the original speech, and when we listened to this error signal the two sentences were comprehendible.

### 6.3 Variation of n

The effect of $n$ on SEG-s/n is displayed in Fig. 13 for a block size of 256. When the interpolation parameters were derived from the original speech sequence using the correlation function given by eq. (14), $\lambda = n - 1$, the SEG-s/n increased by 9 dB to 28.6 dB when $n$ was increased from 2 to 3, as shown in Fig. 13a. Thus, by rejecting every third sample we are able to reconstitute the speech by means of interpolation with only a slight perceptual impairment. For $n = 4$ the distortion in the interpolated speech was imperceptible. Curve b in Fig. 13 applies to λ-with-iteration, $\lambda = n - 1$. When $n = 2$ there is negligible difference between the two curves in Fig. 13, but as $n$ is increased the curves diverge and curve a maintains a minimum mean square interpolation error. We conclude from Fig. 13 that if the block size is 256, the recovered speech will have only minor impairments for $n = 3$ when the interpolation parameters are derived at the transmitter, and $n = 4$ is acceptable when the parameters are computed by the iterative procedure.

### 6.4 Adaptive interpolation results for PCM encoded speech

The sampled speech sequence $\{x_k\}$ was binary encoded by an 8-bit $\mu$-law PCM encoder having $\mu = 255$. From Figs. 4 through 13 we concluded that $n = 4$ was a good compromise, offering the prospect of an acceptable s/n while reducing the 64-kb/s transmission rate to 48 kb/s. With this bit-rate reduction, 16 kb/s of data can be added to the 48 kb/s of speech to give the conventional transmission rate. At the destination (or at some convenient point along the transmission path) the data can be removed, and each of the 6 k-words/s comprising the $\mu$-law PCM signal decoded. In our experiments we assumed that the bits would be regenerated without error, and the 8-kHz sampling rate established by reinserting the missing samples by the interpolation techniques previously described. However, the accuracy of the interpolation process was reduced by the quantization noise produced in the digital encoder.

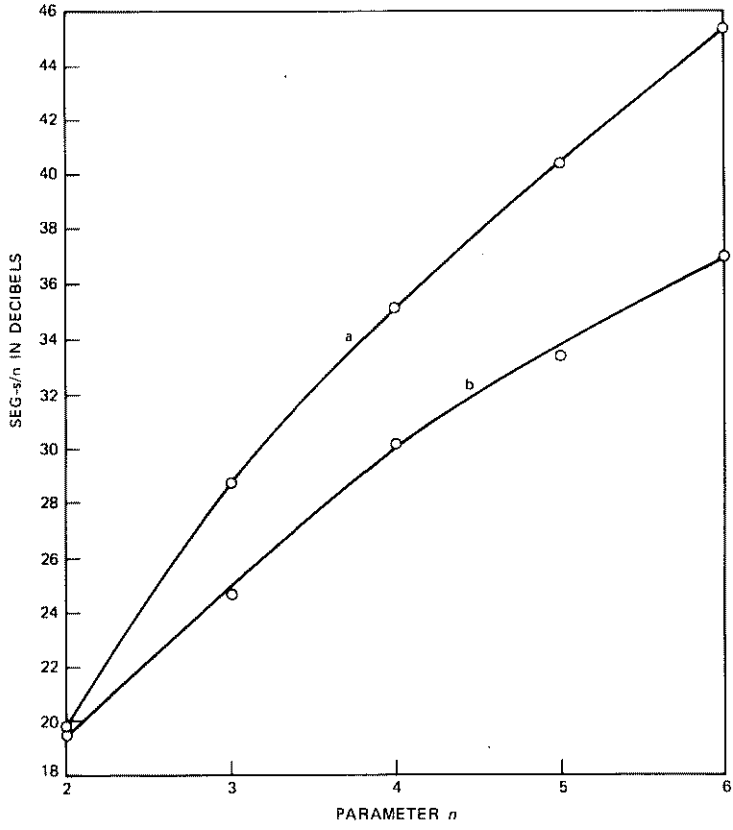

Fig. 13—Variation of SEG-s/n versus parameter $n$, for $\lambda = n - 1$, and the interpolation parameters derived from the original speech sequence, and by the $\lambda$-with-iteration scheme at the receiver. The block size is 256.

Deriving the interpolation parameters from the received data, as described in Section V, yielded the results shown in Fig. 14. The interpolation procedures applicable to curves a, b, c, and d were identical to those employed for curves a, b, c, and d, respectively, in Fig. 7. The respective curves in Fig. 14 are lower than those in Fig. 7 owing to the effect of quantization noise encountered in $\mu$-law PCM encoding. We observe that the quantization noise causes a loss in SEG-s/n of 0.5 dB when the interpolation is performed by adjacent sample averaging. For the cases of $\lambda = 1$ and $\lambda = 3$ the losses in SEG-s/n owing to the effect of quantization noise become approximately 1 and 1.7 dB, respectively, when $W = 256$. As the interpolation process improves, the SEG-s/n becomes relatively more affected by the quantization noise. We observe that the greatest loss in SEG-s/n relative to when there is no quantization noise occurs for the case of $\lambda$-with-

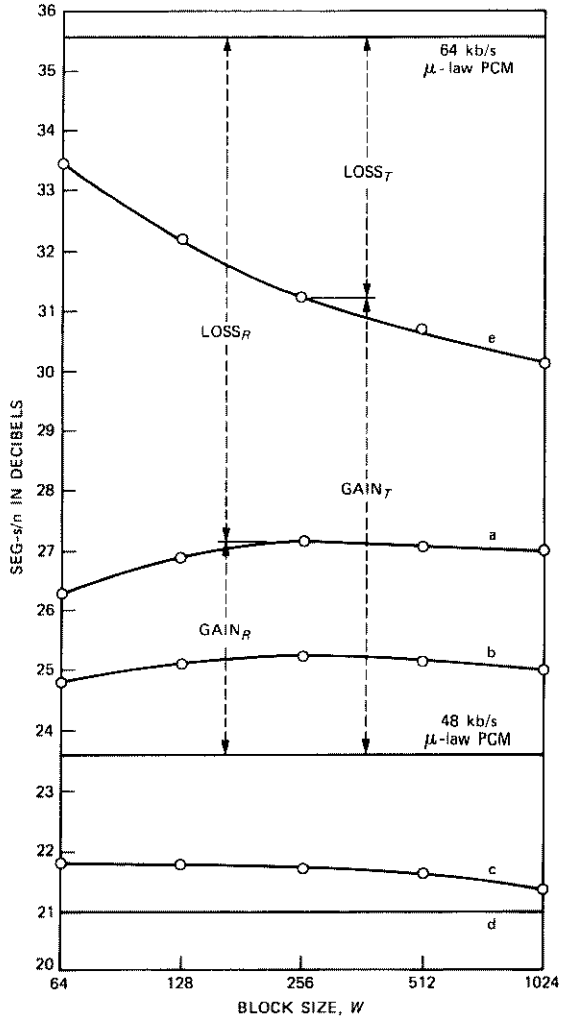

Fig. 14—8-bit $\mu$-law PCM encoding, $\mu = 255$. The effect of block size on SEG-s/n for different conditions. Curves a, b, c, and d apply for $\lambda$-with-iteration, $\lambda = 3$; $\lambda$-interpolation, $\lambda = 3$; $\lambda$-interpolation, $\lambda = 1$; and average of adjacent sample interpolation, respectively. Curve e relates to the interpolation parameters derived at the transmitter using $\lambda = 3$ and $R(k, j)$.

iteration, $\lambda = 3$, and is 2.7 dB for $W = 256$. Also shown in Fig. 14 are the SEG-s/n values for the encoded speech when the sampling rate is 8 kHz, $\mu = 255$, and the number of bits per code word is 8 and 6, i.e., the transmission bit rates are 64 kb/s and 48 kb/s, respectively. The loss in SEG-s/n due to transmitting at only 48 kb/s and reinserting the discarded samples using $\lambda$-with-iteration, $\lambda = 3$, compared to not discarding samples and transmitting at 64 kb/s is given by $LOSS_R$ in

Fig. 14. The subscript $R$ indicates that the interpolation parameters were derived from the received data. The gain in SEG-s/n, $GAIN_R$, is due to interpolating the missing samples compared to the 48 kb/s $\mu$-law PCM encoding where no samples are discarded. Although the 48 kb/s has the 8-kHz word rate, the quantization noise is higher because there are 6 bits per code word. The values of $LOSS_R$ and $GAIN_R$ for $W = 256$ are 8.4 and 3.6 dB, respectively.

The interpolation performance can be enhanced if the interpolation parameters are derived from the locally decoded $\mu$-law PCM signal at the transmitter. The interpolation parameters must be conveyed to the receiver in a binary format as side information. This is not a difficult task in a digital transmission system as fewer than 30 bits per $W$ PCM words are required to be transmitted. When $W$ is 256, the side information increases the bit rate by 2 percent. The bit rate can be maintained at 48 kb/s if the side information replaces the least significant bit in every sixth word transmitted. This will have only a marginal effect on the quality of the recovered speech. When the interpolation parameters for $\lambda = 3$ were determined at the transmitter using eqs. (11) through (14) and subsequently transmitted as side information, curve e in Fig. 14 was obtained. Comparing curve a in Fig. 6 with this curve shows that the presence of quantization noise reduces the SEG-s/n of the interpolated speech signal by 4 dB. Nevertheless, curve e is significantly higher than curve a, and the disparity increases to 7 dB for $W = 64$. The $LOSS_T$ and $GAIN_T$ factors, where the subscript $T$ implies the generation of the parameters at the transmitter, had values of 4.3 and 7.7 dB, respectively, for $W = 256$. The effect of interpolation is equivalent to saving more than one bit per word.

For $\mu$-law PCM encoding and the adaptive interpolation procedure of $\lambda$-with-iteration, $\lambda = 3$, $W = 256$, resulted in the error waveform and its spectrogram displayed in Fig. 11e for the speech segments shown in Fig. 10. Figures 11e and d show that the effect of quantization on the error spectrum is small.

## VII. DISCUSSION

Our intention at the outset of this investigation was to discard one speech sample (or PCM word) in every four, $n = 4$, and to replace the missing samples or words by an interpolation process such that the degradation in speech quality was virtually imperceptible. Further, the implementation algorithm was to be inherently simple. These goals have been reached in good measure.

The central issue in any interpolation process is determining the interpolation parameters. Our approach is to attempt to minimize the mean square error, a nonoptimum procedure for speech signals where

the perception of interpolation noise may be modified by the spectral composition of the speech signal over some 20 ms interval, and temporal effects lasting approximately 200 ms. The justification of the mean square error is based on simplicity, and for $n = 4$ gives good results. In deriving the interpolation parameters of eq. (11) based on $R(k, j)$, we made no assumptions concerning the statistic of the speech signal. The selection of block size $W$ depends upon an acceptable s/n, the need to avoid excessive signal delays resulting from too high a value of $W$, and the amount of side information permitted, where appropriate, when $W$ is small. Our suggested range of $W$ is from 64 to 1024 (see Figs. 4 and 7). These values of $W$ correspond to durations of 8 to 128 ms, i.e., ranging from approximately a pitch to a syllable period. Computing the interpolation parameters using eqs. (11) and (14), we were able to achieve gains in s/n of 16, 14, and 12 dB compared to interpolation using nearest neighbor linear interpolation for block sizes of 64, 256, and 1024, respectively.

When the estimate of the autocorrelation function could not be based on the original speech sequence, but had to be estimated from the received speech samples where every $n$th sample was missing, an iterative estimation procedure was employed. By making a crude estimation of the missing samples, the autocorrelation function $R(\tau)$ was computed, and in general a more accurate set of interpolated samples were found. The autocorrelation function was again determined, and the accuracy of the interpolated samples nearly always improved. By this iterative approach, for $n = 4$, $\lambda$-with-iteration, $\lambda = 3$ had an interpolation gain over nearest neighbor averaging of 8 dB for $W = 256$, as displayed in Fig. 7.

The effect of discarding every $n$th sample, $n = 2, 3, 4$, and 5, showed that it is advisable to maintain $n \geq 4$ for imperceptible perceptual degradation. For highly correlated sounds and where some masking of the interpolation noise occurs, we can satisfactorily deploy $n = 3$ and even $n = 2$. However, in general there is considerable distortion power when $n = 2$, which is hardly surprising as half the samples had been rejected. Nevertheless, for $n = 2$ adaptive interpolation yielded a s/n of approximately 19.5 dB, which is noisy but intelligible speech.

Finally, we found that when conventional 8-bit $\mu$-law PCM encoded speech, $\mu = 255$, had its bit rate reduced from 64 kb/s to 48 kb/s to enable 16 kb/s of other data to be transmitted, the recovered speech after decoding and interpolation had a s/n that approximated that of 56-kb/s $\mu$-law PCM.

# Practical Design Considerations for Coupled-Single-Amplifier-Biquad Active Bandpass Filters

By J. TOW*

(Manuscript received December 10, 1982)

This paper presents a synthesis method and practical design considerations for the Coupled-Single-Amplifier-Biquad (CSAB) realization of all-pole symmetrical bandpass (BP) filters. The CSAB topology consists of a cascade of second-order SAB bandpass sections, together with negative feedback around adjacent sections. A straightforward procedure that leads to the block diagram representation of the CSAB is shown. Explicit design formulas are given for the optimum element values of the Deliyannis-Friend SAB bandpass section, as well as for the feedback resistors. This CSAB design offers improved performance over the cascade SAB approach without using additional operational amplifiers. Also described are the effects on the filter response due to finite amplifier gain, capacitor dissipations, noninfinite pole-$Q$ sections, and their compensation techniques. These are followed by discussions on maximizing the filter dynamic range and tuning.

## I. INTRODUCTION

It is commonly known that in the realization of high-order active filters, properly designed multiple-loop-feedback topologies offer far superior sensitivity performance than the approach of cascading biquadratic filter blocks.[1-6] The multiple-loop-feedback structure is particularly useful in the design of bandpass filters, where reduced sensitivity design is most often needed. Compared with the cascade biquad approach, two drawbacks are usually attributed to these topologies,

namely, the more complicated design procedures and the use of more op amps. However, for the class of all-pole geometrically symmetrical Bandpass (BP) filters, these drawbacks do not exist for a particular multiple-loop-feedback structure commonly referred to as leap-frog, active-ladder, or coupled-biquad.[7–13] The coupled-biquad topology consists of a cascade of second-order sections together with negative feedback around adjacent biquad sections.

Most of the existing coupled-biquad descriptions assumed multiple op-amp biquads, but details on the use of Single-Amplifier Biquads (SABs) are scarce. Our discussion here focuses on the use of SAB and is further restricted to voice-frequency applications. Note that the Coupled-Single-Amplifier-Biquad (CSAB) topology described here requires $n$ op amps for a $2n$-order BP filter.

The first part of this paper presents a general design method for the CSAB realization of all-pole symmetrical BP filters. A straightforward procedure is given that leads to the block diagram representation of the CSAB. Each of the second-order sections is then implemented by the Deliyannis-Friend[14] SAB configuration. Optimum element values for these SABs are computed according to Fleischer's results.[15] The second part of the paper discusses the effects on the filter response due to finite op-amp gain, capacitor dissipations, noninfinite pole-$Q$ sections, and their compensation techniques. These are followed by discussions on maximizing the filter dynamic range and tuning.

## II. CSAB DESIGN PROCEDURE

This section presents a straightforward design procedure for the CSAB realization of all-pole symmetrical BP filters. Optimum design equations are given for the Deliyannis-Friend SAB bandpass section and the feedback resistors.

### *2.1 Block diagram representation of CSAB configuration*

The starting point for the CSAB realization of an all-pole symmetrical BP filter, e.g., a Bessel-, Butterworth-, or Chebychev-type BP filter, is its normalized low-pass (LP) prototype ladder configuration. The ladder configuration is readily available from many existing handbooks and is shown in Fig. 1.

Let $\omega_0$ = center frequency of the BP filter (in rad/s)

$B$ = passband bandwidth of the BP filter (in rad/s)

A block diagram representation of the CSAB topology for the BP filter is given in Fig. 2, where the coupled biquadratic transfer functions,

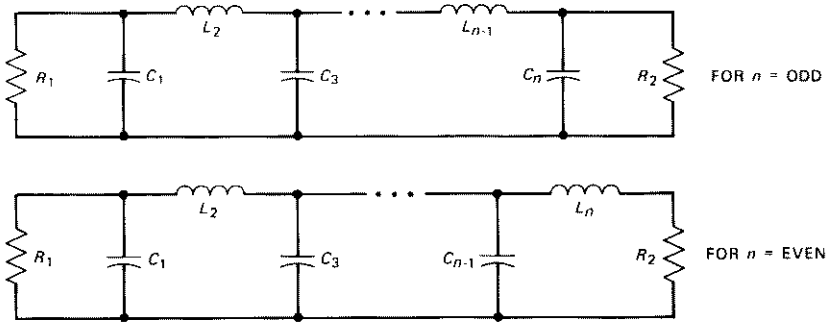

Fig. 1—LP prototype ladder configuration.

$T_i(s)$ and $T_i'(s)$, are related to the element values of the LP ladder by the following equations:

$$T_1(s) = K \cdot \frac{\dfrac{R_1 + R_2}{R_2} \cdot \dfrac{B}{R_1 C_1}\, s}{s^2 + \dfrac{B}{R_1 C_1}\, s + \omega_0^2} \tag{1}$$

$$T_1'(s) = \frac{\dfrac{B}{C_1}\, s}{s^2 + \dfrac{B}{R_1 C_1}\, s + \omega_0^2} \tag{2}$$

$$T_i(s) = T_i'(s) = \frac{\dfrac{B}{X_i}\, s}{s^2 + \omega_0^2} \qquad i = 2, 3, \cdots, n-1 \tag{3}$$

$$\text{and} \quad X_i = \begin{cases} L_i \text{ for } i \text{ even} \\ C_i \text{ for } i \text{ odd} \end{cases}$$

$$T_n(s) = \begin{cases} \dfrac{\dfrac{B}{C_n}\, s}{s^2 + \dfrac{B}{R_2 C_n}\, s + \omega_0^2} & \text{for } n \text{ odd} \\ \dfrac{\dfrac{B}{L_n}\, s}{s^2 + \dfrac{B R_2}{L_n}\, s + \omega_0^2} & \text{for } n \text{ even,} \end{cases} \tag{4}$$

where $K$ determines the overall gain of the filter. For unity (0 dB) voltage gain, set $K = 1$.

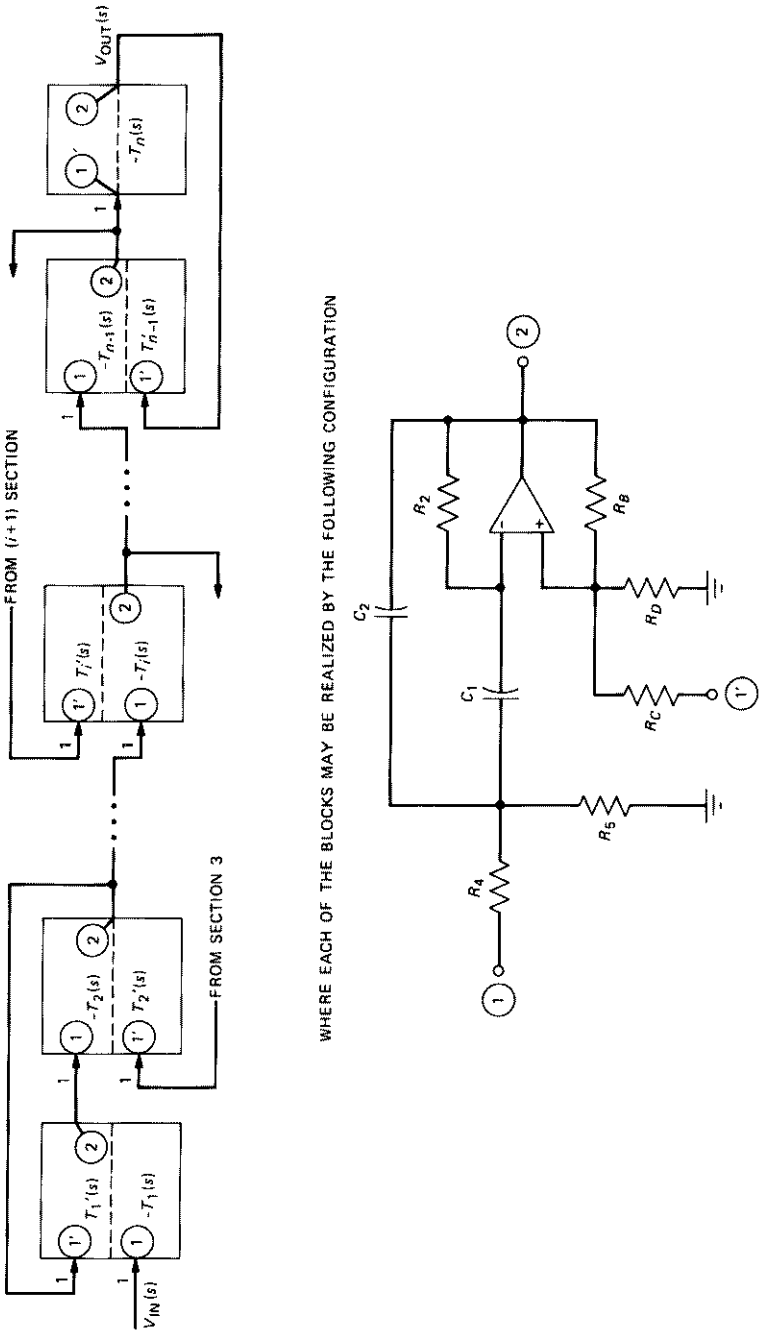

Fig. 2—Coupled SAB configuration for all-pole symmetrical BP filters.

The above derivation is straightforward and is omitted here. For the three-section case, discussions can be found in pages 726 to 729 of Ref. 3 and pages 348 to 351 of Ref. 6. Note that in Fig. 2, the Deliyannis-Friend SAB configuration is also shown. Besides its good sensitivity properties, this particular SAB can simultaneously realize both the forward and the feedback paths as required by Fig. 2.

One final step in the CSAB realization is to obtain the element values for the individual SAB blocks. The optimum formulas are given in the next section.

### *2.2 Optimum CSAB element values*

For each of the second-order blocks shown in Fig. 2, let the forward and feedback voltage transfer functions be represented by:

$$\frac{V_2(s)}{V_1(s)} = -T_i(s) = \frac{-n_1 s}{s^2 + d_1 s + d_0} \tag{5}$$

and

$$\frac{V_2(s)}{V_1'(s)} = T_i'(s) = \frac{n_1' s}{s^2 + d_1 s + d_0}. \tag{6}$$

As shown in Fig. 2 and eqs. (1) to (3), the internal sections, i.e., $i = 2, 3, \cdots, n-1$, have an infinite pole-$Q$ value or $d_1 = 0$. For improved filter performances, a later section suggests the use of a very high-$Q$ value, say several hundreds, instead of the infinite value. This corresponds to the use of a small value for $d_1$ in eqs. (5) and (6). The high but fixed $Q$-value can be designed into the CSAB configuration by the familiar predistortion technique.

Element values are first obtained for the forward transfer function, $T_i(s)$, by the formulas given in Ref. 14, where the conductance value of a fictitious resistor, $R_1$, is first computed and the values of $C_1$, $C_2$, $R_A$, and $R_B$ can be conveniently chosen such that

$$G_1 = \frac{C_2 R_B}{2R_A}\left\{-d_1 + \left[d_1^2 + 4d_0\left(1 + \frac{C_1}{C_2}\right)\frac{R_A}{R_B}\right]^{1/2}\right\} \tag{7}$$

$$R_2 = \frac{G_1}{C_1 C_2 d_0} \tag{8}$$

$$R_4 = \frac{1 + \dfrac{R_A}{R_B}}{n_1 C_2} \tag{9}$$

$$R_5 = \frac{1}{G_1 - G_4} \tag{10}$$

$$R_B = \text{arbitrary [can be chosen according to eq. (15)]} \tag{11}$$

$$R_D = R_A \tag{12}$$

$$R_C = \text{infinite.} \tag{13}$$

As shown by Fleischer,[15] the value of $R_B$ or the ratio of $R_A/R_B$ should be chosen so as to minimize the overall SAB variability (sensitivity) due to the combined active and passive elements variations. His results are given below:*

$$Q_0 = \left[ |A(s_0)|^2 \frac{8\sigma_R^2 + \sigma_C^2}{8\sigma_{A(s_0)}^2} \right]^{1/4} \tag{14}$$

$$\frac{R_A}{R_B} = \frac{C_2}{C_1 + C_2} \frac{1}{Q_0} \left( \frac{1}{Q_0} - \frac{d_1}{\sqrt{d_0}} \right), \tag{15}$$

where $A(s)$ represents the gain of the op amp, $\sigma_R^2$, $\sigma_C^2$, and $\sigma_{A(s)}^2$ correspond to the variances of $\Delta R/R$, $\Delta C/C$, and $\Delta A(s)/A(s)$, respectively, and $s_0$ is the pole location of the particular SAB transfer function.

The values of $R_B$ and $R_C$ are next modified according to the following formulas to implement the feedback transfer function as well [see Fig. 2 and eq. (6)]:†

$$K_F = \frac{n_1'}{\left( \frac{G_1 + G_2}{C_2} + \frac{G_2}{C_1} \right)} \tag{16}$$

$$\text{(new) } R_C = \frac{1 - K_F}{K_F} R_D \tag{17}$$

$$\text{(new) } R_B = \frac{R_B R_C}{R_C + R_D} \tag{18}$$

$$R_D = R_A \text{ (as before).} \tag{19}$$

In summary, the optimum element values can be computed from eqs. (14), (15), (7) to (12), and (16) to (18).

---

* Equations (57), (61), (13b), (2) and (7) of Ref. 15 were used. For the case of $C1 = C2$ and single-pole op-amp characteristics, simpler formulas are given in page 323 of Ref. 2.

† The derivation is given in the appendix. Note that, as shown in pages 362 to 364 of Ref. 6, the feedback transfer function realized is not exactly a BP function but has negative and real transmission zeros. However, in the vicinity of the pole frequency, where the effect of feedback is of interest, the function behaves like a BP function. In any event, the error introduced is negligible.

## III. PRACTICAL DESIGN CONSIDERATIONS

The preceding section describes one practical design consideration, namely, that component statistics are used to obtain an optimum design parameter, $R_A/R_B$, for the individual SAB blocks. This section further discusses some important factors that cause the SAB or CSAB response to deviate from its ideal characteristic. Compensations in the form of predistortion techniques are described. These compensations can be achieved by modifying the pole locations of the individual second-order blocks as given by eqs. (5) and (6). In a good design, they must be considered as part of the original design and optimum element values are to be computed from the modified transfer functions.

### *3.1 Nonideal op amp characteristics*

For a given SAB realizing the transfer functions (5) and (6), the major effect of finite op-amp gain is to shift the desired pole location, or the roots of

$$s^2 + d_1 s + d_0 = s^2 + \frac{\omega_0}{Q} s + \omega_0^2 = (s - s_0)(s - s_0^*) \tag{20}$$

from $s_0$ to $s_0 + \Delta s_0$. Fleischer[15] has shown that this deviation is approximately given by

$$\Delta s_0 = -\left(1 + \frac{R_A}{R_B}\right) \frac{1}{A(s_0)} \frac{D_2(s_0)}{s - s_0^*}, \tag{21}$$

where

$$D_2(s) = s^2 + \left(\frac{C_1 + C_2}{C_1 C_2} \frac{1}{R_2} + \frac{G_1}{C_2}\right) s + \frac{G_1}{R_2 C_1 C_2}. \tag{22}$$

In the actual design, one can apply the negative of this shift to the nominal transfer function. Equivalently, as shown in pages 415 to 416 of Ref. 2, the shift in $\Delta s_0$ can be represented by:

$$\frac{\Delta \omega_0}{\omega_0} = Re\left(\frac{\Delta s_0}{s_0}\right) \tag{23}$$

$$\frac{\Delta Q}{Q} = -2QIm\left(\frac{\Delta s_0}{s_0}\right). \tag{24}$$

Hence, instead of using the design parameters $\omega_0$ and $Q$ in eq. (20), one can use the modified parameters $\omega_0' = \omega_0 - \Delta\omega_0$ and $Q' = Q - \Delta Q$.

As pointed out by Fleischer, eq. (21) shows that the fractional change in the complex pole location is inversely proportional to the magnitude of the amplifier gain at the pole frequency. Hence, the use of a two-pole, one-zero compensated op amp would provide at least an

order of magnitude smaller pole shift magnitude than that obtained from using a single-pole compensated op amp in most of the audio frequency band.* For many practical voice-frequency-band applications, this pole shift is quite small for the former compensation and its effect can often be ignored.

### *3.2 Nonideal capacitor characteristics*

A nonideal capacitor is usually associated with a finite dissipation factor or tan $\delta$. It is commonly represented by introducing a resistor (with conductance $G_i$) in parallel with the capacitor $C_i$, where

$$G_i = \omega_0 C_i \tan \delta_i$$

and $\omega_0$ corresponds to the pole frequency of the SAB block, since we are particularly interested in the variations of the transfer function for frequencies near $\omega_0$.

As with the op-amp finite gain, the major effect of the capacitor dissipation factor is to cause a shift in the desired pole locations, which again can be compensated for. Weyten's approach[16] is described here. For a two-capacitor biquad section realizing eq. (5), Weyten has shown that

$$\frac{\Delta d_1}{d_1} = Q(\tan \delta_1 + \tan \delta_2) \tag{25}$$

$$\frac{\Delta d_0}{d_0} = \tan \delta_1 \tan \delta_2 - \frac{1}{Q}\left(S_{C_1}^{d_1} \tan \delta_2 + S_{C_2}^{d_1} \tan \delta_1\right), \tag{26}$$

where

$$-S_{C_i}^{d_1} = \tfrac{1}{2} + S_{C_i}^{Q} \tag{27}$$

and the coefficients in eq. (20) move from $d_i$ to $d_i + \Delta d_i$. For the SAB under consideration (Fig. 2), Ref. 15 gives

$$S_{C_1}^{Q} = -S_{C_2}^{Q} = \frac{C_2}{C_1 + C_2}\frac{Q}{Q_0} - \frac{1}{2}, \tag{28}$$

where $Q_0$ is as given before.

Hence, instead of using the design parameters $d_1$ and $d_0$ in eqs. (5) and (6), the modified parameters $d_1' = d_1 - \Delta d_1$ and $d_0' = d_0 - \Delta d_0$ can be used. Note that the fractional change of $d_0$ is usually very small and can practically be ignored. Alternately, eqs. (25) and (26) can be rewritten as

$$\frac{\Delta Q}{Q} \simeq -\frac{\Delta d_1}{d_1} = -Q(\tan \delta_1 + \tan \delta_2) \tag{29}$$

* See for example, pages 84 to 85 of Ref. 6.

$$\frac{\Delta\omega_0}{\omega_0} \simeq \frac{1}{2} \tan \delta_1 \tan \delta_2 - \frac{1}{2Q} (S_{C_1}^{d_1} \tan \delta_2 + S_{C_2}^{d_1} \tan \delta_1) \qquad (30)$$

since the variations of $\omega_0$ are usually very small. The decrease in pole-$Q$ value due to capacitor dissipation factors is usually appreciable and should be compensated for. As an illustration, for a medium-$Q$ BP section, say $Q = 20$, and for a capacitor dissipation factor of 0.0015, such as that encountered with thin-film capacitors, this fractional change in the pole-$Q$ value is 6 percent.

### *3.3 Infinite pole-Q sections*

As we see in Fig. 2, all of the second-order sections except the first and the last have an infinite pole-$Q$ value, i.e., $d_1 = 0$ in eq. (5). Note that the negative feedbacks in the coupled-biquad configuration move these poles away from the $j\omega$-axis and into the desired pole locations. Except for very high-$Q$ BP filters, realization of the infinite pole-$Q$ sections in the CSAB configuration is not very critical as long as the value of these pole-$Q$s is high, say several hundreds. The effects of using a high but finite pole-$Q$ value in these sections are a lower overall gain of the filter and a reduction of the effective passband bandwidth.[17] A decrease in gain is easily compensated for in active filter design, while the reduced passband bandwidth may usually be absorbed in the original design margin.

On the other hand, a closer approximation to the desired response is obtained if each of the internal sections is a priori designed to have a high but finite pole-$Q$ value. This value can be chosen to be the highest and practically realizable pole-$Q$ value, say $Q_M$. For the SAB, this is in the order of a few hundreds. Note that in the actual realization, these pole-$Q$ values will deviate a great deal (higher or lower than $Q_M$). Computer simulations have shown that the overall circuit variability is smaller for the finite internal pole-$Q$ design than the design with infinite pole-$Q$s.

Having presented the virtues of noninfinite internal pole-$Q$ sections, we show now how this can be achieved with the classical predistortion technique. If we refer back to Section 2.1, instead of starting with the ladder configuration, we see that the overall transfer function for the normalized LP prototype is used (again this is available from many handbooks). A shift $\alpha$ is introduced to the complex frequency variable $s$, $s = p - \alpha$, where $p$ represents the new complex frequency variable, and

$$\alpha = \frac{\omega_0}{BQ_M}. \qquad (31)$$

In eq. (31) all variables are as defined before. The new transfer function

in $p$ is used to realize the ladder configuration shown in Fig. 1. With the following modifications to eqs. (1) through (4), where $R_1'$ and $R_2'$ are used in place of $R_1$ and $R_2$, respectively, the CSAB configuration is again as shown in Fig. 2:

$$R_1' = \frac{1}{\frac{1}{R_1} + \alpha C_1} \tag{32}$$

$$R_2' = \begin{cases} \dfrac{1}{\frac{1}{R_2} + \alpha C_n} & \text{for } n \text{ odd} \\ R_2 + \alpha L_n & \text{for } n \text{ even} \end{cases} \tag{33}$$

$$T_i(s) = T_i'(s) = \frac{\frac{B}{X_i}\, s}{s^2 + \frac{\omega_0}{Q_M}\, s + \omega_0^2} \qquad i = 2, 3, \cdots, n-1. \tag{34}$$

In addition, the value of $K$ in eq. (1) must be modified to obtain the desired overall gain of the filter. This value is easily determined by computing the gain of the ladder in Fig. 1 after replacing each inductor $L_i$ with a resistor of value $\alpha^* L_i$ and each capacitor $C_i$ with a resistor of conductance $\alpha^* C_i$.

The ladder realization of the shifted LP prototype transfer function can be obtained by the classical synthesis technique, or with a filter synthesis program.[18] For best sensitivity performance, this ladder must correspond to the maximum power transfer design.[19]

### *3.4 Maximizing the filter dynamic range*

A rule-of-thumb design procedure for maximizing the dynamic range of a high-order filter is to make the maximum voltage output level at the various amplifiers equal. Variations among the various amplifier outputs in the CSAB are generally much smaller than in the corresponding cascade SAB design. For many applications, one may find the CSAB design as obtained before to be satisfactory.

The maximum voltage output levels at the amplifiers usually occur at frequencies within the filter passband or the transition bands. A practical procedure to maximize the filter dynamic range is to evaluate the filter frequency responses (via a computer program) at each of the amplifier outputs and at a set of discrete frequencies chosen from the passband and transition bands. The maximum output values thus obtained are used to rescale the gain of each of the transfer functions given by eqs. (1) through (4). More formally, let

$$G_i = \text{Max}(V_i) - \text{Max}(V_{\text{out}}) \text{ in dB},$$

where $V_i$ (in dB) is the voltage level at the output of the $i$th amplifier and $\text{Max}(V_i)$ is the maximum value over the chosen set of frequencies.

Compute

$$H_i = 10^{-\frac{G_i}{20}} \qquad i = 1, 2, \cdots, n-1$$

with $H_0 = H_n = 1$.

Multiply each of the forward transfer functions, $T_i(s)$ by $K_i$, where

$$K_i = H_i/H_{i-1} \qquad i = 1, 2, \cdots, n,$$

and multiply each of the feedback transfer functions, $T_i'(s)$, by $K_i'$, where

$$K_i' = H_i/H_{i+1} \qquad i = 1, 2, \cdots, n-1.$$

### *3.5 CSAB tuning*

When the STAR realization[14] is used to implement the SAB, the manufacturing tuning procedure is to measure values of the two capacitors on the substrate and then compute the resistor values, based on these measurements, from the predistorted transfer function using the equations given in Section 2.2. The resistors are laser-trimmed to these values. The individual SAB blocks are then connected as shown in Fig. 2. In general, this procedure is sufficient for all practical purposes.

For extremely high-precision filter applications where functional tuning may be desirable, the SAB, like any other single-amplifier-biquad configuration, does not exhibit an orthogonal set of tuning parameters. However, when the desired tuning range is small, e.g., during final mop-up trimming, the following tuning sequence is suggested: For the forward BP transfer function, with $R_C$ connected to ground, use $R_4$ to adjust for the gain at the pole frequency, $R_5$ for the pole-$Q$, and then $R_2$ for the pole frequency. The adjustments for the pole-$Q$ and pole frequency can be monitored by the 45-degree phase-shift points and the 180-degree phase-shift point, respectively. Finally, with $R_4$ connected to ground, the feedback factor can be adjusted by $R_C$. As in any coupled-biquad configuration, the CSAB overall response is relatively insensitive to these feedback resistors.

## IV. BP FILTERS WITH FINITE TRANSMISSION ZEROS

Extensions of the CSAB design to BP filters with finite transmission zeros, e.g., elliptic-type BP filters, are available. There are two approaches here. The first is to realize these transmission zeros within the individual SAB blocks;[11,12] however, their design procedures are

rather complicated. A second approach is to form these transmission zeros by a weighted sum of the individual SAB BP sections (Fig. 2) with an additional summing amplifier (in a manner analogous to the feedforward technique described in Ref. 9). Simple design formulas exist for this purpose. The second approach is particularly useful and exhibits excellent sensitivity properties for low-order filters, say fewer than five sections.

## V. CONCLUSIONS

A straightforward design procedure is given for the coupled-single-amplified-biquad realization of high-order, all-pole, symmetrical BP filters. Practical limitations and their compensation techniques are discussed. Many of these considerations, i.e., optimum choice of element values, nonideal op-amp and capacitor characteristics, are the same for the cascade or coupled designs. With this in mind, the CSAB design procedure is seen to be not more (if not less) complicated than the cascade design, since the individual second-order transfer functions are more readily computed.

The CSAB approach uses the same number of op amps as that of the cascade SAB approach. This number is equal to $n$ for a $2n$-order BP filter and is approximately half the number required by the many inductance simulation techniques, e.g., the two-op-amp Generalized Impedance Converter (GIC) designs. Sensitivity performances of the coupled-biquad may be considered as the best among all the various multiple-loop-feedback topologies[20] and are far superior to the cascade biquad. These observations, together with the fact that the Deliyannis-Friend SAB, from a sensitivity point of view, is as good as any other circuit in the audio frequency band,[15] suggest that the CSAB described here should be the choice for the design of low to medium-high $Q$ (say, $Q < 60$) BP filters in the audio frequency band.*

## APPENDIX

### *Derivation of the Element Values for the Feedback Transfer Function*

With ideal op amp, the voltage transfer functions for the SAB circuit of Fig. 2 are given by:

$$\frac{V_2(s)}{V_1(s)} = -\frac{n_1 s}{s^2 + d_1 s + d_0} \tag{35}$$

and

$$\frac{V_2(s)}{V_1'(s)} = \frac{K_F(s^2 + Fs + d_0)}{s^2 + d_1 s + d_0}, \tag{36}$$

where

$$d_1 = \left(\frac{C_1 + C_2}{C_1 C_2}\right) G_2 - \frac{(G_4 + G_5)}{(G_C + G_D)} \frac{G_B}{C_2} \tag{37}$$

$$d_0 = \frac{(G_4 + G_5)G_2}{C_1C_2} \tag{38}$$

$$n_1 = \left(\frac{G_4}{C_2}\right)\left(1 + \frac{G_B}{G_C + G_D}\right) \tag{39}$$

$$K_F = \frac{G_C}{G_C + G_D} \tag{40}$$

$$F = \left(\frac{G_4 + G_5 + G_2}{C_2} + \frac{G_2}{C_1}\right). \tag{41}$$

The element values as given by eqs. (7) through (13) satisfy the forward transfer function, eqs. (35) and (37) through (39). Note that $G_C = 0$.

In the vicinity of the pole frequency, the feedback transfer function, eq. (36), is closely approximated by

$$\frac{V_2(s)}{V_1'(s)} \simeq \frac{n_1's}{s^2 + d_1s + d_0}, \tag{42}$$

where

$$n_1' = K_F \cdot F. \tag{43}$$

To realize the feedback transfer function, the value of $G_C$ must be finite, say $G_C'$. If we let the value of $G_B$ take on a new value, $G_B'$, and, furthermore, let all the remaining elements take on the values as given before, then the forward and feedback transfer functions, Eqs. (35) and (37) through (43), can be simultaneously satisfied if the following two conditions are met:

$$\frac{G_B}{G_D} = \frac{G_B'}{G_C' + G_D} \tag{44}$$

and

$$K_F = \frac{n_1'}{F} = \frac{G_C'}{G_C' + G_D}. \tag{45}$$

Note that in eq. (45) the coefficient $n_1'$ corresponds to the like coefficient of eq. (6).

The new value of $G_C$ is obtained from eq. (45) and is given by:

$$G_C' = \frac{K_F G_D}{1 - K_F}. \tag{46}$$

Equations (44) and (46) yield the new value of $R_B$, which is given by:

$$G_B' = \frac{G_B(G_C' + G_D)}{G_D}. \tag{47}$$

Equations (46) and (47) correspond to eqs. (17) and (18), respectively.

# Modal Structure of an MCVD Optical Waveguide Fiber

By A. CARNEVALE* and U. C. PAEK†

(Manuscript received September 1, 1982)

In this paper we compare modal analyses of a Modified Chemical Vapor Deposition (MCVD) optical waveguide fiber and an idealized fiber. The pertinent profile parameters of the idealized fiber are obtained from the MCVD profile. We have validated the concept of an optimum $\alpha$ developed in our previous work. The reduction of the bandwidth of the MCVD fiber is shown to be directly related to the imperfections in the profile inherent in the MCVD manufacturing process.

## I. INTRODUCTION

Multimode lightguides, produced by the Modified Chemical Vapor Deposition (MCVD) process, are expected to be of continuing importance to the Bell System. Such lightguides with bandwidths exceeding 1 GHz·km have been produced in the manufacturing plant.

The unique MCVD process produces the index gradient in the core by depositing many layers of material with different compositions, leading to a ripple effect in the profile. Other imperfections in the MCVD process include certain mechanical limitations, difficulties at the core-cladding interface, and the altering of the core center index (burn-off) during the collapse of the preform. These imperfections in the MCVD process lead to a unique modal structure in the fiber, which

may differ radically from the modal structure obtained from a perfect power law profile. These differences, for a particular fiber preform and idealization, are analyzed and compared. The effects of the imperfections on dispersion and bandwidth are evaluated.

## II. EXPERIMENT

Our method[1] for solving Maxwell's equations has been described earlier and we shall not repeat it here. A brief schematic of the process is given in Fig. 1. In the experiment, the perfect power law profile ($N_i$)

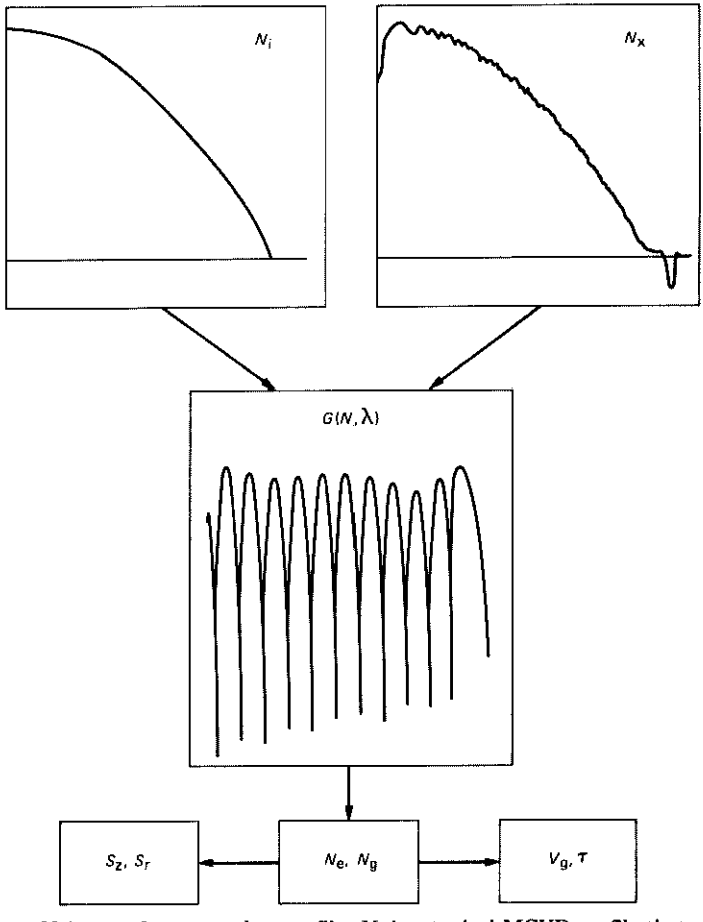

Fig. 1—$N_i$ is a perfect power law profile. $N_x$ is a typical MCVD profile that must be normalized in a particular way to be compatible with the calculations described in Ref. 1. From these calculations we obtain the $G$ function, from which one further determines the effective indices, $N_e$, and the group indices, $N_g$. Further processing leads to the calculation of the Poynting vector, the field functions, the delay times, etc.

is replaced with the actual MCVD profile ($N_x$), which differs from the perfect profile. Thereafter, the data are processed identically to find the effective indices $N_e$, group indices $N_g$, the Poynting vector, and other propagation parameters.

An MCVD preform was given to us by S. Jang of the Western Electric Research Center in Princeton, N.J. This preform had been used earlier to produce fiber for experiments. It was typical in the sense that the bandwidths averaged 1 GHz·km. By means of the laser beam refraction method[2] the refractive index profile was determined and is shown in Fig. 2.

We note in this profile the familiar characteristics of the MCVD preform, i.e., a burn-off region in the center, an undefined core-cladding interface region, and ripples on the profile, which are more pronounced as we near the core center.

The pertinent data required for our analytical testing are the approximate $\bar{\alpha}$ and the maximum $\Delta N$. These data can be obtained from known procedures,[2] or alternatively, as in our case, by utilization of the technique described in one of our earlier publications.[3] Briefly, at a selected wavelength, one obtains the modal display for zero azimuthal numbers, fits the data to a linear least squares equation for $N_g$ vs. $N_e$,

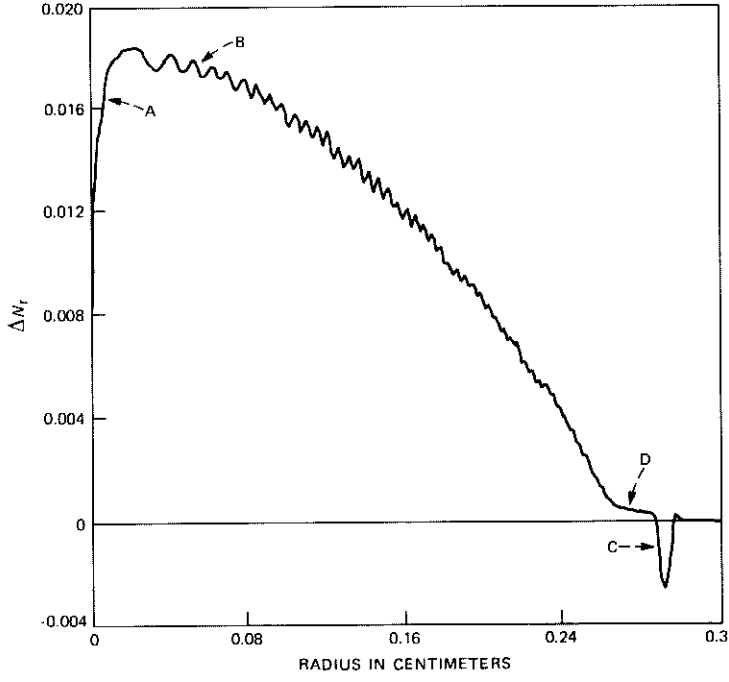

Fig. 2—Typical MCVD profile before normalization.

and compares this slope to the slope vs. $\alpha$, which has been previously calculated for that wavelength. The parameters to be used in this case were $\alpha = 2$, $\Delta N$ is typical for an 11.5-percent $GeO_2$ dopant, and radius $(R_{cc}) = 25$ $\mu$m.

These data are then used to produce modal displays for perfect power law profiles (IDEAL) at the wavelengths and polar indices used for probing the experimental (MCVD) profile. The programs are run in parallel, to be used eventually for comparison purposes only, i.e., there is no communication between the two series of calculations.

Inherent in our calculations is the automatic detection of significant mode splitting between the EH vs. HE, or TE vs. TM, and in the displays to follow, the splittings are shown, wherever possible.

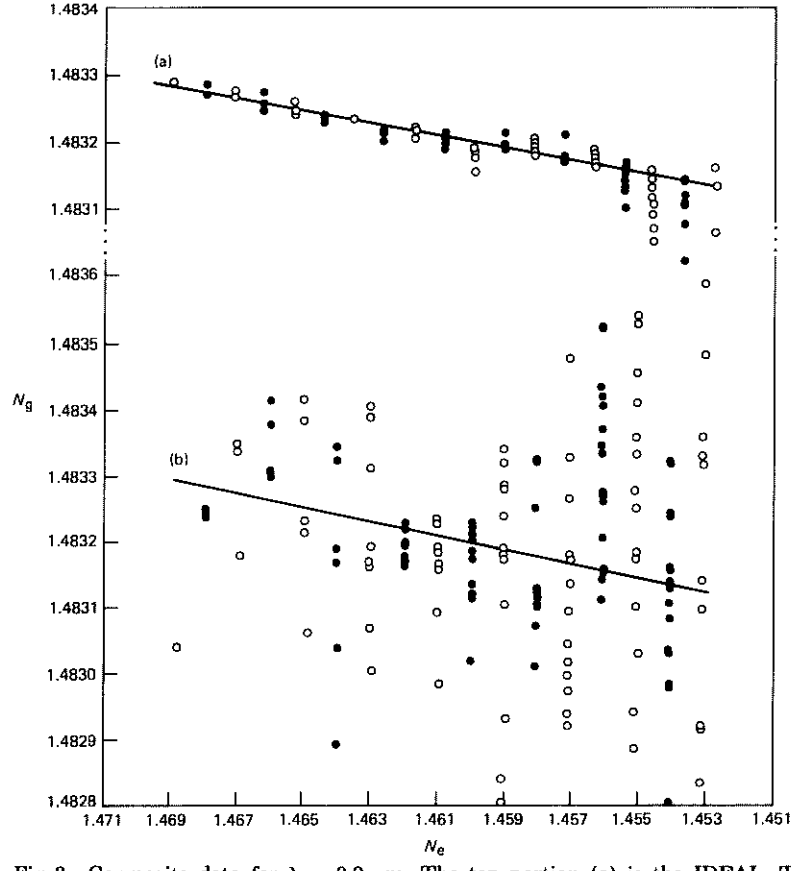

Fig. 3—Composite data for $\lambda = 0.9$ $\mu$m. The top portion (a) is the IDEAL. The bottom portion (b) is the MCVD. The straight lines are the linear least-squares curves fitted to all the data in each case, exclusive of those modes near the cladding, and for those modes widely divergent from the line. In general, the open circles are for polar indices $m = 1, 3, 5, \cdots$ last, while the solid circles are for polar indices $m = 0, 2, 4, \cdots$ last. Split modes are not readily identifiable in this display.

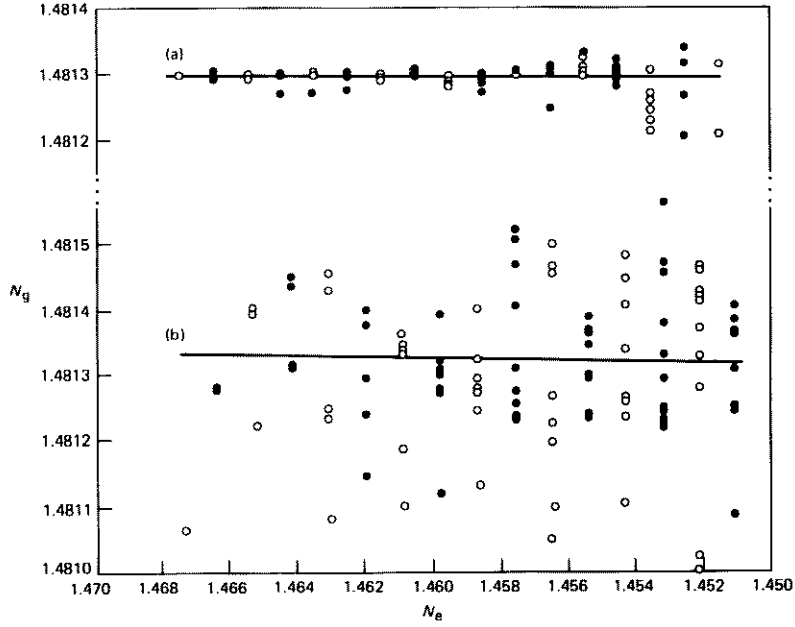

Fig. 4—Same as Fig. 3, $\lambda = 1.0\ \mu m$.

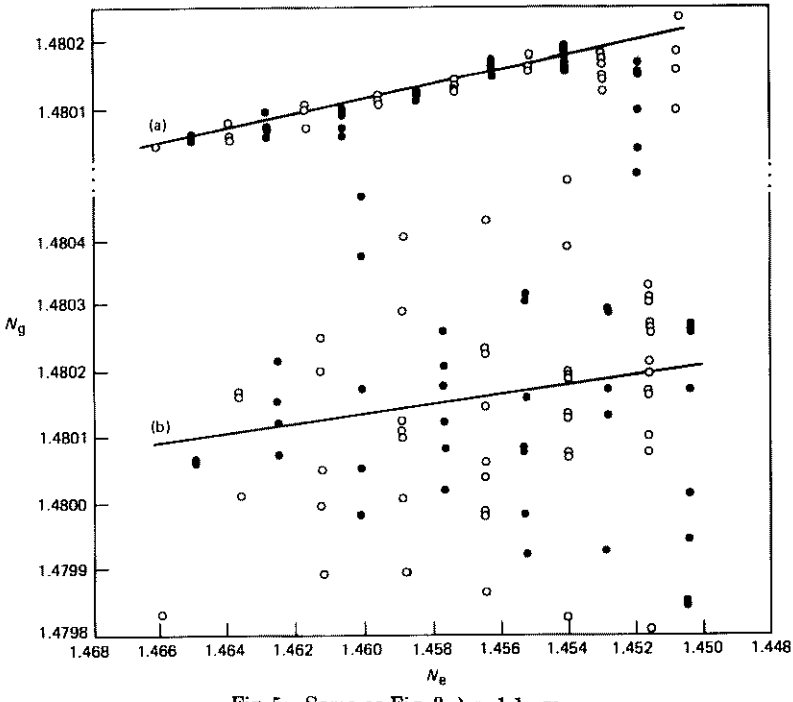

Fig. 5—Same as Fig. 3, $\lambda = 1.1\ \mu m$.

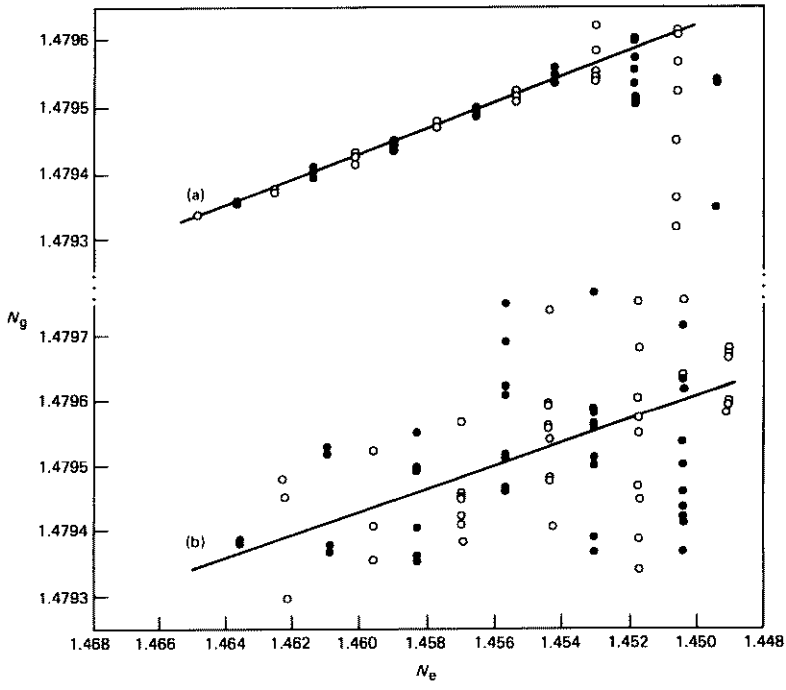

Fig. 6—Same as Fig. 3, $\lambda = 1.2$ μm.

We selected eight wavelengths ($\lambda$) spanning the region

$$0.9 \leq \lambda \leq 1.55 \ \mu\text{m}.$$

Each wavelength was checked for all possible modes ($m = 0, 1, 2, \cdots$ last) for both the IDEAL and the MCVD profiles. Because the extremely large amounts of data required in this analysis involved exorbitantly large amounts of computer time, we reduced the required accuracy to a minimum sufficient for our purposes, thereby saving considerable time and expense. Nevertheless, much computational time was required to accumulate the data given in this report.

Our results on the foregoing procedure are displayed in Figs. 3 through 10. In each figure, the dots represent the modes actually determined, the line is the linear least-squares curve fitted to the data, excluding some of the modes near cutoff, the upper portion (a) is for the IDEAL profile, and the lower portion (b) is for the MCVD profile. Again, some modes that are well off the chart are not shown because of space limitations and were not used to calculate the fitted curves in any case. All the fitted curves, translated where necessary but not rotated, have been condensed into the single plot given in Fig. 11.

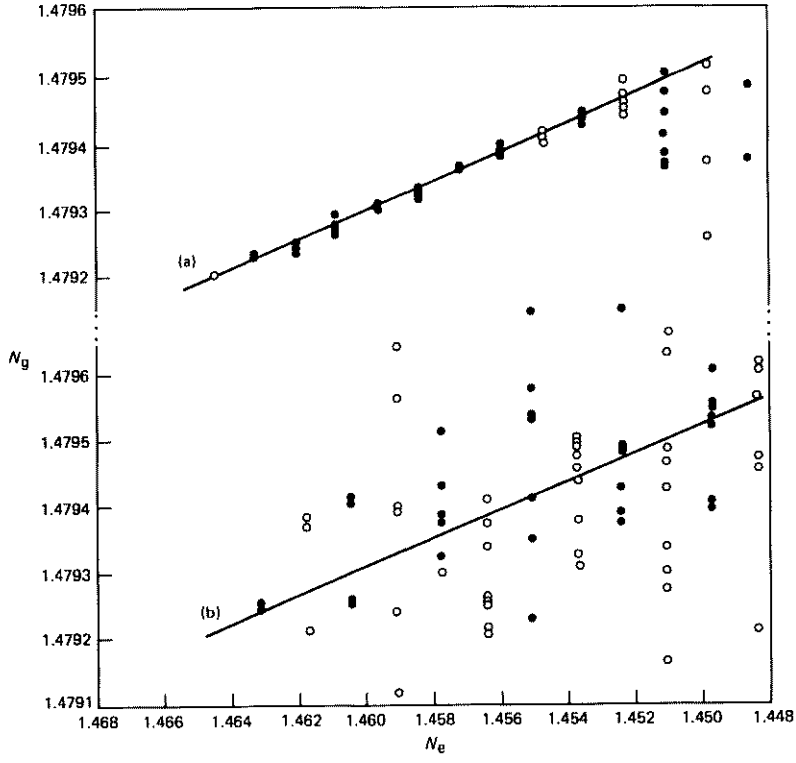

Fig. 7—Same as Fig. 3, $\lambda = 1.23$ $\mu$m.

## III. DISCUSSION

The degree of scatter in the modes for the IDEAL case (Figs. 3 through 10, Part a) is due in part to the inherent splitting of the HE-EH modes, which has been further compounded by the reduced accuracy used in this analysis.

The scattering of the modes for the MCVD case (Figs. 3 through 10, Part b) is much greater than the IDEAL series, perhaps by a factor of 5 to 10. Obviously, the greatly increased scattering for the MCVD series is due to the imperfections in the MCVD profile, such as burn-off and ripple. The contribution of each of these imperfections to increased modal dispersion (poor bandwidth) has been determined and will be the topic of a forthcoming paper.

Further, within the statistical precision and accuracy employed by the authors, one can calculate that the IDEAL and MCVD data will both extrapolate to the same index at the core. We should realize that the MCVD index of refraction data of Fig. 2 was obtained at $\lambda = 0.6328$ $\mu$m. This must be converted to the proper $\Delta N$ at the probing

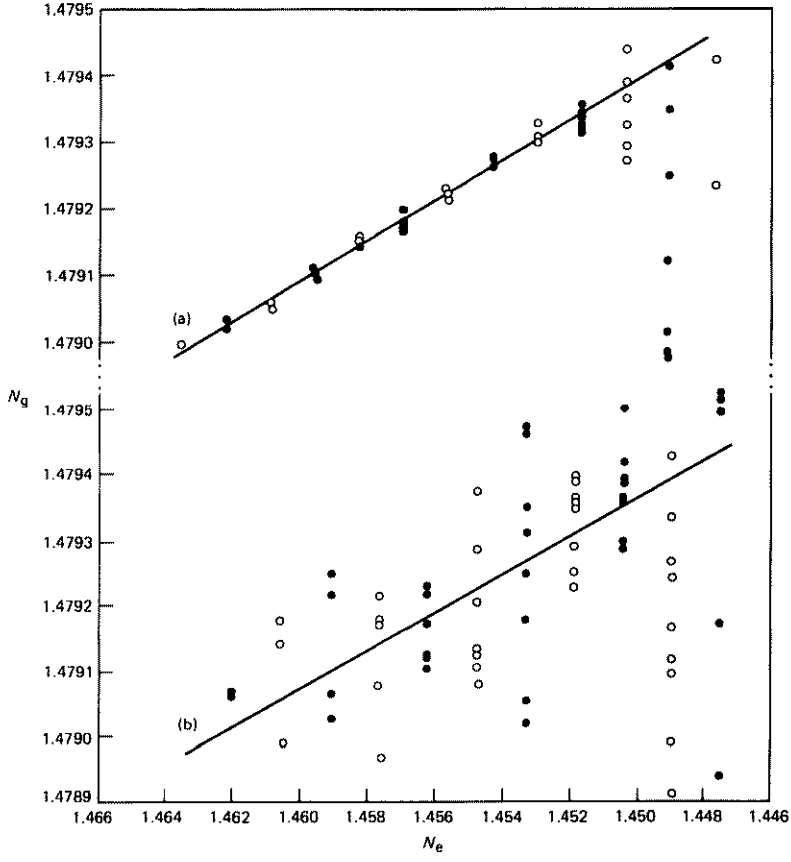

Fig. 8—Same as Fig. 3, $\lambda = 1.32$ $\mu$m.

$\lambda$'s used in any analysis, and was done in this analysis. The results indicate that our parameter $\Delta N$ as calculated at each $\lambda$ is reliable.

The parallelism of the least-squares fitted lines, seen in Fig. 11, indicates that our calculations of the parameter $\alpha$ from the MCVD profile are also reliable, and that an idealized profile may be used to predict characteristics of an MCVD profile. We must realize that $\alpha$ does not vary with $\lambda$, and this is true regardless of whether we are using the IDEAL or MCVD profile. We are immediately struck by the rotation of these curves as we change $\lambda$. We have noted a similar effect[3] at a fixed $\lambda$ for a changing $\alpha$. It should be noted that the previous work[3] and the present work agree closely.

We have one further observation in the present work, which is not readily seen in Figs. 3 through 10: although both the IDEAL and MCVD profiles were normalized to a 25-$\mu$m radius, the IDEAL profile

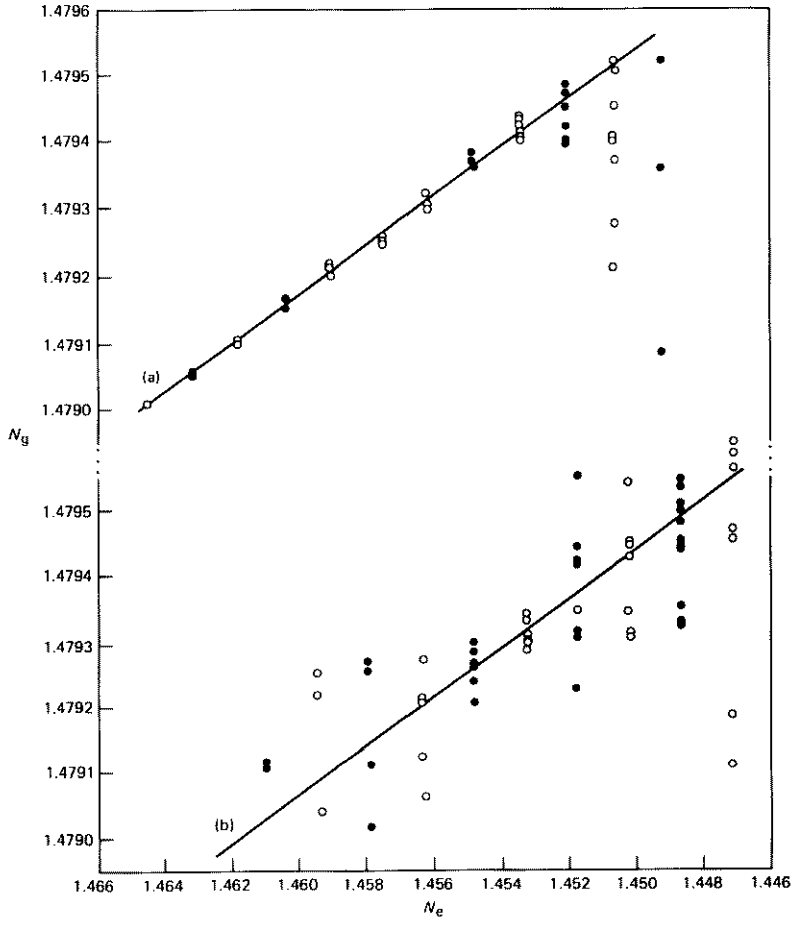

Fig. 9—Same as Fig. 3, $\lambda = 1.40$ $\mu$m.

generated more modes than the MCVD, without exception. To account for the fewer MCVD modes a crude estimation of the effective radius for the MCVD indicates that

$$r_e \approx 23 \ \mu\text{m}.$$

It may be only coincidence that this difference of 2 $\mu$m is of approximately the same magnitude as the width of the burnout.

## IV. REDUCTION OF DATA

Two useful measures of dispersion were derived for this report. The first, which is relatively simple, is the calculation of the dispersion due to the rotation of the line as a function of $\lambda$. This implies that every

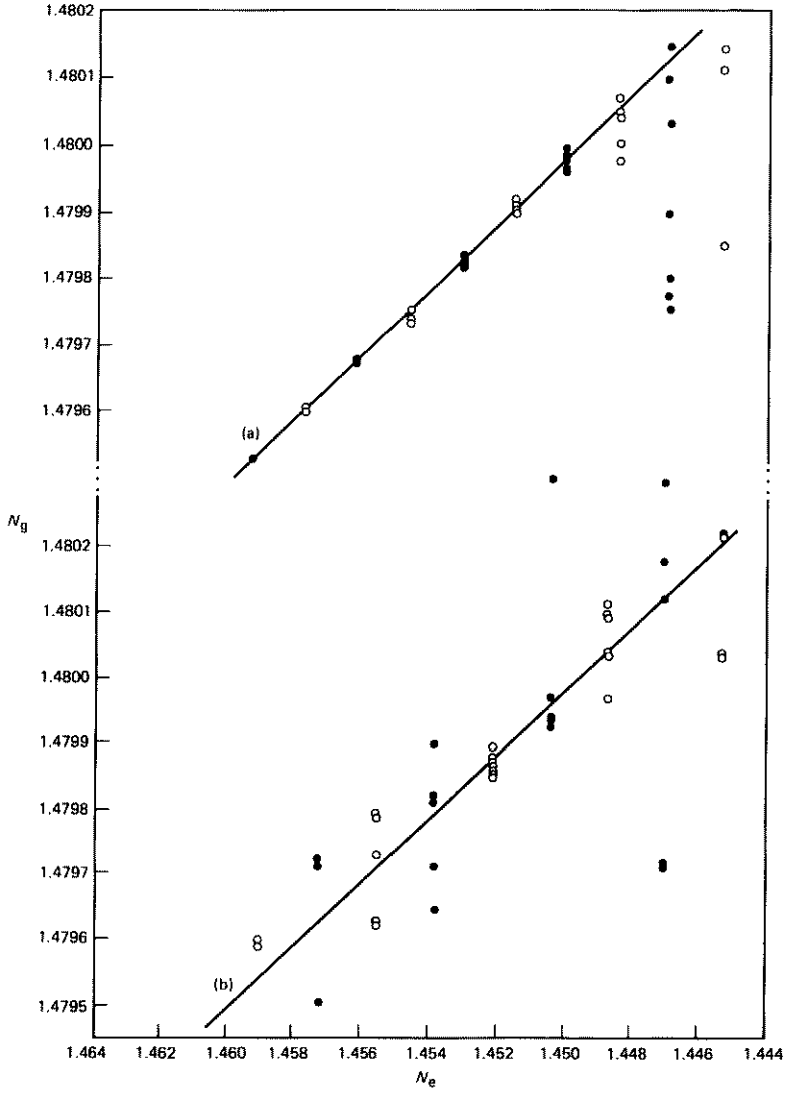

Fig. 10—Same as Fig. 3, $\lambda = 1.55$ $\mu$m.

group index ($N_g$) would be *on* the line. However, the total spread in $N_g$ is now a function of the slope of the line, i.e., the spread in $N_g$ between the $HE_{1,1}$ and the last possible mode that can be obtained on that line. We have given this measure the name "sigma of rotation", ($\sigma_R$). Of course, we must count the number of modes at each $N_e$ to find the mean $N_g$ and then calculate $\sigma_R$ in the conventional manner.

The second measure of dispersion we have utilized is the standard deviation of the group indices determined from the indicated least-

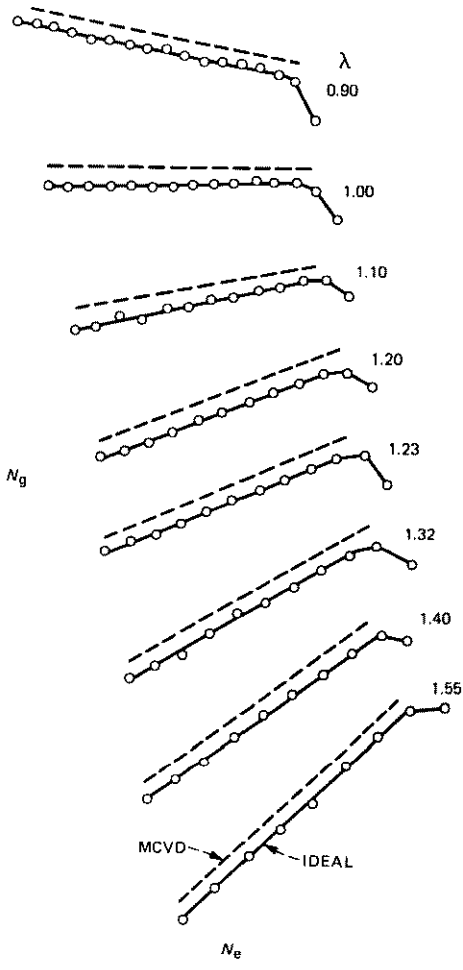

Fig. 11—Composite data. Least-squares fitted lines (IDEAL and MCVD) from the data of Figs. 3 through 10, identifiable in this display.

squares fitted line for $N_g$ vs. $N_e$. Thus, if the curve value of $N_g$ is denoted by $N_g(\text{curve})$, then

$$\sigma_{N_g} = \sqrt{\frac{\Sigma[N_g - N_g(\text{curve})]^2}{n-1}},$$

where $n$ is the total number of modes.

The results of these calculations for $\sigma_R$ are given in Fig. 12, and as indicated in Fig. 11, are about the same for the IDEAL and MCVD fibers. Further, if this were the only measure of dispersion employed,

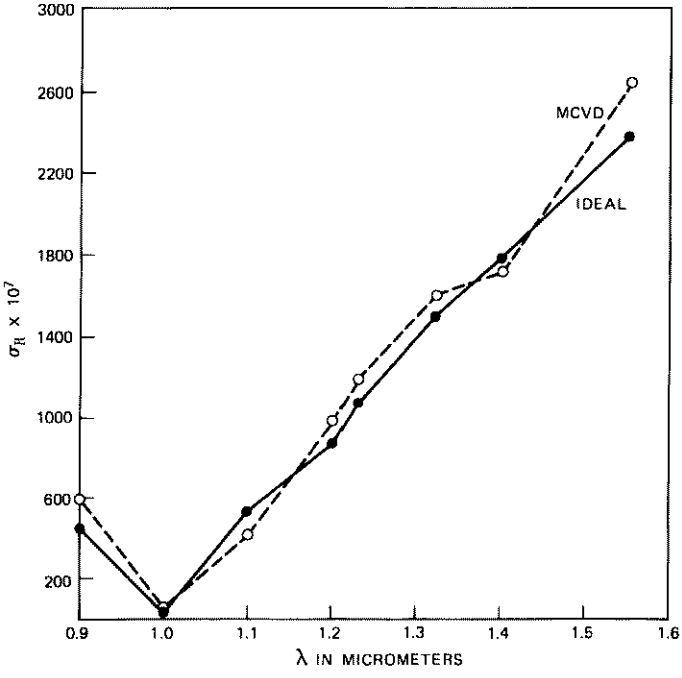

Fig. 12—$\sigma_R$ vs. λ for IDEAL or MCVD.

we would expect this fiber to yield the maximum bandwidth at $\lambda = 1.00\ \mu m$. This agrees precisely with our previous work.[3] The results for the calculation of $\sigma_{N_g}$ are given in Fig. 13 and we can see that:

$$\sigma_{N_g}(\text{MCVD}) \approx 10\ \sigma_{N_g}(\text{IDEAL}).$$

Also, we note further that $\sigma_{N_g}$ is a decreasing function for larger values of λ, and becomes virtually constant when $\lambda \geq 1.2\ \mu m$.

A better understanding of the roles of the two measures of dispersion previously described is given in Figs. 14 and 15. In Fig. 14, $\sigma_R$ and $\sigma_{N_g}$ are plotted for the IDEAL case, and in Fig. 15 the same data are plotted for the MCVD case. Apparently, the $\sigma$ that is dominant at any λ will be the principal cause of inability to maximize the bandwidth.

From theory[4] we have calculated the total dispersion $\sigma_c$ by:

$$\sigma_c = \sqrt{\sigma_R^2 + \sigma_{N_g}^2},$$

and these data are given in Fig. 16. We see that in the region where $\sigma_R$ is dominant ($\lambda \geq 1.2\ \mu m$), the curves are roughly parallel. The larger $\sigma_c$ for the MCVD in this region comes about because the $\sigma_{N_g}$ of the MCVD is greater than $\sigma_{N_g}$ of the IDEAL.

Over the range $0.9\ \mu m \leq \lambda \leq 1.2\ \mu m$, the IDEAL case peaks ($\sigma_c =$

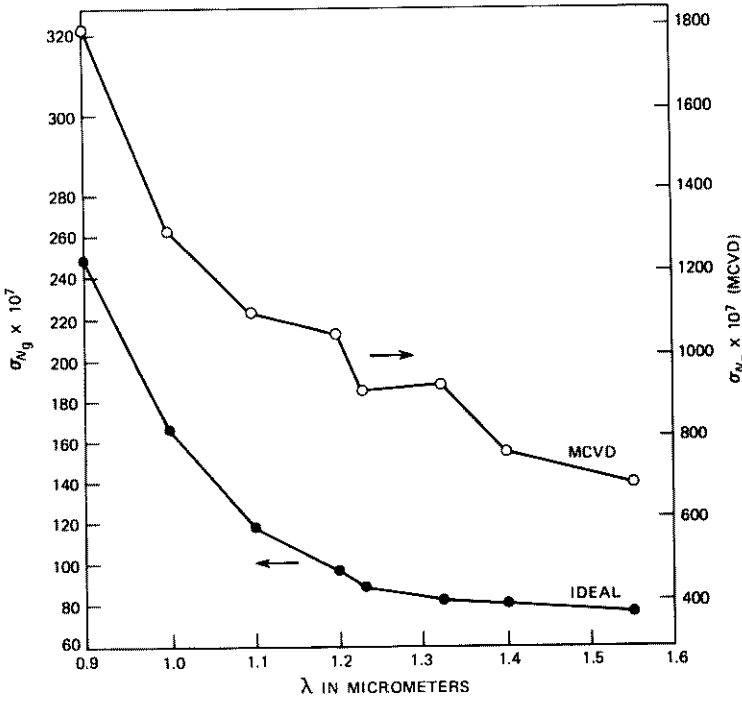

Fig. 13—$\sigma_{N_g}$ vs. λ for IDEAL and MCVD.

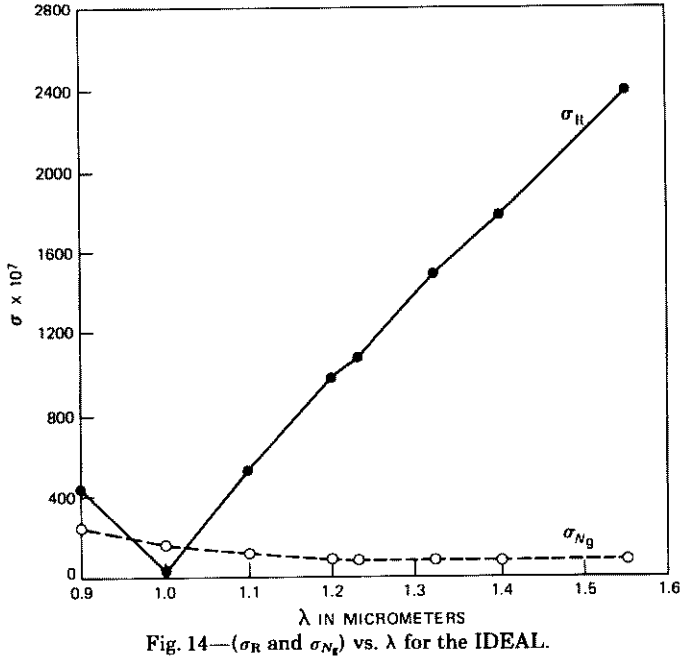

Fig. 14—($\sigma_R$ and $\sigma_{N_g}$) vs. λ for the IDEAL.

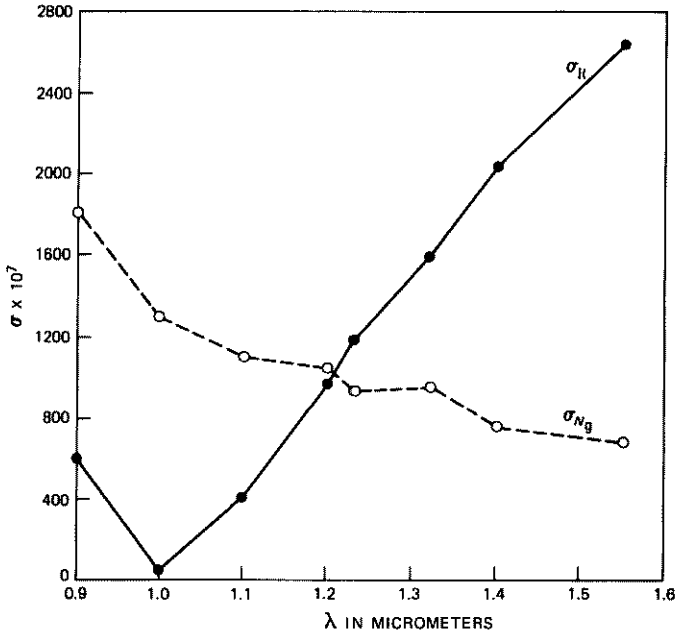

Fig. 15—($\sigma_R$ and $\sigma_{N_g}$) vs. λ for the MCVD.

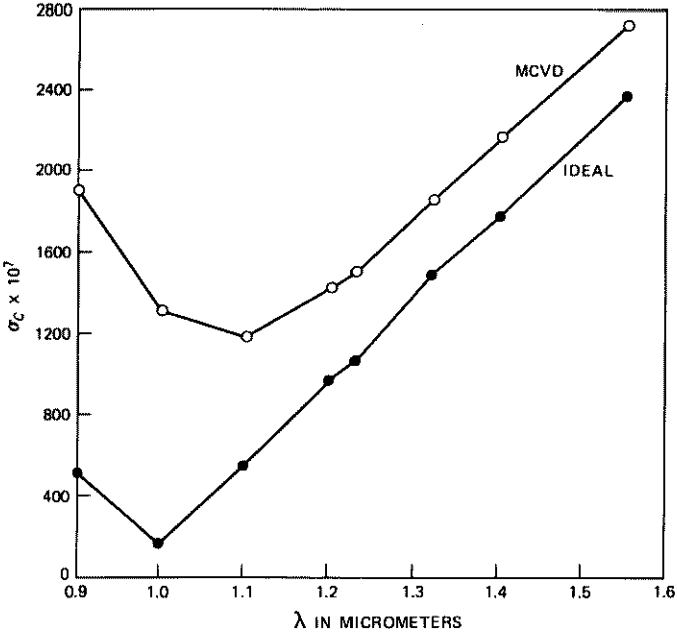

Fig. 16—$\sigma_c$ vs. λ for IDEAL and MCVD.

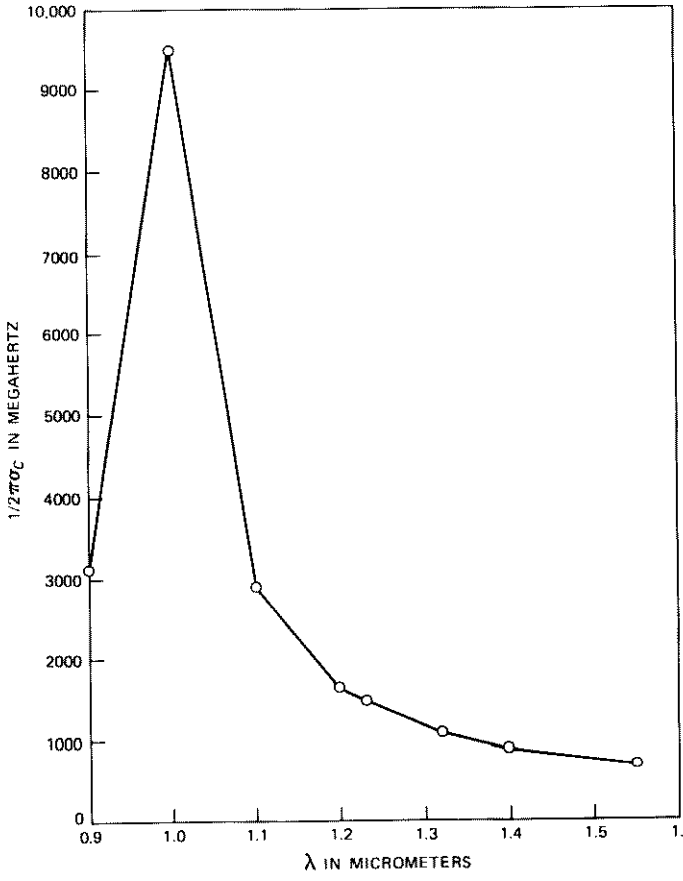

Fig. 17—$1/2\pi\sigma_c$ for the IDEAL case.

minimum) sharply at about 1.0 $\mu$m, while the MCVD displays a very broad response that appears to peak at about 1.1 $\mu$m. A qualitative measure to estimate the pulse shape can be realized by calculating $W(h/2)$; $W(h/2) = 1/2\pi\sigma_c$ (MHz).

These data are given in Figs. 17 and 18 for the IDEAL and the MCVD, respectively. The IDEAL gives a bandwidth of 9 to 10 GHz/km at 1.0 $\mu$m and falls off to half-height at $\pm 0.7$ $\mu$m. The MCVD obtains a maximum of about 1.5 GHz·km at $\approx 1.1$ $\mu$m, and falls off to half height at $\pm 0.2$ $\mu$m.

## V. CONCLUSION

There can be no doubt that the concept of an optimum $\alpha$ is valid for perfect power law and for experimental (manufactured) profiles.[3] The reduction of the bandwidth is directly related to the imperfections

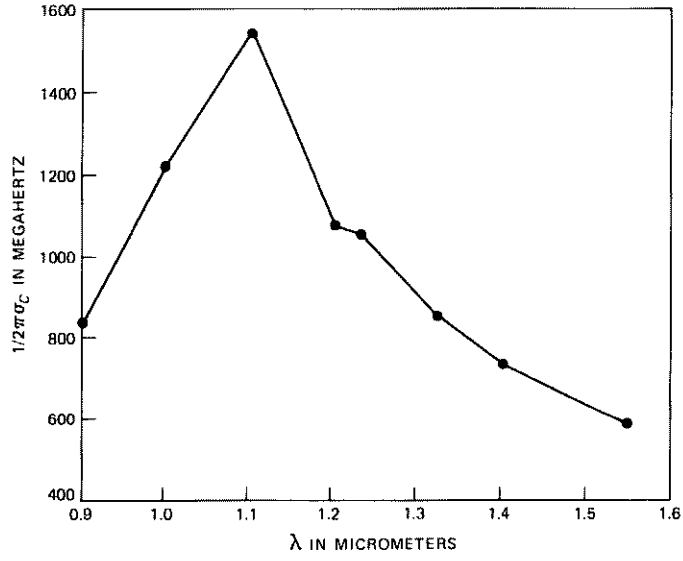

Fig. 18—$1/2\pi\sigma_c$ for the MCVD case.

of the MCVD profile such as burnout, ripples, etc. The direct role of each of these deviations from an idealized profile, in the reduction of bandwidth, has been calculated, and will be the subject of a forthcoming paper. These observations have been substantiated in many respects from direct communication with the materials scientists at Bell Laboratories in Murray Hill and Atlanta, and the Western Electric Company Engineering Research Center. We have also ascertained that we can improve the calculation of $\sigma_{N_g}$ by about a factor of 2. Thus we find the bandwidth for the idealized fiber is about 18 GHz·km, while for the MCVD fiber it is about 2.8 GHz·km. These bandwidths can be further improved by careful computer-aided design of the profile, for which investigations are currently in progress.

## VI. ACKNOWLEDGMENTS

We appreciate the continued support and encouragement given us in this work by M. I. Cohen, R. J. Klaiber, and L. S. Watkins. We are also encouraged by the enthusiasm of the materials scientists engaged in the lightguide program at Bell Laboratories in Murray Hill and Atlanta and Western Electric, as evidenced in a number of informal discussions with them.

# Asymptotic Analysis of a Queueing Model With Bursty Traffic

By D. Y. BURMAN* and D. R. SMITH*

(Manuscript received September 24, 1982)

Assuming a particular model for "bursty" traffic at a packet-switching node, we find expressions for the expected delay of packets that are valid in light and heavy traffic. Each expression consists of a "correction factor" multiplied by the expected delay experienced by packets when the arrivals are "smooth" (Poisson) and of the same average rate. Approximate values for the correction factor in arbitrary traffic can be obtained by interpolation. This provides an example of a method that often gives fast approximate solutions for bursty traffic models that are not themselves tractable but become so when the offered traffic is assumed to be Poisson.

## I. INTRODUCTION

Many models of queueing systems assume that arrivals occur according to a Poisson process. Intuitively, the Poisson process may be characterized by the properties that events occur one at a time and do not depend on the past history of events. Typically, this situation arises when there are large numbers of users of a system, as in the case of arrivals of calls to a central office, since one arrival does not significantly affect the probability of another. Fortunately, these models are often mathematically tractable.

For other systems the Poisson assumptions are not realistic. Often arrivals are indicative of overall activity and give information about the probability of future arrivals. For example, suppose that all arrivals

are generated by a single user who is alternately active and inactive. An arrival indicates that the user is active and hence that there is a greater than average probability of another arrival shortly thereafter. A second example concerns the arrival of packets to a node in a packet-switching network. When virtual calls are employed, the route packets travel for a particular call is fixed for the duration of the call. If we make the assumption that an individual virtual call generates packets according to a Poisson process, then the instantaneous arrival intensity at any node is equal to the sum of the intensities for the calls routed through the node, which varies probabilistically with time. In these examples the arrivals are correlated and the traffic is said to be bursty.

Even the simplest models involving bursty traffic tend to be difficult to solve analytically. Several authors have given approximations. Heffes[1] matched the first three moments of the arrival process to those of an Interrupted Poisson Process. Assuming that an arriving packet requires an exponentially distributed amount of time to be served, he was then able to use the results of Kuczura[2] to analyze this system. Laue,[3] making a similar approximation for the arrival process, assumed that an arriving packet requires a constant service time. The mean waiting time of a packet could then be calculated using the numerical matrix techniques developed by Neuts[4] and Lucantoni and Neuts.[5] A third approach developed by Anick, Mitra, and Sondhi[6] treats a different but related model. The models of Heffes and Laue are based on the assumption that an individual customer generates packets according to a Poisson process. Anick, Mitra, and Sondhi assume that a customer generates packets at a constant rate for a random time. The resulting fluid model was treated numerically by calculating the eigenvalues of the resulting equations.

All of the above works derive numerical techniques to estimate the traffic statistics of interest over a wide range of traffic parameters. It is the goal of this paper to provide simple, closed-form expressions that give insight into the effect of burstiness on delays. This is done by studying queueing systems offered bursty traffic (see Section II for a complete description) in light and heavy traffic.

In light (heavy) traffic, it is obvious that the expected delay tends to zero (infinity). Surprisingly, when the expected delay is divided by the expected delay for the same system offered Poisson traffic of equal average intensity, the ratio goes to a nonzero finite limit in both light and heavy traffic. These limits may be thought of as "correction factors" by which the expected delay for the solvable Poisson system should be multiplied to obtain the expected delay for the bursty system. By interpolating between the light- and heavy-traffic results, one can obtain insight into the approximate effect of burstiness for all values

of traffic. Indeed, similar light- and heavy-traffic limits for the $M/E_k/c$ system have been used to obtain very accurate approximate values of the delay for all values of traffic (see Lauber and Smith[7]).

The remainder of this paper is organized as follows: The queueing model for bursty traffic and our results are discussed in detail in Section II. Rigorous proofs of the light-traffic results are given in Section III when the service times are of the phase type. (Appendix A presents a brief background on phase-type distributions.) Since any service-time distribution can be approximated arbitrarily closely by one of phase type, it is sufficient for practical purposes to establish the light-traffic results for the latter. Appendix B presents an intuitive approach for deriving the light-traffic results. Heavy-traffic results are presented in Section IV and concluding remarks in Section V.

## II. QUEUEING MODEL AND RESULTS

The specific queueing model treated here is one in which the arrival process is a nonhomogeneous Poisson process whose rate equals $\lambda m$, where m is the state of an $M/M/\infty$ queue with birth rate $\alpha$ and service rate $\beta$. The arrivals are offered to a single server whose successive services are assumed to be independent and identically distributed according to some general distribution with mean equal to $\mu^{-1}$. Blocked arrivals queue up and are served on a first-in-first-out basis.

This queueing model supports either of two (essentially identical) scenarios for the queueing of packets of information at a packet switch. In both scenarios, the switch is modeled as a single server with an infinite buffer for queued packets, and the service time of a packet is its length (in bits) divided by the line speed. In the first scenario, an individual virtual call generates packets according to a Poisson process with rate $\lambda$, for an exponentially distributed length of time with mean $\beta^{-1}$. The distribution of requests for virtual calls is Poisson with rate $\alpha$, and the number of simultaneous virtual calls that can be supported by the switch is unlimited. The second scenario is similar to a fluid model treated by Mitra and Anick[8] and Kosten.[9] In this case an individual customer is in one of two states, either "active" or "inactive." It is assumed that the time in each of the states is exponentially distributed with rates $\beta$ and $\gamma$, respectively. While in the "active" state, the customer transmits packets according to a Poisson process with rate $\lambda$. If there are $N$ (large) such customers with $N\gamma \sim \alpha$ and $\gamma\beta^{-1} \sim 0$, then the number of "active" customers is distributed like the number of customers in the $M/M/\infty$ queue described above.

Throughout the remainder of this paper, we will refer to the entities queued at the single server as packets and the entities in the $M/M/\infty$ system as virtual calls or calls. Our analysis will focus on the limiting form for the mean delay of a packet in a lightly or heavily loaded

system. The total number of packets generated during a virtual call is geometrically distributed with mean $\lambda\beta^{-1}$ and the mean total rate of packet generation is $\lambda(\alpha/\beta)$.

There is a technical problem in the analysis for this model since the packet arrival rate is unbounded. Hence, consider first the system where the number of virtual calls is limited to $N$, i.e., the rate of arrivals of packets is $\lambda$ times the number of calls present in an M/M/N/N queueing system. The average rate of arrival of packets to the queue is

$$\lambda_N \stackrel{\text{def}}{=} \lambda(\alpha/\beta)[1 - B(N, \alpha/\beta)], \tag{1}$$

where $B(N, \alpha/\beta)$ is the Erlang Blocking formula. Let $D_B^{(N)}$ be the expected delay of a packet in this system, and let $D_M^{(N)}$ be the delay in an M/G/1 with arrival rate $\lambda_N$ and the same service-time distribution.

Our key light-traffic result (valid for phase-type service distributions) is

$$\lim_{\lambda \to 0} \frac{D_B^{(N)}}{D_M^{(N)}} = k_l^{(N)}, \tag{2}$$

where $0 < k_l^{(N)} < \infty$, and

$$\lim_{N \to \infty} k_l^{(N)} = 1 + \frac{2\mu}{\alpha} \frac{[1 - \phi(\beta)]}{1 + C^2} \stackrel{\text{def}}{=} k_l, \tag{3}$$

where $\mu^{-1} = E(S)$, $C^2 = \text{var}(S)/E(S)^2$ ($S$ is a service-time random variable), and $\phi(\cdot)$ is the Laplace transform of the stationary excess of $S$. The limit (2) is proved by using a simple extension of a lemma established in Burman and Smith.[10] The exact value of $k_l^{(N)}$ is difficult to compute; however, the limit $k_l$ as $N \to \infty$ is computable and can be interpreted as the light-traffic limit of the ratio of the delay ($D_B$) for the bursty system described earlier (with no limit on the number of virtual calls) and the delay ($D_M$) for the M/G/1 queue with arrival rate $\lambda(\alpha/\beta)$. This statement can be summarized (although not explicitly proved) as

$$\lim_{\lambda \to 0} \frac{D_B}{D_M} = k_l, \tag{4}$$

where $k_l$ is given in (3).

In the heavy-traffic case no rigorous limit is available. Nevertheless, diffusion analysis gives the following approximation in heavy traffic:

$$\frac{D_B^{(N)}}{D_M^{(N)}} \approx k_h^{(N)}, \tag{5}$$

where $k_h^{(N)}$ is known explicitly [see eq. (40)] and

$$\lim_{N\to\infty} k_h^{(N)} = 1 + \frac{2\mu}{\alpha}\frac{1}{1+C^2} \stackrel{\text{def}}{=} k_h. \tag{6}$$

This supports the conjecture that

$$\lim_{\lambda\to\frac{\beta\mu}{\alpha}} \frac{D_B}{D_M} = k_h. \tag{7}$$

It should be noted that $1 < k_l < k_h$, and while no proof is available, it is reasonable to conjecture that $k_l < D_B/D_M < k_h$ for all stable values of $\lambda$. (Indeed it is conjectured that $D_B/D_M$ is monotone, as suggested by a similar analysis for the delay in an M/G/c queue normalized by the delay in an M/M/c queue (see Lauber and Smith[7]).

At this point it is worth noting that the manner in which the traffic intensity $\rho = (\lambda/\mu)(\alpha/\beta)$ approached 0 or 1 affects the limiting value of $D_B/D_M$. The previously described results are based on the variation of $\lambda$ only; one can also allow $\alpha$, the rate of arrival of calls, to vary. For an intuitive example of the difference, note that $\lambda \to 0$ corresponds to light traffic with one packet per call, while $\alpha \to 0$ corresponds to light traffic with a geometrically distributed (with mean $\lambda/\beta$) number of packets per call. It can be shown (although it is not explicitly reported here) that $D_B/D_M$ is completely different in the two cases.

We now focus our attention on the behavior of $k_l$ and $k_h$ for a fixed mean number of calls in the system $(\alpha/\beta)$. As $\alpha, \beta \to \infty$, $(\alpha/\beta$ fixed) the arrival process of packets approaches a Poisson process and indeed, by examination of (3) and (6), $k_l$ and $k_h$ both go to 1. As $\alpha, \beta \to 0$ ($\alpha/\beta$ fixed), $k_h$ goes to $\infty$, and $k_l$ goes $1 + \beta/\alpha$. To understand these limits, note that in this case the number of calls remains constant for longer and longer periods of time and steady-state effects become significant. In heavy traffic, the process remains in states for which the packet generation rate is faster than the service rate, so that the delays become large. In light traffic, one may obtain the $1 + \beta/\alpha$ limit in an intuitive fashion by conditioning on the number of calls $m$ at packet generation times and computing the conditional delay (using known expressions for delay) assuming a constant arrival rate $\lambda m$.

In (4) and (7), the delay for the bursty system was normalized by the delay for the M/G/1 system. If instead we choose to normalize by the delay for an M/M/1 system with the same arrival and service rates (denoted by $\tilde{D}_m$), then the limits become

$$\lim_{\lambda\to 0} \frac{D_B}{\tilde{D}_M} = 1 + \frac{C^2-1}{2} + \frac{\mu}{\alpha}[1 - \phi(\beta)] \tag{8}$$

and

$$\lim_{\lambda \to \frac{\beta\mu}{\alpha}} \frac{D_B}{\tilde{D}_M} = 1 + \frac{C^2 - 1}{2} + \frac{\mu}{\alpha}. \tag{9}$$

These results are interesting in that they suggest separation of the effects of variability of the service time $(C^2 - 1)/2$ and the variability of the arrival process (the third term).

In addition to the results for the mean delay $D_B$, we show that the light-traffic limit of the distribution of the delay $D$, given $D > 0$, is

$$\lim_{\lambda \to 0} P(D > t \mid D > 0) = \frac{\int_t^\infty \int_y^\infty [\alpha + \beta e^{-\beta(x-t)}] dH(x) dy}{\frac{\alpha}{\mu} + 1 - \int_0^\infty e^{-\beta x} dH(x)}. \tag{10}$$

Again, in order for this to be rigorously stated it should be in terms of the limit of similar quantities for systems allowing only a finite number of virtual calls.

## III. DERIVATION OF THE LIGHT-TRAFFIC RESULTS

In this section, we derive the light-traffic result stated in (4). Our approach is to show that as the traffic intensity goes to 0, the probability of having $i$ (greater than 0) packets in the system goes to 0 asymptotically as $\lambda^i$. The exact rate of convergence can be derived by a detailed study of the state equations and from there (4) follows trivially.

Consider a single-server queue whose service times are of phase type (see Appendix A). Let the arrival process be a nonhomogeneous Poisson process whose rate is $\lambda$ times a function of the state of a Markov process. Then, the multidimensional process consisting of the number $i$ of packets in queue, the state $j$ of the arrival Markov process, and the phase $k$ of the packet in service is itself a Markov process. A typical state will be denoted by $(i, j, k)$ for $i > 0$ and $(0, j)$ for $i = 0$, where $j \geq 0$ and $k = 1, \cdots, m$, the number of phases. The ergodic distribution will be denoted by $p(\cdot, \cdot, \cdot)$ and define

$$p(i) = \sum_{j,k} p(i, j, k),$$

with the obvious definition for $i = 0$. When there is an upper bound on the arrival rate (as when the arrival Markov process is finite), then the technique used in Burman and Smith[10] to prove Theorem 3.1 therein can be employed to prove:

*Lemma 1: There exists a constant $R > 0$ such that*

$$p(i) \leq \lambda^i R^i.$$

One may define

$$\tilde{\rho}(i, j, k) = \lim_{\lambda \to 0} \lambda^{-1} \rho(i, j, k) \tag{11}$$

with an analogous definition for $i = 0$, and these limits may be recursively related and shown to exist by examination of the balance equations. (See Smith[11] and Burman and Smith[10] for examples of this technique.) Thus, when the arrival rates are bounded, the light-traffic methodology is straightforward. It is quite possible, however, that the resulting equations are difficult to solve.

This is exactly the case when the arrival Markov process is an M/M/N/N queue (finite number of virtual calls). It is difficult to explicitly solve for $\tilde{\rho}^{(N)}$ [the limiting light-traffic normalized probabilities for this system, see (11)], although it can be shown that $\tilde{\rho}^{(N)} \to \tilde{\rho}$ as $N \to \infty$, where $\tilde{\rho}$ is the solution to the equations (assuming Lemma 1) when the birth-death process is the M/M/$\infty$ queue. At the core of this argument (not presented here in detail) are the facts that the equations involving $\tilde{\rho}^{(N)}(\cdot, j, \cdot)$ for $j < N$ are identical with those involving $\tilde{\rho}^{(N+1)}(\cdot, j, \cdot)$ and that

$$\lim_{N \to \infty} \tilde{\rho}^{(N)}(0, j) = \frac{1}{j!} (\alpha/\beta)^j e^{-\alpha/\beta}.$$

The existence of the limits [in (11)] can be shown by recursion on $i$ and the fact that the limit was previously established for $i = 0$. Thus $\lim_{N \to \infty} \tilde{\rho}^{(N)} (= \tilde{\rho})$ may be calculated by studying the system with $N = \infty$.

We now turn our attention to calculating $\tilde{\rho}$ by studying the bursty system with arrival rate $\lambda$ times the number of calls in an M/M/$\infty$ queue. For this system it is not hard to show that $\rho$, the steady-state probability satisfies

$$\begin{aligned} &-(j\lambda + \alpha + j\beta)\rho(0, j) + \alpha\rho(0, j-1) \\ &+ (j+1)\beta\rho(0, j+1) + \sum_n \rho(1, j, n)\mathrm{E}_n = 0, \end{aligned} \tag{12}$$

$$\begin{aligned} &-(j\lambda + \alpha + j\beta - T_{kk})\rho(1, j, k) + \alpha\rho(1, j-1, k) \\ &+ (j+1)\beta\rho(1, j+1, k) + \sum_n \rho(1, j, n)T_{nk} \\ &+ j\lambda\omega_k\rho(0, j) + \omega_k \sum_n \rho(2, j, n)\mathrm{E}_n = 0, \end{aligned} \tag{13}$$

and

$$\begin{aligned} &-(j\lambda + \alpha + j\beta - T_{kk})\rho(i, j, k) + \alpha\rho(i, j-1, k) \\ &+ (j+1)\beta\rho(i, j+1, k) + \sum_n \rho(i, j, n)T_{nk} \\ &+ j\lambda\rho(i-1, j, k) + \omega_k \sum_n \rho(i+1, j, n)\mathrm{E}_n = 0, \quad \text{for} \quad i \geq 2, \end{aligned} \tag{14}$$

where $j \geq 0$ and $\omega\cdot$, $T\cdot\cdot$, and $\mathrm{E}\cdot$, are the initial, transition, and exit rates defining the phase-type distribution of the service-time process. (These are discussed in greater detail in Appendix A.) We also assume that Lemma 1 holds.

Next define the generating functions

$$q(i, z, k) = \sum_j z^j \tilde{\rho}(i, j, k), \qquad i > 0,$$

and

$$q(0, z) = \sum_j z^j \tilde{\rho}(0, j).$$

From (12) to (14), we see that $q$ satisfies the following equations

$$-\alpha(1 - z)q(0, z) + \beta(1 - z)q_z(0, z) = 0, \tag{15}$$

$$q(1, z, \cdot)[T - \alpha(1 - z)I] + q_z(1, z, \cdot)\beta(1 - z)I = -\omega z q_z(0, z), \tag{16}$$

and

$$q(i, z, \cdot)[T - \alpha(1 - z)I] + q_z(i, z, \cdot)\beta(1 - z)I = -z q_z(i - 1, z, \cdot) \quad \text{for} \quad i > 1. \tag{17}$$

Equation (15) immediately gives

$$q(0, z) = e^{-\alpha/\beta(1-z)}. \tag{18}$$

The next lemma relates $D_B$, the expected delay in this system, to $q(1, z, \cdot)$.

*Lemma 2:*

$$\lim_{\lambda \to 0} \lambda^{-1} D_B = -\frac{\beta}{\alpha} q_z(1, 1, \cdot) T^{-1} e,$$

*where e is the vector of ones.*

*Proof:* The mean number $L$ of packets in the queue is given by

$$L = \sum_{i>1} (i - 1) \sum_{j,k} \rho(i, j, k).$$

By Lemma 1,

$$\lim_{\lambda \to 0} \lambda^{-2} L = \sum_{j,k} \tilde{\rho}(2, j, k) = q(2, 1, \cdot)e.$$

From (17), we get that

$$q(2, 1, \cdot) = -q_z(1, 1, \cdot)T^{-1}$$

and by Little's Law we are done. □

We now establish (3). The previous lemma shows that the key

quantity is $q_z(1, 1, \cdot)$. Differentiating (16) with respect to $z$ and evaluating at $z = 1$ gives

$$\alpha q(1, 1, \cdot)I + q_z(1, 1, \cdot)(T - \beta I) = \omega \frac{\alpha}{\beta}\left(\frac{\alpha}{\beta} + 1\right), \tag{19}$$

where we used (18) to give us $q(0, z)$. Substituting for $z = 1$ into (16) gives that

$$q(1, 1, \cdot) = \frac{\alpha}{\beta}(-\omega T^{-1}) = \frac{\alpha}{\beta\mu}\xi,$$

where $\xi$ is the stationary distribution of the service-time process [see (42) and (43)]. Rearranging (19) we get

$$\begin{aligned} q_z(1, 1, \cdot) &= \frac{\alpha^2}{\beta}\omega T^{-1}(\beta I - T)^{-1} + \frac{\alpha}{\beta}\left(\frac{\alpha}{\beta} + 1\right)\omega(\beta I - T)^{-1} \\ &= -\frac{\alpha}{\beta^2}[\alpha\beta\omega T^{-1}(\beta I - T)^{-1} - (\alpha + \beta)\omega(\beta I - T)^{-1}] \\ &= -\frac{\alpha}{\beta^2}[\alpha\omega T^{-1} - \beta\omega(\beta I - T)^{-1}] \\ &= \left(\frac{\alpha}{\beta}\right)^2(-\omega T^{-1}) + \left(\frac{\alpha}{\beta}\right)\omega(\beta I - T)^{-1}. \end{aligned} \tag{20}$$

Finally, from Lemma 2 and Corollary 1, we get

$$\begin{aligned} \lim_{\lambda \to 0} \lambda^{-1} D_B &= -\frac{\beta}{\alpha} q_z(1, 1, \cdot)T^{-1}e \\ &= \frac{\alpha}{\beta}\frac{1}{\mu}(-\xi T^{-1}e) - \frac{1}{\mu}\xi T^{-1}(\beta I - T)^{-1}E \\ &= \frac{\alpha}{\beta}\frac{\mu_2}{2} + \int_0^\infty e^{-\beta x}\int_x^\infty H^c(s)dsdx. \end{aligned}$$

Normalizing by the expected delay in the M/G/1 queue and integrating by parts gives us (3). □

We next calculate the Laplace Transform $E(e^{-sD} \mid D > 0)$. In light traffic, a customer who is delayed ($D > 0$) will usually see only one customer in the system and will just wait for the service completion. This is made rigorous by Lemma 1. The probability that such a customer arrives and finds the server in phase $k$ is given by

$$\frac{\sum_m m\rho(1, m, k)}{\sum_{m,n} m\rho(1, m, n)},$$

or in terms of $q$ this is

$$\frac{q_z(1, 1, k)}{\sum_n q_z(1, 1, n)}. \tag{21}$$

From (21) we get that

$$E(e^{-sD} \mid D > 0) = \frac{\sum_k q_z(1, 1, k) E_k(e^{-s\tau})}{\sum_n q_z(1, 1, n)}$$

$$= \frac{q_z(1, 1, \cdot)(sI - T)^{-1}\mathbf{E}}{q_z(1, 1, \cdot)e}, \tag{22}$$

where $E_k(e^{-s\tau})$ is the Laplace transform of the remaining service time given that the current phase is $k$, and we have used proposition (1) from Appendix A.

Evaluating the denominator first, from (20) and Corollary 1 we see that

$$[q_z(1, 1, \cdot), e] = \left(\frac{\alpha}{\beta}\right)^2 \frac{1}{\mu}(\xi, e) + \left(\frac{\alpha}{\beta}\right) \frac{1}{\mu} \xi(BI - T)^{-1}\mathbf{E}$$

$$= \left(\frac{\alpha}{\beta}\right)^2 \frac{1}{\mu} + \left(\frac{\alpha}{\beta}\right) \int_0^\infty e^{-\beta x} H^c(x) dx$$

$$= \left(\frac{\alpha}{\beta}\right)^2 \frac{1}{\mu} + \left(\frac{\alpha}{\beta}\right) \frac{1 - \tilde{H}(\beta)}{\beta},$$

where $\xi$ is the vector of ergodic probabilities for the service-time variable and $\tilde{H}(s) = \int e^{-sx} dH(x)$ is the Laplace Transform of the service-time density. The numerator, after some algebraic reduction, becomes

$$q_z(1, 1, \cdot)(sI - T)^{-1}\mathbf{E} = \left(\frac{\alpha}{\beta}\right)^2 \omega[(-T)^{-1}(sI - T)^{-1})\mathbf{E}$$

$$+ \left(\frac{\alpha}{\beta}\right) \frac{\omega(\beta I - T)^{-1}\mathbf{E} - \omega(sI - T)^{-1}\mathbf{E}}{s - \beta}$$

$$= \left(\frac{\alpha}{\beta}\right)^2 \frac{1 - \tilde{H}(s)}{s} + \left(\frac{\alpha}{\beta}\right) \frac{\tilde{H}(\beta) - \tilde{H}(s)}{s - \beta}.$$

Combining the two calculations, we get

$$E(e^{-sD} \mid D > 0) = \frac{\alpha\left[\frac{1 - H(s)}{s}\right] + \frac{\beta}{s - \beta}[\tilde{H}(\beta) - \tilde{H}(s)]}{\alpha \frac{1}{\mu} + 1 - \tilde{H}(\beta)}. \tag{23}$$

It is not difficult to show that (23) is the transform of (10).

## IV. DERIVATION OF THE HEAVY-TRAFFIC RESULTS

In this section we describe the technique that allows us to arrive at (5) and (6). This approximation is derived by first proving that the number of packets in the system, when appropriately scaled, converges to a diffusion process $X(t)$ as $\rho^{(N)}$ converges to one. Given the drift and infinitesimal variance of the diffusion process, one can obtain the steady-state mean of $X(t)$, and by using Little's Theorem, we get the approximation given in (5).

The main theorem of this section, which can be proved rigorously using the techniques in Burman,[12] forms the theoretical basis for (6). We will outline its proof and show in detail how to calculate the mean and variance of the resulting diffusion, which from an application point of view is the difficult part of developing these approximations.

Consider a sequence of processes $X_n(t)$, where the $n$th process represents the number of packets at time $t$ in a single-server system to which packets arrive at an instantaneous rate $\lambda_n$ times the state of an M/M/N/N queueing system (representing the number of virtual calls). The heavy-traffic limits are found by defining $\lambda_n$ as follows:

$$\lambda_n E^{(N)}V = \mu - \frac{\delta}{\sqrt{n}}, \tag{24}$$

where $\delta$ is a positive constant and $E^{(N)}V$ is the expected number of calls in the M/M/N/N system. We are initially interested in studying the sequence of scaled processes $n^{-1/2}X_n(nt)$ as $n \to \infty$.

We start by investigating the limiting behavior of the infinitesimal generators of a sequence of Markov processes created by appending supplementary variables to $X_n(t)$. A limiting generator is identified and the Trotter-Kato Theorem (see Kato[13]) implies that the finite-dimensional distributions converge. The form of the limiting generator completely determines the limiting process. Weak convergence can be established via a theorem of Stroock and Varadhan.[14]

Let $V(t)$ be the number of virtual calls at time $t$ and let $Y(t)$ be the time since the packet currently in service entered service. The multi-dimensional process

$$M_n(t) = [n^{-1/2}X_n(nt),\ Y(nt),\ V(nt)]$$

is Markov. We denote a typical element of the state-space as $(x, y, j)$, where $x = 0, n^{-1/2}, 2n^{-1/2}, \cdots, y \in [0, \infty)$ and $j = \{0, 1, \cdots, N\}$. For the remainder of this paper, let $h(y)$ be the density of the service-time distribution,

$$H^c(y) = \int_y^\infty h(s)ds, \qquad \mu(y) = \frac{h(y)}{H^c(y)}$$

and assume that for some constants $\gamma$ and $\Gamma$,

$$0 < \gamma \leq \mu(y) \leq \Gamma \leq \infty. \tag{25}$$

The implications of and conditions for relaxing (25) are discussed in Burman.[12] These conditions are required for the method of proof and do not pose any significant restrictions on the results.

Let $B$ and $Q$ be the infinitesimal generators of the processes $V(t)$ and $Y(t)$, respectively. The generator $B$ is an $(N+1) \times (N+1)$ matrix given by

$$B = \begin{bmatrix} -\alpha & \alpha & & & & \\ \beta & -(\beta+\alpha) & \alpha & & & \\ & 2\beta & -(2\beta+\alpha) & \alpha & & \\ & & & \ddots & & \\ & & & & N\beta & -N\beta \end{bmatrix}$$

and $Q$ is a first-order linear differential operator given by

$$Qf(y) = f'(y) + \mu(y)[f(0) - f(y)].$$

The following two lemmas are needed to carry out the calculations needed in the main theorem of the section (to be stated below):

*Lemma 3: The equation*

$$Bv = w \tag{26}$$

*has a solution $v$ if and only if*

$$(e, w) = 0, \tag{27}$$

*where $e_k = 1/k!(\alpha/\beta)^k = 1/k!\ \rho^k$. In this case $v$ is unique to an additive constant and is given by*

$$v(k+1) = v(0) + \frac{1}{\alpha} \sum_{j=0}^{k} \frac{j!}{\rho^j} \sum_{i=0}^{j} \frac{\rho^i}{i!} w(i). \tag{28}$$

*Proof:* Since $B$ is a finite-dimensional linear operator corresponding to an ergodic Markov process, it has a one-dimensional null space spanned by the vector $e$. Hence, (27) is both necessary and sufficient for a unique solution of (26) to exist. This solution is easily seen to be given by (28). □

*Lemma 4: The equation*

$$Qf = g \tag{29}$$

*has a solution $f$ if and only if*

$$\int_0^\infty g(y) H^c(y) dy = 0. \tag{30}$$

*In this case, $f$ is unique to an additive constant and is given by*

$$f(y) = \frac{1}{H^c(y)} \int_0^y H^c(s)g(s)ds. \tag{31}$$

*Proof:* The operator $Q$ is the generator of an ergodic Markov process with the stationary density $\mu H^c(y)$. A unique solution exists if and only if (30) holds. Solving the first-order linear differential equation gives (31). □

We are now ready to state the main theorem of this section:

*Theorem 1: Under assumption* (25),

$$n^{-1/2}X_n(nt) \Rightarrow X(t),$$

*where $X(t)$ is a diffusion on $R^+$ with pure reflection at the origin, downward drift $\delta$ and infinitesimal variance $s^2$ given by*

$$s^2 = \frac{1}{2}\left\{\lambda E^{(N)}V + \mu^3\sigma^2 + \sum_{k=0}^{N} \frac{1}{\alpha P_k}\left[\sum_{j=0}^{k-1} P_j(\mu - j)\right]^2\right\}, \tag{32}$$

*where*

$$P_k = \frac{1}{k!}\left(\frac{\alpha}{\beta}\right)^k \Big/ \sum_{j=0}^{N} \frac{1}{j!}\left(\frac{\alpha}{\beta}\right)^j$$

*is the steady-state probability of finding $k$ calls in the $M/M/N/N$ blocking system.*

*Proof of Theorem:* As mentioned earlier, we will show how to identify the mean and variance of (32). The infinitesimal generator for $M_n(t)$ is given by

$$A_nf(x, y, j) = n(B + Q)f + \lambda j\left[f\left(x + \frac{1}{\sqrt{n}}, y, j\right) - f(x, y, j)\right]$$
$$+ \mu(y)\left[f\left(x - \frac{1}{\sqrt{n}}, 0, j\right) - f(x, 0, j)\right] \quad \text{for} \quad x \geq \frac{1}{\sqrt{n}}, \tag{33}$$

and

$$A_nf(0, 0, j) = nBf + \lambda j\left[f\left(\frac{1}{\sqrt{n}}, 0, j\right) - f(0, 0, j)\right]. \tag{34}$$

For $f(x)$ twice continuously differentiable with $f'(0) = 0$, set

$$f_n(x, y, j) = f(x) + \frac{1}{\sqrt{n}} f'(x)g(y, j) + \frac{1}{n} f''(x)h(y, j). \tag{35}$$

We construct bounded functions $g$ and $h$ so that

$$A_nf_n \to Af$$

uniformly, where

$$Af(x) = mf'(x) + s^2 f''(x).$$

The constants $m$ and $s^2$ are determined in the process. Given (25), these constructions will complete the proof (see Burman[12]).

From (35) and (33) we see that

$$\begin{aligned} A_n f_n = {} & n(B+Q)f + \sqrt{n} f'(x)[\lambda_n j - \mu(y) + (B+Q)g] \\ & + f''(x)\left\{\frac{1}{2}[\lambda_n j + \mu(y)] + \lambda_n j g(y,j) - \mu(y) g(0,j)\right. \\ & \left. + (B+Q)h(y,j)\right\} + 0\left(\frac{1}{\sqrt{n}}\right). \end{aligned} \tag{36}$$

First note that since $f$ is independent of $y$ and $j$, $(B+Q)f = 0$. Set $g$ equal to the solution of the equation

$$(B+Q)g = -[\lambda_n j - \lambda_n E^{(N)} V - \mu(y) + \mu]. \tag{37}$$

Lemmas 3 and 4 imply that $g$ exists and

$$\begin{aligned} g(y,j) = {} & \frac{1}{H^c(y)} \int_0^y H^c(s)[\mu(s) - \mu] ds \\ & - \frac{\lambda_n}{\alpha} \sum_{k=0}^{j-1} \frac{k!}{\rho^k} \sum_{i=0}^{k} \frac{\rho^i}{i!} [j - E^{(N)} V]. \end{aligned} \tag{38}$$

Let $h$ be the solution of the equation

$$(Q+B)h = -[w(y,j) - s^2], \tag{39}$$

where $w(y,j) = 1/2[\lambda_n j + \mu(y)] + \lambda_n j g(y,j) - \mu(y) g(0,j)$. The constant $s^2$ [see (26)] can be easily calculated from conditions (27) and (30), i.e.,

$$\sum_{i=0}^{N} \frac{\rho^i}{i!} \int_0^\infty H^c(y) w(y,i) dy = 0.$$

Using $g$ and $h$ calculated above we have

$$A_n f_n = -\delta f'(x) + s^2 f''(x) + 0\left(\frac{1}{\sqrt{n}}\right).$$

When $x = 0$ analogous calculations give that $A_n f_n$ converges provided $f'(0) = 0$, and the proof is complete. □

The limit theorem for the M/G/1 queue with arrival rate $\lambda_n E^{(N)} V$ (see Iglehart and Whitt[15]) gives the same mean $\delta$ with the variance $\lambda E^{(N)} V + \mu^3 \mu_2$ for the limiting diffusion. Calculating the steady-state expected number in the limiting systems and using Little's Theorem

(see Cooper[16]) yields the asymptotic expression for the ratio of $D_B^{(N)}$ and $D_M^{(N)}$, the delays in the two systems:

$$\frac{D_B^{(N)}}{D_M^{(N)}} \approx 1 + 2\,\frac{\sum_{k=0}^{N-1} \frac{1}{P_k} \left[\sum_{i=0}^{k} P_i(\mu - \lambda i)\right]^2}{\alpha\mu^3\mu_2}. \tag{40}$$

Letting $N$ go to infinity, $P_k$ goes to the Poisson distribution and (40) goes to

$$1 + 2\mu/\alpha\left(\frac{1}{1 + C^2}\right)$$

as promised. □

*Remark:* We are careful here not to write (40) as a limit but as an approximation. In order to strictly prove convergence in (40), two rather technical steps remain to be proved. The first is that the steady-state number in the queue (when scaled) converges to the steady-state value of the diffusion. The second is that the expected values of these steady states converge. Both are difficult issues in themselves and, aside from mathematical completeness, add little information to the approximation, which is the germaine issue of this paper.

## V. CONCLUDING REMARKS

We considered here a single-server queueing system with a nonhomogeneous Poisson arrival process whose rate is some constant $\lambda$ times the state of an independent M/M/$\infty$ system. In this paper, we derived limiting values for the mean delays as the traffic intensity goes to zero and to one.

This system was used to model the delay of packets at a packet switch. In this setting, an individual data customer generates packets at a constant rate $\lambda$ and the number of customers generating packets is given by the state of the M/M/$\infty$ system. This is, of course, not the only possible model for packet arrivals. Packets generated by an individual virtual call may be "smoother" or more "bursty" than packets generated by a Poisson process. It is also possible that restrictions could be imposed on the total number of simultaneous virtual calls, thereby making the infinite-server assumption unrealistic. Work is currently under way to extend the techniques of this paper to cover these and other more general models of bursty traffic.

Our ultimate goal in studying $D_B/D_M$ in both light and heavy traffic is to be able to derive simple, closed-form approximations for $D_B$ for all values of the traffic intensity $\rho$. One candidate approximation is to

linearly interpolate between the values obtained for $D_B/B_M$ when $\rho \to 0$ and when $\rho \to 1$ [see (4) and (5)]. This approach gives the following estimate for the mean delay:

$$D_B \sim \frac{\rho}{1-\rho}\frac{(1+C^2)}{2\mu}\left[1+\frac{\mu}{\alpha}\frac{1-(1-\rho)\phi(\beta)}{(1+C^2)}\right].$$

More sophisticated interpolations are possible (see Lauber and Smith[7] for applications of these techniques to estimating the delays in an M/G/c queue); however, in the absence of any test data, verification is difficult. One method of verification is to study the accuracy of these approximation techniques when applied to other models of bursty arrivals for which explicit expressions are known (see Yechiali and Naor[17]). This work is currently under way and will be reported on in the future.

## APPENDIX A

### *Background on Phase-Type Distributions*

Appendix A summarizes results for phase-type distributions that are used in Section III. A service time is said to have phase-type distribution if it is distributed like the first exit time from a continu-

ous-time, finite-state Markov chain. Any distribution can be arbitrarily approximated in the sense of weak convergence by one of phase type. We assume that the states (also known as phases) are the nonnegative integers $i$, $i = 1, \cdots, m$. Let the rate of transition from phase $i$ to phase $j$ be $T_{ij}$ $(i \neq j)$, and the rate of exiting from phase $i$ be $\xi_i$. Define $T_{ii} = -\sum_{j \neq i} T_{ij} - \mathrm{E}_i$, i.e., minus the rate of leaving state $i$. We assume that $T$, the matrix of $T_{ij}$, is invertible; this is sufficient to imply that the real part of the spectrum of $T$ is strictly negative. A customer starts service in phase $i$ with probability $\omega_i$. Following Neuts,[4] we use the notation $(\omega, T)$ to describe this distribution, where $\omega$ is the vector of initial probabilities and $T$ is the $m$-dimensional matrix of rates.

The vector $\xi$ of ergodic probabilities for the service phase of the renewal process is determined by normalizing the solution to the equations

$$-\xi_i T_{ii} = \sum_j \xi_j T_{ji} + (\Sigma \xi_j \mathrm{E}_j)\omega_i, \tag{41}$$

or in matrix notation,

$$\xi T = -(\xi, \mathrm{E})\omega. \tag{42}$$

The service rate $\mu$ is defined as

$$\mu = (\xi, \mathrm{E}). \tag{43}$$

It is not difficult to show that $\mu$ is the reciprocal of the mean service time.

Let $\tau$ be the first exit time from the chain; let $\mathrm{M}_i(s) = E_i(e^{-s\tau})$, the Laplace Transform of $\tau$ given the initial state is $i$; and $M_i^n = E_i \tau^n$. The results of Proposition 1 are well known (see Kielson,[18] page 82, and Burman and Smith[12]).

*Proposition 1.* For $\tau$, $\mathrm{M}(s)$, and $\mu^n$ defined above,

$$\mathrm{M(s)} = (\mathrm{sI} - \mathrm{T})^{-1}\mathrm{E} \tag{44}$$

and

$$M^n = n!(-1)^n T^{-n} e, \tag{45}$$

where $e$ is the vector of all ones. In particular, the $n$th moment of the service-time distribution $(\tilde{M}^n)$ is

$$\tilde{M}^n = n!(-1)^n(\omega, T^{-n}e). \tag{46}$$

If $H^c(x)$ equals the tail of the service-time distribution, then the following corollary is immediate.

*Corollary 1.*

$$-\xi T^{-1}e = \int_0^\infty x\mu H^c(x)dx = \frac{\mu\mu_2}{2}, \tag{47}$$

and

$$-\xi T^{-1}(\beta I - T)^{-1}\mathrm{E} = \int_0^\infty e^{-\beta x}\int_x^\infty \mu H^c(s)dsdx. \tag{48}$$

*Proof:* To see (47), observe that $\mu H^c(x)$ is the density of the remaining service time when the process is sampled in equilibrium, and apply Proposition 1. The identity on the integral can be obtained by integration by parts. In a similar fashion,

$$\xi T^{-1}(T - \beta I)^{-1}\mathrm{E} = \frac{\xi[(T - \beta I)^{-1} - T^{-1}]\mathrm{E}}{\beta}$$

$$= \frac{\left[\int_0^\infty \mu H^c(x)dx - \int_0^\infty e^{-\beta x}\mu H^c(x)dx\right]}{\beta},$$

and integration by parts gives us (48). □

## APPENDIX B

### *Intuitive Derivation of the Results in Light Traffic*

The following argument is based on the intuitive notion that, in light traffic, almost all arriving packets arrive to an empty system and are served before the arrival of another packet. Furthermore, the times when there is exactly one packet in the system constitute almost all of the time in which an arriving packet might be subject to delay. Thus, in light traffic, it is easy to derive the proportion of time in which an arrival will be delayed, and to find the delay for such an arrival. A slight complication is introduced in the analysis by the fact that the arrival rate of packets is not constant, but this is easily overcome.

While the overall derivation is not rigorous, it is convincing and gives insight into the light-traffic behavior. The results, of course, are consistent with the rigorous results derived for phase-type distributions in Section III.

We will begin with traffic-independent results for the model described previously in the beginning of Section II, in which the instantaneous arrival rate equals $\lambda$ times the state of an M/M/$\infty$ queue with birth rate $\alpha$ and service rate equal to $\beta$. The equilibrium distribution of the M/M/$\infty$ queue governing the arrival process is easily seen to be Poisson with mean $\alpha/\beta$. However, this is not its distribution immediately after an arrival, since the rate of arrivals is proportional to the

state of the M/M/∞ queue. Thus, the conditional probability that the state of the M/M/∞ queue is $m$ (for $m \geq 1$) immediately after an arrival is

$$\frac{m(\alpha/\beta)^m \frac{1}{m!} e^{-\alpha/\beta}}{\sum_{k=0}^{\infty} k(\alpha/\beta)^k \frac{1}{k!} e^{-\alpha/\beta}} = \frac{1}{(m-1)!} (\alpha/\beta)^{m-1} e^{-\alpha/\beta}.$$

This may be thought of as the distribution of a Poisson random variable with mean $(\alpha/\beta)$ with support right-shifted one unit. This point of view is useful in computing the distribution of the state of the M/M/∞ queue $t$ time units after an arrival of a packet (denoted $N_t$), since the Poisson distribution is stationary, and the additional unit is still present with probability $e^{-\beta t}$. Thus,

$$E(z^{N_t}) = e^{(\alpha/\beta)(z-1)}[1 + e^{-\beta t}(z-1)]. \tag{49}$$

Now consider the system in light traffic. Denote the state of the system by $(N, M, T)$ where $N$ is the number of packets in the system, $M$ is the state of the M/M/∞ queue that modulates the arrival process, and $T$ is the remaining service time of the packet being served.

We first obtain an expression for $E(e^{-sT}z^M\delta_{1N})$ in light traffic, where $\delta_{1N} = 0$ for $N \neq 1$ and $\delta_{11} = 1$. We then show how to use this quantity to obtain the desired limits. In light traffic, almost every packet arrives to an empty system and is served before another arrival. By Little's Law

$$P(N = 1) = E\delta_{1N} \sim \lambda\alpha E(S)/\beta.$$

Again, making the assumption of the last sentence and looking at the system at only those times for which $N = 1$, we obtain by standard renewal theory arguments that

$$E(e^{-sT}z^M N = 1) = \frac{1}{ES} E\left[\int_0^S E(z^{N_t}) e^{-s(S-t)} dt\right] \stackrel{\text{def}}{=} \frac{1}{ES} G(z, s).$$

Multiplying, we obtain that

$$E(e^{-sT}z^M\delta_{1N}) \sim \lambda(\alpha/\beta)G(z, s). \tag{50}$$

By conditioning on $S$ and using (49), we obtain

$$G(z, s) = e^{(\alpha/\beta)(z-1)} \frac{1}{s} \left\{[1 - \tilde{H}(s)] + \left(\frac{z-1}{\beta - s}\right)[\tilde{H}(s) - \tilde{H}(\beta)\right\}, \tag{51}$$

where $\tilde{H}$ is the Laplace Transform of a service time.

Equations (50) and (51) can be used to find desired properties of the queue in light traffic. For example, since nearly all packets that

are delayed are generated when there is only one other packet in the system, and since the rate of generation of packets is $\lambda$ times the number of calls, we find the rate of generation of delayed packets, $\lambda_D$, is

$$\lambda_D \sim \lambda^2(\alpha/\beta)G_z(1, 0), \tag{52}$$

or

$$\lambda_D \sim \lambda^2 \left\{(\alpha/\beta)^2 \frac{1}{\mu} + \alpha/\beta[1 - \tilde{H}(\beta)]\right\}. \tag{53}$$

The Laplace Transform of the delay, given that the delay is greater than 0, defined to be $\phi(s)$, is also found easily since the delay of a packet equals the remaining service time on arrival. Thus,

$$\phi(s) \sim \frac{G_z(1, s)}{G_z(1, 0)},$$

or

$$\phi(s) \sim \frac{\alpha/s[1 - \tilde{H}(s)] + \dfrac{\beta}{\beta - s}[\tilde{H}(s) - \tilde{H}(\beta)]}{\alpha/\mu + 1 - \tilde{H}(\beta)}. \tag{54}$$

Inversion of the Laplace Transform gives (10) and also gives

$$E(D \mid D > 0) \approx \frac{\dfrac{\alpha\mu_2}{2} + \dfrac{1}{\mu} - \dfrac{1}{\beta}[1 - \tilde{H}(\beta)]}{\alpha/\mu + 1 - \tilde{H}(\beta)}, \tag{55}$$

where $\mu_2 = E(S^2)$. Of course, $P(D > 0) = \dfrac{\lambda_D}{\lambda(\alpha/\beta)}$ so that (52) and (54) give

$$E(D) \approx \frac{\lambda}{\beta}\left\{\frac{\alpha\mu_2}{2} + \frac{1}{\mu} - \frac{1}{\beta}[1 - \tilde{H}(\beta)]\right\}. \tag{56}$$

This may be combined with the Pollaczek-Khintchine formula to give (3).

*Modernization of the Suburban ESS:*

# Overview: Evolution of the Suburban ESS

By T. E. GRASSMAN* and J. E. YATES*

(Manuscript received June 8, 1982)

This paper highlights the systematic evolution of the No. 2/2B Electronic Switching System (ESS), describing both hardware and software changes. It also introduces the subsequent articles that describe the modern interfaces and modern development environment enjoyed by the system. The No. 2 ESS was the first electronic switching system specifically designed for the suburban community. Subsequent incorporation of a more flexible and powerful processor provided a basis for a large increase in processing capacity and a continuing modernization of system structure. The evolved system, the No. 2B ESS, is now rich in features and offers modern administrative and maintenance capabilities.

## I. INTRODUCTION

The No. 2 Electronic Switching System (ESS),[1] designed in the 1960s to provide ESS capabilities to suburban communities, was developed under the same constraints as other large real-time control systems of that era. Memory was expensive and processors were not powerful enough to compensate for inefficiencies in software. As a

result, programs were written in assembly language and were tightly coupled. Compared with No. 1 ESS, then being deployed in urban areas, the No. 2 ESS faced a more stringent cost sensitivity due to the smaller number of subscribers supporting a given local switching system.

The original No. 2 Processor was replaced in 1976 with the 2B Processor, which has a more modern architecture based on improved semiconductor technology. This more powerful processor provided capacity for feature enhancement[2] and allowed utilization of more generalized and structured software techniques that have subsequently been incorporated into the system. This incorporation was accomplished by strictly controlling the portions of the software system that were allowed to change. Since that time the programs have continued to evolve and exploit the capabilities of the 2B Processor.

Most recently, the inclusion of modern software constructs in the 2BE3 generic has produced a design containing a modern data link interface that supports such capabilities as the 10A Remote Switching System (RSS), Automatic Message Accounting (AMA) data teleprocessing, and traffic data teleprocessing. Description of these features may be found in the companion articles of this series.

The evolutionary approach used to realize the present No. 2B ESS has resulted in a continuously viable product that remains economically attractive and modern in feature content. This paper will discuss the system evolution, and serve as an introduction to the other papers in this series.

## II. HARDWARE AND SYSTEM CHARACTERISTICS

### *2.1 No. 2 ESS*

The original No. 2 ESS central processor was designed using Transistor Resistor Logic (TRL) in the early 1960s. The architecture consisted of special purpose registers that were designed to accommodate a set of instructions tailored for use in telephone switching. For example, explicit instructions were included to support the software structure that used 8-word control blocks to process each telephone call. Its architecture and instruction set gave the No. 2 ESS the capability to efficiently switch telephone calls in a small to medium (2,000- to 20,000-line) office.

The hardware architecture used in the No. 2 ESS Processor supported two types of stores (memories). One of the stores was a permanent magnet twistor that contained the program as well as the data which specified the characteristics of lines and trunks. This 22-bit-wide memory was magnetically alterable off-line. The memory organization consisted of four 64K modules for a maximum of 256K

words. The selection of a module was independent of the normal addressing mode within a module. This required each program to independently administer the module selection for itself. The other store contained up to 32K 16-bit words and was on-line writable. It contained dynamic information related to the processing of calls.

An additional characteristic of No. 2 ESS was a wired logic unit that autonomously scanned for customer requests, and, under timed control, scanned for short-interval signals. Both of these logic control items deloaded the program and increased the efficiency of the overall system. Scanners and other peripheral units were controlled by a parallel bus system.

This processor was put into service in 1970 in the No. 2 ESS system and provided the desired service level, features, and cost benefits at the time of its initial cutover.

### *2.2 The No. 2B ESS*

#### *2.2.1 Background*

In 1971, a series of cost reduction studies led to the selection of the more powerful 3A Processor Control Complex (3A CC)[3] for incorporation into the No. 2 ESS. The 3A CC was designed for use in both No. 2B ESS and No. 3 ESS. The 3A CC was designed along general-purpose computer principles rather than on the specific switching logic instructions incorporated in the original No. 2 ESS Processor, and made extensive use of integrated circuits. The new processor could address up to one million words of relatively inexpensive semiconductor memory, provided a general-purpose instruction set and a serial bus access to peripheral units, and used a microprogram-based instruction decoder.

The principal asset of the 3A CC Processor was its microprogrammed instruction set. This feature allowed the processor to not only encompass the No. 3 ESS commands, but also to be extended in a relatively simple manner to emulate the original No. 2 ESS instruction set, and to add additional instructions that were parallel in nature to the No. 2 ESS set. This allowed the retention of most of the programs that had previously been developed to provide features and maintenance on the existing No. 2 ESS (except for the processor maintenance itself).

To minimize changes in the control of major peripheral equipment, a new interface [the 2B Input/Output (I/O) unit] was developed to connect the 3A CC to the parallel peripheral bus system. (The combination of the 3A CC, the 2B I/O unit, the increased memory, and the microcode for emulation is referred to as the 2B Processor.) In addition, programs already developed for the 3A CC, e.g., teletype-

writer (TTY) handlers and processor maintenance software, were adopted intact to avoid duplicate software development.

### *2.2.2 Instruction emulation*

The key element in replacing the No. 2 Processor was the emulation of the existing No. 2 ESS instruction set. The existing 22-bit data and instruction format of the No. 2 ESS did not fit in the 16-bit 3A CC memory. Converting each No. 2 ESS word to two 3A CC words would have resulted in an addressing incompatibility between the old and new systems, i.e., the same instruction would exist at different addresses in the two systems. If this were allowed to occur, object-level changes to correct field problems would have to be developed twice, once for the No. 2 ESS and again for the No. 2B ESS. By keeping the object-level addresses synchronized, this duplicate effort was avoided. The decision was made to expand the 3A CC store to 24 usable bits to allow exact emulation of No. 2 ESS instructions and data. Half-word instruction pairs could be accommodated in the same addressable word, and data packing was then identical in the two processors. A further decision was made to use the No. 2 ESS instruction manual as the requirements for the emulated instructions and to map the functional No. 2 ESS registers into the general-purpose registers of the 3A CC. Each register and instruction was fully emulated.

These restrictions gave several distinct advantages although they did not allow improvements in program techniques through use of the richer 3A CC instruction set. The advantages were as follows: a test program that previously tested the instruction logic on No. 2 ESS provided the acceptance test for the microprogrammed instruction set (i.e., no new program was required); an immediate check on correct program compilation was available by comparing raw program sizes, symbol values, and linkage characteristics between the existing and the emulated programs; debugging of these programs was required only on one machine (No. 2 or 2B Processor) since they could be automatically assembled from the same source for the other machine without human interference (this allowed nearly simultaneous program releases on the two different systems); and most existing documentation and procedures for the No. 2 ESS were usable with the 3A CC since most user interfaces were identical between the systems.

With these constraints, the bulk of No. 2 ESS programs (85 percent) could be used as they were currently written. Most of the remaining 15 percent were No. 2 ESS Processor maintenance programs, which were replaced in total by the 3A CC Processor maintenance programs. The programming effort of the 2B introduction then was completely restricted to the support programs (assemblers, loaders, etc.), six

interface programs, and new diagnostics and recovery programs for the wide store.

#### *2.2.3 Input/output emulation*

The No. 2 ESS wired logic I/O performed two functions. It looked for new customer service requests and collected the digits as they were dialed by the customer. In the new system, software was used to scan for service requests. The digit collection functions were exactly duplicated by an interrupt-level microcode sequence on the 3A CC. This provided an unchanged interface to existing programs that had depended on the wired logic. The only associated changes required were in recovery programs for handling digit collection failures.

The interface between the 3A CC and the No. 2 peripheral equipment was provided by the 2B I/O unit. This was implemented to be driven by the existing 3A CC serial channel interface. Driver programs were implemented in microcode so that controlling programs, issuing I/O instructions, were not required to change.

### *2.3 No. 2B ESS field introduction and evolution*

The No. 2B ESS was successfully put into service in 1976. Less than one year later the same program was used to provide service in an office requiring increased capacity through a retrofit of the processors. Since the 3A CC is much faster than the No. 2 ESS Processor, the No. 2B ESS call capacity (35,000 calls/hour engineered load) is much greater than that of the No. 2 ESS (16,500 calls/hour engineered load). By 1977, No. 2 ESS Processors were no longer being manufactured.

The No. 2/2B ESSs continued to evolve gradually—and in step—for several years while their programs were kept locked together by the restrictions discussed above. As the number of in-service No. 2 ESSs began to decline through processor retrofits, and the pressure to provide new and expanded features increased, a decision was made to discontinue new development on the No. 2 ESS, and to take further advantage of the 3A CC Processor's capabilities in No. 2B ESS.

The 2BE3 generic program, put into service in November of 1981, utilizes significant software restructuring in certain areas. The resulting advantages range from achieving expanded capacities for per-line features (e.g., call forwarding) to the development of several major new features and the communications interface that supports them.

### *2.4 A modern data communications interface*

The need for data communications between local switching offices and other systems (remote switches and various operation support

systems) has expanded in recent years. To meet this increasingly important need, the No. 2B ESS has incorporated, in the 2BE3 generic program, a modern data communications interface capability. This interface is based on the Serial Peripheral Unit Controller/Data Link (SPUC/DL), a cost-effective and flexible hardware element utilizing microprocessor control capable of supporting various communications protocols. The 3A CC serial channel I/O capability provides the high-speed communication path between the host and the SPUC/DL. An accompanying article, "A New Data Link Controller," describes the SPUC/DL and its architecture, design, and capabilities in considerable detail.

Firmware has been developed for the SPUC/DL to support levels 1 and 2 of the BX.25 data communications protocol. This capability is utilized in provision of interfaces to the Automatic Message Accounting Collection System (AMACS) and to the Engineering and Administrative Data Acquisition System (EADAS). Firmware has also been developed to support the RSS protocol, which predated the BX.25 standard, enabling the No. 2B ESS to provide control of the 10A RSS. The features associated with these interfaces are also described later in this series.

## III. NO. 2B ESS SOFTWARE EVOLUTION

Soon after the No. 2B ESS was successfully cut into service, an effort was begun to exploit the capabilities of the new processor. This effort, which had been planned from the beginning, aimed at eliminating data and program constraints. The success of these initial enhancements led to other incremental improvements. The program has matured to the point that enhancements driven by modern software practices, as well as the 2B Processor's architecture, are being pursued. These include operating-system-type primitives, data independence, and program decoupling.

This section will review some enhancements that demonstrate progress in a variety of areas. The techniques used are not new nor innovative by current standards. What is perhaps unique is the manner in which they have been applied to a large, complex, existing system.

The enhancements have been pursued in a systematic fashion. First, the software was extended to utilize the capabilities of the 2B Processor while still remaining functionally compatible with the original No. 2 ESS software. Commercial versions of these compatible programs were released in 1976 and 1977. Eventually the compatibility restriction was lifted and the software was extended to exploit noncompatible 2B capabilities. In about the same time frame, modifications to enhance functional and data independence were added.

### *3.1 2/2B compatible extensions*

Functional compatibility between the No. 2 ESS and the No. 2B ESS at the time of conversion was important not only to minimize risk, but also to ensure that future enhancements applied to both systems. The types of enhancements that could be introduced were severely limited by this restriction. Generally, they took the form of increasing the maximum quantity of a particular resource that the system could handle.

A prime example is the memory spectrum. Immediately following the conversion, the 2B Processor was limited to the 256K-word spectrum of the No. 2 Processor simply because the software was tailored to handling 18-bit addresses. The program modifications required to handle 20-bit data addresses and exercise the full megaword spectrum of the 2B Processor were scattered throughout the software. A pervasive change of that nature with its attendant risk is precisely the kind of complication that was intentionally avoided during the initial conversion process. With the converted system functioning well, exploiting the million-word address spectrum could be attacked as a separate problem. It was scheduled, designed, and implemented in 1976.

The implementation modified all affected programs to be able to handle 20-bit addresses. Since both the 2 and 2B versions were modified, they remained compatible and both were able to handle the larger addresses. The No. 2 version would, of course, never encounter an address that exceeded 256K.

Similar extensions followed in a well-defined and controlled manner. The maximum number of scanners, peripherals used to sense the states of circuits and/or lines, was increased from 12 to 31. The number of buffers utilized to control peripheral units was increased from 12 to 20. Each extension was scheduled and implemented separately, thereby avoiding the coincident introduction of complex changes.

### *3.2 Noncompatible extensions*

The number and nature of compatible extensions are limited. To make more fundamental structural changes to the software system required exploiting aspects of the 2B Processor for which there is no No. 2 counterpart. As an example, one could not begin to use the superior 2B instruction set since the No. 2 Processor did not contain those instructions. In like manner, the larger No. 2B ESS memory could not be utilized for program instructions. In 1977, the decision was made to decouple the new and the old systems, thereby eliminating the compatibility constraint on the program system.

This decision opened new vistas for improving the structure of the software system. The first step was to simply eliminate methodology

and operations that existed only because of the No. 2 Processor. For example, the No. 2 Processor cannot support relocatable programs. The 2B software system has now been converted to be mostly relocatable. Certain instruction sequences can be coded more efficiently using the 2B instruction set. Some sequences, in fact, were not needed at all and were simply eliminated. We were particularly fortunate to have available the excellent text processing facilities provided by the *UNIX** time-sharing system to aid in the search for these sequences.[4] These changes were collectively called program "clean up" and were performed as the first step in moving primary system development to the No. 2B ESS.

### *3.3 Modernizing the control structure*

#### *3.3.1 Isolating application software from the control programs*

One definition of an operating system is a set of standard functions that provide a hospitable environment for application programs. The call processing control mechanism in the No. 2B ESS did not supply this feature. Nevertheless, certain steps toward providing common, general functions for use by application programs were possible. Emphasis was on the introduction of these functions with a minimal perturbation to the overall system. In particular, designs that did not cause existing programs to become inoperative were selected for the implementation of these functions. Once a function is available, all new development can use it. On an independent schedule and subject to independent evaluation, a plan could be developed to convert existing application programs to use the new functions.

#### *3.3.2 Isolating application software from a resource manager*

This philosophy of gradual introduction has also been used to reduce the coupling between an existing resource manager and the application programs. The manager is responsible for finding and allocating paths through the switching network. To efficiently use the network, it attempts to share a portion of an existing path with the next path to be found for the same call. The shared portion is known as the A link and the operation is known as A-link sharing. As originally designed, the manager provided the mechanism, but the application programs were required to save the identity of any A link to be shared and to specifically request sharing when invoking the manager.

Consistent with this new philosophy, a universal mechanism for sharing A links has now been implemented. The path manager now has complete control over the sharing mechanism. Sharing is at-

* Trademark of Bell Laboratories.

tempted in every situation and not just at the discretion of the application program. The A-link sharing information has been eliminated from the application interface. The significant point is that once again this was accomplished in a fashion that did not require the wholesale change of existing programs. Unchanged application programs would still go through the motions of making A-link sharing decisions, but these would be ignored by the manager. In no way would the application program affect or compromise the control now centered in the path manager. All known A-link code was in fact stripped out of application programs for reasons of clarity and efficiency. Significantly, this was a conscious decision and not a foregone conclusion. In the event that some application A-link code was not detected, only the efficiency of the system and not its integrity was affected.

## IV. MODERNIZING THE DATA STRUCTURE

### *4.1 Isolating application software from data*

The original application interface to the No. 2 ESS database system (it was known as translations in those days) was reasonably well structured. All of the update routines were concentrated in one place, as were the access routines. Most application programs even used the access routines to retrieve the data. The fundamental problem was the transparency of the access routines. While they shielded the user from the gross structure of the data, returning the address of an individual record was not unusual. That practice, while promoting the ultimate in efficiency, resulted in the known record formats propagating throughout the application programs.

This data problem is more insidious than the corresponding control problem. It can be, and was, attacked with the same philosophy of installing the new without breaking the old. While exhibiting many of the same benefits as the new control interface, the database does not really pay dividends until the new interface is used to streamline the access and packing efficiency by allowing the records to be reformatted. All programs, including preexisting ones, had to be decoupled from the data by the new interface before any records containing that data could be modified.

Despite this observation on the general intractability of the problem, where it made sense to reorganize a portion of the database, a two-phased approach was used. The application programs were first decoupled from the data by a uniform and opaque interface supplied by the database programs. Since the underlying data structures did not change, converted, nonconverted, and "unaffected" data accesses continued to operate properly. The "unaffected" class contained some accesses for which the need for conversion was not predicted. The

existence of these oversights did not affect the operation of the system during the entire conversion process. Even assuming perfect analysis, the two-phased approach eliminated any coordination in the data access conversions. It was only necessary that all conversions occur before the database was modified.

The data were reformatted during the second phase. When the data changed, implicit and embedded data dependencies that were overlooked in the first phase surfaced and were dealt with. Certainly the disruption of the system was minimized by a two-phased approach. In the case of the No. 2B ESS conversion being reported herein, the entire decoupling of the application software from the data was not accomplished during Phase 1. Some converted code had to be reexamined and modified during Phase 2. Nevertheless, the final result was very successful based on the relative absence of conversion problems uncovered during testing. This method allowed the complete reformatting of the originating and terminating translators, which in turn allowed more features and provided a more regular data structure that could be enhanced gracefully.

### *4.2 Isolating application software from hardware*

Superimposing a logical structure and nomenclature on top of the physical one is a well-established mechanism for insulating application software from the details of the real world. Application programs typically direct output, not to a real device, but to a logical channel number. The operating system is charged with mapping this logical number to a real device. Unfortunately, the need for similar flexibility in identifying terminals of the No. 2 ESS switching network was not foreseen. There was but one type of network whose terminals were universally identified by their actual equipment location. With the introduction of a second type of network, the use of equipment location numbers to identify terminals became ambiguous. Rather than imbuing all application programs with the knowledge of two network types, a logical identification scheme similar to the one used for channels was created. The logical scheme identifies each terminal by a unique virtual equipment number. A mapping algorithm is used to go from real to virtual equipment number and vice versa.

The merits of a virtual numbering scheme are self-evident and will not be discussed. The feasibility of introducing a virtual numbering scheme into a large, complex software system developed almost two decades ago for a modest development effort is less evident. The 2BE3 generic program is an existence proof.

First, a few sensible limitations were imposed. The spectrum of the virtual equipment numbers was made to coincide with that of the original real equipment numbers. This, of course, means that the

maximum number of actual terminals of all types is still the same. The required performance of the No. 2B ESS is such that this is a reasonable restriction. Making the spectrums compatible means that all existing programs and data structures could at least handle the identifying number. The change would, therefore, be entirely transparent to all programs that used the number strictly as an identifier. The new number could still be passed as a parameter, stored in the same slot in the call control block, and used to index into data tables to retrieve per terminal information. Only the programs that actually required the real equipment number (equipment control programs and programs that print equipment locations for human use) needed to be modified. The subset of affected programs was relatively small. In addition, the required modifications were reasonably straightforward. Functions to do the mappings were added to the database interface. The modifications to other programs consisted mainly of inserting calls to these new functions.

The virtual equipment numbering scheme is now in place and functioning well. Because its introduction is thought to have saved development effort in other areas of the project, the consensus of opinion is that its overall development effort was less than other considered methods. It will, of course, continue to provide benefits in the future when, and if, additional network types are added to the No. 2B ESS.

## V. FEATURE EXTENSIONS

No. 2 ESS began on a small suburban switching machine. In the early 1970s, centrex features were added. With introduction of No. 2B ESS in 1976, real-time capacity was almost doubled, allowing even more business-type features.

The 2BE3 generic added compatibility with the 10A RSS (using the virtual terminal concept and the database modernization), EADAS, and AMACS, while allowing greater penetration of custom calling features (via the database modernization). Several of these features are described in accompanying articles.

## VI. CONCLUDING REMARKS

The No. 2/2B ESS experience demonstrates that a mature system can evolve its hardware and software systems to more modern technologies. The successful methodology included making only one major change at a time, and, where possible, introducing a modern software structure without, or at least before, breaking the existing structure. The evolution reported herein spans the 1970s. The No. 2B system was proposed in 1971. It was developed during the middle years of the

decade and was placed in commercial service in February 1976. The compatible software enhancements occurred between that time and the next release of the system in December 1977. The noncompatible enhancements have occurred since that time and continue at present.

The software changes as a group have simplified software administration and the introduction of code changes to support new telephone features. The development effort has been quite modest. Introducing standardization has introduced some inefficiencies. Certainly the general-purpose control and data functions require more memory and in many cases a small real-time overhead. These penalties are not a large price to pay for the advantages of improved software structure.

## VII. ACKNOWLEDGMENTS

Several people were instrumental in the No. 2B ESS concept and its original design. These included J. A. Herndon, C. E. Ishman, W. R. Nehrlich, P. D. Mandigo, and P. C. Richards. Beyond these few, the authors wish to thank the entire No. 2/2B ESS development organization that made the system a success. This paper is based in part on earlier works by Mandigo and Nehrlich.

## *Modernization of the Suburban ESS:*

# Adding Data Links to an Existing ESS

By C. E. ISHMAN,* R. B. SANDERSON,* L. M. TAFF,* D. P. TRUAX,* and C. T. TULLOSS*

(Manuscript received June 21, 1982)

As a major modernizing improvement data links for three important functions have been added to the 2B Electronic Switching System (ESS). The data-link system was designed with a layered architecture using an enhanced subset of the X.25 protocol. Levels 1 and 2 of the protocol are implemented in the hardware and software of a new device, the Serial Peripheral Unit Controller/Data Link (SPUC/DL). Within the SPUC/DL itself, check circuitry and software are used for error detection. A second SPUC/DL for each critical application provides redundancy on either a dedicated or dial-up basis. An elaborate diagnostic program within the 2B ESS can be invoked automatically or manually. This paper discusses some of the issues in retrofitting the BX.25 protocol to pre-X.25-speaking machines.

## I. INTRODUCTION

This paper describes the addition of real-time data-link capability to the No. 2B Electronic Switching System (ESS)†. The paper combines a technical description of the project with explanations of certain

* Bell Laboratories.

key decisions. We attempt to be candid in assessing both the virtues and pitfalls of such decisions.

The No. 2B ESS is a medium-sized telephone switching system designed for rural and suburban offices with 5000 to 20,000 customer telephone lines. The addition of data links to the system was but one of several major enhancements in the development of a new generic program developed for the 2B—the 2B Extended feature generic #3 (2BE3)—described in accompanying papers.

### *1.1 Project goals*

Our major goal in this project was to create appropriate hardware/software systems to provide data-link capabilities from the 2B to each of three different remote Bell System *applications*. Each application had different characteristics and reliability requirements. An overview of the desired network capabilities is shown in Fig. 1. Note that other types of ESS machines as well as additional 2B ESS offices may interface to the Automatic Message Accounting Recording Center (AMARC) and Engineering and Administrative Data Acquisition System (EADAS) applications. This constrained the freedom to choose interface specifications freely. We wanted flexibility in our design so various combinations of these applications could be configured without trouble or extra cost.

A secondary goal was that as much as possible of the data-link subsystem resulting from our efforts be "portable;" the system should be adaptable to other applications on the 2B, and even other machines, after suitable hardware alteration.

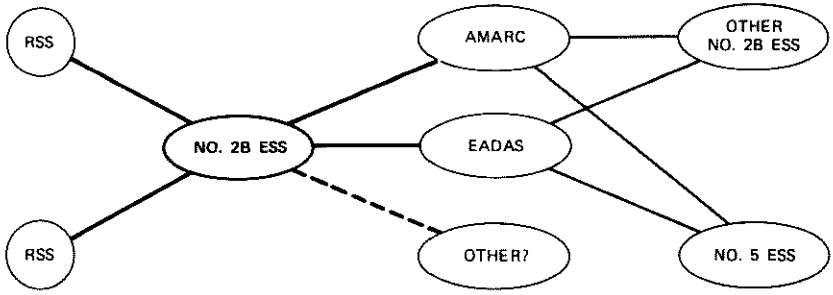
### *1.2 Boundary conditions*

#### *1.2.1 Use of BX.25 protocol*

The development of our project proceeded roughly in parallel with the developments of the AMARC and EADAS projects within Bell Laboratories, as well as with the No. 5 ESS project, which was also to interface with AMARC and EADAS. A general consensus was reached to adopt recommendation X.25 of the *Comite Consultatif International Telephonique et Telegraphique (CCITT)*. BX.25, an enhanced subset of X.25, has since become a standard within the Bell System. Its adoption had important consequences in the total design of a data communications system, as will become clear below.

#### *1.2.2 10A Remote Switching System*

The 10A Remote Switching System (RSS) is a small space-division system intended for rural communities with fewer than 2000 subscribers. It requires a larger *host* machine to switch interoffice calls. Its controlling program is resident in firmware, and has been developed



AMARC – AUTOMATIC MESSAGE ACCOUNTING RECORDING CENTER
EADAS – ENGINEERING AND ADMINISTRATIVE DATA ACQUISITION SYSTEM
RSS – REMOTE SWITCHING SYSTEM

Fig. 1—Global view of planned No. 2B ESS.

over several years in conjunction with the No. 1/1A ESS, which provided host capability. The 10A RSS feature of the 2BE3 generic program will allow the 2B ESS to be a host as well. Up to 31 RSS machines can be supported by one 2B ESS.

The 10A RSS, having been developed before BX.25, constrained the generality of the data-link system. Nearly 100 units were in service as the 2BE3 generic was being completed. We were required to interface to the RSS with no changes to its firmware.

## II. GLOBAL SYSTEM ARCHITECTURE

We address in this section the architectural issues, both hardware and software, involved in the next level of detail from Fig. 1. For this purpose it may be useful for some readers to review briefly the structure of the BX.25 protocol.

### *2.1 Overview of BX.25*

BX.25 is a *layered* protocol consisting of independent layers or *levels* (see Fig. 2). Each level at one side of a data link communicates (in a logical sense) with the corresponding level on the other side. We use three levels, not counting the application program. A call-processing program (say) believes it is conversing with a billing program, for example, at the AMARC. To send a *message* to its counterpart the program simply calls a protocol level 3 interface routine. For its part, the conversation is complete.

Level 3 software will break the message, if necessary, into *packets* of length appropriate to the implementation (depending for practical reasons on the kind of transmission facility, available buffering capacity, etc.). It will then send the packets to the level 3 software at our destination, expecting—as one of its standard functions—a "message-

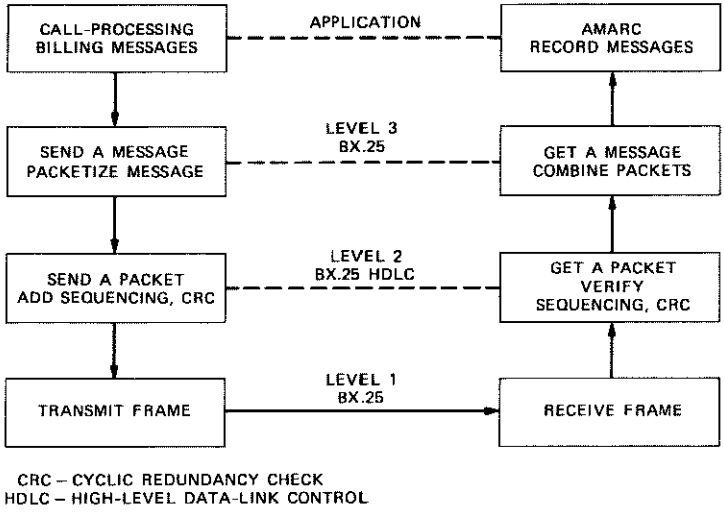


Fig. 2—Application layer and three layers of BX.25.

received" *acknowledgment*. It normally will not rest easy until such acknowledgment is forthcoming within a timed interval; it typically will retransmit the packets until a further interval expires, when it will begin recovery actions. Note, however, that "sending the packets" simply means handing them off to level 2 software.

Level 2 software is very analogous to level 3 in that suitable numbering is attached to the data, which are then delivered as *frames* to level 1.

Level 1 is implemented directly in hardware and is responsible for physically transmitting the data to the remote site. Level 2 frames are specified to contain a Cyclic Redundancy Check (CRC) at their trailing end, though in practice this is computed and inserted by an industry standard hardware chip. Thus there is a slight blurring of the line between levels 2 and 1.

While level 1 is supposed to transmit the data, the primary task of level 2 is to ensure that they arrive safely. Level 2 will retransmit unacknowledged frames, occasionally transmit *receiver-ready* messages on a temporarily unused link ("idle line assurance"), and handle initialization and disconnection functions. The numbering and acknowledgment functions of level 3 are primarily for flow control rather than verification purposes. A primary function of level 3 not yet mentioned is the routing of *logical channels* to their proper physical destinations.

Readers interested in more details about this protocol are referred to Refs. 1 through 3.

### 2.2 Architectures considered

One possible configuration would be to attach data-transmission hardware directly to the 2B ESS and write level 3 and level 2 software for the ESS. All the detail work of keeping track of unacknowledged frames, and time-consuming interrupts from transmission and reception, would be incurred by the switching machine itself. Since such overhead increases with the number of data links, real-time constraints made this an unrealistic option. In particular, we note that the link traffic increases just at least opportune times—when the machine is busy servicing telephone calls and has the least time available to handle link work. This configuration was never considered seriously. All realistic options use a separate autonomous processor to off-load the ESS.

We will discuss three such options given serious consideration. In the first option, level 3 and level 2 software are wedded together within a small auxiliary processor also containing the data-link hardware. In the second option, level 3 software resides with level 2 software capable of handling multiple data links, many of which are installed on the separate processor. The third option splits levels 3 and 2 into the ESS and attached processor, respectively, with level 2 servicing only one data link. This last option was eventually adopted.

#### 2.2.1 Monogamous levels 3 and 2 together

A configuration with levels 3 and 2 residing in a microprocessor was chosen by the designers of the AMARC side of our data network for their "AMARC Protocol Converter" (APC). This choice has the advantage that level 3 as well as level 2 is off-loaded from the main processor. The disadvantage of concern to us is that when it is necessary to change traffic to the standby link in a multi-link configuration, all level 3 current parameters as well as *all data currently queued at level 3* must be unloaded from one device and transferred to another. At the AMARC side of the link this is not as serious a matter as on the ESS side, where large volumes of data may be generated.

#### 2.2.2 Polygamous level 3 with multiple level 2's

A data link device for up to 16 independent links controlled by common level 3 and level 2 software is currently in use with the Bell System No. 1/1A ESS. This device, named the Peripheral Unit Controller (PUC), was the original model for our own system. Such a configuration has the advantage that links can be changed without intervention of the main processor. However, the PUC turned out not to be suitable for a machine the size of the 2B ESS; with enough power to drive 16 links there is a mismatch in the capacities and costs of the 2B ESS and the data-link controller. This consideration changed the

original direction of our project away from the PUC. Our device was originally to have been a PUC modified from parallel communication with the host to high-speed serial (6.67 Mhz); hence the name Serial Peripheral Unit Controller/Data Link, or SPUC/DL.

#### *2.2.3 Levels 3 and 2 living separately*

To answer the previous objection to high overhead cost for the office with few data links, we wished a small and inexpensive basic hardware unit. Vulnerability to failures could then be countered by duplicating units on applications requiring high reliability. An individual link need only be enough more reliable than the communications channel not to add significantly to the failure rate. Furthermore, difficulties in changing links could be reduced by keeping level 3 of the protocol and level 3 buffers within the ESS, which is fully duplicated, including all writable memory. In addition, where a controller implementing Level 3 would almost certainly need to be duplicated and have elaborate checking and matching circuitry to meet reliability requirements, the controller implementing Level 2 can use a simpler reliability check such as parity. Finally, of the three configurations discussed, this last seemed to us to be the most flexible, as well as the most fully portable to other applications and/or hosts. With this scheme substantial new code needed to be written for the 2B ESS—the level 3 protocol, and the maintenance software for the links. Furthermore, complete off-loading of the ESS processor does not occur. Though most of the work and interrupt processing is done in the SPUC/DL, there will be a small traffic-dependent load for managing level 3.

### *2.3 Configurations by application*

As we mentioned previously, each of the three initial applications for the SPUC/DL had its own requirements and the simple hardware could be configured separately for each.

#### *2.3.1 10A RSS*

Data links for each RSS are fully duplicated with hard-wired dedicated lines for both links, thus providing a "hot" spare. It is recommended that diverse transmission facilities be used for each data link. These rather strong requirements underscore the high reliability expected of this application. Call processing for lines connected to the 10A RSS is done on the host machine, in our case the 2B ESS. The data links are used to control the progress of calls. Thus, loss of data-link capability means loss of most service for RSS customers. (The RSS can be configured to provide local calls if the host connection becomes lost.) The 10A RSS machine is described at length in Ref. 4.

### 2.3.2 AMARC

Traffic on the AMARC data links does not carry information that affects customer service, and therefore does not have the intrinsically stringent reliability requirements imposed on RSS links. However, the billing information carried is valuable, and long outages could be costly. Short outages—some tens of seconds—would be tolerable if suitable buffering capacity were provided to avoid losing billing data. AMARC links were therefore configured with one data link on a dedicated hard-wired line, supplemented with a "cold" spare connected to the switched network. Changing to the cold spare after a dedicated primary link outage exceeding some minimum duration involves dialed telephone calls between the ESS and AMARC machines. Such a scheme saves the considerable cost of a second dedicated connection.

### 2.3.3 EADAS

Though data gathered on EADAS links are useful for planning telephone network growth, their temporary loss does not compromise either customer service or revenue. EADAS applications can therefore be configured with a single data link, equipped with a dedicated line.

### 2.4 Architectural summary

A diagram of a No. 2B ESS with its three types of configurations is shown in Fig. 3. We emphasize that the duplication on critical applications is for reliability; only one link is active at any time, and there is no load sharing.

## III. FUNCTIONAL REQUIREMENTS OF THE SYSTEM COMPONENTS

### 3.1 Hardware

The general requirements of the hardware are as follows:

1. Basic hardware. Hardware for the data-link controller must execute level 1 (the physical level) of BX.25, and provide enough memory space and processing power to implement level 2.
2. Link speeds. Initial applications were to use 2400 or 4800 bits/second (bps), but for possible new applications a goal was set for 56K-bps hardware capability.
3. Link Reliability. Our goal was to have data communication failures be caused predominantly by transmission facility failures rather than by data-link controller failures.
4. Repairability. The controller required self-test capability to isolate faults to a single-printed circuit board wherever possible.
5. Cost. The initial cost of the data links was required to be low for smaller offices with only a few links.
6. Expansion. Expansion should be modular, smooth, and trouble-free.

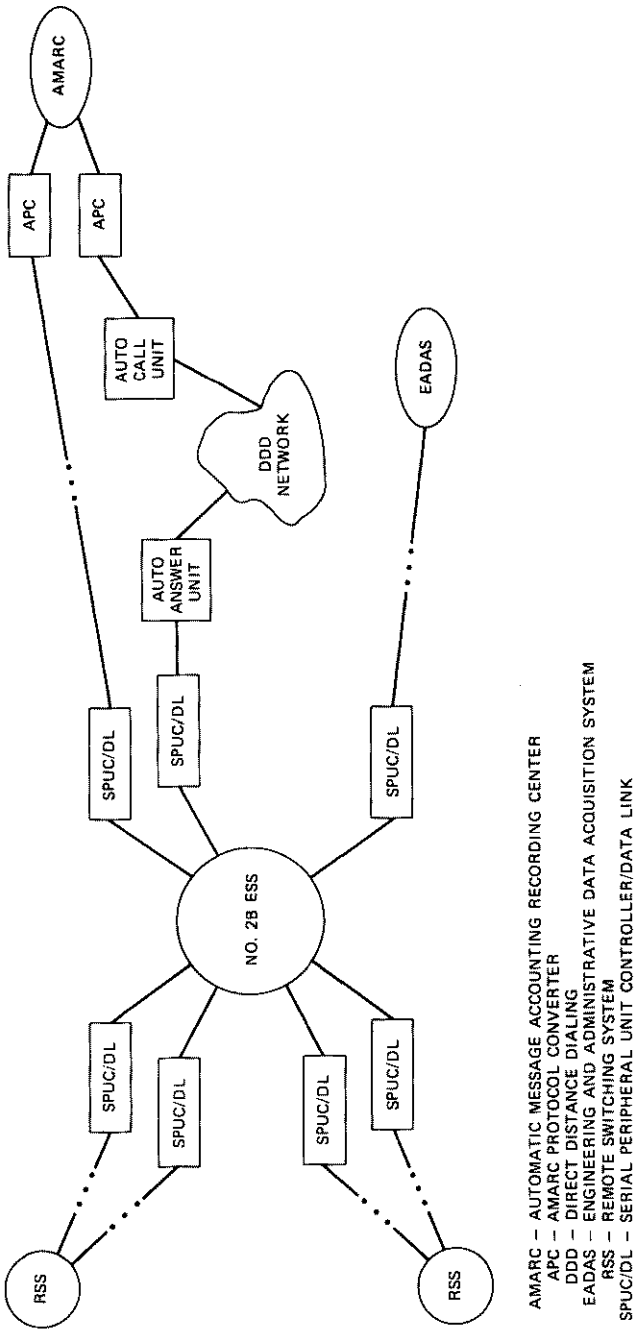

Fig. 3—The three data-link applications of the 2B ESS.

### 3.2 Software for the SPUC/DL

Stated simply, the SPUC/DL software requirement was to implement level 2 of the data-link protocol. Unfortunately, the three data-link applications for 2BE3 required two sets of protocol rules for level 2. The AMARC and EADAS applications use the procedures defined by the BX.25 specifications,[3] which were derived from the CCITT X.25 "Link Access Procedure B" or LAPB. The third application, RSS, uses the older version of the X.25 level 2 procedure "LAP." LAP and LAPB, though similar, are not compatible (LAP cannot communicate with LAPB). However, except for the initial handshake, some error recovery procedures, and a few differences in command formats, the core of information processing procedures is the same.

Initial SPUC/DL applications were to use link speeds of 2400 bps, although future applications of AMARC requiring 4800 bps were foreseen. These requirements can be easily met by a microprocessor device.

Data traveling over common carrier facilities are inherently susceptible to any noise disturbances afflicting such facilities. It is essential that data altered during transmission be detected and the correct data retransmitted. This is the *raison d'etre* for level 2 of X.25. To this end, X.25 employs a 16-bit Cyclic Redundancy Check (CRC) to detect frames altered by noise, and a sequence numbering scheme to facilitate retransmission of frames discarded because of bad CRC. Flow control procedures at level 2 also prevent data loss from buffer overflow.

An additional requirement for maintenance purposes was for some diagnostic capability "on board" the SPUC/DL. The on-board (resides in SPUC/DL memory) diagnostic was to be used by the ESS diagnostic to test hardware inaccessible to the ESS or requiring excessive ESS resources to test. When the ESS wished the SPUC/DL to begin its diagnostic routines, it was to instruct the SPUC/DL operating system to relinquish control to the on-board diagnostic programs. To go back to normal the ESS must issue a master reset of the SPUC/DL, since some diagnostic procedures would destroy the normal operating state.

Diagnostic requirements include a "loop around" test in which data packets would be sent out on the link, directly echoed back by the remote end, and received by the SPUC/DL and 2B ESS. This would normally be a protocol violation in the use of an *address* field at the frame level. We have enhanced the implementation to suspend normal protocol address checking when the diagnostic is running.

### 3.3 Software within the 2B ESS

We discuss here our requirements for both the protocol software and the maintenance, or fault-tolerant, software. Most of the protocol

requirements are general and serve to elaborate on our previous discussion of BX.25.

#### *3.3.1 Protocol-implementing software*

The 2BE3 generic program requires dedicated point-to-point (permanent virtual circuits), full-duplex, 2400 (or 4800) bits per second communication facilities. The No. 2B ESS software implements only those portions of the BX.25 specification needed to meet the 2BE3 generic requirements.

Level 3 of the BX.25 protocol controls the transfer of data between level 2 and the next higher level (the application layer in No. 2B ESS). Transferring includes several processes, namely: packetization, multiplexing, sequencing, and flow control.

***3.3.1.1 Packetization.*** Packetization is the process of a transmitter's dividing large messages into practical-sized packets, transmitting the packets, and having the receiver concatenate the packets to form the original messages. BX.25 does this by setting a "more-data" (M) flag bit in the level 3 header in all but the last packet of a message. The AMARC billing data messages have a maximum of 512 bytes; EADAS thirty-minute traffic data messages vary, with an average of 4,000 bytes depending on the central office. The packet size of 256 bytes was determined appropriate for the throughput desired and the expected error rate of the data transmission facility. If the packet size is large and the transmission facility error rate is high, many packets may receive errors and need to be retransmitted, which decreases the throughput.

***3.3.1.2 Multiplexing.*** Multiplexing is the process whereby a transmitter combines data packets with identical destinations but associated with various application functions (logical channels). The receiver separates (demultiplexes) the packets via the logical channel numbers and distributes them to the appropriate application function. AMARC has a billing-data logical channel, EADAS a traffic-data logical channel, and both applications have a time-of-day logical channel; thus, multiplexing is required with both the AMARC and EADAS applications.

***3.3.1.3 Sequencing.*** Sequencing of BX.25 level 3 data packets is required to assure packets are received in the identical sequential order of transmission. Each level 3 data packet header contains two modulo eight sequence numbers: a send sequence number P(S), which identifies the data packet itself, and a receive sequence number P(R), the expected number of the next data packet received.

BX.25 permits a level 3 transmitter to send a prescribed number of packets to level 2 without obtaining acknowledgment that earlier

packets were received correctly. These unacknowledged level 3 packets sent to level 2 are in the *window* until their reception has been acknowledged. The *window size* of each logical channel is the number of packets that can be sent to level 2 without being acknowledged; the AMARC window sizes are both five while EADAS windows are both two.

***3.3.1.4 Flow control.*** Flow control is provided by BX.25 to permit receivers a method to regulate the rate at which data packets are sent to it. A packet received with send sequence number $n$ is acknowledged with the next packet sent by setting the receive sequence number to $n + 1$. Any receiver having a data-capacity problem may delay the acknowledgment of received packets and avoid data loss.

***3.3.1.5 Requirements for the 10A RSS.*** RSS level 3 was originated with No. 1 ESS before the acceptance of X.25 and is not compatible with BX.25. RSS level 3 messages contain a unique "SYNC word" in the first two bytes. Received messages are discarded if they do not begin with a SYNC word. The SYNC word is manipulated entirely by the RSS level 3 program and is transparent to the No. 2B ESS application call-processing software.

A two-byte remote terminal header following each SYNC word contains the RSS message type in a five-bit "client identity" field. The level 3 software distributes (demultiplexes) received messages to the call-processing application programs by interpreting the client identity. An RSS level 3 header also contains an eight-bit word count field specifying the number of data words in the message.

Packetization of messages is also used in RSS level 3 communication. The maximum RSS packet size is sixteen bytes and the packet boundary is totally asynchronous with messages from an RSS. RSS-bound messages transmitted from the No. 2B ESS always begin a new packet but may require several packets, depending on their length.

Communication concerning only the No. 2B ESS and SPUC/DLs is passed in *control packets* with a unique packet descriptor. A *packet descriptor* is the first two bytes of *all* packets passed between the 2B ESS and a SPUC/DL, identifying the packet type (data or control) and specifying the packet length in bytes. Packet descriptors are not transmitted over the data links. Control packets are external to level 3 and pass directly between the SPUC/DL and its maintenance configuration and diagnostic programs.

***3.3.1.6 Timing requirements.*** We have mentioned previously that the decision to put level 3 in the 2B ESS imposes a penalty in traffic-dependent processing power. In requirements terms, level 3 had to be fast.

*3.3.1.7 Other requirements.* It was foreseen that part of the protocol-handling software package would include low-level routines for physical I/O to each SPUC/DL. Two requirements were imposed on these I/O routines: error routing and monitoring. Packets whose reception was not completely normal were to be routed to the data-link maintenance software. This includes nondata (control) packets, I/O errors, and packets from a nonactive SPUC/DL. A manually invoked monitoring utility was to report part or all the data sent to and read from an application. The monitor proved to be of value during system debugging and integration.

### *3.3.2 Maintenance (fault-tolerant) software*

There were several general requirements assigned to the data-link maintenance function.

1. Initialization and Loading. On certain rare events there may be occasion to reinitialize any or all links in the system. This may require a down-load of the SPUC/DL program from its magnetic-tape residence at the ESS. This would also be done when field-updating SPUC/DL software.

2. Handling Error Reports. Maintenance software is required to maintain records of such reports, which may include frequent loss of facility carrier, low efficiency of transmission, etc.

3. Error Recovery/Link Reconfiguration. Serious faults (e.g., loss of communication with a SPUC/DL) or slow degeneration of a link may require removal of the affected link from service and changing of traffic to the standby link, if available. Thus, data-link maintenance is charged with trying to reconfigure a failing system to maintain traffic.

4. Regulation of the Diagnostic Program. The diagnostic, controlled by the maintenance software, is to be executed automatically when a failure occurs, and routinely on a nightly basis to detect faults on standby links before they are needed in service.

5. Audits. Maintenance "audit" programs were required to check periodically the legitimacy of the control-block database of data-link maintenance, to correct and report single errors, and to reinitialize if multiple errors were found.

6. Console Operator Interface. The final requirement of the data-link maintenance software was to interface with the human operator of the system, providing keyboard input service and output of various responses, as well as spontaneous reports of normal and abnormal events.

### *3.3.3 The diagnostic program*

The diagnostic program had to detect and locate faults in the 2B

processor I/O interface, the SPUC/DL, and the component parts of the transmission facility. In the RSS application, it must also locate faults in the remote data-link control hardware. The diagnostic control structure was required to be sufficiently flexible to permit systematic testing during the installation of the SPUC/DL, the near- and far-end data facilities, and (for RSS) the remote data-link equipment. It had to be able to stress the overall data link enough to recreate faults observable only during heavy traffic.

## IV. DESIGN AND IMPLEMENTATION—SPUC/DL HARDWARE AND SOFTWARE

### *4.1 SPUC/DL hardware*

We can identify three key decisions in the evolution of our design. All three involved hardware/software trade-offs, the software being in the 2B ESS. The first decision involved the scope of the SPUC/DL, as we have discussed in Section II. The second decision was the use of periodic polling of the SPUC/DL rather than program-interrupt hardware. We will elaborate on this in Section V. The third decision was to use writable Random Access Memory (RAM) instead of Read-Only Memory (ROM).

#### *4.1.1 Use of writable memory*

The advantage of RAM is that updates of SPUC/DL software for circuits in the field are much less costly, requiring only software procedures rather than replacement of physical chips. The main disadvantage is that the memory is volatile; the program is destroyed (and must be reloaded by the 2B ESS) if power to the SPUC/DL fails; therefore, software within the 2B ESS had to be developed for downloading. In addition, the SPUC/DL software must have a nonvolatile residence from which it can be loaded. In our case this was to be the magnetic tape cartridge of the 2B ESS. The need for loading would cause concern only if long delays were incurred by the loading process. However, since 2B ESS-SPUC/DL communication proceeds nearly at memory speeds, the loading time mostly comprises the time it takes to retrieve the program from tape.

#### *4.1.2 Logical design*

The data-link controller itself consists of a single 16-bit microprocessor, its associated RAM, and two Direct-Memory Access (DMA) controllers, DMA1 and DMA2. Duplication within a single SPUC/DL is not necessary because of the relaxed reliability the distributed architecture allows. DMA controller 1 is a multiple-channel device allowing data transfers to take place between the 2B ESS and the

SPUC/DL independently of the microprocessor. Similarly, DMA controller 2 provides independent transfers between the SPUC/DL and the transmission facility (see Fig. 4). This architecture minimizes demands on the microprocessor while allowing high throughput. Level 1 protocol is incorporated in a Universal Synchronous-Asynchronous Receiver-Transmitter (USART) and standard interface chips.

### *4.1.3 Physical design*

To meet the requirements of modular growth and high multiple-

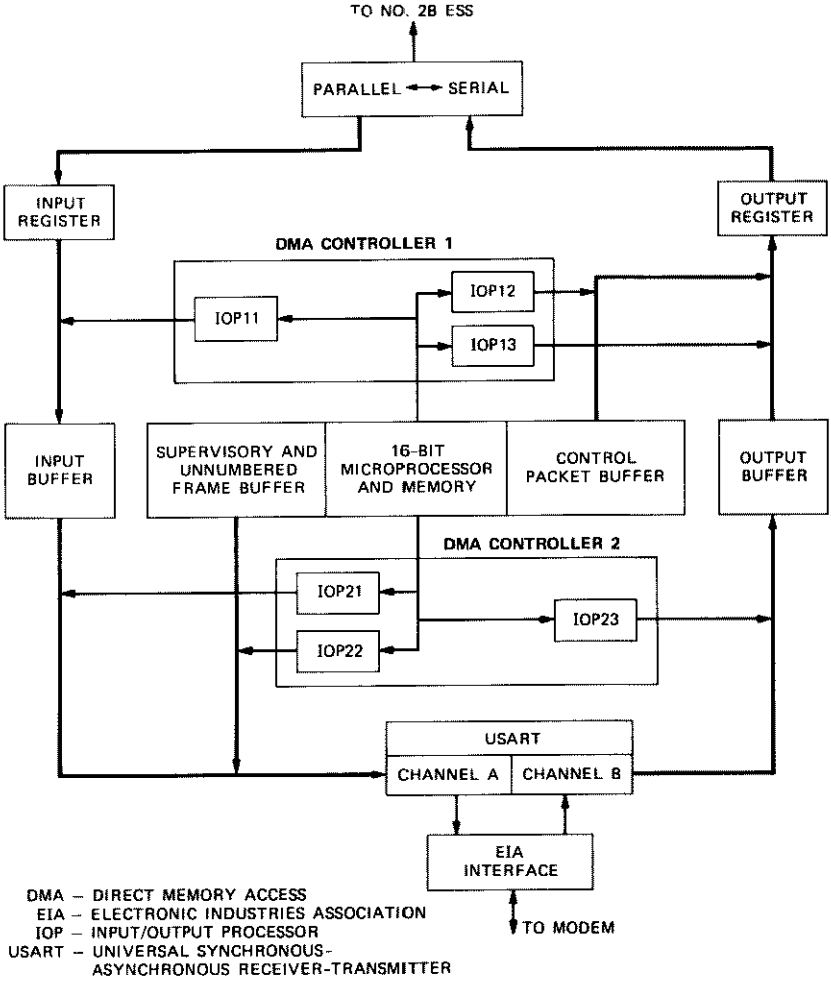

Fig. 4—SPUC/DL hardware components and architecture.

link reliability, each data-link controller was made a separate circuit. Pairs of controllers share a −48 volt power lead. Each SPUC/DL has its own power supply, transmission facility interface, microprocessor, memory, and communications channel to the 2B ESS. There are four printed circuit boards per SPUC/DL, containing the microprocessor and associated logic, memory, the data communications hardware, and the logic for I/O to the 2B ESS. Four complete SPUC/DL circuits, their associated power supplies, fuses, and connectors are housed in a single chassis.

A concentrated effort was made to provide a straightforward maintenance procedure. Each circuit has its own power fuse and modem cable. Each circuit is numbered, and this numbering is used on the circuit board enclosure, power supply housing, power fuse, and modem connector. In addition, each circuit is color coded, and the identifying color appears everywhere the circuit number is used. The 2B ESS SPUC/DL diagnostic program prints both the circuit name and color when it refers to a particular SPUC/DL.

#### *4.1.4 Reliability issues*

To provide sufficient reliability, the data-link controller's memory (program and data) is stored with parity and the parity is checked whenever data are read out or written. In addition, write-protection hardware is provided for the program memory. Any attempt to write into program memory will be prevented, and the 2B ESS will be informed. The status of the SPUC/DL hardware is summarized in a hardware status register that the 2B ESS can read.

The SPUC/DL on-board diagnostic program first computes a check sum over the program memory, tests the data memory, and then confirms proper operation of the microprocessor itself. Once the basic sanity of the microprocessor and correctness of its program is established, the diagnostic program goes on to test both the DMA controller that oversees data-link communication and the USART. The USART is tested by actually transmitting on the link. Additional loop-around circuits at the EIA interface, the associated modem, and the far-end modem allow faults to be isolated and identified easily. This philosophy of testing sections of the controller nearest to the central processor and then relying on those sections to test sections further removed allows economical and rapid fault isolation. Fault isolation is enhanced by partitioning the SPUC/DL into its four circuit boards. All interface circuitry to the 2B ESS is on one board. The second board contains DMA controller 1 and address decoding circuitry. The third board contains all data and program memory. The fourth board has the microprocessor itself, DMA controller 2, and the USART and modem

interface. Since the proper functioning of each board relies on the previous board but not on subsequent boards, most faults can be isolated to a single board.

### *4.2 Software within the SPUC/DL*

Because of the commonality between LAP and LAPB, it was decided to implement both of them in one software load; the ESS would specify one or the other with a parameter sent to the SPUC/DL on initialization. Though this decision increased the space used for code in the SPUC/DL, it eliminated keeping track of which code to download into which SPUC/DL and the need for extra space on the cartridge tape. Separate codes would also have caused complications with the diagnostic. Perhaps the largest factor in the single-program decision was the expense of having to design, code, test, and administer two separate programs.

First we look at the SPUC/DL software structure from a functional data flow viewpoint, and then at the overall structure of the operating system that implements these functions.

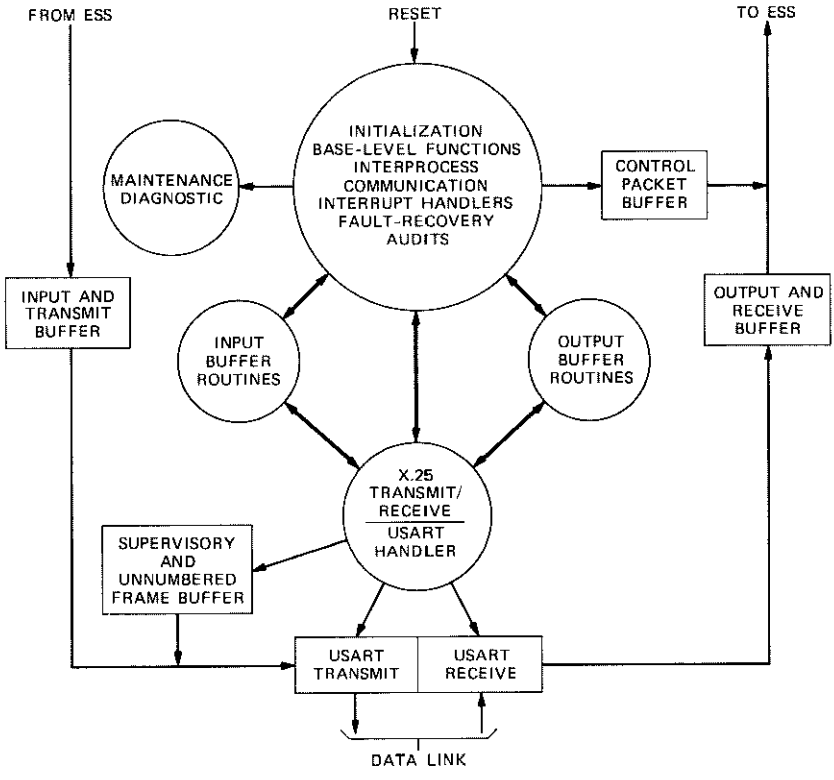
#### *4.2.1 Data flow within the SPUC/DL*

The hardware architecture of the SPUC/DL shown in Fig. 4 closely parallels the flow of data through the device. Internal to the SPUC/DL the send and receive processes run simultaneously. Data packets from the ESS enter the input buffer under control of DMA1 and are cataloged by the input routines, with *control* packets (messages for the SPUC/DL itself rather than for transmission) being processed immediately. Once packets have been cataloged, they are processed by the X.25 routines, which assign sequence numbers and set up the DMA2 transfer to the USART for output over the link as X.25 frames. Simultaneously with transmission, frames are coming in from the receive channel of the USART, are processed by the X.25 routines, and pointers to information frames are passed to the output routines. The output routines add packet descriptors to the information frames, and then set up the DMA transfer to the ESS.

This is a high-level view of the SPUC/DL and there are many other software processes involved in its operation, including maintenance routines, which play a large role in support of data handling.

#### *4.2.2 SPUC/DL Operating System*

The SPUC/DL Operating System may be visualized as a hierarchical multiprocessor operating system. In this system the 16-bit main processor acts as a master while the six individually programmable DMA channels are slave processors. Once a DMA channel has been



ESS – ELECTRONIC SWITCHING SYSTEM
USART – UNIVERSAL SYNCHRONOUS-ASYNCHRONOUS RECEIVER-TRANSMITTER

Fig. 5—SPUC/DL software processes; interprocess communication has been emphasized.

given a process, it will run that process to completion without further attention from the master. We denote these single channels as I/O processors, or IOPs. Most interprocessor communication is one way between the master and the IOP. Interprocess communication is handled using producer/consumer semaphores.

Figure 5 shows how the SPUC/DL software processes use the hardware to carry out the data communications function. Each I/O processor handles a specific I/O function. Communication between the SPUC/DL and ESS is handled by three channels of DMA1. In Fig. 4 they are labeled IOP11, IOP12, and IOP13. IOP11 runs the process of moving data from the input register to the input buffer. Once the SPUC/DL has been initialized by a master reset, the master processor starts this process running on IOP11. This process runs continuously and becomes inactive only when input buffer space is

exhausted or the process may be preempted by the microprocessor for status updates. This status information consists of "where will the next word be placed in the input buffer," or "deallocate *n* input buffer words." Unlike IOP11, IOP12 and IOP13 run only when there are processes scheduled for them (packets to be sent to ESS). IOP12 transfers control packets from scratch memory to the output register and IOP13 transfers data packets from the output buffer to the output register.

The DMA2 processors have almost mirror-image functions. IOP21 moves packets from the input buffer to the USART where they are serialized and sent out over the link. Packets are scheduled for IOP21 on a first-in/first-out (FIFO) basis with priority for packets being retransmitted. IOP22 moves supervisory and unnumbered frames from scratch memory to the USART. IOP23, which moves data in from the link, does not run continuously because of the intervention of the master processor to handle alignment of the start of incoming data. All other processes are run by the master processor, including the considerable primary task of processing X.25 frames.

#### *4.2.3 SPUC/DL software reliability*

In developing SPUC/DL programs considerable attention was given to reliable software design through modularity. Both the SPUC/DL Operating System and the level 2 procedures were coded in the C language and a top-down design structure was used wherever practical. Assembler-level code was used only where necessary for speed or to handle hardware-dependent functions. The high-level language had advantages both from an implementation and a testing standpoint. However, because both the hardware and software were new to us, during debugging it was occasionally necessary to look at the assembly code or binary output of the C compiler to determine the source of some problems.

The hardware of the SPUC/DL provided three features that also enhanced software reliability. First, the use of DMA hardware controllers for I/O eliminated the need for complex scheduling algorithms to move blocks of data. This is especially important in an I/O-intensive application such as a data-link controller. Second, write-protection hardware was provided. Since the program store of the SPUC/DL is in writable memory, without the write-protection feature of the hardware, the program would be vulnerable to bugs that alter the program itself. If a write-protect violation occurs, the SPUC/DL software is not altered but an interrupt routine attempts to save as much pertinent information as possible and then proceeds normally. The ESS is notified by a message from the SPUC/DL containing the hardware status register. The third hardware feature is a "sanity" timer, which

expires unless periodically serviced by the software. The timer guarantees that the microprocessor will not get stuck in any one place for an inordinate amount of time. If the sanity timer should expire, an interrupt is generated and is handled similarly to the write-protect error.

In addition to the hardware mechanisms mentioned, reliability is increased by periodic software audits. The audits check major global data structures, looking for inconsistent or out-of-range values. No attempt is made to correct audit-detected errors. The event is reported to the ESS, which prints a message.

### *4.3 System performance*

The SPUC/DL software has an average one-way delay of about 4.5 ms. It has been tested at 5 to 10 times the speed expected in initial field use.

## V. 2B ESS HOST SOFTWARE

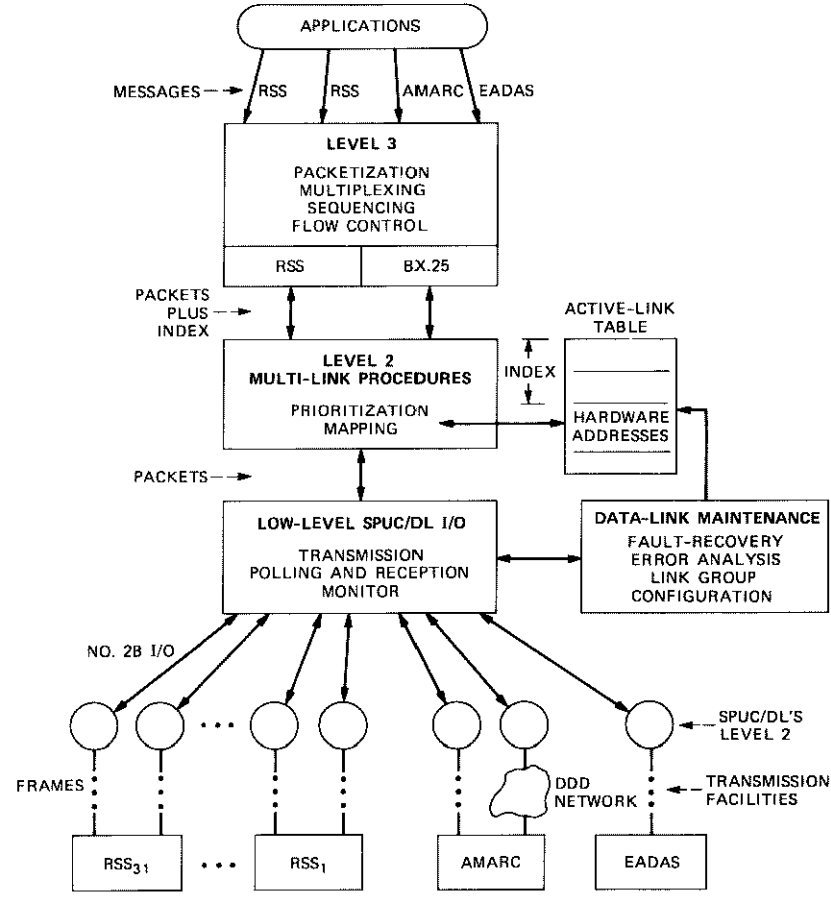
### *5.1 Architectural overview*

Figure 6 is a high-level diagram of the data-link software in the 2B ESS. When they have a message to transmit, call-processing routines, billing routines, and data-collection routines enter appropriate points in level 3. Level 3 converts the messages into packets, breaking large messages into multiple pieces if necessary. Multiple logical channels (logical destinations) are sorted for their physical destination (multiplexing). Appropriate sequence numbers are attached. The packets are transmitted immediately, if possible, or put on a queue if flow is currently under control.

When the packets are ready to be transmitted, the software passes them to the level 2 Multi-Link-Procedures. These routines sort the packets by priority, and then do a *mapping* to a definite hardware address (i.e., physical SPUC/DL). The mapping is done through a table managed by the data-link maintenance software. Thus, the routines doing transmission need have no knowledge of which link they are using.

The Multi-Link-Procedures pass the packets to the low-level transmission software, which physically outputs them to the SPUC/DL whose hardware address was passed as an argument. The link-traffic-monitoring utility is implemented at this level. Level 2 in the SPUC/DL ensures error-free transmission to the destination.

The inverse process, packet reception and assembly into messages, is similar. Note that on reception, not all packets get routed to the Multi-Link-Procedures. Control packets originating within the SPUC/DL, and information packets from links not currently active are given to the data-link maintenance software. The maintenance



AMARC – AUTOMATIC MESSAGE ACCOUNTING RECORDING CENTER
DDD – DIRECT DISTANCE DIALING
EADAS – ENGINEERING AND ADMINISTRATIVE DATA ACQUISITION SYSTEM
RSS – REMOTE SWITCHING SYSTEM
SPUC/DL – SERIAL PERIPHERAL UNIT CONTROLLER/DATA LINK

Fig. 6—Data-link software within the No. 2B ESS.

software also uses the low-level common I/O routines to transact its business with each SPUC/DL. In this way the monitoring utility will report *all* communication to any link or link group.

### *5.2 Device polling and timing considerations*

To have the SPUC/DL request attention from the 2B ESS, a polling method was adopted owing to complications in the 2B ESS demand-interrupt hardware. When it requires attention from the 2B ESS, the SPUC/DL sets a bit in its status register. The status register's bit controls a *ferrod*, a ferrite device whose magnetic state may be sensed

under program control by a *scanner*. These particular ferrods are arranged in rows of 16, so the status of 16 SPUC/DL "packet-present" ferrods may be read simultaneously. Once every base-level loop (100 milliseconds) the 2B ESS will poll all scanner rows containing SPUC/DL packet-present ferrods.

Clearly, such polling is inefficient; for polls on which no SPUC/DL has data, the polling time is wasted. The total time available for processing calls is reduced, and so therefore is the performance of the 2B ESS. The actual time penalty depends on how fast the software is. In our case the loss is around 0.6 percent with idle data links.

Of greater concern are the effects of measured-service billing (billing every telephone call) to the AMARC, and of RSS data-link traffic (several messages are required per call). In the AMARC case, the data links shorten the time spent on billing by about 30 percent relative to the previous use of magnetic tape. In the RSS case, only around 7 percent of the real-time of a typical call is due to the presence of the SPUC/DL. We can conclude that level 3 processing and programmed I/O to each SPUC/DL are not serious drains on the time available to the ESS, relative to its other tasks.

### *5.3 Maintenance software*

The link(s) from the 2B ESS to any single remote site make up a *link group* of one or two links. It is the task of data-link maintenance to ensure that a link is always active in every link group.

#### *5.3.1 Architecture*

The highest-level component of data-link maintenance is called *link-group control*, and has responsibility for keeping a link always active in every group. Because of the substantial differences in the three main applications, link group control was divided into three independent sections, one handling the EADAS link group, one handling the AMARC link group, and one handling all RSS link groups.

Link-group control depends on a collection of utility routines called *link-state control*, which performs tasks on single links, independent of the type of link group of which the link is a member. Conceptually, a given link may be thought of as controlled by, or belonging to, either link-group control or link-state control (but not both) at any one moment. Link-group control manages links that are "in service," that is, actively carrying data ("active") or available for such use if needed ("standby"). Link-state control operates on links that are "out of service" by virtue of having been "removed"—either automatically after detection of a fault, or manually through issuance of a console keyboard command by the operator of the system.

The link-state-control routines depend in turn on a *loader* for down-

loading the SPUC/DL software from its residence on the system magnetic tape cartridge, and on the diagnostic program, which is described in more detail below.

The software of the 2B ESS continuously executes a fundamental "base-level loop" of some 100 milliseconds. Within the loop various functions are given control with the understanding that no function will exceed its own allotment of time. That is, instead of being driven by a clock interrupt, context switches (task changes) are the responsibility of the base-level routines themselves. They must save and restore their own contexts if completion of their functions requires more than one allotment of loop time. For this purpose and for keeping longer-term records, data-link maintenance makes use of control blocks.

#### *5.3.2 Data structures*

Two main types of control areas are maintained by the software. The link-group control keeps a link-group control block for each link group. In addition to current-function context information for link-group control, records are maintained of the number of changeovers between links in the group. This can prevent thrashing back and forth during periods of trouble, such as a lightning storm. In general, this block is intended for those records associated with the entire group, rather than with one specific link.

The second main type of control block is maintained by the link-state control routines, and is called a link-state control block. One such block is reserved for every link defined in the 2B ESS database. Here is stored information on the current context of link-state control for each link. In addition, a collection of records is maintained about the recent history of each link. For example, it is remembered at what time the diagnostic program was last run (to prevent too frequent use of the diagnostic), as well as its result. Over 30 fields are reserved for counting each of the types of errors reported by the SPUC/DL or recognized by the 2B ESS. Cumulative counts are also kept for each of several classes of errors, a class being defined by its relative seriousness.

The other major data structures used by data-link maintenance are the permanent (read-only) office records defining the data links present and their attributes (modem type, hardware address, etc.) These structures are accessed through special database routines.

#### *5.3.3 Recovery strategies*

The primary strategy for recovering from data-link failures is to use the redundancy engineered into the system—that is, to move link traffic to the other link in a two-link group.

The 2B ESS can detect failures of various natures and degrees of severity. The most obvious and straightforward is an inability to communicate with the SPUC/DL because of failures of hardware input or output orders. Here it is first attempted to change, if possible, to the standby 2B ESS processor to see if the orders can then be executed. If not, the fault is classified as *hard*. This is the fault detected when the power supply of a SPUC/DL fails (or is turned off).

A wider range of problems can be discovered by the checksum mechanism. During initialization sequences and when returning an out-of-service link to service, the ESS resets the SPUC/DL by setting a bit in the status register. This action forces the SPUC/DL program counter to an absolute address where its initialization code begins. As part of this code, a checksum is computed on the entire program memory of the SPUC/DL. The computed checksum is returned to ESS along with a prestored value it is supposed to match. The return of a matching checksum shows that the ESS can access the SPUC/DL, that the processor within the SPUC/DL is functioning, that the program is loaded and is probably correct, and that the device is in a known state. A bad checksum probably means a memory fault. In an emergency, a link can be "forced" into service even with a bad checksum comparison, so long as some checksum is returned.

Some symptoms are generally associated with the carrier facility rather than the data link. As mentioned previously, when troubles such as carrier loss are encountered, they are recorded. Noise on the facility will cause low link *efficiency*, defined as the ratio of bytes acknowledged properly to the total number transmitted. These troubles and a variety of others are individually counted within the data-link maintenance software. When the cumulative counts of such errors exceed some threshold value, recovery action begins. The counts of each type of event are weighted by their relative seriousness or impact on the system. The recovery strategy for these (individually) "nonfatal" errors is to compare the recent history of such errors for both links in an RSS link group, changing links if the standby SPUC/DL seems better. In an AMARC link group, since there is no guarantee that a standby link is available at the AMARC site, the 2B ESS must depend on the AMARC to detect facility problems and to change links. Only a severe problem will cause the 2B ESS to remove an AMARC link.

#### *5.3.4 Changing links*

The operation of changing traffic from one link to another in a link group is fundamental in the data-link recovery strategy, and required considerable development effort. The two applications for which the

operation is required, AMARC and RSS, are quite different. We will give a brief overview of each.

*5.3.4.1 Changing AMARC links.* The change operation on an AMARC link group attempts to follow the BX.25 protocol in most respects. Carrier is detected on the standby link after automatic dialing and answering hardware completes the connection via the DDD network. The ESS sees that the AMARC machine issued a "disconnect" on the primary link within its protocol level 2. Next, level 2 of the protocol becomes active on the standby link. Suitable security precautions are now taken to ensure the connection is genuine. Finally, level 3 of the protocol begins, and the operation is complete.

In the other direction the procedure is simpler. After the protocol has initialized at level 2, receipt of any information frame on the primary link will cause the 2B ESS simply to disconnect (hang up) the standby link.

*5.3.4.2 Changing RSS links.* For historical reasons, changing traffic between RSS links is complicated. The procedure was originally developed for the 1/A ESS. As we described in Section II, in the 1/1A environment both RSS links are connected to a single processor, the PUC/DL. Since there is no level 3 protocol for the RSS, resetting protocol level 2 (such as might be expected when changing links) has serious repercussions. Level 2 resets cause loss of data because they clear frame buffers. In the PUC/DL a changeover procedure was designed so no level 2 reset would occur and no data would be lost. The PUC/DL transfers the outstanding frames and current values of the protocol parameters (sequence numbering) to the new hardware by changing a pointer in its database. Thus, after changing links the old level 2 is running on the new link. Similar actions occur in the RSS; no reset of level 2 takes place, and no data are lost.

Since it was part of our design goal to leave RSS code unaltered, it was necessary for the 2B ESS and SPUC/DL to emulate the actions of the PUC/DL during the changing of the links. This was done by the following sequence: (1) protocol level 2 is brought up on the standby link, though transmission of data is disabled; (2) transmission stops on the active link while it is emptied of received data; (3) untransmitted and transmitted but unacknowledged data are read out of the active link and written into the standby link; (4) the protocol state of the active link is transferred to the standby to preserve the sequence numbering; (5) a "change links" message is transmitted to the RSS on the standby link, which turns the standby into the active link, and causes the RSS to change also.

### *5.4 Diagnostic software for the SPUC/DL*

Fault location for the SPUC/DL data links can be best characterized

by its diversity. The diagnostic must contend with three different link configurations—AMARC, RSS, and EADAS—each having its own testing requirements. There are three execution environments: the 2B ESS, the SPUC/DL microprocessor, and for RSS, the remote terminal microprocessor. In addition, the diagnostic faces unusual conditions within the 2B ESS. It must be executable in the off-line processor, and must accommodate several instances of itself executing in parallel.

We have added two features to the diagnostic that are new to the 2B ESS. First, the SPUC/DL diagnostic specifies explicit replaceable units in the TTY output messages, rather than coded trouble location information. Second, to simplify installation and growth of a SPUC/DL configuration, we have implemented *partial* diagnostic capabilities—the ability, for example, to run only the first few tests so uninstalled hardware will not cause error messages.

To achieve flexibility in dealing with different link configurations, the diagnostic was organized for table-driven execution of independent tests, the table being specified either by the application type, as defined in the 2B ESS database, or by an operator-generated input message. This permitted maximum use of common diagnostic code, yet flexibility in tailoring specific tests for specific applications. The table also provided a simple means of providing special test functions not normally run—for example, an exhaustive SPUC/DL program memory test rather than the checksum test normally used by the routine diagnostic.

The diagnostic proceeds with the 2B ESS executing directly initial interface tests to the SPUC/DL, then requesting the SPUC/DL to run tests of its internal hardware. It then uses the SPUC/DL to do analog loop-back testing to the local modem, followed by digital loop-back to the remote modem, and finally (for RSS) requesting remote terminal hardware tests to be run. For those tests not executed by the 2B ESS, the diagnostic acts as a control program and analyzes data to convert the cryptic test failure information into human-readable messages specifying the replaceable unit.

While most of the diagnostic tests for the SPUC/DL data links use conventional diagnostic testing techniques, the digital (remote) loop attempts to find faults normally discovered under heavy-traffic conditions. This test sends 1000 sixteen-byte packets from the 2B ESS through the SPUC/DL, over the link, through the remote loop-back, and back to the ESS through the SPUC/DL. The SPUC/DL uses its operational link efficiency algorithms to quantify the quality of the link. A link is reported as a good link, a failing link, or a "degraded" link—usable but performing below what is considered optimum.

After a fault has been repaired, it is necessary to test the 2B-SPUC/DL interface from both the on-line and off-line central processors.

This ensures not only that faults in the off-line interface are located but that repair of an interface board has not introduced a fault in the standby processor to SPUC/DL interconnection.

The SPUC/DL diagnostic is the first program to take full advantage of a newly enhanced 2B ESS software subsystem for maintenance, which provides a degree of multitasking convenience. Use of the "Multi (base-level) Scan Function" (MSF) program allows for multiple simultaneous executions of the diagnostic on different data links with a single copy of the diagnostic and several instances of its data memory, one for each execution. The only significant complication is message routing from each SPUC/DL to the appropriate data memory, which is done through interfaces with the I/O and the data-link maintenance programs.

## VI. PROJECT POSTMORTEM

### *6.1 Problem areas during development*

Though the difficult problems of the project integration phase are freshest in our minds as this paper is written, there were problems of various kinds throughout the project. The most difficult *technical* problems in the data-link area were met in the integration and final debugging phase of the project. The problems were usually lost words of data, or protocol failures that stopped communication. They occurred randomly in time, usually when data-link traffic was high, and were not easy to reproduce. At least three factors interacted to increase the difficulty in solving the problems.

First, the SPUC/DL test facility did not have enough capacity to stress the links. Only the 2B ESS laboratories could drive the links at the acceptance-test levels, and time in these laboratories was in great demand by people working on all aspects of the 2BE3 generic program. The SPUC/DL test facility was improved, but only after it was clear that serious but infrequent problems were present in the SPUC/DL. The test-facility shortcomings meant that the SPUC/DL had more problems than it should have during the integration phase. The service-affecting problems had been mostly resolved by the time the test facility became really adequate.

The second factor lies in the distributed nature of our systems: with three asynchronous processors, it was often difficult to isolate where any particular problem arose—the 2B ESS, the SPUC/DL, or the application (AMARC, EADAS, or RSS).

Third, debugging tools for the system as a whole lacked some desirable features. The 2B ESS laboratories had powerful debugging hardware for halting the processor, dumping memory locations, tracing execution paths, etc. These facilities were not available on the SPUC/DL, particularly in the late stages of the project when factory-made

units were installed in the laboratory to find any remaining troubles in the production hardware. There were several occasions where it would have been very desirable, for example, to have an event within the ESS halt the microprocessor within the SPUC/DL. We mention in passing that a commercially obtained data communications analyzer proved to be a key instrument in finding certain protocol problems. Ours could record data traffic onto a cartridge tape, stopping after an event of interest; it could also recognize X.25 frame and packet types.

The last few insidious problems in the SPUC/DL turned up in both the hardware and software. The hardware problems were typically sensitivity to "glitches," causing, for example, an erroneous extra DMA cycle. The software problems were usually those of process synchronization and shared resources. The internal architecture of the SPUC/DL, both hardware and software, supports a high degree of concurrency. This increases throughput and minimizes delay, but leads to these internal process synchronization problems. Perhaps more rigorous monitors for shared resources and synchronization semaphores would have paid dividends during the integration phases.

### *6.2 Particularly successful areas*

The problems outlined above led to intense activity as the project neared completion. We were relieved, however, to experience a happy ending; the underlying problems were found and corrected for all observed symptoms.

The climax of our development effort came with the acceptance test for the first 2B ESS—10A RSS field installation. During the 24-hour test, some 60,000 telephone calls were originated on the RSS, processed by the 2B ESS through the SPUC/DL, and properly completed back to the RSS. There were no indications of any problems in the data-link area.

It seems to us that one factor contributing to this success was the attitude that the problems should be *understood* and solved. It might be possible, for example, to stop printing an error message if the message announces some event that seems not to have a harmful effect on the system. We have chosen to explore such events as deeply as resources permit, with gratifying results.

Thus, we feel we have a data-link system essentially free from operational errors. It remains to be seen if our reliability goals will be met.

## VII. ACKNOWLEDGMENTS

We acknowledge the considerable contributions of several people to various phases of the project. G. Dobrowski was involved with the

preliminary analysis leading to the architecture of the system. Most of the original SPUC/DL hardware design is by T. Peterson. T. Brinkman assisted with the initial versions of the SPUC/DL microprocessor code. W. McCalla was responsible for most of the original design and strategy decisions in the data-link maintenance area. Much of the data-link maintenance coding was done by R. Atkins, E. Bily, and H. Williams. J. Kent and D. Sikora produced the program for the 2B ESS to diagnose the SPUC/DL. We thank D. K. Ford and S. C. Yuan for their contributions to troubleshooting the hardware, G. Mannon for assistance with modem issues, and D. R. Bierma for continuous attention to testing and administering new issues of both hardware and software.

## *Modernization of the Suburban ESS:*

# Hosting the No. 10A Remote Switching System

By D. W. BROWN,* J. J. DRISCOLL,* F. M. LAX,* M. W. SAAD,* and J. G. WHITEMYER*

(Manuscript received August 31, 1982)

The No. 10A Remote Switching System (RSS) has brought a new dimension to telephone switching in the rural area. The capability to host a 10A RSS was first made available on the metropolitan switches, the No. 1 and No. 1A ESS. The capability has now been extended to the suburban switch, the No. 2B ESS. This article describes the additions and modifications made to the No. 2B ESS to allow it to host the 10A RSS. The discussion also covers the administrative and maintenance features provided and their associated host software implementation.

## I. INTRODUCTION

### *1.1 Definition and basic description*

A local Electronic Switching System (ESS) provides the call control for a 10A Remote Switching System (RSS). The 10A RSS acts as a slave executing orders sent to it from the host ESS and reports events, such as line originations, to the host. A major advantage of this type of distributed control is that the complex tasks of call processing can use existing host software and share host equipment and trunking facilities. This sharing of host ESS software makes it possible to easily

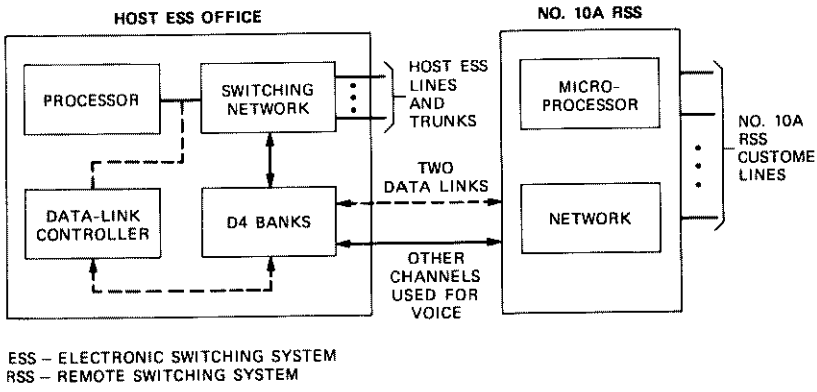

Fig. 1—RSS configuration using digital carrier.

provide RSS lines with the sophisticated features that are offered to host ESS lines.

The major components required for 10A RSS operation include a host ESS, one or more 10A RSS frames, a data-link controller, interconnecting voice channels, and data links. Figure 1 shows this configuration for an application using digital connectivity between the host ESS and a 10A RSS (remote terminal). At this time, the host function has been developed for the Western Electric No. 1 ESS, No. 1A ESS, and No. 2B ESS machines. The data links are used for communication between the host ESS and the 10A RSS and provide the means by which orders from the host are transmitted to the 10A RSS and acknowledgments are returned to the host. Voice channels are used to provide the RSS lines with access to the host network and are selected dynamically. The data link employed for the No. 2B ESS-RSS communication function is a new design utilizing an intelligent Serial Peripheral Unit Controller Data Link (SPUC/DL).* The 10A RSS data-link communication makes use of portions of the X.25 protocol.

The 10A RSS basic frame can serve up to 1024 lines. A companion frame may be added to allow up to 2048 lines to be served by a single RSS entity. The design is such that the basic element of growth can be as small as eight lines. Voice and control communications between the remote and the host can be made over either digital or analog carrier facilities and the range may be as great as 280 miles, depending primarily on the type of transmission facility.

In the event of total carrier system or data-link outage, the 10A

* Acronyms and abbreviations used in this paper are defined at the back of this Journal.

RSS is arranged to automatically transfer to a stand-alone mode of operation, which provides basic telephone service between stations connected to that RSS unit. In the stand-alone mode, special provisions can be made to handle emergency types of traffic such as "911". Details regarding stand-alone operation may be found in an earlier BSTJ article, "Remote Terminal Firmware," by D. A. Anderson et al. in the April 1982 issue on the 10A RSS.

All major units of the 10A RSS are duplicated, and a continuous dialogue is exchanged between the host and remote site concerning the overall health of the system. The basic system philosophy is that the remote unit is a complete slave to the host and merely reports events to the host; the RSS then receives a stream of explicit orders from the host concerning that event. All maintenance procedures must be controlled from the host. Initiation of diagnostics and other functions may be further remoted to a Switching Control Center (SCC).

## II. CALL PROCESSING

### *2.1 Data communications*

#### *2.1.1 Hardware overview*

Figure 2 shows the 10A RSS—No. 2B ESS host interface and the

USC – UNIVERSAL SERVICE CIRCUITS

Fig. 2—10A RSS—No. 2B ESS host interface.

hardware components involved in the transmission of data between the remote terminal and the host. Communication between the two machines takes place over a pair of low-speed data links that share the same transmission facilities as the voice channels that interconnect the remote terminal with the host. Each data link is placed on a separate transmission facility for reliability. Where carrier facilities are used, the links are assigned to a dedicated voice channel on the carrier system, with each link being assigned to a separate carrier terminal.

Both RSS links are 2400 bps synchronous links. The on-line link is active and carries the entire data traffic between the host and 10A RSS, while the off-line link is maintained in a standby state as a spare. The on-line, off-line status of the links is determined by the host office and is based on error information accumulated by the software responsible for driving the links. At the remote terminal the link is interfaced to the RSS microprocessor through a Data-Link Interface (DLI) circuit. The DLI provides a small amount of data buffering and performs a number of control functions essential to implementing the synchronous link protocol.

At the host, the link interfaces with a functionally similar line interface unit that is part of the SPUC/DL. The function of the SPUC/DL is to provide the control for physically transmitting and receiving data on the links and to provide data buffering for the host office. The data being transmitted and received by the SPUC/DL are buffered on a per-link basis within the terminal. Sufficient data buffering is provided to allow the host to efficiently exchange large blocks of data with the terminal on a schedule that is efficient to the host.

#### *2.1.2 Software overview*

The routines that control the data transmission between the remote terminal and host are located in the remote terminal, the SPUC/DL, and the host office. There are two basic functions to be performed: data must be transferred reliably over the link and an interprocess communication system must be provided to allow software processes in the host to communicate with processes in the remote terminal. These two functions are provided by the data-link protocol software and a set of message-routing routines. The protocol provides virtually error-free transmission of data over the link by executing a set of error-detection and error-correction procedures. The message routines allow a process in one machine to direct a message to a process in the other. These two systems are largely independent and bear a hierarchical relationship to one another in the sense that the message routing routines rely on the link protocol routines to accurately transmit data from one end of the link to the other.

### 2.1.3 Data-link protocol

The protocol routines are executed in the remote terminal and the SPUC/DL. The 10A RSS application uses the link-level portion of the X.25 protocol to control the link. It is a bit-oriented protocol designed for synchronous link operation. To provide for error detection and correction, the data to be transmitted are segmented into numbered blocks termed frames. As frames are transmitted they are sequentially numbered and a cyclic check code is computed over the data in the frame. The frame numbering scheme makes it possible to identify frames for retransmission and to detect missing frames in the received data. As frames are processed at the receiving end of the link, the cyclic check code is recomputed and compared to the one transmitted with the frame. A mismatch indicates that a transmission error has occurred. A positive acknowledgment is returned to the data transmitter for all frames received correctly, and a retransmission request is returned if a frame is received in error.

The protocol software at the SPUC/DL has the additional function of providing link status reports to the host machine. Error conditions such as high transmission error rate, frame acknowledgment timeouts, and loss of data carrier are monitored by the protocol and reported to the host. The transmission error rate is determined from the number of retransmission commands received and sent by the SPUC/DL protocol program. From this data the host data-link state control can take action to remove a link from service if it becomes inoperative or if its throughput is restricted because of excessive data errors.

### 2.1.4 Message-routing routines

The routines that are responsible for routing data between individual processes in the two machines are executed by the remote terminal and the host processor. These programs assume that data received from the link protocol programs are error free and that any additional error control procedures for detecting transmission errors are unnecessary. These programs are designed to transmit data between buffers associated with client programs in the two machines. A program having data to transmit will load the data into its associated buffer. The buffer will be activated for the message-routing routines and the data will then be transferred to a buffer associated with the destination program in the other machine. The message format is shown in Fig. 3.

### 2.1.5 Host data transmission

The buffering technique adopted for the transmission of peripheral orders to the remote terminal was designed to be compatible with the structure of the existing host software. The order buffering and mes-

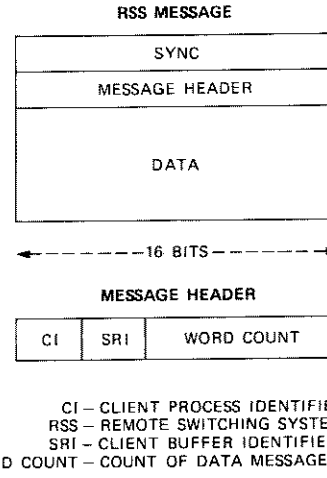

Fig. 3—RSS message structure.

sage transmission must be tailored to the host software structure if the existing call-processing and maintenance routines are to be preserved. A few remarks on the nature of the call-processing programs are necessary to understand the interface requirements.

The host call-processing programs are divided into call segments that process an input from a subscriber or a peripheral circuit to completion in one real-time segment. All the peripheral orders required to process the input are generated by the separate set of input/output (I/O) programs. Peripheral operations in the host or remote terminal take tens or hundreds of milliseconds to execute, which precludes their direct execution within the call segment. During execution, a typical program segment may generate several remote terminal peripheral messages that are destined for different RSSs. In most cases it will also generate a number of orders to be executed in the host periphery in conjunction with the remote terminal actions. The execution routines must be able to coordinate the transmission of the remote terminal orders to the different RSSs. Frequently, it is necessary to execute the remote terminal-host peripheral actions in a predefined sequence where either the host or the remote terminal action must occur first.

The call-processing and maintenance programs are coupled to the I/O programs through a set of I/O buffers that are loaded with the peripheral orders to be executed. All host peripheral orders are buffered in Peripheral Order Buffers (POBs), where they are executed by the POB execution programs designed to handle the timing requirements presented by the host periphery.

A set of Remote Order Buffers (ROBs) in the host machine buffer

the peripheral orders being transmitted to the remote terminals. They are loaded and administered by the call-processing programs in the same manner as the peripheral order buffers. The orders to be sent to the remote terminal are loaded in the ROB via a set of order macros that provide a high-level interface with call processing. When order loading is complete, the ROB is activated and the I/O routines transmit the orders to the remote terminal. An individual ROB may be used to send orders to any RSS. The host can have any number of ROBs pending to send orders to an RSS; however, each remote terminal has a fixed set of eight ROB records that are used to store orders received from a ROB at the host. The ROB records are buffers associated with the peripheral order execution program in the remote terminal that executes the orders transmitted from a ROB.

#### *2.1.6 ROB execution protocol*

A rudimentary protocol has been established to coordinate the activities of the call-processing routines at the host with the execution of ROB orders at the remote terminal. Several orders will be grouped together into a single message at the host to be transmitted to the remote terminal. The orders in the message are executed at the remote terminal and upon completion an acknowledgment is returned to the host. The acknowledgment will indicate whether all the orders in the message were successfully executed and must be received by the host before any further actions will be permitted on this call. If the remote terminal encounters a failure in executing an order, the acknowledgment message will specify the failed order to the host and the remote terminal will suspend execution of all remaining orders in the ROB record.

It is essential to receive a positive confirmation on the status of the orders for several reasons. If an order failure occurs, the host fault-recovery routines can be scheduled to clear the call from the system. In addition, the acknowledgment allows the host to correctly sequence any other peripheral actions with the remote terminal orders. When the acknowledgment is received, the host can activate an associated POB or return to a call-processing program to implement the next action on the call. The restriction that additional RSS orders will not be transmitted until the acknowledgment is received also prevents the host from transmitting multiple sets of orders for the same call that would be executed in an arbitrary sequence at the remote terminal.

### *2.2 RSS network associated data*

The processing of RSS calls requires the allocation and management of resources that are physically located at the 10A RSS or shared between the host ESS and the 10A RSS. These resources include the channels that interconnect the host and 10A RSS, receiver off-hook

(ROH) tone circuits located at the 10A RSS, and the 10A RSS network crosspoints. Also, the status of RSS lines is maintained at the host. Several factors were considered in deciding whether to place these functions in the 10A RSS or in the host ESS. These factors are:

1. The effect on service because of the additional time delay if the 10A RSS has to be interrogated to determine line status and to hunt voice channels and network paths.
2. The additional software development required if the host ESS programs have to take a real-time break to interrogate the 10A RSS to obtain a line's status. Host software is structured around data that can be accessed without taking a real-time break.
3. The duplication of development effort that is required to provide the same functions in several host ESS systems.

Factor 3 indicates that the overall development effort would be reduced by placing the line, channel, and 10A RSS network path administration in the 10A RSS. However, the service criteria and the effect on the existing host software were judged to be more important. Therefore, these functions are allocated to the host ESS.

The overall development effort is reduced by making the program and data structure designs independent of the host ESS. Thus, they are highly portable between ESS machines. This section describes the data structures required to administer the RSS resources.

#### *2.2.1 Data structures*

Data structures are required in the host ESS memory (call store) to record the status of the RSS facilities and to provide for their administration. To simplify the engineering of the office, these data structures are provided in sizes that correspond to the three basic network sizes of the 10A RSS. Each of these structures is described below.

***2.2.1.1 Network block.*** One network block is provided for every 10A RSS. Its size is fixed regardless of RSS equipage. Among the subblocks contained in the network block are the network map, the channel status blocks, and the remote miscellaneous scan-point status map.

Scan points are provided at the 10A RSS for uses such as alarms, make-busy keys, and stop-hunt keys. The remote unit periodically scans these scan points and, via the data link, reports any changes to the host ESS, which updates the bits in its map to indicate the present state of the scan point.

***2.2.1.2 Path memory remote record.*** A Path Memory Remote (PMR) record is provided for each possible line and channel network appearance. Since the 10A RSS network can be equipped in three different sizes, considerable ESS memory is saved by also providing PMRs in block sizes corresponding to the network size. PMRs contain information about the state of the terminal and a pointer that is used to

point to another memory block (call register or path memory for junctor) involved in the call.

*2.2.1.3 Path memory for junctor record.* A Path Memory for Junctor (PMJ) record is a block of call store that is associated with a junctor in the 10A RSS network. It is used to store path and terminal information when the junctor is in a network path. A PMJ also contains a state and pointer, which are used to link to another PMJ or to a call register. A PMJ is provided for each equipped junctor. Blocks of PMJs are allocated based on the RSS network size.

### *2.3 Call-processing strategy*

The RSS host call-processing software provides an ESS central office with the capability to supply ESS features to lines served by the remote switching system. Since most of the call-processing functions for RSS lines are performed by the host ESS office, a full family of ESS features can be provided to the remote subscribers. The RSS call-processing software resident in the host ESS provides the means of controlling a remotely located switching system by taking advantage of existing equipment and control capability in the ESS. Firmware in the remote terminal supplements the host call-processing software appropriately. All call-processing control resides in the host ESS and any required actions at the RSS are requested via data-link messages to the RSS. This permits the host to exercise total call control.

#### *2.3.1 Originating call*

A line originating in the RSS is first recognized during line scanning performed by the RSS microprocessor. The RSS line-scanning program in the remote terminal recognizes the line off-hook, performs hit timing, and sends an origination request data-link message to the host ESS. If service is allowed, the host marks the RSS line busy and hunts an idle voice channel between the RSS and ESS. It also hunts a path through the RSS network from the originating line to the selected voice channel, and selects a customer digit receiver in the host along with a host network path from the voice channel to the receiver. A Remote Order Buffer (ROB) is then executed to send appropriate data-link messages to the remote terminal to set up the RSS network path and set the line supervision mode to repeat supervision of the originating line over the channel in the dialing (fast repeat) mode. To minimize the dial-tone delay interval, when the above ROB is initiated the host executes orders to its periphery (via a POB mechanism) to set up the host network path between the voice channel and receiver to provide dial tone. That is, the ROB and POB are executed in parallel.

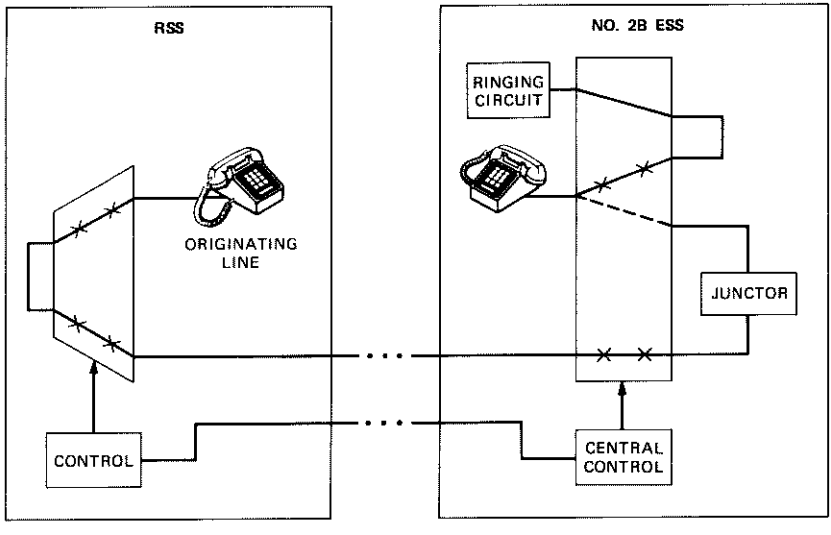
Processing of the call from this time on proceeds basically the same

way as an origination by a host line. Digits are collected and analyzed by the same host software used to process host calls. At the completion of dialing and digit collection, a data-link message is sent from the host to the remote terminal to set the line supervision mode to repeat the supervision of the originating line over the channel in the talking (slow repeat) mode. This mode conserves remote terminal microprocessor real-time capacity.

The RSS originating call, from this point on, is routed and completed normally (excluding terminations to RSS lines) just as non-RSS line origination processing. This originating call configuration is depicted in Fig. 4. Upon answer by the called party or completion of outpulsing, the talking connection is established from the voice channel through the host network. RSS answer timing, billing, traffic, and other administrative functions are all applied and performed by the host just as for non-RSS calls. If the call terminates to an RSS line, special terminating RSS functions are performed, as discussed in the following sections. When either the calling or called parties disconnect, disconnect functions are performed, as discussed in Section 2.3.5.

### *2.3.2 Terminating call*

An RSS terminating call is recognized when the host ESS performs the called number [terminating Directory Number (DN)] translation on digits collected from an originating host line or trunk. RSS lines



ESS – ELECTRONIC SWITCHING SYSTEM
RSS – REMOTE SWITCHING SYSTEM

Fig. 4—RSS originating call.

are distinguished from host lines by special RSS indicators in the terminating line translation output. After the translation is completed, special actions, as with the RSS originating call, are required to set up ringing. The host hunts an idle voice channel to the RSS, hunts a path in the RSS network between the voice channel and the terminating line, and seizes an idle host ringer and audible service circuit with associated host network paths to the voice channel and originating line or trunk, respectively. In addition, a talking path through the ESS network (between the voice channel and the originating line or trunk) is reserved.

A ROB is activated to send data-link messages to the remote terminal to connect the terminating line to the voice channel and apply ringing to the line. Upon receipt of the data-link orders, the remote terminal selects an idle universal service circuit along with a metallic bus and time slot to provide the type of ringing specified in the data-link message. Supervision of the line is transferred across the voice channel to the host in the fast repeat mode.

Upon successful execution of the ROB data-link orders in the remote terminal, the host executes a POB to set up paths in the host network from the voice channel and the originating line or trunk to its associated service circuit. Power cross and low-line resistance tests are done on the voice channel from the host ringing circuit. The host ringing circuit is then left in a state to monitor ring trip sent by the remote terminal over the voice channel to the host. Actual ringing is applied to the line by the Universal Service Circuit (USC) at the remote terminal; the ESS host ringing circuit does not apply ringing voltage to the voice channel, but is only used to monitor for ring trip. This call configuration, as depicted in Fig. 5, maximizes use of the existing terminating call sequences in the host.

When the called party answers, the remote terminal automatically releases and idles the ringing facilities (USC, metallic access bus, and time slot), relays the ring trip report (off-hook signal) of the line across the voice channel, and sets the supervisory mode to slow repeat.

The host ESS detects answer over the voice channel at the ringing service circuit, tears down the ringing and audible circuit connections in the host, and sets up the talking path that was previously reserved between the voice channel and the originating line or trunk. If the originating line in the RSS terminating call description is actually another voice channel to the same RSS as the terminating line, the call is considered an intra-RSS call and special actions are invoked as described in Section 2.3.4.

Disconnect actions are identical to those for the RSS originating call except for the disconnect timing associated with the terminating versus the originating party.

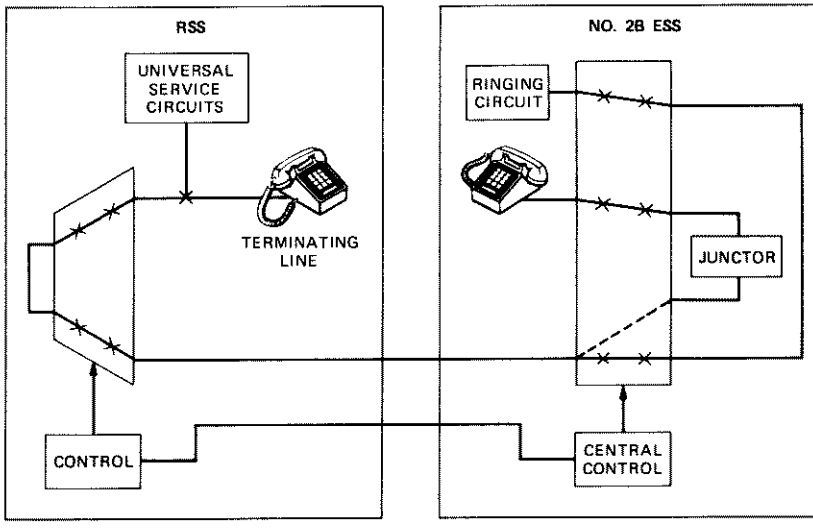


Fig. 5—RSS terminating call.

### *2.3.3 RSS reverting calls*

RSS reverting calls involving a call between two parties on a party line are handled in a manner similar to host reverting calls. However, ringing is provided in a way similar to how it is applied on RSS terminating calls with the exception that two time slots are needed in the RSS remote terminal so that ringing can be applied to both customers. This RSS ringing option, which can be either ac/dc or superimposed, is completely independent of the host ESS office ringing option, or any other RSS served by the same host. The RSS universal service circuit has the capability to provide either ringing option under firmware control.

### *2.3.4 Intra-RSS call*

An intra-RSS call, where both the originating and terminating parties are served by the same RSS, is handled initially as a combination of an RSS originating call and an RSS terminating call. In the No. 1 ESS and No. 1A ESS applications, after answer, the host initially establishes a talking path within its network between the two voice channels. Immediately following the establishment of this talking connection, certain RSS actions are invoked to reswitch-down the call so that the talking connection resides entirely within the RSS network. This releases the ESS network path and voice channels for use on other calls. In the No. 2B ESS application, when answer is received

and both parties are served by the same RSS, the call is reswitched-down immediately without first establishing a talking connection through the host. This sequence will not result in a momentary open interval after the initial talking connection has been established.

The reswitch-down action is initiated when the host hunts an RSS network path within the RSS between the originating and terminating lines. A ROB is activated to send data-link orders to the remote terminal to disconnect both line-to-channel network paths and connect the two lines through the RSS network. The supervisory mode of the RSS lines is set to scan for either a disconnect or switchhook flash, depending on the features associated with each line. Since the intra-RSS connection is entirely within the RSS, a change in supervisory state of the line must be reported over the data link to the host. The sequence of intra-RSS call configurations including reswitch-down is illustrated in Fig. 6.

If a network path in the RSS is not available or if one of the lines is an RSS coin line, the intra-RSS call is not reswitched-down and is connected through the host ESS network. Intra-RSS calls involving coin lines are not reswitched-down in order to utilize host coin-disconnect routines and thus simplify disconnect actions.

The use of various custom calling services or other special services requires a reswitch-up of an intra-RSS call to establish a talking path between the two parties via the host network using two voice channels. This allows existing host software and equipment to be utilized to provide these customer services. The following operations require a reswitch-up operation on an intra-RSS call:

1. A flash by an RSS customer to add on a third party
2. A terminating call to one of the two parties of an intra-RSS call that has the call waiting/terminating feature
3. A busy verification test by an operator of one of the two parties of an intra-RSS call.

When the host determines that a reswitch-up function must be performed, for any of the reasons given above, the host seizes two idle voice channels to the RSS and hunts a path between them in the host network; the host also hunts a path between the two voice channels and both lines in the remote terminal. A POB is executed in the host to set up a talking connection between the two voice channels followed by a ROB to send data-link messages to the remote terminal to disconnect the intra-RSS talking connection, connect each line to a voice channel, and set the supervision state of each line to the talking mode (repeat supervision of the line over its respective voice channel). Once the intra-RSS call is reswitched-up to a talking connection via the host ESS network, the original service requested can be provided just as it would to a normal line-to-line connection of two host lines.

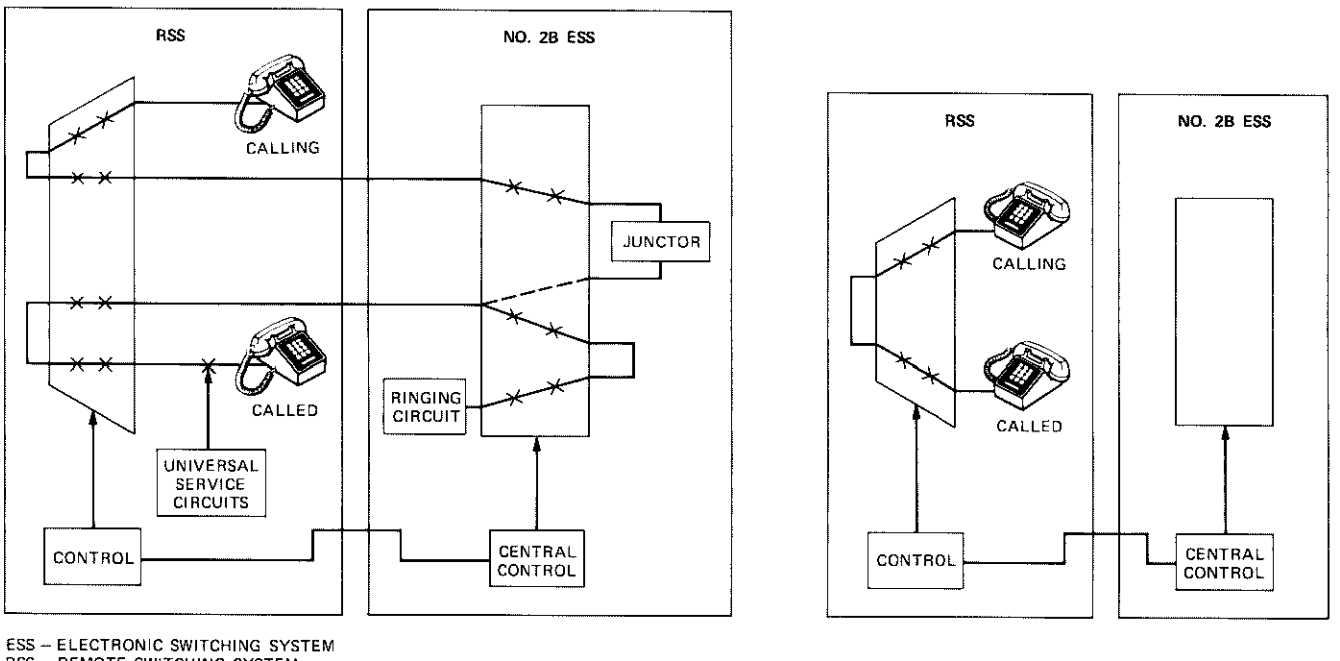

Fig. 6—Intra-RSS connection sequence. (a) Ringing connection. (b) Talking connection.

### 2.3.5 Disconnect functions

Disconnect actions for RSS calls are a function of the particular call configuration involved, i.e., intra-RSS calls or RSS calls through the host network. For call configurations involving both RSS and ESS paths, the ESS disconnect programs control the call-disconnect actions. The same disconnect sequence that is performed on ESS host lines is used on RSS channels that terminate on the host line network. This disconnect control strategy provides the ability to centrally recognize an RSS channel during normal host-disconnect processing. This recognition occurs when ESS programs perform a restore-verify action on the RSS channel. At this point in the host-disconnect processing, unique host RSS disconnect modules are invoked to disconnect the network path of the RSSs. The normal host-disconnect program and RSS-disconnect module then autonomously complete their respective disconnect actions. The only common resource between the two control programs is the RSS channel. The ESS host-disconnect program administers the host end of the channel on its network, and the RSS host-disconnect program administers the RSS end of the channel on its network.

In the case of an intra-RSS call, where the call configuration involves a connection totally within the RSS network and no channels or ESS network paths are involved, the RSS lines are supervised in the 10A RSS. Hits, flashes, and on-hooks are detected by the RSS; flashes and on-hooks are reported to the ESS host via data-link message. These messages are routed to unique RSS disconnect control modules in the host for proper processing. In the case of an on-hook, these programs perform the proper disconnect timing and then execute ROBs to disconnect the intra-RSS network paths and idle the lines involved. The intra-RSS call is reswitched-up on receipt of a flash message (as discussed in Section 2.3.4).

## 2.4 Database integrity

In an electronic switching system, the status of resources and telephone calls is recorded in temporary memory. This data can become mutilated because of program bugs, hardware errors, or program design errors, resulting in the loss of resources or system degradation. The problem is further complicated by RSS because parts of the new data structures in the host ESS are duplicated in the remote terminal. The new structures are:

1. PMRs for lines
2. PMRs for channels
3. Network map
4. Remote order buffers (ROBs)
5. Remote miscellaneous scan point map.

The actual data stored in the two copies of these structures are not identical in all cases since the host and remote terminal do not perform identical functions. For example, the state stored in a line PMR at the remote terminal represents the supervisory state of the line (origination, repeat supervision onto a channel, high and wet, etc.), whereas the state in the host PMR represents both the status of the line (idle, busy, maintenance) and the type of path memory configuration, as discussed previously. However, there is a mapping between the two sets of states in that the host-line state implies the possible supervisory states of the line. Deviations from this mapping should only be due to the time lag of the data link.

To ensure the integrity of the data structures, the first step is to prevent as many errors as possible. RSS software applies many of the techniques that have been successfully used in other ESS projects to avoid potential causes of errors. Some of these are good documentation, standardized program interfaces, structured design, structured programming, a high-level programmer's language, and a standardized data definition language. In addition, access to the new data structures introduced into the host is limited to the administrative programs that have the responsibility for that particular database.

The second step is to make the programs as error tolerant as possible since data errors will still occur. The main technique for this is defensive programming. The degree to which a data error is propagated through the system depends upon how the programs use the data. In order to have a minimal effect upon the system, programs should account for bad data. Some specific types of defensive coding techniques are:

1. Range checks on data to prevent overindexing tables
2. Accounting for all possible subroutine return code values
3. Use of symbolic definitions for data values
4. Accounting for all possible program inputs
5. Invalid data value checks.

Despite the preventive and defensive techniques that are employed, errors can still occur in the data. Programs are required to detect these errors and restore the facilities to the proper condition to avoid system degradation. These audit programs are responsible for detecting and correcting data errors and the initialization programs are responsible for restoring system facilities when the degradation is severe enough to cause major system degradation.

#### *2.4.1 Audit programs*

The integrity of the data structures is checked and corrected by a set of audit programs. Each audit program is individually tailored to a specific data structure or group of data structures and determines if

the data items follow certain established rules. If the checks fail, the audit programs make appropriate corrections to all resources (both software and hardware) associated with the particular error and print error messages on the teletypewriter. The audit programs also aid in the initialization of the data structures.

The audit philosophy adopted for RSS is that each entity will maintain the integrity of its databases independently. If the host finds a discrepancy in its database, it corrects the problem by resetting the state of all host resources involved and instructs the remote terminal to put its facilities into a known (usually idle) state. If the remote terminal finds a discrepancy in its database, it sends a message to the host and the host audit programs initiate the actions given above.

Thus, there are three classes of audits associated with the RSS system:

1. Host audits that maintain the internal integrity of the data structures in the host
2. Remote terminal audits that maintain the internal integrity of the data structures in the remote terminal
3. Audits that guarantee that the host and remote terminal data structures are consistent.

Audit classes 1 and 3 are discussed below.

***2.4.1.1 Host audits.*** Existing host audits are extended to include the new data structures and new data values introduced with RSS. The main audit modifications are for the RSS path memory, the RSS network map, channels, and ROBs.

The RSS path memory and network map are audited by making the following checks:

1. Point-to-point-back checks are performed between PMRs and PMJs.
2. Point-to-point-back from a PMR or PMJ to a call register are performed if linkage to a call register is indicated.
3. The junctor busy-idle bit in the network map is checked to ensure that it is idle if and only if the PMJ is idle.
4. Each of the other network map bits that is marked busy is checked to guarantee that it is in a valid path.

ROBs are audited by periodically rebuilding the idle link list and by timing ROBs associated with transient call records. If a ROB remains busy for an extensive length of time, the ROB and any associated call register are idled. All paths and circuits are also idled.

The corrective action taken by the host audits is to idle facilities (hardware and software) in the host and to send orders to the remote terminal to cause the facilities at that end to be idled.

***2.4.1.2 Synchronization between host and remote terminal.*** The problem of maintaining the data structures in the host and remote terminal in

synchronization is greatly simplified by taking advantage of the normal system operation. The remote terminal updates its data in response to orders from the host. Bits in the remote copy of the network map are marked busy or idle in response to orders to set up or tear down network paths. Thus, no network map audit is required between the host and remote terminal since the host does the hunting and idling of paths and the remote copy will tend towards the proper state even if it does temporarily get out of step.

Similarly, ROBs are controlled from the host end and normal operation will result in the remote copy being brought back into step with the host.

The remote terminal audits check that all equipped lines have supervision turned on. Any equipped lines that are unsupervised are reported to the host via a data-link message. If the host audits determine that the line state really calls for supervision to be on, the line and any associated resources are idled.

Periodically, the host sends a copy of its version of the remote scan point map to the remote terminal, which overwrites its map with the host's data. If the hardware state of the scan point differs from the map, the normal scan program will detect this as a change and report it to the host, resulting in both copies being brought back into step.

#### *2.4.2 Remote terminal initialization*

System initialization programs are responsible for correcting errors that prevent the system programs from cycling correctly. The initialization programs are usually executed as a consequence of errors being detected by the processor check circuits that monitor the sanity of the system operation. In the remote terminal, the primary checks for monitoring proper program operation are the system sanity timer, which monitors the main program cycle time; the write protect circuitry, which prevents illegal writes into program store; and certain peripheral error checks, which detect attempts to access unequipped areas of the periphery. If any of these errors are detected, it is indicative of an error in the system database. The method of recovery is to initialize a segment of the data and then return to the normal program cycle.

Since the initialization process inherently destroys a portion of the call-processing data, a corresponding set of calls will be lost, and it becomes a requirement for the initialization program to release the peripheral circuits associated with these calls. Any network links, channels, or service circuits employed on these calls must be idled by the initialization program before a return to normal system operation is begun. This is accomplished by releasing all the circuits that are marked idle in the initialized database.

Whenever an error is detected by a fault-detection circuit, a processor interrupt is generated that executes the fault-recovery programs. Various fault-recovery actions are taken, depending on the type of errors detected and their frequency.

The amount of data that is initialized on the first error is small. As successive errors are detected, the severity of the initialization is increased with the consequent loss of progressively greater numbers of calls. The ultimate action is to initialize the entire database and restore the system to an idle state. The goal of handling the fault recovery in stages, with increasingly more severe initializations, is to restore the system to a working mode with the loss of a minimal number of calls.

At either the remote terminal or the host, there are three fundamental levels of initialization: a minimal clear, a transient clear, and a stable clear. A minimal clear involves the initialization of the variable data associated with the active processes in the system and has the potential of disrupting, at most, several calls. A transient clear will initialize all the data in the system that is related to any call in progress. All calls in the process of being established or disconnected will be lost; however, calls in a stable talking state will be preserved. The final state of initialization is a stable clear where the entire database is reinitialized and all calls are lost.

For the RSS system, the initialization process is somewhat more involved than normal because the host and remote terminal databases are interrelated and an initialization level (phase) in one machine affects the database of the other system. Although the host machine is responsible for the control of the remote terminal on a call-related basis, the operation of the processors in the two machines is fairly autonomous with respect to their instantaneous activities. This is the situation for fault detection where the two systems are entirely independent. Each machine is responsible for initializing and carrying out its own fault-recovery actions and the level of the accompanying initialization will be solely determined by the conditions within the machine that detected the error. In effect, either machine is able to initiate any level of initialization on its own database independently of the other. However, as part of the initialization procedure, the hardware and software within the two machines must be synchronized so that the databases reflect a consistent set of calls. The calls that were destroyed in one machine must be reported to the other so they can be cleared from that system also. For example, a host-transient clear will destroy a number of calls that involve remote terminal lines. These calls must be cleared in the remote terminal so that periphery and call records are in agreement with those in the host.

The exact procedure for synchronizing the two machines will depend

on which system has initiated the phase. Since the host is in charge of call control, its call records are regarded as the master copy and the remote terminal state is brought into agreement with its set of records. The host is therefore in charge of synchronizing the two machines.

Whenever a phase occurs in the host, the synchronization procedure is straightforward. The host will initialize its database and periphery and will then send initialization orders to the remote terminal to bring it into agreement with its updated records. When the remote terminal undergoes an initialization, it reports the level of the initialization to the host. In some instances, on a stable clear, for example, this is sufficient information to allow the host to initialize its database. In the case of a transient clear, it is also necessary to transmit a map of the lines that are in a transient state in the remote terminal. From the data specifying the initialization level and the map of transient lines, the host is able to update its call records and periphery. Once this is accomplished, it will conduct an initialization of the remote terminal in the same manner as for a host-initiated phase.

During a high-level initialization, interactions between the host and the remote terminal must be modified. For example, during the resynchronization of the host and remote path memory transient databases, it is necessary to prevent these databases from being accessed by call-processing routines. To implement this capability, the RSS is modeled as a finite-state machine with ten possible states. The state of each remote terminal together with a list of activities allowed in that state is maintained by the host in a database. Software, which functions differently based on the state of the remote terminal, checks this database to determine what action is appropriate in the given RSS state.

## III. MAINTENANCE ENHANCEMENTS

Extension of telephone communication service through the 10A RSS brings with it an associated extension of maintenance capabilities. An obvious maintenance need relates to the SPUC/DL and data-channel facility between the No. 2B ESS and No. 10A RSS processors. Integrity and maintenance issues for this subsystem are dealt with in the companion article of this series, "Adding Data Links to an Existing ESS," by C. E. Ishman et. al.

Another area requiring maintenance enhancement is related to the addition of voice channels to the network architecture of the combined systems. Unlike other "links" of the No. 2B ESS network, the voice channels are nonmetallic, largely external to the central office environment, and are maintained by a separate craft force. These factors require the design to deal with issues of availability, transmission and

noise performance, and trouble sectionalization. The channel maintenance software package, developed to address these issues, is described in the following sections.

Other maintenance additions, for telephone customer loop testing, are necessitated by the remoteness of the RSS and the nonmetallic network upon which these loops terminate. Testing capabilities, similar to those available for host-terminated lines, must be provided for RSS customer loop trouble detection and resolution. Such capabilities are described in the following sections on line maintenance. Finally, as a means of achieving test hardware economies in the RSS, the host diagnostic capabilities were expanded to test Dual-Tone Multifrequency (DTMF) receivers at the RSS as well.

### *3.1 Channel maintenance*

Basic needs for the effective maintenance of RSS voice channels may be divided as follows:

1. The system must provide routine, automatically initiated tests that periodically diagnose individual channels to detect performance-affecting faults—particularly faults characterized by progressive and marginal degradation.
2. The above set of tests should also be initiated by call-processing programs in instances where in-process integrity checks indicate errors that could be caused by faulty channels.
3. The resolution of some hardware faults will require manual intervention. This is accomplished by: (a) allowing the above diagnostic tests to be executed upon demand, and (b) providing dc and ac test access to each channel for voltmeter-type testing. This latter facility has been provided through an enhancement of the existing central office Trunk Test Panel (TTP).

#### *3.1.1 Channel diagnostics*

The channel diagnostics, which play a major role in fulfilling all three needs, have been designed with a "start-small" philosophy; the sequence of tests is selected so as to confirm basic functions first, and then to build upon this knowledge in carrying out subsequent evaluation. The following sequence of tests is terminated when a failure is detected at any step:

1. Power cross test
2. False cross or ground test
3. Supervision test
4. Restore-verify test
5. Low line resistance test
6. Dial pulse test

7. ac far-to-near test
8. ac near-to-far test.

The power cross test, shown schematically in Fig. 7a, uses the same detecting circuit as do customer lines and is designed to detect crosses to central office battery or commercial power in the cabling between the No. 2B ESS switching network and the carrier terminal. By performing this test first, potential damage to other test circuits is avoided. The False Cross or Ground (FCG) test cannot use the existing test method since it is overly sensitive to the capacitative load seen at the input of the carrier's channel unit. Instead, the existing continuity and polarity test circuit is connected, as shown in Fig. 7b, to detect the existence of conductor-to-conductor and conductor-to-ground shorts (up to approximately 2000 ohms) in the same cabling.

The supervision test verifies the ability of the channel to pass on-hook and off-hook signals from the RSS remote terminal to the No. 2B ESS host. With the channel idle, on-hook supervision is first confirmed by applying loop battery toward the channel with the continuity test circuit (as diagrammed in Fig. 7c). After sending an off-hook order to the RSS (via the data channel), the central office current detector is scanned for the expected off-hook.

The restore-verify test, in a manner similar to that used with customer lines, verifies that the supervisory attending element can be reconnected to the channel and can detect the off-hook signal associated with a channel "origination." This is accomplished, as shown in Fig. 7d, by causing the RSS to transmit an off-hook signal toward the host when the host has its line attending element connected to the channel.

The low line resistance test is still another carry-over from host-line testing. Here, the objective is to detect the existence of high-resistance (up to approximately 15,000 ohms) crosses from conductor to conductor and from conductor to ground. While the intent of making such a test on a customer line is to prevent false ring tripping, the benefit to channel testing is to better characterize the nature of a fault. This test connection is shown in Fig. 7e.

Since originating RSS customers make use of central office digit receivers, the voice channels must be capable of conveying dialed digits, which are transmitted on the channel as a series of supervisory transitions. The dial-pulse test performs this function by: (1) connecting the central office end of the channel to a digit receiver, and (2) requesting the RSS to transmit a digit "0" (ten dial pulses). The test passes if the digit receiver shows that ten dial pulses have been received. The associated connections are shown in Fig. 7f.

The final two tests on the channel form a gross verification of its two-way transmission capability. The ac far-to-near test, shown in Fig. 7g, connects a source of milliwatt level 1-kHz tone at the remote

end and a tone detector at the central office end. The complementary near-to-far test, shown in Fig. 7h, verifies transmission in the opposite direction and employs a similar technique. Since the tone detectors used in these tests are sensitive down to −30 dbm, the diagnostic results cannot confirm adherence to rigid (±1 dB) limits. The Remote Office Test Line (ROTL) feature has therefore been enhanced to perform accurate transmission measurements on voice channels as well as on trunks. This capability is discussed in the following section.

#### *3.1.2 Automatic channel transmission testing*

The ROTL feature, first implemented in the No. 2-EF-1 generic, was designed to allow automatic transmission testing of trunks by the Centralized Automatic Reporting on Trunks (CAROT) processor. Since the RSS channels have a functional role similar to that of local interoffice trunks, enhancement of the ROTL feature was selected as an efficient method for channel transmission testing. The resulting design, as implemented in the 2BE3 generic, proceeds along the following typical sequence in the testing of a channel:

1. The CAROT center connects to the ROTL access (incoming) port via the standard Direct Distance Dialing (DDD) network.

2. Priming data specifying the test parameters is sent from the CAROT, through the ROTL access port, to a Multifrequency (MF) receiver. This digit receiver is accessed via a normal central office connection from the ROTL test port, as shown in Fig. 8.

3. Upon receipt of the channel identity, the central office releases connections to the MF receiver, establishes a connection between the ROTL test port and the selected channel, and requests the RSS to connect a transponder to the remote end of the selected channel.

During this sequence of events, considerable data "handshaking" takes place between the CAROT and the No. 2B ESS—much of this communication in the form of bursts of "test progress tone" sent by the ROTL circuitry to the CAROT. The end result is a composite connection, as shown in Fig. 9, which permits the RSS transmission measuring transponder (termed a miniresponder) to interact with the CAROT in performing transmission measurements in either direction on the channel. The CAROT may then restore or remove channels from service based on the test results.

Since the CAROT-ROTL system can make loss and noise measurements accurate to 0.1 dB, this design provides a low-cost means of maintaining voice channel transmission characteristics within acceptable limits. Also, because the RSS miniresponder can be accessed in a similar fashion using a portable ROTL System Test Set, the same high-resolution measurements are available to the maintenance craft on a demand basis.

### *3.1.3 In-process error detection*

While routine testing is an essential ingredient in the channel maintenance package, means must also be provided to deal with channel-related failures encountered during the processing of a telephone call. Such a facility will properly dispose of channels with transient faults (which are not detected during periodic exercise) and channels with newly occurring faults.

Once a channel is implicated by a failure in call processing, automatic routines dispose of the channel as follows:

1. A diagnostic test is run on the channel and, if the test fails, the channel is removed from service (subject to previously specified numerical limits).

2. If the diagnostic passes or cannot be run because of resource blockage, a report of the incident is made to error analysis programs running at the RSS.

3. The error analysis routines, which accept failure input from the remote terminal as well as the host, evaluate the failure history of each channel. This evaluation is carried out using two algorithms: a peer group comparison and a "quick check."

4. If the peer group analysis indicates that a given channel's error rate is significantly higher than that of its peers, that channel will be removed from service (subject to the specified maintenance limits).

5. If the error analysis indicates a "quick check" failure (three successive channel errors occurring on the same channel), channel diagnostics are run on the suspected channel. Depending on the

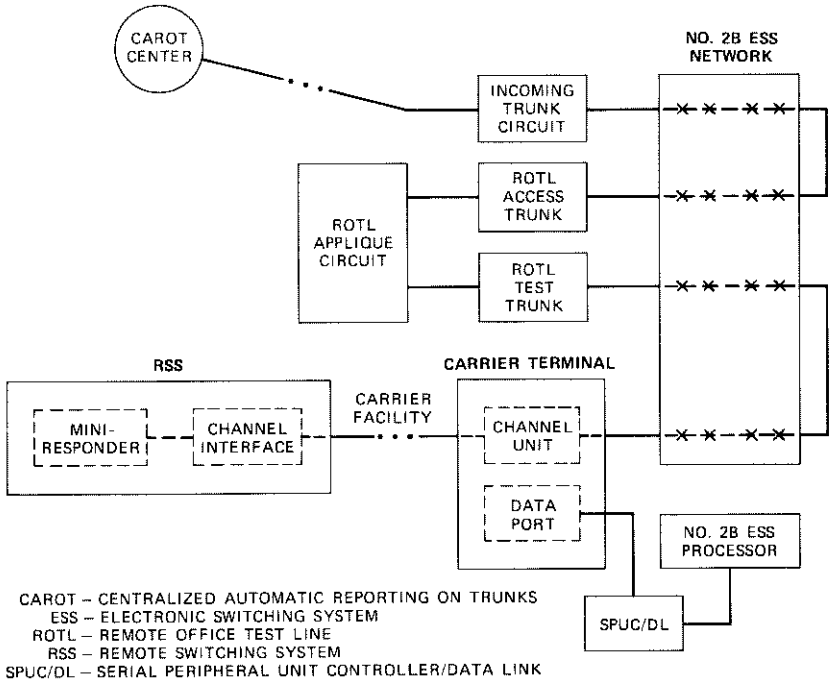

Fig. 9—Channel testing with CAROT and ROTL.

success or failure of the diagnostic exercise, the action taken is the same as that listed in (1) and (2) above.

### *3.1.4 Manually controlled channel testing*

As previously mentioned, the ROTL capability for channel (a) testing may be used automatically (via CAROT) or manually. In addition, to provide direct metallic access to the channel and control of its associated circuit states, the central office trunk test panel programs have been modified to provide test functions similar to those available for trunks.

A typical sequence, which permits a loop-around connection of two channels, is itemized below. Such a connection is used in two-way transmission loss measurements on channels.

1. Using the panel-mounted telephone set at the trunk test panel, digits are dialed that direct a specified channel (a) to be connected to a source of milliwatt tone (i.e., a 102-type test line) at the RSS. This connection, shown in Fig. 10, permits the TTP transmission measuring set to determine the loss of the channel in the far-to-near direction.

While this channel is accessed, existing keys at the TTP may be used to change the circuit state of the channel at the RSS. (These

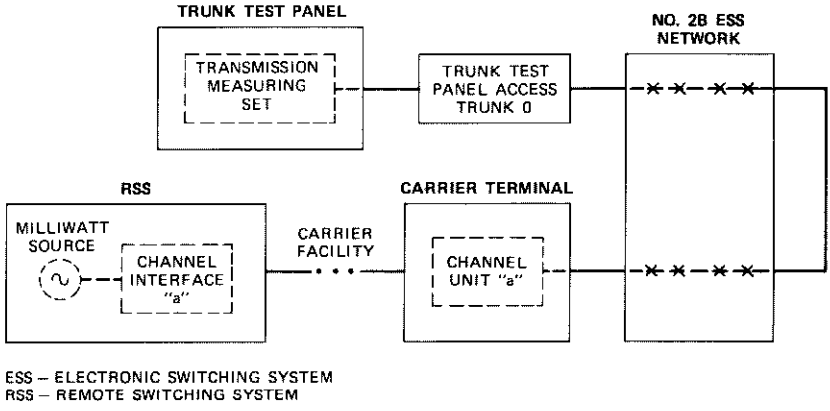

Fig. 10—Measurement of channel far-to-near loss.

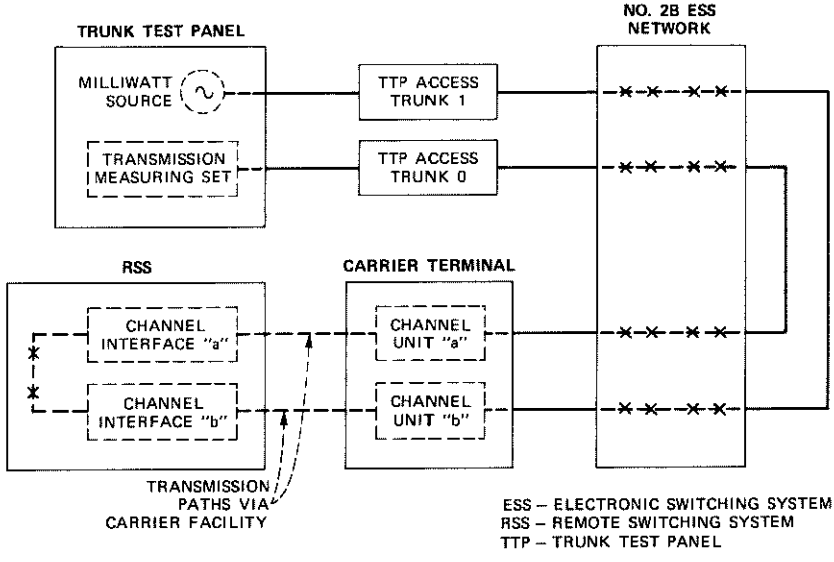

Fig. 11—Measurement of channel near-to-far loss.

states correspond to supervisory conditions, loss pads in and out of circuit, and the connecting of a balanced terminating network.)

2. Dialing a different test code and channel identity will cause a second channel (b) to be connected between another TTP access trunk and a loop-around connection at the RSS. This connection, shown in Fig. 11, has produced a configuration in which both ends of a two-channel transmission path are connected to the TTP. Now with a source of 0 dbM connected to the second channel and a transmission-

measuring set connected to the first, the near-to-far loss on the second channel may be determined.

3. When any channel is released from the TTP, several options are possible, depending upon the channel's previous status and the method of TTP disconnect. For example, if the channel had initially been out of service, TTP release will initiate a diagnostic test of the channel, restoring it to service if the diagnostic passes. If an initially idle (in-service) channel is released with the "make busy" key operated, the channel is unconditionally removed from service.

### *3.2 Line maintenance*

Like channel maintenance, line maintenance may be subdivided into capabilities that: (1) by periodic, automatically initiated testing, attempt to detect progressive hardware degradation before service is affected; and (2) by allowing demand-type human-controlled testing, enable the maintenance craft to resolve the nature and location of faults. Automatic Line Insulation Testing (ALIT) occupies the first of these categories and, like its counterpart for host-terminated lines, detects high-resistance crosses and grounds on metallic pairs between the RSS and the customer premises. The second category of features includes an interface to the Local Test Desk (located in a centralized repair service bureau) and the station ringer test, which verifies the correct operation of the subscriber's station set.

#### *3.2.1 Line insulation testing*

If it were not for the nonmetallic network in the RSS remote terminal, line insulation testing could be performed by the host No. 2B ESS. Instead, the remote terminal is equipped with its own insulation testing circuit and the means to make a metallic connection between this circuit and all customer line terminations.

As shown in Fig. 12, the RSS ALIT circuit accesses the customer line via the Metallic Access Bus (MAB), the Line Test Access Bus (LTAB), and the Universal Service Circuit (USC), the latter in the "bypass" state. RSS firmware has exclusive control of this connection and testing sequence once a line and test parameters are specified via data order. That is, after the RSS receives a line test request from the host, the remote terminal selects an idle USC, connects the MAB, performs the test, disconnects from the line, and returns the test results in an acknowledgment message over the data channel. The test parameters received in the requesting message are similar to those specified for host line testing and permit testing sensitivities ranging from 80 kΩ to 5 MΩ. In addition to the line identity, the requesting order also includes a specification of the test mode. The mode, an

operating company and craft option, selects the extent of the testing performed on an individual line. The choices are:

1. A foreign EMF (electromotive force) test, which looks for false power crosses to either conductor,
2. The TRG (tip-ring to ground) test, which measures resistance between the conductors (tied together) and ground,
3. Leakage test, which measures resistance between the conductors,
4. A "general" test, consisting of a sequential application of all the preceding tests.

RSS line insulation testing is included in the automatically initiated sequence and follows, RSS by RSS, the insulation testing of host lines. While the testing of RSS lines could have been done concurrently with the testing of host lines (since separate and dedicated hardware is involved), such a design would have increased the complexity of teletypewriter output messages, which identify line failures. By completing the testing of all lines in one entity (i.e., the host, or one of the RSSs) before proceeding to test lines in the next, a single "header" message serves to identify the entity for all line failures that follow. This has the added benefit of grouping those reports corresponding to their geographic locations.

#### *3.2.2 Local test desk*

Demand-type line testing of host and RSS lines may be performed from a test cabinet, located within the No. 2B ESS central office, and from a Local Test Desk (LTD) at some remote location. To accommodate the variation of metallic and carrier facilities between the LTD and the host and between the host and an RSS, a number of options have been provided. The simplest case, from a design point of view, exists where there is a low resistance (less than 2600 ohms) metallic path from the LTD to the RSS customer's telephone. As shown in Fig. 13, the connection from the LTD to the host uses the standard No. 2B ESS—LTD incoming trunk circuit and a dedicated metallic facility between the RSS and the host. This metallic connection is completed in the RSS by connection through the Metallic Line Access Port (MLAP), the USC, and the MAB. LTD testing, which consists of various voltage and resistance measurements, may then proceed over the established connection.

Since such low-resistance facilities are expensive and rarely found in the rural and suburban environment, an alternative implementation is provided. This arrangement takes advantage of the Remote Testing System (RTS), which was previously provided to work over nonmetallic facilities between the LTD and the central office. The resulting design employs a multifrequency telemetry Remote Line Test (RLT) unit at the RSS. As shown in Fig. 14, the microprocessor-controlled

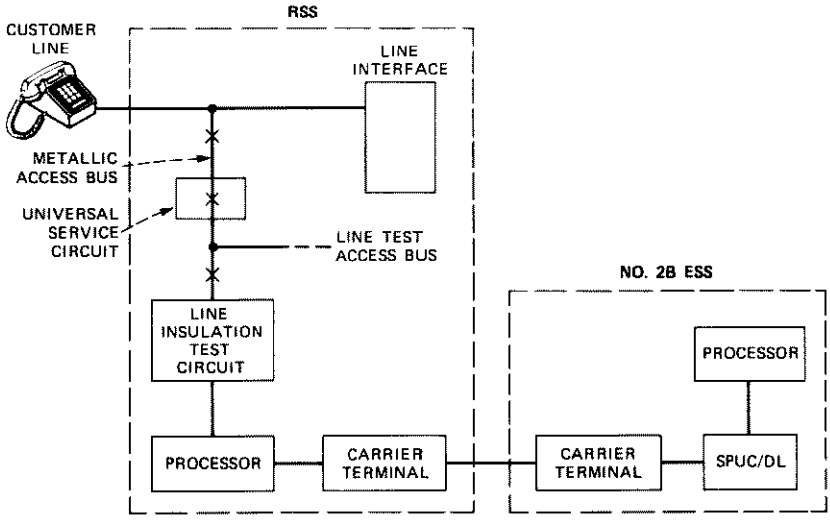

Fig. 12—RSS line insulation testing.

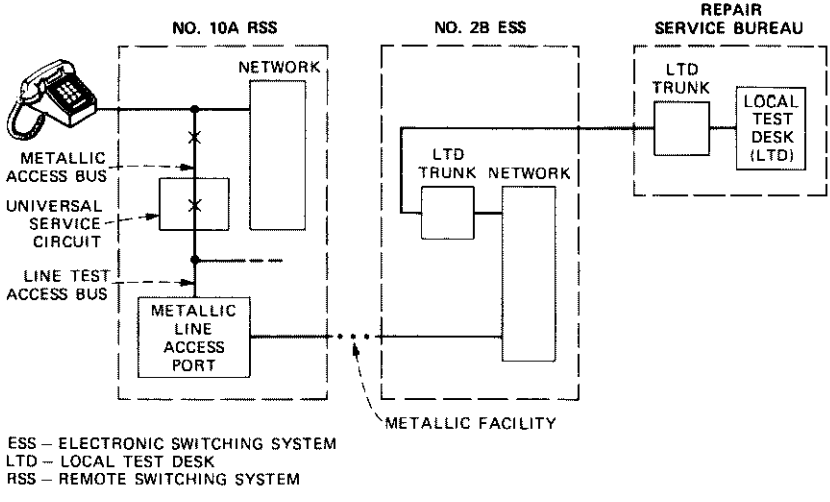

Fig. 13—Metallic option for the local test desk.

RLT has metallic access to the customer line via the MLAP, USC, and MAB. The connection of the LTD and RLT provides for test requests being sent to the RLT and for test results being returned to the LTD. Supervisory signals from the LTD (e.g., disconnect) are

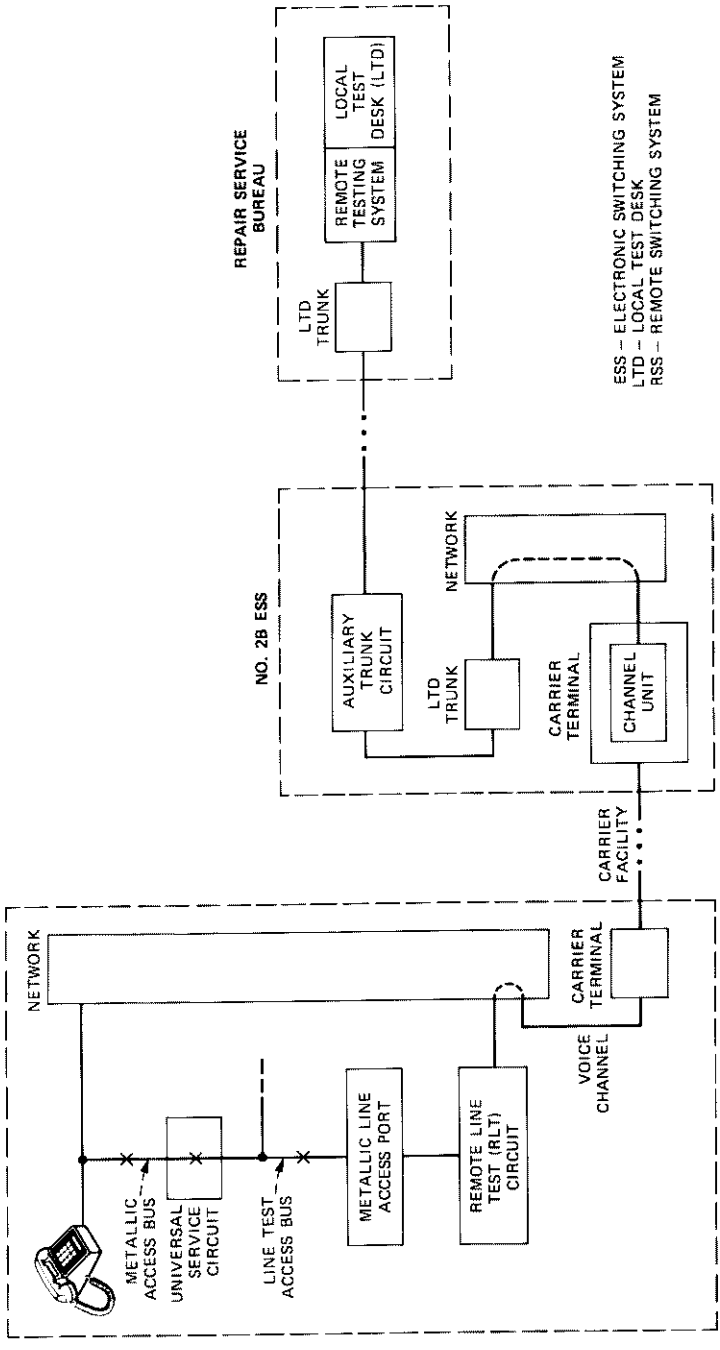

Fig. 14—RLT option for the local test desk.

intercepted by the auxiliary trunk circuit in the No. 2B ESS, since the host is responsible for maintaining and tearing down the entire connection. The RLT and the auxiliary trunk circuit at the host have therefore functionally replaced the central office equipment associated with the remote testing system.

### *3.2.3 Differences between host and RSS LTD line testing*

Since the two testing options (RLT or MLAP) require different trunk circuit hardware at the central office, the incoming call from the LTD may appear on either type of trunk. This requires the LTD operator to know the testing option associated with a particular RSS, and it requires the host No. 2B ESS to verify that the incoming LTD trunk type agrees with the testing option of that RSS. This latter confirmation is performed when the line's directory number is translated into an RSS identity.

The Local Test Cabinet (LTC), normally located near the distributing frame in the central office, is not equipped with the remote testing system. Thus, the LTC is incompatible with RLT-equipped RSSs and can test RSS lines only if that RSS is equipped with the MLAP option.

Another difference between LTD/LTC testing of host versus RSS lines concerns the action taken if the line is found busy when the initial test connection is made. When a host line is being tested, a suitably marked incoming LTD trunk can be connected to the busy line by means of the no-test facility of the No. 2B ESS switching network. If the host line becomes idle during the LTD connection interval, the line is marked busy (again) and the LTD is reconnected using a normal network path. In the analogous RSS case, the LTD is bridged onto the existing line connection in the RSS network. Since the software line status may not be changed, a camp-on request is registered at the RSS. When the line becomes idle, the pending LTD request causes the line to be rebusied, but no path reconfiguration is required.

One of the LTD functions is to verify whether a given line can originate. This is done on host lines by requesting the line attending element (ferrod) to be reconnected to the customer loop and then placing a resistive bridge across the loop. When the off-hook condition is sensed, dial tone is returned to the tester via the LTD trunk circuit, as shown in Fig. 15. Such operation is not possible with RLT testing of an RSS line since returning dial tone through the LTD trunk would open the LTD-RLT path and prevent further communication between them. Instead, when a line origination test is to be performed on an RSS line, that line is connected to a digit receiver in the host (shown in Fig. 16). The digit receiver then performs the functions of: (1)

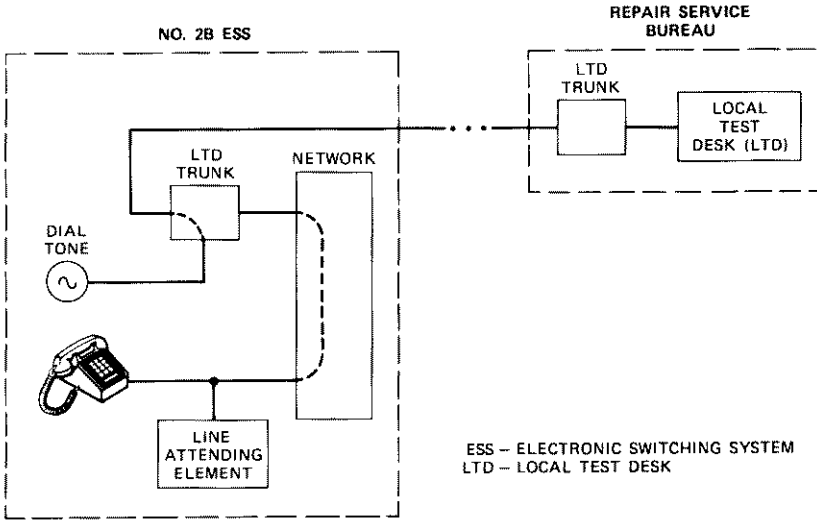

Fig. 15—Local test desk line origination test for host lines.

detecting supervisory changes on the line, and (2) returning dial tone when the off-hook signal is detected. Dial tone attachment and removal can then be monitored by the LTD, which is connected to the customer's line.

#### *3.2.4 Station ringer testing*

The station ringer test is under the control of the customer station and permits the verification of:

1. Station dialing capability
2. Party-identifying ground (in the off-hook state)
3. On-hook leakage, and
4. Ringing code and ring trip.

Since the sequence of actions required to perform these tests is well known to craft accustomed to testing host lines, a basic requirement for the service was that the craft interface remain unchanged for RSS lines.

The procedure, and its implementation for RSS lines, is diagrammed in Fig. 17. The test sequence begins by dialing a special code, normally a unique NNX, followed by the last four digits of the line's directory number. The RSS line is then connected to the host's station ringer test circuit via the same channel that had previously been connected to the customer digit receiver. The first step, the off-hook resistance test, is initiated with a switchhook flash by the tested line. A data-link order sent to the RSS causes the resistance test to be made by a

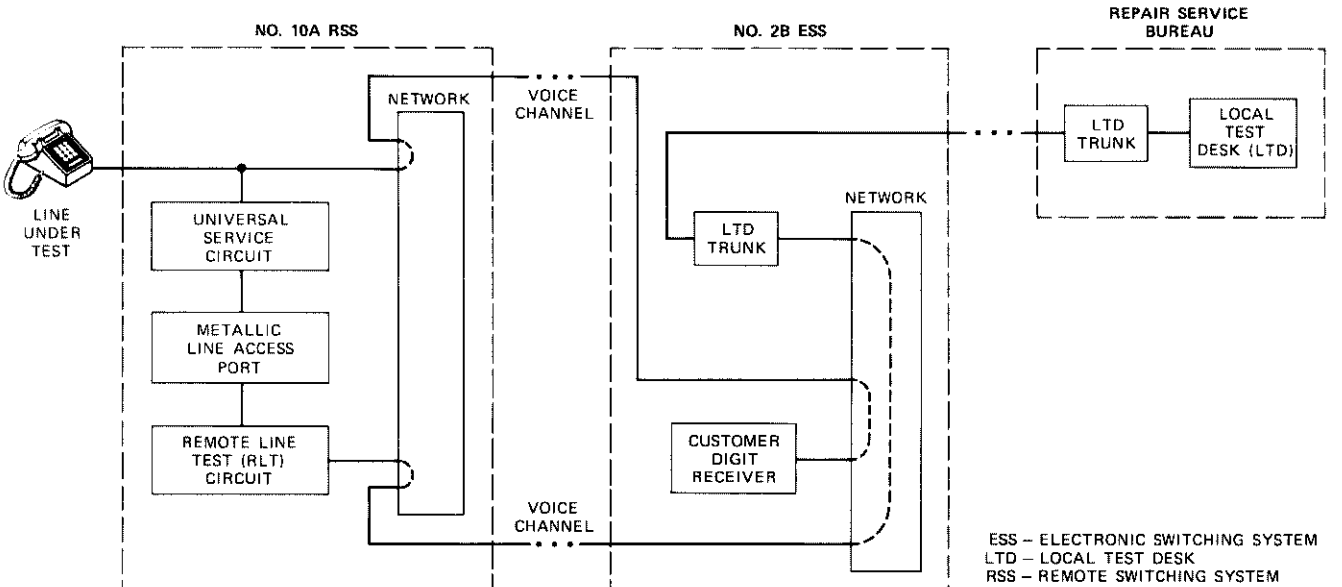

Fig. 16—Local test desk line origination test for RSS lines.

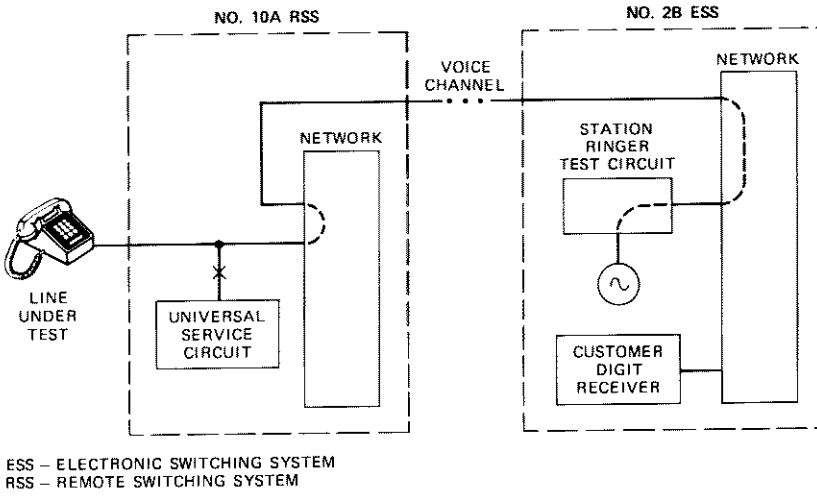

Fig. 17—Station ringer testing for RSS lines.

USC. The results of this test are then indicated with a steady vs. interrupted tone returned by the station ringer test circuit.

The second test on a (noncoin) customer line is an on-hook leakage test and is initiated by on-hook supervision. Again, the USC at the RSS is directed to perform the resistance test; its results are returned to the host via data-link message. If the resulting leakage measurement is acceptable, terminating ringing is applied to the line by the USC. Ringing indicates the result of the leakage test as well as confirming that the station set ringer is functional and that the correct ringing code is applied. The final test, ring trip, is made if the station set is taken off-hook within the next 3 minutes. As in the previous instances, since the ringing is applied by the RSS's USC, the tripping of ringing must be reported to the host via a data message.

At this point, the station ringer test circuit is connected to the line under test. A station set on-hook would idle all connected resources or, if a repeat test is desired, a switchhook flash causes the off-hook resistance test to be made, starting another test cycle.

### *3.3 DTMF receiver testing*

As we mentioned previously, the RSS is capable of "stand-alone" operation should its interface with the host be lost. This feature therefore required that DTMF receivers be equipped in the RSS so that customers utilizing *Touch-Tone** dialing may be served. To

* Trademark of AT&T.

achieve design economies in the RSS, a DTMF test circuit (like that in the host) was not provided. The alternative to manual routine testing was to provide an automatic diagnostic using the host's DTMF test circuit.

Such operation is possible because the stand-alone circuits (including the DTMF receivers) have access to the RSS voice channels via a link "multiple" arrangement shown in Fig. 18. This network design, originally intended for mutually exclusive connections of RSS lines to either channels or stand-alone circuits, permits a voice channel connection to a DTMF receiver without use of the RSS network junctors. The resulting configuration during the execution of the diagnostic involves the host's DTMF receiver test circuit, as shown in Fig. 19.

Maintenance software is furnished to diagnose one or more receivers on a demand or automatic basis. For the automatically initiated case, diagnostics of the RSS receivers are carried out one RSS at a time following the corresponding diagnostics for host digit receivers.

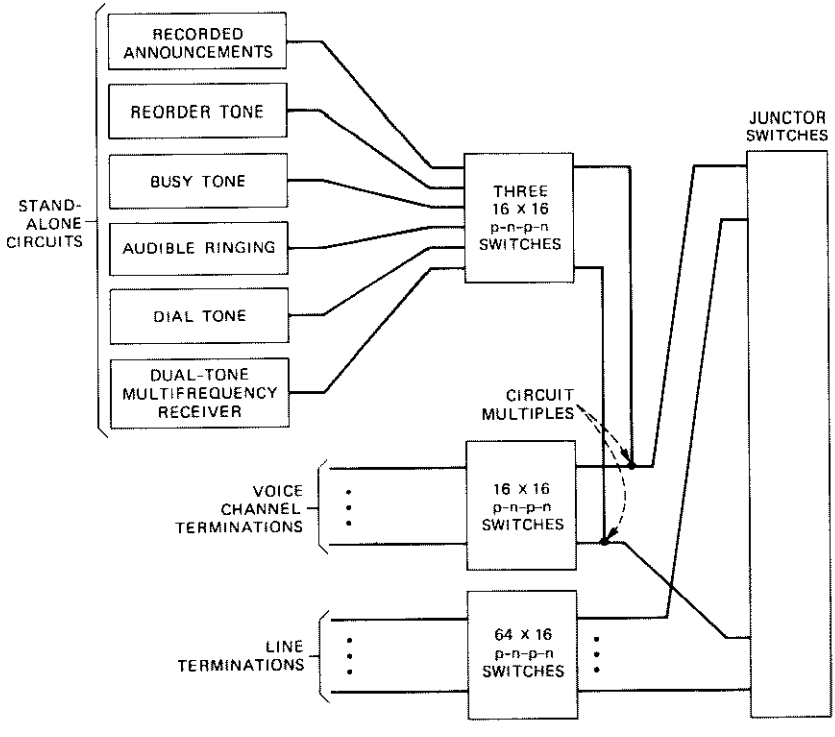

Fig. 18—Stand-alone circuit network connections.

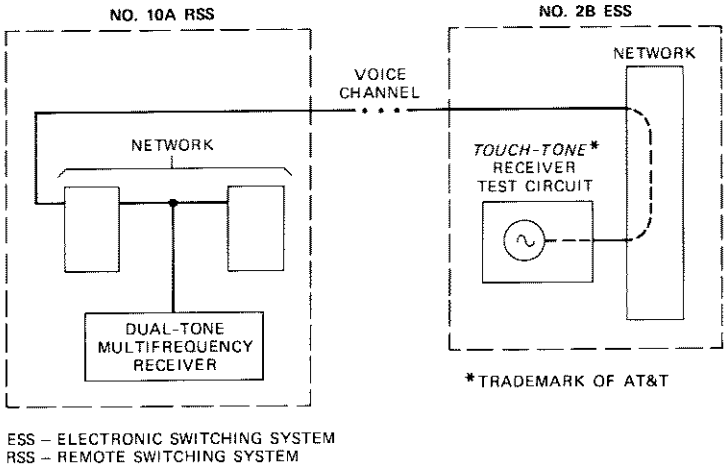

Fig. 19—*Touch-Tone* receiver diagnostic connections.

## IV. REAL-TIME PERFORMANCE

This section discusses two aspects of the RSS feature: the real time required to process an RSS call and the effect of RSS on the call capacity of an office.

The many components of an RSS call were determined by performing extensive measurements in the system laboratory. The results of this study indicated that an ESS line-to-RSS line call requires about 33 percent more processor real time than a host line-to-line call. Similarly, an RSS line-to-ESS line call requires about 49 percent more real time and an intra-RSS call (reswitched-down) requires about 113 percent more processor real time than a host line-to-line call.

Because of overhead associated with each RSS hosted by a No. 2B ESS and real-time factors associated with each RSS call, the No. 2B ESS call capacity is reduced with an increasing proportion of RSS traffic. The amount of this reduction is a function of the number of RSSs hosted and the RSS traffic.

When this project was still in the initial planning stages, it was evident that providing RSS capabilities would affect the host office capacity. Throughout the entire development of the feature, considerable emphasis was placed on performance issues. This included such items as: planning effective communication strategies between the host and SPUC, minimizing RSS-related work in non-RSS segments of code, and optimizing and fine tuning frequently executed functions. The result of these activities is a relatively small penalty in host capacity due to RSS.

## V. ACKNOWLEDGMENTS

The authors wish to acknowledge the outstanding efforts of the many individuals at Bell Telephone Laboratories, American Telephone and Telgraph, and Western Electric who have contributed to this work.

## *Modernization of the Suburban ESS:*

# Billing and Measurements Modernization

By J. P. LODWIG* and D. A. WARD*

(Manuscript received May 28, 1982)

With the introduction of the 2B Extended Feature Generic #3 (2BE3), No. 2B Electronic Switching System has modernized its arrangements for billing and traffic measurements. High-speed, synchronous data links are used to teleprocess billing information to the No. 1A Automatic Message Accounting Recording Center and to forward traffic data to the No. 1A Engineering and Administrative Data Acquisition System Center. This article describes the implementation of these features in the 2BE3 generic and how these new interfaces have resulted in more precise and more reliable data.

## I. INTRODUCTION

The billing and traffic measurements capabilities available in the No. 2B Electronic Switching System (ESS)† today are the culmination of an evolutionary process spanning more than a decade. During that period, the ESS environment was changing at a very rapid pace, and as a result the billing and traffic measurements processes were continually being upgraded to meet the demands for each generic. Repre-

senting the latest capabilities for billing and traffic measurements in the No. 2B ESS are the No. 1A Automatic Message Accounting Recording Center (AMARC) Interface feature and the No. 1A Engineering and Administrative Data Acquisition System (EADAS) feature, respectively. Both the AMARC and EADAS features require near-real-time data collection at the No. 2B ESS. The data are then passed to I/O message buffers for subsequent transmission to an AMARC or EADAS data center. The AMARC formats the billing information for a Revenue Accounting Office (RAO) to use in preparing customer bills, while EADAS provides real-time surveillance and disperses traffic data to various Operation Support Systems (OSSs) for use in maintaining the switching system and planning future growth. Data to the AMARC and EADAS systems are transmitted via synchronous, 2.4-kb data links using the BX.25 protocol. The AMARC feature also uses 4.8-kb data links for those offices presenting too large a load for the 2.4-kb link.

### *1.1 No. 1A AMARC*

Although several hardware and software versions of an AMARC exist today, the No. 2B ESS interfaces only with the No. 1A AMARC equipped with the 1AAM4 generic. The AMARC provides service to various types of switching systems today with several different interfaces giving flexible format, protocol, and data-link speeds between the switching systems offices and AMARC. The AMARC combines the data received from the switching systems into a format acceptable by an RAO. The data are then recorded on magnetic tape, which is sent to the RAO for processing into telephone bills for the customers. Figure 1 represents the interface of a No. 2B ESS with an AMARC.

### *1.2 EADAS*

An EADAS data center (with the 1AED4 generic) connected to the No. 2B ESS (with the 2BE3 generic) receives traffic data and plant data from the No. 2B ESS. The traffic data are load measurements such as peg and usage counts for office totals, and peg, usage, and overflow counts for trunk and service circuit groups. The plant data are measurements that indicate the health of the system. Examples are control unit and peripheral unit diagnostic all-tests-passes and faults. The traffic and plant data sent to EADAS and processed by the EADAS data center are then used by other associated OSSs. The Network Operations Report Generator (NORGEN), part of EADAS, accesses the processed EADAS data directly for its near-real-time reports. Downstream OSSs process EADAS data after they have been sent to them via magnetic tape. Two such downstream OSSs to access the data via the Traffic Data Administration System (TDAS) are

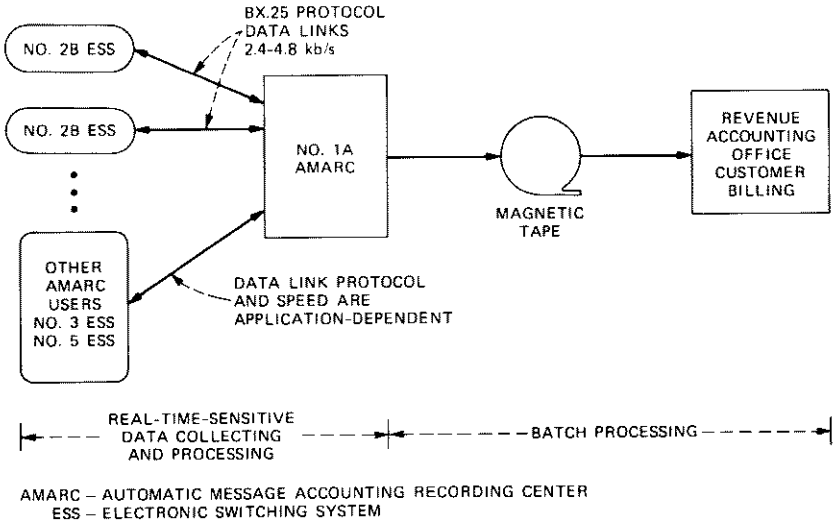

Fig. 1—Interface of a No. 2B ESS with an AMARC.

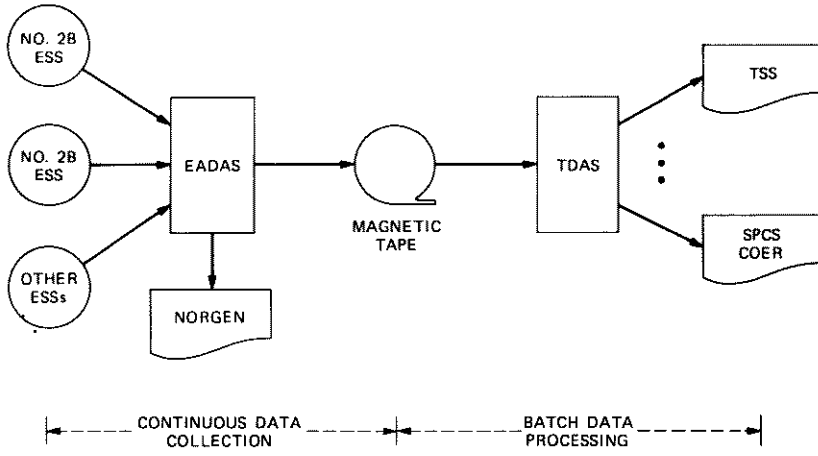
SPCS COER (Stored Program Control Systems Central Office Equipment Reports) and TSS (Trunk Servicing System). The reports generated by SPCS COER and TSS are needed by network administrators to monitor switching system services, measure utilization, and calculate capacity of the switches, and by trunk administrators to compute trunk group traffic load and current trunk requirements as part of their day-to-day jobs. The capability of providing timely data to SPCS COER and TSS is advantageous (see Fig. 2 for layout). The OSSs can now develop additional needed reports (e.g., summarizing centrex group counts). Also, with the addition of RSS host capability in 2BE3, the traffic data for an RSS is collected by the No. 2B ESS. Extreme Value Engineering (EVE) techniques are used for the engineering of an RSS. The EVE selection is done by EADAS and the engineering calculations are done by SPCS COER.

## II. No. 2B ESS HISTORY AND LIMITS

### *2.1 Billing data collection*

Prior to the installation of the 2BE3 generic, the primary method of billing calls was through Local Automatic Message Accounting (LAMA). Other methods used to a lesser degree were Centralized Automatic Message Accounting (CAMA) and in some instances message registers. The choice of billing arrangement was based on applicable tariffs (flat rate or local measured service) and resulting call volumes. Flat rate areas used message registers or CAMA while local measured service areas used LAMA.



COER – CENTRAL OFFICE EQUIPMENT REPORTS
EADAS – ENGINEERING AND ADMINISTRATIVE DATA ACQUISITION SYSTEM
NORGEN – NETWORK OPERATIONS REPORT GENERATOR
SPCS – STORED PROGRAM CONTROL SYSTEMS
TDAS – TRAFFIC DATA ADMINISTRATION SYSTEM
TSS – TRUNK SERVICING SYSTEM

Fig. 2—No. 2B ESS and Operation Support Systems.

The LAMA version of No. 2B ESS billing provides the most complete and versatile billing process. However, in some cases daily collection of LAMA tapes could be costly. One possible solution to this first problem was to enhance the software and upgrade the tape recorder to accommodate full measured service billing. However, the collection of the tapes on a daily basis still presents an unattractive cost factor.

### *2.2 Traffic data collection*

In a No. 2B ESS office, each teletypewriter (TTY) will serve as a primary output device for one function. A 110-baud data link could be connected from the traffic TTY controller circuit to an EADAS monitored interface. Once it is output to any device, the data no longer exist in the corresponding register, and subsequent output to any other device is not possible. In addition, a large office could not transmit all of the data to EADAS because of the limited data-link speed. Thus, only a subset of the total data was sent (i.e., one or two hours worth each day, assigning different data to the schedules). Another problem was the data skew associated with these output processes. The TTY print rate was 10 characters per second. At this rate it took a minimum of 5 minutes to print a traffic schedule of 600 registers. (Most No. 2B offices have more than 600 registers on a schedule and some require

15 minutes print time for even larger schedules.) The last line of data on a printed schedule is therefore skewed from the first line by the print time. To solve the need for all the data all the time and for accurate data (i.e., prevent data skew) holding registers are added to the 2BE3 generic.

## III. SOLUTION AND NEW PROBLEMS

The inclusion of AMARC and EADAS in the 2BE3 generic provides the increased billing capacity required by the switch and improved traffic information for engineering the switch. This does not preclude the use of billing arrangements available prior to 2BE3 (e.g., LAMA), where increased billing capacity is not required. Also, most of the traffic information capabilities available prior to 2BE3 have been retained. However, as with any new approach, new problems appeared for both AMARC and EADAS. In the early planning phase, one of the more basic problems was establishing interface requirements acceptable to Bell Laboratories systems engineering, AMARC development, EADAS development, and the No. 2B ESS development organization. The selection of a data-link protocol that could be used for both EADAS and AMARC was a highly desirable consideration. Also, during this same time frame, No. 5 ESS committed to AMARC and EADAS for its first application. This further complicated the situation in that now there was another system with a dissimilar architecture and software environment that could affect the development schedule and interface requirements.

## IV. NEW PROTOCOL

Selection of the communications protocol was a major consideration in establishing AMARC and EADAS requirements. A protocol represents a formal agreement on the exchange of information between two or more entities. It provides a multilayered set of rules that govern the interconnecting electrical signals (level one), packetized data (level two), complete message (level 3), and user application data transfer procedures (level 4 and above). Several protocols were considered, e.g., DDCMP, BYSYNC, X.25, etc., but only X.25 had the recommendation of the Comite Consultatif International Telephonique et Telegraphique (CCITT). Eventually a subset of X.25, now referred to as BX.25, was proposed and accepted as the AMARC feature protocol. Subsequent investigation of this proposal revealed that the proposed BX.25 protocol was also suitable for the EADAS feature. A more detailed presentation of this capability in the No. 2B ESS 2BE3 generic is provided in this issue of the *Journal* in an article entited "Adding Data Links to an Existing ESS."

## V. INTEGRATION OF AMARC

The AMARC feature encompassed many areas of call processing as well as data integrity and transmittal. Some areas were related to AMARC alone, while others were a consequence of a retrofit constraint that required simultaneous recording by AMARC and LAMA. Rather than attempting to cover the entire scope of AMARC, we will discuss only the basic operational capability and selected concerns.

### *5.1 Basic operation*

The AMARC feature collects billing data in real time in the No. 2B ESS and then transmits this data using either a dedicated 2.4- or 4.8-kb/s full-duplex transmission facility or an automatic-dialed backup data-link facility of the same transmission speed in case of primary link failure. The No. 2B ESS/AMARC interface uses a double-entry billing system consisting of an initial/answer entry and a disconnect entry. LAMA recording, however, uses a triple-entry billing system consisting of initial, answer, and disconnect entries. Data for each LAMA entry are collected in real time and loaded into a dedicated LAMA buffer prior to being directed to the tape recorder via I/O control at interrupt level. The use of special AMA registers allows the basic billing structure to remain as it had been for LAMA and still achieve the double-entry billing required by AMARC. Each AMA register is linked with a specific call by direct extension of the Transient Call Record (TCR) memory already designed into the No. 2B ESS architecture. These TCR extensions are then referred to as TCRX registers. The initial billing data are collected and placed into the TCRX registers until answer time and then, upon verification of Minimum Chargeable Duration (MCD), the data are moved into an AMARC data buffer. At disconnect, the data are again collected in the TCRX. When the entry is assembled, it is then loaded into the AMARC data buffer.

### *5.2 Entry association*

An obvious requirement for assembling the double entry into one call record by AMARC is the need to associate the initial/answer entry with the corresponding disconnect entry. The method provided by the No. 2B ESS is to map an equipment number (the physical location of a call on the No. 2B ESS or RSS network) into a 15-bit Virtual Equipment Number (VEN) and record the VEN as the low-order 16 bits of a 24-bit Call Assembly Index (CAI) that accompanies each billing entry. The CAI high 8 bits are zeroes except for the case of call-forwarded calls. The special use of the high 8 CAI bits for call-forwarded calls will be described later in this article.

The CAI counterpart in LAMA recording is the Call Identity Index

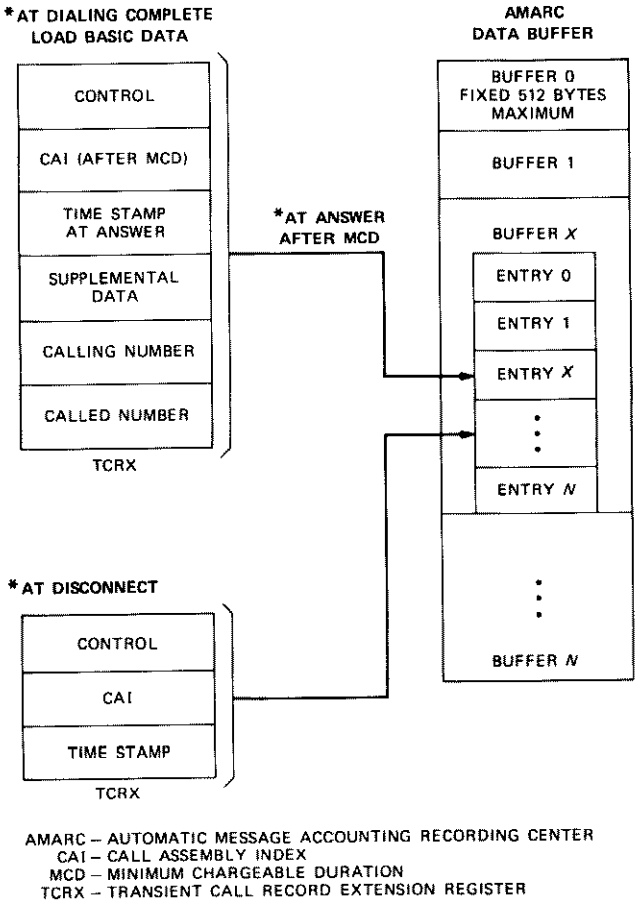


Fig. 3—Basic billing information flow between internal AMARC registers and buffers.

(CII). LAMA recording guaranteed that CIIs appearing on the tape would be unique for the duration of a call by maintaining a table of the active CIIs derived using a time-consuming hashing scheme based upon the VEN. Since the method of call sequencing associated with the CAI no longer requires the ESS to provide a hashing algorithm, significant real-time savings are achieved for the No. 2B ESS call-processing execution environment. Figure 3 represents the basic billing information flow between internal AMARC registers and buffers.

### *5.3 AMARC data buffer*

The No. 2B ESS AMARC data buffer is an engineerable area of read/write memory. The maximum size is designed to provide up to two minutes of billing data storage during a data-link failure. Auto-

matic recovery to the dialed backup data link can be obtained within this two-minute period. The buffer is segmented into message size entities of 512 bytes each. When a buffer segment has insufficient room for the next data entry, or a fixed time limit has expired, the data are either sent immediately or queued for later transmission through the I/O program. The decision depends on available buffer space on the Serial Peripheral Unit Controller for Data Links (SPUC/DLs). Further information on this subject can be found in the article "Adding Data Links to an Existing ESS," also in this issue of the *Journal.*

### *5.4 Real-time benefit*

The I/O process that moves the data buffer to a SPUC/DL is accomplished at a significant real-time savings compared with the I/O interrupt process for LAMA. Whereas LAMA had a data acceptance limitation (primarily related to hardware design) of three bytes of data within a 20-millisecond interval, the hardware structure of the SPUC/DL allows software definition of the maximum number of data bytes in a message. The I/O design in 2BE3 is flexible but currently allows 256 bytes of data to be sent to the SPUC/DL during one 100-millisecond cycle of the operating systems main loop. Thus, the repetitive I/O overhead associated with small segments of information pertaining to each LAMA recorded call is very significant compared to the AMARC overhead for sending 256 bytes of data for 15 to 20 calls. The overall real-time savings due to the AMARC billing feature, including I/O changes, was 2.8 milliseconds per call (3.6-ms AMARC versus 6.4-ms LAMA). This has the effect of increasing the overall call-billing capacity of the No. 2B ESS when full measured service is offered.

### *5.5 Auxiliary registers*

For some cases where the data required for a specific call type cannot be contained in a single TCRX register, auxiliary registers are provided to hold the overflow data and are referred to as auxiliary overflow registers. The auxiliary registers are unique to the AMARC feature, while the TCRX registers may be used for other features not related to call processing. The auxiliary registers are associated with the call by placing an index pointer into the TCRX used for the call. Figure 4 shows the connectivity of auxiliary overflow registers plus an extension into auxiliary call-forwarding registers.

### *5.6 Multiple calls associated with one CAI*

Each leg of a call-forwarded call requires separate billing to each of the parties involved with the call. Since separate billing is required,

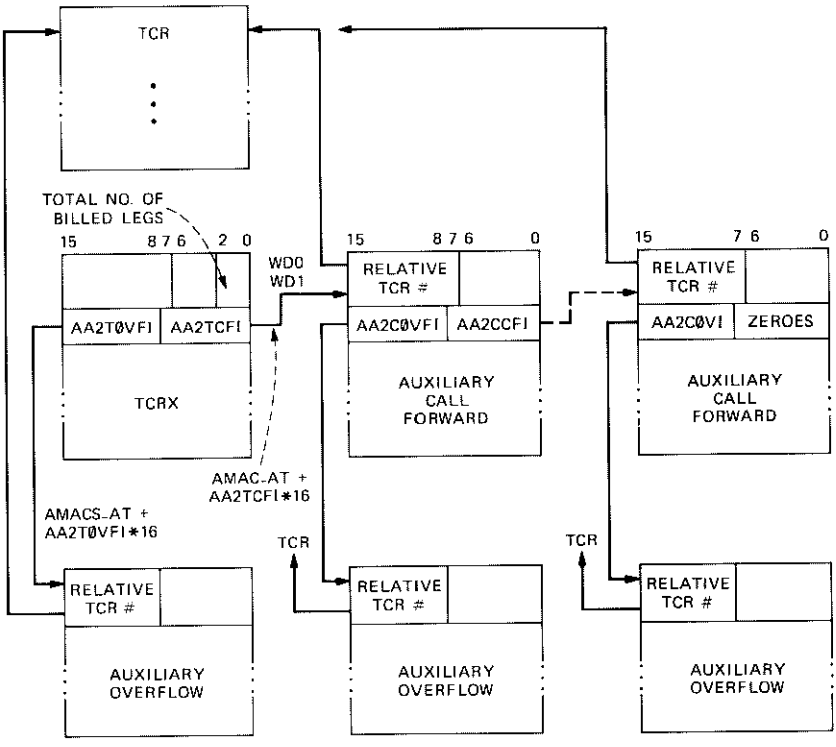

Fig. 4—AMARC message register interrelation.

the simplest method of administration is to provide a separate initial/answer entry followed by a corresponding disconnect entry for each leg of the call. This requires a different CAI for each billed leg and thus presented a problem in that the only VEN available at disconnect is the originating party VEN. This occurred since the No. 2B ESS call-processing structure prior to the 2BE3 generic did not provide a record of the intervening call legs once the call was made stable. The LAMA billing relied on the CII record table to provide the correct billing entry association. In the 2BE3 generic a record of the number of billed legs of the call is kept in a Stable Information Entry (SIE) during the stable state of the call. The SIE itself is accessed based upon the originating party VEN and codes defining the specific use for that SIE.

Correct billing entry association for AMARC call-forwarded billing records is achieved by prefixing an incremental count to the CAI at answer time for each call-forwarded billing entry except for the first

billed leg of the call. The CAI can then be expressed as the CAI = (N-1)*2**16 + VEN, where VEN represents the 16 low-order bits of the CAI and N equals the billed leg number (1–3) for call-forwarded calls. At disconnect, a billing entry is made for each billed leg of the call by once again prefixing a count to the CAI for each additional billed leg of a call exceeding the first leg. The correct number of disconnect entries is determined by the data available in the SIE.

The initial billing information for call forwarding is collected in the associated TCRX and in supplemental auxiliary registers as required. As in the case of auxiliary overflow registers, call-forward registers are associated with the call by loading an index point to the current register into the register servicing the previous leg of the call. An audit capability is provided by placing the TCR number in each register. Thus, random audits may test a register for activity and, by going to the specific TCR, test for the expected connectivity back to the auxiliary registers originally interrogated. This connectivity is illustrated in Fig. 4.

### *5.7 Retrofit considerations*

Several items of concern exist for the case of an AMARC retrofit into an office previously served by LAMA. One concern relating to the LAMA/AMARC simultaneous recording requirement during retrofits is the administration of call types, e.g., measured service, toll, etc. LAMA entry codes (equivalent to AMARC call types) relating to various calling conditions do not map directly with AMARC call types. This required careful preparation of administrative documentation to allow in some cases a temporary association of call-type categories for LAMA and AMARC. A significant consequence of the call-type association is the ability of the telephone operating companies to validate system operation by comparing the billing records of LAMA and AMARC during the retrofit mode of operation. Another consideration for the retrofit case is the recovery strategy. Since LAMA was the prime billing medium prior to retrofit, all calls billed during the retrofit are obtained from LAMA data tapes; thus all failure modes default to promoting successful LAMA billing.

## VI. INTEGRATION OF EADAS

The EADAS feature modified the traffic and plant-collecting and printing routines. With the BX.25 protocol as a common base, developing the interface requirements became a matter of resolving application-level interfaces between No. 2B ESS, No. 5 ESS, and No. 1A EADAS. There are interface differences between the No. 2B ESS to No. 1A EADAS and the No. 5 ESS to No. 1A EADAS due to the

different architecture structures of No. 2B ESS/generic 2BE3 and No. 5 ESS. Having the No. 2B ESS conform to the identical interface between No. 5 ESS and No. 1A EADAS would cause a real-time penalty to No. 2B ESS. The resulting operational interface between the No. 2B ESS and No. 1A EADAS is described next.

### *6.1 Basic operation*

The high-speed EADAS interface feature provides for the collection and transmittal of both traffic and plant measurement data to No. 1A EADAS. With this implementation the traffic and plant measurement data are collected on two schedules—a 30-minute schedule and a 24-hour schedule. The schedules start collecting 30 seconds before the clock 00 minute and 30 minutes and finish by one minute after 00 or 30. The data are collected and stored in holding registers within 90 seconds, resulting in a maximum of 90 seconds of data skew. The data for most offices will be collected within 30 seconds. The resulting data skew of 30 to 90 seconds is significantly more accurate than the previous skew of 5 to 15 minutes. Schedules are not transmitted until a poll is received from No. 1A EADAS requesting a schedule. The No. 2B ESS and No. 5 ESS communicate with the 1AED4 generic of No. 1A EADAS using the BX.25 protocol.

The interface between the No. 2B ESS and the No. 1A EADAS is a poll-and-answer mechanism. The No. 1A EADAS polls for four types of data:

1. Time of day
2. 30-minute data
3. 24-hour data
4. Record base (working member) data.

The No. 2B ESS answers with the:

1. Time of day
2. Data from the H (specified busy hour), C (specified nonbusy hour), W (specified weekly), and PLT (specified plant) schedules
3. D (daily or division of revenue) schedule
4. Working member count of trunk and service circuits for each poll.

The No. 1A EADAS also sends a message when it is planning to discontinue operation temporarily for such things as maintenance. The No. 2B ESS accepts the message and prints out a message to the TTY to inform the craft. The No. 2B ESS can send error response messages to No. 1A EADAS: (1) when the data for a message have been overwritten because current polling from the No. 1A EADAS is still continuing when the next collection is started, or (2) if a poll comes in when the 2B is collecting data for a message.

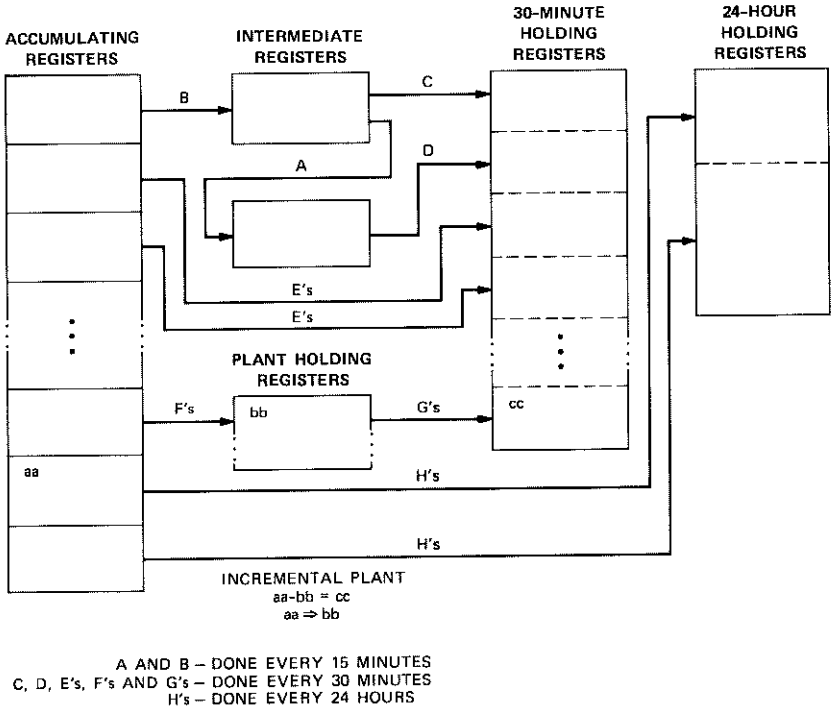

Fig. 5—Data collection.

### *6.2 Data collection*

Data collection is started every quarter hour to collect the intermediate counts and every half hour to collect the 30-minute counts. Also, the 24-hour counts are collected at midnight before the 30-minute counts. In Fig. 5 the lines A through H match the description of each type of count. The quarter-hour counts, load service measurements, are moved to the intermediate registers (A and B). The intermediate registers contain two sets of these registers, the previous quarter hour's and the current quarter hour's. The two sets of counts are kept until the half hour when both sets are moved to the 30-minute holding registers (C and D). Also, every half hour the counts such as office totals, service circuit, trunk circuit, multiline hunt, and simulated groups, junctor usage, centrex, and network usage are moved to the 30-minute holding registers (Es). Then the half-hour increment of the plant counts are moved to the 30-minute holding registers (Fs and Gs). This is done by subtracting from the current plant accumulating counts the intermediate plant holding registers, storing the difference in the 30-minute holding registers, and moving the accumulating plant

counts to the intermediate plant holding registers. The 24-hour counts, division of revenue, are moved to the 24-hour holding registers (Hs).

### *6.3 Override No. 1A EADAS*

If necessary, the 2BE3 generic can revert to the standard H, C, W, and D schedules through human intervention. When an office has EADAS active, the 30-minute data are from all the data that could have been on the H, C, and W schedules and the 24-hour data are from the D schedule. An office could revert to the standard schedule output if desired or if the No. 1A EADAS center would go off-line for an extended period of time. The No. 2B ESS office would then provide the data on hard copy and paper tape punch. In the No. 2B ESS, the standard schedules are printed automatically under the control of the Traffic Work Table (TWT) from the holding registers. This arrangement (non-EADAS) does not support RSS EVE engineering needs for SPCS COER. This mechanism is overridden when EADAS is active and it can be reenabled with a single TTY input message to inhibit EADAS.

### *6.4 Interface differences*

Because of the differences in No. 2B and No. 5 ESS architecture, the interface with No. 1A EADAS does differ on three points:

1. The No. 2B ESS keeps time differently than the No. 5 ESS.
2. The No. 2B ESS does not indicate overflow of registers through the special register values as does No. 5 ESS. The values 65,526 through 65,535 are used as special register values, i.e., for overflow, bad data, and unequipped register.
3. The 2B transmits two-byte data low byte first instead of the reverse.

Therefore, the No. 1A EADAS does handle these differences. For the No. 2B ESS to have followed the same interface as between No. 5 ESS and No. 1A EADAS on these three points would have cost the No. 2B ESS a real-time penalty.

## VII. SUMMARY

The addition of the AMARC and EADAS features to the 2BE3 generic enhanced the No. 2B ESS capability. AMARC achieves the billing systems goals of reduced operating expense while providing full measured service billing capability for the No. 2B ESS. Also, owing to a redistribution of tasks and restructuring of the programs, AMARC allows higher call capacity in the No. 2B ESS compared with LAMA billing.

All traffic and plant data are sent to EADAS, which allows for the efficient integration of the local switching systems into Total Network

Operation Plan (TNOP). Also, owing to the addition of holding registers there is virtually no data skew. The EADAS feature is using a communication interface that could support network management messages and controls in a future generic.

## VIII. ACKNOWLEDGMENTS

The authors extend their appreciation to all of the 2BE3 development team for their cooperation in providing the AMARC and EADAS capabilities for the No. 2B ESS. In particular, we wish to thank Iris Dowden and Eric Kampmeier for their contributions towards AMARC and Wendell Savino for his participation with EADAS.

## AUTHORS

**Deborah A. Ward,** A.A.S. (Computer Technology), Purdue University Calumet Campus; Bell Laboratories, 1973—. After joining Bell Labs in 1973, Mrs. Ward worked on No. 3 ESS and No. 2B ESS projects. During this time, she was involved in the translations design and the program design, coding and testing of the translations access routines for No. 3 ESS. She also was involved in maintaining the administrative traffic program for No. 3 ESS. Her work on No. 2B ESS has also been in the administrative traffic area. Mrs. Ward has been a member of the No. 5 ESS Data Base Design Department at Bell Laboratories in Naperville, Illinois, and since early 1982 has been working on the No. 5 ESS project.

**John Lodwig,** B.S.E.E., 1971, Illinois Institute of Technology; Bell Laboratories, 1967—. Mr. Lodwig's initial work at Bell Laboratories involved circuit design with the No. 101 ESS, and later the 3A Common Controller, which has been used as a central processor for several electronic switching systems, e.g., No. 2B ESS, No. 3 ESS, etc. In 1976, he made the transition from circuit design to software design and became involved with automatic message accounting billing. It was during the period from 1976 through 1980 that he became involved with the Automatic Message Accounting Recording Center (AMARC) billing feature for the No. 2B ESS. More recently, Mr. Lodwig has been working with common channel interoffice signaling and domestic local planning for the No. 5 ESS.

## *Human Factors and Behavioral Science:*

# Introduction

By E. E. SUMNER*

(Manuscript received March 15, 1983)

Human factors and its parent discipline, behavioral science, help us understand human capacities, interests, and needs. This understanding is especially important now, because modern technology makes unusual demands on its users. Knowledge and techniques derived from the behavioral sciences can help identify and design new products. This paper discusses the background and roles of the behavioral sciences, and it summarizes the contents of this issue.

This special issue of *The Bell System Technical Journal* presents a sample of recent activities of the behavioral science and human factors community at Bell Laboratories. Articles were drawn from several areas to give the reader an idea of the ways behavioral science and human factors contribute to the work at Bell Laboratories and, now, American Bell, a new subsidiary of AT&T.

This issue is intended for three groups of readers. First, behavioral scientists should gain a perspective of how their discipline is used in our Company. Second, members of the engineering and technical community who read this journal will see how behavioral science and human factors can contribute to the best use of technical innovation. The third audience this volume serves is the growing population of students who might find work in the field to be as interesting and challenging as we have.

## I. HUMAN USES FOR NEW TECHNOLOGY

We are now in a qualitatively new era of invention. Throughout history, imaginative people have known what they would like to do, but they have not had the means to do it. They wanted to fly, to communicate with each other from afar, to be entertained easily, and to have knowledge at their fingertips. Until now, reality has lagged behind imagination. Today, inventions such as the transistor, the laser, and large-scale circuit integration have reduced the gap between what we can imagine and what we can do. The future seems unlimited; but we face a new problem—how to make wise choices among unlimited opportunities.

Choices between alternative designs of a product have always reflected trade-offs among technical feasibility, cost, and utility to the user. But new technology has increased engineering flexibility and lowered the cost of components until the balance among these trade-offs has shifted dramatically toward the needs and desires of the user. Ways of designing a product to best fit users' interests can now be addressed as never before.

Word processing is a vivid example of this shift. When Christopher Sholes and his associates designed the typewriter a little over 100 years ago, even a slow operator would tie up the keys. Since faster machine action wasn't possible, Sholes' answer was to spread the high-use keys far apart in the key basket, which in turn forced a keyboard arrangement that is less than optimal for the user.[1] In contrast, it is not surprising to anyone now that a computer-based word processing system can keep up with a dextrous typist entering text from a keyboard. The machine can even operate on the text between key strokes. Such processing systems can instruct new users, provide page- or line-oriented editors, and format output according to users' needs. Computer-based text handling can thus be "user friendly"; it can allow the novice typist to substitute rudimentary knowledge of a set of computer programs for the psychomotor skills of an advanced typist. The balance is seen to have shifted even further toward the user when we consider the computer language analysis techniques described later in this issue (see the articles by Frase,[2] Macdonald,[3] and Gingrich[4]).

As human issues become more central to design, pressure increases to provide a technology of invention, design, and evaluation for human use. This technology is the focus of human factors or human performance engineering. It is an application of behavioral science concerned with the design of machines and procedures for human use. Bell Laboratories established the first industrial human factors laboratory in the late 1940s under the direction of John E. Karlin. Examples of early work include all-number-dialing studies, design of better dial layout, and development of objective preference methods. (Hanson[5]

provides a history of human factors work at Bell Laboratories in this issue.) The need for this work has increased, and participation of human factors specialists has grown explosively in recent years. For example, the number of people with primary work assignments in human factors or behavioral science has tripled in the last decade, from a starting point of about 100 workers. Many of these people recently joined American Bell, a new subsidiary of AT&T, which designs and markets enhanced services and equipment such as telephones and PBXs. Human factors specialists are now involved in virtually every Bell Laboratories and American Bell development having an important human performance component.

Even so, the potential for the applied behavioral sciences has only begun to be realized, partially because technology has just begun to challenge our ability to imagine new applications, and partially because the contribution of behavioral and related sciences has been difficult to foresee. This volume shows, by example, the contribution of behavioral science to an understanding of human perceptual, cognitive, and motor behavior, and how human factors applies this understanding to the design of new products.

Today, we are not only faced with choices between alternative designs, we must also decide what *should* be designed. This is the hardest question. Currently, we have technologies searching for applications, and new computer applications increasingly resemble intelligent, almost human, actions. Hence, an active role for behavioral science in planning these applications is crucial.

## II. BEHAVIORAL SCIENCE RESOURCES

Most of the people doing applied and basic behavioral science research at Bell Laboratories and American Bell have been trained as experimental psychologists. Not many have degrees in human factors, because until recently there have been few programs in the field. In the past fifteen years, psychological research on learning and perception has broadened to include cognitive psychology, which studies thinking, language, and other aspects of information processing. Psychologists are well acquainted with sensory and central nervous system limits on human information handling, through studies of thought processes, linguistic and problem-solving skills, learning and forgetting, social communication, perceptual motor skills, and strength and endurance. Psychologists are also trained in experimental design, statistics, and the measurement of human performance, attitudes, preferences, and motivation.

Behavioral science work in Bell Laboratories has been differentiated mainly by its intent and the clientele that uses it. Basic research has been directed more at understanding the processes underlying behav-

ior, while applied research, emanating from human factors groups, has been associated with designing specific products to meet the needs, interests, and performance capabilities of its users. If research and applications specialists were to collaborate on a study, the measures taken of a person's performance—for instance, reaction time to red or green lights—would be of equal interest to both, but would have been collected for different reasons. For research, we would interpret these measures as a reflection of some underlying process, while for applications we would see the behavior as a fact to be reckoned with in product design. For example, Pierce and Karlin[6] found that reading rate is independent of the number of alternative words on a list of fixed length. The researcher might interpret this result as a reflection of channel capacity of humans as information processors. The applications designer might find the invariance of reading rates important for determining transmission requirements for a speech communication system.

In basic research, we attempt to structure work to provide generality beyond the experimental conditions under which data were collected. Researchers routinely publish work, which is read by other researchers, academics, students, and their colleagues. Applied research, on the other hand, often requires team cooperation, and people are responsible to others for providing information needed to complete a design. Although information gathered is often private and is generally collected to answer questions about the product being designed, data collected in one application often find good use in other applications (see McCormick[7] and Woodson[8]). Applied work has sometimes been seen by some as just the use, refinement, and dissemination of existing methods, rather than the invention and development of tools that generalize across tasks. This is wrong. Many behavioral concepts and techniques, important to theory as well as application, have arisen from practical problems. Aptitude testing and the measurement of human channel capacity are only two examples.

The role of basic research in Bell Laboratories in the study of psychological processes is well known to the outside world through research published over the last 20 years. Hanson[5] briefly summarizes highlights of that work in this volume. An example of applied work completes this section.

The human factors specialist contributes to product design at each stage in product development. One trade-off of particular concern is the extent to which the operation of a product can be made self-evident and require only minimal user training. Training can represent a substantial investment for a new electronic telephone system being installed in a large business having hundreds or thousands of users. The number and range of features available to each user mean that even a well-designed system will have to be carefully explained.

Dooling and Klemmer[9] have described work conducted on training procedures for business telephone users. The problem was that, although customers were happy with their systems, they wanted more training. But telephone companies found that two-hour training sessions, run with small groups of users, were too expensive. The results of several studies led to a more efficient training package that required only one hour of training time. The highlights of these studies are as follows.

Originally, participants in a session were trained in the detailed operation of as many as a dozen features in the two-hour session. More information was being presented than many participants could absorb. Testing showed that a card summarizing the operation of the features was a powerful performance aid. Consequently, training people to use the card replaced much of the detailed explanation and contributed to a reduction in training time. Learning to use telephone features is a cognitive task with only a minor motor component. If it is not a difficult manual task is it necessary to give hands-on experience? A set of laboratory and field studies showed that working the features on the telephone in the session did not significantly aid user performance. Here was a way to further shorten the training session, by eliminating unnecessary activities. Finally, self-instruction was found to be as effective as the group sessions both in laboratory experiments and in field studies. Thus, it was not crucial for all users to attend the training sessions.

Human factors specialists contributed here by proposing alternative training schemes based on what they knew about training and the ways people learn efficiently. They then devised studies and gathered data on the efficiency of those alternatives. Providing recommendations from theory alone would not have been enough to convince either the human factors people or telephone company management to use new procedures.

The skills of behavioral science personnel are critical now. Throughout the computer industry, much is said about "user-friendly" systems, yet in few places are the tools of behavioral science well understood, much less effectively applied. Computers are no longer just science and engineering tools; they are used every day at work, at school, and at home. Computers are for everyone, and for the Bell System this means finding new ways to relate technology to human needs and abilities.

## III. STRUCTURE AND THEMES OF THIS SPECIAL ISSUE

This issue is divided into five sections. The "History and Methods" section describes the growth of human factors work at Bell Laboratories and techniques that have been used to study human response

to communications products. Hanson's paper reviews human factors history, while Eigen's paper describes field test methods. Many techniques are used by behavioral scientists, of which field testing is only one. However, Eigen's paper gives an overview of one traditional use for human factors work—i.e., to evaluate products created by communications engineers.

The second section, "Characteristics of Human Performance," describes fundamental properties of human perception and performance. Julesz' and Bergen's paper describes mechanisms of visual perception, concentrating on the perception of texture. The paper by Rosenbaum explains how people control the timing of finger movements, and this may, in the future, help us understand how better to design keyboards and other control devices and tools. The final two papers in this section address higher-level cognitive processes. The paper by Cleveland, Harris, and McGill describes studies of how people derive information from graphic displays, while the paper by Egan explores how people reason when solving verbal problems. In particular, Egan shows that people can be trained to think in new ways, using strategies they normally do not use. These papers provide context for understanding possible limits and potentials for human adaptation to new technology.

The third section, "New Technological Demands," includes papers that deal with the unusual requirements that modern technology places on us. The paper by Donegan and Koppes introduces the three papers that follow it; their introduction emphasizes the wide variety of skills and characteristics that are needed by the craft personnel who install, maintain, and repair telecommunications equipment. The paper by Kohl describes work on the design of shapes to improve handling physical objects, the paper by Paul describes improved designs for splicing connectors, and the final paper in this trilogy, by Flamm, describes connecting-block design changes that reduce errors often made with complex apparatus. Following these papers, the article by Cohen moves on to the design of keyboards and people's ability to use new technology, such as membrane keyboards. Thus, papers in this section progress from simple to more complex performance.

The fourth section, "Interface Design," expands the theme of verbal interactions demanded by new technology. The paper by Furnas, Landauer, Gomez, and Dumais explores alternate ways to design key words to ease people's interactions with computers. The paper by Streeter, Ackroff, and Taylor extends this concern to the design of abbreviations for command names. The theme of human interactions involving verbal information is carried forward in the paper by Karhan, Riley, and Schoeffler, as they describe the design of telephone cards to provide easy access to dialing information people need when phoning. This theme is extended in the paper by Coke and Koether, which

explores the match between people's ability to read and the reading demands placed on them by the language of telecommunications documents. The final paper, by Holmgren, shows that technology, too, has limits, and that proper adaptation of humans to the limited speech of machines can make it possible for machines to understand what humans say.

The fifth and final section of this issue, "New Functions for Technology," is an example of bringing behavioral science to bear on the design of new products. The papers in this section, by Frase, Macdonald, and Gingrich, describe the *UNIX* Writer's Workbench software, a set of programs that do many things editors do when they proofread and comment on various features of written material. This section exemplifies the issue raised at the start of this introduction; we have the technology, we understand the physical principles needed to design new electronic tools; we have the engineering skills to build those tools, and we have the computing techniques to program them. But we need a behavioral perspective to know where human minds falter and need help, and where they excel and are best left alone. Human factors—behavioral science, generally—is an essential resource in this new era of communication design.

## IV. ACKNOWLEDGMENTS

This special issue was created through the efforts of many people. Paul A. Turner proposed this special issue to the Editorial Committee of *The Bell System Technical Journal*, with the encouragement of Thomas H. Crowley, a member of that committee. V. G. Stetter, followed by Eric Wolman, served as administrative coordinator for the issue. A working-level group, chaired by Barry L. Lively (now of American Bell) and including Lawrence T. Frase, Thomas K. Landauer, and Christine A. Riley (American Bell) solicited, edited, and organized the papers in the volume. Special recognition should be given to Lawrence T. Frase and Barry L. Lively for their contributions. A panel of more than 30 behavioral scientists and human factors specialists within Bell Laboratories and American Bell read and commented on the papers. The ground rules for that procedure discourage acknowledgment of those reviewers by name, but the reader should know that their contributions were vital to the issue.

## AUTHOR

**Eric E. Sumner,** B.M.E., Cooper Union, 1948; M.S. (Physics), 1953 and professional degree (Electrical Engineering), 1960, Columbia University; Bell Laboratories, 1948—. Upon joining Bell Laboratories, Mr. Sumner worked on wire spring relays, trouble recording apparatus, and ESS circuits. He was responsible for the first commercial PCM system for exchange trunks. He was promoted to Director and served in positions responsible for various transmissions systems. He was Executive Director of the Loop Transmission Division from 1967 to 1979, when he was appointed Executive Director of the Customer Network Operations Division. He assumed his present position as Vice President, Software and Processor Technologies, in 1981. Mr. Sumner is a member of the Advisory Board to Georgia Institute of Technology's School of Electrical Engineering; Chairman of the Advisory Council to Cooper Union's School of Engineering; President of IEEE Communications Society; Chairman of IEEE Policy Board; and recipient of the Alexander Graham Bell Medal of the IEEE for pioneering contributions to the field of digital communications. Mr. Sumner is author of a number of technical articles and talks and has been granted 11 patents. Fellow, IEEE; member, Tau Beta Pi and Pi Tau Sigma.

# History and Methods

This special issue begins with a brief history of human factors and behavioral science at Bell Laboratories. Bruce Hanson traces the expansion of applied and basic behavioral science at Bell Laboratories over more than three decades. His account shows the important role of laboratory studies and field tests in helping us understand how people interact with new telecommunication systems. The second paper in this section, by Daryl Eigen, discusses field test methods. Laboratory studies are often conducted early in a product or system development, while field tests occur later and involve realistic simulations. Eigen shows how field tests help to ensure that the human interface to complex telephone services meets the user's needs.

***Human Factors and Behavioral Science:***

# A Brief History of Applied Behavioral Science at Bell Laboratories

By B. L. HANSON*

(Manuscript received March 16, 1982)

The history of applied behavioral sciences at Bell Laboratories follows two main paths. The first, the primarily customer-oriented "human factors" tradition, began in the late 1940s and has been characterized by an empirical approach, relying heavily on laboratory and field simulation. The second, the employee-oriented "human performance technology" tradition, had its roots in Bell Laboratories behavioral research organization formed in the late 1950s. It has been characterized by a more rule-oriented approach to the integration of human users and operators into large, computerized systems. This paper traces the evolution of these two applied traditions and the behavioral research organization and examines the people and the events that influenced their growth and success.

## I. INTRODUCTION

From the earliest days of telephony when Alexander Graham Bell and Thomas Watson worked to perfect Bell's invention into a useful and convenient communication device, designing for users has been an important goal of the Bell System. As the number of Bell System

employees has grown to more than a million, there has been an equal concern for using people efficiently in satisfying assignments. But it was not until the 1940s that specialists began to be hired to address customers' and employees' needs, and today Bell Laboratories employs hundreds of such specialists working in the behavioral sciences.

This article traces the major lines of evolution of applied behavioral science at Bell Laboratories and examines some of the forces that have shaped and continue to shape its growth, particularly the behavioral research organization. While there were some early applications elsewhere in the Bell System (the Western Electric Hawthorne studies conducted in the late 1920s and early 1930s, for example[1]), these are not treated here, except as they influenced events at Bell Laboratories.

## II. SETTING THE STAGE

Human factors, human performance technology, and engineering psychology are a few of the many names used to describe the application of the behavioral sciences (psychology, sociology, anthropology, etc.) to the design of systems that involve people. While each of these names has its own connotations, human factors will be used here for simplicity to denote the entire discipline. Human factors traces back to World War II when American and British psychologists worked to match complex new weapons systems to the people who would employ them. Most human factors specialists, then and now, have been trained in psychology as specialists in learning, human performance, visual and auditory perception, motivation, social behavior, or decision making. Many have received training in systems analysis, industrial engineering or specifically in human factors engineering.

Human factors at Bell Laboratories has evolved along two paths which have only recently begun to come together. The first arose from the needs of telephone customers. The second arose in response to the needs and skills of employees, and led to a "pure" behavioral research organization as well as applied activities. This article describes the two applied paths and the path of behavioral research. To prevent getting lost in digressions, a chronological road map is provided in Fig. 1. References point to sources of additional information.

## III. TELEPHONES AND CUSTOMERS

From the beginning of telephony, human factors decisions were being made about telephones. The first concern was to improve the quality and intelligibility of transmitted speech. Signalling was also important, especially as the number of users started to grow. Other, more subtle innovations also helped to make the telephone more useful

and convenient. The invention of the switchhook meant users no longer had to remember to throw a switch after each call. More calls went through and many batteries were saved because when the receiver was "hung up" on the switchhook (it had to go somewhere), the job was done automatically. The one-piece telephone handset added portability and convenience, but only because designers calculated the dimensions of the heads of potential users to ensure that when the receiver was placed to the ear the microphone would be the right distance from the lips. At Bell Laboratories in the 1920s and 1930s, work was focused on designing better telephone sets by considering the physical dimensions of customers' heads and hands[2] and on understanding the properties of the human ear and voice so that electrical transducers and circuits could be improved.[3] It was in this second area, known as psychoacoustics, that behavioral science was formally instituted at Bell Laboratories.

The pioneering work in this field was conducted at Bell Laboratories under the leadership of Harvey Fletcher, Wilden A. Munson, and others,[4] but, by the 1940s, laboratories at other institutions were doing similar work for communications systems for the World War II effort. One such laboratory was managed by S. Smith Stevens, an experimental psychologist at Harvard. Fletcher was aware of the work in Stevens' lab and, in 1945, hired John E. Karlin from the list of notable psychologists who worked there.

Karlin worked only briefly in psychoacoustics before realizing that there were many other opportunities for valuable behavioral sciences work. On the basis of his observations, he made a proposal to his management for a broad program of customer studies. Shortly thereafter, the User Preference Research Department was formed, headed by Walter A. Shewhart (widely known for his work in quality control), and staffed by Karlin, Robert R. Riesz, and others. In 1951, Karlin succeeded Shewhart as head of the department.

Karlin's department continued to expand, performing a growing range of studies on user preference, telephone design, and network applications. Notable among these was a series of studies confirming people's inability to make reliable preference judgments about things they have never experienced. In one of these studies, customers were asked to judge their preference for handsets lighter than those already on their telephones. They all preferred the existing 18-ounce weight. But when they had the opportunity to handle handsets of various weights, they preferred ones that were much lighter. No one showed a preference for handsets as heavy as the standard one. Even 12-ounce handsets were heavier than people preferred. The customers could not predict their own preferences without having actual experience with the alternative choices. This rejection of armchair opinions set the

tone for the activities in Karlin's department. The work was empirically based and it depended on providing people with product experience through laboratory simulation of alternatives.[5] At the root of this approach were the research methods and empirical orientation of experimental psychology.

The activities of Karlin's department in the early 1950s included studies comparing the use of seven-digit telephone numbers, termed "All Number Calling," with the two-letter, five-digit numbers in use at the time.[6] Both the telephone companies and customers were concerned that this change, designed to increase the number of available telephone numbers, would make dialing more of a problem. Laboratory studies showed that dialing performance was slightly faster with all digits, although long-term memory for numbers appeared to be slightly reduced. The small size of these effects led to the overall prediction, later confirmed, that All Number Calling would not impair customer dialing.[7] Other projects included design of dials for the 500-type telephone set (the little dots in the dial make dialing significantly faster, because they make it easier to see when the dial has stopped rotating from the previous number dialed). There were some futuristic studies demonstrating the feasibility, from the customers' viewpoint, of machine recognition of spoken digits (people with speech difficulties actually did better when they thought they were talking to a machine), and effects on customer perceptions of transmission quality of Time-Assigned Speech Interpolation (TASI)—a procedure for using the natural pauses in a telephone conversation to send bits of another conversation over the same line.

### *3.1 Military work*

By the mid-1950s, word of the success of Karlin's enterprise had reached Bell Laboratories military development organization at Whippany, New Jersey, which was dealing with some complex control systems with significant human factors implications. At that organization's request, M. Paul Wilson was transferred from Karlin's department to organize a military human factors effort.

In complex systems, the division of responsibility between human operators and hardware called for some creative new analytic techniques. In a series of projects, each characterized by complex command-control systems—such as the XM3-H tactical radar: the Nike-Ajax, Nike-Hercules, and Nike Zeus missile systems; and the SAGE air defense system—Wilson and his colleagues developed this new approach to command/control systems. Two major characteristics were:

1. The emphasis on the human's role as decision maker in the system; and

2. The importance of information displays in conveying critical information required for correct and timely decisions.

Shortly thereafter, Wilson became head of the newly formed Command Systems Department, with a single human factors group supervised by W. L. Lee, another former Karlin employee. In the mid-1960s, this group was supervised by Robert I. Rosenthal, who extended the Wilson formulations to the design of control panels and display systems.

One of the interesting developments from this organization was the design of a network control center for the AUTOVON military communications system.[8] It was significant for two reasons. First, the human factors specialists conceived and designed the system rather than serving as consultants. Second, it introduced the concept of "exception reporting"—limiting displayed information to unusual or abnormal conditions that the system operator needs to know. As a result, system operators could focus on analyzing and solving problems, the most critical job and the one they could do best, while the computer's ability could be used to sort through large quantities of data to find abnormal conditions. This work exemplified the kinds of things the military human factors people could do for the Bell System. In fact, Rosenthal's group later designed the display system for the No. 4 Electronic Switching System (ESS) electronic toll switching machine using the principles established in military work.

Human factors studies had a significant part in notable government-sponsored projects that included the Safeguard Antiballistic Missile System and the Bellcomm company that was organized to provide technical support for NASA's Apollo project. Work on the antiballistic missile system began in 1967 with a human factors system evaluation at White-Sands, New Mexico, and continued with Arthur S. Kamlet's Command and Control Test Facility.[9] Human factors at Bellcomm was led by A. N. Kontaratos and focused on basic studies of problems of extended isolation and the dynamics of small technical groups. Some of this work, led by Nicolas Zill, used Tektite II, a small undersea laboratory where groups of scientists worked for extended periods. The Bellcomm effort was quite independent of other Bell System human factors activities.

By the mid-1970s most of the military work had been phased out at Bell Laboratories and the people had been reassigned to telecommunications projects, bringing with them the command/control system approach and experience in broader aspects of system design.

### *3.2 Sibyl, station equipment, and network applications*

About the time Wilson left in the mid-1950s, the Karlin organization began development of a new, complex system for conducting simula-

tion studies. This new system, called Sibyl, could be programmed to insert a wide range of network transmission and switching impairments into real telephone calls, record user-calling behavior, and record user-preference judgments.[10] Up to 100 Bell Laboratories volunteers could be connected to the system.

Sibyl's first use was in the evaluation of push-button vs. rotary dialing. It recorded dialing times, intervals between digits, and errors. In later applications, Sibyl varied factors such as dial tone delay, network blocking, or delay after dialing. Following each test call, Sibyl would call the user back to get a subjective evaluation. Users would dial one of several digits to express their opinions. Knowledge of customer opinions of various levels of service enabled designers to engineer the telephone network to satisfy customers without spending money on improvements that customers did not care about.

In 1966, Sibyl and other transmission quality activities were consolidated in a separate department under Richard W. Hatch. In 1970, psychologist Herman R. Silbiger was chosen to supervise a new human factors group in Hatch's department, specializing in subjective evaluation of network performance. Although it has undergone much modification Sibyl is still in use.[11]

Karlin's department also continued its work in customer instructions (design of flowchart dialing instructions for centrex users), transmission (defining the optimal parameters for trading off echo suppression with the listener's ability to interrupt, especially on long-delay satellite connections) and telephone set design. Particularly notable was Richard L. Deininger's work on the design of the *Touch-Tone** telephone. Most of the telephone set design work was carried out in cooperation with the Station Instrumentation Department (headed up by Alfred H. Inglis, and then Harris F. Hopkins), and the *Touch-Tone* telephone design was no exception. Deininger's responsibility was to determine the optimal parameters of the push-button dial, particularly the arrangement of the 10 buttons.

Deininger's studies led to the selection of the now ubiquitous *Touch-Tone* telephone dialing arrangement. His studies showed that it was strongly preferred over the now equally familiar calculator arrangement.[12]

Karlin's department also worked jointly with the Station Instrumentation people to design the *Trimline** telephone.[13] Early efforts to design a dial-in-handset telephone had been unsuccessful because the sets were uncomfortably bulky and unattractive. Invention of the space-saver dial by Charles F. Mattke enabled Lionel W. Mosing of Karlin's department to fashion a comfortable and attractive telephone

* Trademark of AT&T.

of angular design, which he called the *Trimline* telephone. The final version of this set is now installed in millions of homes and appears on display in the design collection of New York's Museum of Modern Art. Much additional customer work was conducted primarily by engineers in the Station Instrumentation department. In 1964 this work was inherited by Leo Schenker's Telephone Station Studies Department, and Deininger was named to supervise the human factors work.

### *3.3 Station studies*

For several years, Deininger's group was heavily involved in design and evaluation of the *Picturephone** visual telephone service, particularly aspects of image and quality and camera placement.[14] In 1970, after Deininger's untimely death, the group was managed by Gaber P. Torok, who worked to bring human factors work closer to the product-development activity, speeding up the development cycle by reducing the need for lengthy field testing and subsequent modifications.

In 1973, Murray J. Katz replaced Torok as supervisor of this group. Advancing technology, increasing customer demand for new products and the Bell System's entry into a more competitive environment all led to steadily increasing demand for the services of Katz's group. As a result of Katz's human factors evaluations, modifications were made to many new station products including the *Touch-a-matic*† repertory dialer (changes in labels, button characteristics, handset location), *Design Line*† decorator telephones (modifications to improve transmission characteristics, balance, and comfort), and *Dataphone*† II data communications terminal (design of maintenance panels and instructions). They also conducted extensive studies of the effects of mobile telephone usage on driving behavior[15] and worked jointly with Karlin's department on design of calling procedures for the Advanced Mobile Phone Service (AMPS).

Throughout the 1970s, station design work was changing from largely physical design ("knobs and dials" as it is sometimes called) to more procedural or feature-oriented work. Human factors specialists were addressing questions of how to implement new and complex features for residence and business customers. There was also a growing awareness of the role of human factors in identifying and satisfying customer needs. As a result, human factors was playing a larger role in the product design process. In the late 1970s, increasing demand for human factors support led to the formation of new groups in both station and business terminal development.

### 3.4 Repositioning of human factors

In the mid-1960s, Karlin's department addressed a wide variety of customer issues such as the potentially disruptive effects of satellite delay on telephone conversations,[16] design of flowchart instructions, and diagnosis of network impairments. The problem with diagnosing network troubles was to correlate customer descriptions of problems with the problems, themselves. The solution was to create the same network impairments in the laboratory and ask test customers to describe the problems. Once the customer descriptions were tied to the difficulties, customer complaints could be used to pinpoint and repair the troubles.

Feasibility studies were also conducted to see whether business customers, if given computerized switching systems, could successfully program their own rearrangements and changes, e.g. reassignment of telephone numbers and features when employees moved offices. Such changes tend to occur frequently, and can be costly to both the customer and the telephone company if an installer must be dispatched to make them. It was found that, with the right user interface, customers could make their own changes with little difficulty, so long as they had a way to trace and correct their errors. An added benefit of this capability, which now exists in a number of Bell System customer switching systems, is that customers can make changes instantly, without having to wait for a telephone company employee to be dispatched.

The Human Factors Department had started in the research area and still viewed itself largely as an applied research department, but by 1970 it found itself in a development organization which was interested in increasing the direct, near-term payoff of human factors. Where the department had previously been organized around psychological topics (visual studies, interpersonal communication, etc.) it was asked to realign along Bell System lines (e.g., operator services, loop and outside plant). Along with this realignment, groups were given the responsibility for identifying and addressing existing human factors opportunities in their assigned areas and for contacting the appropriate organizations to discuss them.

During this same period there was a growing concern throughout Bell Laboratories about the impact of technology on customers and employees. While there is question as to cause and effect, the growing sensitivity to the impact of new products on customers and employees and the refocusing of human factors research were followed by remarkable growth in the human factors area. Within two years, Bell Laboratories "consumers" of human factors work were negotiating for long-term commitments of human factors support and were exploring the option of starting their own human factors efforts to guarantee

adequate staffing of their work. By 1976, new human factors efforts had begun in both operator services and loop operations, and a director-level committee, conceived and led by Herbert M. Zydney, was assembled to plan an orderly expansion strategy.

The resultant plan, known as the Crowley-Dorros plan after the two executive directors who commissioned it—Thomas H. Crowley and Irwin Dorros—outlined a strategy for all human factors work at Bell Laboratories, including both customer and employee issues. The plan called for Karlin's department to focus on customer issues and to serve as a centralized resource to a growing number of satellite human factors groups that would be closely tied to specific development activities. The plan also viewed Karlin's department as a training ground for individuals to start such satellite groups.

As a case in point, an entire group, led by Edmund T. Klemmer, was transferred from Karlin's department to continue its work on business customer telephone systems. The group started with five people and an emphasis on procedures and instructions, and has since grown to two groups working on all aspects of business services, from customer needs studies to field introduction.[17]

In 1977, Karlin retired from Bell Laboratories after 32 years of service. (See Ref. 18 for Karlin's entertaining and insightful parting comments on the state of human factors at Bell Laboratories.) He was replaced by Charles B. Rubinstein, an electrical engineer from the Research Area who had done work in the psychophysics of color perception and visual thresholds. Shortly after Rubinstein arrived, Robert I. Rosenthal, who had supervised military control-display work under M. Paul Wilson and later worked on network management display systems, joined the department. In the late 1970s, the department's work included design of customer dialing procedures for AMPS,[19] and other new services that relied on recorded instructions to customers, such as the Voice Storage System,[20] the Automated Credit Card Service,[21] and Automated Coin Telephone Service (ACTS).[22] Each of these services depended on recorded instructions that could explain to customers what they were to do next. Computer-controlled voice recording and playback equipment enabled human factors people to conduct extensive laboratory simulations of these services, identifying deficiencies in procedures or instructions that led users to make mistakes. ACTS, for example, uses recorded messages to tell coin telephone customers how much money to deposit in the telephone. Laboratory and field studies were required to determine how long to wait for customers to deposit coins, and how often to prompt them for the remainder. Time limits had to be established to ensure that a human operator could come on the line to assist customers having difficulty. Customer satisfaction was also monitored to

ensure that people would be comfortable with the less personal approach to coin service. As a result of the attention to human factors, ACTS has met with complete success. Customers have few difficulties with the service, and customer acceptance has been outstanding.

Recently a new focus has emerged. Bell Laboratories is developing new, complex products whose success will depend on the quality of the user interface. As a result, Rubinstein's department and other customer-oriented human factors groups are directing their efforts to human/computer interface issues.

## IV. THE RESEARCH CONNECTION

### *4.1 Behavioral research beginnings*

The second path in the evolution of applied behavioral sciences at Bell Laboratories began in the early 1950s at AT&T. The Personnel Relations department had been doing applied field work for some time, but had become frustrated by lack of knowledge of the social processes which influenced organizational success. Bolstered by a 1953 commitment by the AT&T Board of Directors to attracting and developing capable employees and first-rate leaders, Robert K. Greenleaf, Director of Personnel Research at AT&T, asked Bell Laboratories to start a new research group, the Communications Social Science Research Department.

The new department was led by Robert N. Ford who transferred from AT&T Personnel Relations, and its charter was to focus on problems of communication, organization, and leadership in small groups. The department was established at Bell Laboratories because BTL had experience in managing basic research and because of the stimulation other Bell Laboratories research activities could provide. Ford was to report directly to William O. Baker, then Vice President and Director of Research. To help get the effort under way, and to help recruit good research people, psychologist Carl I. Hovland was brought in from Yale as a consultant.[23]

The first person hired was Alex Bavelas, whose specialty was human motivation. Bavelas left after only a short time to join the Stanford faculty. Morton Deutsch, another social psychologist, was the second to arrive, and stayed for several years. Both Bavelas and Deutsch went on to establish major reputations in the academic world.

In addition to this venture in social psychology, efforts were begun in experimental and educational psychology. The experimental psychology activity began in 1957 with Herbert Jenkins (a disciple of Harvard behaviorist B. F. Skinner), who established a lab to study learning in pigeons. He was followed by Ernest Z. Rothkopf, an educational psychologist specializing in learning and instruction, and

Roger Shepard, another Harvard experimentalist recruited by Hovland and specializing in information processing.

In 1958, H. O. (Ollie) Holt, an educational psychologist who had been Deputy Director of George Washington University's Human Resources Research Office (HumRRO), took over operation of the center from Ford, who returned to AT&T to pursue his interest in job enrichment. Holt immediately began to develop a plan for entering the new field of programmed instruction. He worked primarily with consultants such as Hovland, Tom Gilbert from the University of Tennessee, and Skinner, himself. Given the massive sums of money spent by the Bell System in training its employees, the payoff from such work was potentially enormous.

This work showed such promise that Holt was transferred to AT&T in 1962 to head the Office of Training Research which had the job of implementing individualized instructional technology throughout the Bell System.[24] It is Holt who provides the ultimate connection to applied behavioral sciences, so the path of applied work follows him. But the Behavioral Research organization, with its worldwide reputation for excellence, deserves a short history of its own.

#### *4.2 Basic research in psychology*

Research on the social psychology of group interaction was the initial focus of the Behavioral Research Center. The problems ranged over issues of cooperation, influence, and social perception and the communicative behavior entailed. The amount of work in these areas gradually diminished, and the original social psychologists had all left by 1966. However, social psychology reemerged from 1978 to 1982 with a new central concern in interpersonal communications. The issues now involved the reasons why people choose one communication modality over another (e.g., voice-only versus face-to-face) and the consequences. This work was headed by Myron Wish, whose involvement in a study of the use of *Picturephone* visual telephone service sparked renewed interest in such matters.

There were other topics that, like group psychology, were pursued only for limited periods. Most notable of these were efforts in auditory neurophysiology between 1964 and 1968, and the psycholinguistics of grammar from 1963 to 1971.

By contrast, the research in human learning and instructional technology, which was under way by 1958, has continued, expanded, and diversified up to the present. For example, Ernst Z. Rothkopf and Lawrence T. Frase conducted a large number of experiments on the effect of adjunct questions on learning from text. These not only showed practical means for greatly improving instruction, but also deepened understanding of the active role of learners in studying.

Pioneering studies of the role of organization (e.g., the placement of repetitions of information) and surface structure (e.g., word choice) in learning from written prose led, among other things, to the development of computer methods for determining text difficulty (see Ref. 25). The fundamental work on instructional materials contributed to the development of widely used editorial aids such as the *UNIX** Writer's Workbench software (see Refs. 26, 27, and 28), and AT&T's Training Development Standards, a guide used in course development throughout the Bell System.

Two other areas that have continued since their establishment in the 1950s are human information processing and psychological measurement. Human information processing research at Bell Laboratories goes at least as far back as the work of John R. Pierce and John Karlin on estimating human channel capacities[29]; but as a continuous institutional activity, it can be dated from George Sperling's discovery and description of a visual memory that stores, for about a second, considerably more information than can be read out intact.[30] Saul Sternberg's elegant work on rapid scanning of active symbolic memories followed shortly.[31] He and his collaborators also made important advances in the study of temporal order judgments, and most recently, the control of rapid action sequences in speech and typing.

The Human Information-Processing Research Department, headed by Sternberg since 1970, has also been the home of pioneering work and major contributions in many other parts of cognitive psychology: verbal learning, picture memory, semantic memory, word recognition, visual perception, motor control (see article by Rosenbaum,[32] this issue) and adaptation, attention, and reasoning. In 1979 a new group was formed under Tom K. Landauer's leadership to explore cognitive problems in human use of computers. Its work has centered on issues in interactive language design and the proper representation of human knowledge to assure mutual understanding of the messages passed between machines and users (see article by Furnas et al., this issue).[33]

Measurement and scaling were among Roger Shepard's many interests when he first joined the Labs in 1958. Along with Joseph B. Kruskal, he developed the first effective methods for nonmetric multidimensional scaling of human similarity judgments.[34] There has been an almost continuous development of new theory, computational methods, and applications ever since. For example, in recent years J. Douglas Carroll and his collaborators have developed the method of individual differences multidimensional scaling, a method that identifies psychological dimensions by their orderly variations in perceptual importance as reflected in judgments of object similarity by

* Trademark of Bell Laboratories.

different people. These methods have found extensive use in such diverse areas as marketing research and telephone tone-ringer design.[35]

Over the last 20 years, the Research division has also sponsored a variety of other efforts with behavioral science content. There has been much noteworthy work in vision, color vision, and visual perception under the leadership of Bela Julesz. One example is his own invention and use of random-dot stereograms to demonstrate the independence of depth perception from object recognition and his explorations of fundamental mechanisms of perceptual processing. (See Ref. 36.) Speech analysis and evaluation research was conducted in a department headed by Peter B. Denes, and elsewhere. Linguistic research has been under way since 1971 in a department led by Osamu Fujimura, who himself has studied the production of motor action sequences, an interest shared recently by several other investigators. Finally, mention should be made of the important fundamental analyses of speech acoustics and perception carried out by James F. Flanagan's Acoustics Research Department and Manfred R. Schroeder's Hearing and Speech Synthesis Research Department.

Over the years there has been fairly regular communication between the behavioral research groups and the applied behavioral scientists. There have been many seminar series attended by both, frequent consultations and visits, and since 1977 a Bell Laboratories-wide convention of all behavioral scientists every 18 months. There are occasional cross-assignments of months or a year's duration, and a steady trickle—averaging perhaps one per year—of people moving from one kind of work to the other; most movement has been from the smaller population of research to the larger applied areas. There has been a great deal of useful stimulation in both directions.

## 5. HUMAN PERFORMANCE TECHNOLOGY

### *5.1 Human performance and employee systems*

The Bell operating telephone companies, with their huge billing and accounting systems, were among the first businesses to make widespread use of computers in their operations. During the late 1950s and early 1960s, computers became an integral part of their accounting operations. While the development of computerized systems had resulted in substantial savings and better service, there had also been some difficulties, largely because of a mismatch between such systems and the employees who worked with them. The initial solution to these problems was thought to be in better training, so Ollie Holt and Harry A. Shoemaker of AT&T's Office of Training Research were asked to get involved.

At about the same time, it became clear that centralized planning

and development of such systems would be more efficient and would ensure system-wide standards. Finally, in 1967, largely through the efforts of AT&T Assistant Vice President Bruce Warner, the Business Information Systems Programs (BISP) organization was created from parts of the AT&T Planning Department. Holt was asked to join the new organization as Director of the Human Performance Technology Center. After several months Holt moved, along with the whole BISP organization, to Bell Laboratories.

Holt brought with him several of his former staff members including Fred L. Stevenson, a training specialist originally with Pacific Telephone. The group's early experience showed that training was not going to be a universal cure for design deficiencies, so they set about to develop an organization that could influence system design.

One of the first additions to Holt's staff was Bill F. Fox, a psychologist with human factors training and experience. Fox had worked with HumRRo and Lockheed Aircraft. Fox's assignments were to adapt military experience with large hardware systems to the development of large software systems and to build a team of psychologists to do the work.

Holt also recruited Ralph Marion, a psychologist and personnel specialist from Southern Bell. Marion's assignment was to develop documentation that would enable system designers to do as much of the job as possible, themselves. Together, they continued to recruit both operations people from the Telephone Companies and behavioral scientists. By the end of 1970 they numbered over 40.

They called their work personnel subsystems (PSS), a phrase with military roots, rather than human factors roots, a term which they felt referred narrowly to control-display design rather than systems concerns. In later years, the name was changed to human performance engineering to more clearly characterize the major objective. In 1970 the Human Performance Center was organized into three departments. Fox's Personnel Subsystems Department provided direct consultation and support to projects and worked to develop PSS technology; Marion's Personnel Subsystem Analysis and Development Department refined the technology and documented it; and Stevenson's Systems Training Department trained others in the use of the technology.[37] This organization worked well, and the technology, documentation, and training it developed are in use in information systems organizations throughout the Bell System.[38]

In many ways Fox's department was the BISP homologue of John Karlin's Human Factors Department. Both were staffed primarily by behavioral science professionals who provided consultation to system designers and developers, and both experienced significant successes in the 1970s. The primary difference between them was in their way

of approaching the job. The Karlin approach was to solve each design problem empirically; the Fox approach was to assist the project in utilizing the PSS technology to solve its own problems. In each case, the approach was appropriate to the problem—Karlin dealt with a number of specific problems, each with significant implications for many telephone users, while Fox was faced with vast needs for job requirements, training, etc., which could not have been efficiently done by behavioral scientists alone.

Typically, Fox's people would be assigned to projects as technical advisors to the project people who had design responsibility. For the most part, these project people were telephone company people on rotational assignment who had no prior experience with PSS. These people used the documentation produced by Marion's department and were trained in Stevenson's. The success of this work and the desire of the project organizations to have complete responsibility and guaranteed support led to the spin-off of separate PSS groups. In 1973, George A. Schweickert and Mort H. Kahn left Holt's center to form groups in Business Information System Customer Service Facilities Assignment and Control System (BISCUS/FACS).[39] Shortly after, the organization involved in the Trunks Integrated Record Keeping System (TIRKS) formed its own group under Roy J. Porterfield.[40] Barry K. Schwartz also left to work on systems engineering for network administration systems and later formed a group to work on the Total Network Data System (TNDS). By 1976, most of the projects which had started as part of BISP had their own groups of specialists, and few of Fox's people were assigned to specific BISP projects. Instead, many of them were working on user aspects of Operations Support Systems (OSSs) developed elsewhere in Bell Laboratories to aid in the operation and maintenance of various aspects of the Bell System network. The first of these to come to Fox's attention was the Loop Maintenance Operations System (LMOS).[41] By 1976, one of Fox's groups, led by Grace H. Leonard, had transferred to the LMOS organization.

In late 1976, the Crowley-Dorros plan—which had called for Karlin's department to serve as a centralized customer human factors resource—named Fox's department as the resource for employee human performance activities, serving as both consultants and the source of trained people to start satellite groups. Since that time, a number of new groups have been created in LMOS and other OSS projects, employing the methods and procedures developed in the late 1960s by Holt and Fox and their colleagues.

The growth of groups and activities has continued unabated through the late 1970s and early 1980s. Again the increasing complexity resulting from new technology has placed new burdens on employees

and provided new opportunities and challenges for behavioral scientists.

## VI. SUCCESSES. . .AND CHALLENGES

Measured by its impact and its growth, human factors has had notable success at Bell Laboratories, particularly since the early 1970s. Both the empirical orientation of Karlin and the technological approach of Holt and Fox have had significant impact. Why has human factors been a success at Bell Laboratories when external efforts in both industry and the military have fared less well? There are several possible explanations.

First, the philosophy and structure of the Bell System have been important. Its strong tradition of good customer service implies a need to give explicit consideration in the design process to the customers. The vertical integration of the system encouraged Bell Laboratories to design products and systems which are not only attractive at time of purchase, but which also continue to perform cost-effectively. In such an environment, design goals such as minimizing customer errors or increasing employee efficiency and decreasing turnover become more important. The numbers of employees and customers potentially affected by new designs also multiply the benefits that result from human factors.

The growing complexity of technology has also played a significant role. While technological advances have provided many new products and services, these products and services have become more complicated for the customers who use them and the employees who install and maintain them. Computerization of internal operations has led to substantial complications in some aspects of employee jobs. Human factors specialists have the responsibility to minimize the problems imposed by this complexity and to make new products and services "friendlier," more useful, and more attractive.

In addition to the technical challenges of the information age, the major challenge to human factors in the 1980s is to continue to expand its role in the design/development process. This implies both applying existing human factors skills in new areas and developing new skills which complement existing ones. For example, extension of human factors methods to the definition of customer needs for new products will lead to earlier and more influential involvement in product design. Development of systems engineering skills will result in improved communication with engineers and greater influence over design decisions. Specialized knowledge in electrical engineering and computer science will enable evaluation of the trade-offs that must often be made between human factors and hardware and software constraints. With a broader view of its responsibilities, human factors should continue to grow and contribute at Bell Laboratories.

## VII. ACKNOWLEDGMENTS

The author would like to thank the many people who provided information and insights for this history. I am particularly indebted to H. O. Holt for his encouragement and perspective and to W. F. Fox and T. K. Landauer for their generous assistance. Thanks are also due to J. E. Karlin, M. J. Katz, and R. I. Rosenthal for the significant background material they provided. Special thanks go to B. L. Lively for resolving the many thorny issues generated by a project of this nature.

## AUTHOR

**Bruce L. Hanson,** B.A. (Psychology), Johns Hopkins University; M.S., Ph.D. (Psychology), Pennsylvania State University; Bell Laboratories, 1972–1982; American Bell, 1983—. After joining Bell Laboratories in 1972, Mr. Hanson worked on the human factors aspects of central office craft jobs. He also has helped evaluate hardware, instructions, and procedures for outside plant craftspeople, engineers, and managers, and he has studied human factors in new services such as the Advanced Mobile Phone Service. In 1977, he became Supervisor of the Network Systems group, designing user interfaces for voice storage services. Before he assumed his present position, he also supervised studies of customer aspects of billing, PhoneCenter® and Business Office service. Mr. Hanson is currently Supervisor of the Customer Interfaces Group in the Product Family Services Planning Department and ABI. This group is engaged in the design and planning of user-computer interfaces for ABI products. Member, Human Factors Society, the American Psychological Association, and Sigma Xi.

# Methods for Field Testing New Telephone Services

By D. J. EIGEN*

(Manuscript received December 29, 1981)

Telephone services are increasingly complex and diverse, and they require more human-machine interaction than ever before. A field test can help improve a new service by ensuring that it is easy to use with little chance for error. This paper discusses the methodology of field testing. Specially tailored telephone service evaluation methods, based on field test experience with the Calling Card Service, are presented in detail.

## I. INTRODUCTION

New telephone services involve more customer-system interaction than ever before, and making the use of these services easy and error-free is a major goal of their development. Properly designed dialing plans, announcements, timings, tones, and instructions increase customer acceptance, minimize customer errors, and promote use of the service. The design of new services can be evaluated by coordinated studies that include:

- Analysis of present services,
- Interviews with customers,

- Laboratory studies of proposed protocols for customer-system interactions,
- Field tests of services, and
- Product follow-up studies.

Field testing is the largest and most costly step in this coordinated set of studies. This paper discusses the methodology of field testing, using a field test of the Calling Card Service as an example.

## II. CALLING CARD SERVICE FIELD TEST OVERVIEW

An analysis of operator-handled credit card service indicated that a reasonable proportion of credit card calls could be automated. Interviews with credit-card, bill-to-third-number, and collect customers verified their interest in and need for an automated Calling Card Service, and laboratory studies provided evidence that customers could use the Calling Card Service successfully.

The Calling Card Service field test was conducted in Milwaukee from November 1977, to June 1978.[1,2] Regular telephone credit card numbers could be dialed in order to place Calling Card calls from about 3000 noncoin phones in the Milwaukee area and from 70 coin phones at Milwaukee's airport, two downtown hotels, and a few local restaurants. Bright orange placards on the trial coin phones instructed customers on how to use their telephone credit card number. In addition, operators were trained to assist callers and answer questions. (Calls from unequipped stations were handled as usual.)

To use the trial Calling Card Service, customers first dialed zero plus the number they wished to call. Special programs in the Traffic Service Position System (TSPS) routed incoming "0+" calls from trial stations to a small team of specially trained operators who helped simulate Calling Card Service—in actual service no operators are used. Besides the TSPS console, these operators had a video display terminal linked to a minicomputer (see Fig. 1).

When a call arrived from a specially equipped station, the trial operator notified the minicomputer, which then delivered a tone to prompt the customer to dial a Calling Card number. Detectors received the dialed digits and sent them to the minicomputer over a data link for verification. Calls with valid Calling Card or credit card numbers were allowed to proceed and were billed appropriately.

Depending on the protocol being tested, the minicomputer displayed step-by-step instructions on a terminal screen to guide the operator in handling each call. For example, to encourage customers to redial after making errors, the minicomputer might display the instruction, "Please hang up and dial zero plus the number you are calling," which was to be read to the customer. By making simple changes in the minicomputer program, the operator's treatment of calls could be

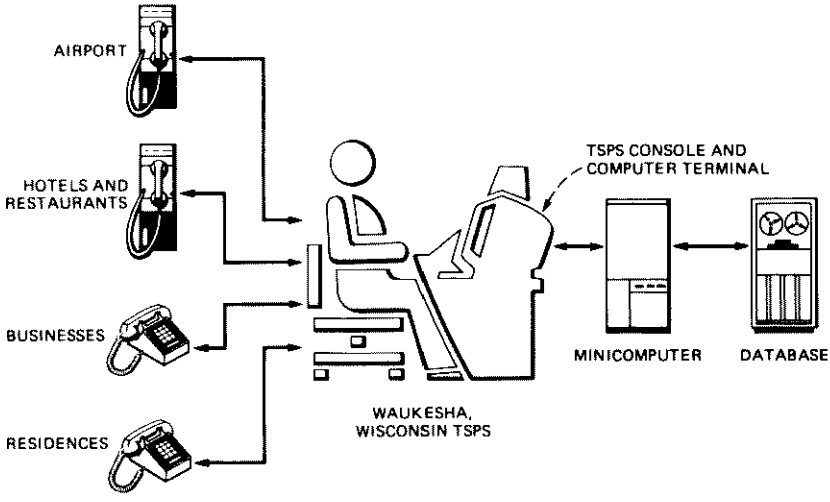

Fig. 1—Test setup.

altered, often without additional training. This flexible arrangement allowed easy testing of many different protocols and rapid changes among them.

The minicomputer recorded the time and details of each call. These records were analyzed rapidly to determine how the protocol could be improved. Throughout the trial, protocols were varied by changing announcements, timings, access to operators, error-correction procedures, and other aspects of the caller interface. In all, 24 variations of the protocol were tested at equipped coin phones, 14 at noncoin phones. Over 10,000 customers dialed more than 30,000 automated Calling Card calls during the trial and more than 5,000 customer interviews were obtained.

## III. FIELD TEST ACTIVITIES

### *3.1 Field tests*

In a field test such as that for Calling Card Service, a simulation of the proposed service is actually offered to a limited, but representative, set of customers on a trial basis. In some circumstances, when there is sufficient confidence in the form of the service, the actual product can be used as a test vehicle.

The field test can be used to adjust the technical and operational aspects of the service. It can be used to determine whether the service fits a customer need, and it can also be used to improve estimates of willingness to pay. And finally, it can be used to evaluate customer performance, satisfaction, and usage in the effort to provide a service

that optimizes the customer-system interaction on which new services rely.

The greater the fidelity of the test to the real service situation, the greater one's confidence in the final success of the service being tested. Field tests provide increased fidelity over more indirect techniques for evaluating services.

### *3.2 Study plan*

Developing a study plan is the first task in planning a field test. A study plan must include the following five steps:

1. State the objectives of the study and delineate issues to be resolved by it. The primary objectives of the evaluation of the human-machine aspects of telephone services are to:
   a. Determine if usage, satisfaction, and performance are at acceptable levels.
   b. Predict the levels of usage, satisfaction, and performance in the final service.
   c. Refine the service to improve usage, satisfaction, and performance.

Many other detailed issues for a particular service may require resolution.

2. Determine constraints on study service and resources necessary to accomplish the test. Decisions on test methodology necessarily involve practical choices. For example, the marketplace often imposes serious time constraints on the development, deployment, and evaluation of a telephone service.

3. Design and refine the service and the human-machine interfaces involved. Some initial human-machine telephone service interface must be defined before the evaluation process can be initiated. Continued analyses, interviews, and laboratory studies are best used to generate and refine the service alternatives prior to the field test itself.

4. Delineate variables that may influence the results and hypothesize their interactions. Three categories of variables need to be specified for the field test:
   a. Independent variables—those variables that are to be deliberately manipulated or held constant. Among the possible variables of this type (with some examples) are the following:
      (1) Service protocol—announcements, tones, timings, error-handling strategies, and digit strings.
      (2) Capabilities of the service—billing, routing, and screening.
      (3) Availability—geographic constraints, time-of-day constraints, and station-type constraints.
      (4) Type of instruction for customers—media and format.
      (5) Marketing effort—promotion.
      (6) Rate—price structure.

b. Dependent variables—those variables whose values are affected by changes in the independent variables. Some examples are given below.
   (1) Subscription—initial interest and sign-up rate.
   (2) Usage—rate of first and repeated use.
   (3) Acceptance—judged worth and satisfaction.
   (4) Customer performance—speed, error, and abandonment rate.
c. Parameters—those identifiable variables that are free to vary. Among these are:
   (1) A priori condition—predisposition toward service, demographic mix of customer population, etc.
   (2) Internal characteristics—the test design or method used, intrinsic characteristics of the customer in the test, etc.
   (3) External characteristics—the geographic, environmental, and temporal setting of the test.

These variables are not necessarily mutually exclusive. Some parameters might be fixed or systematically varied, and, thus, be made independent variables.

It helps to have hypotheses about how these variables will interact. Figure 2 demonstrates one model of several possible models of the relationships among variables for telephone services. A different model might assume that instruction may affect acceptance and subscription more directly than is shown in Fig. 2.

5. Define methods for increasing confidence in the results of the study. Some of the most important aspects of a good study plan are motivated by the need to counteract rival explanations of the results

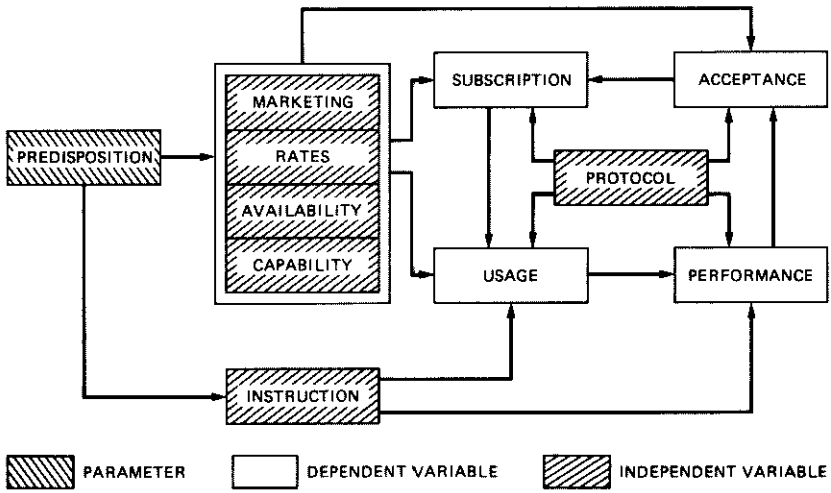

Fig. 2—Variable block model.

and, thereby, increase confidence in the validity of the field test as an indicator of the success of the service.[3–5] Section IV is devoted to this component of the study plan.

### *3.3 Test development*

After the study is designed, the following tasks must be done.

1. Define data gathering tools.
2. Define data analysis techniques.
3. Define test service delivery vehicle.
   a. Define test service requirements.
   b. Design test service delivery vehicle.
   c. Implement service delivery vehicle (hardware/software development).
   d. Integrate trial system and test.
4. Acquire and prepare customers.
5. Acquire and prepare site(s).
6. Define test operations and procedures for utilizing results.

Figure 3 is an illustration of the interrelationships among these tasks.

#### *3.3.1 Data collection*

The following data collection methods were used in the Calling Card Service field trial.

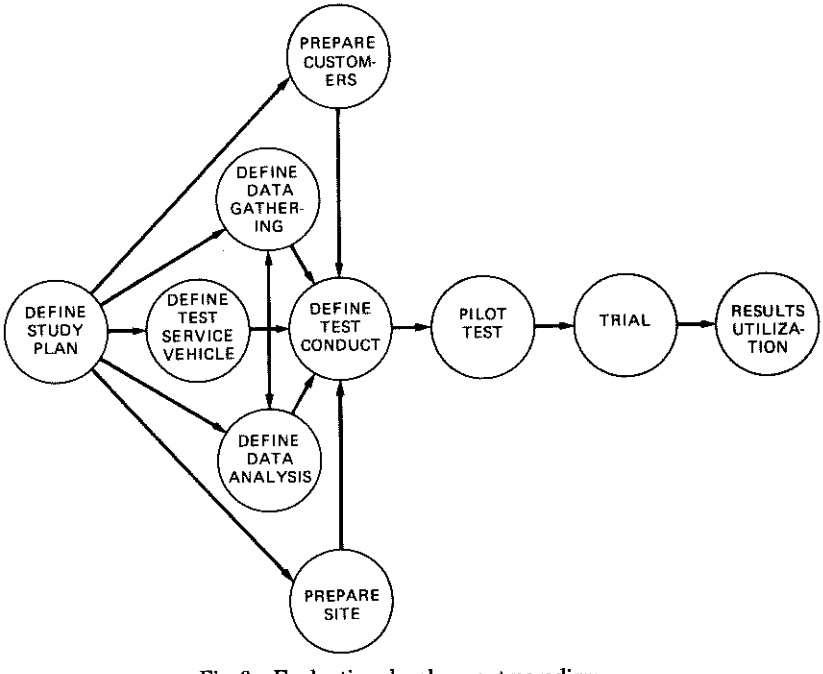

Fig. 3—Evaluation development paradigm.

*3.3.1.1 Interviews/questionnaires.* Interviews and questionnaires provide measures of attitude, as well as corroborative measures of usage, and can be given before, during, and after the field test. In-person, face-to-face interviews with customers who had used the Calling Card Service provided some of the more compelling evidence of the success of the service. The following spontaneous comments illustrate the range of such data.

Example of positive response:

1. "It's excellent. I compliment the phone company for coming through with this. Makes it a lot easier."

Example of negative response:

1. "In the past, you dialed Helen (operator) and said, 'I want to talk to Joe,' and right off Joe was on the line—it seems you are trying a lot of new services to get rid of Helen."

*3.3.1.2 On-line measurements.* These measurements are the machine recording of customer and system events, such as picking up a receiver or placing it back on the switchhook (hanging up), dialing digits, tones or announcements, error detection, and call progress states. By recording, time stamping, and storing these events, the sequence of customer-machine interactions can be reconstructed.*

*3.3.1.3 Billing.* Billing records routinely provide various data on a call, such as calling and called number, call duration, date, time of day, class of charge (e.g., collect, DDD, and so forth).

*3.3.1.4 Observation.* Observation provides a crude but valuable technique for gathering data that cannot be obtained by other means.

*3.3.1.5 Customer feedback.* Feedback mechanisms for customer complaints and suggestions are maintained by the telephone companies offering the service.

*3.3.1.6 Records.* Records and logs of equipment malfunction and events recorded in newspapers are important for detecting or counteracting erroneous or misleading results. Data in such records can be used to measure dependent variables.

These methods of collecting data are all relatively insensitive to one another in that a specific error in one measurement is very unlikely to affect another measurement. Thus, the methods can be used to corroborate each other.

---

* The Bell System as a common carrier is entitled to certain privileges to monitor the quality of its services. Bell Laboratories as an agent of the Bell System is extended these privileges. Only data necessary to ensure good service are gathered, and they are kept secure, in strict confidence, and statistically anonymous. To guarantee customer privacy, data are never gathered after a call is placed, i.e., after called party answers.

### 3.3.2 Analytic tools and techniques

The practice of feeding back the results as input to the experimental design process, while providing an efficient data gathering technique, places an additional burden on analysis. Results must be provided in a timely manner to be of use in formulating the next service improvements to be tested. Figure 4 illustrates a data processing stream used to field test the Calling Card Service.

Standard statistical routines must be used with caution since the assumptions on which they are based may be violated. For example, sampling is often nonrandom.

One heuristic is to leave the service unperturbed for some reasonable period of time (two or more weeks depending on the call volume). The extent of variations or noise in the data is measured and later used as a benchmark to assess meaningful variations potentially due to service manipulations.

### 3.3.3 Test service provisioning

A system to deliver a voice-prompted test service should include the ability to deliver tones and announcements, to route to an operator, and to receive dialed digits. Connection to the network, billing, and data processing and storage also need to be considered.

### 3.3.4 Acquire and prepare sample

Obtaining sufficient numbers of representative customers for the field test is important. The field test approach usually requires thou-

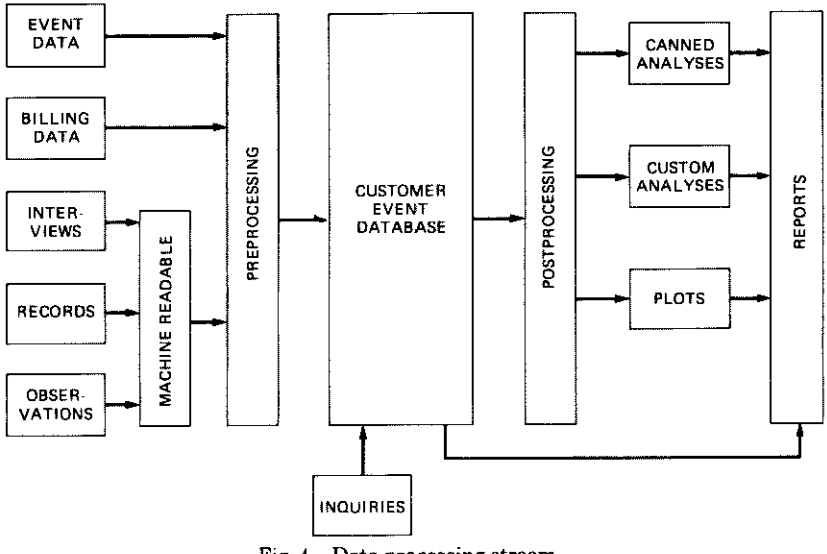

Fig. 4—Data processing stream.

sands of calls to provide adequate data. Inability to obtain sufficient customers, if not attributable to test limitations alone, may be a key indicator of the potential failure of a new service. The means for selecting and acquiring customers has to be designed with test validity in mind.

The process of obtaining participants and assigning them to groups can be the source of some of the strongest rival hypotheses. Random selection is the principal counteraction to ensure the representativeness of the population sample and group equivalence. But, randomization is not always possible. Moreover, even when it can be used, aspects of the customer acquisition and assignment process can still introduce biases that will limit the ability to generalize.

Selection processes are outlined below:

1. Determine target population using interviews and market studies.
2. Characterize the history, predisposition, environmental influences, etc., of target population.
3. Draw customers randomly from within the target population and from a similar group outside the target population. Sampling customers outside the target population will help to validate the use of the target groups for tests. If random selection is not possible, select customers who are matched to characterization of the target population.
4. Solicit participation for the test in a representative way. Preferably, contact customers in the same way they would be contacted for the final service.
5. Check participants for degree of similarity to target population characterization.
6. Interview random samples of those who agree and disagree to participate to determine the reasons for participation or nonparticipation. For example, the fact that it is a test rather than an actual service may have influenced either decision. Also, use a priori factors to account for any differences between those who agreed and those who refused.
7. Randomly assign participants to control groups and treatment groups. If random assignment is not possible, use self-selection of treatments.
8. Use measurements taken before the test to help determine the nature of group differences.

#### *3.3.5 Results utilization*

One of the largest pitfalls in the practice of implementing an evaluation of telephone service can be the lack of assurances and mechanisms for integrating evaluation results into the final product. Results from the test must be timed to allow development of changes

in the final product. A responsible organization must be named for coordinating the integration of results and the final product itself must be designed to allow changes. Appropriate flexibility in the initial design of the product can reduce delays in product introduction.

## IV. DESIGNING TO COUNTERACT OTHER EXPLANATIONS

Steps taken in designing the test—which decrease confidence in rival hypotheses and increase confidence in the working hypotheses (the one we wish to prove)—are called counteractions. In laboratory research, some typical counteractions are:

- Orthogonality and counterbalancing of independent variables
- Control and preclusion of extraneous variables
- Random collection of subjects in the attempt to eliminate selection bias.

Field settings require adapting such measures to real-world constraints.

The counteractions useful in field tests can be divided into those required for evaluating a static service (i.e., determining if a service meets a priori acceptability standards) and those required for evaluating attempts to improve a service. Counteractions can be adapted to preclude, disconfirm, or control rival hypotheses.

### *4.1 Service evaluation*

One of the simplest counteractions is to take multiple measurements of the same service, such as measurements of usage, satisfaction, and performance. Taking these measurements in more than one way (multiple methods) is also useful. Confidence in a particular result is increased if different sources point to the same conclusion.

One fear (rival hypothesis) that occasionally strikes is that the data are somehow mutilated to spuriously inflate results. This fear became real in the Calling Card Service field trial when the service began performing better than expected. Interviews, observation, and billing data corroborated the computer-collected data so strongly as to explode this rival hypothesis. Test calls removed any remaining shards of doubt.

Many rival hypotheses are based on test time. For example, the results may be due to some unusual circumstance or event, or the test may give rise to a trend in usage or performance that may be transitory (e.g., novelty effects or start-up effects) or the test may give rise to cyclic or delayed effects. One simple counteraction used in the Calling Card Service field trial to account for these problems was to repeat a test or take continued measurement of the service over time. If a unique circumstantial or historical event affected the outcome of a

test, then subsequent measures could provide evidence to support or negate this rival hypothesis.

Before, during, and after usage measurements of all coin stations (trial and nontrial) at the airport were inspected to determine if any events, trends, or cyclic phenomena confounded the data. Specifically, the Christmas holiday season and an airline strike had to be taken into account.

While multiple measurements and time-spaced testing counteract many problems, they give rise to problems of their own. One measurement may affect another. For example, repeated interviewing may cause customers to change their behavior more as a function of the interviewing process than the service itself.[6] Fortunately, the bulk of the measurements typically taken in a telephone service field trial are made on-line and are unknown to the telephone caller.* The customer is not usually aware in these tests that digits dialed, on-hooks and off-hooks are recorded and time stamped. These measures are presumably nonreactive, and thus there is no plausible explanation of measurement affecting customer behavior and attitude.

One could avoid the problem of reactivity by using only nonreactive measures. But interviews and questionnaires provide invaluable data. We handled this problem in the Calling Card Service field trial by interviewing some customers once, others twice, and still others not at all. Comparisons of these groups in terms of nonreactive measures and subsequent interviews, however, did not substantiate a reactivity effect.

Establishing a control group is another strategy that can be used to help determine if the results were due to historical events or arbitrary circumstances. The assumption is that those extraneous events or circumstances that affect the treatment group also affect the control group. To the extent that the precision of the measures allow, differences between the control group and the treatment group can, therefore, be attributed to the presence of the treatment, that is, the service.

People at nontrial coin stations at the airport were interviewed as a control for interviews taken at trial coin stations. This procedure allowed us to determine if there were any changes in customer attitudes that might have been attributable to events alone and not to service. The interview control group thus served as a counteraction to the rival hypothesis of history. For example, those people interviewed some days were angry because of plane delays. If this irritation had an effect, it would show up in both treatment and control group scores.

---

* The customer generally is aware that a test is being conducted and that service is being measured; thus, the problem of test reactivity cannot be completely discounted.

Randomization in the selection process assures equivalence between the treatment and control groups. If randomization is not possible, a plausible rival hypothesis is that the people assigned to one group differ, on the average, from those in the others and that these intrinsic differences are the real cause of any observed difference among the groups. A method for determining whether such rival hypotheses are correct is to make measurements of the groups before the treatment (service) is administered. Comparing the pretreatment and post-treatment observations of the group given the trial service with simultaneous observations of the control group (not given the trial service) tests the rival hypotheses that these two groups are inherently different, or in other words, that results are due to the history of the customers or their maturation or learning during testing.

Customers were interviewed and billing data were tracked before and after the Calling Card Service field trial. These data were used to determine the differences among customers and between trial and nontrial stations.

### *4.2 Improving service*

In the preceding discussion, counteractions for a static service evaluation were discussed. A new service can be said to consist of a set of variables that may be manipulated to possibly improve service.

The key question is: How can we be sure that changes in service outcome are due to our service manipulations? Establishing causal connections for what improves or degrades service increases understanding. Increased understanding will tend to increase confidence in predictions of how the final service will fare.

#### *4.2.1 Varying the service*

A simple model of service variation is depicted in Fig. 5. The knobs in the figure represent the independent variables; the meters, the dependent variables. The object of varying the service is to manipulate the knobs in such a way as to cause the meters to register a beneficial change in service. If the meters are considered to show customer satisfaction, usage, and performance, the object then is to find the combination of knob positions that maximizes the readings on each meter (metaphorically speaking).

With every knob manipulation, knowledge and understanding is increased, whether the meters change positively, negatively, or not at all. Knowledge gained from the previous adjustment permits efficient and effective design of subsequent service adjustments. However, such a test-adjust-test method requires a system that can provide very quick analysis of results.

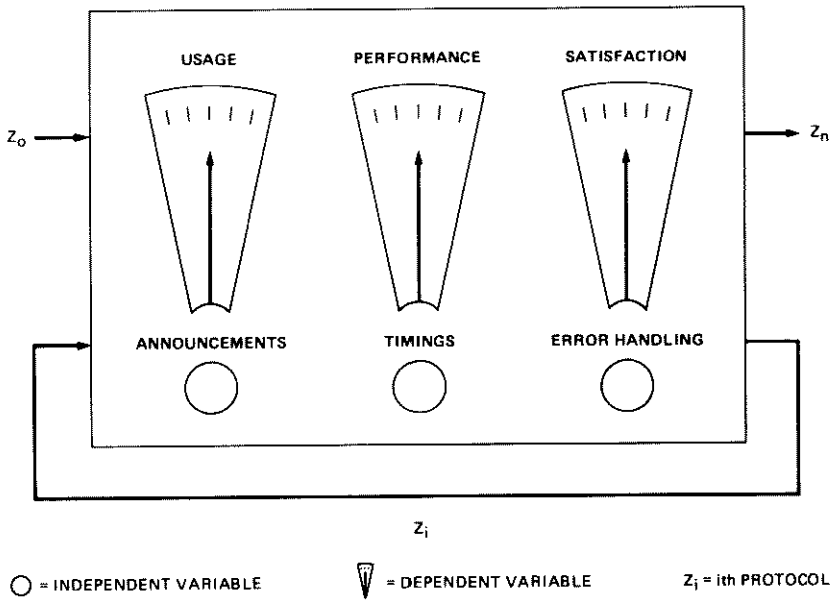

Fig. 5—Field trial metaphor—with results fed back as input into the field trial design.

#### *4.2.2 Increasing confidence in service manipulations*

Improving service can be thought of as repetitions of static service evaluation. The same counteractions discussed earlier can be used and augmented for service improvement. To account for the possibility of other events interposing effects on the dependent variables coincident with the adjustment of a service, the concept of the control group is again appropriate.

One new problem that is introduced in improving service is that multiple treatments (changes) may interact with each other. That is to say, customers' responses to a subsequent service may not be the same as those to the first service they experienced. Further, the very act of changing the service may impact attitudes and customer performance.

Adding a new group of customers for every new protocol iteration counteracts this threat to validity. (Appendix A contains notations for representing this design consideration and the others discussed here.)

The rudiments of these design principles were used in the Calling Card Service field trial. Service was manipulated in the trial in an attempt to improve service. A particular service configuration is here called a service protocol. Because many of the trial phones were in the airport, there were always a great number of new customers trying the service, more than enough to support the manipulations.

When customers dialed 0+NPA NXX XXXX at trial stations a tone prompt was given (sometimes followed by an announcement prompt) and the following things (in most protocols) could happen:

1. The customer could dial a credit card number.
2. The customer could time out without dialing and be connected to an operator.
3. The customer could dial 0 after the prompt and be connected to an operator.
4. The customer could abandon the call.

Ideally, all customers with credit card numbers would dial them. All others would dial 0 after the tone prompt to reach an operator. Practically speaking, this was not possible. Rather, different protocols were tested to attempt to increase the proportion of dialed credit card calls, increase the proportion of customers who needed an operator to dial 0, or decrease abandons.

Figure 6 summarizes the service manipulations for the placarded coin stations. Figure 7 shows the proportion of the four classes of call dispositions: (1) dial credit cards, (2) dial 0, (3) abandons, and (4) time-outs for each protocol for the placarded coin stations. The area under each curve represents the incremental proportion of 0+ calls.

While these curves are revealing, they cannot be used alone to determine the best protocol, i.e., the one with the highest satisfaction, performance, and usage. However, unacceptable protocols can readily be identified: they are those with abandonment rates in excess of 25 percent and those with dialed credit card call rates less than 25 percent.

Fortunately, the first coin placarded service protocol had low abandonment rates and high credit card dialing rates. The subsequent

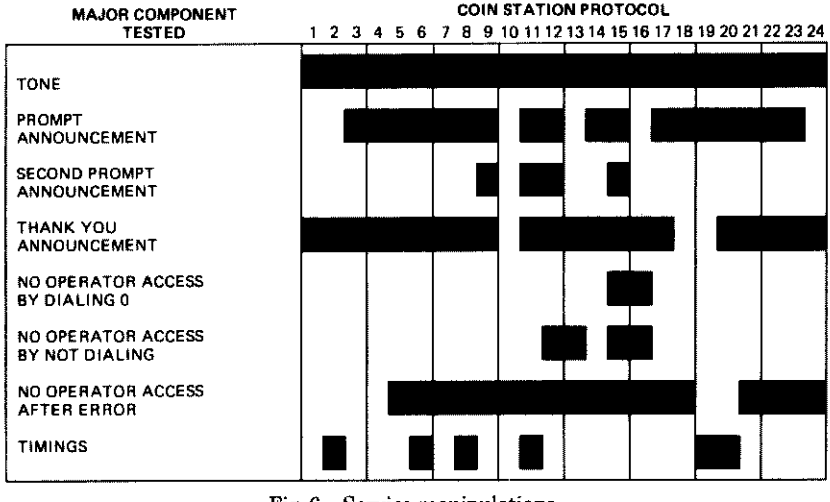

Fig. 6—Service manipulations.

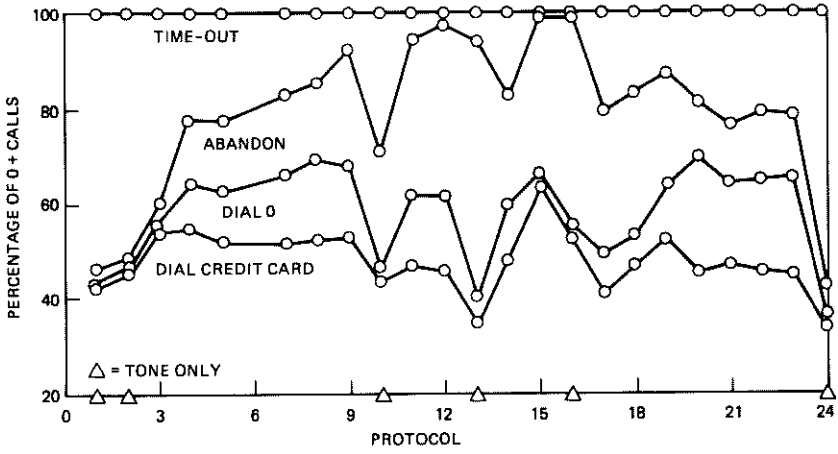


NOTE: PROTOCOLS WITHOUT A TONE-ONLY INDICATOR HAVE A TONE AND AN ANNOUNCEMENT. PROTOCOL 17 INCLUDES A SPECIAL ANNOUNCEMENT DESIGNED TO DISCOURAGE CALLS FROM UNENABLED ROTARY STATIONS.

NOTE: THESE CURVES REPRESENT INCREMENTAL PERCENTAGES.

Fig. 7—Dialing performance at placarded coin stations by protocol.

manipulations were primarily aimed at improving service, although clearly the opposite effect was sometimes achieved.

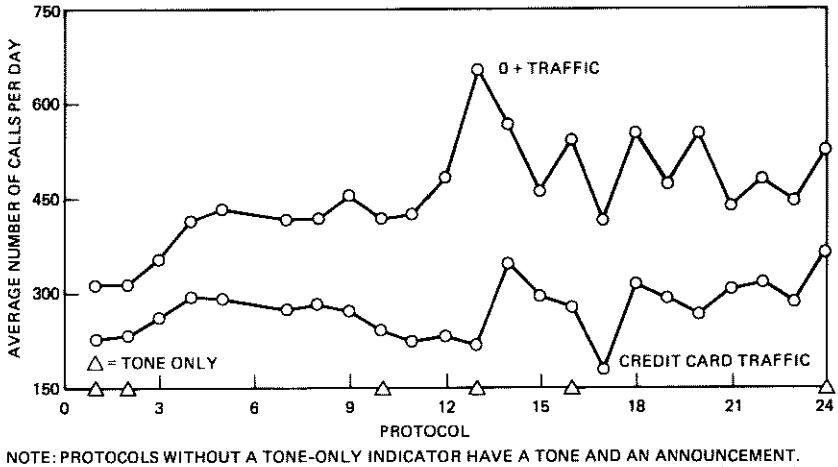
A changing volume of 0+ calls and a changing call mix were plausible explanations for one service protocol doing marginally better than another. As Figure 8 shows this was sometimes a consideration.

Another rival hypothesis was related to assumptions about those who abandoned. If all or a large number of those who abandoned were credit card customers, estimates of the proportion of credit card dialers could vary significantly. Figure 9 shows the percentage of dialed credit card calls (of all credit card calls) with and without abandons counted as credit card calls. Including and excluding abandons in this way provides lower and upper bounds, respectively, of the percent of credit card calls dialed.

Still another rival hypothesis was that usage (or attempts) may be higher, but performance lower when comparing one protocol to another. Figure 10 illustrates success rates by protocol.

Rival hypotheses due to repeated usage (familiarity and learning) were accounted for by sorting out and examining results from repeat users.

Service protocols were compared to determine the effect of a particular manipulation. Figures 11 and 12 compare two protocols in terms of abandonments and percent of 0+ dialing. These figures lead to the conclusion that repeating a prompt announcement in this service does not increase dialing but does increase abandons. Thus, repeating announcements is a less desirable alternative.



NOTE: PROTOCOLS WITHOUT A TONE-ONLY INDICATOR HAVE A TONE AND AN ANNOUNCEMENT. PROTOCAL 17 INCLUDES A SPECIAL ANNOUNCEMENT DESIGNED TO DISCOURAGE CALLS FROM UNENABLED ROTARY STATIONS.

NOTE: PROTOCOLS WITHOUT A TONE-ONLY INDICATOR HAVE A TONE AND AN ANNOUNCEMENT. PROTOCOL 17 INCLUDES A SPECIAL ANNOUNCEMENT DESIGNED TO DISCOURAGE CALLS FROM UNENABLED ROTARY STATIONS.

Fig. 9—Dialed credit card calls with and without abandonments by protocol.

### *4.2.3 Comparison groups*

There are two ways of making service comparisons in the test design just discussed, which consisted of staggered subjects and measurements of responses to service refinements. First, customer comparisons can be made across service changes. This consists of multiple measurements or time-spaced measurements of the same customer. The

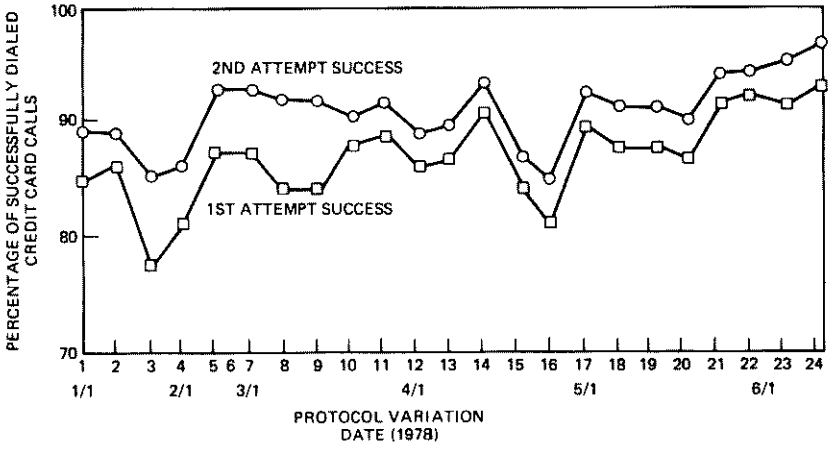

Fig. 10—Customer dialing success rate.

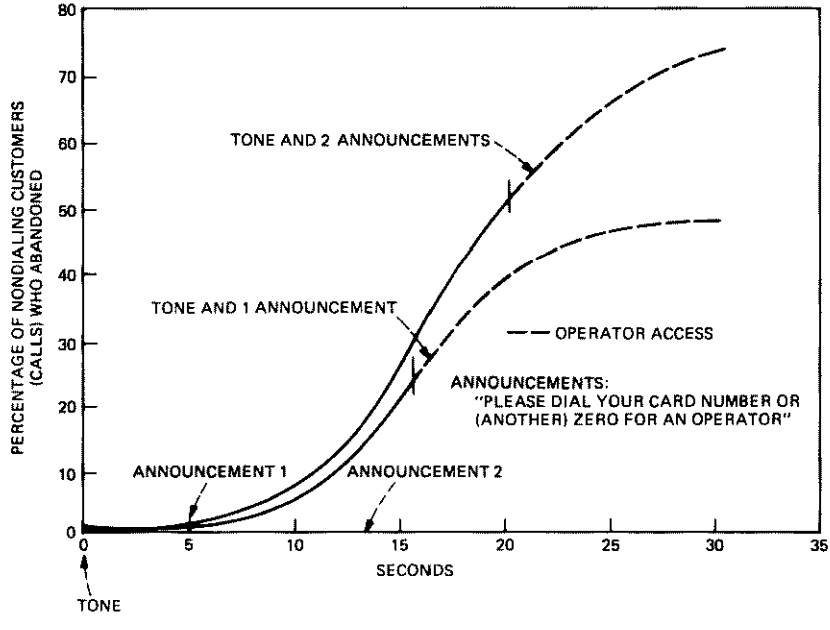

Fig. 11—Abandonments as a function of repeated announcements at coin placarded stations.

error variance is small because there are no intersubject differences, but there is multiple treatment interference. Second, service comparisons can be made across new subject groups, but treatment effects are confounded with history and by any bias introduced by the selection of groups.

Comparison groups can be arranged to preclude history as a con-

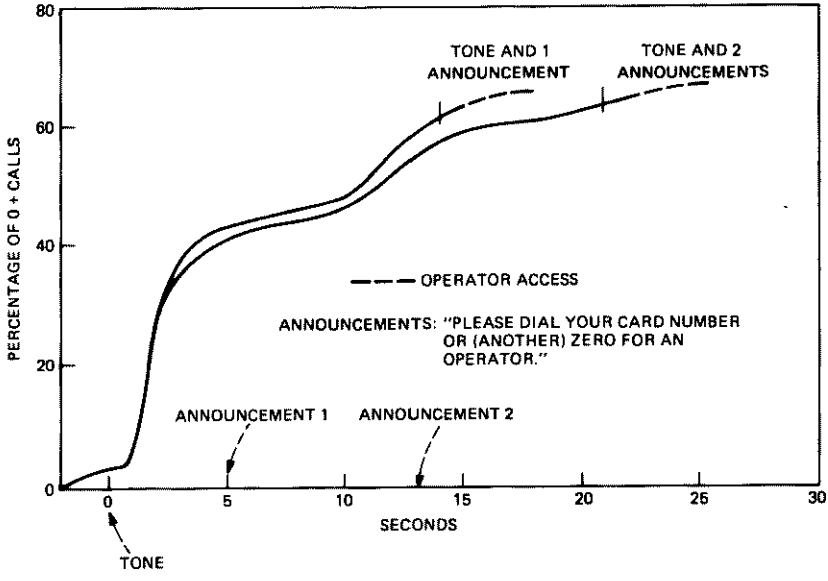

Fig. 12—Dialing as a function of repeated announcements at coin placarded stations.

founding variable by offering different service arrangements simultaneously (at different telephones, for example). For best results, each of these comparison groups should be as similar as possible except for any planned differences in treatment (service).

In the Calling Card Service field trial, we devised three comparison groups: noncoin stations, placarded coin stations (with special bright orange instruction cards), and placardless coin stations. These comparison groups were not mutually exclusive. Crossovers occurred, especially between placarded coin and placardless coin groups. But for every comparison group, and, as discussed, for every manipulation, there were new customers. Service changes were replicated across these comparison groups further increasing confidence and providing information about the effects of the station type.

#### *4.2.4 Refinement*

Because the number of variables and variable states in a field test of this kind is usually large, only a small subset of the number of possible treatment combinations can be used. Moreover, the protocol is evolving and a delay is often necessary in the testing of different combinations. Unfortunately, this delay means the manipulation is confounded with the history of the customer population. However, prudent selection of changes and repetitions within a treatment group and across comparison groups can yield a more complete understanding of the effects of the service components and their interactions.

In the Calling Card Service, the primary objective of the service manipulations was to make reasonable changes which were hypothesized to increase usage, satisfaction, and performance. This objective was sometimes subjugated to the purpose of increasing confidence in the belief that the changes in the independent variables (and not the parameters) caused the observed changes in the dependent variables. One such manipulation was to deliberately make it progressively more difficult for the customer to get to an operator, i.e., protocols 12, 13, 15, and 16. It was hypothesized that more customers would use their credit card if it were made relatively more difficult to obtain an operator. However, this hypothesis was not borne out; the proportion of credit card calls dialed was either unchanging or decreasing, and abandons increased as one would suspect. Clearly, other manipulations were more successful.

As the treatment change chart shows, changes in the state of more than one independent variable were made more often than not. The large number of variables prohibited single sequential changes in each variable. For example, the error-leg protocol was manipulated independently and simultaneously with the access-leg protocol many times. Evidence gathered from protocols prior to this practice showed little or no interaction from changes in the access leg and the error leg, except that the number of people making errors fluctuates.

Inferences made about the protocol change were made in terms of the multiple change because the independent variables were confounded. Inferences based on effect separation and independence assumptions were made cautiously and verified, when possible, in later manipulations.

#### *4.2.5 Replication*

Any changes in the dependent variables caused by a change in the protocol (or service) and not by history should be present in successive identical tests (within the bounds of measurement error). Replication of effects increases confidence in the hypothesis that a change in protocol actually causes a change in the dependent variable being measured. As a practical matter, the utility of repeated replications of a single treatment is sharply reduced by the need to manipulate as many variables as possible in the time allowed. However, intermittent replications can serve to benchmark drifting or trending data.

On several occasions, we repeated protocols within and across comparison groups in the Calling Card Service field trial. Replications afforded an increase in confidence by allowing an assessment of changes in dependent variables due to confounding of external and internal parameters with the independent variables. The replications, in effect, provided a basis for comparison. And the replications in-

creased confidence in the assertion that the observed changes in the dependent variable were caused by the deliberate change in the independent variables. For example, protocol 14 amidst protocols 12, 13, 15, and 16 (coin placarded stations) was a replication of an earlier protocol and supported the hypothesis that the poor performance of the other protocols was real and not an artifact of internal or external conditions.

Some replications were designed to provide more information about the contributing effects of certain service components. Most notably, major service changes were tested with both the tone-only and tone-and-announcement conditions. For example, protocol 13 (coin placard station) was the same as protocol 12, but without the prompt announcement. This is similarly true for protocols 15 and 16.

#### *4.2.6 Partial counterbalancing*

Arranging the treatment order in special ways—e.g., the Latin Square design—across comparison groups provides for pairwise comparisons of different treatment orderings. Such arrangements, however, are often not practical in field trials of telephone services because of the large number of variables and variable states (treatment conditions) that should be tested. The large number of treatment combinations required of typical counterbalancing techniques preclude their use. Manipulation of protocols on the basis of data gathered from prior manipulations also precludes planned counterbalancing.

But it may be possible partially to counterbalance treatment pairs across comparison groups in order to assess some multiple treatment order effects. If the manipulations evolve, the application of counterbalancing schemes have to be delayed by at least one time frame to have knowledge of the treatment pair.

#### *4.2.7 Post-manipulation static study*

After service manipulations are finished, it is useful to study the final service at rest. In this period in the Calling Card Service field trial (protocol 24), transient effects due to changes in the service were not present, thus improving predictions of the final service.

## V. CONCLUSION

Many service issues were resolved by the trial of Calling Card Service. Most important, the customers who tried the service continued to use it because they felt it was faster and more convenient than operator-assisted credit card calling. Moreover, the design of the service was critically dependent on the results of the field trial manipulations. Both announcements and instruction placards were found to be very effective in stimulating customers to dial. The field trial data

provided objective measurements of optimum customer usage and acceptance and lower rates of error and abandonment in the service offered. Table I lists the criteria found most useful in selecting the attributes of the final service.

When Calling Card Service was first offered in Buffalo in July 1980, a product follow-up evaluation study was conducted to monitor customer use, performance, and acceptance levels. The measurements of actual service conformed closely to estimates made from field trial data and, thus, support the utility of test methodology in guiding service design choices. The methodology developed for evaluating Calling Card Service is now being applied to the next generation of services, such as teleconferencing.

## VI. METHODOLOGY SUMMARY

The pre-field trial activities of analysis, interviews, and laboratory studies are undertaken to refine the service definition and assess the potential of its success. A study plan is constructed which defines objectives, resources and constraints, study variables, acceptance criteria, and study design. Field test requirements are developed that specify the data collection, analysis, and customer acquisition and preparation procedures as well as specify the hardware, software, and network aspects of a telephone service test vehicle.

Given adequate requirements the test is developed and implemented. During the test, the service is manipulated and data are collected and analyzed to optimize criteria of usage, performance, and satisfaction. Trade-offs are made relative to available resources, data validity, confidence in results, and time constraints. If success is predicted for the service being tested, results are then integrated into the design and the service is offered and monitored. Figure 13 summarizes the total process of conducting a field test of a telephone service.

Table I—Criteria for selecting service attributes

| Independent Variables | Dependent Variables |
|---|---|
| 1. Announcement Presence | a. Percentage Dialed<br>b. Abandons |

## APPENDIX A

### *Field Evaluation Design Notation*

To provide another perspective on the field design methods, the following notation is provided.

#### *A.1 Service*

A service (or treatment) can be defined by set of dependent variables with specific values, represented here as a vector $\dot{Z}$.

$$\dot{Z} = \begin{vmatrix} z_1 \\ z_2 \\ \cdot \\ \cdot \\ \cdot \\ z_n \end{vmatrix}$$

#### *A.2 Measurements*

Let 0 stand for observation. A matrix of $n$ kinds of measurement taken in $m$ different ways is represented by $\ddot{0}$.

$$\ddot{0} = \begin{vmatrix} 0_{11} & 0_{12} & \cdots & 0_{1m} \\ \cdot & & & \\ \cdot & & & \\ \cdot & & & \\ 0_{n1} & 0_{n2} & \cdots & 0_{nm} \end{vmatrix}.$$

When multiple measures (taken multiple ways) are repeated, the notation is:

$$\ddot{O}^m = \ddot{O}_1 \cdots \ddot{O}_m .$$

### A.3 Improving service

Two aspects of the field study, static service evaluation and improving service, could be represented as:*

| Static Service Evaluation | | Improving Service |
|---|---|---|
| $\dot{O}_0^m \dot{Z}_0 \ddot{O}_1^m$ | $\dot{Z}_1$ | $\ddot{O}_2^m \cdots \ddot{O}_n^m \dot{Z}_n \ddot{O}_{n+1}^m$ |

This design effectively constitutes repetitions of the static service evaluation.

### A.4 Control group

| | |
|---|---|
| ${}_{A'}\ddot{O}_0^m \dot{Z}_0 {}_A\ddot{O}_1^m \dot{Z}_1 {}_A\ddot{O}_2^m \cdots {}_A\ddot{O}_n^m \dot{Z}_n {}_A\ddot{O}_{n+1}^m$ | Treatment Group |
| ${}_{A'}\ddot{O}_0^m {}_{A'}\ddot{O}_1^m {}_{A'}\ddot{O}_2^m \cdots {}_{A'}\ddot{O}_n^m {}_{A'}\ddot{O}_{n+1}^m$ | Control Group |

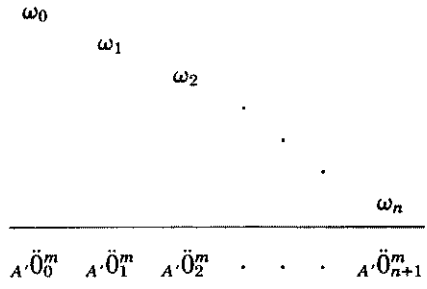
### A.5 Staggered treatment groups

New subjects are added (or are available) at each treatment change. Limited resources usually necessitate the continued manipulation of the variables within treatment groups. The line offsets the control group from the treatment groups and denotes unequivalence of the groups.

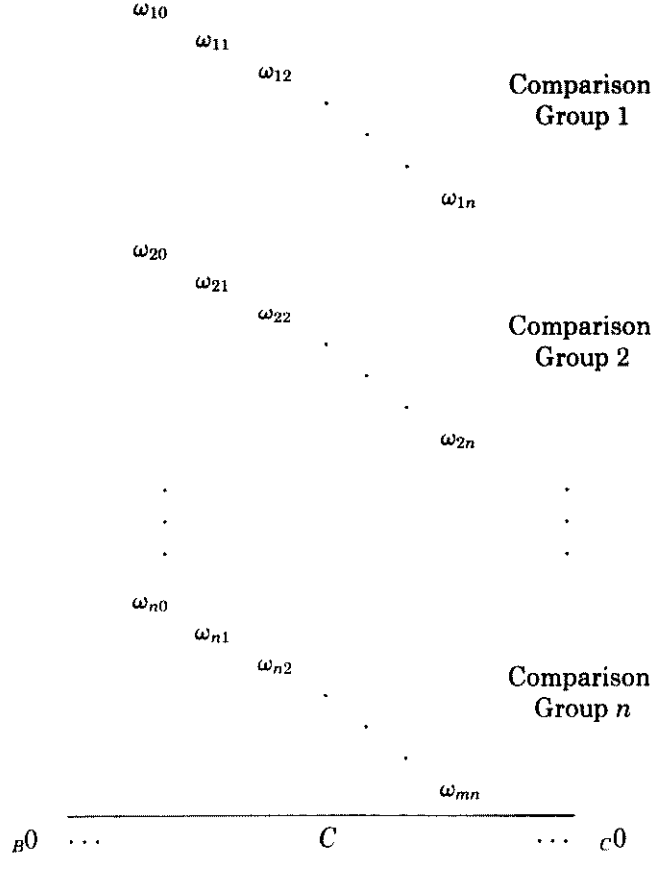
| | | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| ${}_{A'}\ddot{O}_{10}^m$ | $\dot{Z}_0$ | ${}_{A'}\ddot{O}_{11}^m$ | $\dot{Z}_1$ | ${}_A\ddot{O}_{12}^m$ | $\cdots$ | ${}_A\ddot{O}_{1n}^m$ | $\dot{Z}_n$ | ${}_A\ddot{O}_{1n+1}^m$ | Treatment Group 1 |
| | | ${}_{A'}\ddot{O}_{21}^m$ | $\dot{Z}_1$ | ${}_A\ddot{O}_{22}^m$ | $\cdots$ | ${}_A\ddot{O}_{2n}^m$ | $\dot{Z}_n$ | ${}_A\ddot{O}_{2n+1}^m$ | Treatment Group 2 |
| | | | | | | ${}_{A'}\ddot{O}_{nn}^m$ | $\dot{Z}_n$ | ${}_A\ddot{O}_{nn+1}^m$ | Treatment Group $n$ |
| ${}_{A'}\ddot{O}_{n+10}^m$ | | ${}_{A'}\ddot{O}_{n+11}^m$ | | ${}_{A'}\ddot{O}_{n+12}^m$ | $\cdots$ | | | ${}_A\ddot{O}_{n+1n+1}^m$ | Control Group |

* $\dot{Z}_i$ denotes the vector of service-independent values for the $i$th service change (treatment). ${}_A\ddot{O}_i^m$ denotes the matrix of multiple measurements by multiple methods measured $m$ times for the $i$th service (treatment) change. The left-hand $A'$ subscript (versus $A$ subscript) denotes that some measurements present in the trial may not be available in the pretrial measures (or in the control group).

To reduce the notational burden, let $\omega_i$ denote the $i$th staggered treatment group.



### *A.6 Staggered treatment groups with comparison groups*



Note that the Control Group, $C$, is augmented with historical and follow-up measurements.

### A.7 Replications

Replications are denoted by the appropriate repetition of protocol time frame subscripts on the independent variable vector:

$$ {}_{A'}\ddot{O}_0^m \boxed{\dot{Z}_0} {}_{A'}\ddot{O}_1^m \dot{Z}_1 {}_{A}\ddot{O}_2^m \boxed{\dot{Z}_0} {}_{A}\ddot{O}_3^m \dot{Z}_2 {}_{A}\ddot{O}_4^m \cdots \dot{Z}_n {}_{A}\ddot{O}_p^m. $$

### A.8 Partial counterbalancing

$$ \begin{array}{llll} \boxed{{}_{A'}\ddot{O}_{101}^m \dot{Z}_0 {}_{A}\ddot{O}_{111}^m \dot{Z}_1} & \ddot{O}_{121}^m \dot{Z}_2 \cdots & \Big\} & \text{Comparison Group 1} \\ {}_{A'}\ddot{O}_{211}^m \dot{Z}_1 & {}_{A}\ddot{O}_{221}^m \dot{Z}_2 \cdots & & \\ & {}_{A'}\ddot{O}_{321}^m \dot{Z}_2 \cdots & & \end{array} $$

$$ \begin{array}{llll} {}_{A'}\ddot{O}_{102}^m \dot{Z}_0 \; {}_{A'}\ddot{O}_{112}^m \dot{Z}_1 & {}_{A}\ddot{O}_{122}^m \dot{Z}_0 \cdots & \Big\} & \text{Comparison Group 2} \\ \boxed{{}_{A'}\ddot{O}_{212}^m \dot{Z}_1} & {}_{A}\ddot{O}_{222}^m \dot{Z}_0 \cdots & & \\ & {}_{A'}\ddot{O}_{322}^m \dot{Z}_0 \cdots & & \end{array} $$

The two boxed groups are the time-delayed counterbalanced treatment pairs $\dot{Z}_0$ and $\dot{Z}_1$.

# Characteristics of Human Performance

Vigorous efforts to improve understanding of underlying processes in human behavior have been made at Bell Laboratories. Current interests include most major aspects of human information processing and performance, including perception, thinking, movement control, and learning. This section includes samples of recent work on fundamental mechanisms in visual pattern recognition (Julesz and Bergen), the timing of repetitive actions (Rosenbaum), the perceptual interpretation of graphical displays (Cleveland, Harris, and McGill), and individual variations in modes of mental problem solving (Egan). While these four papers by no means exhaust the problem areas under investigation, they do give a fair picture of the wide range of issues, methods, theory, and data involved, and the diverse domains of knowledge being enriched.

# Textons, The Fundamental Elements in Preattentive Vision and Perception of Textures

By B. JULESZ* and J. R. BERGEN*

(Manuscript received September 23, 1981)

Recent research in texture discrimination has revealed the existence of a separate "preattentive visual system" that cannot process complex forms, yet can, almost instantaneously, without effort or scrutiny, detect differences in a few local conspicuous features, regardless of where they occur. These features, called "textons", are elongated blobs (e.g., rectangles, ellipses, or line segments) with specific properties, including color, angular orientation, width, length, binocular and movement disparity, and flicker rate. The ends-of-lines (terminators) and crossings of line segments are also textons. Only differences in the textons or in their density (or number) can be preattentively detected while the positional relationship between neighboring textons passes unnoticed. This kind of positional information is the essence of form perception, and can be extracted only by a time-consuming and spatially restricted process that we call "focal attention". The aperture of focal attention can be very narrow, even restricted to a minute portion of the fovea, and shifting its locus requires about 50 ms. Thus preattentive vision serves as an "early warning system" by pointing out those loci of texton differences that should be attended to. According to this theory, at any given instant the visual information intake is relatively modest.

## I. INTRODUCTION

In this article we give an overview of some insights into the workings of the human visual system gained during two decades of research at Bell Laboratories, and culminating in the discovery of a few local conspicuous features that we call textons. Textons appear to be the basic units of preattentive texture perception,[1] when textures are viewed in a quick glance with no further effort or analysis. Although this article goes beyond texture perception into preattentive vision in general, studies of texture discrimination led to the basic insights presented here and provide excellent demonstrations of the main findings. Based on our findings we propose a novel theory of vision in which the preattentive visual system inspects a large portion of the visual field in parallel and detects only density differences in textons. It then directs focal attention to these loci of texton differences for detailed scrutiny.

Now, after 20 years of research, when we know what textons are and their role in vision is clarified, we can save the reader from following the rather difficult steps that led to their discovery. [The reader interested in the history of these developments, and in the sophisticated mathematics necessary to generate textures with certain stochastic constraints, should turn to the original articles referred to in a recent review by one of us[1] and to the Appendix.] Here we follow an axiomatic treatment. The main findings are presented in Section II as heuristics (similar to axioms, but not necessarily totally independent), immediately followed by many demonstrations. The reader can test the power of these newly acquired heuristics by being able to predict and then verify which texture pairs will be perceived to be different, and which will appear as a single texture. The reader can thus understand the new theory of vision without mathematical knowledge.

Section III emphasizes the essentially local nature of texture perception. Section IV relates the psychologically identified textons to some neurophysiological results concerning local feature analyzers in primate cortex. Section V extends the texton theory from texture perception to the discrimination of briefly presented patterns. In Section VI a model of human vision is proposed that postulates two different modes of visual system function. Section VII discusses some implications of this model.

## II. HEURISTICS: DEFINITION OF TEXTONS AND THEIR INTERACTIONS IN PREATTENTIVE VISION

Visual textures are defined as aggregates of many small elements. The elements can be either dots of certain colors (e.g., black, white, grey, red) or simple patterns. For purposes of this article, we consider

only elements that do not overlap, and are placed at either regular or random positions, in identical or in random angular orientations.

Usually in our demonstrations two textures (composed of two different elements) are placed side-by-side, or one is embedded in the other, as shown in Fig. 1. When the reader cursorily inspects Fig. 1, an area made up of +'s will appear to stand out from the surrounding texture composed of L's. Indeed, without scrutiny, that is without detailed element-by-element inspection, the reader might not notice that a third area composed of T-shaped elements is also embedded in the texture of L's. We call this effortless perceptual segregation of the texture composed of +'s from the surrounding texture of L's *preattentive texture perception.* On the other hand, if texture discrimination requires element-by-element scrutiny, as is the case of finding the T's in the L's, we call this way of looking with scrutiny *focal attention.* We will show many other preattentively indiscriminable texture pairs (e.g., Figs. 3c and 6b), which, because they do not segregate, often are not even perceived as containing different elements until this is pointed out.

Although in all texture perception the preattentive system is dominant, the role of focal attention can be even further reduced by brief presentation. The reader who is not convinced by the qualitative difference between preattentive and attentive texture discrimination

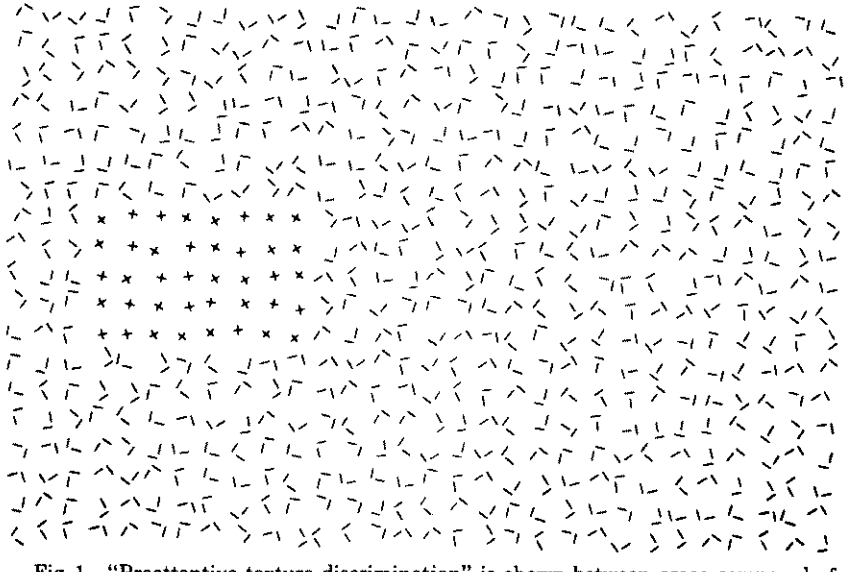

Fig. 1—"Preattentive texture discrimination" is shown between areas composed of +'s and L's, while element-by-element scrutiny, called "focal attention" is required to find the T's embedded in the L's.

might inspect Fig. 1 through a camera shutter set at 1/10 second exposure time.

*Heuristic 1: Human vision operates in two distinct modes*

1. Preattentive vision—parallel, instantaneous, without scrutiny, independent of the number of patterns, covering a large visual field, as in texture discrimination.
2. Attentive vision—serial search by focal attention in 50-ms steps limited to a small aperture, as in form recognition.

*Heuristic 2: Textons*

1. Elongated blobs—e.g., rectangles, ellipses, line segments with specific colors, angular orientations, widths, and lengths.
2. Terminators—ends-of-line segments
3. Crossings of line segments

*Heuristic 3: Preattentive vision directs attentive vision to the locations where differences in the density (number) of textons occur, but ignores the positional relationships between textons.*

Before we discuss the implications of these heuristics, let us apply them to a few pairs of elements and predict whether the texture pairs formed from these elements will yield preattentive texture discrimination or not. This application of the rules also helps to clarify them. For instance, elongated blobs of different widths or lengths are different textons, as Fig. 2a demonstrates. The larger sized R's containing longer and wider line segments form a texture that segregates (i.e., is preattentively discriminable) from its surround, which is composed of smaller R's with shorter and narrower line segments.

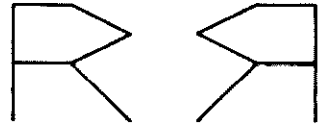
Similarly, elongated blobs of different orientations are different

(a) (b)

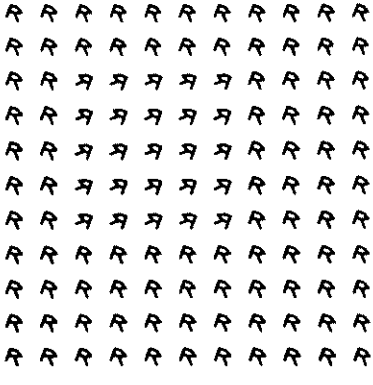
Fig. 2—Preattentive texture discrimination based on texton differences between line segments of (a) length and width and (b) angular orientation. (*Nature*, March 12, 1981[1])

textons. Indeed, in Fig. 2b the texture pair composed of the same sized R's having two different orientations in the two textures, yields preattentive discrimination. Obviously, the same elongated blob shape with the same orientation yields different textons if the colors (e.g., black, gray, white, red, green, etc.) are different.

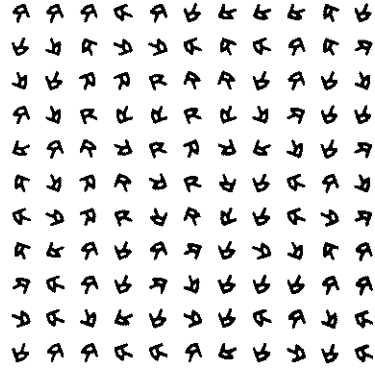
Now, let us predict what would happen if we took an R and a mirror-image R, as shown in Fig. 3a, and formed a texture pair by throwing them in random orientations. Obviously, without randomizing the orientations, the two textures would yield texture discrimination, since even though their widths and lengths agree, some of the line segment textons have different orientations in the R and in its mirror image, though the widths and lengths agree, as shown in Fig. 3b. However, if the two elements are thrown at random orientations, then the two textures formed have the same average density of textons (i.e., in some area of integration the number of line segments with the same color, width, length, and orientation is identical). Therefore, the preattentive visual system should not be able to direct focal attention to loci of texton differences that form the boundary between the two regions. Indeed, an inspection of Fig. 3c yields a single, uniform texture. It requires laborious element-by-element inspection for several seconds



(a)



(b)



(c)

Fig. 3—Demonstration of how the heuristics given in text predict why (a) R and its mirror image in aggregates yield texture discrimination (b), or are indistinguishable (c). (*Perception*, 1973[3])

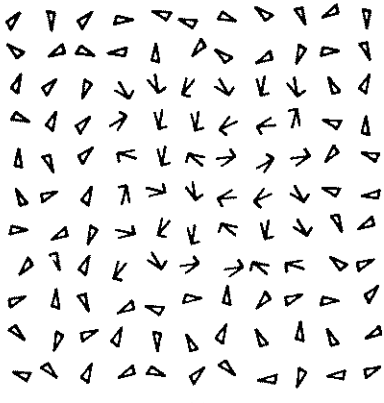
to find the boundary between the array of R's and mirror-image R's. Obviously, in a 100-ms presentation discrimination of these textures is impossible.

Let us note that if one were to select a pair of elements without knowing the rules given above, most probably the resulting texture pair would be discriminable. Only through the joint effort of our colleagues (D. Slepian, M. Rosenblatt, E. Gilbert, L. Shepp, H. Frisch, T. Caelli, and J. Victor) from 1962 to 1978 were some elegant methods found that yielded indistinguishable textures, even though their elements appeared very different.

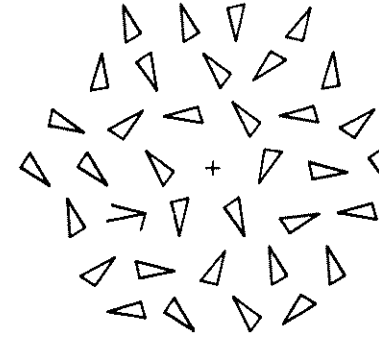
In the next examples we stress the importance of terminator textons. For instance, in Fig. 4a the two elements are composed of three identical line segments (i.e., same orientation, width, and length). The only difference is in the number of their ends-of-lines (terminators). The triangle-shaped element has no open ends, while the "dual" element has three ends-of-lines. One should expect texture segregation, given such a large difference in terminator number, and as Fig. 4b demonstrates, this is the case.

As a matter of fact, discrimination is so strong that a single element can be preattentively detected among 35 dual elements, as shown in Fig. 4c. This arrangement is now routinely used by us in studying

(a)



(b)

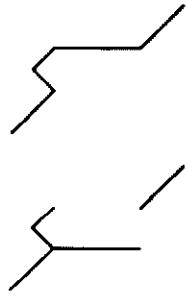


(c)

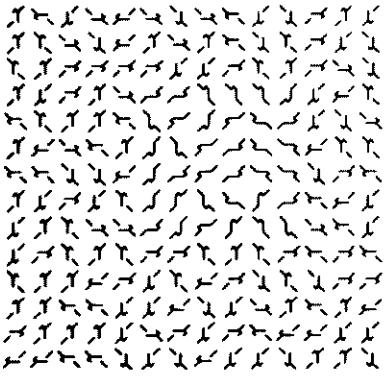
Fig. 4—Demonstration of how the heuristics given in text predict preattentive texture discrimination (b) and even discrimination of a single element among many (c), based on terminator number difference (zero versus three) between elements (a). (*Nature*, March 12, 1981[1])

pattern discrimination in preattentive vision, as discussed in Section V. Here we note only that when there is a texton difference (as in Fig. 4c) detecting one element in the midst of 35 other elements is almost as easy as detecting the difference between two elements (shown in Fig. 4a) for presentation times as brief as 100 ms.

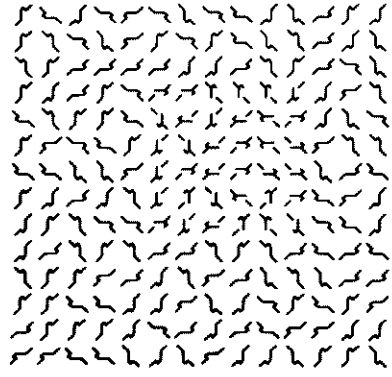
In the next example, both members of the element pair of Fig. 5a are again composed of the same five line segments (each corresponding line segment in the two elements has identical width, length, and orientation, respectively) but one element contains only two ends-of-lines, whereas the other contains five. This large difference in terminator numbers should yield texture segregation, and inspection of Fig. 5b demonstrates that it does. Figure 5c consists of the same texture pair as Fig. 5b, except that the texture containing the five terminators is now the surround. Although, as predicted, the large difference in terminator numbers again yields texture segregation, the appearance of the boundary between the two regions is different for Fig. 5b and 5c.



(a)



(b)



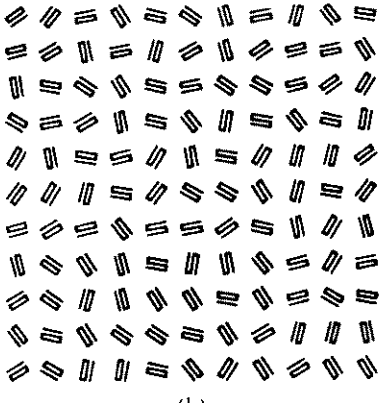
(c)

Fig. 5—Similar to Fig. 4 except the terminator number between elements is two versus five.

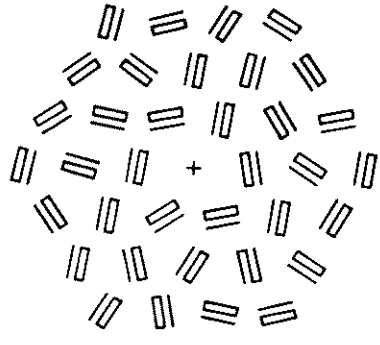
The next example, shown in Fig. 6a, consists of the "S"- and "10"-shaped elements, that in isolation appear quite different. However, the two contain the same number of line segment textons (three identical horizontal and two identical vertical line segments) and both contain two ends-of-lines. The fact that the positional relationship between these textons is different (as it is in Fig. 3b) can be perceived only by the attentive visual system (yielding the percept of an S versus a 10). However, according to Heuristic 3 the preattentive system can count only the density (number) of textons and ignores their relative positions. So, according to our rules, a texture pair composed of these elements contains the same average density (number) of textons, and thus should be indistinguishable. Surprising as it may seem, the texture pair is indeed preattentively indistinguishable as demonstrated by Fig. 6b. [Readers who find this demonstration of the distinction between preattentive and focal vision not adequately convincing without brief presentation should note the contrast between the attentively different percepts of Fig. 6a, and the texture pair in Fig. 6b, which remains difficult to distinguish even with element-by-element scrutiny.]

Finally, let us demonstrate the third texton, the crossing of elongated blobs (line segments). Figure 7a shows the conspicuous difference between a texture pair that segregates based on the presence or absence of elements having crossing versus not-crossing line segments.

(a)



(b)



(c)

Fig. 6—Demonstration of how the heuristics given in text predict why (a) the differently appearing S- and 10- shaped elements in aggregates (b) and one S in 10's (c) are indistinguishable. (*Nature*, March 12, 1981[1])

If the elements have identical textons, including crossing (or not-crossing line segments) the texture pairs become preattentively indistinguishable. The positional relationship between the line segment textons is unnoticed by the preattentive system. The difference in gap size between the L-shaped elements in Fig. 7b yields a preattentively indistinguishable texture pair. Particularly interesting is the demonstration in Fig. 7c where T- versus L-shaped elements yield an indistinguishable texture pair. Although we have kept a small gap between the perpendicular line segments that make up the L's and T's, preattentive discrimination of texture pairs composed of these elements is impossible even when the gaps are not resolvable. Apparently, the difference of a single end-of-line terminator is not adequate to yield texture segregation. Finally, Fig. 7d depicts a preattentively indistinguishable texture pair, where, with scrutiny, it is obvious that the

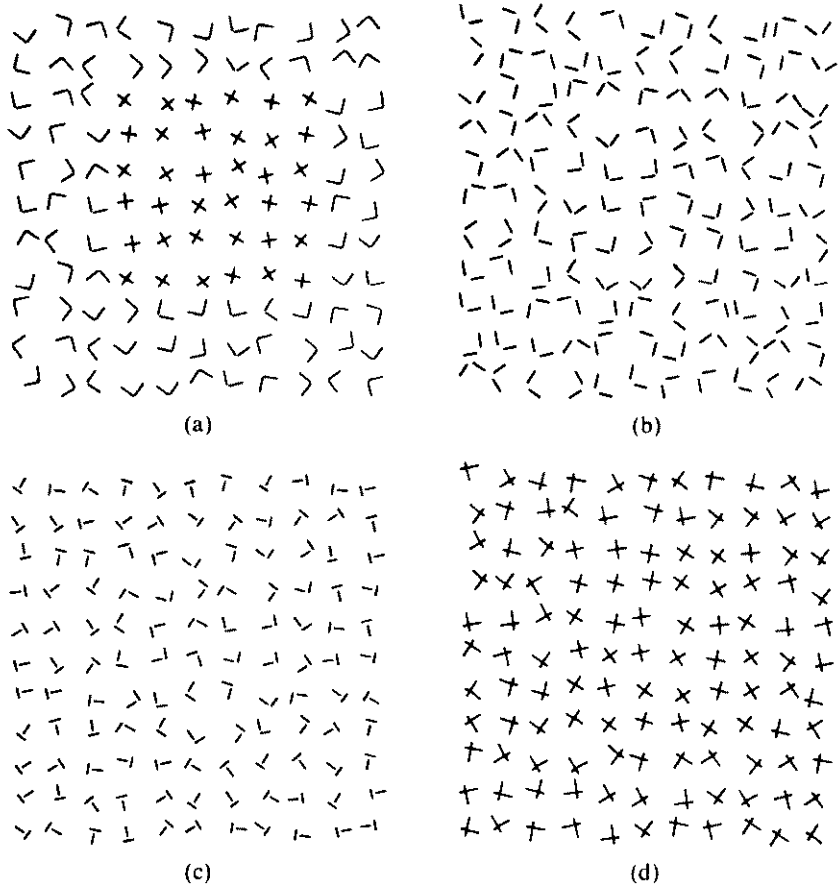


Fig. 7—Demonstration that crossing of line segments is a texton.

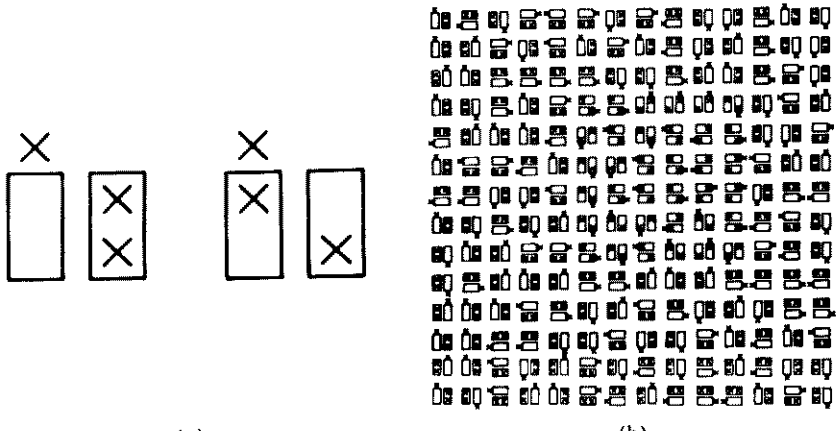
elements contain line segments that either cross at midpoint or cross far from the midpoint.

The last two examples are given in Figs. 8a and b and Figs. 9a, b, and c. From the element pairs containing the same textons, the reader can predict that although their elements in isolation appear very different, the resulting texture pairs will be indistinguishable.

In all these demonstrations the texture elements consisted of line segments. For line segments the definition of terminators (ends-of-lines) and their crossings are straightforward. For elongated bars with substantial width these definitions are less direct. Particularly difficult is the notion of terminators, because instead of terminators some combination of white elongated bars in a black surround with black elongated bars in white surround might suffice. So, we are not certain whether terminators are independent textons. Nevertheless, as a first approximation these three heuristics work remarkably well.

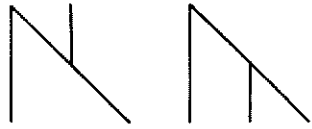
## III. PREATTENTIVE TEXTURE PERCEPTION IS ESSENTIALLY A LOCAL PROCESS

The essence of all the findings reported in the previous section can be summed up as follows: In texture perception the preattentive visual system utilizes only local conspicuous features, textons, and these textons are not coupled to each other (i.e., a vertical and horizontal line segment do not cohere to form an L or T). The preattentive system utilizes globally only the textons in the simplest possible way by counting their numbers (densities). This might surprise many of our readers who assume that texture perception utilizes complex global statistical interactions between textural elements.

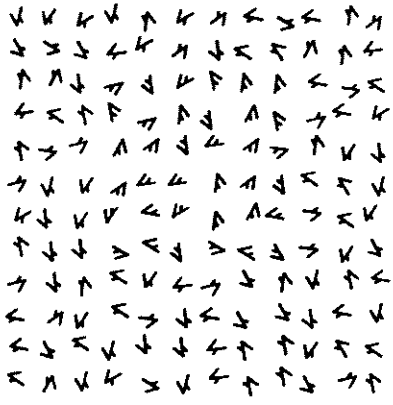


(a) (b)

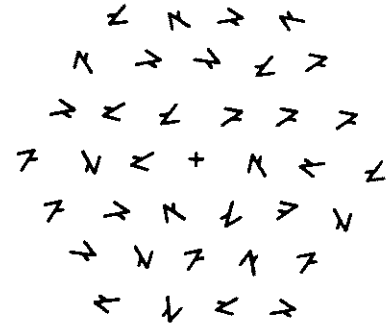
Fig. 8—Since the element pair in (a) is composed of the same textons, the texture pair (b) composed of these elements is preattentively indistinguishable. (*Philosophical Transactions*, 1980[25])



(a)



(b)

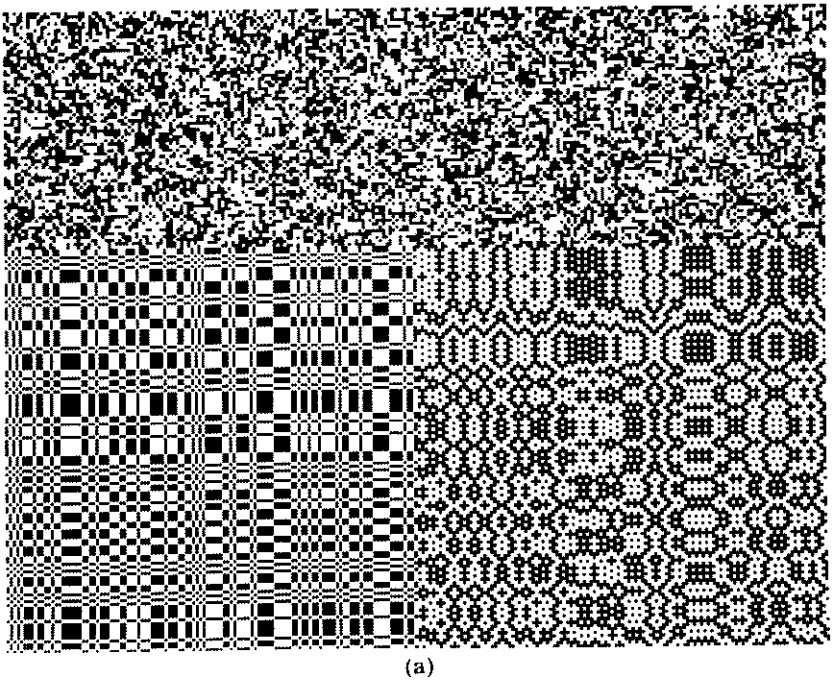


(c)

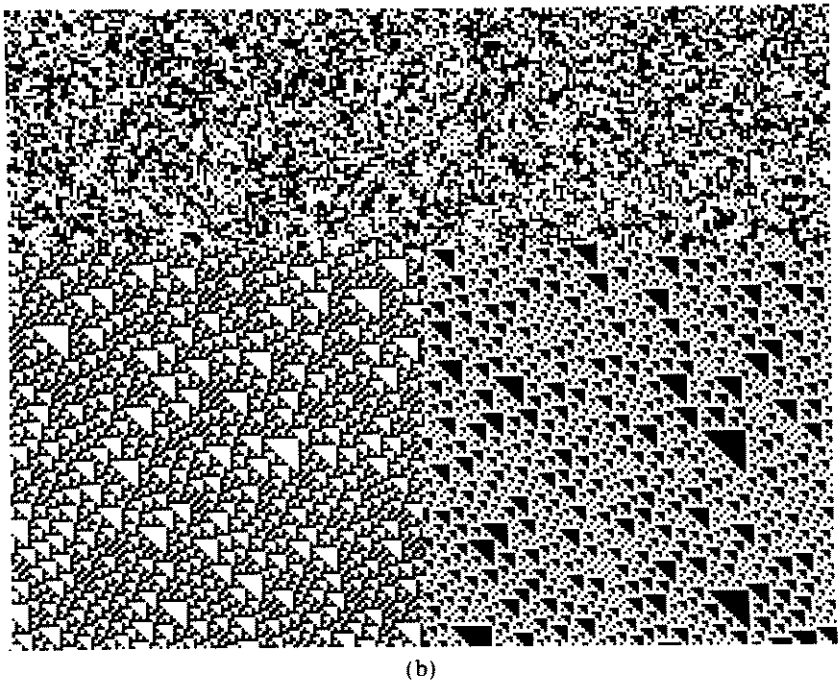
Fig. 9—Similar to Fig. 8, showing that aggregates of elements composed of the same textons cannot be preattentively discriminated. (*Philosophical Transactions*, 1980[25])

One of the simplest *global* computations routinely performed on images by engineers, and recently by psychologists in vision research, is to determine the images' Fourier power spectra. This process involves the decomposition of the images into one-dimensional sinusoidal luminance gratings whose specific amplitudes, spatial frequencies, phases, and angular orientations depend on the spatial characteristics of luminance distributions across the entire image. The amplitude of the spectral components ignoring phase determine the power spectra. When Fourier power spectra of textures are taken, it is a common misconception that differences in these will reveal differences in texture granularity. That the preattentive visual system does not perform Fourier analysis is demonstrated next.

Figure 10a consists of three areas that have identical Fourier power spectra (invented by Julesz, Gilbert and Victor[2]) and yet appear as very distinct textures. [The mathematically sophisticated reader might appreciate that the three areas have identical third-order statistics, and differ only in their fourth-order statistics. Those interested in the definition of *n*th-order statistics should consult Refs. 3 and 4 and the Appendix.] Figure 10b also consists of three areas with identical Fourier power spectra, and again these areas appear conspicuously different. Conversely, in Fig. 11a the lower left quadrant of the bottom



(a)



(b)

Fig. 10—Discriminable texture pairs with identical Fourier power spectra (*a* has even identical third-order statistics[1] based on local granularity (texton) differences. (*Biological Cybernetics*, 1981[2])

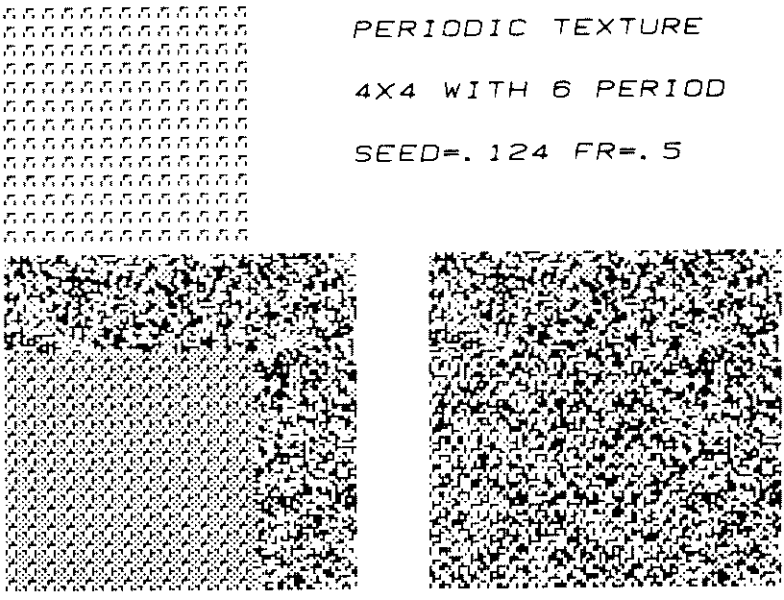
right array has a very different power spectrum from the remainder of the array, yet no preattentive texture discrimination results.[5] The derivation of this texture pair is presented in three steps. The top left array, in Fig. 11a, consists of 4x4 dot elements (8 black and 8 white) with 6-dot periodicity. The bottom left array contains this periodic array in one quadrant, but the 2-dot-wide gaps are filled by a checkerboard screen, while the rest is covered with uniformly random black and white dots. The bottom right array is similar to the bottom left array, except the 2-dot-wide gaps between the periodic patterns are now randomly speckled with dots. Obviously, the periodic patterns in the lower quadrant of the bottom right array in Fig. 11a yield a very different Fourier power spectrum from the rest, which has a flat (white noise) spectrum. The reason that this texture pair is indistinguishable can be easily understood in the light of the texton theory. The periodic patterns are not different from the surrounding random-dot array in the density of elongated blob textons, and therefore are indistinguishable. Indeed, if the 4x4 dot micropattern consists of vertical stripes, which contain textons different from the surrounding random-dot array, as shown in Fig. 11b, the periodic quadrant embedded in randomness is easily perceived.

In all these densely packed dot textures, discrimination is based on local granularity differences that correspond to differences in the density (number) of elongated blobs of certain sizes and orientations. Global statistical descriptors of textures, including the Fourier power spectrum, apparently are ignored in preattentive vision.

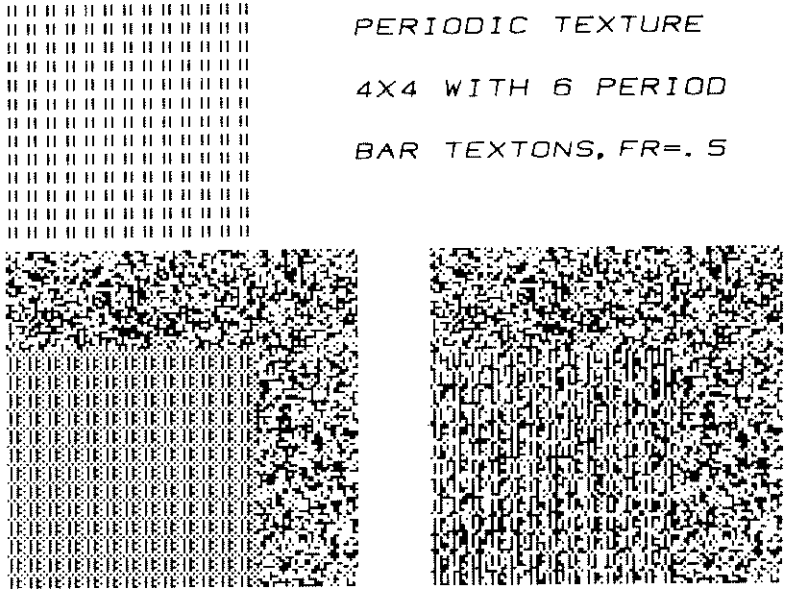
## IV. TEXTURES AND NEUROPHYSIOLOGICAL FEATURE ANALYZERS

We have seen how elongated blob textons are crucial in preattentive texture perception. These human psychological findings have a parallel in primate neurophysiology. Neural units have been found by Hubel and Wiesel[6] in the visual cortex of monkeys that fire optimally for elongated blobs of specific width, length, and orientation. These neural units in the cortex have *retinal receptive fields* consisting of elongated, blob-shaped, excitatory regions, which are surrounded by inhibitory regions. Some of these elongated blob detecting units—which fire optimally for black elongated blobs surrounded by white flanking areas—are called simple "off" detectors. Other neural units are excited optimally by white elongated blobs surrounded by black. These are called simple "on" detectors. The exact shape of the receptive fields of these simple neural units varies a great deal, and is of secondary importance. The important property of these cortical units is that the weighting of the excitatory and inhibitory areas of their receptive fields is about equal, so that for homogeneous stimuli they do not fire.

It should be stressed that the textons reported here were found by



(a)



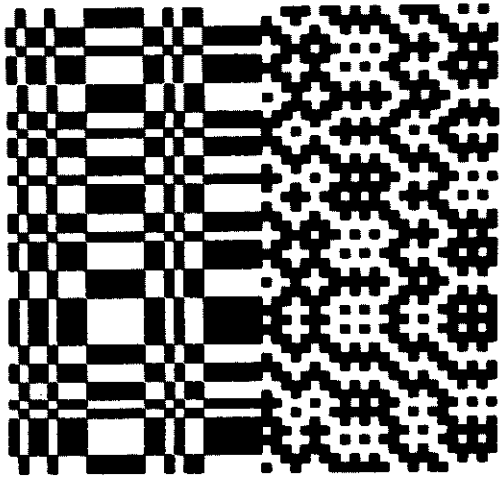
(b)

Fig. 11—Demonstration that the preattentive system cannot perform even such a simple global computation as Fourier power spectra, as described in text. (*Biological Cybernetics*, 1978[5])

psychological methods, and imply that simple neural units found as early as the striate cortex of the monkey might be used in texture perception. However, the relationship between a texton—for example, a perceived line segment—and a Hubel and Wiesel type of neural feature analyzer with a receptive field whose excitatory center matches the shape of the line segment is not a simple isomorphism. As we pointed out years ago (Ref. 7, p. 3), a single simple neural unit might respond equally for a broad line of high contrast or a narrow line of low contrast, while perceptually one can preattentively perceive both the width and contrast of a line segment. Thus, obviously a perceived line segment is encoded by many neural units of similar orientations but tuned to different widths, and having different firing thresholds. It is some combination of these units that would correspond to a perceived line segment. Until more is known about the relationship between perception and neurophysiology, the textons must be defined as perceptual entities, that is conspicuous local features as we actually perceive them. Nevertheless, even though textons and neural units are not simply related, one can easily conceptualize how a "perceptual analyzer" could be built from known neural analyzers that could extract, say, a line segment texton. The question of whether terminators and crossings of line segments—which have been regarded as textons—could be related to the complex and hypercomplex neural analyzers found by the neurophysiologists remains to be seen.[6]

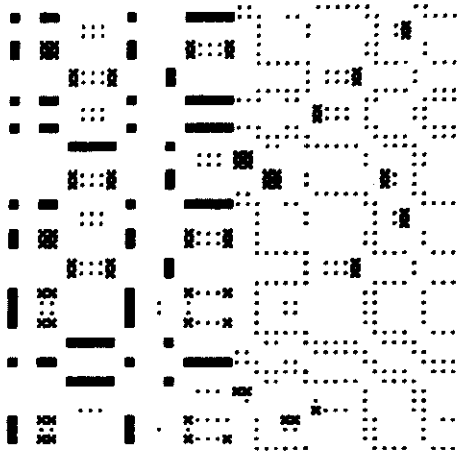
David Marr, in his primal-sketch model of machine vision, also incorporated such elongated blob detectors, by assuming that the neurophysiological findings had direct relevance to vision.[8] The work reported here followed an opposite trend. It took almost two decades to find evidence for the utilization of simple cortical units in texture perception. Caelli and Julesz found the first elongated blob textons that could account for texture discrimination locally, when all global statistical properties of the texture pairs were kept identical.[9] Later demonstrations such as Figs. 10a and b illustrate even more strikingly the importance of local blob textons.

To demonstrate the possible role of the Hubel and Wiesel type of neural units in preattentive texture perception, we developed a computer program called TEXTONS that filters any image with a pool of elongated bar-shaped receptive fields. Each pool of filters consists of "on" and "off" types having the same width, length, orientation, and firing threshold and placed at each point of the array. Figure 12 (bottom) shows the three largest response levels of a pool of 3x3 dot square-shaped receptive fields as this pool processes the texture pair of Fig. 10a, shown also in Fig. 12 (top). These filters have 2x2 dot excitatory centers flanked by one-dot-wide inhibitory margins, as shown in Fig. 12 (right). Of course, there are several pools consisting



(a)

(b)



(c)

Fig. 12—Automatic texture segregation, shown in (c), by applying a texton filter (b) to texture pair (a) (also shown in Fig. 10a).

of filters having receptive fields with some other dimensions and orientations that would be even more effective in segregating the two textures of Fig. 12 (top). Here we stress again that the combination of several filters would be required to yield the best texture segregation, corresponding to human texture discrimination. This combination of filters would correspond to a texton detector.

What our psychological findings show, however, could not have been

guessed by physiologists and theoreticians of artificial intelligence. In preattentive texture perception the various textons are not coupled, that is their relative positions are ignored. T- and L-shaped pairs of line segments cannot be discriminated preattentively in textures. Marr thought that elongated blobs and terminators would form some higher molar unit, which he called place tokens.[8] However, in preattentive vision no such higher interactions are found; the textons appear to be independent of each other.

## V. EXTENSION OF THE TEXTON THEORY TO RAPID PATTERN DISCRIMINATION

The success of the texton theory in predicting phenomena of texture perception is the result of the spatial complexity of the patterns. This complexity over a large area exceeds the capacity of focal attention and thus allows the preattentive system to dominate. This same deemphasis of focal attention can be achieved in simpler patterns by very brief presentation. We will show that under these conditions the same texton theory can be applied.[10]

Because brief temporal presentation is required, the stimuli used in these experiments can be produced only in the laboratory. Consequently, they cannot be demonstrated as the texture discrimination results have been. Thus, in this section we present the main findings as curves describing observers' performance.

The stimuli used in these experiments are shown in Fig. 13. In Fig. 13a there are 35 T's and one L arranged on a hexagonal grid with slight random positional jitter added. In Fig. 13b the T's have been replaced by + elements, and in Fig. 13c only two of the 36 possible positions actually contain an element. In all cases, a disk surrounding the central fixation marker is kept empty. Stimuli of this type are presented for 40 ms, followed by a blank interval of variable duration and a 40-ms erasing field. This erasing field consists of elements, which are the union of the two being discriminated, arranged in the same way as the test field. Use of this erasing technique allows restriction of the inspection interval to times shorter than the duration of the retinal afterimage. The times used are all too short to allow eye movements to be initiated during the presentation. In half of the presentations the test field consists of all identical elements, while in the other half one element is different, as in the examples shown. The task of the observer is to discriminate between these two conditions.

Results obtained using the three stimuli of Fig. 13 are shown in Fig. 14. On the abscissa is the time in milliseconds between the onsets of the test and erasing fields, or the stimulus onset asynchrony (SOA). On the ordinate is the percentage of correct discrimination. The results

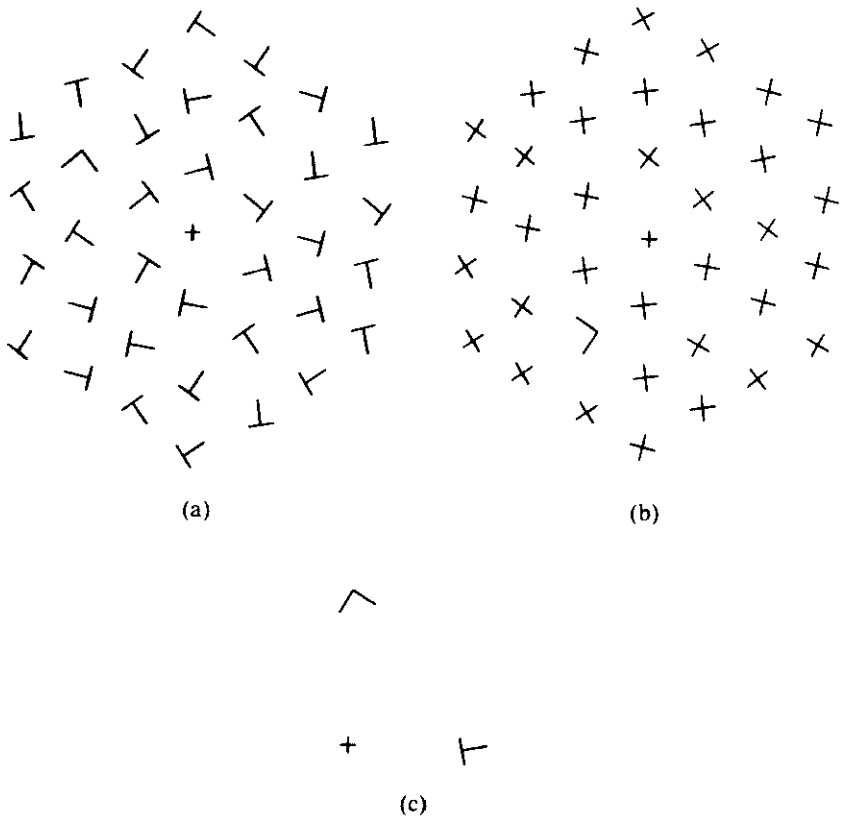


Fig. 13—The three types of stimuli used to obtain the results of Fig. 14. In all cases the task is to discriminate these from a control stimulus in which all elements are identical.

are very different for the case in which the elements share the same textons (T vs L. solid circles) from that in which they contain different textons (+ vs L, open circles). Note that in the T vs L case, not only does performance never exceed 65 percent correct, but it takes over 300 ms to reach this asymptote, while in the + vs L case the asymptote is reached within 200 ms. In fact, by the time the asymptote in the T vs L case is reached, the afterimage resulting from the test flash has largely disappeared. In the case in which only one T and one L are presented (filled squares), the results closely resemble those for 35 +'s and one L. Perceptually, the difference between the same-textons and different-textons cases is simply that the L in the field of T's stands out almost as if presented alone on a blank field, while the same L in a field of T's must be sought out. Attention is rapidly shifted to the L in the former case, while in the latter the search process is apparently still going on after 300 ms have passed. When there are only two elements to choose from, this search time is very brief.

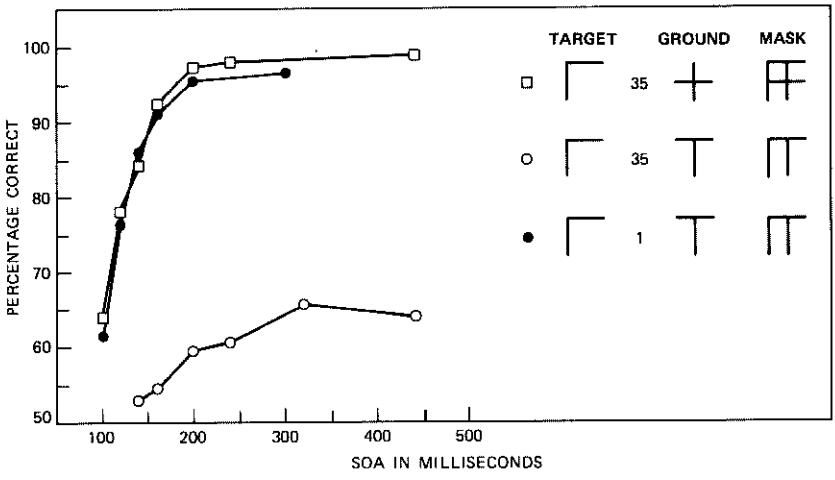

Fig. 14—Results of discrimination experiments using Fig. 13. The open circles, filled circles, and squares correspond to stimuli of Fig. 13a,c,b, respectively. SOA is the abscissa, and percent correct discrimination is the ordinate.

It is interesting to note that the observed asymptotic level of about 65 percent correct is what would be expected if seven or eight of the possible positions could be searched in the time available. Combining this number with the afterimage persistence time of 300–400 ms[11,12] gives a figure of about 50 ms per position inspected.[10]

This process of sequential inspection seems to be essentially independent of the overall angular subtense of the stimulus. Figure 15 shows results from an experiment in which the observer is required to distinguish a stimulus consisting of six T's and one L, or vice versa, from one in which all elements are identical. The stimulus was uniformly contracted so as to fall entirely within the fovea (<3 degrees across), or dilated to extend almost 14 degrees across, with no systematic variation in performance.

Another way of describing this is to say that the measurements are independent of the distance from which the stimulus is viewed, assuming that all of the elements remain resolvable: This independence suggests two important points. First, the fovea is not better than the near periphery in the extraction of this type of visual information. Second, the aperture of attention changes its spatial scale according to the size of the feature being sought. Thus, the same number of sequential fixations of attention are needed when the stimulus is reduced in size uniformly, because the sizes of the features upon which the discrimination is based are proportionally reduced. This extension of the scope of the texton theory from texture perception to rapid pattern discrimination suggests a model of vision in general as described in the following section.

## VI. A MODEL OF THE "TWO VISUAL SYSTEMS"

When a visual scene changes suddenly in time or space, and our attention encompasses the entire visual scene, only those areas in which density differences in textons occur are conspicuous. These textons are elongated blobs with specific colors, widths, lengths, orientations, terminators, and crossings between them. Furthermore, because binocular disparity, movement disparity, and flicker are locally conspicuous features that can be detected in a brief presentation,[7,11,13] they, like color, are also properties of elongated blob textons.

Focal attention is directed to areas of spatial or temporal texton changes. The preattentive process appears to work in parallel and extends over a wide area of the visual field, while scrutiny by local or foveal attention is a serial process, which at any given time is restricted to a small patch. Focal attention can be shifted in 50-ms steps, four times faster than the fastest scanning eye movements. Furthermore, the aperture of focal attention can vary in size and can be a minute portion of the fovea, that is, extending to only a few minutes of arc (as shown in Fig. 15). Therefore, if the visual environment is rich in detail even when slowly changing in time, or is rather lacking in spatial detail but changes rapidly, we perform the major portion of our spatio-temporal processing in the preattentive state.

The focus of visual attention seems to be characterized by a texton class as well as a spatial locus. In particular, just as it apparently is impossible to attend simultaneously to two different places, it also seems impossible simultaneously to attend to very different sizes of features. This fact has been noted previously by other psychologists.[14] Stimuli widely separated in space produce cortical responses which are far apart. Similarly, stimuli of differing sizes often generate re-

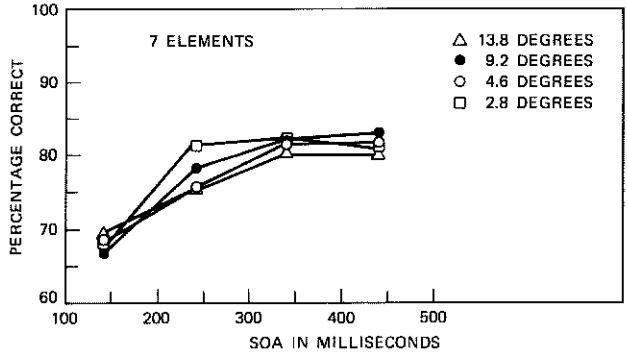

Fig. 15—Size invariance while the angular subtense of seven elements is varied from 2.8 degree of arc diameter to 13.8 degree of arc. Findings imply that the aperture of focal attention can be as small as a few minutes of arc.

sponses in different cortical areas.[6,15] These results seem to imply that the focus of attention is restricted to a very small region of visual cortex, and that stimuli producing responses far apart in the cortex cannot be attended simultaneously.

The essence of our findings is illustrated in Fig. 16. The left array contains a texture composed of "L"-shaped elements (formed by two perpendicular line segments with a gap), except for one "+" shaped and one "T" shaped element (formed by two perpendicular line segments which cross, or have a gap, respectively). The "+" shaped element (target) differs from the many surrounding L's in one texton, namely the "crossing", and perceptually stands out immediately. On the other hand, the T-shaped target can be detected only after some search, by directing the aperture of attention to the target itself.

The right array of Fig. 16 is identical to the left but illustrates our model of vision. The parallel preattentive system instantly detects the location of texton differences and directs the aperture of focal attention to this location, as indicated by the dotted disk around the "+". Since the T contains the same textons as its surround, its detection requires the aperture of attention (symbolized as a "cone" of a searchlight) to scrutinize the texture elements in sequence. Therefore, this

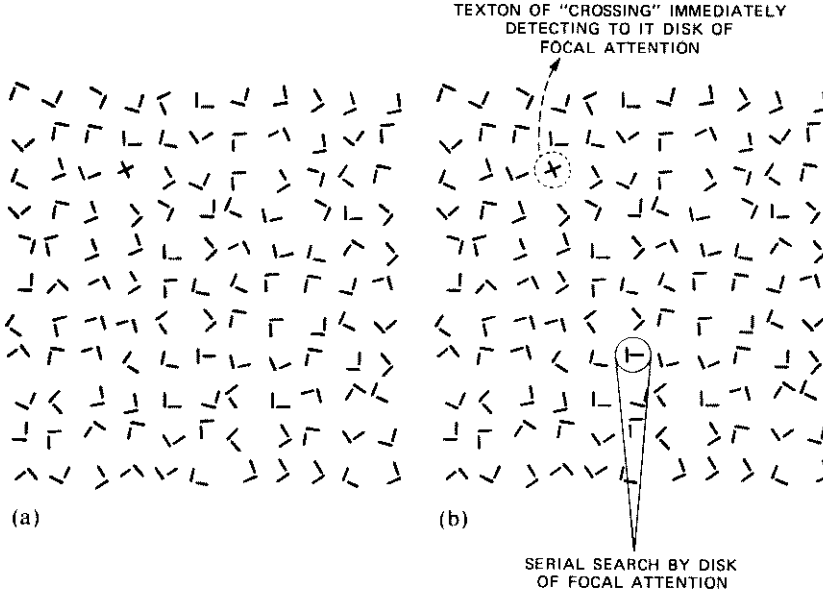

Fig. 16—Model of the two visual systems (b), showing how the preattentive system directs the aperture of focal attention to the loci of texton differences [the + in the L's in (a)], while without such texton differences [the T in the L's in (a)] focal attention requires time-consuming search.

serial search for the T-shaped target depends on the number of texture elements and may take considerable effort and time. However, after the T has been found, and the aperture of focal attention surrounds it, both the + and the T targets are seen with the same clarity. Obviously, form recognition, restricted to the aperture of focal attention, does not depend on the way attention has been directed to the targets. Whether a local difference in textons quickly directed focal attention to the target, or in the absence of texton differences it required time-consuming search to find the target, is immaterial for processing of the target by the attentive visual system.

This mode of behavior of the preattentive and attentive visual systems can also be observed in texture perception, when the reader inspects Fig. 1. The preattentive system immediately detects the texton differences at the boundary of the + and L aggregates, and a quick inspection by focal attention of a few elements on the two sides of the boundary lets the observer conclude that the two areas must contain +'s and L's. Only detailed scrutiny will reveal that the area believed to contain L's only has a region of T's as well.

In summary, the reason that texture discrimination is such a revealing process for showing the workings of the two visual systems is that textures usually cover wide areas of the visual field, while the texture elements are a small portion of the textural area. When the observer is inspecting an extended field, there is an "uncertainty region" in which the relative spatial position of local features is ignored. This is very different from a resolution limit due to visual acuity. In all of the indistinguishable texture pairs, the line segments which make up the texture elements are clearly resolved; nevertheless, if these textons fall within this uncertainty region, it is impossible to tell a T from an L. Many physiologists and psychologists have proposed two visual systems, one ambient and the other focal.[11-20] Yet, without the notion of textons, whose spatial and temporal changes are detected by the preattentive system, which in turn directs focal attention to these loci, the model of the two visual systems is not complete. We hope that the model outlined here gives some useful insights into human vision.

## VII. IMPLICATIONS AND CONCLUSIONS

Some conspicuous local features called textons have been identified by psychological means. These textons, particularly the elongated blobs, are quite similar to features found to stimulate the simple neural units in the striate cortex of the monkey, which are selectively tuned to elongated blobs of certain colors, orientations, width, and length.

Our findings, that in preattentive vision objects are distinguished only through their texton decompositions, might be of considerable

importance. Since in preattentive vision these textons are not coupled, and furthermore the resolution of texton properties—i.e., the perceptual threshold for color, width, length, and orientation differences—is rather limited, the number of distinguishable textons is within practically useful bounds. (For example, the width of periodic bars can be judged with an error of 4 to 6 percent,[21] while accuracy of bar orientation is measured to be only 6 degrees of arc.[22]) This limitation makes practical the devices that simulate preattentive vision. This contrasts with attentive vision for which virtually an infinite number of recognizable patterns exist whose biological, social, or intellectual interest to the observer is unknown. Whether additional textons will be discovered remains to be seen. But as long as they remain independent of the previously isolated textons, the model outlined here will not be importantly affected.

The main implication of our findings is as follows: A considerable amount of vision is carried out by the preattentive system whose workings appear to be much simpler than that of the attentive system. This is important in judging the information requirements of the human visual system realistically. Furthermore, it is important to realize that even in the attentive mental state, with all its prodigious processing powers, complex feats of form recognition are restricted to a small spatial aperture, often as small as a few minutes of arc. Also, changing the position or extent of the aperture of focal attention requires considerable time. The shortest time is about 50 ms when eye movements are prevented, and as long as about 200 ms if saccadic eye movements are necessary.

This dichotomy between preattentive and attentive mental states, the first limited in its power of information processing, the latter limited in its spatial extent, gives a model of human vision that could be exploited in visual communication. Here we do not want to invent specific methods, but only indicate some obvious possibilities. With the advent of fast, perhaps parallel computers, the textons that direct the human observer's attention could be simultaneously extracted by hardware. Detailed images need only be presented in such areas.

Also, one could program computers to extract local features other than textons. For instance, a parallel computer might rapidly detect the difference between an L and a T, rather than between a + and an L. If an observer's attention were directed by such a machine, whose capabilities are very different from human preattentive vision, perhaps a new way of inspecting the visual environment could be made available and possibly learned.

The textons reported here help to discriminate textures, mainly surfaces of objects, without the need of complex familiarity cues. Such an early separation of the visual environment into figure and ground,

or objects and their backgrounds, is a fundamental operation of visual perception. Lack of understanding of this process is, as of now, the greatest bottleneck in machine vision, which in turn is necessary in extending the capabilities of robots.

Regardless of the feasibility of such ambitious schemes, the finding that texton differences can be almost instantaneously perceived over large areas of the visual field can be practically exploited in traffic signs and in directing attention to select areas of visual displays. Traditionally, flickering or static colored lights have been used as traffic signs, or in instrument panels. Now we can add other texton classes—for instance, gaps to increase the terminator number—to enhance visibility. For example, in Fig. 17 we show how a single gap introduced in the conventional alphabet draws attention to the word STOP, which otherwise would require a long time to be segmented and detected. Such slight modification of the alphanumeric characters (amounting to a new "font") might be beneficial in improving legibility. For instance, dyslexic children—children who cannot distinguish well between similar characters with different symmetric transformations such as b, d, or p—might greatly benefit if a gap or stroke were added to one of the characters, so that all characters would differ in at least one texton.

It should be stressed that the textons of preattentive vision only draw attention to certain areas, and we do not claim that these same textons are also the building blocks of form vision. If they were, our findings would prove preattentive vision to be the basis of attentive vision. Even if textons are restricted to vision in the preattentive state, we feel that to know those conspicuous features that grab our attention, wherever they appear, is of interest to everyone who wants to communicate through visual means.

## VIII. ACKNOWLEDGMENTS

We thank our many colleagues who contributed to this research effort throughout the years, and who are mentioned in Section II and in the references. We also thank Max V. Mathews for his helpful comments while reading the manuscript. We are indebted to Walter

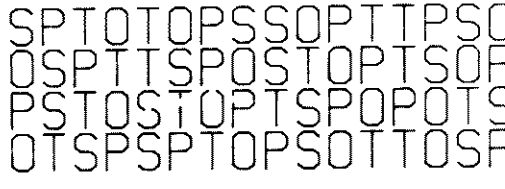

Fig. 17—Demonstration that the introduction of textons into the alphabet (here through increasing the terminator numbers by adding a gap) can help to segment and detect certain areas in a dense letter array.

Kropfl who developed the display hardware, and to Peter Burt who wrote the GENTEX program permitting the rapid generation, display, and manipulation of texture arrays. We thank our summer student, Franklin Schmidt, for developing the TEXTONS program.

## APPENDIX

It required two decades of research efforts to discover that preattentive texture perception depends on local features alone and that global higher-order statistical parameters can be ignored. In 1962, Julesz asked mathematicians to generate stochastic texture pairs that would be identical in their first ($n$-1)th order statistics, but different in the $n$th- and higher than $n$th-order statistics.[20] The $n$th-order statistics are similar to the well-known $n$th-order joint probability distribution of $n$ samples. The $n$ samples are $n$ points of a texture selected at random. However, in random geometry the shape of the $n$ samples is of importance.

These $n$ points can be regarded as the vertices of an $n$-gon. The $n$-gon (or $n$th-order) statistics are obtained when these $n$ points (having the same $n$-gon shape) are selected at random, and statistics indicate that these $n$ points have certain color values. For instance, the second-order statistics can be obtained if a 2-gon (dipole, or needle) is randomly thrown at the texture and the probability is determined that the two end-points of the dipole—of given lengths and orientations—fall on certain color combinations: e.g., black and black; or black and white; or black and gray, etc.

In the intervening years many such stochastic textures were discovered, particularly with identical first- and second-order statistics, but different third- and higher-order statistics.[3,23–25] As a matter of fact, the texture pairs in Figs. 3–6, and 8–10 have this property. The finding that many of these *iso-second-order* texture pairs differing only in third- and higher-orders are indistinguishable suggests that the preattentive visual system cannot compute statistical difference beyond the second order. The recent finding by Julesz, demonstrated in Fig. 11a, suggests that the preattentive visual system cannot even process second-order statistical parameters.[4] From the second-order statistics the autocorrelation function can be uniquely determined—as a matter of fact, for two-tone textures composed of black and white dots, the second-order (dipole) statistic *is* the autocorrelation function[26,27]—and the Fourier transform of the autocorrelation is the Fourier power spectrum.[28] Therefore, all the texture pairs with identical second-order statistics also have identical power spectra. The finding that texture segregation can be obtained in iso-second-order textures, after it was established that the preattentive system cannot process third-order statistics (and, as Fig. 11a demonstrates, not even second-order statis-

tics), implies that this segregation must be based on *local* density differences. Finally, it was proposed that the density changes of certain local conspicuous features, the textons, explain preattentive texture discrimination.[1,25]

# Central Control of Movement Timing

By D. A. ROSENBAUM*

(Manuscript received October 14, 1981)

How do people control the delay between successive finger movements? A reaction-time experiment suggests that the delay is controlled by setting an internal "alarm clock."

## I. INTRODUCTION

A fundamental concern of behavioral science is to understand how we control the movements of our bodies. This paper examines the timing of body movements: As we walk, talk, or type, how are the delays between the phases of these various activities controlled?

A popular means of approaching this question has been to consider two extreme views of how movements might be timed. One view holds that delays between the phases of a movement sequence are controlled by using feedback from each phase to trigger the next. Since the feedback can arise from receptors in the peripheral nervous system—within the muscles, joints, and skin—this view is often referred to as the "peripheralist" theory.[1] The other view holds that movement timing is controlled by plans or "programs" that allow sequences to be performed without the aid of feedback. This view is often called the "centralist" theory.[2]

Two main arguments have been leveled against the peripheralist position. One argument is that times between successive movements may often be shorter than the time needed for feedback from one movement to be used to trigger the next.[3] The other argument is that animals and people in whom peripheral feedback is physiologically disrupted can often perform movements effectively.[4,5] Both of these observations indicate than when feedback cannot be relied on, central programs may be used. What the observations do not resolve, however, is whether central programs are also used when feedback is available. The experiment reported here was meant to answer this question. The experiment was also meant to provide detailed information about the nature of the programming of movement sequences when it appears that programming is used.

## II. THE EXPERIMENT

The experiment, which has been reported in detail elsewhere,[6,7] used a simple procedure (see Fig. 1). The subject's task was to perform a sequence of two responses, made with the left and right index fingers, in such a way that the produced interresponse interval approximated a target interval. Feedback given at the end of each trial indicated whether the produced interval was longer or shorter than the target interval and by how much. In addition to producing the specified

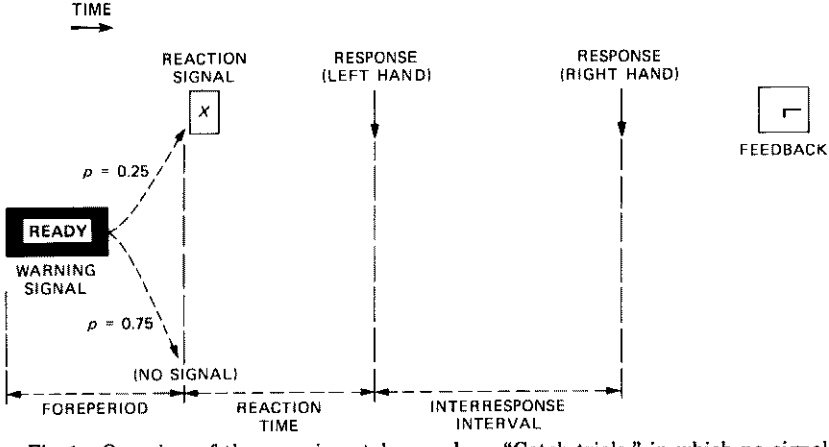

Fig. 1—Overview of the experimental procedure. "Catch trials," in which no signal was presented and no response was allowed, were used to discourage anticipation responses. The warning, reaction, and feedback signals were displayed on a CRT screen. The feedback signal consisted of a vertical line that pointed up if the produced interval was too long and down if the produced interval was too short, where the length of the line indicated the size of the proportional error; the length of a horizontal line indicated how much the Reaction Time (RT) exceeded a target of 130 ms. The foreperiod was fixed at 0.5 second, the reaction signal remained on the screen until the last required response was made, and the feedback signal came on 0.5 second after the offset of the reaction signal and remained on the screen for 2.5 seconds.

interresponse interval, the subject was also required to make the first response as quickly as possible after the onset of a visual reaction signal.

The rationale for the experiment can be understood by noting that several investigators have found that RTs are longer for the first of two responses, performed approximately simultaneously, than for single finger responses.[8–14] If it is assumed that the lengthening of RTs for response doublets results from the demands associated with coordinating two responses, the question that arises is how long the delay between two responses must be before the RT for the first response is as short as the RT for a single, isolated response. According to the peripheralist theory, one would expect the RT for the first of two responses to equal the RT for a single, isolated response whenever the delay between the two responses equals or exceeds the time required to use peripheral feedback from the first response to trigger the second response. Thus, if it takes 200 ms to use peripheral feedback from one response to trigger the next, the peripheralist theory would predict that, whenever the delay between the two responses is greater than or equal to 200 ms, the RT to initiate the two responses in series should be no longer than the RT to initiate the first response alone. By contrast, according to the centralist theory, the RT to initiate the two responses in series should be longer than the RT to initiate the first response alone, even if the delay between the two responses exceeds the feedback loop time; for according to the centralist theory the availability of peripheral feedback does not suffice to control the onset of the second response relative to the first.

Figure 2 shows the results from the main experiment designed to test these predictions. In this experiment, the target interresponse intervals ranged (in a blocked design) from 0 to 1050 ms. In the control condition no second (right-hand) response was required, so the target interval was effectively infinite ($\infty$). The data are averaged over three adult female subjects. In the "stringent" condition, the length of the vertical feedback line was directly proportional to the deviation of the produced interval from the target (nonzero, finite) interval such that the line reached the edge of the CRT screen for deviations exceeding 100 percent of the target interval. In the "relaxed" condition, the scale factor relating the size of the deviation to the length of the vertical feedback line was reduced by a factor of 25 so that generally subjects could only see whether their produced interresponse intervals were too long or too short. About 1300 observations contribute to each point in Fig. 2.

Inspection of Fig. 2a reveals that none of the two-response sequences had mean RTs less than or equal to the mean RT in the control condition, as was confirmed statistically. Since the larger interre-

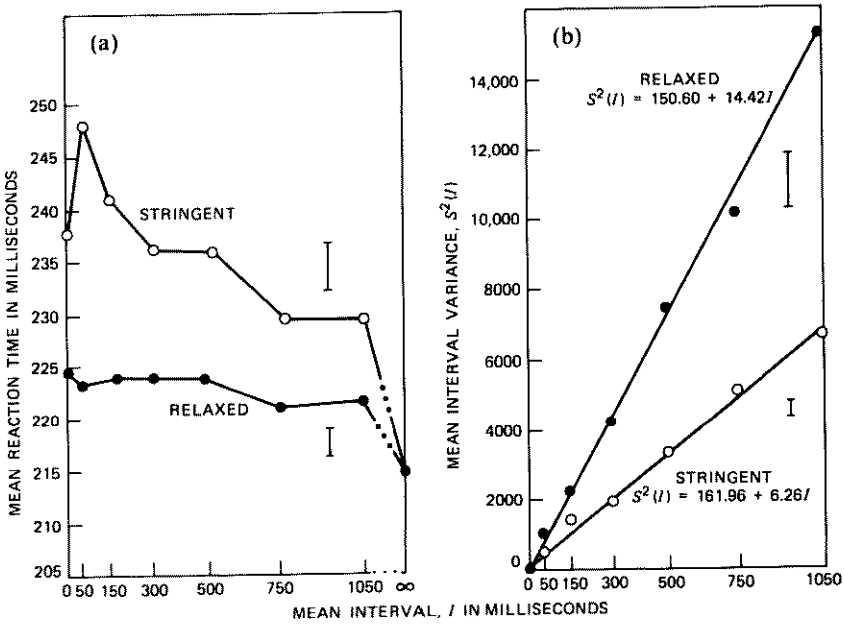

Fig. 2—Results of the experiment. (a) Mean reaction times and estimates of standard error (±SE) for the two accuracy conditions. (b) Mean variances of produced interresponse intervals, fitted linear functions, and estimates of ±SE. The zero intercepts of the fitted linear functions for the two accuracy conditions were not significantly different from one another. (Estimates of ±SE are based on mean squares from fits of mean functions to individual subject data.)

sponse intervals were certainly large enough to allow for the use of peripheral feedback,[15] this result is consistent with the centralist prediction and inconsistent with the peripheralist prediction.

Given that control of the interresponse interval was apparently not based solely on peripheral feedback, what was the nature of the central activity that allowed for control of the intervals? A plausible hypothesis is that the interresponse intervals were controlled by a kind of hydraulic system in which the amount of energy made available to the second response increased as the time until its occurrence decreased. If the total energy available to the two responses was fixed, then the amount of energy available to the first response would decrease as the desired interresponse interval decreased, leading to an inverse relationship between RTs and interresponse intervals. This is a response competition model. (For a more general discussion of response competition, see Ref. 16.)

An alternative hypothesis is that the interresponse interval was controlled by a central clock that was set just before the production of the first response (i.e., during the RT). If the time needed to set the clock depended on the precision of setting, which in turn was reflected

in the variability of the interresponse interval, this alarm clock model predicts that RTs could depend on interval variability rather than interval size.

To test these predictions, we manipulated the analog feedback that subjects received concerning the accuracy of their interresponse intervals. Recall that the analog feedback took the form of a vertical line that pointed up if the produced interval was larger than the target interval and down if the produced interval was smaller than the target interval. By changing the scale factor relating the length of the line to the proportional difference between the produced and target interresponse interval, we could impose stringent or relaxed accuracy requirements on the subject's timing performance. When the scale factor was small, a large error resulted in a small error line ("relaxed" condition), but when the scale factor was large, even a small error resulted in a large error line ("stringent" condition). The relaxed-stringent manipulation was a within-subject variable, which we introduced to get subjects to alter the variability of their interresponse intervals while keeping the means of the intervals constant.

As is seen in Fig. 2a, mean RTs in the relaxed condition were essentially constant over the range of finite intervals. However, mean RTs in the stringent condition were longer than in the relaxed condition and decreased as intervals increased for targets 50 ms or greater. [The discontinuity in the stringent mean RT function at the 0-ms target confirmed subjects' reports that control of the intervals in this condition was qualitatively different from the other conditions (e.g., because the fingers and wrists were kept stiff when simultaneous responses were attempted). Sequences begun with the right hand, which were only permitted in the 0-ms condition, did not have shorter RTs than sequences begun with the left hand.] Thus, Fig. 2a shows that mean RTs were not simply related to mean intervals, contrary to the prediction of the response competition hypothesis. Instead, mean RTs were related to the required precision of the intervals, consistent with the alarm clock model.

The question that now arises is whether the actual precision of the intervals was affected by the differential precision requirements imposed by the stringent-relaxed manipulation. If the actual precision was affected, such that greater precision was achieved in the stringent condition, the evidence would be stronger for the hypothesis that during the RT an internal alarm clock was set to varying degrees of precision. In Fig. 2b variances of produced intervals are plotted against their corresponding means. As is seen in the figure, variances were larger in the relaxed condition than in the stringent condition. That the interval means were approximately equal in the two conditions is demonstrated by the approximately vertical alignment of the filled

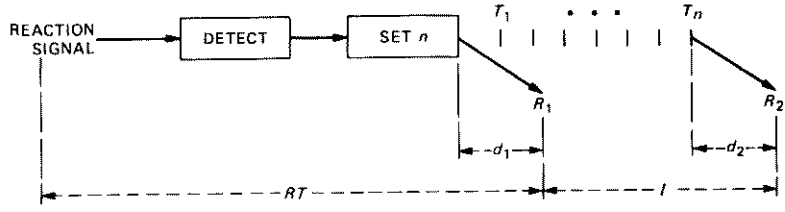

Fig. 3—Overview of an alarm-clock model for performance in the experiment.

and empty points corresponding to each target interval. As is also seen in Fig. 2b, the mean interval variances were well fit by linear functions. Linear regression accounted for 99.7 percent and 99.9 percent of the variance among the mean variances (averaged over subjects) in the stringent and relaxed conditions, respectively. The linearity of the variance functions allows for a simple elaboration of the alarm clock model, which is discussed below.

## III. AN ALARM CLOCK MODEL*

The elaborated alarm clock model is shown in Fig. 3. It says that the size of the delay between the first and second response ($R_1$ and $R_2$, respectively) depends on the number, $n$, of pulses of an internal clock, where the value of $n$ is set during the RT interval. The model assumes that the interval, $I$, between $R_1$ and $R_2$ equals the sum of the times, $T_1, T_2, \cdots, T_n$ for the $n$ clock pulses, plus the difference between the motor delays, $d_1$ and $d_2$, of $R_1$ and $R_2$, respectively. That is,

$$I = T_1 + \cdots + T_n + d_2 - d_1. \tag{1}$$

It is also assumed that the times for the successive clock pulses fluctuate randomly about a mean and are stochastically independent. Hence, as $n$ increases, the variance of the cumulative pulse time increases linearly.[17,18]

The model affords two plausible ways of explaining the difference in slopes for the fitted variance functions in the stringent and relaxed conditions. One possibility is that the variability of interpulse times was greater in the relaxed condition than in the stringent condition. The other possibility, which will be pursued here because of its interesting ramifications for the proposed clock-setting process, is that the variance of $n$ was greater in the relaxed condition than in the stringent condition. It is possible to express precisely how the variance of $n$ in the relaxed condition would be related to the variance of $n$ in the stringent condition, given that the slopes (but not the zero intercepts) of the variance functions differed in the two conditions. Let the

* This is a greatly simplified version of a model presented in Ref. 6.

random variable $N$ be the number of clock pulses between the triggering of response 1 and 2. Let the time between pulses $i-1$ and $i$, for $1 \leq i \leq n$, be a random variable $T$, where the random variables $T_i$ are independent of $N$ and identically distributed as a random variable $T$ with finite mean and variance. Allowing the random variable $D$ to represent the difference $d_2 - d_1$, and assuming $T$, $N$, and $D$ are mutually independent, it is possible to use the expression for the variance of a random sum[19] to obtain

$$\mathrm{Var}(I) = E(N)\mathrm{Var}(T) + \mathrm{Var}(N)E^2(T) + \mathrm{Var}(D). \tag{2}$$

Assuming that the only terms in (2) that differ in the relaxed and stringent conditions are $\mathrm{Var}(I)$ and $\mathrm{Var}(N)$, and using subscripts R and S for the relaxed and stringent conditions, respectively, we can subtract $\mathrm{Var}_S(I)$ from $\mathrm{Var}_R(I)$ and rearrange terms to obtain

$$\mathrm{Var}_R(N) - \mathrm{Var}_S(N) = [E^2(T)]^{-1} \cdot [\mathrm{Var}_R(I) - \mathrm{Var}_S(I)]. \tag{3}$$

Since $\mathrm{Var}_R(I)$ and $\mathrm{Var}_S(I)$ were found to be linear functions of $I$ with what are assumed to be identical zero intercepts, and since $E^2(T)$ is assumed to be a constant, eq. (3) becomes

$$\mathrm{Var}_R(N) - \mathrm{Var}_S(N) = kI, \tag{4}$$

where $k$ is a constant greater than 0. Equation (4) shows that $\mathrm{Var}_R(N)$ and $\mathrm{Var}_S(N)$ are related in a simple way. As is seen below, however, the relationship can be shown to be even simpler.

Consider how the variance of $N$ changes with $I$ within the stringent or relaxed condition. Relying on the fact that we found $\mathrm{Var}(I)$ and $I$ to be linearly related, and noting that

$$E(N) = [E(I) - E(D)]/E(T), \tag{5}$$

eq. (2) can be rewritten to solve for $\mathrm{Var}(N)$ as

$$\mathrm{Var}(N) = \frac{\alpha + \beta \cdot E(I) - \mathrm{Var}(D) - \left[\dfrac{E(I) - E(D)}{E(T)}\right] \mathrm{Var}(T)}{E^2(T)}. \tag{6}$$

All the terms in eq. (6) are constant except for $\mathrm{Var}(N)$ and $E(I)$. Therefore, eq. (6) can be rewritten

$$\mathrm{Var}(N) = u + vE(I), \tag{7}$$

where $u$ and $v$ are constants. Since the clock presumably would not be used (i.e., $N$ would not be set) when $E(I) = 0$, $u$ can be set to 0, leaving

$$\mathrm{Var}(N) = vE(I). \tag{8}$$

On the basis of the simple relation shown in eq. (8), we can indicate how $\mathrm{Var}(N)$ in the stringent condition, $\mathrm{Var}_S(N)$, is simply related to

$\mathrm{Var}(N)$ in the relaxed condition, $\mathrm{Var}_R(N)$. Let $\mathrm{Var}_R(N) = rE(I)$. As we saw in eq. (4), $\mathrm{Var}_R(N) - \mathrm{Var}_S(N) = kE(I)$. It follows, then, that $\mathrm{Var}_S(N) = (r - k)E(I)$. Thus, $\mathrm{Var}_R(N)$ and $\mathrm{Var}_S(N)$ differ with respect to the size of the proportionality constant relating each of these quantities to $E(I)$.

To summarize, the above discussion reveals that the variance of $N$ is proportional to $E(I)$, and that the slope of this function differs in the relaxed and stringent conditions.

The simplicity of these theoretical results allows for the proposal and test of a simple model of the process that may have given rise to the mean RT effects shown in Fig. 2a. The model is suggested by the observation that shorter RTs were associated with larger (predicted) values of $\mathrm{Var}(N)$. Essentially, the model says that the time to set $N$ increases as the range of possible values of $N$ decreases. (A possible reason will be given in Section IV of this paper.) Let $\theta$ denote the time to set $N$ and recall that the range of a distribution is proportional to the standard deviation of that distribution. The model says

$$\theta = \frac{\gamma}{\sqrt{\mathrm{Var}(N)}} = \frac{\gamma}{\sqrt{\delta E(I)}} = c[E(I)]^{-1/2}, \tag{9}$$

where $c = \gamma/\sqrt{\delta}$ is an empirical constant and $0 < E(I) < \infty$. From the previous observation that the proportionality constant relating $\mathrm{Var}(N)$ to $E(I)$ distinguishes the relaxed and stringent conditions, it follows that only the size of $c$ in eq. (9) needs to differ in the relaxed and stringent conditions. Moreover, as is implied in Fig. 3, the RT is assumed to equal $\theta$ plus the time to detect the reaction signal and execute the first response. Hence, the model predicts that the RT in the relaxed and stringent conditions can be expressed as

$$\mathrm{RT}_R = k + \theta_R$$

and

$$\mathrm{RT}_S = k + \theta_S, \tag{10}$$

respectively, or

$$\mathrm{RT}_R = k + r[E(I)]^{-1/2}$$

and

$$\mathrm{RT}_S = k + s[E(I)]^{-1/2}, \tag{11}$$

respectively, where $k$, $r$, and $s$ are empirical constants. Equation (11) has the appealing property that RTs increase with decreases in $E(I)$ at a rate related to the size of the linear coefficient. Thus, changing the linear coefficient in eq. (11) produces a set of curves two of whose members look like the pair of curves seen in Fig. 2a.

For purposes of finding out how well eq. (11) actually fit the RT data, an iterative procedure was used to find the values of $k$, $r$, and $s$ for which it was possible to minimize the sum of squared deviations of the obtained RTs from the predicted RTs. The obtained RT values used were the mean RTs in the conditions where nonzero finite interresponse intervals were required. The best-fitting values of $r$ and $s$ turned out to be 25 and 236, respectively, and the best-fitting value of $k$ turned out to be 221 ms. With these estimates the fitted model accounted for 94.6 percent of the variance of mean obtained RTs. (When $k$ was held at 216 ms, which was the mean RT in the control condition, only 67.5 percent of the variance was accounted for. Because the goodness of fit was so much poorer here, it appears that the time required for detection of the reaction signal and execution of the first response differed in the finite and infinite-interval conditions, or that some extra process, not identified in the model, in fact occurred in the finite-interval conditions.)

## IV. CONCLUDING REMARKS

This paper has examined the mechanisms of movement timing. Of necessity, the experiment that has been reported involved a restricted type of movement, namely simple finger sequences. Yet the experiment appears to have fairly broad theoretical importance for our understanding of how movements are timed. In particular, the experiment suggests that *even when peripheral feedback is available, central programs play a controlling role in movement timing.* The basis for this conclusion is that the mean RT for the first of two responses was longer than the mean RT for a single, isolated response, even when the time between the first and second response exceeded 1 second. That the lengthening of RTs at such long delays was in fact attributable to some aspect of the control of movement timing is suggested by the fact that the lengthening of RTs was greater when the interresponse interval was controlled more precisely.

Besides supporting a general, qualitative principle about movement control, the data from the present experiment also allow for a relatively detailed model of the control of movement timing. The model likens the selection and control of an interresponse interval to the setting and running of a conventional alarm clock: First, the desired number, $n$, of clock pulses is selected (during the RT), and then the clock is allowed to produce the $n$ pulses so that the first response is triggered at the time of the first pulse and the second response is triggered at the time of the $n$th pulse. The proposal that there is a clock-pulsing mechanism is motivated by the finding that the variance of the interresponse interval increased linearly with the interval mean, which is suggestive of a *stochastic wait* process (see Refs. 17 and 18) where

times between successive pulses fluctuate randomly about a mean and are stochastically independent. Through some algebra, it was seen that another factor contributing to the interval variance is the variance of $N$, which was seen to be proportional to the interval mean. The size of this proportionality factor was seen to depend on the slope of the linear function relating the interval variance and mean, and this slope was observed to differ in the relaxed and stringent conditions of the experiment. Having established the above relationships, it was observed that the mean RTs in the nonzero, finite-interval conditions were inversely related to the (predicted) variance of $N$. Then, through a curve-fitting procedure, it was seen that this relationship could account for almost 95 percent of the variance of the mean RTs in the nonzero finite-interval conditions. The inverse relationship between the mean RT and predicted variance of $N$ can be explained by saying that it takes longer to select a particular value of $N$ as the range of allowable values decreases. Such a relationship can be understood in statistical terms as reflecting a decreasing likelihood of selecting an allowable value of $N$ as the range of allowable values of $N$ decreases. If reselection of a value of $N$ is required when an unallowable value has been picked, the average time to select an allowable value would vary in a way consistent with the mean RT results obtained here.

It is interesting to note that the physiological basis for an alarm-clock system has been demonstrated. In the cortex of the cerebellum, rows of regularly spaced neurons known as Purkinje cells are connected to other neurons in such a way that the delay between the entry of a signal into the row and the exit of a signal from the row depends on which Purkinje cell is permitted to conduct the output signal.[20,21] The process of selectively permitting a given Purkinje cell to conduct an output signal on the basis of the delay that would occur prior to that output signal is physiologically analogous to the clock-setting process proposed here.

# Experiments on Quantitative Judgments of Graphs and Maps

By W. S. CLEVELAND,* C. S. HARRIS,* and R. McGILL*

(Manuscript received August 18, 1982)

Behavioral studies are essential for devising guidelines for effective communication of quantitative information from graphs. Three experiments in which subjects made quantitative judgments from three different kinds of graphs lead to several recommendations: use pastel rather than highly saturated colors on statistical maps; standardize the point cloud size relative to the frame on a scatterplot; scale circles by making the circle area proportional to the variable represented, but expect widely varying judgments of the areas.

## I. INTRODUCTION

With the proliferation of computer graphics, there is an increasing reliance on visual displays to convey quantitative information. Maps, graphs, and diagrams have been in use for a long time, but in recent years the variety, complexity, and ease of preparing such visual displays have increased greatly. It is often assumed that visual displays allow people to quickly and accurately appreciate quantitative information and relationships that might be much harder to grasp from other representations, such as tables of numbers, equations, or verbal

descriptions. Graphs, for example, are regarded as powerful tools for analyzing data[1] and for presenting data to others.[2]

In preparing a graph, the usual assumption is that if the mathematical relationships are represented accurately in visual form, they will convey the correct quantitative impressions. But this may not be right. Numerous experiments with very simple displays have shown that people's perceptual judgments often differ from physical measurements of such attributes as length, area, orientation, separation, brightness, and color (for reference lists, see Refs. 3 through 5). A much smaller number of studies have used displays that are similar to graphs or maps (see Refs. 6 through 9). Considering the enormous usage and variety of graphs, the number of directly applicable experiments is quite small. More information about human factors in graphical judgment is essential for the design of better visual displays.[10,11]

We summarize here three sets of experiments on quantitative judgments of three kinds of graphs. (More detailed accounts are given in Refs. 6, 7, and 12). The experiments differ in the information being conveyed, the coding of the information, the experimental procedures, the subject populations, and the methods of statistical analysis of the results. In passing, we will mention some useful statistical techniques that may be new to many readers.

## II. A COLOR-CAUSED ILLUSION OF AREA

A clear example of erroneous perception of a relatively simple display is shown in a study of the perception of areas of colored regions within a map.[12] Figure 1 is a map of the counties in Nevada. Maps like this, with subsets of the counties colored red or green, were shown to 24 subjects (12 scientists and 12 secretaries, clerks, and craftspeople, all from Bell Laboratories). In each map the total red area differed from the total green area by no more than 0.01 percent. Each subject saw ten variations of the map, with different subsets of counties colored red or green. The maps for one group of 12 subjects had the same partitioning of counties as for the other group, but the counties that were red for one group were green for the other, and vice versa. The maps were paper prints produced by a Bell Laboratories Printing System-Multicolor (PRISM) printer (a computer-driven modified Xerox 6500 copier), using standard options, which include highly saturated colors. Matching the colors with Munsell color chips,[13] under illumination similar to that in which subjects viewed the maps, gave Munsell values of hue = 7.5 red, value (brightness) = 4, chroma (saturation) = 14 and hue = 2.5 green, value = 5, chroma = 12. Thus, the red and green were quite similar in brightness and saturation.

An instruction sheet told the subjects that the colors indicated various geological features in each county. The subjects' task was to

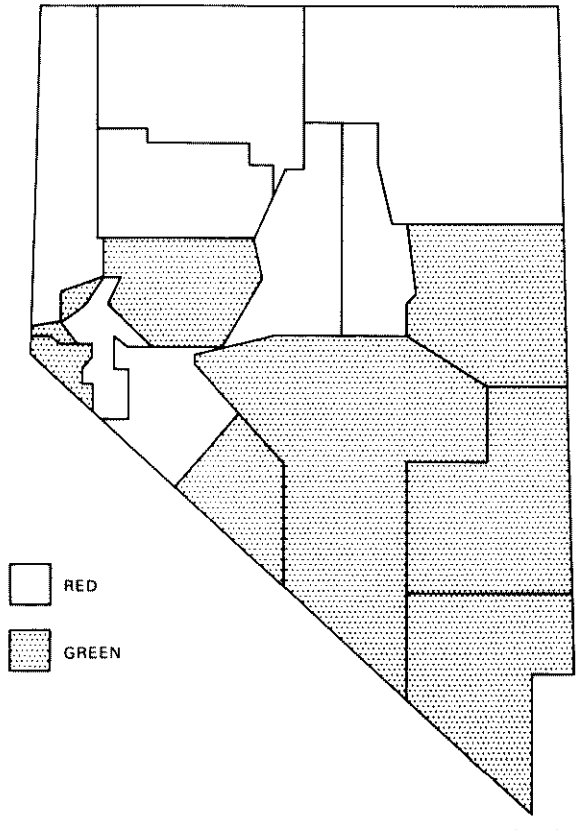

Fig. 1—Map of Nevada, where light and dark areas represent red and green, respectively.

decide which colored area within each map was larger and to mark "more red," "more green," or "same" on a checklist. The outcome was that most of the 24 subjects marked "more red" more frequently than "more green." That is, although the red and green areas were actually equal, they didn't look equal.

Figure 2 shows the data on a trilinear plot,[2] which accommodates within a single graph three variables that sum to a constant (100 percent in this case). Each open circle represents a single subject's data. The vertical axis indicates the percentage of maps for which a subject said the areas of the two colors looked the same. The two diagonal axes measure the percentage of maps in which the red or green area was called larger. Just as in the more familiar Cartesian xy plot, the three percentages for each data point are given by its perpendicular projection onto each of the three axes.

Because each subject made ten judgments, all data points represent multiples of 10 percent. Therefore, to avoid overlapping the values

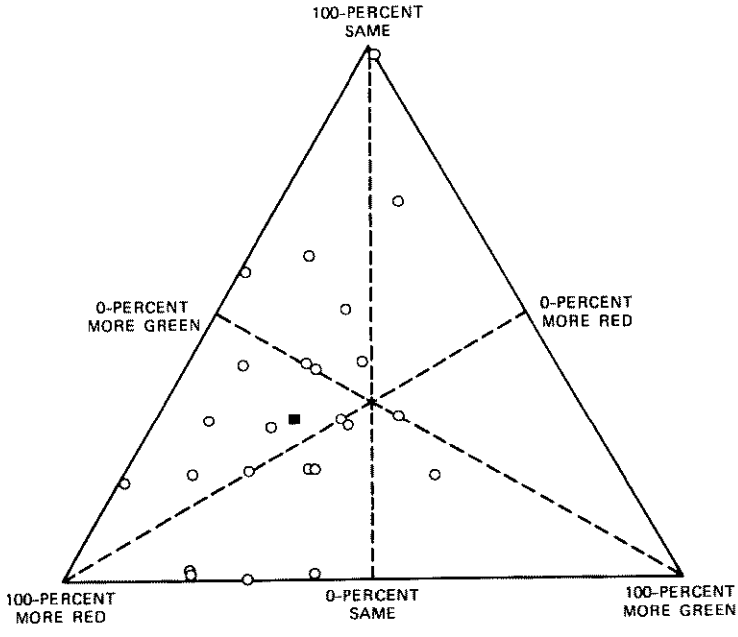

Fig. 2—Area judgments of highly saturated red and green regions.

were jittered: a randomly generated number from the interval −1 percent to +1 percent was added to each value.

First note that most of the 24 subjects' points fall to the left of the vertical axis. This indicates that most subjects judged the red area to be larger more often than they judged the green area to be larger. The filled square is the "robust center of gravity" for the data points. This statistic is calculated by an iterative procedure called "bisquare", using the distances of the data points from the current estimate as input for the next estimate. Using the bisquare[14] produces a statistic that is robust;[15] that is, unlike an arithmetic mean, it is insensitive to outliers, and is highly efficient for a broad class of distributions. The coordinates of this filled square give us another way to summarize the red/green illusion: it falls at about 50 percent "more red" judgments, 20 percent "more green," and 30 percent "same."

To estimate standard errors for the robust center of gravity, the bootstrap method[16] was used. Bisquare estimates were computed on 1000 24-point samples, drawn with replacement. The difference between the green and red coordinates is 49 percent − 22 percent = 26 percent, with a bootstrap standard error of 5.3 percent. Since the bootstrap distribution of the difference was well fit by a normal distribution, the percentage of red-larger judgments is very significantly higher than the percentage of green-larger.

Thus, the likely result of accepting the saturated colors that the PRISM printers normally produce is to make the red areas look too big or the green areas too small. Is there a way around this perceptual distortion? The printer was modified to fill the areas with two unsaturated pastel colors: a half-tone screen composed of red and pale yellow dots and a half-tone screen composed of green and pale yellow dots. The filled square for the robust center of gravity in Fig. 3 shows that for the group as a whole, the percentages of judgments of "more red" and "more green" are nearly equal. Using pastel instead of saturated colors eliminated the overall tendency to call the red area larger than the green.

Additional research could determine whether these findings hold for other pairs of hues, other combinations of brightness and saturation, and other display media (e.g., video displays). For the PRISM printer, it is clear that for accurate judgments of relative area, pastel colors are preferable to the standard saturated red and green.

### III. JUDGMENTS OF CIRCLE SIZES

In most of the perceptions that we label "illusions," some extraneous aspect of the stimulus seems to be distorting perception of another aspect. For example, in the familiar Müller-Lyer illusion the arrowheads added to the ends of two horizontal lines distort perception of

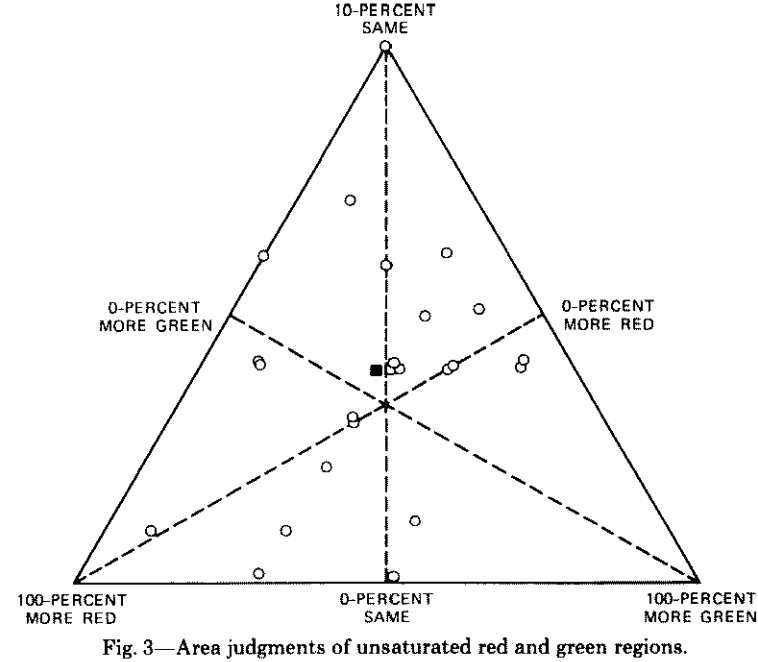

Fig. 3—Area judgments of unsaturated red and green regions.

the lengths of those horizontal lines. Similarly, in the experiment with maps of Nevada, the colors distorted perception of areas. But, in fact, many of our perceptions—perhaps even most of them—are illusions, in the sense that what we see does not match the usual measurements obtained with instruments other than the human observer. For a wide variety of attributes (such as loudness, brightness, tactual roughness, and weight), laboratory studies have found that people's judgments of quantities or intensities seldom vary in direct proportion to these measurements of the physical stimulus. In most cases the relation between subjective judgments and physical measurements can be described by a power function of the form $s = kp^e + c$, where $s$ is the subjective magnitude, $p$ is the physical magnitude, $k$ and $c$ are scaling constants, and $e$ is an exponent that depends on what is being judged, ranging from 0.3 for the brightness of an isolated disk of light to 3.5 for the intensity of an electric shock.[5]

What does this imply for the communication of quantitative information by means of graphs or maps? Consider a common kind of statistical map in which circles of different sizes are used to represent, for example, the number of toll calls from various cities. For laboratory studies of the judgment of area, Stevens (see Ref. 5) gives 0.7 as a typical value for the exponent in the psychophysical function. Such a low exponent would mean that a circle that is double the area of another would be called only 1.6 times as large, and one with five times the area would be called only three times as large, whereas one with 25 percent of the area would be called almost 40 percent as large.

Since the purpose of a map or graph is to convey quantitative relations quickly and accurately, shouldn't areas be scaled to give the correct subjective impressions rather than to be physically correct? Some writers[17,18] have suggested just such a procedure. They recommended scaling the plotted areas to compensate for the low-exponent function found in psychophysical experiments.

However, the exponent found in studies of area judgments might not apply to an actual statistical map. We therefore prepared 24 maplike pages that depicted the average daily telephone toll charges for businesses at different locations in a city.[7] An example is shown in Fig. 4. Fourteen scientists from Bell Laboratories were told that the circle marked with an X represented toll charges of $100. They were to write down, for each of the three circles marked with a dot, their estimate of the dollar amount represented. The word "area" was not used.

The results were quite different from the usual laboratory findings on judgments of area: Most of the exponents in the fitted power functions for individual subjects were closer to 1.0 than to 0.7. There was considerable variation from person to person, with exponents

Figure 467

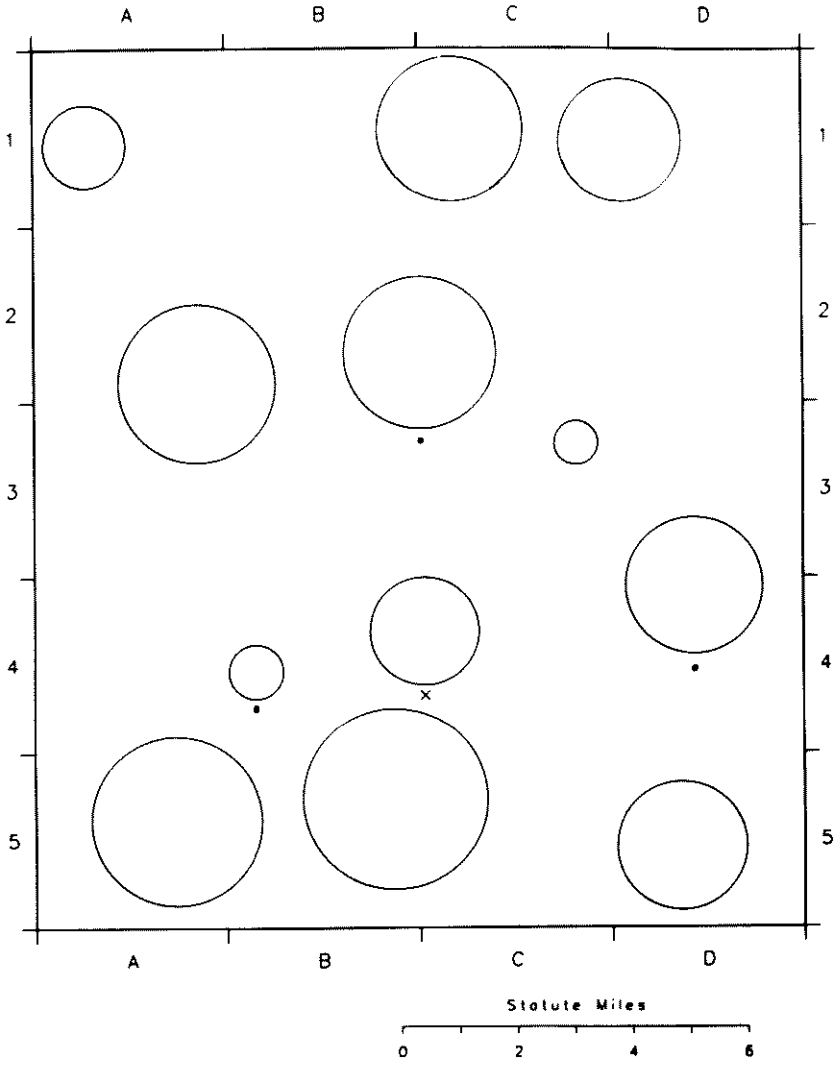

Fig. 4—Maplike display of circles.

ranging from 0.6 to 1.3. This implies that for an actual chart-reading situation, no single form of compensatory scaling of area would give everyone correct impressions. In fact, since the median exponent (0.94) is close to 1.0, these data suggest that the best scale is the simple one with circle areas directly proportional to the represented quantities. (Note that judging diameter or circumference instead of area would

yield an exponent of 0.5 for judgments as a function of area. None of our subjects had an exponent that low.)

Why do our exponents differ from those typically found in psychophysical studies? Is it because we asked for a different kind of judgment—dollars represented, rather than area—and displayed a maplike frame and tick marks? We can answer this question because we had the same subjects make area judgments of the same 24 sets of circles on plain pages, without maplike markings (Fig. 5). All of them did this perceptual task after judging the maplike stimuli. The instruction was to judge the areas of the circles, calling the one marked X 100 units of area. We found no difference between the two types of displays and tasks.

Figure 179

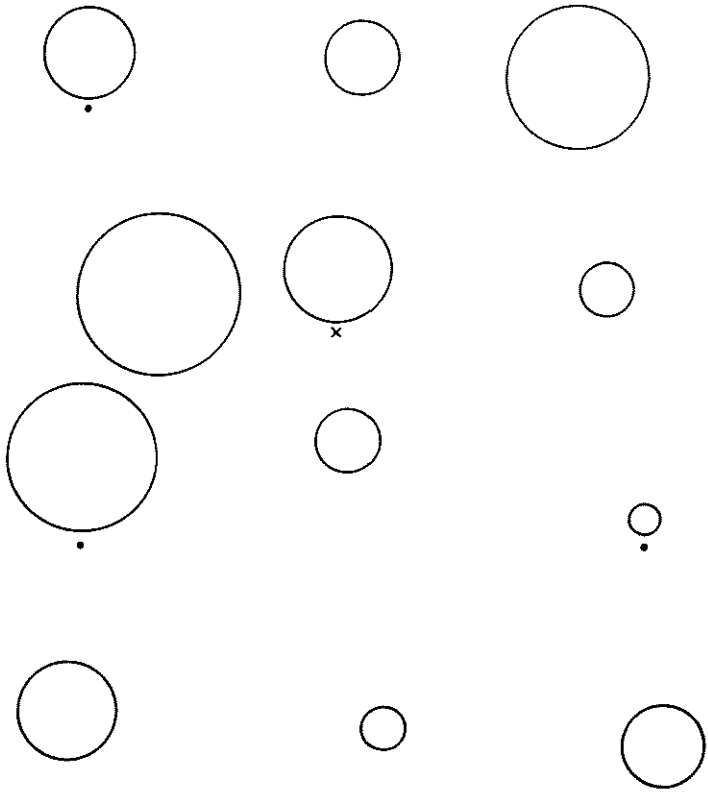

Fig. 5—Display without maplike markings.

Our next thought was that our subjects' scientific training might enable them to judge areas more accurately, on the average, than subjects in previous laboratory experiments. We therefore asked 10 high school students to carry out the same two tasks. Figure 6 presents a comparison of the exponents estimated for the scientists (on the left) and 10 high school students (on the right). Functions of the form $s = kp^e + c$, relating subjective judgment ($s$) to physical area ($p$), were fitted to each subject's data. The digits to the left of the colons are the first digits of the estimated exponents ($e$). Each digit to the right of the colon is the next digit in the exponent for a single subject. The distributions are similar for the scientists and the high school students, with medians at 0.94 and 0.97, respectively. These stem-and-leaf diagrams[19] can be interpreted as enriched histograms. The digits to the left of the colons are the first one or two digits of the estimated exponent, while each single digit to the right of the colon is the next digit in the exponent for a single subject. For example, the stem-and-leaf diagram tells us not only that four scientists had exponents in the range from 1.00 to 1.09, but also that the specific values were 1.00, 1.04, 1.05, and 1.07. There is not much difference between the distributions for the scientists (median = 0.94) and for the students (median = 0.97). Scientific training doesn't have much influence.

The students' data also rule out another possible explanation of the difference from previous psychophysical studies. The scientists judged all of the maplike displays before seeing the ones that contained only circles. When estimating the toll charges, they were free to adopt any strategy they cared to, unlike subjects in psychophysical studies who are told to judge area. Even though the scientists were then asked to judge areas in the second half of the experiment, they might have simply persisted in using the same judgmental strategy as in the first half. This choice of strategy could explain why judgments were the same for maplike displays and plain circles, and also why the results differ from earlier experiments on area estimation. However, half of the students made their area judgments *before* making dollar estimates, and their estimates were quite similar to those made by the students who completed the tasks in the opposite order. The agreement between

| EXPONENTS FOR 14 SCIENTISTS | EXPONENTS FOR 10 HIGH SCHOOL STUDENTS |
|---|---|
| 0.5 : | 0.5 : 8 |
| 0.6 : 3 | 0.6 : 9 |
| 0.7 : 29 | 0.7 : 4 |
| 0.8 : 8 | 0.8 : 8 |
| 0.9 : 01349 | 0.9 : 7799 |
| 1.0 : 0457 | 1.0 : 3 |
| 1.1 : | 1.1 : 8 |
| 1.2 : 7 | 1.2 : |

Fig. 6—Power-function exponents for judgment of circle sizes.

area and dollar estimates shows that neither the type of judgments, nor the order in which they are made, nor the presence of maplike frames is responsible for the high exponents.

One obvious difference between our experiments and many previous ones is that our subjects always judged circles within a simultaneously visible set, whereas in most psychophysical studies the stimuli are presented one at a time. It may be that higher exponents are obtained when the standard circle is visible along with the circles that are compared with it, instead of being displayed and then removed before the judgments are made. Examination of previous studies offers some support for this hypothesis; for several comparable studies (mostly by psychologists) in which the standard was not visible during the area judgments, the median exponent was 0.7, whereas in several studies (largely by cartographers) in which the standard was always present, the median exponent was 0.9.[7]

These findings suggest that when one is preparing statistical maps, it is probably better simply to make circle areas directly proportional to the quantities represented (exponent = 1) rather than to scale with a very different exponent, as a direct application of psychophysical studies of area judgments might suggest. Future research may enable us to specify what variables contribute to higher or lower exponents, but certainly our multiple-circle displays resemble statistical maps more closely than do circles viewed one at a time.

## IV. JUDGED ASSOCIATION IN SCATTERPLOTS

The judgments discussed so far—areas of circles or colored regions on maps—do not require technical training; indeed high school students' judgments proved to be quite similar to those made by scientists. The experiments to be described now, on the other hand, called for subjects with some statistical training. In these experiments[6] all subjects had at least a basic knowledge of statistics (university statistics students and faculty, and practicing statisticians). They were asked to assess the degree of linear association between two variables portrayed by a scatterplot. The most frequently encountered measure of linear association is the correlation coefficient, $r$. The value of $r$ ranges from 0, when there is no linear association, to +1 or −1, when the linear association is perfect and the plotted points fall on a straight line. In many basic statistics courses, $r$ is the only measure of correlation that is taught.

In the study with maps of Nevada, discussed earlier, perceptions of one aspect of the displays—area—was found to be strongly influenced by another aspect—color—which should have been irrelevant. A similar influence was found with judgments of association in scatterplots. The two scatterplots in Fig. 7, projected alternately on a screen, were

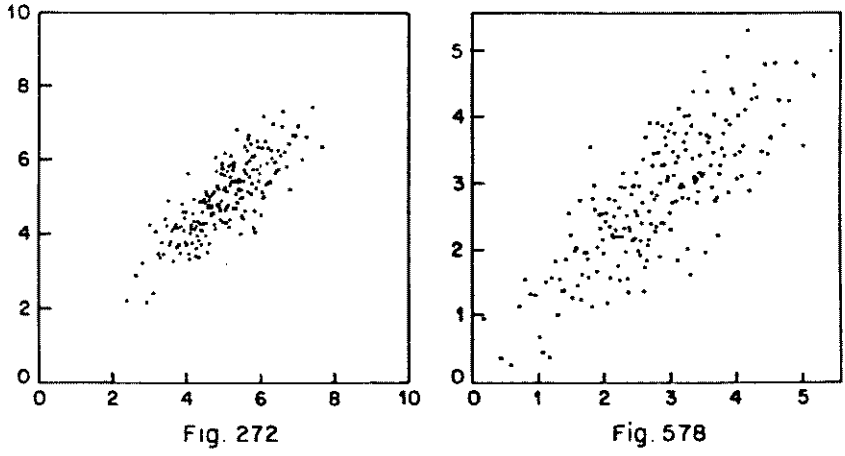

Fig. 7—(Left panel) Scatterplot with correlation $r = 0.8$. (Right panel) Scatterplot with same correlation as in left panel, but with x and y scales expanded.

shown to 109 subjects. They indicated the degree of association of the two variables by assigning a number from 0 to 100 to each plot. In fact, the correlation is identical for the two plots ($r = 0.8$); only the scale of the axes, and hence the size of the point cloud, is different. Judgments of the amount of association on the two plots should therefore be identical also. But they are not; judgments of the association portrayed by the left panel of Fig. 7 were generally higher than for the right panel.

To quantify this difference, each subject's estimate for the right panel of Fig. 7 was subtracted from the estimate for the left panel, and the 10-percent trimmed mean was calculated by dropping the largest 10 percent of the differences and the smallest 10 percent and taking the arithmetic mean of the remaining values. (Unlike means, 10-percent trimmed means are robust measures that are not influenced by extreme outliers. Ten-percent trimmed means can be thought of as a compromise between medians, which are nearly 50-percent trimmed means, and means, which are 0-percent trimmed.) The result (after dividing by 100 to bring the judgments into the range 0 to 1) was a difference of 0.068 between the panels of Fig. 7, with a standard error of 0.011. Thus, the estimated association was significantly higher for the smaller point cloud than for the larger one.

A second experiment corroborated this finding. The scatterplots in Fig. 7 were shown to 32 subjects who were told that the correlation coefficients were identical. The subjects were asked whether one plot *looked* more correlated than the other and if so, which one. Sixty-six percent of the subjects reported that the left panel looked more correlated than the right, 22 percent that they looked the same, and

only 13 percent that the right panel appeared more correlated. So even explicit information that the two correlations are identical does not dispel the illusory impression that the smaller point cloud depicts a higher correlation.

To obtain more detailed information on judgments of association another study was carried out. In this study 74 subjects each judged 19 scatterplots, assigning a number from 0 to 100 to denote the linear association. The 19 stimuli included 10 with the same axis scales, representing 10 different levels of association, plus an additional 9 with 3 different axis scales (that is, different point-cloud sizes) at 3 of those levels of association. A number of other attributes (such as number of points, standard deviations of the variables, sign of the correlation, and size of the square frame) were identical for all of the scatterplots.

The 10-percent trimmed means across subjects are plotted against actual correlation in Fig. 8. The circle radii portray the standard errors of the trimmed means. Thus the circle areas are proportional to the estimated variances of the trimmed means. The numbers to the left of the circles indicate the point-cloud sizes (1 is the smallest). When

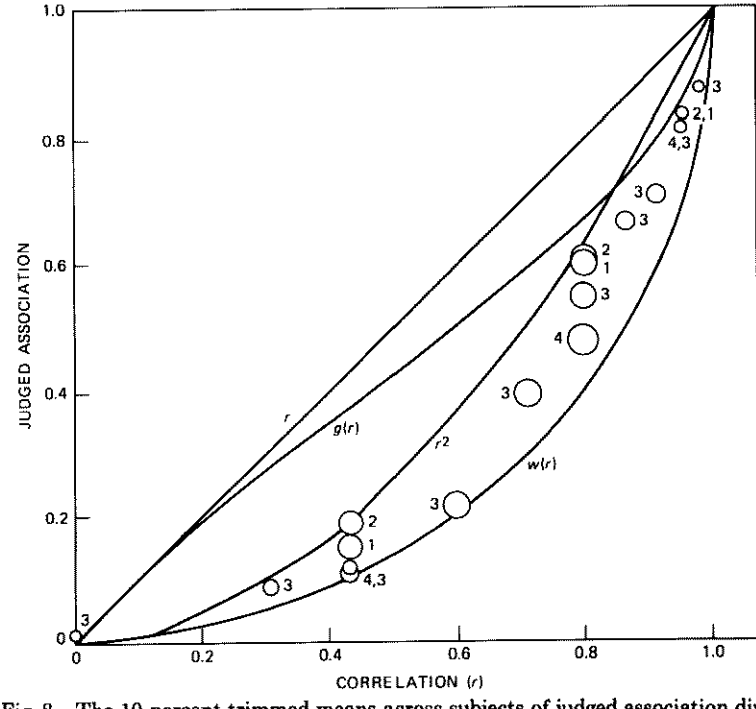

Fig. 8—The 10-percent trimmed means across subjects of judged association divided by 100 for 19 scatterplots are plotted (by the circle centers) against the values of $r$, the correlation coefficient, of the scatterplots.

two numbers are shown, separated by a comma, two circles are nearly coincident and the first number refers to the circle with the smaller trimmed mean. The information on the plot leads to two conclusions: judged association tends to be higher for smaller point-cloud sizes; judged association is not proportional to any of four standard numerical measures of association [the points do not fall on any of the curves, which plot $r$, $g(r)$, $r^2$, and $w(r)$ as a function of $r$]. Thus, the circles for $r$ near 0.4 and 0.8 corroborate the finding that smaller point clouds tend to elicit higher judgments of association.

The new information is that subjects' judgments are far from proportional to the usual measure of linear association, $r$. Since the actual correlation coefficient $r$ is given by the horizontal axis, if the subjects had been judging $r$ accurately, the data would have fallen on the 45-degree line. Instead, the points fall well below it. On the average a correlation of 0.4 was judged to be less than 0.2, a difference of more than a factor of 2.

Two other measures of linear association come closer to fitting the data: $g(r) = 1-\sqrt{(1-r)/(1+r)}$ and $w(r) = 1-\sqrt{1-r^2}$ (see Ref. 20). Unlike $r$, both $g(r)$ and $w(r)$ offer intuitively plausible geometric bases for visual judgments. If we draw the ellipse of the bivariate normal distribution that generated a scatterplot, as in Fig. 9, the ratio of the minor axis to the major axis is $(1-r)/(1+r)$. The smaller this ratio is, the higher the association; so $g(r)$ tells how narrow the ellipse is relative to a zero-correlation circle. The ratio of the area of the ellipse to the area of the rectangle circumscribed around it is $\pi/4\sqrt{1-r^2}$; so $w(r)$ tells how far the ellipse is from filling the rectangle. Unfortunately, neither $g(r)$ nor $w(r)$ fits the data very well, as can be seen from the departure of the data points from both curves in Fig. 8. Another measure, $r^2$, does not fit the data particularly well either. However, there is a two-parameter family of curves, $1-(1-r)^{\alpha}(1+r)^{\beta}$, that includes all four measures of association that we have mentioned (and many others as well). If such a curve is fitted to the data in Fig. 8, the estimates of $\alpha$ and $\beta$ and their standard errors are $0.71 \pm 0.04$ and $0.66 \pm 0.11$, respectively. These estimated parameter values fall between (and are significantly different from) those for $w(r)$ ($\alpha = 0.5$, $\beta = 0.5$) and for $r^2$ ($\alpha = 1$, $\beta = 1$). [For $r$, $\alpha = 1$ and $\beta = 0$; for $g(r)$, $\alpha = 0.5$ and $\beta = -0.5$.] This middle position of the parameter estimates is what we would expect since the circles in Fig. 8 lie between $r^2$ and $w(r)$.

Thus the parameters of the best-fitting curve have values that are significantly different from those of any of the four measures of association that we have considered.

On the face of it, the poor fit of the subjects' judgments to $r$, $r^2$, $g(r)$, and $w(r)$ seems to imply that these highly trained subjects do not base

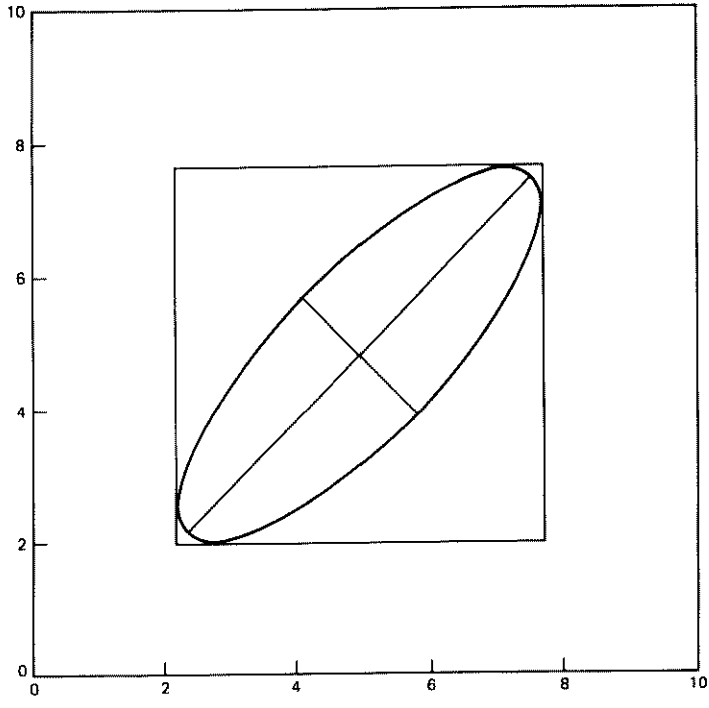

Fig. 9—Geometrical bases for $g(r)$ and $w(r)$.

their estimates of linear association on the visual counterparts of any of these standard measures. However, there is an alternative that remains to be explored. Perhaps subjects do make judgments (for instance, of the ratio of minor to major axis) that are appropriate for one of these measures of association, but misperceive the basic visual attributes on which the judgments are based. For example, if judgments of length were not directly proportional to actual length, then judgments of the ratio of minor to major axis of an ellipse would not be proportional to the actual ratio.

The finding that the size of the point-cloud can have a big effect on judged association means that the axis scaling that many statistical plotting programs apply automatically is not optimal for all purposes. To facilitate comparisons of the degree of association in different plots, it would be wise to make the point-cloud sizes similar; Cleveland and McGill (see Ref. 21) propose a way to do so. The size effect also suggests that when estimates of degree of association are required, the numerical value of a measure of association should also be computed. Even experienced statisticians can have judgments of association affected by extraneous factors.

## V. CONCLUSIONS

Behavioral studies of the kind summarized here are essential for devising guidelines for effective communication of quantitative information. These studies confirm that people can make consistent judgments of a wide variety of visual displays. However, those judgments may not match the usual physical measurements of stimulus attributes: People overestimated bright red areas on maps, relative to bright green areas, and judgments of the degrees of linear association in a scatterplot did not agree closely with any of four standard statistical measures of association [$r$, $w(r)$, $g(r)$, and $r^2$]. Other findings lead to some recommendations about how to convey quantitative relations more accurately. For example, for output from PRISM plotters, substituting pastel colors for saturated red and green reduced the biasing of area judgments. The finding that smaller point-clouds in a scatterplot are judged to portray higher linear association implies that to permit accurate comparisons of association, axes should be scaled to produce similar point-cloud sizes. And finally, our subjects' judgments of arrays of circles suggest that in statistical maps one should not scale to compensate for the distortions in area judgments that are found when stimuli are viewed one at a time; instead, symbol sizes should be directly proportional to the quantities represented.

With reliance on both old and new forms of visual display becoming increasingly widespread, we will need more behavioral studies like the ones summarized here to guide effective communication of quantitative information.

# Retrospective Reports Reveal Differences in People's Reasoning

By D. E. EGAN*

(Manuscript received January 14, 1982)

Reasoning for a class of transitive inference problems was studied and the following questions were experimentally investigated: (1) Can people give reliable retrospective reports about their reasoning processes? (2) Do people who report different reasoning processes actually reason in different ways? (3) Can people be trained to use different reasoning processes? In the situations studied, subjects' retrospective reports about reasoning contained sufficient information to classify the subjects reliably. Subjects classified as using different reasoning strategies made different amounts and different kinds of reasoning errors. As a result of training, subjects could use reasoning processes that they would not have used spontaneously. These results have implications for developing theories of reasoning and for assessing and modifying reasoning-like processes in practical situations.

## I. INTRODUCTION

Reasoning, the ability to draw conclusions or inferences from given information, is a prized intellectual talent. Reasoning is known to be associated with successful learning of mathematics.[1] A "reasoning

factor" plays a prominent role in reading comprehension.[2] Practical problem-solving tasks such as balancing a checkbook or troubleshooting equipment undoubtedly involve reasoning. Because of its pervasive importance, tests of reasoning have been included in virtually every battery of aptitude tests, and experimental psychologists have studied reasoning extensively in various forms.

Reasoning may play an especially prominent role in the future as more occupations and everyday tasks involve computers. For example, reasoning test scores to some extent predict people's success at computer programming,[3] an occupation that is growing in importance. Reasoning probably is required to use the host of new computer-like devices ranging from automated banking machines and appliance timers to systems for editing and data retrieval. The small bit of "programming" required to activate many new telephone services appears to require mental processes akin to reasoning.

### *1.1 Three basic questions about reasoning*

This paper presents results of basic psychological research concerning three questions about reasoning. The first of these questions is, "Can people give reliable retrospective reports about their reasoning processes?" This question is important, because it asks whether a potentially useful kind of data about the reasoning process meets the scientific standard of repeatability. Using subjective reports to analyze reasoning processes poses much more severe problems of reliability than, say, using meter readings to analyze physical processes.

To be useful data, retrospective reports about reasoning processes must, as a minimum, admit to consistent classification. Reports should contain enough information so that two raters would classify a given report in the same category. Different methods of reporting (e.g., verbal reports and nonverbal reports such as drawings or checklists) should agree with each other so that a reasoner would be classified in the same category no matter which particular method of reporting is used. The classification of reports given by the same person on different occasions should be consistent, as long as other indicators show that the person is using the same reasoning process on those occasions. Retrospective reports must meet each of these requirements to be considered reliable indicators of people's reasoning processes.

A second fundamental question considered here is, "Do people who report different reasoning processes actually reason in different ways?" If different people actually reason in different ways consistent with their reports, two conclusions follow. One conclusion would be that retrospective reports about reasoning are valid evidence about the reasoning process. Reports could be valid simply if people who give a particular kind of report tend to use a particular reasoning process,

even if the content of the report does not accurately describe the process. Formally, such reports would have validity because their content would be correlated with performance. A more powerful and interesting kind of validity would require that the content of people's reports accurately reflects how they reason.

Another conclusion would be that data (e.g., reasoning errors) from people giving different kinds of reports do not result from a common underlying reasoning process. To understand reasoning, people using a given reasoning process first may have to be identified and their reasoning data grouped together. Models for the reasoning process appropriate to each group then could be developed.

A very practical aspect of this question is that retrospective reports are often the most easily obtainable data and sometimes they are the only data available in practical situations involving mental processes like reasoning. For example, people's reports about how they do a task or how they use a complex device often are used to evaluate new services or products requiring human interaction. It would be advantageous to have at least one assessment of the validity of these kinds of reports, and to know whether different people are likely to use different reasoning processes spontaneously. The extent to which laboratory studies of reasoning generalize to specific practical situations involving reasoning is not known. However, one benchmark for the validity and variety of retrospective reports about reasoning can be obtained in laboratory studies where it is possible to validate reports.

The third question about reasoning addressed in these studies is, "Can people be trained to use different reasoning processes?" This question introduces a distinction between the reasoning processes people might use spontaneously, and those they could use if trained to do so. In particular, for a specific kind of problem people may be able to follow directions to use a certain reasoning process, even if they would not use that process if left to themselves.

This question has theoretical and practical interest. To the extent that training can induce people to use different reasoning processes, reasoning cannot be conceptualized simply as a stable ability that some people have more of or are better at doing. Instead, a theory of reasoning must explain what factors cause people to discover and use a particular reasoning process when they are competent to use others. Moreover, if people can be trained to reason in different ways, then they probably can be trained to think in various ways about practical tasks involving reasoning. Directions on "how to think about" a task may be an effective aid for learning new procedures (perhaps activating telephone services or interacting with computers) that require reasoning.

### *1.2 Reasoning problems used in these studies*

In all of the studies presented here, people solved reasoning problems involving a simple transitive inference. The problems, known as "three-term series problems," have a common basic form. Examples of the problems are given in Table I.

Three-term series problems were selected for these studies over many other possible kinds of reasoning problems for the following reasons. First, these problems require no specialized content knowledge and therefore seem to be good tools for examining "pure reasoning" uncontaminated by whatever specific information people might know about a problem. Second, the simple verbal structure of problems like those in Table I makes it easy to manipulate certain problem characteristics while controlling others (see below). Finally, three-term series problems have been studied extensively. They have been used on standard tests as markers for deductive reasoning ability[4,5] and much is already known about factors that influence the difficulty of these problems.[6]

Each three-term series problem consists of two premises followed by a question. The premises state a relationship between two of the three terms in the problems. The question concerns the inferred relationship between the remaining pair of terms.

In describing three-term series problems, an important distinction must be made between *relations* and *inverses*. This distinction is based on well-substantiated findings demonstrating that one member of a pair of opposite relational words typically produces better performance than the other member. For example, using the word "above" results in more rapid and accurate performance than the word "below" in a large range of tasks. Similarly, the word "fatter" leads to better performance than "thinner," etc. The psycholinguistic theory of lexical marking[7] may account for some of these differences. For present purposes, an inverse is defined as that member of a pair of opposing relational words that is known to cause the greater difficulty. Conse-

Table I—Sample of the reasoning problems used

| Positional Relations | Visual Comparative Relations |
|---|---|
| Triangle is above circle.<br>Square is below circle.<br>Is triangle above square? | Square is smoother than triangle.<br>Circle is smoother than square.<br>Is triangle smoother than circle? |
| Circle is left of triangle.<br>Square is left of circle.<br>Is triangle left of square? | Circle is darker than square.<br>Circle is lighter than triangle.<br>Is triangle darker than square? |
| Square is in back of triangle.<br>Square is in front of circle.<br>Is triangle in front of circle? | Triangle is fatter than circle.<br>Triangle is thinner than square.<br>Is circle thinner than square? |

quently, "above" will be referred to as a relation, but "below" will be referred to as an inverse. Similarly, "fatter" is called a relation, but "thinner" is called an inverse.

Having thus defined relations and inverses, the terms of the problems will be distinguished as follows: the "A term" is the initial term in the linear order established by the premises (e.g., when using the relation "rougher" or its inverse "smoother," the A term would be the roughest); the "B term" is the pivot, or middle term; the "C term" is the end term of the linear order (e.g., the smoothest when using rougher/smoother).

Several other details of the problem set are noteworthy. The terms and relationships of each problem were selected to encourage the use of spatial mental representations. The terms were the geometric figures circle, square, and triangle. The relationships involved either positional comparisons (relation/inverse pairs above/below, right of/left of, or in front of/in back of), or nonpositional visual comparisons (rougher/smoother, darker/lighter, or fatter/thinner). For each relation/inverse pair, 16 different problem types were generated. These different problem types resulted from a $2^4$ factorial combination of the following factors: (1) the use of a relation or inverse in the premise relating the A term and B term; (2) the use of a relation or inverse in the premise relating the B term and C term; (3) the order of the premises; and (4) the use of a relation or inverse in the problem question. The pattern of reasoning errors made on these different types of problems will be analyzed to test whether various reasoning processes are being used.

## II. CAN PEOPLE GIVE RELIABLE RETROSPECTIVE REPORTS ABOUT THEIR REASONING PROCESSES?

### *2.1 Approach*

Regarding the question of the reliability of reports about reasoning, we will consider data from two experiments.[8] In both studies, high school students solved a large number of three-term series problems, and then described their reasoning processes. In the first study, 12 subjects each solved 384 problems. In the second study, 100 subjects each solved 192 problems.

The problems were presented on an audio-tape-playback machine. Each problem began with a speaker saying "Next," then reading the problem, and then pausing five seconds to allow the subject to answer before beginning the next problem. Subjects answered problems by crossing out "Yes" or "No" or "?" next to the number of the problem on an answer sheet. They were not allowed to write anything else. Answers were scored as errors if either the wrong response or a "?" was used.

Several methods of retrospective reporting were used. In the first experiment, subjects were interviewed by the experimenter, and these interviews were tape-recorded and analyzed. In the second experiment, subjects gave written reports—essentially the equivalent of the oral reports in the first study. Following the written reports, subjects then were asked to draw pictures representing how they thought about the problems. As a final method of reporting, subjects were shown two written descriptions of reasoning processes that attempted to capture the two most common kinds of reports found in the first study. Subjects had to choose which of the two descriptions more closely matched their own way of reasoning.

### *2.2 What people reported*

The most striking aspect of subjects' reports was that different subjects claimed to use quite different sets of processes or *strategies* to deal with simple three-term series problems. The difference was most apparent for reports about the visual comparative relations rougher/smoother, darker/lighter, and fatter/thinner. Some subjects claimed to establish an order for the three geometric figures no matter what relation was used. For these subjects, "rougher," for example, would be identified with one end of a vertical or horizontal scale, as would "darker" and "fatter". Subjects described making the transitive inference by mentally arranging the geometric figures roughest to smoothest, darkest to lightest, etc. Other subjects claimed to attribute physical properties to the geometric figures in the case of the visual comparative relations. For example, these subjects described their representation of a rougher triangle as an image of a triangle having a roughly textured surface, or a lighter circle as a picture of a very bright round object. These subjects described making the transitive inference by scanning the images. Distinctions among reports about positional relations were more subtle (see below). Actual examples of written reports are given in Table II.

Reasoning data from subjects who reported similar reasoning strategies were grouped together. The rule for assigning subjects to groups was that if a subject described a representation that clearly involved physical properties for any relation, then the subject was placed in a group labeled "Concrete Properties Thinkers." A subject who claimed to use an ordered mental array for every relation was placed in another group labeled "Abstract Directional Thinkers."

Using this rule, all subjects in the first experiment could be classified into either the Concrete Properties Group ($N = 5$) or the Abstract Directional Group ($N = 7$). In the second experiment, the consensus rating of written reports by two judges identified 18 subjects as

Table II—Examples of written retrospective reports

| | | |
|---|---|---|
| **Abstract Directional Thinkers** | | |
| Rougher–Smoother | S#005: | "Rather than imagining a rough/smooth figure, I put the figures in a horizontal line, in my mind, in the order of left/right rather than rough/smooth." |
| | S#049: | "I pictured the objects in my mind in a line of sequence." |
| Darker–Lighter | S#003: | "I set up a scale with the lightest on the far right and darkest on the far left and placed the figures on their appropriate spots." |
| | S#051: | "Placed them in a line up and down, darkest being on top." |
| Fatter–Thinner | S#086: | "I also used a mental horizontal grid for this relation with the left side of the grid being the 'thin end' and the right side the 'fat end.'" |
| | S#099: | "Put shapes in order from thinner to fatter." |
| **Concrete Properties Thinkers** | | |
| Rougher–Smoother | S#008: | "I also drew a picture, and if something was rough—I would put craters in it in my mind—smooth was just plain white." |
| | S#098: | "The picture came to mind of corners and smooth edges, then the question was solved." |
| Darker–Lighter | S#062: | "In my mind, I 'colored in' the object that was darkest." |
| | S#080: | "I listened to the problem and tried to solve it mentally, at times picturing the objects colored in or not." |
| Fatter–Thinner | S#022: | "This (fatter/thinner problem) was hard. I had to think of the shapes as squeezed or pulled." |
| | S#100: | "Made them (the figures) fatter and thinner in my head." |

Concrete Properties Thinkers, and 42 as Abstract Directional Thinkers.

The classification rule identifying a subject as a Concrete Properties Thinker on the basis of a single concrete report was motivated by simplicity. Subsequent analyses suggest that the rule, while admittedly crude, did manage to separate people into two groups that used a particular set of reasoning processes fairly consistently. First, subjects who reported a concrete representation for one relation were very likely to report using such a representation for other relations. For example, 17 of 18 subjects identified as Concrete Properties Thinkers in the second study gave reports having a concrete representation for two or more relations. Second, in the statistical analysis of reasoning errors, reasoning groups did not interact with the different relation/inverse pairs, suggesting that each group consistently used one reasoning process. Third, a key-word analysis of the written retrospective reports suggests that the two groups also handled positional relations differently. People classified as Concrete Properties Thinkers used more words in their reports that suggest the use of a visual image (variants of the words "picture" and "draw") for positional problems

(e.g, "I pictured the objects in a row"). People classified as Abstract Directional Thinkers used more words suggesting the use of an order-preserving scale (variants of the words "put", "order", "line," and "horizontal/vertical") for positional problems (e.g., "I put the objects in order on a horizontal line"). This interaction of key-word types and reasoning groups was statistically reliable.

To summarize, the majority of people reported one of two sets of reasoning processes or strategies for the three-term series problems. Some people claimed to preserve the information in the premises of at least some problems by means of an image capturing the visual features or stated position of the geometric terms. Others claimed to preserve the information in all premises by means of an abstract ordering of the geometric terms.

### *2.3 Reliability of retrospective reports*

Several methods were employed to assess various aspects of the reliability of the retrospective reports. The first, alluded to earlier, was to assess the agreement between two different judges who categorized subjects on the basis of their written reports in the second experiment. Each judge classified the 100 subjects as Abstract Directional, Concrete Properties, or Other/Not Clear. Table III shows that the two judges agreed on the classification of 82 percent of the subjects. Almost all cases of disagreement occurred when one judge classified a subject as using one of the two identified strategies, but the other judge classified the subject as using an Other/Not Clear strategy. Compared to several additional studies[9] the consensus shown in Table III is the "worst case." Other estimates of interjudge agreement have ranged up to 95 percent.

A second analysis assessed the agreement among different methods of reporting in the second experiment. The pictures drawn and forced-choice strategy selections made by subjects were compared to the classification of their written reports. Pictures were classified as indicating the Concrete Properties strategy if they depicted geometric objects with altered physical properties (e.g., a pockmarked surface

Table III—Classification of written reports by two judges (Experiment II)

| | 2nd Judge's Categories | | |
|---|---|---|---|
| 1st Judge's Categories | Concrete Properties | Abstract Directional | Other/Not Clear |
| Concrete Properties | 18 | 0 | 6 |
| Abstract Directional | 1 | 42 | 5 |
| Other/Not Clear | 3 | 3 | 22 |

depicting "rougher," shading depicting "darker," etc.). Pictures showing horizontal or vertical orderings of rather standard geometric figures were classified as indicating the Abstract Directional strategy. The classification of drawings agreed with the classification of written reports for 56 of the 60 subjects (93.3 percent) whose written reports had been classified by consensus as Abstract Directional or Concrete Properties. The analysis of forced-choice strategy selections showed that 51 of the 60 subjects (85 percent) chose the strategy description consistent with the classification of their written report.

To assess the long-term stability of reported reasoning strategies, 38 subjects who participated in the second experiment and who had been classified by consensus as Abstract Directional or Concrete Properties Thinkers were recalled six months later for another study. After solving some warm-up problems, subjects gave written reports describing their reasoning strategies. These reports were classified in the previously described manner and this classification was compared to the classification of the subjects performed six months earlier. The results in Table IV indicate that subjects' reports about reasoning have some, but not perfect, stability over time and across different presentation conditions (the former reports were given after listening to problems, the latter after reading problems). The stability of verbal reports estimated by the four-fold point correlation based on Table IV is $r = 0.59$ ($p < 0.01$). Specifically, 95-percent of the subjects earlier classified as Abstract Directional again reported that strategy, but only 59 percent of the original Concrete Properties Thinkers reported that strategy again six months later. The instability of the latter group may have been due to unreliable reports or classification procedures on one hand, or actual changes in reasoning strategies[9] on the other.

### *2.4 Summary*

The reliability of retrospective reports about reasoning has been established in that: (1) different judges show considerable agreement on how to classify reports, (2) the classification of written reports agrees to a large extent with classifications based on other nonverbal methods of reporting, and (3) the classification of reports given by

Table IV—Number of subjects using strategies initially and six months later

| | Strategy Used Six Months Later | |
|---|---|---|
| Strategy Used Initially (Experiment II) | Abstract Directional | Concrete Properties |
| Abstract Directional | 20 | 1 |
| Concrete Properties | 7 | 10 |

people at different times has some stability. On the other hand, retrospective reports about reasoning or perhaps the present procedures for classifying reports are not perfectly reliable. Compared to paper-and-pencil tests having finely graded scores, the reliability of retrospective reports is somewhat low. In particular, the classification of reports given at different times and under different conditions of presenting problems is not always the same. Despite these difficulties, the great majority of retrospective reports about reasoning in these studies contain sufficient information to be classified consistently. This is a necessary condition for reports to be useful in exploring the process of reasoning.

## III. DO PEOPLE WHO REPORT DIFFERENT REASONING PROCESSES ACTUALLY REASON IN DIFFERENT WAYS?

### *3.1 Approach*

Reasoning errors from the two studies previously described will be used to analyze the validity of retrospective reports about reasoning and to gain further understanding of reasoning processes. Error data from the two groups of subjects reporting different reasoning strategies will be compared at successively finer levels of detail. The overall error rates from the two groups will be analyzed first. Then, general patterns of interaction in the error data will be discussed. Next, the effects of specific problem factors hypothesized to affect a particular reasoning process will be tested. Finally, two models of the process of making a transitive inference will be described and tested. The goal of this section is to demonstrate that different models of the reasoning process are required to account for reasoning errors made by the two groups of subjects who reported different reasoning strategies.

### *3.2 Differences in reasoning errors between groups reporting different strategies*

The first attempt at assessing the validity of retrospective reports asked whether the overall reasoning error rate was different for people giving different reports. In the two studies described above, subjects giving Abstract Directional reports made significantly fewer errors than those giving Concrete Properties reports. In the first study, Abstract Directional Thinkers had an error rate of 10.3 percent compared to the Concrete Properties Thinkers' error rate of 38.0 percent. In the second study, the corresponding error rates were 21.0 percent and 27.9 percent. This difference in error rate favoring the Abstract Directional subject now has been found repeatedly.[10] One interpretation of this result is that the Abstract Directional strategy is more efficient for the transitive inference problems used in these studies.

A further study[9] required subjects to describe their reasoning processes at a number of points in a lengthy sequence of three-term series problems. In that study, a change in the strategy reported by a subject was accompanied by a corresponding change in the reasoning error rate. Thus, if a subject reported shifting from the Concrete Properties strategy to the Abstract Directional strategy, the subject's performance improved. For subjects reporting no shift in reasoning strategy, reasoning performance was fairly stable at a low or high level, depending on the strategy reported. This study provides evidence of the validity of different reports given by the same subject. It also suggests why reports by some subjects changed after six months in the previous study: the subjects' reasoning processes may have changed over time.

People reporting different reasoning strategies not only exhibited different overall levels of reasoning errors, but they also exhibited different patterns of reasoning errors. This fact is demonstrated in a general way by a statistically reliable interaction between Report Groups and Problem Types found in the two original experiments.[8] This interaction means that factors causing reasoning problems to be more or less difficult in one group of reasoners were not the same as the factors causing difficulty in the other group. People who gave different reports made different amounts and different kinds of reasoning errors.

Thus far, the validity of reports has been assessed in a formal but rather indirect way. At the next level of detail, we might ask whether the patterns of reasoning errors made by subjects are consistent with the reasoning process subjects claim to be using. Consider reports of Abstract Directional Thinkers who claim to construct an ordered mental array of the geometric terms used in these problems. Previous theories[11,12] have asserted that it should be easier to construct a direct spatial array from the ends toward the middle, rather than from the middle outward. This so-called "end-anchoring principle" leads to a prediction regarding the difficulty of solving various types of three-term series problems. For Abstract Directional Thinkers, reasoning errors in a problem should be directly related to the number of premises that have the middle or pivot term stated first. For people using the Concrete Properties strategy, the end-anchoring principle should be irrelevant.

This prediction was confirmed by patterns of reasoning errors. In both studies, reasoning error rate for Abstract Directional Thinkers was a monotonic function of the number of premises in a problem that began with the middle or pivot term. This factor accounted for highly significant amounts of the variance in the difficulty of different types of problems for Abstract Directional Thinkers (82.2 percent of the variance in Experiment I, 71.8 percent in Experiment II). Data for

Concrete Properties Thinkers were quite different. Reasoning error rate was not a monotonic function of the number of pivot-first premises in either experiment, and this factor accounted for much smaller amounts of the variance in problem difficulty for this group of subjects (17.6 percent in Experiment I, and 20.3 percent in Experiment II). This analysis suggests that Abstract Directional Thinkers are constructing a mental array as they report, and that Concrete Properties Thinkers are reasoning in a different way.

Other analyses of specific problem factors[8] have found that reasoning errors by Concrete Properties Thinkers depend on the number of inverses used in a problem (e.g., using words like "smoother" and "thinner"), as well as the number of times a relation and inverse are alternated in the statement of a problem. Inverses cause extra difficulty for Concrete Properties Thinkers because concrete representations of a property like smoothness may not be as easy to generate as concrete representations of a property like roughness. Abstract Directional Thinkers were less sensitive to such factors. The most difficult kind of problem for Concrete Properties Thinkers was one with premises like, "Circle is rougher than square. Circle is smoother than triangle." In such problems, the Concrete Properties Thinker presumably imagines first a rough circle next to a square, and then imagines a smooth circle next to a triangle. Such problems are difficult to answer when this inconclusive image is scanned.

### *3.3 Two models of reasoning*

Models attempting to capture the reasoning process used by Abstract Directional and Concrete Properties Thinkers are presented in Tables V and VI, respectively. These models try to give a coherent account of the patterns of reasoning errors and the kinds of reports given by subjects. Each model contains parameters representing hy-

Table V—Model for abstract directional thinkers

| Process | Problem Factors | Model Parameters |
|---|---|---|
| 1. Encode Premise 1 | | |
| 2. Establish abstract scale | | |
| 3. Arrange first two terms placing grammatical subject first on scale | | |
| 4. Encode Premise 2 | | |

| 9. Respond | | |

Table VI—Model for concrete properties thinkers

| Process | Problem Factors | Model Parameters |
|---|---|---|
| 1. Encode Premise 1 | | |
| 2. Generate Image Pair 1 by assigning property to grammatical subject | Is difficult (inverse) relation used? | GENERATE |
| 3. Encode Premise 2 | Is relation the same as that in #1? | ENCODE |
| 4. Generate Image Pair 2 by assigning property to grammatical subject | Is difficult (inverse) relation used? | GENERATE |
| 5. Encode question | Is relation the same as that in #3? | ENCODE |
| 6. Scan images | Are the images conclusive? | SCAN |
| 7. Respond | | |

pothetical mental processes that are executed various numbers of times depending on the structure of a specific type of problem.

### *3.3.1 The abstract directional model*

Abstract Directional Thinkers (see Table V) are assumed to encode the first premise and establish a mental scale for a problem. Then, the two terms stated in the first premise are arranged on the scale, the grammatical subject being placed first. The second premise is then encoded, and the subject searches for the third, or missing, term. This search is easier if the third term is the grammatical subject rather than the object of the second premise. The value of the SEARCH parameter (0 or 1, respectively) reflects this difficulty, and accounts for the effect of starting the second premise with the pivot term. Next, the third term is positioned on the mental scale, and it is assumed that there are three distinct cases for this operation. The easiest case (POSITION = 0) occurs when the third term is placed next in the sequence established by the first two terms. For example, if the first two terms are arranged smooth → rough, positioning the third term is easiest if it is roughest. If the first two terms are placed rough → smooth, then positioning the third term is easiest when it is the smoothest. Two more difficult cases exist and correspond to problems beginning with a pivot-first premise. In the easier of these cases (POSITION = 1) the third term does not fall next in sequence, but instead it must be placed at the end of the scale associated with the relation. In the remaining, most difficult case (POSITION = 2), the third term again does not fall in sequence, but must be positioned at the end of the scale associated with the inverse.

### *3.3.2 The concrete properties model*

The model for Concrete Properties Thinkers suggests that these subjects generate and compare images of objects having the stated properties. For each premise, Concrete Properties Thinkers (Table

VI) are assumed to encode the premise and then generate an image pair in which the grammatical subject takes on the property stated in the premise, while the grammatical object remains neutral. After two such pairs have been generated, the question is encoded, and then the two image pairs are scanned for the answer. Differences in difficulty among problems are assumed to arise from three sources, each corresponding to a parameter in the processing model for Concrete Properties subjects. One kind of difficulty has to do with whether the relation or inverse is used in each premise. Using an inverse presumably makes the appropriate image pair more difficult to generate. For a given problem, the parameter GENERATE takes on a value equal to the number of difficult images required (0, 1, or 2). The parameter ENCODE reflects the difficulty of alternately accessing a relation and its inverse. This parameter equals the number of alternations between a relation and inverse as a problem is read (0, 1, or 2). Finally, the parameter SCAN reflects the difficulty of dealing with images that are inconclusive. As noted previously, problems in which the B term takes on a property in one image pair and then takes on the inverse property in the other pair are especially difficult for Concrete Properties Thinkers. Such problems produce inconclusive image pairs in which the A and C terms are both neutral. Confronted with this type of problem, Concrete Properties Thinkers may guess or reformulate one of the premises to arrive at an answer. The SCAN parameter has the value 1 for such problems and 0 otherwise.

### *3.4 Comparing models to data*

The two models were compared to the data of Abstract Directional and Concrete Properties Thinkers from each experiment. The proportion of variance in problem difficulty uniquely associated with each parameter in each model was determined by stepwise multiple regression. The data are shown in Table VII. For both experiments, the Abstract Directional model was the better predictor of performance for Abstract Directional Thinkers, while the Concrete Properties model was the better predictor for Concrete Properties Thinkers. If errors on the various problem types are combined across experiments, the Abstract Directional model accounts for 90.3 percent of the variance in problem difficulty for Abstract Directional Thinkers (the Concrete Properties model accounts for 80.4 percent of the variance for this group). Both the SEARCH and POSITION parameters account for significant and unique portions of variance in problem difficulty for Abstract Directional Thinkers. The Concrete Properties model accounts for 80.1 percent of the variance in problem difficulty for the combined Concrete Properties Thinkers (the Abstract Direc-

Table VII—Proportion of variance* in problem difficulty attributable to parameters of two models

| | Abstract Group | Concrete Group | Abstract Group | Concrete Group | Abstract Group | Concrete Group |
| Abstract Directional Model | | | | | | |
| 1. SEARCH | 0.576† | 0.021 | 0.668† | 0.105 | 0.668† | 0.076 |
| 2. POSITION | 0.288† | 0.305‡ | 0.208† | 0.201 | 0.235† | 0.311‡ |
| $\sum R^2$ | 0.864† | 0.326 | 0.876† | 0.306 | 0.903† | 0.387‡ |
| Concrete Properties Model | | | | | | |
| 1. SCAN | 0.794† | 0.372‡ | 0.724† | 0.374‡ | 0.768† | 0.474† |
| 2. GENERATE | 0.001 | 0.185‡ | 0.016 | 0.166‡ | 0.011 | 0.221† |
| 3. ENCODE | 0.024 | 0.079 | 0.024 | 0.087 | 0.025 | 0.106‡ |
| $\sum R^2$ | 0.819† | 0.636† | 0.764† | 0.627† | 0.804† | 0.801† |

* These proportions are increments in $R^2$ values due to each parameter. The order in which the parameters are given corresponds to the step at which they entered the regression equation for the group of subjects appropriate to a particular model.

† $p < 0.01$

‡ $p < 0.05$

tional model accounts for 38.7 percent of the variance for this group), and each of the parameters SCAN, GENERATE, and ENCODE accounts for significant and unique variance.

Two aspects of the results of the model-fitting procedure should be clarified. First, the reliability of the error rates on the 16 problem types imposes a theoretical upper limit on the amount of variance for which any model can account. Therefore, it is important to estimate the data's reliability and compare that estimate to the $R^2$ of the best-fitting model.

Reliability estimates suggest that it would be difficult to improve the fits of the models appropriate to each group of subjects in Table VII. The estimated reliability of the Abstract Directional data combined across experiments was 0.951, so the Abstract Directional model ($R^2 = 0.903$) accounted for 0.903/0.951 or 95.0 percent of the reliable variation in the Problem Type data for those subjects. The fit of the Concrete Properties model ($R^2 = 0.801$) actually slightly exceeded the theoretical upper limit of the reliability of the combined Concrete Properties data (estimated reliability was 0.727).

Second, it is important to note that certain parameters of the two models are correlated in the 16 problem types used. The most important example of this confounding occurs for the parameter SCAN in the Concrete Properties model, which is correlated with both the SEARCH and POSITION parameters in the Abstract Directional model. These correlations account for the contribution of SCAN to variance in problem difficulty for Abstract Directional subjects. This interpretation of the contribution of SCAN is consistent with the fact that it is the only parameter in the Concrete Properties model that correlates with performance for Abstract Directional subjects, and that the two-parameter Abstract Directional model accounts for more variance in that group than the three-parameter Concrete Properties model.

### *3.5 Summary*

Retrospective reporting under the conditions studied here apparently is one case in which reports about reasoning processes contain valid information. The fact that the two groups of people who reported different reasoning strategies actually reasoned in different ways is supported by (1) the different overall levels of reasoning errors made by the two groups, (2) the different general patterns of reasoning errors made by the groups, (3) the differential effects of specific problem factors hypothesized to influence difficulty in one group but not the other, and (4) the fits of different process models of reasoning to the reasoning error data of the two groups.

## IV. CAN PEOPLE BE TRAINED TO USE DIFFERENT REASONING PROCESSES?

### *4.1 Approach*

A further study[9] dealt with the question of whether people can be trained to use different reasoning processes. In that study, 65 adult women solved a small number of three-term series problems and reported their reasoning processes. As in the experiments described previously, these reports identified the reasoning strategies that subjects spontaneously used. The subjects were then randomly assigned to two groups. One group received training in applying the Abstract Directional strategy to a new set of three-term series problems. The other group was trained to apply the Concrete Properties strategy to the same problems. Reasoning errors made by the two groups of subjects after receiving training were compared.

### *4.2 Training in reasoning strategies*

The training consisted of short descriptions of the models in Tables V and VI and examples showing how to apply them. The training was tailored specifically to a new set of problems involving the relation/inverse pair happy/sad. The terms for these problems were the names of three imaginary people, "Rich", "Dot", and "Harry". A typical problem was therefore, "Rich is happier than Dot. Harry is sadder than Dot. Is Harry happier than Rich?"

Subjects in the Concrete Properties training group were told to represent premises by vividly imagining faces having different features. Illustrations of the faces were drawn such that the people's names suggested the image of the correct face. Thus, "Rich" was depicted as a man wearing an expensive top hat, "Dot" was drawn with freckles, and "Harry" was pictured with a beard and mustache. Subjects were told to represent each premise by visualizing a pair of faces in which the face of the grammatical subject was smiling or frowning, depending on the wording of the problem. The two pairs of images then were to be scanned to answer the question for each problem.

Subjects given the Abstract Directional training were told to imagine a scale with "Sad" on the left and "Happy" on the right, and to place the names of the people on the scale appropriately as a problem was read. The order of the names on the scale then was to be used to make the transitive inference required to answer the question.

Following training, subjects solved 32 happy/sad problems. Subjects next rated the difficulty of applying the strategy they were trained to use. The rating scale ranged from 1 (extremely easy to use the strategy) to 6 (extremely difficult to use the strategy). After giving these ratings,

subjects described the strategy they would have used if they had not received training.

### *4.3 Results of strategy training*

Reasoning errors made by the two training groups were compared at successively finer levels of detail. The analyses parallel those applied previously to errors from subjects giving retrospective reports of spontaneously adopted strategies.

First, the group trained to use the Concrete Properties strategy had a significantly higher overall error rate (34 percent) than the group trained in the Abstract Directional strategy (17 percent). Second, the two training groups exhibited different general patterns of reasoning errors, as indicated by a statistically reliable interaction of training groups and problem types. Third, the specific problem factors found to distinguish the spontaneous report groups had analogous effects in the training groups. Errors made by the Abstract Directional training group were related strongly to the number of premises in a problem beginning with the pivot term (the "end anchoring effect" described previously), but were not strongly related to the number of inverses in a problem (uses of the word "sadder"). Subjects trained in the Concrete Properties strategy tended to show the complementary pattern. Fourth, when the process models in Tables V and VI were fitted to the error data of each group of subjects, the appropriate process model gave the better fit in each case (see Table VIII).

Two further analyses related the strategy reported by subjects prior to receiving training to their performance after training. In the first of these analyses, subjects were grouped by the strategy they reported prior to training, and the reasoning errors of the different groups were

Table VIII—Proportion of variance* in problem difficulty attributable to two strategy models

| Parameters | Abstract Directional Group | Concrete Properties Group |
|---|---|---|
| Abstract Directional Model | | |
| 1. SEARCH | 0.691† | 0.330‡ |
| 2. POSITION | 0.003 | 0.198 |
| $\sum R^2$ (Percent of Reliable Variance) | 0.694† (93.9%) | 0.528† (57.4%) |
| Concrete Properties Model | | |
| 1. SCAN | 0.372‡ | 0.743† |
| 2. GENERATE | 0.067 | 0.113‡ |
| 3. ENCODE | 0.014 | 0.012 |
| $\sum R^2$ (Percent of Reliable Variance) | 0.453 (61.3%) | 0.868† (94.4%) |

* These proportions are increments in $R^2$ values attributable to each parameter. The order in which parameters are given corresponds to the step at which they entered the regression equation.
† $p < 0.01$
‡ $p < 0.05$

compared (see Table IX). The general result was that subjects trained to use the Abstract Directional strategy made fewer errors than those trained to use the Concrete Properties strategy no matter what strategy was initially reported. This result suggests that people can be trained to use a particular reasoning strategy even if they have not adopted that strategy spontaneously.

Subjects given Concrete Properties training rated their strategy significantly more difficult to use ($\bar{x} = 3.81$) than those given Abstract Directional training ($\bar{x} = 2.36$). These ratings then were related to the strategy reported by subjects prior to training. All subjects given Abstract Directional training found that strategy relatively easy to use no matter what their initial strategy had been. For people trained to use the Concrete Properties strategy, the results were different. The Concrete Properties strategy was rated more difficult to use by Abstract Directional Thinkers ($\bar{x} = 4.41$) than by Concrete Properties Thinkers ($\bar{x} = 3.20$). Virtually all the subjects who initially reported using the Abstract Directional strategy indicated that they would have applied that strategy to the happy/sad problems if there had been no training. This pattern of results suggests that people can appreciate a good reasoning strategy: subjects rated a less efficient reasoning strategy as "difficult to use," especially if they knew a more efficient strategy.

### *4.4 Summary*

People can be trained to use different mental processes for making transitive inferences in three-term series problems. This fact has been demonstrated by analyses of the reasoning errors made by people after receiving training in different strategies. Results closely parallel the results of previous analyses of errors made by people retrospectively reporting the different reasoning strategies. Further results suggest that training in a particular strategy can be effective even for those people who did not report the strategy in spontaneous reasoning. People also appear to be sensitive to the difficulty of using various reasoning strategies, and rate a less efficient strategy "difficult to use," especially if they know a better one.

Table IX—Reasoning error rates made by subjects after strategy training

| | Strategy Reported Prior to Training | | |
|---|---|---|---|
| | Abstract Directional | Concrete Properties | Other/Not Clear |
| Strategy trained to use | $\bar{X}$ (N) | $\bar{X}$ (N) | $\bar{X}$ (N) |
| Abstract Directional | 0.10 (12) | 0.09 (6) | 0.25 (15) |
| Concrete Properties | 0.33 (11) | 0.33 (5) | 0.36 (16) |

## V. GENERAL DISCUSSION

### *5.1 Retrospective reports about reasoning*

These studies provide a direct test of the reliability and validity of retrospective reports about reasoning. Generally, reports by different subjects contained sufficient information to classify the subjects consistently. The content of subjects' reports also was related systematically to the patterns of reasoning errors subjects made.

While retrospective reports proved very useful in these studies, they also had definite limitations. The classification of different people on the basis of their reports was not perfectly reliable. Another limitation was that a sizable minority of people gave reports that were either idiosyncratic or incoherent (Other/Not Clear reports). Subjects also reported metaphors or general descriptions of reasoning strategies (see Table II) rather than complete and detailed models like those in Tables V and VI. Using a crude classification rule, the majority of subjects' reports could be grouped reliably into two categories, and people giving different kinds of reports tended to exhibit different amounts and patterns of reasoning errors.

The fact that different people reported and used different reasoning processes has two practical implications. One is that it may be possible to obtain useful reports of reasoning-like processes in practical situations where a procedure or device is to be evaluated. Reports may lead to redesigning tasks to make them more compatible with people's reasoning processes. Another implication is a methodological suggestion. If reports on reasoning-like processes are used, it may be wise to obtain them from a large number of different people to gauge the range of mental processes people are likely to adopt.

The general conditions under which retrospective reports about thought processes are reliable and valid remain to be established. The method used in these studies was to have subjects carefully describe how they thought through specific kinds of problems immediately after attempting to solve a large number of the problems. Subjects were not asked why they chose a particular strategy, a kind of judgment that people are notoriously poor at making.[13] Subjects also were not asked to "think out loud" while solving problems, a technique that might have yielded more precise descriptions of the reasoning process. The cost of that technique in the present experiments on reasoning is that it would have prevented the collection of unbiased reasoning error data, and therefore would have clouded the test of the validity of reports. For other purposes, the technique of "thinking out loud" may be quite acceptable. What kinds of mental processes are reportable and which techniques are best for reporting them are two questions that must be answered before reports about thought processes generally can be used with confidence.[14]

### *5.2 Differences in people's reasoning*

An important result of these studies is that different people spontaneously adopted different reasoning strategies for solving very simple, highly stereotyped, three-term series problems. Different models of reasoning processes accounted for large amounts of the variance in problem difficulty for people classified as using different reasoning strategies. These models also received support from results of the training study in which people were directed to use one reasoning strategy or the other (Table VIII). While the process models provide a good first approximation to the reasoning processes employed by different people, the more basic and important result is that people spontaneously reason in different ways.

Training has been shown to cause people to adopt different reasoning processes in a rather simple way: people can follow different sets of directions on how to reason. Subsequent studies[9] identified two other factors that influence in a subtle way whether people use one reasoning strategy or another. One factor is aptitude for visualizing spatial transformations of figures. People good at spatial visualization are more likely to adopt the Abstract Directional strategy spontaneously than those who have difficulty with spatial visualization. The use of different reasoning strategies for three-term series problems is not, however, influenced by verbal aptitude. A second factor influencing the adoption of a reasoning strategy is the context in which reasoning problems are posed. The strategy used for a particular problem is influenced by surrounding problems. Some context problems apparently suggest or allow the development of good strategies while others inhibit strategy development.

A new theory of reasoning is required to account for differences in people's reasoning. The emerging picture includes a dynamic and modifiable process in which reasoning strategies are developed. This phase of strategy development may be influenced by people's basic capacities, the context in which the reasoning occurs, and training. The fact that people can rate the difficulty of using different reasoning processes suggests that feedback of this kind also may be involved in strategy development. Certainly this picture is a far cry from the idea that reasoning is a fixed ability in which people differ by the amount they have or how well they can perform. The emerging picture holds the hope that reasoning processes used by different people can be understood, and that the understanding might lead to redesigning some tasks that many people find very difficult.

### *5.3 Training in reasoning*

The training study reviewed here demonstrates that people can learn to use different reasoning processes with consequent effects on

their reasoning performance. A good characterization of the Abstract Directional training would be that it suggested an efficient general approach that most subjects could use, but that some subjects would not have discovered spontaneously. This result tends to confirm informal observation that a suggested strategy for dealing with a complex problem (e.g., thinking of a queueing problem in terms of a "pushdown stack", adopting spatial metaphors for programming problems, etc.) can be very helpful and will lead to certain patterns of performance. Perhaps there are many situations in which directions on "how to think about" a task (e.g., activating a telephone service or interacting with a computer) might reduce errors and lead to more predictable patterns of performance compared to directions in which learners must develop a strategy on their own.

The training study did not address the very important question of whether people can be trained to reason better in general. It is unlikely that the effects of strategy training for a specific simple transitive inference problem would generalize to cause subjects to reason more efficiently in many other situations. People who in general are good reasoners probably have discovered and used a large set of strategies that they can retrieve in given situations. Because of their basic capabilities (e.g., good spatial visualization) and previous experience, good reasoners probably are also very good at generating new alternative strategies for novel problems. The results reviewed here suggest that people can be trained to deal more effectively with some specific situations involving reasoning. This basic fact certainly does not reduce the likelihood of finding ways to train people to reason better in a large range of situations.

## VI. ACKNOWLEDGMENTS

Dorothea Grimes-Farrow collaborated on the first two studies reviewed here. Peter Meany and Anthony Rooney assisted in collecting and analyzing data for several of the studies. E. Z. Rothkopf gave many helpful suggestions for revising previous drafts of this paper.

# New Technological Demands

The articles in this section sample a range of task requirements, from turning a knob to the complex motor activities involved in typing. The common objective in these studies is to find ways to make tasks fit the abilities and prior learning that humans bring to them.

Donegan and Koppes introduce three articles on perceptual and motor factors affecting the design of equipment used by craftspeople who install and maintain telephone equipment. These articles deal with knob characteristics (Kohl), cable splicing techniques (Paul), and the perceptual problem of locating corresponding terminals in two high-density connector fields that are mirror images of one another (Flamm). Finally, Cohen describes a study comparing the perceptual motor effects of typing with membrane keys, which move little when pushed, with conventional travel keys.

No fundamentally new human factors issue is addressed in the articles appearing in this section. They collectively illustrate that old questions will need new answers whenever the human/system interface changes.

# Human Factors Engineering for the Loop Plant

By J. DONEGAN* and D. N. KOPPES*

(Manuscript received

Bell System Loop Plant operations employ 150,000 craftspeople. New technology is changing the demanding jobs they perform, and the range of physical characteristics of craftspeople is increasing as women join the traditionally male work force. Both of these factors indicate the need for human factors contributions to designing the tools and apparatus that craftspeople use. This article introduces three other articles describing different aspects of human factors work for the Loop Plant.

## I. INTRODUCTION

The installation, testing, operation, and maintenance of the Loop Plant (the customer cable network) requires the full-time employment of some 150,000 outside plant and central office craftspeople—a significant portion of the total Bell System craft work force. An important element of the human factors work in the Loop Transmission Division is knowing the characteristics of the craftspeople and their tasks so that we may supply engineers with human factors criteria for the design of loop apparatus and systems.

The published literature on anthropometrics, biomechanics, human factors, and applied psychology is, of course, a valuable resource.

However, the literature is often incomplete with respect to Bell System tasks and the data often describe what can be done by people under ideal conditions, not what must be done by craftspeople under stressful conditions. Traditionally, physically demanding tasks have been performed by these craftspeople in suboptimal conditions: up on poles, down in manholes, and during foul weather conditions. While such work is still done, new technologies such as loop electronics, fiber-optic cable, and computer-controlled equipment have overlaid old jobs with more sophisticated tasks, requiring different physical and mental characteristics. Consider loop plant splicers responding to a major alarm concerning a fiber-optic cable repair. The first set of tasks could include lifting a 300-pound manhole cover, pumping "water" out of the manhole, and setting up a work station—perhaps 10 feet down, but still 10 feet from the bottom of the manhole. The next set of tasks could then involve the precision and fine manipulative skills described in the article entitled "Human Factors Comparison of Two Fiber-Optic Continuous-Groove Field-Repair Splicing Techniques" by Larry Paul, in which he compares two methods of field splicing fiber-optic cable that are currently under development at Bell Laboratories in Atlanta.

In addition to the introduction of new tasks, an increasing number of people of slight stature, particularly females, has altered the anthropometric characteristics of the loop plant work force. Where possible, the physically demanding tasks are redesigned to accommodate this new work force. A case in point is the ubiquitous use of torque knobs in loop plant equipment. In particular they are used to secure splicing equipment, and female craftspeople complain of difficulty in exerting enough torque to hold this heavy equipment in place. The experiment described in the article by George Kohl, entitled "Effects of Shape and Size of Knobs on Maximal Turning Forces Applied by Females," provided design guidelines for matching torque knob shapes and sizes with female capabilities.

The loop plant also includes two main areas for planned manual access to the network: the main distributing frame, and the feeder/distribution interface. At these points a constant "churning" of the loop network takes place in daily installation, removal, and rearrangement of cross-connecting wires. These areas have been very troublesome in the past and any new equipment, hardware, or tasks designed for these crucial access points are closely scrutinized to preclude wiring congestion or poor work practices. Well-motivated, trained craftspeople can always make equipment work but superior designs are required to accommodate the less skilled craftsperson who at one time or another will work on all of the in-place plant. Such attention to design detail and human factors issues is illustrated in the article by Lois

Flamm entitled "Performance in Locating Terminals on a High-Density Connector." This article describes an experiment that identified and helped resolve visual complexities associated with a new and compact protector block designed for use on the main distributing frame.

Many of the more significant loop plant hardware and systems developments are subjected to a full-scale evaluation at the Chester Field Laboratory.[1] Such evaluations take place prior to final production and utilize New Jersey Bell craftspeople to install, operate, and maintain preproduction models in realistic scenarios. However, laboratory experiments play a significant role at a much earlier stage of the design and development process. They may address questions related to the design of specific apparatus or resolve more general questions related to the capabilities of Bell System craftspeople. The articles by Lois Flamm, George Kohl, and Larry Paul are examples of such human factors experiments carried out in Department 54525 as an integral part of the development process of the new Loop Plant.

# Effects of Shape and Size of Knobs on Maximal Hand-Turning Forces Applied by Females

By G. A. KOHL*

(Manuscript received December 23, 1981)

Outside plant craftspeople use knobs to apply turning forces on clamp mechanisms that hold field equipment temporarily in place. A study was performed to develop a set of data that provide guidance for determining knob size and shape characteristics most appropriate for various outside plant working conditions. Forty female participants applied maximal isometric turning force to each member of a set of twenty experimental knobs that systematically varied in shape and size. In half the trials the participants applied force with greased hands and in the other half used nonslip compound. In addition, two arm-wrist positions were observed. In general, triangular knobs allow more hand torque to be generated and require significantly less material than square, pentagonal, hexagonal, or circular knobs of comparable size. However, this effect depends upon the arm-wrist position and grip conditions. A 3.5-inch turning diameter is desirable when both cost and performance are considered.

## I. INTRODUCTION

Outside plant craftspeople in the Bell System use knobs to apply turning forces on screw-operated clamp mechanisms used to hold heavy field equipment temporarily in place. Female craft who use these

knobs report that the knobs they currently use do not enable them to easily generate sufficient torque to clamp down equipment. The question raised by these reports and addressed here is: What characteristics of a knob allow turning forces to be easily generated? Considering the variety of torque knobs in the world (e.g., door knobs, small valve wheels, faucets), and the considerable body of knowledge the human factors community has acquired about control knobs, it is perhaps surprising to find that the literature sheds little light on this rather straightforward and practical question (see Refs. 1 and 2 for the best existing treatments of torque knobs).

The following experiment was designed to provide a set of data that can assist designers in developing torque knobs, and we hope will be of value to the hand tool industry in general. The approach taken in this study was strictly empirical and consisted of measuring the amount of turning force that participants can generate using knobs of various sizes and shapes under several different conditions.

## II. METHOD

### *2.1 Participants*

Forty right-handed females from the Whippany, New Jersey, area responded to newspaper and intracompany bulletin board ads, and served as paid participants. Mean and standard deviation of the group's age, height, and weight were respectively: 37 years, SD = 13.5; 64.7 inches, SD = 3.4, and 132 pounds, SD = 27.2.

### *2.2 Independent variables*

Variables were identified that could affect knob-turning performance, including features of the knobs and the conditions under which the knobs might be used. To render the study manageable in size, only five of the most intuitively and/or practically relevant variables to the Bell System application were included in the study.

#### *2.21 Knob shape*

There are a limitless number of possible knob shapes. A shape attribute, "sidedness," was chosen to succinctly capture the spectrum of shapes that could affect knob-turning performance. Five shapes were chosen, as shown in Fig. 1, varying from few sides to infinite sides (i.e., triangle, square, pentagon, hexagon and circle).

#### *2.2.2 Knob size*

An operational definition of size was generated so that knobs of different shapes could be compared. The "diameter" of a knob is the diameter of the circle bounding the outermost points of the knob. Thus the triangular knob always has about half the area of a circular

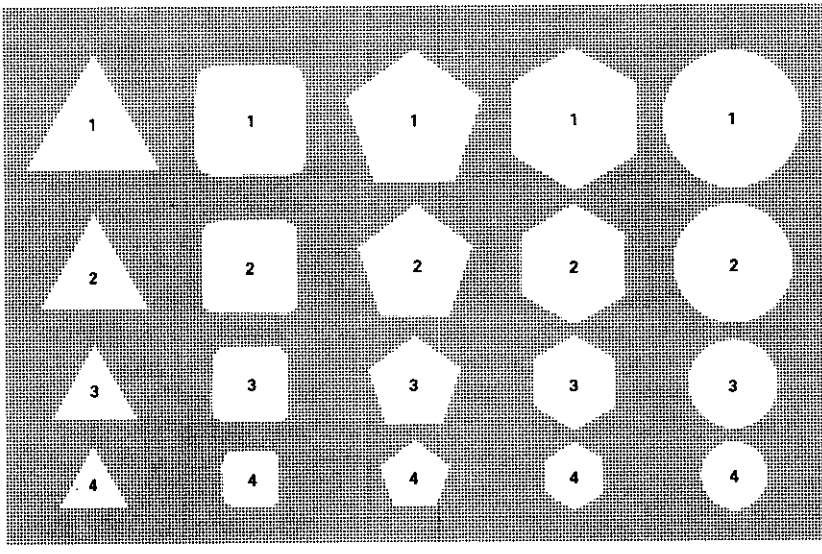

Fig. 1—The set of experimental knobs.

knob with an equivalent diameter. The definition has real-world validity in that the envelope in which a knob turns is likely to be a design constraint. Four diameter sizes were included in the study: 2.5, 3.5, 4.5, and 5.5 inches. Preliminary evidence showed these sizes to represent plausible end- and middle-point values for diameters of knobs to be used to generate turning force.

#### *2.2.3 Grip condition*

The types of knob surface conditions that could be tested are numerous, for example, knurled surfaces, serrated edges, slippery surfaces. The surfaces of the knobs in this study were all the same—smooth, anodized aluminum. However, an attempt was made to study the extremes of surface conditions by including two grip friction conditions under which the knob was turned. In the *greased* condition participants greased their hands before turning; in the *nonslip* condition they applied a nonslip compound.

#### *2.2.4 Position*

The hand-arm position was varied to emulate various real-world conditions, where knobs must be turned from many different vantage points. Two standing positions were included; in both conditions the height of the knob was adjusted to the level of the elbow joint for each participant. In the *front position* the participant stood straight in front of the knob, forearm parallel to the floor and perpendicular to the upper arm and frontal plane of the body, the axis of knob rotation

coincident with the longitudinal axis of the forearm. The wrist was bent so that the hand pointed up, the palm of the hand against the knob face, fingers spread around the knob edge. In the *side position* the participant stood to the side of the knob with the forearm parallel and perpendicular to the axis of rotation of the knob. The palm of the hand pressed against the face of the knob with the fingers spread around the knob edge.

#### *2.2.5 Participant size*

Size was included as a subject variable. Although hand size was originally targeted as the variable that would most affect performance, weight was found to be a better predictor.[3] Four weight groups of ten participants each were formed on a post hoc basis. The mean and standard deviation of the four group's weights in pounds were: 106 pounds, SD = 5.72; 120 pounds, SD = 3.65; 132 pounds, SD = 5.87; 171 pounds, SD = 22.96.

### *2.3 Experimental design*

A complete factorial design was employed (5 knob shapes × 4 knob sizes × 2 grip conditions × 2 positions × 4 participant weight groups). All participants were included in all possible within-participant treatment conditions.

### *2.4 Procedure*

Each participant attended for one day on two consecutive weeks for approximately four hours each day. On each day each participant performed four blocks of twenty trials, each block consisting of one appearance of each of the twenty knobs. For each trial participants were instructed to apply maximal isometric turning force to a knob specified by the experimenter, using the right hand for a period of three one-second beats of a metronome. The order of the knob appearance was randomized for each block of trials for each participant. On each day, the front position was employed on two blocks of trials, the side position on the other two; one of the side position and one of the front position trial blocks were performed with a greased hand. The remaining two blocks were performed using a nonslip compound.

Participants were observed in groups of three or four, every participant performing a single trial before any given participant performed her next trial. Roughly two minutes intervened between any given participant's trials, and breaks of twenty minutes were taken between blocks of trials.

### *2.5 The knobs*

The relative size and shape of the knobs is shown in Fig. 1. They were made of machined aluminum and had an anodized smooth

surface. All corners and edges of the knobs were rounded and the smallest radius on any edge was 0.25 inch. The knobs were 1.25 inches thick.

## III. RESULTS

The data were submitted to an analysis of variance,[4] with knob shape, knob size, grip conditions, position, and day of participation treated as within-subjects variables, and participant weight as a between-subjects variable. The most important results are summarized here.

The most informative effect obtained was a four-way interaction of the shape, size, position, and grip variables [$F(12,432) = 5.2$, $p < 0.00001$]. Fig. 2 shows this interaction. The top two panels show performance as a function of knob shape and size for the side position, the left panel for the nonslip blocks and the right panel for the greased blocks of trials. The bottom two panels show performance using the front position, the left panel for the nonslip condition and the right panel for the greased condition.

Several effects are apparent from a visual inspection of Fig. 2. The greased condition performance (right two panels) is lower than the nonslip condition [$F(1,36) = 289.6$, $p < 0.00001$]. Further, over all other variables, performance decreases as the number of knob sides increases [$F(4,144) = 183.2$, $p < 0.00001$]. This main effect is qualified by an interaction with the grip variable [$F(4,144) = 71.0$, $p < 0.00001$], indicating that the main effect of shape is much more pronounced in the greased condition than in the nonslip condition. Figure 3 shows this two-way interaction.

The effect of size is apparent in Fig. 2; across all other variables, the bigger the knob diameter, the more torque developed [$F(3,108) = 246.8$, $p < 0.00001$]. The left-to-right convergence of the curves in Fig. 2 reflects the two-way interaction of the knob size and shape variables: over all other variables, the greater the number of sides, the less advantage size has [$F(12,432) = 53.6$, $p < 0.00001$]. The fact that the convergence of the curves is more pronounced in the greased (right two panels) than the nonslip panels is reflected in a two-way interaction of knob shape, knob size, and grip condition [$F(12,432) = 8.4$, $p < 0.00001$]. The reversal of the sidedness advantage for smaller knobs in the nonslip, top left panel is counter to the patterns in the other three panels and is reflected as the four-way interaction illustrated in Fig. 2.

Participant weight was only a marginally significant main effect [$F(3,36) = 2.6$, $p < 0.07$] but did interact with the knob size variable [$F(9,108) = 4.8$, $p < 0.0001$], indicating that the advantage larger people have over smaller people dwindles as knob size decreases.

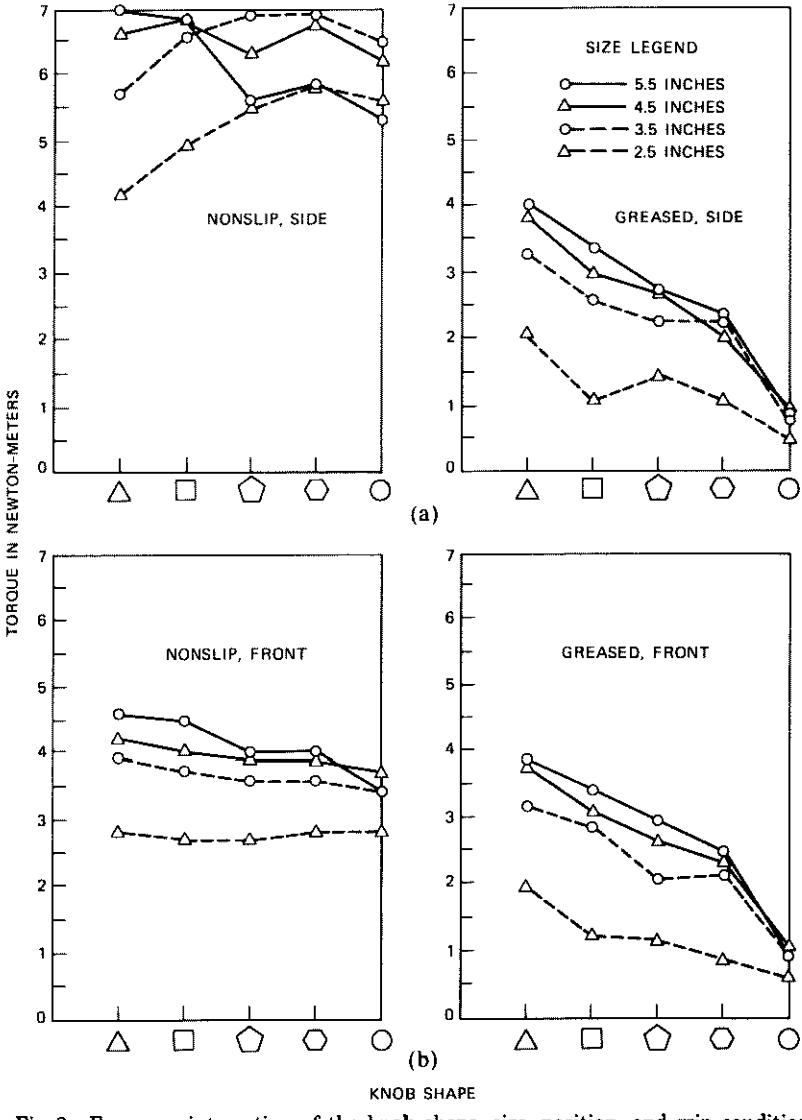

Fig. 2—Four-way interaction of the knob shape, size, position, and grip condition. (a) Performance as a function of the knob shape and size for side position. (b) Performance as a function of knob shape and size for the front position.

Several other main effects and interactions were obtained: position, day, grip × position, grip × knob size, position × knob size, position × shape, day × shape, grip × position × knob size, grip × position × shape, and position × knob size × shape.

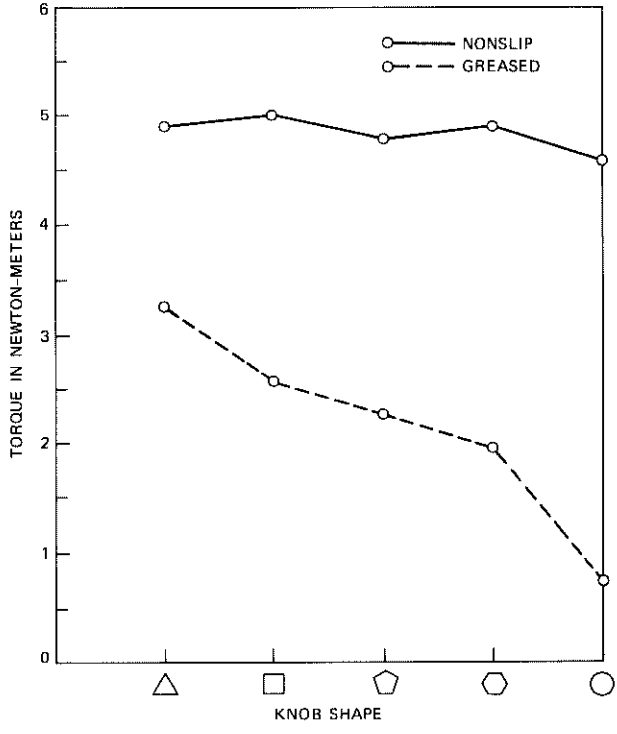

Fig. 3—Knob shape by grip condition.

## IV. SUMMARY AND DISCUSSION

The practical difference between means in Fig. 2 will have to be decided by individual designers. Note that if the application involves a nonslip, front approach, the shape of the knob has little effect, and the knob size is very important (Fig. 2, bottom left panel). However, in both the front and side greased conditions, shape is very important; note the smallest triangle results in better performance than the largest circle (Fig. 2, bottom right panel). The savings in materials in this case is roughly 10 to 1.

In general, triangular knobs allow for the generation of as much or more torque than any of the other shapes. However, subjective comfort ratings indicate that the smallest triangular knob causes discomfort. Also, the smallest triangular knob does not fair well in the nonslip, side condition. Therefore, for 2.5-inch diameter applications the square is probably a better choice.

The biggest jump in performance with respect to knob diameters comes between 2.5 and 3.5 inches; thereafter performance increases as diameter increases, but at a smaller rate.

Considering materials, torque and comfort, the triangular and square 3.5-inch knobs are recommended for general application. If more torque is required than can be obtained with these knobs, larger diameter triangular or square-shaped knobs should be used. For these or any other knobs, all corners and points should be rounded for best performance and comfort.

# Human Factors Comparison of Two Fiber-Optic Continuous-Groove Field-Repair Splicing Techniques

By L. M. PAUL*

(Manuscript received December 23, 1981)

Two Bell System fiber-optic splicing techniques that are under development were experimentally compared in a human factors study. In addition to splicing technique, the variables explored were the uniformity (evenness) of fiber spacing in the 12-fiber "ribbon," and the hand (preferred or nonpreferred) that was used to splice. Performance was measured by the time to insert fibers, the number of fibers broken, and the time taken to complete a series of insertions for each technique. The preference of the participants between the two techniques was also determined. All of the measures except participant preference showed the vacuum technique to be statistically superior to the hold-down bar technique, with participant preference suggesting the same conclusion, although it was not statistically significant.

## I. INTRODUCTION

A human factors study compared two techniques under development for the repair splicing of damaged Bell System fiber-optic cable in the field. The goal of the study was to determine the preferred technique from a human factors viewpoint. This information combined with economic considerations would then allow the technique's designers

to choose one of the techniques for further development and release to operating telephone companies.

## II. DESCRIPTION

Bell System fiber-optic cable consists of one to twelve multiple-fiber "ribbon" arrays. Each ribbon consists of twelve optical fibers embedded in a plastic tape. Currently, each ribbon of the cable is shipped with a silicon connector on each end to facilitate the splicing (joining) of the ribbons of one cable section to the ribbons of the next section.[1] In joining one ribbon to another, the splicer first places silicon wafers on either side of one ribbon array connector, forming a sandwich, and secures this arrangement with a spring clip. The second ribbon connector is then slipped into this sandwich and a second spring clip is added. The final operation consists of the application and curing of a refraction index-matching gel.

These procedures are reasonably straightforward and have been successfully used by operating telephone companies. On the other hand, in certain situations the splicer must refabricate a ribbon's silicon connector in the field.[2] Refabrication is required when the fragile silicon ribbon connector is received damaged, is damaged in craft handling, when it is necessary to reposition ("swap") fibers within the ribbon, or when an additional splice point becomes necessary. In part, refabrication involves grinding and polishing of the individual fiber ends in the reconstructed silicon connector to minimize losses when the connector is spliced (joined) to another connector. Although field refabrication is successfully being done by operating telephone companies as the field-repair method, the two techniques described in this report are being developed to simplify field-repair splicing basically by eliminating the grinding and polishing operations.

Figure 1 schematically depicts the continuous-groove approach shared by the two splicing techniques. In both techniques, the silicon array connectors are first removed from the ribbons to be spliced. After fiber preparation, which includes removing the plastic tape, removing the individual fiber coatings, and developing square fiber ends, fibers of one ribbon are "combed" into the set of 12 continuous grooves. The fibers of the second ribbon are then similarly inserted into the continuous grooves. Once the fibers of each ribbon are inserted, they are brought into proximity and index-matching gel is applied and cured as in the standard joining procedure. Thus connector refabrication, with its necessary grinding and polishing steps, and the subsequent connector joining have been eliminated and replaced by a single operation.

The two continuous-groove techniques that were evaluated differ in the method for inserting fibers into the continuous grooves. The

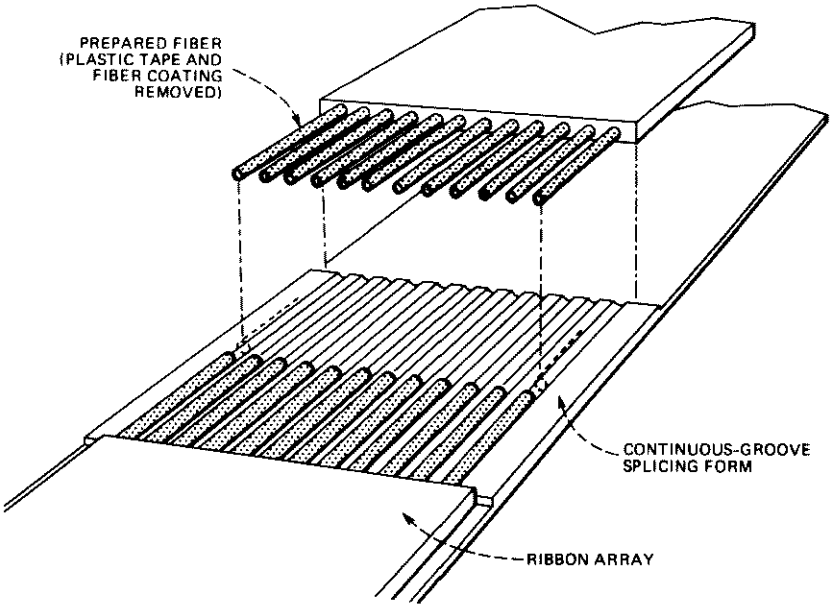

Fig. 1—Basics of a fiber-optic ribbon, continuous-groove splice.

vacuum technique uses a vacuum assist to help secure both the prepared fibers (tape and coating removed) and a portion of the ribbon beyond the prepared fibers. The splicer then uses a lateral motion to "coax" the 12 fibers into their respective grooves. In the hold-down bar technique, the splicer combs the prepared fibers into their respective grooves with the use of an alignment comb without any additional aid. The splicer first registers the twelve prepared fibers in the twelve slots of the alignment comb and then carefully pulls the ribbon back until the ends of the fibers go below a bar in the comb and fall to the continuous grooves below. The splicer then gently pushes the ribbon forward under the bar that holds the ribbon in the continuous grooves (hence the "hold-down bar" name), and pushes the ribbon along the continuous grooves to approximately the middle of the splicing form. The proprietary nature of these techniques, which are still under development, prohibit the use of photographs to illustrate the two techniques.

## III. HUMAN FACTORS EXPERIMENTAL COMPARISON OF SPLICING TECHNIQUES

A human factors study was designed to compare the two field-repair splicing techniques on the basis of craft performance. An analysis of the sequence of operations in the techniques suggested that the only difference between fully developed techniques would be the method of

inserting fibers into the grooves. Both techniques would likely share the same or similar methods of fiber preparation, index-matching gel application, etc. Therefore, it was decided to limit the scope of this study to assessing performance differences between techniques for successfully inserting fibers into the continuous grooves.

### *3.1 Method*

#### *3.1.1 Design*

The experiment was a within-participants design. Each participant was trained and tested under every combination of experimental variables. The three experimental variables were: splicing technique (vacuum or hold-down bar), fiber spacing uniformity (uniform or nonuniform), and splicing hand (preferred or nonpreferred).

Fiber spacing uniformity refers to the uniformity of spacing of the twelve fibers in the ribbon. Previous experience with handling of fibers showed that nonuniformly spaced fibers are more difficult to guide into grooved structures than uniformly spaced fibers. Nonuniformly spaced fibers can result from manufacturing and from the removal of the coatings on each fiber. Since nonuniform ribbons occur infrequently, they were created for the study by making a hole with a small awl in the plastic tape at the point where the prepared fibers emerge from the tape.

The third variable, splicing hand, was chosen to reflect the fact that *all* splicing techniques require the splicer to use both left and right hands on the ribbons coming from the left and right sides, respectively, and thus the potential interaction between splicing hand and field-repair technique is of interest. Although it is possible to rotate the splicing form so that the splicer uses the preferred hand for both ribbons, concern over building in transmission loss caused by bending the fibers precluded further consideration of this approach.

Four dependent measures selected to contrast the two field-repair techniques were:

1. Average insertion time
2. Number of broken fibers
3. Elapsed (clock) time
4. Participant preference.

Average insertion time, measured with the participants' knowledge, was the time between beginning an insertion and its successful completion. If a fiber was broken the clock was stopped, a new ribbon was provided, and the clock was restarted. Similarly, the clock was stopped and restarted if a question was asked or the experimenter wanted to clarify a procedure.

Elapsed (clock) time was simply the total time required to complete all 14 insertions required in each technique. It included training and

questions in addition to the actual insertion time reflected in the average insertion time.

Participant preference was gauged at the end of the experiment by asking the question: "If you were a Bell System splicer, which of the two splicing techniques you used would you prefer to use on a regular basis?"

#### *3.1.2 Experimental apparatus*

The work platform measured 14 × 24 inches and was chosen to closely approximate the current splicing work station. This rather small area is dictated by the limitations of many splicing situations. A stand-mounted 3× magnifier to allow close viewing of the fibers (approximate 0.005″ diameter with coating removed) and splicing form, and two halogen lamps to evenly illuminate the work station were chosen as a result of previous work. A beam splitter plate, television camera, and monitor comprised the observation system that allowed unobtrusive monitoring of participant performance and the demonstration of insertion technique by the experimenter, as discussed below.

#### *3.1.3 Procedure*

Participants were individually tested in a session lasting approximately two hours. They were first familiarized with Bell System fiber-optic cable and current procedures for splicing ribbons together. Half of the participants were then trained and tested on the hold-down bar technique first, with the other half receiving the vacuum technique first.

Training consisted of the experimenter demonstrating the correct insertion procedure. Participants first watched "over the experimenter's shoulder" and then observed the detailed aspects on the closed-circuit television monitoring system. After this initial training, all participants performed the sequence of splicing insertions outlined in Table I.

The first insertion was designed as practice with the participant using a uniform ribbon and his or her preferred hand. In addition, the ribbon was free, i.e., it was not anchored at one end. All subsequent

Table I—Sequence of experimental ribbon insertions for both splicing techniques

| Step | Fiber Spacing | Task |
|---|---|---|
| 1 | Uniform | Practice with free ribbon using preferred hand |
| 2 | Uniform | One practice insertion using preferred hand |
| 3 | Uniform | Six insertions alternating hands |
| 4 | Nonuniform | One practice insertion using preferred hand |
| 5 | Nonuniform | Six insertions alternating hands |

insertions were timed with the 20-inch ribbon anchored approximately 16 inches from the splicing form to simulate a ribbon emerging from a cable.

As shown in Table I, nonuniform ribbons were not introduced until later in the splicing sequence, and thus any comparison of the effect of fiber spacing uniformity on splicing performance within a particular splicing technique is confounded by the additional training for nonuniform ribbons relative to uniform ribbons. This point will be discussed further in Section 3.2.

After completing the insertion sequence using one splicing technique, participants were given a five-minute break and then trained and tested in an identical manner using the other technique. After completing both techniques, participants were asked a short series of questions to obtain more detailed information on their performance. Questions were asked concerning any hobbies requiring fine motor control such as knitting, use of glasses (including bifocals) during the experiment or at other times, general comments, and their preference between the two field-repair techniques.

#### *3.1.4 Participants*

It was considered useful to select two distinct subpopulations as participants, each with some degree of demonstrated motor skill, in order to be able to generalize the results of the experiment to operating telephone company craftspeople. Nine people from the Bell Labs wiring shop and nine from the Bell Labs clerical pool participated.

### *3.2 Results*

Performance of the two subpopulations, wiring shop and clerical, was virtually identical. The subpopulation variable was not significant ($F < 1$) and did not interact with any of the other independent variables. This similarity of results for the two subpopulations presumably reflects the fact that both groups did indeed possess a similar degree of general motor skill with which to approach the learning of this new motor skill.

#### *3.2.1 Average insertion time*

Figure 2 shows average insertion time for the nonpractice insertions (Steps 3 and 5, Table I) as a function of splicing technique and fiber spacing uniformity for all 18 participants. The superiority of the vacuum technique over the hold-down bar technique was significant [$F(1,16) = 19.6, p < 0.001, \mathrm{MS_e} = 0.52$]. This statistical superiority of the vacuum technique was obtained despite the fact that four participants had to be stopped on one or more insertion attempts using the hold-down bar technique and the time to that point used as an

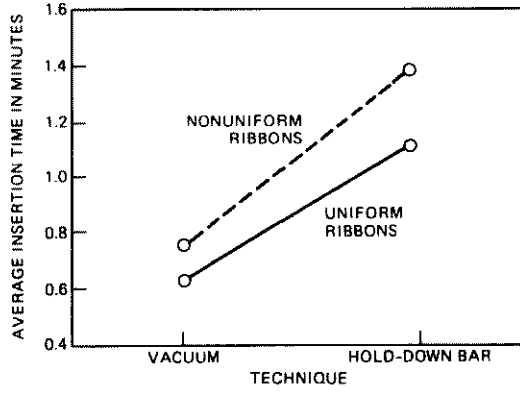

Fig. 2—Average insertion time on uniform and nonuniform ribbons for each splicing technique.

(under) estimate of that insertion attempt. Participants were stopped whenever an attempt exceeded approximately four minutes in order to allow completion of the experiment in a two-hour period.

The smaller average insertion time for uniform ribbons relative to nonuniform ribbons shown in Fig. 2 was statistically significant [$F(1,16) = 5.6$, $p < 0.05$, $MS_e = 0.23$]. As previously noted (and shown in Table I), nonuniform ribbons were presented after uniform ribbons, introducing a confounding between fiber spacing uniformity and training. However, since it is reasonable to assume that performance with the nonuniform ribbons benefitted from this additional training relative to the uniform ribbons, the smaller average insertion time for the uniform ribbons may be interpreted as a valid effect. Neither the interaction between splicing technique and fiber spacing uniformity, nor interactions between any of the other independent variables were statistically significant.

Participants performed marginally better with their preferred hand, although this difference was not significant ($p > 0.05$). The lack of an interaction between splicing hand and technique was surprising since a distinct preferred-hand advantage was expected for the hold-down bar technique given the motor skill required for this technique.

#### *3.2.2 Additional measures*

Table II contrasts the two field-repair splicing techniques using the other three dependent measures. The number of broken fibers was significantly less in the vacuum technique [$F(1,16) = 14.6$, $p < 0.005$, $MS_e = 3.25$]. No other main effects or two-way interactions were found using number of broken fibers as the performance measure. Elapsed (clock) time was also significantly less in the vacuum technique

Table II—Additional ribbon insertion measures

| Measure | Technique | |
|---|---|---|
| | Vacuum | Hold-Down Bar |
| * Number of broken fibers (total) | 4 | 24 |
| * Elapsed (clock) time | 33.6 min | 56.9 min |
| Participant preference (total) | 12 | 5 |

* Statistically significant at $p < 0.005$.

(Wilcoxon test, $p < 0.002$). Participant preference (with one abstention) favored the vacuum technique, although it was not significant as assessed by a Sign test.

## IV. DISCUSSION

### *4.1 Vacuum technique superiority*

The various measures strongly suggest the superiority of the vacuum technique over the hold-down bar technique. This superiority is basically a time advantage realized both directly in using the technique, and indirectly by reducing the number of repeated fiber preparations required when fibers are broken. However, it should be noted that 14 of the 18 participants were successful in completing all 12 of the nonpractice insertions required of them in the hold-down bar technique. Further, even the four participants who had to have one or more of their insertion attempts terminated because of time limitations completed at least 10 of the 12 attempts. This relative facility is important as it was not clear, a priori, whether inexperienced people could be easily trained to use the hold-down technique, especially with the brief (approximately 10-minute) training.

In interpreting the results of this study, it should be remembered that the study focused on only one of the operations required in field repair, i.e., ribbon insertion. Although ribbon insertion is undoubtedly the most difficult operation for the splicer, the time required by the other operations common to any field-repair technique may somewhat overshadow the vacuum technique time advantage. Thus, other factors such as economics and manufacturability are important in selecting the technique to be developed for release to the operating telephone companies.

### *4.2 Unanswered questions*

Two relevant human factors concerns remain unanswered by this study. One unknown is the amount of additional training that would be required to improve the performance of those people experiencing difficulty with the hold-down bar technique. A second question is the stability of the learned field-repair skills over time, i.e., the memory for the skills. The ability to perform either technique will probably

decrease as a function of the time since a person's last splicing experience. This forgetting is particularly relevant to the scenario in which a period of weeks or months elapses between splicing experiences. It is not clear, for example, that the vacuum technique would remain superior to the hold-down bar technique over time. Further studies will help to answer these questions.

# Performance in Locating Terminals on a High-Density Connector

By L. E. FLAMM*

(Manuscript received October 6, 1981)

In two experiments thirty participants located terminals on variations of a new main distributing frame connector. Abutting individual connectors in mirror image led to a higher termination density. Location times and errors were evaluated using deadline procedures. Experiment 1 results showed a high incidence of parallax, counting, and left-right reversal errors. Design modifications aimed at reducing these errors led to improved performance in Experiment 2. Parallax, counting errors, and location times were significantly reduced. The continued occurrence of left-right reversal errors is discussed.

## I. INTRODUCTION

Main distributing frame (MDF) connectors provide termination points for outside plant cable and protect central office personnel and equipment from harm due to foreign electrical potentials. Some connectors also have provision for making cross-connections. Over the years connector design has responded to increased space demands on main frames. A new 309-type protected connector achieves a higher density of terminations by putting two independent connectors to-

gether in mirror image. Although the physical arrangement of the two abutted connectors differs, functionally they are equivalent.

Figure 1 shows prototypes of the original 309-type connector and a modified version with designation labels to identify terminal numbers. The modified connector incorporates features based on recommendations from the human factors studies described below. The direct spatial correspondence between cross-connect and protector fields and the familiar grouping by fives or tens found on previous connectors is missing in the new composite. Because each connector row consists of two cross-connect pairs and five protector units, it was important that the designation labels reflect users' expectations of direction of count and facilitate their making the appropriate associations.

The aim of a preliminary pencil and paper experiment (unpublished) was to choose the most natural numbering scheme. For both connectors, results showed consistent but independent horizontal left-to-right counting patterns associated with cross-connect and protector locations. Concern was generated from the preliminary study about potentially high error rates within connectors and possible confusions between connectors. The loss of spatial correspondence with the new design and the above results led to the hypothesis that shading connector backgrounds would help users to localize specific cross-connect and protector terminals. In the first experiment, two shading schemes were compared with the unshaded connector version in both slow and fast deadline conditions. It was anticipated that any differences in performance between the shaded and unshaded connector versions would be more evident with the rigorous work pace of the fast deadline.

## II. EXPERIMENT 1

### *2.1 Method*

#### *2.1.1 Subjects*

The participants in Experiment 1 were 18 male Bell System employees, several of whom had relevant experience as craftspeople.

#### *2.1.2 Design and Materials*

The experiment can be characterized as a within-subjects design in which each participant located cross-connect pairs and protector units on each of the three connector versions in both deadline conditions. As schematically illustrated in Fig. 2, the version 1 connector represents the original prototype 309 connector with the preferred labeling; in addition versions 2 and 3 include cross-connect field background patterns grouping cross-connect pairs by fives and tens, respectively. The layout of each connector version is a mirror image, but the

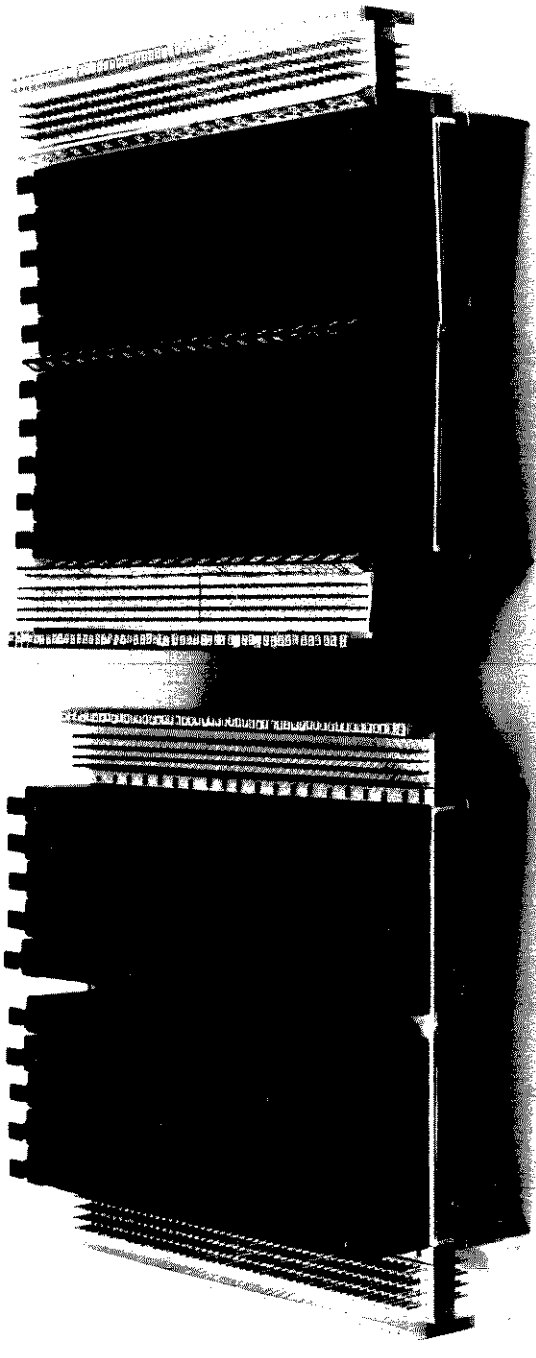

Fig. 1—Originally proposed (left) and modified (right) 309-type protected connector.

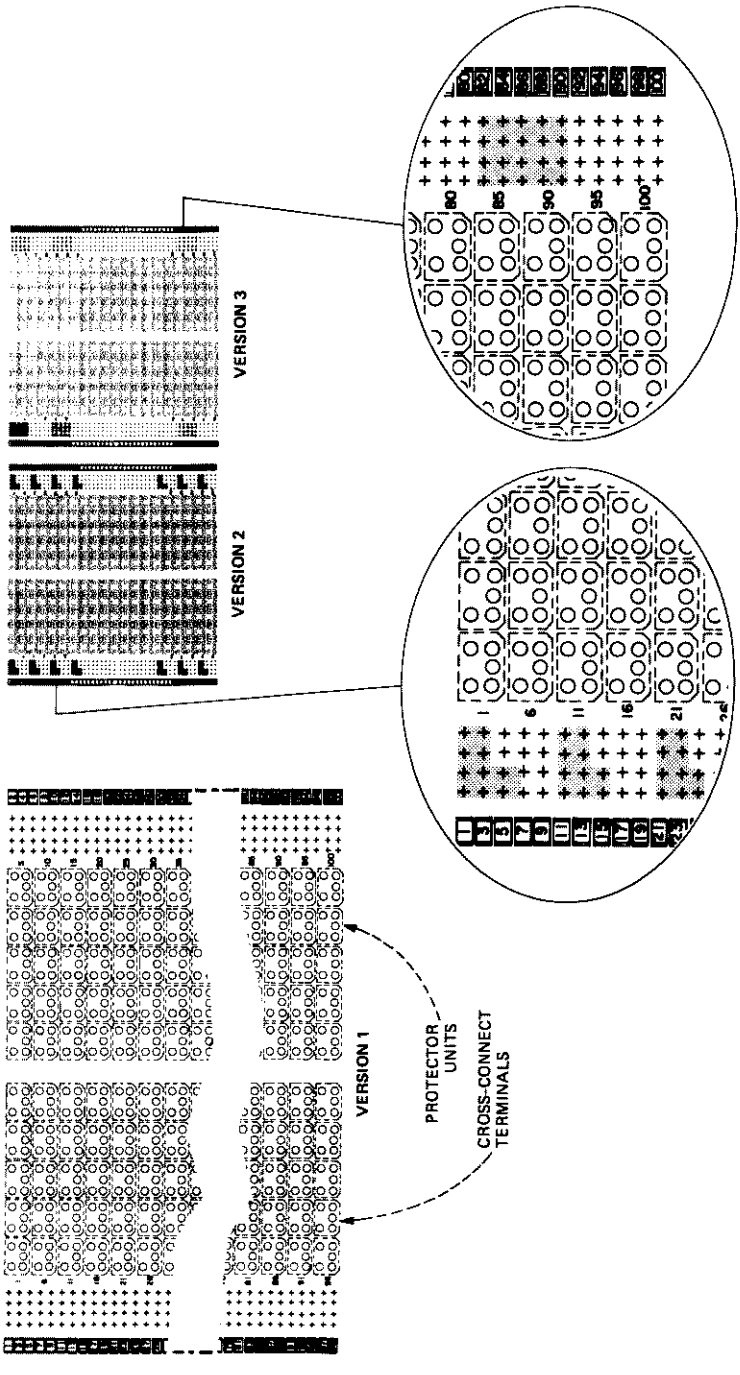

Fig. 2—Schematic illustrations of connectors (Experiment 1).

numbering scheme is not. The option of carrying the cross-connect field background patterns up to the designation strips was rejected as too costly. For purposes of these studies, the independent mirror image connectors of each version are labeled A and B.

A work assignment consisted of twenty trials of locating and marking cross-connect pairs and corresponding protectors. Cardboard trays with 20 plastic cups provided work assignment information. Each cup contained the material for one trial, a cross-connect cap and protector unit each marked with an A or B to designate which connector, and a specific number from 1 to 100 for position within the connector. Time to locate and install each set of cross-connect caps and protector units was recorded on a *Datamyte** Data Collector. If the participant did not complete a trial and press the response button by the imposed deadline, a brief beep occurred. The 34-second slow and 16-second fast deadline times were chosen from the results of a pilot study. In that study, response times measured in an unpaced task showed that 34 seconds was ample time to complete a trial and that a 16-second deadline would be inadequate about 50 percent of the time. Search time was measured as the interval between response button presses. In addition to time data, the position of each cross-connect cap and protector unit was recorded for identification of type as well as number of errors.

#### *2.1.3 Procedure*

Each participant completed a practice work assignment of ten trials followed by one work assignment on each of the three connector versions at each of the two deadlines. Order of presentation of connectors within as well as between deadlines was counterbalanced across participants, and the six work assignments were completely rotated through the six connectors every six participants.

Each participant was read instructions describing the physical arrangement of the A and B connectors and the procedure to be followed. For each trial, the procedure was to find the terminal marked on the cross-connect cap and protector unit, place the cap over the cross-connect pair, replace the corresponding protector with the labeled one, and then press the response button to denote completion of the trial. The experimenter emphasized that a clock which was reset by depressing the response button would be running; the goal was to complete each trial before the buzzer sounded.

### *2.2 Results*

Mean time to locate cross-connect and protector unit sets was used

* Trademark of Data Acquisition Equipment, Electro/General Corporation.

in an Analysis of Variance (ANOVA) computed with subjects (18) and connectors (3) with both slow and fast deadline conditions (2) as variables.[1] No significant differences in search times were found for the three connector versions, nor were there deadline x connector interactions.

In determining errors each cross-connect cap member and protector unit was considered separately. The overall error rate was 4.5 percent. Results of the data analysis showed error rates were not affected significantly by the connector background or by the pace of the work (slow versus fast deadline). Percent and types of errors are summarized in Table I.

Three main error categories were found: parallax, left-right reversals, and counting errors. Parallax errors were responses incorrectly displaced vertically by some number of rows. If a terminal was marked on the wrong connector but in the correctly numbered position, e.g., A3 instead of B3, it was called an L-R reversal error. Counting errors were mistakes in locating terminals in any row within a correct connector that did not fit any obvious pattern.

### *2.3 Discussion*

The addition of background patterns to cross-connect fields did not aid in locating connector terminals. Errors were useful in pinpointing areas for design modifications. Parallax, a problem associated with high-density connectors, is likely to be accentuated because cross-connect and protector fields, as well as numbers referring to them, are in different planes. With the 309-type composite connector, additional difficulties may be related to the abutment of two independent connectors. The large number of L-R reversal errors suggested the need

Table I—Errors in locating terminals

| Cross-Connect and Protector-Unit Errors | Experiment 1 ($N = 18$) | Experiment 2 ($N = 12$) | |
|---|---|---|---|
| Type | Average for All Connectors | Original Connector | Modified Connector |
| Left-right reversals | 1.4% of all responses (31% of errors) | 1.88% of all responses (20.2% of errors) | 1.25% of all responses (46% of errors) |
| Parallax | 1.5% of all responses (34% of errors) | 5.1% of all responses (55% of errors) | 0.5% of all responses (19.2% of errors) |
| Counting | 1.25% of all responses (27% of errors) | 1.5% of all responses (15.7% of errors) | 0.3% of all responses (11.5% of errors) |
| Other | 0.7% of all responses (8% of errors) | 0.8% of all responses (9% of errors) | 0.6% of all responses (23.3% of errors) |

for a clearer demarcation between the two connectors, and counting errors pointed to difficulties in locating terminal positions.

Based on the results of Experiment 1, the design of the 309-type connector was modified and a second experiment was conducted. A modified 309-type connector included an angled center designation strip with a vertical black line over the ridge for more distinct separation between connectors, and angled designation strips between cross-connect and protector fields for labeling rows on both sides. Angled rather than flat strips were used to minimize any change in connector dimensions and confusion between adjacent labels. To help further, cross-connect and protector fields were placed in more nearly the same plane by raising the cross-connect field and shortening the cross-connect terminal pins slightly so that the ends of the pins were in the same plane as the corresponding designation strip (see Fig. 1).

A similar experimental design was used in a second experiment to compare performance on the modified connector version and the original unpatterned connector of Experiment 1. Neither connector was patterned on the cross-connect field since patterning did not prove to be effective in Experiment 1. Only the fast deadline was used.

## III. EXPERIMENT 2

### *3.1 Method*

Twelve new Bell System participants with comparable experience to those of Experiment 1 took part in the study.

Designation strips on the modified connector were angled back 62 degrees from the vertical plane. The original connector was labeled as before. Four of the six work assignment trays and the practice assignment were used. After the practice assignment, the participant completed a 20-set assignment on each of the two connectors, followed by a break and a repeated measure on the two connectors. The order of connector presentation was counterbalanced and work assignments were rotated as before.

### *3.2 Results*

As in Experiment 1, search time and error rate were the dependent measures. Subjects (12), connectors (2), and the repeated measure, trials (2), were the variables for the ANOVAs. Mean times to find and complete a connection on the original connector were 13.6 and 11.9 seconds for the first and second trials, respectively; these were 12.4 and 11.3 seconds on the modified connector. The modified connector version resulted in a modest but significant savings in search time ($F = 9.11$, $df = 1,11$, $p < 0.05$). The improvement in speed from the first

to second trials on both connectors led to a significant practice effect ($F = 34.5$, $df = 1,11$, $p < 0.001$).

The overall mean error rate was 9.25 percent on the original connector and 2.70 percent on the modified version; an ANOVA showed that errors were significantly lower on the modified connector ($F = 10.36$, $df = 1,11$, $p < 0.01$), and improved with practice ($F = 7.31$, $df = 1,11$, $p < 0.05$). Interactions were not significant. Of greatest interest is the marked reduction in errors on the modified 309-type connector. As shown in Table I, using the same error categories, numbers of parallax and counting errors decreased substantially. Unfortunately, L-R reversals did not decrease.

### *3.3 Discussion*

From a human factors standpoint, the lack of a one-to-one correspondence between cross-connect and protector fields and the abutment of two connectors in mirror image are not ideal. On the other hand, there is a real and immediate need for additional space on the MDF.

It is not clear whether the L-R reversal errors were due to difficulties associated with the left-right nature of the task, the mirror image arrangement, or even the proximity of the composite connectors. Although the two sides of each composite connector were called A and B, in all likelihood they were recognized in terms of their relative positions as left and right. People have difficulty discriminating left from right.[2] Despite the random assignment of work order pairs to the A and B connectors, 69 percent of the reversal errors in Experiment 1 and 73 percent in Experiment 2 were preceded by a correct response on the same side, as if participants were not paying attention to which of the connectors they had just worked on, and so continued to work on the same connector.

The terminal location task was chosen as it was assumed it would be sensitive to the spatial arrangement of the connectors. Time-consuming wiring operations were not included in the task as they should be constant. On the main frame, however, these and many other operations would interrupt the left-to-right scan. The search would also necessarily extend over a much wider area since a main frame consists of large arrays of connectors. The identification of main frame connectors at the top of vertical frame modules should also result in vertical top-to-bottom search. Thus, the predominant left-to-right orientation of the task may have been somewhat artificial. It is likely that L-R reversal errors would be reduced on the main frame where the inclusion of other operations should make the craftperson's job more sensitive to a connector's specific position.

While eliminating the one-to-one correspondence between cross-

connect and protector fields results in higher density terminations on the MDF, craftspeople, like the experimental participants, may locate associated elements on the two fields independently. The potentially small difference in time should not affect productivity. In reality, a work assignment would not necessarily require work on both cross-connect and associated protector units. More important for the craftsperson's job may be the advantage of the front-facing work surface. There is some assurance that the craftsperson will keep his/her gaze nearly perpendicular to the angled designation strips on the modified 309-type connector, since numeral positions on the sides of the wedge-shaped strips preclude reading both sides from the same point. Besides providing clear labels and end points for rows, then, the angled designation strips may lead to more concentration that results in greater accuracy in terminal location.

In summary, the number and consistency in errors on the initially proposed 309-type connector were unacceptably high. Performance on a modified version was improved with significant reductions in parallax and counting errors. The resultant 309-type connector represents the integration of design and human factors efforts.

# Membrane Keyboards and Human Performance

By K. M. COHEN LOEB*

(Manuscript received January 7, 1982)

This paper describes systematic human factors research in which typing performance using a membrane keyboard and using a conventional, full-travel keyboard were compared for subjects representing different levels of typing proficiency. Membrane switch technology has become increasingly popular in many consumer-oriented products because of its low production cost and design flexibility. However, the absence of familiar key travel associated with membrane switches removes an important, direct source of feedback to the user with respect to specific keystrokes. Hence, the conventional wisdom has been that membrane switches without key travel are unacceptable for such keyboard applications as typing tasks. The results of the research discussed here indicate that for nontouch typists there was little difference in performance between keyboards. For touch typists, performance with the conventional keyboard was initially much better than with the membrane keyboard. Rapid learning resulted in improvement in typing performance with the membrane keyboard—both within an experimental session and across sessions—such that the advantage of the conventional keyboard over the membrane one for touch typists was reduced substantially, although not completely. Future work will be aimed at measurement of the additional improvement in performance that may result from extended practice with better-designed membrane keyboards.

## I. INTRODUCTION

Membrane switch technology has become increasingly popular in consumer-oriented products such as pocket calculators and kitchen appliances. Application of this technology to the design of full-size, alphanumeric keyboards has resulted in products that differ markedly from conventional keyboards in terms of keystroke feedback to the user. Membrane switches usually consist of mechanical contacts on two layers of material, separated by a nonconductive third layer of material (see Fig. 1). The upper, membrane layer is usually a thin polyester material with flexible conductors applied to its underside. Graphics may be silk-screened on this surface or on a second surface placed on top of the membrane layer. The substrate may be either a printed circuit board with conductors or a flexible film with printed conductors. This is usually mounted on a rigid, smooth surface. The spacer layer is an insulating material that separates the membrane and substrate layers by 5 to 7 mils. It has holes through which the upper, flexible layer may be depressed, causing contact closure. When pressure on the membrane layer is removed, the resilient, flexible membrane breaks contact with the substrate and returns to its original position.

Membrane switch technology has become popular for several reasons. Its production costs are low because there are no key-plunger mechanisms. It also affords considerable design flexibility in terms of panel layout, "key" size and shape, and graphic labels. Good switch enclosure can also be assured for hostile environments and for protection against dust accumulation, spills, and vermin infestation. Easy cleaning of the upper surface is also an advantage associated with membrane switch technology.

Although there are several technical advantages of membrane switches, there are potential user-related problems when this technology is applied to full-size keyboard design. First, familiar key travel is absent as a source of keystroke feedback to the user. Second, high actuation forces are often used with membrane switches to prevent accidental switch closure that may occur from pressure exerted by hands or fingers in a resting position on the contact area of the switch. Finally, the actual contact area ("sweet spot") of the switch often is indiscriminable for the user, compared with traditional mechanical switches that use key caps on top of key-plunger mechanisms.

Despite these disadvantages, membrane switch technology is currently being introduced into the design of full-size keyboards because of its considerable cost advantages. There is little question that membrane switches may be used successfully for simple on-off function keys. There is, however, considerable doubt about the use of this technology for keyboard tasks such as typing because of the assumed

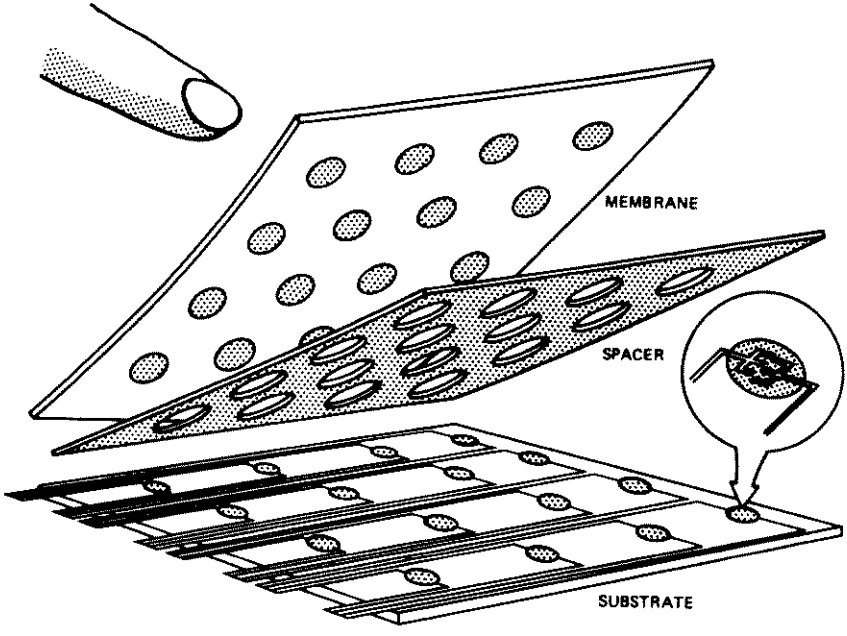

Fig. 1—Membrane switch technology.

importance to the user of key-travel feedback associated with individual keystrokes. Despite an absence of empirical evidence to support this claim, the conventional wisdom has been that membrane keyboards cannot be used as high-speed data- or text-entry devices.

Systematic human factors research was thus undertaken to determine whether performance using membrane keyboards differs from that using a conventional, full-travel keyboard. It was expected that large performance differences between keyboards would be present initially, but that with practice these performance differences might be reduced. Thus, this research was designed to provide subjects with several experimental sessions using each keyboard. It was also hypothesized that typing skill would be directly related to initial performance differences between keyboards and, perhaps, to the speed of learning to use the membrane keyboard. Specifically, it was expected that better touch typists would initially show greater performance differences between the membrane and conventional keyboards than less skilled touch typists because of the greater familiarity of the better touch typists with conventional keyboards. However, it was also possible that skilled touch typists would demonstrate greater transfer of typing skills to a novel keyboard and, hence, would learn to use the membrane keyboard more rapidly than less skilled touch typists.

Unskilled, nontouch typists, who tend to look at the keys as they are struck, were expected to show little difference in performance between membrane and conventional keyboards. A within-subject design with multiple sessions was used so that each subject would serve as his/her own control. This design also facilitated direct comparisons of typing performance on the membrane and conventional keyboards over time.

## II. METHOD

### *2.1 Subjects*

Twenty-one subjects (17 females and 4 males) participated in this study. Subjects were either employees of Bell Laboratories or volunteers from the local community. Volunteers were paid nominally for their participation in the study. Subjects varied in their typing ability and their average typing time per week.

### *2.2 Facilities and equipment*

Two commercially available keyboards were used in this study. The presence or absence of familiar key travel associated with each keystroke was the most distinguishable difference between these keyboards. One keyboard was considered a conventional keyboard in terms of key travel (about 100 mils to contact and an additional 50 mils to bottoming out), average actuation force (68 grams or 2.4 oz.), keytop size (450 mils diameter), and interkey spacing (750 mils, center-to-center). The other keyboard was a flat membrane keyboard with virtually no key travel. The average actuation force was 82 grams or 2.89 oz. A 1-mil-thick grid overlay delineated individual "keys." The "keytop" diameter size was about 600 mils with interkey spacing of 750 mils, center-to-center. Both keyboards had a QWERTY layout of alphanumeric keys and also a DELETE key that permitted subjects to make corrections. Audio feedback associated with each keystroke was achieved upon "key" depression with the key plunger mechanism for the conventional keyboard (an audible "click") and with an internal audio tone generator for the membrane keyboard.

Hardware and software interfaces were developed to permit on-line experimentation and data collection using these keyboards. Both keyboards were interfaced with a MINC-11/03 (DEC) minicomputer via an RS-232 port. The output from the keyboard was displayed simultaneously on a 9-inch video monitor placed directly in front of the subject behind the keyboard and on a VT-105 (DEC) display in front of the experimenter (see Fig. 2).

The study was conducted on-line with the MINC computer displaying appropriate prompts (e.g., "type text") to the subject prior to each of the experimental tasks. Three types of data were collected during each task: the actual characters displayed on the monitor, the actual

Fig. 2—Experimental setup.

characters typed by the subject (including deletions and corrections), and each interkeystroke time interval.

### *2.3 Experimental tasks*

Each subject participated in six sessions, three with the membrane keyboard and three with the conventional keyboard. Three types of tasks were used twice during each session: dialing telephone numbers, typing text, and answering questions. The typing-text and dialing-numbers tasks were viewed as experimental tasks, while the answering-questions tasks were viewed as practice tasks. Each experimental task was considered a "trial" so that there were two trials for each type of experimental task per session. In addition, there were two sets of questions for the practice tasks per session. The stimulus materials for each of these tasks were placed on a typing stand to the right of the keyboard and monitor.

Each "dialing" task consisted of 30 seven-digit phone numbers that were to be dialed from the keyboard. Two different lists of numbers were used for each of three sessions with a given keyboard, for a total of six different lists. The two lists used for each of the first, second, and third sessions with the conventional keyboard were identical to those used for the respective sessions with the membrane keyboard. Hence, direct comparison of performance using the two keyboards for a particular session was possible.

Each "typing text" task consisted of a paragraph from a standard

typing textbook that is used to train and assess typing speed.[1] The paragraphs were of comparable typing difficulty, based upon syllabic intensity ratings. These ratings reflect the average number of syllables per word and are traditionally used to assess the typing difficulty of textual material.[1] As with the phone number list, two different paragraphs were used for each session with the given keyboard, for a total of six different paragraphs. The two paragraphs for each of the first, second, and third sessions for the conventional keyboard were identical to those used for the respective sessions with the membrane keyboard. Hence, direct comparison of performance between keyboards for a particular session was possible. These tasks were considered the most critical ones with respect to the major objectives of this study.

Each answering-questions task consisted of a few questions on a general topic (e.g., favorite sport and how it is played, most recent vacation activities). Subjects answered these questions using the conventional or the membrane keyboard. Two different sets of questions were used during each session, for a total of 12 different sets. This task was primarily designed to provide a structured exercise by which the subject would gain experience using each keyboard.

### *2.4 Procedure*

At the beginning of each session, a standard 3-minute typing test was given to each subject. This test was conducted using an IBM Selectric typewriter. Following this test, each subject completed six tasks on either the conventional or the membrane keyboard. The tasks were administered in the following order: dialing numbers, typing text, answering questions, answering questions, typing text, dialing numbers. This order of tasks allowed the subject about one-half to three-quarters of an hour of practice on each keyboard (e.g., the answering-questions trials) in between the two dialing-numbers and typing-text trials. This order of tasks, then, maximized observation of practice effects over trials within a session but also minimized warm-up and fatigue effects on the critical typing-text trials. There were also four general questions that were answered as a warm-up exercise at the beginning of the first session with each type of keyboard.

Each subject completed three sessions with one keyboard and then three sessions with the other keyboard. Sessions took place on consecutive (or nearly consecutive) days, one session per day. At the conclusion of each session, subjects completed a questionnaire that probed their rating of various features of each keyboard. At the conclusion of the third session with each keyboard, another typing test with an IBM Selectric typewriter was administered to assess changes in typing performance over the course of a session. Though these changes in performance on the IBM Selectric are not reported here, they helped

determine the typing skill classification for each subject. Biographical data regarding touch typing ability, weekly amount of time typing, and prior use of membrane switches were also obtained.

### *2.5 Typing groups*

Subjects were categorized according to their typing ability based upon two criteria. First, assessment was made of their use of touch typing techniques in which all ten fingers and "home row" positioning of the fingers are used. Second, their average gross words per minute (WPM) on the eight typing tests given on an IBM selectric typewriter during the six experimental sessions was computed (i.e., the typing tests preceding each session and the test following the third session with each keyboard). These post-hoc criteria resulted in the following five categories of typing proficiency (see Table I): excellent touch typists (more than 60 WPM), good touch typists (50–60 WPM), fair touch typists (40–49 WPM), poor touch typists (26–39 WPM), and non-touch typists (16–25 WPM). There were 3, 5, 5, 4, and 4 subjects in these respective typing groups, for a total of 21 subjects.

The order in which keyboards were used by subjects was counterbalanced within each touch typing group through random assignment of subjects to one of the two possible keyboard orders. This balancing scheme for keyboard order was limited by the fact that the post-hoc categorization of subjects into typing groups resulted in an unequal number of subjects per group. Hence, to the extent possible, half the subjects in each touch typing group experienced the membrane keyboard first (total = 9 subjects) while the remainder of each touch typing group used the conventional keyboard first (total = 8 subjects). Also, by chance, all of the subjects who were categorized post hoc as nontouch typists used the membrane keyboard first. Hence, for the nontouch typing group, there was no variation across subjects in keyboard order.

### *2.6 Experimental design*

Typing Group (5 levels) was the major between-subject factor. Order of keyboards (2 levels) was considered a minor between-subject factor. Analyses using this factor across the touch typing groups were not

Table I—Number of subjects per typing group

| Touch Typing Group | Gross Words Per Minute | Total Number | Membrane First | Conventional First |
|---|---|---|---|---|
| Excellent | >60 | 3 | 2 | 1 |
| Good | 50–60 | 5 | 3 | 2 |
| Fair | 40–49 | 5 | 2 | 3 |
| Poor | 26–39 | 4 | 2 | 2 |
| Non | 16–25 | 4 | 4 | 0 |

reported since the number of subjects per unit of analysis was extremely small, making interpretation of results complex. In addition, there was no variability across the order variable for the nontouch typists, and the basis for estimating the variance attributable to keyboard order for this group was inadequate. Within-subject factors included keyboards (2 levels), sessions (3 levels), and within-session trials (2 levels). Separate analyses were conducted for the different types of experimental tasks (dialing and typing text). The data from the answering-questions trials were not analyzed.

## III. RESULTS

Several dependent measures were computed for each subject for the dialing and typing tasks. These measures were based upon the speed and/or accuracy of performance using both the conventional and membrane keyboards. Of particular importance to this study were the performance differences between the two keyboards for the various typing groups. Hence, difference scores and percent difference measures were also computed for each subject, and mixed-factor analyses of variance (ANOVAs) were performed. In addition, for the typing tasks the speed and accuracy data were combined to compute each subject's average words per minute, a throughput measure of performance.

### *3.1 Dialing results*

For each dialing task, the number of phone numbers dialed incorrectly and not subsequently corrected was computed. This measure included both misdialed digits as well as insufficient or additional digits per phone number. However, if a subject corrected a dialing error through use of the DELETE key, the resultant phone number was considered correct. There were 30 phone numbers per dialing task. On a few trials, a subject either omitted a phone number or redialed a phone number, a mistake no doubt attributable to the experimental set-up. These omitted or redialed phone numbers were not scored as dialing errors. Hence, the percent error rate for dialing phone numbers for each subject was computed from these data, and an ANOVA was performed.

As shown in Table II, the error rate for the dialing tasks was low for all groups using either the conventional or the membrane keyboard (less than 3 percent). The ANOVA indicated no significant difference in dialing accuracy as a function of keyboard or typing group ($p = 0.259$ and $p = 0.720$, respectively). There were also no significant effects when difference scores between keyboards were computed for each subject and served as the unit of analysis.

Table II—Percent error rate for dialing tasks*

| Keyboard | Touch Typing Group | | | | |
|---|---|---|---|---|---|
| | Excellent | Good | Fair | Poor | Non |
| Membrane | 1.11 | 2.66 | 2.01 | 2.50 | 1.30 |
| Conventional | 2.61 | 2.85 | 1.88 | 2.78 | 1.52 |
| Mean | 1.86 | 2.98 | 1.95 | 2.64 | 1.24 |

*Error rate is for uncorrected errors.
Each dialing task has 30 phone numbers.

### *3.2 Dialing summary*

Accuracy of dialing performance did not vary as a function of keyboard used or typing proficiency level. Given the simplicity of the task, relative to typing text, this result is not surprising. The data do, however, provide an anchor point for comparison of performance between the two keyboards as task complexity increases.

### *3.3 Typing results*

For each typing task, the number of "words in error" that remained after the subjects' corrections was computed according to traditional methods of scoring typing tests.[2] Hence, an incorrect letter(s), a missing letter, a letter reversal, a punctuation error, and/or a spacing error were all scored as a "word in error." The six passages, while equated in difficulty based upon the traditional syllabic intensity level, varied somewhat in the total number of words per passage (number of words per passage, where 5 character spaces equals 1 word, were: 64, 57, 79, 77, 73, 84).

#### *3.3.1 Typing accuracy*

Typing accuracy was measured in terms of both uncorrected errors and corrections. As shown in Table III, the total number of words in error was quite small (range: 1.8 to 4.5 words). The ANOVA did not indicate a reliable difference for this measure among typing groups or between keyboards. There was, however, a significant trial effect [$F(1,16) = 20.01$, $p < 0.0005$], with errors declining as a function of practice (4.2 vs. 2.7 errors).

Unlike standard typing tests, subjects were permitted to correct errors during the typing tests through use of the DELETE key. An ANOVA was performed on the number of corrections made by subjects during each typing task. The results indicated significant effects of keyboard [$F(1,16) = 5.27$, $p = 0.035$] and of session [$F(2,32) = 3.63$, $p = 0.038$]. In general, more corrections were made using the membrane keyboard than using the conventional keyboard (4.61 vs. 3.14), as shown in Table IV. Also, more corrections were made in the second

Table III—Average words typed in error

| Keyboard | Touch Typing Group | | | | |
|---|---|---|---|---|---|
| | Excellent | Good | Fair | Poor | Non |
| Membrane | 1.99 | 1.83 | 3.77 | 3.79 | 4.54 |
| Conventional | 2.56 | 4.13 | 3.90 | 3.13 | 3.79 |
| Mean | 2.28 | 2.98 | 3.83 | 3.63 | 4.17 |

Table IV—Average number of corrections for typing tasks

| Keyboard | Touch Typing Group | | | | |
|---|---|---|---|---|---|
| | Excellent | Good | Fair | Poor | Non |
| Membrane | 3.22 | 4.57 | 6.10 | 6.13 | 2.38 |
| Conventional | 4.00 | 2.47 | 3.83 | 2.96 | 2.67 |
| Mean | 3.61 | 3.52 | 4.97 | 4.54 | 2.52 |

and third sessions than in the first session, even though there was no reliable session difference in typing accuracy (i.e., uncorrected words in error). This session effect for number of corrections may be related to passage length; the average passage length was shorter for the first session (61 words) than for later sessions (78 words), and the probability of making a typing error increases as passage length increases. There was also a significant interaction between keyboard and trial factors [$F(1,16) = 5.48$, $p = 0.033$]. This interaction reflected a more dramatic practice effect (i.e., decline in errors corrected) for the membrane keyboard than for the conventional one.

#### *3.3.2 Typing speed*

The total typing time for each trial was also computed and an ANOVA was performed. The results indicated, as expected, a significant effect of typing group [$F(4,16) = 6.94$, $p = 0.002$]. As expected, typing speed varied directly with typing proficiency level, as shown in Table V. There was also a significant keyboard effect [$F(1,16) = 64.7$, $p < 0.005$]. Typing performance was somewhat faster with the conventional keyboard than with the membrane keyboard (130 seconds vs. 171 seconds).

Though there were other reliable effects related to the trial and session factors on speed of typing, it should be noted that, as with the typing accuracy data, variation in passage length (57 to 84 words) for the six test passages could readily have contributed to differences in typing time per trial and/or session.

#### *3.3.3 Differences between keyboards in typing speed*

Because of the variation in passage length, ANOVAs were performed on the difference in typing time between the two keyboards for

Table V—Average time for typing tasks (in seconds)

| | Touch Typing Group | | | | |
|---|---|---|---|---|---|
| Keyboard | Excellent | Good | Fair | Poor | Non |
| Membrane | 134.1 | 143.5 | 166.8 | 193.6 | 213.1 |
| Conventional | 97.0 | 101.4 | 106.7 | 149.0 | 169.9 |
| Mean | 115.5 | 122.5 | 136.7 | 171.3 | 206.2 |

corresponding trials. Each difference score was thus based upon the same passage typed on each keyboard.

The ANOVA results indicated significant effects of both the session [$F(2,32) = 3.68$, $p = 0.036$] and the trial [$F(1,16) = 27.0$, $p < 0.0005$] factors. These findings reflect practice effects both across and within sessions. There was also a significant interaction between trial and session factors [$F(2,32) = 3.5$, $p = 0.042$], as shown in Table VI. This interaction was attributable to larger practice effects between trials during the first two sessions, compared with those during the last session. This practice or learning effect within a session is based primarily upon greater improvement in typing speed using the membrane keyboard, compared with that using the conventional keyboard.

The main effect of typing group for this measure approached significance ($p = 0.084$). The largest speed difference between the keyboards occurred for the fair touch typists and the least difference occurred, as expected, for the nontouch typists. Post-hoc analyses (Duncan's Multiple Range Test) indicated that the difference in typing speed between the two keyboards for the fair touch typists was reliably greater than that for all groups other than the poor touch typists ($p < 0.05$), and the difference score for the nontouch typists was reliably less than that of all the touch typing groups ($p < 0.05$).

#### *3.3.4 Words per minute*

Perhaps the most relevant measure for the assessment of typing performance is the calculation of each subject's typing ability in terms of words per minute (WPM). This measure reflects a throughput measure of performance that takes into account both speed and accuracy:

$$\frac{\text{number of words typed} - \text{number of words in error}}{\text{total time in minutes}}$$

It was obviously expected that WPM for the typing tasks would vary directly with the typing group categories since this measure for a similar typing task was the basis for classifying individuals into typing groups. It was also likely that the experimental set-up per se might result in lower WPM scores than those calculated from the standard

Table VI—Average typing time difference between membrane and conventional keyboards (in seconds)

| | Touch Typing Group | | | | |
|---|---|---|---|---|---|
| | Excellent | Good | Fair | Poor | Non |
| Session 1 | | | | | |
| Trial 1 | 48.5 | 61.5 | 89.2 | 74.6 | 25.1 |
| Trial 2 | 24.2 | 27.0 | 52.8 | 40.1 | 11.6 |
| Session 2 | | | | | |
| Trial 1 | 59.0 | 67.2 | 62.9 | 52.5 | 32.3 |
| Trial 2 | 30.4 | 45.9 | 50.8 | 34.0 | 7.9 |
| Session 3 | | | | | |
| Trial 1 | 39.0 | 20.6 | 56.2 | 42.4 | 6.1 |
| Trial 2 | 21.7 | 32.8 | 48.7 | 23.6 | 16.5 |
| Mean | 37.1 | 42.5 | 60.1 | 44.5 | 14.0 |

typing tests given to each subject since many touch typists were unfamiliar with an electronic keyboard attached to a visual display.

The ANOVA on WPM scores confirmed these predictions. The main effects of all four experimental factors were significant: typing group [$F(4,16) = 9.45$, $p < 0.0005$]; keyboard [$F(1,6) = 58.7$, $p < 0.0005$]; session [$F(2,32) = 24.6$, $p < 0.0005$]; and trial [$F(1,16) = 23.0$, $p < 0.0005$]. Practice improved performance both across sessions and between trials within a session. The poor and nontouch typing groups differed reliably from the other groups, as shown in Table VII. Performance was also significantly better for the conventional than the membrane keyboard (35.4 vs. 25.9 WPM). However, a reliable interaction between keyboard and typing group [$F(4,16) = 3.74$, $p = 0.025$] indicated that the keyboard effect was attributable to performance differences for the excellent, good, and fair touch typing groups. Post-hoc analyses showed that performance differences between keyboards were not reliably different ($p > 0.05$) for either the poor touch typists or the nontouch typists.

The trial factor interacted significantly with the keyboard factor [$F(1,16) = 1.7$, $p = 0.003$] and with the session factor [$F(2,32) = 4.31$, $p = 0.022$]. The improvement with practice across trials within a session was somewhat greater with the membrane keyboard than with the conventional keyboard. Also, the degree of improvement between trials within a session diminished as practice (i.e., number of sessions) increased, with the largest difference between trials occurring, as expected, during the first session.

#### *3.3.5 Differences between keyboards in words per minute*

The relative, rather than the absolute, performance of each subject using the two keyboards was of primary concern in this study; hence,

Table VII—Average words per minute for typing tasks

| | Touch Typing Group | | | | |
|---|---|---|---|---|---|
| Keyboard | Excellent | Good | Fair | Poor | Non |
| Membrane | 32.1 | 30.4 | 25.4 | 22.1 | 20.2 |
| Conventional | 43.4 | 43.0 | 39.0 | 28.9 | 21.6 |
| Mean | 37.7 | 36.7 | 32.2 | 25.5 | 20.9 |

the percent difference in WPM using the two keyboards was computed to evaluate the relative advantage of the conventional keyboard over the membrane keyboard:

$$\frac{\text{WPM on conventional} - \text{WPM on membrane}}{\text{WPM on conventional}} \times 100.$$

This measure was computed for each subject for each typing task such that each difference score was based upon the same paragraph of text using each keyboard.

The ANOVA based upon this measure indicated significant main effects of the session [$F(2,32) = 3.57$, $p = 0.04$] and the trial [$F(1,16) = 17.6$, $p = 0.001$] factors. Both the session and trial effects reflected a decrease with practice in the percent difference in WPM between keyboards. The third session differed reliably from the first and second sessions (19.0% vs. 26.6% and 24.3%, respectively). The performance difference between keyboards was also reduced from the first to the second trial within a session (26.5% to 20.1%). The main effect of typing group approached significance [$F(4,16) = 2.93$, $p = 0.054$]. The conventional keyboard had relatively little advantage over the membrane keyboard for the nontouch typing group (6.5%), while this advantage was much more pronounced for the other touch typing groups (excellent = 26.0%, good = 25.5%, fair = 34.2%, and poor = 21.7%). The pattern of results for this measure for each group is depicted in Fig. 3. The difference between the touch typing groups and the nontouch typing group as well as the effect of practice are readily apparent. For the nontouch typists there is virtually no advantage of the conventional keyboard over the membrane keyboard; for one trial, subjects even performed slightly better with the membrane keyboard than with the conventional keyboard. For the touch typing groups the performance with the conventional keyboard was initially much better than that with the membrane keyboard. However, the percent advantage of the conventional keyboard over the membrane one was reduced substantially, although not completely, as a function of limited practice.

It is noteworthy that, despite this rapid learning function, the excellent touch typists appear to "forget" during the interval between sessions what they learned during a session. This phenomenon is

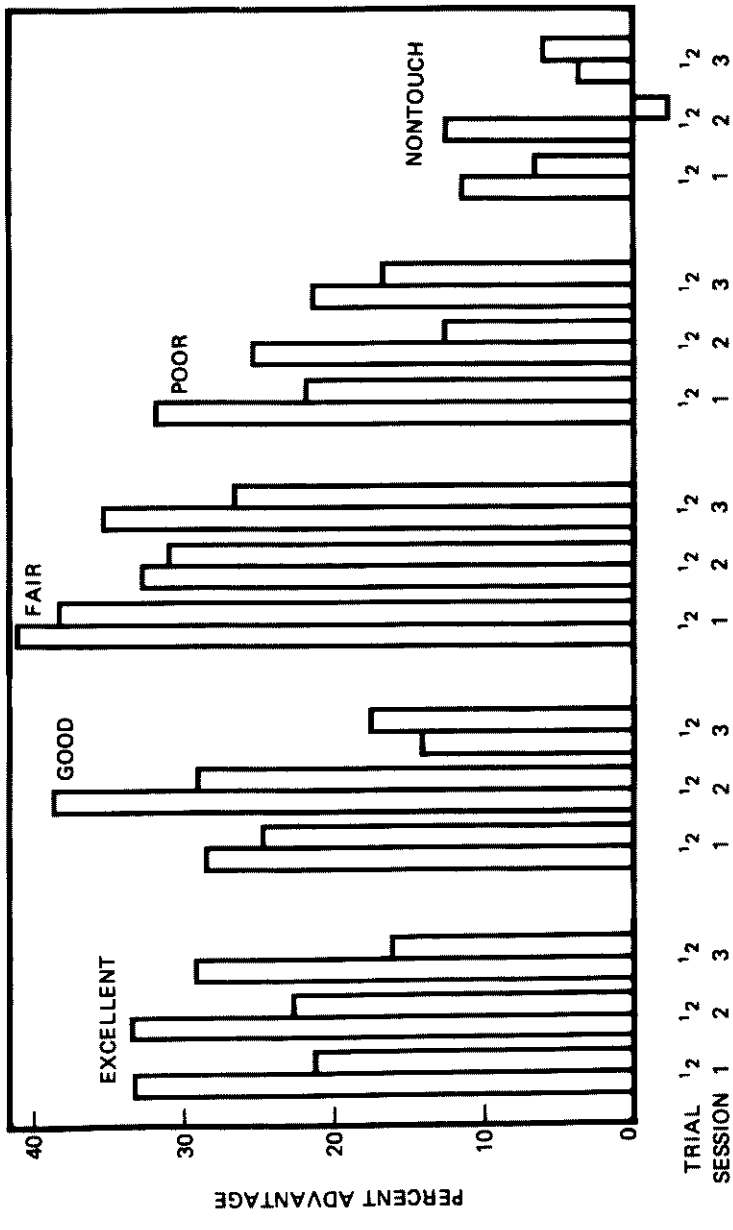

Fig. 3—Average words per minute advantage of conventional keyboard over membrane keyboard as a function of experience and touch typing group.

depicted by the larger advantage of the conventional keyboard over the membrane keyboard for the first trial of a new session, compared with that for the last trial of the prior session. This result, however, is less surprising when biographical data from these subjects are examined; these data indicate that the excellent touch typists spend about 28 hours per week using a conventional keyboard. These subjects were returning between sessions to a keyboard similar to the conventional one used here, and this activity between sessions may have produced retroactive interference, resulting in their forgetting what they had previously learned with respect to the membrane keyboard. Hence, the advantage of the conventional keyboard over the membrane keyboard was most pronounced at the beginning of each new session.

### *3.4 Typing summary*

For the typing tasks, there was evidence of rapid learning that resulted in improved performance on the membrane keyboard, relative to the conventional one, both within and across sessions. Practice effects were found on measures of both speed and accuracy. Keyboard effects were also evident. Performance was faster on the conventional keyboard than on the membrane one. Differences in speed between the two keyboards were most pronounced for the fair touch typists and virtually nonexistent for the nontouch typists. Also, more corrections were made with the membrane keyboard than the conventional one, especially at the beginning of a session.

When speed and accuracy data were combined to produce the WPM measure, practice effects were still evident. Keyboard effects were also evident, but primarily for the excellent, good, and fair touch typists. When the relative difference between keyboards in throughput performance was examined (i.e., percent advantage in terms of WPM), keyboard effects were apparent for the touch typing groups. Performance with the conventional keyboard was initially much better than it was with the membrane keyboard for touch typists. There was, however, rapid learning to use the membrane keyboard such that the advantage of the conventional keyboard, relative to the membrane one, was reduced substantially, although not completely. For nontouch typists there was virtually no advantage of the conventional keyboard over the membrane one. Finally, "forgetting" between sessions for excellent touch typists appears attributable to their customary use of another conventional keyboard during the interval between sessions.

## IV. SUMMARY

The purpose of this study was to compare performance using a membrane keyboard with that using a conventional keyboard for

different levels of typing proficiency. In general, the results indicate little difference in performance between keyboards for nontouch typists. For touch typists the results demonstrate better performance on conventional keyboards than on membrane ones. However, the results also demonstrate rapid learning to use the membrane keyboard. With just three hours of experience, performance differences between keyboards for touch typists reflected, at worst, a 27-percent advantage of the conventional keyboard over the membrane one and, at best, a 16-percent advantage.

These results provide human factors evidence that the difference in performance using membrane and conventional keyboards is much smaller than might be expected, given the absence of key travel feedback associated with each keystroke. Moreover, touch typists who are familiar with conventional, "full-travel" keyboards quickly learn to use membrane keyboards. For most touch typists, there remains an advantage for the conventional keyboard over the membrane keyboard after a limited exposure (only about three hours) to the novel keyboard.

These results are encouraging in terms of the application of membrane switch technology for some keyboard tasks. First, the particular membrane keyboard tested in this study does not necessarily represent an optimal membrane keyboard. Features of this particular keyboard that were identified as bothersome to subjects will be used in guiding the design of membrane keyboards for future evaluation. Second, extended practice with membrane keyboards may diminish residual differences in performance between conventional and membrane keyboards. Given the cost advantages and design flexibility afforded by membrane switch technology, such avenues may be well worth pursuing in the design of new products.

## V. ACKNOWLEDGMENTS

The contribution of the following people to this research project is greatly appreciated: R. Rosebrock for providing the experimental keyboards; P. Vittorio for measuring actuation forces; D. Kelly for developing the hardware and software interfaces; D. Lewis for testing subjects and reducing data; A. Glance, J. Papay, and P. Keany for reducing data; and M. Katz for making helpful comments and suggestions.

Ms. Cohen's field of specialization is human visual information processing and cognition. At Bell Laboratories, she has done human factors research in support of product development, market research, systems engineering, and software development. Projects have included videoteleconferencing, terminal design, videotex trials, voice messaging systems, and business communication systems. Member, Human Factors Society.

# Interface Design

Recent behavioral science work at Bell Laboratories and American Bell has focused on a portion of the user-machine interface, best characterized as dialogue design. This work has included the design of dialogues used for human-computer interactions, such as command languages, menu systems, and text editors. All of these are used in systems provided to customers and in the complex operations support systems used by telephone company employees. Dialogue design has also included new methods for interacting with advanced telephone services, such as call forwarding and teleconferencing.

The papers in this section focus on interface design. At best, from a human factors viewpoint, right from the start behavioral scientists were able to influence system design so that the most desirable interface was provided. In other cases, the functioning of machines was already determined, so that the behavioral scientist's job was to provide the best training or instructions to help users with their side of the dialogue.

The papers by Furnas, Landauer, Gomez, and Dumais, and by Streeter, Ackroff, and Taylor, are examples of research that guide the design of user-computer dialogue. The paper by Karhan, Riley, and Schoeffler describes the design of printed instructions to assist users of public telephones. The dialogue between people and telecommunications equipment often includes such interactions with printed material. The paper by Coke and Koether examines the readability of frequently used Bell System documents and the reading abilities of those who use them. Finally, the paper by Holmgren discusses the design of dialogues for users of automatic speech recognition devices.

# Statistical Semantics: Analysis of the Potential Performance of Key-Word Information Systems

By G. W. FURNAS,* T. K. LANDAUER,* L. M. GOMEZ,* and S. T. DUMAIS*

(Manuscript received February 10, 1982)

This paper examines how imprecision in the way humans name things might limit how well a computer can guess to what they are referring. People were asked to name things in a variety of domains: instructions for text-editing operations, index words for cooking recipes, categories for "want ads," and descriptions of common objects. We found that random pairs of people used the same word for an object only 10 to 20 percent of the time. But we also found that hit rates could be increased threefold by using norms on naming to pick optimal names, by recognizing as many of the users' various words as possible, and by allowing the user and the system several guesses in trying to hit upon the desired target.

## I. INTRODUCTION

Computer-based information management systems can store, manipulate, and transmit enormous quantities of information. They can allow almost unlimited organization, multiple indexing and cross referencing, and are capable of performing rapid and complex search operations. Thus, they can provide far more powerful tools for knowl-

edge management than have been available previously. Such tools will be important to almost everybody: cooks wanting to find recipes, doctors needing patients' histories, managers tracking inventories, clerks filling orders and keeping records, and buyers looking for products. It would be fine if such systems could be used directly by inexperienced and occasional users, people whose main job or talents lie elsewhere. The hope is that new information-seeking tools could be operated with no more training than is needed to use a card-file or a book index, but with much greater success.

We believe that some of the greatest difficulties blocking this dream are psychological. Certainly, more available speed and capacity, and new algorithmic and data structure developments involving deep and difficult problems will be needed before the arrival of fully satisfying information systems. But, progress along these lines has already been enormous and continues at a brisk pace. Meanwhile, although even existing computational capabilities are very great, our ability to make them easily usable by nonspecialists has been quite limited. An important psychological problem is in understanding the relationship between what people say and what they want. This understanding is the key to designing systems that can infer what services or information users need from the input they provide. This basic capability is needed by information systems of many sorts, bibliographic reference search systems, business management databases, airline reservation systems, plant inventory and customer record systems, and even text processors. We believe that current systems generally fall very far short of the ideal of always knowing just what to give the user.

At this time although it is clear that there is a problem, very little relevant work has been done (see Carroll[1] and Landauer, Galotti, and Hartwell[2]). We do not even know the locus of the problem in the chain of actors and events. For example, the main problems may lie at the source; perhaps the human intellect is basically incapable of forming information specifications that are very precise. If so, perhaps no system could do much better than the current ones. But, it is also possible to believe that if systems could understand people as well as, say, close friends understand each other, there would be much less of a problem.

We have tried to get some idea of the extent of this problem by attacking a small but important part of it. We have asked people to give descriptions of various information objects, and analyzed their responses to determine how well the objects to which they refer can be inferred from what they say. We have begun by studying the referential properties of isolated words and short phrases.

Our goals in this research have been twofold; first, to advance understanding of the psychological processes by which human seman-

tic reference is generated, and second, to model and estimate the strengths and weaknesses of information systems that take human-generated descriptions of sought items as their input. Empirical observations of naming behavior provide the necessary data for both enterprises.

In this article we first describe four sets of object-description data, the way they were collected and reduced, and some of their more interesting features. Then we present a series of analyses in which we treat the collected descriptions both as representative of what users would provide as input to information retrieval systems, and as the source of the information that the system would use in determining user wants. The hypothetical systems we consider are limited to ones in which the user's initial entry or query consists of a single word or short phrase. We do not attempt to analyze the possible performance of systems that make use of sentential syntax, or linguistic or real world context. The reason for this limitation is largely pragmatic; it postpones analysis of many difficult complexities. However, the characteristics and limitations of single-word to object reference that we have investigated have strong implications for many access methods (by which we mean the access method provided for the user, not that used by the program). We are, of course, aware that there are data access methods that do not start with the user entering a key word or phrase; for example, there are strictly menu-driven systems, ones that rely on well-formed queries and restricted query languages, and also ones that attempt some form of natural language understanding. These other methods share some, but not all, of the same conceptual and practical difficulties of key-word methods, and each raises somewhat unique and interesting psychological issues of its own. Where our data bear on these issues in reasonably direct ways, we offer some comments, but we focus primarily on the key-word comprehension process and its ramifications. In the final section of this paper, we discuss some of the reasons why key-word access is as limited as we find it to be and consider several potential methods for overcoming the deficiencies.

## II. DESCRIPTION OF DATA SETS

There are things a computer system has or does to which a user might wish to refer. These "information objects" are just the objects, e.g., operations or data sets, to which commands and queries apply. We have collected descriptions of information objects in four quite disparate domains, chosen in an intentional effort to achieve variety, and also for their relevance to a number of special problems that are outside the concerns of this paper. The four sets are: the verbs used in spontaneous descriptions of the operations needed to perform

manual text-editing operations, descriptions of named common objects designed to induce another person or a computer to return the name in a game like the *PASSWORD*™ game, superordinate category names for items available in a swap-and-sale listing similar to classified ads in newspapers, and index words provided for a set of main-course cooking recipes.

In this section we will describe how the object specifications were obtained from people, how they were reduced to single-word or short-phrase keys, and then summarize a few qualitative and statistical characteristics of the responses.

### *2.1 Text-editing operations*

The first data came from language applied to text editing. The study was one of two conducted to explore "naturalness" in command names.[2] Forty-eight secretarial and high school students were asked to provide instructions to another hypothetical typist describing what operations needed to be performed on text marked by an author for correction. These corrections involved two examples each of 25 sorts of edits: five basic operations (insert, delete, move, change, and transpose) on each of five textual units (blanks, characters, words, lines, and paragraphs).

Preprocessing in this case reduced each response to the main verb or phrase in the instruction describing how to perform the editing operation. While this was in fact accomplished manually here, we believe that a simple parser and English word list could in principle have given nearly identical results. These expressions may be considered candidates for command names for editing systems.

Perhaps the most striking result was that there was extensive disagreement in the verbs people produced. This point is the main focus of the current article, and will be dealt with in considerable detail later. For now let us just make a few preliminary notes, e.g., that the three most popular names for each operation accounted for only 33 percent of the total number of responses. The intersubject agreement, the probability that any two people used the same verb in describing a particular text correction, is only .08. Since each of the 25 sorts of edits occurred twice, we also have a measure of within-subject (with 1200 observations) agreement. The probability that an individual subject used the same main verb in the two cases was .34.

What agreement there was did not favor the terminology used by our locally popular editor (the *UNIX** Operating System text editor ed). For 24 out of 25 of the types of edits, the name in ed was not the most frequent spontaneously given name. Use of the terms "delete" and "substitute" was quite rare, for example. (Landauer et al.[2] went

* Trademark of Bell Laboratories.

on to show, however, that this caused no problems initially in learning the basic editor.) People preferred "add" for the insert operations, "omit" for delete operations, and "change" for the replace operations. There was little consensus in describing the transpose and move operations.

### *2.2 Common object descriptions*

These data were originally collected in a study by Dumais and Landauer[3] that examined how people naturally obtain information from one another. The information objects here were names of 50 common items chosen from 10 "categories." The categories were: cities, proper names, clothing, animals, food, household items, abstract words, a category of words with highly associated opposites (e.g., black, love), and two categories whose members were words selected in such a way that negation might figure strongly in the descriptions, e.g., to eliminate the unwanted set members. A total of 337 New York University students were asked to write down a description that would enable another person (or in half the cases a hypothetical computer) to guess the object. There were no restrictions as to the form or content of the descriptions, except that they could not contain the target word itself. Subjects also indicated whether they had any computer experience. Those with at least one computer course were classified as computer-"experienced" in the data summaries discussed below.

A subsequent study was conducted to evaluate the effectiveness of the descriptions generated in the first study. Twenty-five subjects (6 Murray Hill area homemakers and 19 employees of Bell Laboratories) were each given 150 descriptions randomly selected from those generated by the NYU students. They were asked to: (1) guess (without knowing the alternatives) the item being described, and (2) indicate on a five-point scale their confidence in their guess.

Principal results from the main study include the finding that when communications were intended for computers, people with computer experience were relatively more terse, and nonexperienced people were relatively more verbose than when communications were intended for people. However, there was no simple relationship between verbosity and effectiveness, i.e., guessing accuracy as indicated by the second study. People were somewhat more successful in guessing the target items when the descriptions had been provided by people without computer experience (81.2 percent vs. 78.5 percent), but this difference is not statistically significant.

A point of considerable interest here was the style of specification that subjects used. Subjects' descriptions were not very precise; typically they refer to a whole set of items, not just the intended target (although we have no good measure of this other than informal ratings

of denotative class size). Still, the average successful guess rate of the second group of subjects was over 80 percent. We will return to a discussion of this paradoxically high success rate towards the end of this paper. The most frequent way of specifying target items, used about 60 percent of the time, was to describe them in terms of a superordinate (sometimes followed by characteristics or attributes that distinguish the intended target from other members of the superordinate category). Another fairly common form of description (~20 percent) was the use of exemplars. For several of the target words (e.g., motorcycle, magazine, sports, games, science), subjects listed examples of more specific items falling into the target category (e.g., Harley, Suzuki ..., in the case of motorcycle) instead of attempting a more formal definition. Negations (and opposites) were used less than 50 percent of the time for the words we thought were particularly amenable to this form of description.

For the purposes of the analyses undertaken in the current paper, these descriptions were preprocessed to merge minor variations in as automatic a fashion as possible: uppercase was folded to lowercase, word endings were stripped (plurals, tense markers, etc.), and "non-content" words (including articles, imperatives, conjunctions, prepositions, pronouns, and tenses of the verb "to be") were removed.

An average of 8 words per description were in this way condensed to an average of 5.4 words. The first of the remaining words (i.e., first standardized content word) was tabulated for the statistical analyses.

### *2.3 Superordinate categories for swap-and-sale items*

The major purpose of collecting these data was to develop empirical networks of "ISA" relations, that is, classification hierarchies based on user knowledge and representations, for a set of items to be incorporated in an experimental menu-driven information access system.[4]

The information objects were 64 items taken randomly from roughly 300 entries on a monthly bulletin board listing of items for swap and sale at Bell Laboratories. The subjects were 30 local New Jersey homemakers. Each subject worked with a random 32 of the 64 target items. They were told that they were participating in the study to find out how they classified various items being sold on local bulletin boards. The use of these categories in helping people in future computerized retrieval systems was mentioned. Subjects were instructed to complete successive "All ____ are ____" sentences. Beginning with the specific target they were to give its immediate superordinate (e.g., "all red Delicious apples for sale @10¢ ea. are apples"). Then they copied the first given superordinate ("apples") to the beginning of the next incomplete sentence and finished the new sentence with a still

more general category (e.g., "all apples are fruit"). They were to continue in this way (e.g., "all fruits are food") until they could go no further. They were then to go back and find some category that had another superordinate in addition to the one they had already cited, and list that category with its new superordinate. These data were also standardized by stripping off endings and discarding noncontent words.

On average, an individual subject produced 2.1 different chains of successively more general superordinate categories for each stimulus. The chains averaged 2.5 superordinates each, with superordinate categories named in phrases containing an average of 1.7 standardized (content) words. For the current paper, only the lowest level (most specific) category, from the first generated chain of superordinates, was used. The category name was used in its (standardized) entirety.

The categories given in this study make it apparent that the construction of a network that will faithfully match all users' conceptions of a domain is not an easy matter. People have difficulty in generating superordinates and show considerable disagreement as to how things should be grouped under those superordinates. Categorization and indexing schemes currently in use always depend on a user's either generating the same superordinate as the system knows about, or at least being able to choose the right one from a list. Perhaps the difficulty and lack of agreement among people in categorizing information objects account for much of the perceived deficiency of current menu-driven data access methods.

### *2.4 Recipe index words*

The original motive for this data set was to study the effect of domain expertise (i.e., cooking skill) on indexing and key-word usage.[5] The information objects were 188 main-course cooking recipes (French, Italian, Mexican, and American cuisine) taken from 12 cookbooks of explicitly varied sophistication (ranging from a garden club's cookbook,[6] through *The New York Times Cookbook*,[7] to *The Art of French Cooking*[8]).

There were three groups of eight subjects each: experts, who taught cooking classes; and intermediates and novices, selected from local homemakers who came out at the high and low extremes of several self-rating scales on culinary sophistication.

Subjects were told their task was to describe each of the recipes in key-word form, selecting at least three but no more than seven descriptive words or brief phrases for each recipe. They were told that their job was similar to that of a librarian who is creating an index or card catalog, and that the descriptions should be useful to another person trying to locate that recipe in a large set of recipes. Half of the subjects

in each experience group were instructed to direct their descriptions to expert cooks using the index, the other half to novice cooks. The description task was self-paced by each subject in her home. Subjects required between 5 and 10 hours to complete the task.

Terms here were again preprocessed to remove word endings and noncontent words. All multiple-word productions were scored by two judges (the experimenters) to determine if the phrase could be decomposed into its constituent words and maintain its meaning. Subjects produced an average of 5.4 key words per recipe, the first, "most important" of which was studied here.

Again we found considerable diversity. For the 188 recipes, a total of 303 different word types were used by the 8 experts, 220 by the 8 intermediates, and 252 by the 8 novices. It is interesting to speculate on the reasons why these groups differ. Perhaps the experts have a large and specialized vocabulary and the novices have an unruly, haphazard one. In any case, there seems to be something more conventional about the word use of intermediates, a point to which we will return later.

### *2.5 General comments on the data sets*

These data sets all pertain to information objects that one might want accessible on a computer. They were also all of modest size. Other than that, though, they tapped very different knowledge domains, they asked for specification in a number of different ways, and they were provided by different kinds of people. Moreover, the method of reducing the free-form descriptions given by our participants to single words and short phrases varied somewhat from one case to the other. This variety of data is important for our purposes. In order for results to have any pretense of robustness, it is important that they be obtained on a sufficient variety of cases to assure that it is not the particulars of the objects at hand that are responsible for the observed characteristics. We know of no way to actually sample data domains, descriptive methods, and reduction methods in a representative way. However, we believe that results that hold for all of the disparate sets that we have studied stand a good chance of holding for most others.

For each domain, our data can be represented as a table in which the rows are words provided by the subject, the columns are the objects to which these words were applied as descriptions, and the cell entries indicate the number of times each word was used in the description of a given information object. The questions we ask concern how the information contained in such a table might be used to guess from an input word what object is intended. Two partial tables are shown in Tables Ia and b. Table Ia is derived from the text-editing study (for five objects) and Table Ib from the common object data. The numbers

Table I—Word-object data

(a) Sample data from the text-editing study

| Words | Objects | | | | |
|---|---|---|---|---|---|
| | insert | delete | replace | move | transpose |
| change | 30 | 22 | 60 | 30 | 41 |
| remove | 0 | 21 | 12 | 17 | 5 |
| spell | 4 | 14 | 13 | 12 | 10 |
| reverse | 0 | 0 | 0 | 0 | 27 |
| leave | 10 | 0 | 0 | 1 | 0 |
| make into | 0 | 4 | 0 | 0 | 1 |
| ... | | | | | |

(b) Sample data from the common object study

| Words | Objects | | | | | |
|---|---|---|---|---|---|---|
| | calculator | lime | Lucille Ball | pear | raisin | robin... |
| small | 17 | 0 | 0 | 0 | 7 | 4 |
| machine | 4 | 0 | 0 | 0 | 0 | 0 |
| green | 0 | 18 | 0 | 7 | 0 | 0 |
| bird | 0 | 0 | 0 | 0 | 0 | 21 |
| fruit | 0 | 1 | 0 | 19 | 1 | 0 |
| red | 0 | 0 | 8 | 0 | 0 | 7 |
| female | 0 | 0 | 2 | 0 | 0 | 0 |
| ... | | | | | | |

in the tables represent the frequency with which a word was used to refer to an object.

In fact, there is an implicit third dimension to these tables, representing the person from whom the description was obtained, and sometimes a fourth dimension, representing which of several words of a multiple-word description provided by a given subject is involved. However, for most of the analyses we consider only the first word given, and the matrices are all very sparse, so we have chosen to collapse across subjects. It is worth noting that the tables are not sparse simply because we have failed to collect enough data. Word usage tends to resemble Zipf's distribution[9] (supposedly straight line relation between occurrence frequency and rank frequency when both are plotted logarithmically) in that a few words are used very frequently and many words (over 340 here) used only once (see Fig. 1). As more and more data are collected some cells increase in frequency, but the number of unique words also grows so that the sparseness of the table tends to be preserved. Moreover, most words refer only to a limited number of objects, so that such tables usually have a large number of empty cells.

## III. INTRODUCTION TO ANALYSES TO DETERMINE REFERENT EFFECTIVENESS

In the analyses that we report in Section IV, we have been interested in how much information about referent object identity is contained

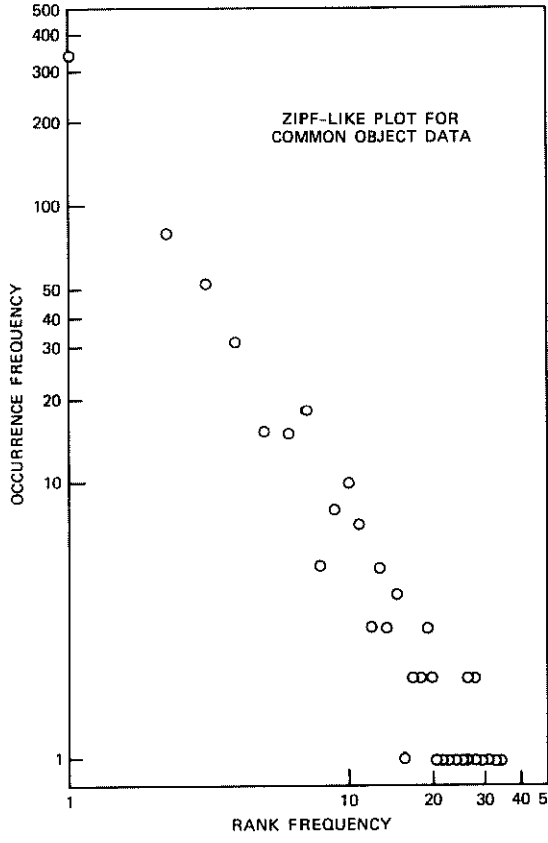

Fig. 1—Plot of common object word usage data.

in the words used to describe them. To consider how good a word or expression is as a reference to some object, it is necessary to suppose some sort of a mechanism by which the expression is comprehended. We can only estimate the value of inputs as determinants of output if we can specify the function that takes one into the other. The inputs of our problem are the words provided by people in specifying information objects. The output is a guess or set of guesses about which object was intended. Our approach has been to specify various ways in which the input can be made to yield the output. We have considered models or functions that are intended to mimic what happens in typical information systems and also ones that try to improve on current methods in various ways. We also develop models that allow us to estimate what ideal input/output mappings could accomplish. It is in this sense of ideal or asymptotic performance that we can appraise the limits of word reference.

The models that we examine have in common that they use the frequency table of users' word reference, and only this data, to guide the system in guessing users' intents.

### *3.1 The general model*

In the sections below we consider a number of special cases of the following rather general baseline model. To retrieve a desired item the user is assumed to enter one (though in some instances, $K$ different) key word(s). The system is assumed to make either one or $M$ guesses as to the user's intent. Success is counted if the intended object is among the system guesses.

As an actual system, our baseline model would operate as follows. The user would enter one (or more) key words or phrases. If it could recognize the input at all, the system would return one or more potential objects according to some rule, perhaps relying on data in a table of observed word-use frequencies. (If it could not recognize the input, it would return nothing.) In cases where the system returns several alternative objects, it can be assumed that the user would be able to select from among them the one intended without error. This corresponds to a simple case of what might be called a "menu-on-the-fly" technique, in which the first entry is a freely chosen key word, and the next step is a choice among a menu of items selected on the basis of the system's knowledge about referents the human user might have intended by that key word.

We will now describe the models that we have analyzed, beginning with the simplest ones, those closest to the way typical systems are currently set up, and proceed to more sophisticated models. Each model is characterized by a set of assumptions or constraints on the input/output function of the system.

Sections 3.2 to 4.7 consider a number of models and analyses in considerable technical detail. Some readers may wish to skip these sections and continue to a summary of the highlights in Section 4.8.

To give a preview, the results convince us of three major points. First, the vocabulary problem is a serious one for untutored users of computers, particularly given the poor naming techniques typical of current practice. Second, the difficulties come from a severe and fundamental lack of consensus in the language community on what to call things. Finally, our research suggests that, by using a very non-standard approach, namely trying to make the best possible guesses on all user words, substantial improvements could be made in meeting the underlying objective of providing access to the things people want.

### *3.2 Formalizing the general model*

Let us make things more formal. We have two sorts of entities, the user-generated inputs, referred to here as "words," "terms," or "de-

scriptors," and the system outputs, called "information objects," "targets," or just "objects." We are concerned with two relationships between these entities. On the system's side are the associations dictating how the system will respond to a user's words—which words will be associated with what system objects. On the user's side are the actual intended associations—what the user in fact meant by a given word. Both the system's and the user's relationships can be shown in the form of a table. The *system table* gives the input/output mapping of which object the system will retrieve (execute, etc.) for what words, with a 1 wherever a word is associated with a system object, and a 0 otherwise. The *user table* shows the frequencies with which people say what words for what objects. Examples of a user table were shown in Table I. This table can be used in the evaluation, and, if one wishes, in the design of the system table.

#### *3.2.1 The system table*

The system table has two aspects. First is what might be called the set of structural constraints. These concern how much and what variety of input the system will respond to, and are imposed by capacity limitations on memory, processing, data collection, or sometimes by the computer algorithms used. Second is the choice of a particular instance of the input/output system table, that is, the assignment of exactly which words the system will respond to, and with what objects. One design problem centers on whether assignments will be made in an effective or possibly optimal way.

Structural constraints in the system's input/output table correspond to general restrictions on which cells may be used in the mapping of input to output. We consider patterns based on limiting the number of cells in rows and columns (e.g., the number of words understood as referring to each object and the number of objects taken as possible referents for each word). In particular, we will be considering models where, in the system table, there are various restrictions on:

1. Total words recognized by the system (number of nonzero rows in the system table)
2. Number of words recognized for each object (column totals)
3. Total objects referenced (number of nonzero columns)
4. Number of objects referenced by each word (row totals)
5. Total word-object associations "understood" by the system (grand total of cells).

Once a general structure has been determined, one still must choose which associations to give the system, i.e., exactly which cells to include in the mapping. We consider three cases that give rise to different versions of each model. The first is a purely random assignment. Within the specified structural constraints, the cells defining

the system's associations between words and objects are chosen randomly. Clearly, this is not a realistic system model, but it is useful in the conceptual analysis of other models and as a baseline of comparison. The second case is a weighted random assignment, assigning a word to an object with the same probability that the word and object occur together in usage. That is, input/output associations are chosen with probabilities proportional to their frequency of use, as indicated by the user table. This is, in fact, a very important case to consider, since it approximates the way many systems are currently designed. We will often refer to this as the "armchair" method: a single human designer sits in his or her proverbial armchair and makes the name-object associations by some sort of intuitive guessing. The user table is in effect a compendium of many humans' "armchair" attempts to assign good words to the system objects. A weighted random sample from the table thus corresponds to a random person's "armchair" nomination. Such weighted sampling therefore allows us to estimate the effectiveness of "armchair" design. The last assignment technique is by the best available optimization procedure. Optimization methods make generous use of the empirical data in the user table to pick the best cells. For some system constraints we do not know a combinatorially feasible way to find the best configuration, but it is possible to improve substantially upon the weighted random method. Note that the success of any optimization attempt is also limited by the quality of the data available in the user table.

#### *3.2.2 The user table*

The user table is a data matrix compiled from the studies mentioned earlier in this paper. It records the frequency with which untrained users employed various terms in referring to the system objects.

We assume that the descriptions given by our subjects for the information objects in the various sets bear a close resemblance to the entries similar users would make in trying to specify the same objects in a database system. This assumption may be wrong in detail; in using actual systems people might give descriptions somewhat different from those induced by our instructions. However, when we varied the intended recipient of the descriptions, as in the recipe (experts, novices) and common object data (people, machines), there were only small changes in the descriptions. So we believe that descriptive language would change little in attempts to communicate with real, as compared to hypothetical, systems. (We cannot, however, estimate the effect that prolonged interaction with a given system might have on a user's vocabulary.)

We also assume that collection of user descriptions is a good basis for predicting actual user intent from key-word input. In approaching

a data access system, the user must have some information object in mind, and must give a description to the system. In actual use, it is difficult to know what the user really has in mind. Sometimes the user has no clear idea at all. It is not apparent whether this "diffuse target" case is easier or harder for a system to handle. A user with an unclear goal may or may not be more easily satisfied, but is probably less likely to give precise specifications.

It is obvious, however, that the diffuse target case is harder to study. Reliably inducing such a state in the user is difficult, and the system's success is not easily appraised. Therefore, we have collected data and investigated models based on the clear target case.

Thus, in these models it seems to us that the best information the system could start with is to know what typical users would give as descriptions, given the intended object was well known and clearly defined. Our assumption is that the descriptions people give of objects when we specify them will closely resemble the description they would give if they had thought of the specific objects themselves. This seemed a practicable and, we hope, realistic starting point.

#### *3.2.3 Going through the models*

Insofar as possible, we will use a consistent expository framework to describe each model. The framework is as follows:

1. Name: A mnemonic title, by which the model will be referenced.
2. Interpretation: What the model is all about.
3. Motivations: Where and why it might come up.
4. Structural constraints: The general form of the system's input/output table ("system table") for the model. This will be given as clearly as possible in English, with a more formal summary of the constraints for each model appearing in Appendix A. This appendix is a very useful reference source in comparing the models.
5. Analyses: For each of three methods of selecting cells for the system table (random, weighted random, and optimized), the following information will be given whenever possible.
   (a) Version: what the method means in this model.
   (b) Evaluation by: what statistic is used to assess its success.
   (c) Result: Statistics are computed for the four data sets:
      (1) Edit command data
         (a) All 25 Operation x Text-Unit combinations (abbreviated: "Ed25")
         (b) For purposes of comparison we include a second analysis of the same data: the five basic operations collapsed across textual units ("Ed5")
      (2) Common object data, all 50 objects ("CmOb")
      (3) Swap-and-sale data, the 64 sale items ("Swap")
      (4) Recipe data, the 188 main course recipes ("Recp")

The following statistics will be given:

Recall probability: how often the method succeeds in returning the desired object.

Mean number returned: when the system is able to make a guess about the user's desired object; this is a record of how many guesses it makes to achieve the reported probability of recall.

A few comments are needed about the "number returned" statistic. First note its importance in considering recall success probabilities. If the system returns a large number of guesses, it can obviously be expected to have a greater chance of including the target. Thus, comparisons of performance demand that this number be kept in mind. Second, note that these indicate the number of things returned when the system in fact recognizes the user's input and so is in fact able to hazard a guess. For some systems it will be common to have insufficient data and to make no guess at all for many user words.

We denote the number of objects, or columns, in the table by $C$, and the number of user words, or rows, by $R$. The former is in part well defined by the designers of the system but the latter, the vocabulary size, is usually an artifact of data collection, as it would tend to expand if more data were collected. Here it refers to the size of the vocabulary in the corpus of data we collected.

## IV. ANALYSES TO DETERMINE REFERENT EFFECTIVENESS

### *4.1 Model 1: "One name per object."*

#### *4.1.1 Interpretation*

Each object in the system is assigned a single term or name. The user enters one term. Success depends on the user's word coinciding with the system's.

#### *4.1.2 Motivations*

This approach is common in computer systems—each entity has one and only one name. The name is usually chosen by the designer or by an expert indexer. The designer hopes to establish a convention about what system objects will be called. Users must either learn or guess the names to make the system work. Such learning may be feasible in small systems or for highly practiced users. The growing community of novice and infrequent users, however, are often reduced to trying to second-guess the system, even to find documentation. This is often frustrating and we shall see that in principle the approach is far from adequate. Moreover, the real difficulties of such a scheme often go unremarked simply because traditional computer users have come to accept as normal the necessity of extended learning, repeated second-guessing, lengthy searches, or expert consultation in finding the correct names for programming commands, file names, or information categories.

#### 4.1.3 Structure

The only constraint is that there be exactly one word for each object. Note especially that this model allows the possibility that any given word can be used to name more than one object. This is a situation that designers often try to avoid. It nevertheless arises in several situations, as when programs, commands, file names, or index categories are assigned by many independent users, or to highly similar objects (like bibliographic subject or author specifications, or the case of several functions being collapsed under a single command name). We evaluate models that disallow such "collisions" later. Note that for the likelihood of recalling a given object at all, the aspect of the problem on which we focus in these first analyses, assigning a word to more than one object as we do here, can only improve the expected system performance.

#### 4.1.4 Analyses

***4.1.4.1 Version: random.*** For each object one name is chosen randomly from the total vocabulary for that object, i.e., one cell from each column. That is, the name of each object is a random choice among all the total set of descriptors given to all the objects.

*Evaluation: by theoretical value.* In this case we can calculate the expected performance of the system exactly. The success rate is given simply by the ratio of $t$, the total number of cells included in the system mapping, to $RC$, the total number of cells in the matrix. A simple proof of this appears in Appendix B. See Results Table 1.

Results Table 1

| | |
|---|---|
| recall probability = | $C/RC = 1/R$, i.e., the reciprocal of the total number of words that users use for all the objects |
| | Ed5 Ed25 CmOb Swap Recp |
| recall probability = | .012 .008 .002 .001 .001 |
| mean number returned = | $1 + (C - 1)/R$ |

The "mean number returned" is a measure of the amount of ambiguity or imprecision in the terms as the system understands them. It is the average number of things the system knows by a given name that the system recognizes; the system must return all of these objects when trying to guess a target. For some of our models the number of objects that the system returns will be fixed ahead of time by design, but here it is the mean of a random variable, easily calculated to be $1 + (C - 1)/R$.*

* Under the pure random method, each object has one of the $R$ words associated with it randomly and independently. Thus, for each object, any given word arising or not becomes a Bernoulli event with probability $1/R$. So having chosen a word for one object,

*4.1.4.2 Version: weighted random.* A system name is assigned to an object with the same probability that users attributed the term to the object. Here the user enters one key word; and the system has had a key word assigned to each object, based on one other person's nomination. This model mimics, more or less, a currently fairly typical situation for key-word systems (or program-name or command-name access systems) in which the system designer has provided an entry name for each object, obtained only from one usage datum (the designer or indexer's "armchair" introspection), and the user is required to enter just that name. We assume that system designers or indexers are like our subjects in their choice of names, so that the relative frequency with which a name was given to an object by our subjects provides an estimate of the likelihood that a designer would choose that name for that object. (One source of support for this assumption is that experts gave no more consistent names than novices; see below.)

*Evaluation: by the "column repeat rate" statistic.* We estimated how well such a system is likely to work by estimating the probability that a given word chosen randomly from our population (e.g., by one user on one occasion) would match another word chosen from the same population (e.g., by one designer). This probability is known as the repeat rate.[10] If we index rows (words) by $i$, and columns (objects) by $j$, in a word-by-object table, then repeat rate for a given object, $rep_j$ is defined as:

$$r_j = \sum_i p_{ij}^2.$$

This formula can be understood by considering that a match between two randomly chosen words occurs when, for any given word first chosen, the second word is the same. Say the first word was $word_i$; the second word will match it with the probability of $word_i$ occurring in the population, $p_{ij}$. The probability of a $word_i$ being the first word is also $p_{ij}$, so the probability of $word_i$ being involved in a match is $p_{ij}^2$. Summing across all possible words, we get the equation given above.

An unbiased estimate of the population probability of such a match comes from calculating the true probability of such a coincidence in drawing from our sample without replacement, given by:

---

the number of the other $C - 1$ objects having randomly been assigned that same word is given by a binomial distribution with parameters $p = 1/R$ and $C - 1$. Thus the mean number of other objects with the same name as our given object is the mean of this distribution, $(C - 1)/R$. The system will return any of these objects plus the original object, or $1 + (C - 1)/R$ objects.

$$\hat{r}_j = \sum_i \frac{n_{ij}}{N} \frac{n_{ij} - 1}{N - 1},$$

where $N$ is a column total and $n_{ij}$ is the frequency of the $i$th cell in the column $j$.

Here we are interested in the average probability of success, given any particular target, throughout the table. So we decompose the overall probability by conditionalizing on columns, calculating the repeat rate for each column, and then average these success probabilities using weights proportional to the column total frequencies. (In our data these column totals are approximately equal by design.) These weighted average column repeat rates are given below for our four sets of data. These numbers may be interpreted as answering the following question: Given that all objects are equally often the desired target, what is the probability that the name given by a user trying to specify a target would match the name assigned to it by a designer? See Results Table 2.

Results Table 2

| | Ed5 | Ed25 | CmOb | Swap | Recp |
|---|---|---|---|---|---|
| recall probability = | .07 | .11 | .12 | .14 | .18 |

While there is some variation among the values, they are all quite small. People do not agree with one another very well as to the first word or phrase with which to label an object. The probability that two typists will use the same main verb in describing an edit operation is less than one in fifteen. The probability that two people will use the same first key word for a recipe is less than one in five. (These numbers also tell us something about the size of the set of alternatives that people use in their disagreement. It is a property of repeat rate that the set of alternatives must be at least $1/r$, and can be quite a bit larger if they are not equally likely, as is the case here.)

Most of the interesting comparisons will be between the different models presented (e.g., this model with the subsequent ones), and not the different data sets. To facilitate model-to-model comparison, all results appear together in a summary table in Appendix C.* The reader is strongly encouraged to refer to this table throughout Section IV.

* Of course, some comparisons between data sets are also of interest. Note for example that the value for Ed25 is higher than for Ed5. This says that the set of words applied to the individual objects is more sharply restricted than for the collapsed classes. This is to be expected, since any diversity between objects in the pattern of terms applied becomes within-class diversity, when the objects are collapsed together, driving the column repeat rate down. Only if all objects in a class had identical naming patterns would the repeat rate not decrease.

The mimicked method is one in which the designer provides the system with only one entry word that it can understand, and the user enters just one key word. This is clearly unsatisfactory for untrained users. The usual solution has been for system designers to rely on users learning the chosen vocabulary, i.e., to try to force the user's table to adapt to a fairly arbitrary system table. When the system is small and the user's interaction frequent, this can work quite well. Indeed, Landauer et al.[2] have shown that using unrelated random names has little or no detrimental effect on initially learning to operate a small editor. But, if the system is large and its use intermittent and nonexpert (as for example in large-scale information retrieval systems like library catalogs, recipe files, or classified product catalogs), it is simply unreasonable to require users to learn a specialized vocabulary.* Despite the designers intentions, the uninitiated will try to make the system work without memorizing extensive naming conventions. Thus the problem remains a real one.

One approach we might consider at this point is to seek expert advice in choosing names. This is a fairly common approach, taken in the hope that experts in a given subject area know what things are, or should be, called and so might generate words of more general currency. Indeed, the indexes to books, libraries, user manuals, and other information sources are customarily created either by subject matter experts or by professional indexers.

We have collected some data relevant to this issue in the recipe study. Our key-word providers represented several levels of expertise. The situation is not unrepresentative; usually the indexes of cookbooks and recipe collections are created by cooking experts, presumably on the assumption that their characterization and labeling will be superior, even for less sophisticated users. We calculated repeat rates separately for the three groups of key-word providers (experts, intermediates, and novices) subdivided by whether they had produced the key words under instructions to make them appropriate to novices or to experts. The results are shown in Table II. The repeat rates shown were calculated in a special way. For each cell, the index words were provided by particular subsets of describers, and the proportion of matches was calculated on a pool of descriptor words provided by other subjects. Thus, the (ee, ee) cell estimates how likely a word provided by one expert for other experts was to match that provided by another expert with the same, expert, audience in mind. The (en, ne) cell estimates the probability that a word provided by an expert

* In intermediate cases, like program and command names for an operating system, the method may be satisfactory for expert users, while leading to dissatisfaction for others (see Refs. 11 and 12).

Table II—Repeat rate measures of agreement between indexers and users for the recipe data set

| Group | ee | en | ie | in | ne | nn |
|---|---|---|---|---|---|---|
| ee | .11 | .17 | .14 | .15 | .10 | .22 |
| en | .17 | .11 | .18 | .17 | .16 | .21 |
| ie | .14 | .18 | .20 | .20 | .21 | .23 |
| in | .15 | .17 | .20 | .19 | .17 | .26 |
| ne | .10 | .16 | .21 | .17 | .16 | .16 |
| nn | .22 | .21 | .23 | .26 | .16 | .32 |

for novice users would match the word provided by a novice for expert users. Clearly, the differences among marginal values (i.e., the averages of repeat rates for different index providers) are not large, and more clearly still, expert cooks do not provide better descriptions for the use of either other experts or novices. (If anything, novices do the best in using each other's words.)

The usual armchair approach, even if undertaken by subject matter experts, has only a small rate of success. The obvious step at this point is to seek explicitly optimal choices of names, treating this as the empirical question that it clearly is.

***4.1.4.3 Version: optimized (best).*** If we want to use the name that has the greatest currency among subjects, we must choose the term that is in fact maximally used by subjects for each object. We pick the maximum cell in each column and use the corresponding term.

*Evaluation: by various estimates of the range of expected performance.* The lower bound is based on split halves analysis; the upper bound is based on a transformation of the column repeat rate and from an analysis that assumes that the sample data exactly reflect the population probabilities.

To know the performance of this model we need to know the true population magnitude of the maximum cell in a column. That cell is the one we would choose according to an optimum name assignment scheme, and its size would be the proportion of future users' terms for the given object that would coincide with our optimal choice. Problems arise in that there are no known distribution-free, unbiased estimators of the population magnitude of the maximum probability cell. We have, however, been able to devise a few techniques that let us put bounds on the performance of this system. The first uses a split-halves technique to give a lower bound estimate. The data in each column are split into two halves, and the maximum cell chosen on the basis of the first half (as though we had to design our "optimal" system on the basis of half the data). This cell is then matched against the second half to see how well it succeeds. Thus, the second half acts as a virtual experimental test of the performance of the "optimal" method. The split-half results shown here are the average performance of ten independent splits of each data set. See Results Table 3.

Results Table 3

| | Ed5 | Ed25 | CmOb | Swap | Recp |
|---|---|---|---|---|---|
| recall probability = | .15 | .19 | .26 | .26 | .31 |

These numbers are an unbiased estimate of how well a system would do using this optimum strategy but constrained to a small amount of data (namely the amount in each half). It clearly underestimates how well one could do with more data. We have used two approaches to obtaining an upper bound. One is based on an interesting inequality relation that holds between the size of the maximum cell and the repeat rate statistic described above: It can be shown that the former is no greater than the square root of the latter.*

Thus, the performance of the optimum model is expected to be no greater than the square root of the performance of the weighted random (armchair) model. This statistic will overestimate performance to the degree that individual words other than the maximal one are also applied frequently to a given object. Since our own data suggest that this is commonly true, this upper bound is likely to be quite generous. It has an important pragmatic advantage, however, in that it is independent of sample size and easy to obtain. Other estimates of optimal performance require collecting detailed data on the precise pattern of naming. This estimate requires only that one observe the probability that two people use the same name (i.e., the repeat rate), without even having to note what particular terms they use. Taking the square root then yields an upper bound estimate for the best possible single name per object. For our data, these quantities are listed in Results Table 4.

Results Table 4

| | Ed5 | Ed25 | CmOb | Swap | Recp |
|---|---|---|---|---|---|
| recall probability = | .27 | .32 | .33 | .35 | .42 |

The final way to estimate the performance is to let the data predict itself. The observed largest proportion falling in a cell is taken as the estimate of the population maximum. A familiar result in rank order

* This relation follows from two inequalities. First note that the repeat rate is the sum of the squared cell probabilities. This sum is clearly greater than or equal to any of its terms, since all are positive. In particular, it is larger than the square of the maximum probability cell. Thus, the expectation of the repeat rate is larger than the expectation of the squared maximum cell. Second, note that the expectation of any squared variable is always greater than or equal to the square of that variable's expectation. Putting these together, the expectation of the repeat rate is greater than or equal to the square of the expected magnitude of the maximum cell. Thus, an upper bound on the maximum cell is estimated by the square root of the repeat rate.

statistics is that in the presence of error the observed maximum of a number of observations is expected to be larger than it should be. Thus, using the maximum to estimate itself is likely to be an overestimate for any limited sample size. This is particularly true for small samples. In the extreme case note that if a column of cells has only one observation, the observed maximum will be in the one cell where the single observation fell, which will have an estimated probability of 1.0, regardless of the true underlying probabilities. This will become more relevant later when we calculate similar statistics on rows of the matrix, where many of them will involve small numbers of total observations in each row. For now, however, the samples are not too small, and the results are presented in Results Table 5.

Results Table 5

| | Ed5 | Ed25 | CmOb | Swap | Recp |
|---|---|---|---|---|---|
| recall probability = | .16 | .22 | .28 | .34 | .36 |

#### *4.1.5 Discussion*

It appears that performance would be about twice as good when using an optimum naming strategy than when using the weighted random model (which we believe to be an approximation to typical current practice) in a one-word-per-object system. Still, the overall levels are not very impressive. It should be noted that these optimal strategies represent the best *any* single-name scheme could do. No expert, human or otherwise, could choose single names that would work better.

Is this the best that we can hope to do for people? The answer is no. There are other, more effective approaches. One is to use multiple names, sometimes called "aliases", for each object, which leads us to our second general structure for a system model.

### *4.2 Model 2: "Several names per object."*

#### *4.2.1 Interpretation*

Each object in the system is assigned $M$ terms or names. The user enters one term. Success depends on the user's word coinciding with any one of the system's $M$ words.

#### *4.2.2 Motivations*

Giving things single names is not adequate for the uninitiated, so a reasonable next step is to try giving the system several names by which to recognize each object.

#### *4.2.3 Structure*

The constraint is that exactly $M$ words are stored for each object.

#### 4.2.4 Analyses

***4.2.4.1 Version: random.*** For each object $M$ names are chosen randomly from the total vocabulary, i.e., $M$ cells are chosen from each column. The recall probability is $M/R$, and in our sample tables would range from .01 to .04 for three names per object ($M = 3$).

***4.2.4.2 Version: weighted random.*** The first name is chosen with a probability proportional to its frequency in the given object's column of the table. Each successive name is then similarly chosen, without replacement, from the remaining cells. This is as though someone "sitting in an armchair" thought up several distinct names, any one of which the user could use with success. We make an independence assumption that the probability of a word being chosen is independent, except for renormalization, of the words already chosen. This is probably a faulty approximation for a single human generating a series of words, where the first word thought of may influence the next. If the words were separately proposed by different designers, this independence assumption might be more nearly correct.

Note that by reversing the roles of the system and the user we obtain a very interesting dual interpretation of this model. That is, let the system store a single word and the user make $M$ different guesses. Success would be counted if any of the user's $M$ words matches the system word. Either of these interpretations merely involves the probability that a single sample from the column will match one of $M$ samples drawn without replacement from the cells of the same column (that is, without replacing the whole cell, not just the observation from the cell).

*Evaluation: by "M-order repeat rate" statistic, within columns.* These success probabilities can be estimated using an extension of the repeat rate statistic to this case of multiple samplings without replacement of types. The probability for column $j$ can be shown to be estimated by:

$$\hat{r}_j^{[m]} = \sum_{i_1} \frac{n_{i_1 j}}{N} \frac{n_{i_1 j} - 1}{N - 1} \left[ 1 + \sum_{i_2 \neq i_1} \frac{n_{i_2 j}}{N - n_{i_2 j} - 1} \left[ 1 + \sum_{i_3 \neq i_1, i_2} \frac{n_{i_3 j}}{N - n_{i_2 j} - n_{i_3 j} - 1} \left[ 1 + \cdots \right. \right. \right.$$

$$\left. \left. \left. \cdots \sum_{i_m \neq i_1, i_2, \ldots, i_{m-1}} \frac{n_{i_m j}}{N - \left( \sum_{k=2}^{m-1} n_{i_k j} \right) - 1} \left[ 1 \right] \cdots \right] \right] \right].$$

This formula requires a calculation time that grows exponentially in $M$. We therefore limit results to $M \leq 3$. See Results Table 6.

Results Table 6

| recall probability | Ed5 | Ed25 | CmOb | Swap | Recp |
|---|---|---|---|---|---|
| ($M = 1$) | .07 | .11 | .12 | .14 | .18 |
| ($M = 2$) | .14 | .21 | .21 | .25 | .33 |
| ($M = 3$) | .21 | .30 | .28 | .34 | .45 |

Note that allowing the system (or, equivalently, the user) several words for each object in trying to match its partner achieves considerable gain. Performance almost doubles and triples as we go to two and and three guesses.

It should be remembered that the estimated probabilities of success for 1, 2, and 3 guesses were calculated on data from subjects' first responses only. Under the interpretation of this model in which subjects make repeated guesses at a system's single word, this is equivalent to assuming that successive guesses, given that previous guesses had failed, would resemble other first-provided words. To get a true estimate of the expected performance of a system that actually used this technique, we would need data on people actually making successive guesses. One would have to know how many such guesses can actually be made and with what quality before one could know what the maximum performance would be. However, if one supposes that the system, or perhaps the users' desires and abilities, limited input to three guesses, performance of such a system would not be likely to exceed about one chance in three of correct return.

***4.2.4.3 Version: optimized.*** Choose as the $M$ names for each object those terms that are maximally used by subjects for the object; that is, pick the highest $M$ cells in each column and use the corresponding terms. This is a simple generalization of the single-name case.

*Evaluation: by split halves and self-estimation.* We again run into the problems involved in estimating maximum, and now also the nearly maximum, cells. The split-half and self-estimation procedures were used here to estimate upper and lower bounds. The split-half results represent the average performance of ten independent splits of each data set. The results are presented in Results Table 7.

Results Table 7

| recall probability | Ed5 | Ed25 | CmOb | Swap | Recp | |
|---|---|---|---|---|---|---|
| ($M = 1$) | .15 | .19 | .26 | .26 | .31 | (split half) |
| | .16 | .22 | .28 | .34 | .36 | (self-estimation) |
| ($M = 2$) | .26 | .32 | .36 | .36 | .49 | (split half) |
| | .28 | .37 | .41 | .50 | .56 | (self-estimation) |
| ($M = 3$) | .37 | .42 | .42 | .45 | .58 | (split half) |
| | .38 | .49 | .48 | .59 | .67 | (self-estimation) |

#### 4.2.5 Discussion

Considerable benefit is obtained both from using data to optimize choices and from giving the system several names for each object (or, equivalently, allowing the user several guesses). Though it was not undertaken here, it would be interesting to explore the possibility of letting both the user and the system use several names to try to match each other.

The improvement gained by storing multiple words has associated with it a potential cost in ambiguity. Nowhere in either this model or the previous, one-name model has there been any concern that the names be distinct. The names for each object were picked from the corresponding column, with no regard for what names were being chosen for other objects. This means that two objects could be assigned the same name, with consequent ambiguity should the user give that name. The system would be unable to tell which object the user intended, and would have to present the user with a menu of choices to differentiate among them. (Recall that at the outset we stated that we would be assuming such a system, and, moreover, that choices among the items on the subsequent "menu-on-the-fly" would be assumed error free.)

Naming choices will collide when two different objects have the same words applied to them. One might expect this to happen, for example, if two objects are very similar, so that the same words apply to them. We have collected some data that confirm the existence of this similarity effect. For both the recipe and the common object data we compared the probability of a naming collision for random and similar objects in the set. Subjects were given 5 "focal" objects and 25 "match" objects, all drawn at random from the set. For each of the focal objects, they were told to select the one match object that was most similar to it. Using the weighted random naming method, the naming collision rates were compared for these five pairs of similar objects and the same five focal objects paired with random members of the match set. That is, we calculated the probability that a word applied by one user to the first object would be the same as the word applied by another user to a second object. Using subject differences as a random error estimate, there was a highly significant increase in naming collisions for the pairs of objects judged to be similar [$t(14) = 3.86$ and $t(24) = 5.37$ for the recipe and common object data, respectively].

To examine the effects of trying to avoid collisions, we studied the next model.

### 4.3 Model 3: "A distinct name for each object."

#### 4.3.1 Interpretation

Each object in the system is assigned a single term, with the proviso

that no term may be used more than once. Success depends on the user's spontaneously produced word coinciding with the system's distinct name for the intended object.

#### 4.3.2 Motivations

Note that in typical naming circumstances the intent is often to establish conventions about terminology so as to avoid the ambiguity that would otherwise arise. Naming conventions are used not only to set by fiat the name by which an object will be known to a system, but also to proclaim that *only* that object will be so known. Often interaction will reach a stage where complete precision is needed, e.g., for actual command execution.

It may be the designer's motivation in selecting names that users learn terminology that allows them to be precise. As had already been pointed out, however, the designer's intent may not correspond with the user's reality; the untutored may try to deal with the system anyway. Thus, we explore the user-guess success for systems designed with the unique name constraint.

The models discussed here are just like those of the "one-name" case, except that words cannot be used more than once.

#### 4.3.3 Structure

One distinct word is stored for each object, i.e., this is the same as Model 1, except that the words must all be distinct, so that at most one object is referenced by each word. This imposes strong constraints on the system table, on both row and column totals, and the number of rows and columns used overall. This high degree of constraint makes mathematical treatment difficult, as will be discussed shortly.

#### 4.3.4 Analyses

***4.3.4.1 Version: random.*** For each object, one name is chosen randomly from the total vocabulary. Once a vocabulary item is used, however, it is eliminated from any future consideration.

Recall probability would be $1/R$ and range from .002 to .014 for these data. The "number returned" is easy to give for this case, as it is set by the structural constraint, that each name have a unique referent. It is therefore 1 for all models having this structure. That is, when the system finds a target it returns exactly one candidate. However, there are many occasions when the user word matches no system word, and so no target is returned.

***4.3.4.2 Version: weighted random.*** Here the name is chosen with a probability proportional to its frequency in the given object's column of the table. Then the chosen word is eliminated, and a name is chosen in an analogous way for another object from the remaining words, etc.

The results are clearly influenced by the sequence in which objects are dealt with. The approach used here was to choose in the following way: a word/object pair is chosen by a weighted random sampling from the whole table. This gives the right distribution within each column and allows appropriate representation of each column. Once such a cell is chosen, the corresponding object has been named and the word used, so both are eliminated, and the procedure is iterated on the table, now reduced by one row and column, until all objects have been named.

*Evaluation: by Monte Carlo simulations with split halves.* We could devise no way to evaluate this model analytically, so we used a Monte Carlo simulation on split halves. We divided the data in the user table in half and randomly picked names, according to the model outlined above, using the data from one half. The second half of the data was then used to evaluate the effectiveness of the names thus chosen. The results presented here are the average for ten split halves with ten independent Monte Carlo simulations of name selection in each. See Results Table 8.

Results Table 8

| | Ed5 | Ed25 | CmOb | Swap | Recp |
|---|---|---|---|---|---|
| recall probability = | .07 | .08 | .11 | .12 | .09 |
| number returned = 1.0 (by design) | | | | | |

Note that, as might be expected, success is less than for the comparable model in which names did not have to be distinct. In some instances this decrease is small, as with the edit studies; in others it is large, as with the recipes. This should depend on whether there were a few high-frequency words that were used for many different objects.

***4.3.4.3 Analysis of precision versus popularity of terms.*** In all of our data sets there was a slight trend for high-frequency words to be less discriminating than low-frequency words. In studying this relation quantitatively, the measure of discriminating power of a word was given by the repeat rate statistic, this time applied within each row. This row-repeat rate is a measure of the probability that two uses of a word refer to the same object. When this probability is high, the word is very discriminating. Below we present the correlation (Spearman $r$) of row-repeat rates with the marginal frequency of the words. See Correlations Table 9.

Correlations Table 9

| | Ed5 | Ed25 | CmOb | Swap | Recp |
|---|---|---|---|---|---|
| corr: | −.28 | −.30 | −.21 | −.24 | −.16 |
| ($N$ words): | (74) | (84) | (301) | (145) | (167) |

This correlation points to the cause of the difficulties run into by the constraint of distinct names. There is something of a conflict. If one chooses high-frequency names, they will be likely to collide. If one chooses less frequent names, the chances of collision will be somewhat less, but fewer users' queries will be handled. Unfortunately, there is no correspondence between the size of these correlations and the size of the decrease in performance for each data set. The reasons for this are not clear.

***4.3.4.4 Version: optimized (though not best possible).*** The idea is to choose the distinct names such that the total probability in the cells chosen is maximal. The method used here is a greedy algorithm that is not truly optimal, but it is a reasonable improvement over the weighted random method. It begins by picking the highest cell in the matrix; then, after eliminating the corresponding row and column from the matrix, it iterates, picking the next highest cell, etc., until all objects have been assigned a name. Algorithms like this are called "greedy" because at each step they take the biggest possible chunk of what is left, without regard for what later problems that may cause. In this case, it is possible that an early choice will eliminate a word that would be very good for another object, when there was an alternate word that would have done almost as well at no such cost. Algorithms that would take such future complications into consideration, or equivalently consider so many possibilities at once, are typically combinatorially explosive. Thus we present the results of the straightforward greedy algorithm approach.

*Evaluation: by split halves.* There is no simple method to estimate the performance of such an approach. Again we turned to the split-halves technique of dividing the data in half, applying the algorithm to one half and then testing the chosen names on the other half. The results, averaged over ten independent splits, are given in Results Table 10.

Results Table 10

| | Ed5 | Ed25 | CmOb | Swap | Recp |
|---|---|---|---|---|---|
| recall probability = | .14 | .11 | .23 | .19 | .11 |
| number returned = 1.0 (by design) | | | | | |

### *4.3.5 Discussion*

As we expected again, the optimization attempt, even though imperfect, has a dramatic effect, in many cases doubling the performance of the system. Even in the best case, however, the system succeeds only about one quarter of the time, and typically little more than a tenth of the time. We note that the numbers here are substantially lower than in the case where there was no requirement that names be distinct. In fact this improved method really does no better than an

armchair (weighted random) version of the unconstrained model, and often worse. The lesson here is that adding the requirement of uniqueness, common in establishing conventions, hurts naive users quite a bit. The need for such conventions is not denied, it is simply asserted that auxiliary aids will be needed for systems that make heavy use of such conventions. It is worth noting that, for our data sets, the number of objects that are not disambiguated and would have to be presented for a second stage choice is always small, and the gain in recall always large. Thus, the "menu-on-the-fly" method implicit in several of the models presented here appears to be very promising as an aid to unsophisticated users.

### *4.4 Model 4: "Distinct names, augmented with M extra referents."*

#### *4.4.1 Interpretation*

Each object is given a distinct name. $M - 1$ other referents for those words are also stored.

#### *4.4.2 Motivations*

Part of the inferiority of the distinct-name models, when compared to the unconstrained models, came from the fact that people often want to use the same names to refer to several objects. The motivation for the next model is to recapture access to some of those other interpretations of the term. A simple extension of the distinct-name structure is to begin with the situation where each object is associated with a distinct name, one that can be memorized and used unambiguously by experts, but also to store $M - 1$ other objects that the term applies to, explicitly for use in a "menu-on-the-fly" for the untutored. A reasonable system implementation might be to give the "distinct" name a special status (the "real" meaning of the term), and to admit the other interpretations as secondary, perhaps to be verified in the context of use.

This is the first model in which we explicitly design in more than a single system guess as to the intended object. To be sure, several guesses for the meaning of a term could (and would) have arisen in the uncontrolled name cases of Models 1 and 2, but here we predetermine exactly how many guesses the system makes and evaluate performance as a function of this parameter.

As more objects are returned, the likelihood of including the intended target is increased, but a certain cost is incurred—the cost associated with discerning the true target among all the returned objects. Data searches can fail not only by not giving access to a desired object, but also by returning too many unwanted objects. In information science the problem is familiar as the trade-off between *recall*—the number of desirable items returned—and *precision*—the

proportion of items returned that are desirable. This is also similar to the hit versus false alarm trade-offs of signal detection, familiar to psychologists and communication theorists. In the latter context the trade-off is sometimes examined by tracing out operating characteristics and interpreting them in terms of parameters of an underlying statistical theory. There does not currently exist a corresponding statistical theory for our precision and recall rates, but it is useful to be able to examine, or in this case, control, precision explicitly and see what gains in recall result. This yields an operating characteristic. Any version of the general baseline model in which the system is set up to return an explicit number of guesses provides a direct way to do this.

#### *4.4.3 Structure*

At least one name is given to each object, but each name that is used by the system also refers to $M$ different system objects.

#### *4.4.4 Analyses*

***4.4.4.1 Version: random.*** Here the primary cells are again chosen completely blindly, eliminating rows and columns already used in an iterative manner exactly as in the distinct-name case. After the $C$ primary cells are chosen, the $M - 1$ additional or secondary cells are chosen randomly from each new row chosen.

The resulting probablity is $M/R$ and would range from .001 to .035. The number returned is, of course, $M$ by design for all versions of Model 4.

***4.4.4.2 Version: weighted random.*** Cells are chosen at each step with a probability reflecting their magnitudes. Thus, first $C$ distinct names are picked, as in the distinct-name model (Model 3). Then, in the row of each cell just picked, $M - 1$ more objects are chosen with a probability equal to their relative frequencies in the rows.

Again, the weighted random case is an approximation to what an individual designer might do without collecting data from other people. The process of coming up with additional interpretations requires a bit of further explanation. The asymmetries found in free association data suggest that people starting from terms and generating objects would yield probabilities quite different from those obtained from people starting with objects and generating terms.[13] This asymmetry means, in this model, that the additional interpretations cannot be thought of as the result of the designer sitting in an armchair and thinking up other interpretations for the terms. The efficacy of such an approach is not estimable from our data.

A scenario that might better satisfy the assumptions of this model would have the system memorize the first $M - 1$ nonstandard uses of its known terms that it comes across.

*Evaluation: by Monte Carlo simulation on split halves.* The data are given in Results Table 11.

Results Table 11

| recall probability = | Ed5 | Ed25 | CmOb | Swap | Recp |
|---|---|---|---|---|---|
| ($M = 1$) | .07 | .08 | .11 | .13 | .08 |
| ($M = 2$) | .13 | .15 | .15 | .17 | .15 |
| ($M = 3$) | .18 | .21 | .18 | .20 | .20 |

The number of guesses that the system is requiring to achieve this performance is of course, $M$, the number returned by design.

***4.4.4.3 Version: optimized (though not best possible).*** Again it was not feasible to find the completely optimal choice of cells. Instead, the primary cells were found in the same "greedy" way used for the simple distinct-name "optimal" case. The subsequent choice of secondary referents for the words so selected can be optimized by choosing the $M - 1$ largest cells remaining in the row. Note that it is possible for some of these remaining cells to be larger than the primary cell, as when they refer to an object that was eliminated before the row was chosen. (It is the vagaries of the need for convention in names that brings about this ironic use of the term "primary.")

*Evaluated: by split halves.* In the now familiar procedure, the data are split and the first half used to choose the cells following the algorithm just outlined. Then the second half of the data is used to evaluate the choice of cells. See Results Table 12.

Results Table 12

| recall probability = | Ed5 | Ed25 | CmOb | Swap | Recp |
|---|---|---|---|---|---|
| ($M = 1$) | .14 | .11 | .22 | .21 | .11 |
| ($M = 2$) | .21 | .20 | .28 | .27 | .17 |
| ($M = 3$) | .27 | .29 | .31 | .30 | .22 |
| number returned = $M$ (by design) | | | | | |

These results, for one to three total guesses, are plotted in Fig. 2. The model curves can be viewed as operating characteristics, giving total recall as a function of decreasing precision. The dashed diagonal lines represent expected chance performance if the system returns guesses at random. Note that in the case of the Ed5 data, the random performance is *better* than that of this model. This is possible because this model, like most current computer systems, makes no response at all to any but a few words. By failing on so many of the words it encounters, it can be surpassed by a system that only guesses, but at least guesses for all words. Admittedly, in the context of command execution any level of guessing without confirmation may be danger-

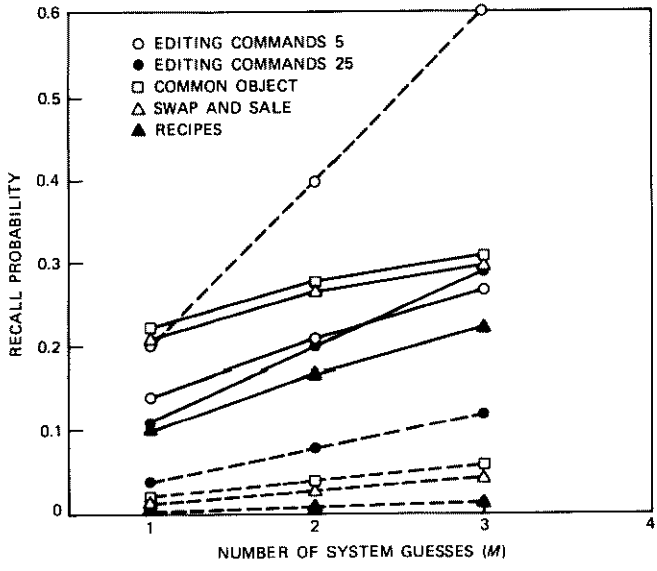

Fig. 2—Recall as a function of the number of system guesses for Model 4 ('distinct names, augmented with $M$ extra referents') is shown by the solid lines. The dashed lines represent expected chance performance if the system returns guesses at random. (Different chance performance for the different data sets simply reflects the different number of objects in each set.)

ously out of place, but there are safer arenas, like help facilities, that could benefit. In any case the cost of ignoring so many user words is made clear. Notice that the total probability does not approach one, even in the case of command verbs for editing operations where there were only five objects. The reason is again that many words were used by our subjects to describe these objects, and the algorithm picked only a maximum of $C$ of them to recognize. The modeled assumption was that if a subject supplied any word not recognized by the system, no choices would be returned and a failure would result.

#### *4.4.5 Discussion*

These models use the same number of cells as the multiple-names models, yet do not do as well. The implication, presumably, is that there is considerable cost in limiting oneself to a small number of words. The users distribute their descriptors too broadly for any such limitation to be very satisfactory.

Thus we are motivated to try a completely different approach. All the models up to this point have inherently focused on what the system brings to the interaction. The modus operandi has been to set all the system's objects before us and then try various ways to guess what users will call them, albeit with some improvements as we give

deference to the empirical characteristics of the user's language as seen in the user table.

Suppose we turn the tables, so to speak, and focus on what the users bring to the interaction: the terms they use when trying to specify things. Start with the terms, all of them, and concentrate on trying to guess to what object they refer. This brings us to our next model.

### *4.5 Model 5: "Recognize one referent for every word."*

#### *4.5.1 Interpretation*

The system stores every word that it can, and for each has one guess as to the intended object.

#### *4.5.2 Motivations*

One of the principal problems with the approaches studied so far has been that a large proportion of the recall failures can be attributed simply to not recognizing many of the user's words. The systems modeled have paid too little attention to the wide variety of the terms people use spontaneously. Here we focus on this essential character of what the users bring to the interaction. For every word produced during the collection of the data for the user table, a guess is made. The different versions vary as to how these guesses are made.

It is useful to note that these models, and their generalizations in the next section, are really duals of the single- and multiple-names models. In those models the system had words for each object, and it succeeded when its name was the same as the word the user would use. Thus, to evaluate those models we calculated the conditional probability that, given a target object, the system and user names would coincide. Then we summed probabilities across objects, weighting each by its column's marginal probability (all essentially equal in our data, by design). Here we conditionalize the other way. Given the word used, we find the probabilities that the system and user associate the same object with the word. Then we sum across words (rows), weighting by the very uneven observed marginal frequencies for each word, to get the overall performance.

#### *4.5.3 Structure*

The system makes use of every word in the table, associating each with one, and only one, system object.

#### *4.5.4 Analyses*

***4.5.4.1 Version: random.*** Here the system will associate random objects with the input words. That is, the system will simply make a

random guess for anything the user says. The recall probability is just $1/C$, and ranges from .005 for the recipes to .200 for the Ed5 data. The number of guesses being made to achieve these performances is predetermined by design to be 1 for all these models.

***4.5.4.2 Version: weighted random.*** Here an object is associated with each word by a random method that takes each object with probability proportional to its relative frequency in the row. Arguments similar to those made for the augmented distinct-name model here imply that this is not the analog of having the designer sit down with the list of words and hazard guesses as to what they mean; the data used here go in the other direction. The more appropriate scenario is as if a system records the first encounter with a new word, and its intended referent, and makes a single pointer based on this single observation, forever freezing the meaning of the word. This is perhaps an unreasonable scenario, but the model is worth investigating because the statistics that result have other valuable interpretations.

*Evaluation: by row-repeat rate statistic.* The probability of success in this case is the probability that two users will mean the same thing by a given word. The results below are the average row-repeat rates, weighted by total row frequency. (Rows with a frequency of one were excluded, since the repeat rate is not calculable in that case.) This number is an unbiased estimate of the overall probability that any two occurrences of any word will be in reference to the same object. See Results Table 13.

Results Table 13

| | Ed5 | Ed25 | CmOb | Swap | Recp |
|---|---|---|---|---|---|
| recall probability = | .41 | .15 | .52 | .62 | .13 |
| number returned = 1.0 (by design) | | | | | |

We note how variable the probabilities are. They are low where the same words mean different things, and high where any one word refers to only one object. Apparently these domains differ in this aspect. There are at least two possible explanations. First is the similarity effect discussed in connection with Model 3. There it was shown that pairs of objects judged to be similar had higher overlap in the patterns of names applied to them than did random pairs. The resulting naming collisions meant that it was more difficult to find distinct names for similar pairs. Here we are explicitly interested in a different, though related, effect. We can use the previous experimental data (see Section 4.3.4.3) again, this time to demonstrate the similarity effect on a row-repeat rate measure. In this version we consider pairs of cells in each row: one cell from the target column, and one from either a column

rated similar or from a random control column. The repeat rate is calculated on the two cells and summed (weighted by row sum) down all the rows. Since a low repeat rate for a given word indicates that it does not discriminate well between the objects, we predict a lower repeat rate for the similar pairs of objects, and that is what we obtain. In the recipe data the mean repeat rate of the similar pairs was .73 and for the random pairs was .91 [$t(14) = -5.83$]. For the common object data, the similar pair repeat rate was .89 and the random repeat rate was .95 [$t(24) = -5.71$]. Thus similarity has a strong effect on repeat rate. Unfortunately, what we need to make sense of the varied results is some measure of the relative internal similarities of the various domains. Such data are neither available nor easily obtained. Still, it might be agreed that the set of common objects is more diverse than is a set of cooking recipes, or text editor operations, corresponding to observed differences in average repeat rates.

There is another factor that might be helping the swap-and-sale descriptors. Analysis of the other data sets was either strictly limited to single words, or else only to short phrases with few content words. Swap-and-sale descriptors contained an average of 1.7 content words, where there were fewer than 1.2 content words in the others. If these words tend to be used in a conjunctive sense and if they are not redundant, they should contribute to the high selectivity of the descriptors seen for the swap-and-sale data.

A final note should be made of the higher repeat rate for Ed5 compared to Ed25. Part of this is due simply to the fact that even with a purely random, undiscriminating distribution of name usage across objects, there would be an increase in repeat rate as the number of objects is decreased. If there are only two objects, people will have to mean the same object by any given term at least half the time. A more intriguing possibility is that the classes are more distinct entities than are the individual objects, and that this makes word usage more discriminating, above and beyond the chance effect just mentioned.

***4.5.4.3 Version: optimized.*** In this case the user matrix is used to find the best possible choice for a word's referent. This is done by picking the maximum cell from each row, the object to which the word has most commonly referred.

*Evaluation: by split halves, square root of the row-repeat rate, and self-prediction.* Evaluation is again problematic. While there is no question that picking the maximum cell is the best possible strategy, there is no unbiased estimate of its true magnitude. Thus we resort to the same three methods used when similarly confronted in the optimal version of the one-name model (Model 1): the split-half technique, an unbiased estimate of how well one could expect to do with half the data; and two estimates of upper bounds. See Results Table 14.

Results Table 14

| | Ed5 | Ed25 | CmOb | Swap | Recp | |
|---|---|---|---|---|---|---|
| recall probability = | | | | | | |
| | .49 | .18 | .43 | .35 | .13 | (split half) |
| | .62 | .35 | .65 | .72 | .28 | (square root of row-repeat rate) |
| | .54 | .26 | .69 | .81 | .25 | (self-prediction) |
| number returned =1.0 (by design) | | | | | | |

#### *4.5.5 Discussion*

There is considerable variability, both in the performance and in the range of these estimates. The largest range is for the swap-and-sale estimates. This is due to the very large number of descriptors that occurred only a few times. The data for each such descriptor are statistically unreliable, so the maximum cell cannot be accurately identified; this problem is severely aggravated by splitting the data and only using half to make the identifications. Note that this is not an experimental artifact. A very long tail on a descriptor distribution is a legitimate real-world problem, because it means that new terms will keep arising that the system will not have seen before, and about which it will not be able to make any educated guesses. A wide range in the estimate reflects the fact that very large amounts of data would be needed to approach asymptotic performance.

As for the overall diversity of scores from domain to domain, the arguments about similarity and number of words in the descriptors, given above for the repeat-rate case, are equally applicable here.

The most important point to be made about this optimized model is that it represents the best one could possibly do. We can do no better than to recognize every word users use and make an optimal guess as to its meaning. Clearly, if we have insufficient data to do this well, either preventing us from recognizing a word, or from being able to estimate the modal referent, performance will suffer. But the upper bound estimates represent the real, strict limits of performance. No other pattern of structural constraints could do better, except at the cost of precision. This trade-off with precision is explored in our final model, in which an explicitly prespecified number of multiple guesses is returned to increase the chance of including the user's intended object among them.

### *4.6 Model 6: "M referents for every word."*

#### *4.6.1 Interpretation*

The system stores every word that it can, together with a set of $M$ possible referents. Whenever the user enters a word, the system returns the $M$ guesses, possibly ranked in some way.

#### 4.6.2 Motivations

The "one referent for every word" model (Model 5), in its optimized version, gave the best possible performance for a system that hazards only one guess for a user's word. The only way to increase the chance of returning the user's intended object is to return more than a single guess. These guesses could be returned in the form of a menu of $M$ items, among which users would choose.

As we mentioned, this is the dual of the multiple-name set of models, and several of the evaluation procedures differ only in that rows have traded roles with columns.

#### 4.6.3 Structure

Like the previous model, the system makes use of every word in the table, but here it associates $M$ system objects with each.

#### 4.6.4 Analyses

***4.6.4.1 Version: random.*** The system makes just $M$ pure guesses, without replacement, from the set of system objects. The recall probability for these cases is thus exactly $M/C$, and the number returned is $M$, by design, for all versions of Model 6.

***4.6.4.2 Version: weighted random.*** In a manner following the single referent weighted random model, the $M$ cells are chosen with a probability that is proportional to their relative sizes. The $M$ choices are required to be distinct, and so a cell is excluded from further consideration once it has been selected.

The scenario that this might correspond to would be one in which the system learns the first $M$ distinct referents of the word that it comes across in use. Its encounters would be governed by exactly these probabilities.

*Evaluation: by M-order repeat rate statistic, within rows.* We want the probability that the user's single intended referent coincides with any of the system's candidates, when both sets are drawn from the same probability matrix. These success probabilities are estimated using the same extension of the repeat rate statistic used in evaluating success of the many-names-for-one-object model (Model 2, Section 4.2.4.2). Here though, it is applied to the cells within a row, rather than within a column.

It should be noted that the formula requires there to be $M$ nonempty cells in the row, to prevent some of the denominators from going to zero. For example, it is not possible to give an unbiased estimate of how well three guesses would do if the data only show two objects. Note that while rows with highly discriminating words should in general have high $M$-order repeat rates, it is exactly such rows that will be less likely to satisfy this requirement, especially at lower

marginal frequencies. Thus, ignoring rows where this statistic cannot be calculated biases the average value of this statistic downward. Though it is not clear how to get an upper estimate, there is another way to get a lower bound, by recognizing that performance for $M$ guesses is at least as good as performance for $M$-1 guesses. Thus, a lower bound on the average performance comes from using for each row the calculable repeat rate of highest order not greater than $M$. See Results Table 15.

Results Table 15

| | Ed5 | Ed25 | CmOb | Swap | Recp |
|---|---|---|---|---|---|
| recall probability = | | | | | |
| ($M = 1$) | .41 | .15 | .52 | .62 | .13 |
| ($M = 2$) | .66 | .26 | .65 | .74 | .21 |
| ($M = 3$) | .81 | .36 | .71 | .80 | .27 |

***4.6.4.3 Version: optimized.*** This version takes the optimal strategy for multiple guesses. The user gives one word, and the system makes guesses that the user means one of the $M$ most likely things the word has meant in the past, as deduced from the data in the user table. That is, it returns the objects associated with the $M$ highest cells in the row corresponding to the word given. (A sequential version of the model would give the user the guesses in decreasing observed frequency, beginning with the maximum cell.)

*Evaluation: by self-estimation and split halves.* As in other cases where evaluation of performance depends on the estimation of true population ordered frequencies, we must resort to indirect methods to give a range. We use split halves to give a lower bound and self-estimate to give an upper bound. See Results Table 16.

Results Table 16

| | Ed5 | Ed25 | CmOb | Swap | Recp | |
|---|---|---|---|---|---|---|
| recall probability = | | | | | | |
| ($M = 1$) | .49 | .18 | .43 | .35 | .13 | (split half) |
| | .54 | .26 | .69 | .81 | .25 | (self-estimation) |
| ($M = 2$) | .70 | .30 | .53 | .43 | .20 | (split half) |
| | .76 | .42 | .82 | .92 | .37 | (self-estimation) |
| ($M = 3$) | .83 | .40 | .58 | .47 | .26 | (split half) |
| | .88 | .53 | .88 | .96 | .46 | (self-estimation) |
| number returned = $M$ (by design) | | | | | | |

The recall rates, as estimated by the conservative split-half procedure, are given in Fig. 3. The curves can be interpreted as operating characteristics; the distance between the curves and the corresponding dashed diagonal line reflects how much the implied system could be expected to outperform a simple menu system based on the pure random model given above, i.e., on a random choice of $M$ objects. All

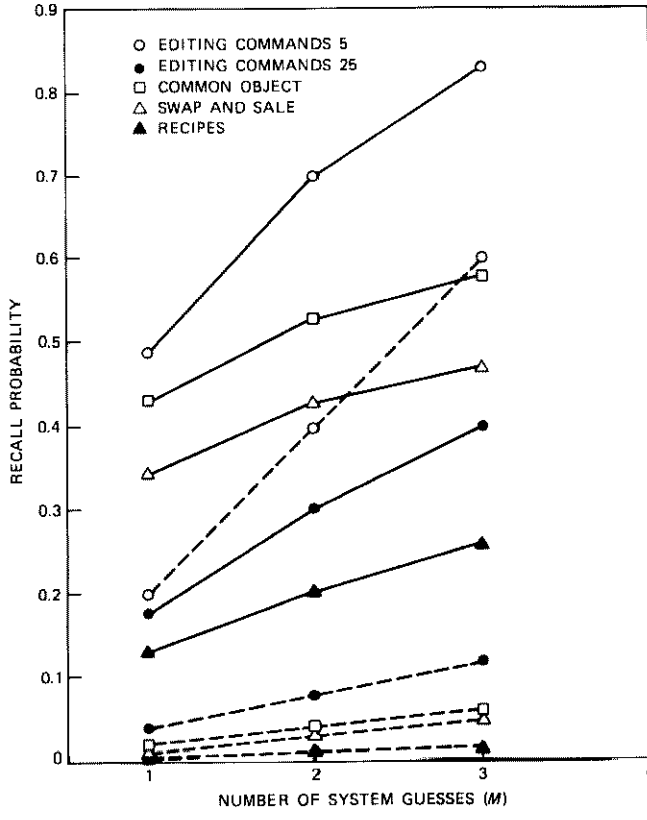

Fig. 3—Recall as a function of the number of system guesses for Model 6 ('*M* referents for every word') are shown by the solid lines (split-half estimation). The dashed lines represent expected chance performance if the system returns guesses at random. (Different chance performance for the different data sets simply reflects the different number of objects in each set.)

of our models do substantially better than chance. More importantly, they do much better than the augmented distinct-name model (Model 4) presented in Fig. 2.

#### *4.6.5 Discussion*

There are really two important points to be made about these results. The first is that these performances are variable and but moderately high. Note that the very high value of the three-system-guess case in Ed5 is rather vacuous, since there were only five objects to guess from. In the common object case, however, the high values are quite meaningful, since there were 50 objects.

The legitimate high values lead us to the second observation, that substantial improvement has been gained over the traditional, one-

distinct-name approach. The presumption is that this gain is due in part to the increase in capturing all the user's inputs. There are, after all, two ways for the system to fail in retrieving the user's target. One is by making wrong guesses, the other is by being unable to make any guesses at all. To give an idea of the size of this problem: for three of our data sets, no system using only $C$ words (e.g., one for each object) could recognize even half the user's words. Thus, recall rates can only increase as the system is taught more words, and often this can be a sizable improvement. The only conceivable decrements (except those associated with time and space in index management) would be if the additional words were less precise, thus decreasing precision for a fixed recall rate, or decreasing recall for a fixed precision. But our finding of a consistent, albeit small, negative correlation between a word's frequency and its selectivity suggests that the opposite is true. As a greater number of lower-frequency words are included, precision will go up.

Recall also increases dramatically if the choice of algorithms is optimized, though it never exceeds the square root of the performance obtained by "armchairing", i.e., making pointers based on a single observation. The cost is in the trouble it may take to collect data. In some cases the variety of terms is so great that data collection must continue for quite a time before asymptotic performance is approached. Performance also increases as the system is allowed to make more guesses; this involves a direct trade of recall probability for reduced precision. In many circumstances, particularly in help facilities, this presents little problem. The user need only be given the various options and whatever additional information it takes to decide what is really sought.

### *4.7 Other possible models and some limits*

The models presented so far have covered a large share of the space of simply constrained models where the user makes one guess, but they do not exhaust the ways in which a system could use empirical data on user descriptions to guess the user's desired objects.

One might consider, for instance, models that take advantage of redundancy in the tables. A good theory or description of what such tables are like could be used to augment the data to make better estimates of true population usage probabilities. For one example, if we knew that some single shape of distribution characterized all columns, we could use the data to estimate parameters of that distribution instead of individual cell probabilities. This would reduce the number of parameters that need to be estimated from the data, and consequently improve stability and reliability of predictions.

A related, and perhaps more interesting, idea would be to look for

latent structure in the similarity between objects, and between words, and use this to improve predictions. For example, if we knew or could infer from the data that two words were used almost identically, we might pool the cell frequencies for the two words; or if we knew that the objects and words related to each other by some more elaborate structure (e.g., a hierarchical tree), we could base predictions on calculated indirect reference paths.

While these ideas might be useful, the research presented in this paper puts strict limits on the success of any such approaches. As noted above in Models 5 and 6, the self-prediction evaluation procedure (determining the best guesses from the data and then using the same data to estimate success) and the "square root of repeat rate" evaluation procedure yield upper bounds on expected performance. Indeed, no analysis method of the kind we have just been discussing, no matter how clever, could improve on this result. The reason is as follows. Even using inherent structure to improve predictions could do no more than increase the accuracy of estimation of the population values for the input/output tables. Even with true population probabilities, however, the guessing decision rule would be the same; choose first the most probable referent of each word, and so forth. The input/output tables are inherently probabilistic, as a result of disagreement in word usage, not just of the estimation uncertainties. For a given user population, with a given degree of training, a certain amount of disagreement in word usage will occur. Even with perfect knowledge of the probabilities describing this usage, we could not predict individual referents perfectly. Now, the objective of having true population probabilities as cell entries is mimicked by our upper bound estimating procedure. It pretends that the values observed for each cell are exactly the probabilities that would exist in further sampling from the population. Thus, no method of "cooking" the data to reduce sampling error could achieve a better result than is illustrated by our upper bound values.

To improve performance beyond these limits, it would be necessary to construct systems that use different input, e.g., multiple words or interactive dialogues, or make the user learn to use more easily interpretable language. The last of these is the current default approach—make the user learn everything—and it has its limits for large systems or occasional users. Thus, we believe a more fruitful direction to explore further is multiple-word inputs.

The simplest models of multiple-word query might assume only content words (no syntax) and a statistical independence between words. Independence would allow the performance of such a system to be estimated from single-word data of the sort we have collected. Multiple words could be used disjunctively. In this case the system

would return any objects that matched any of the input words. This would result in an increase in probability of recall. Alternately, the words could be used conjunctively, so that the system would return only objects matching all the key words. The result would be higher precision. Mixtures of these two approaches (e.g., conjuncts of disjuncts) then clearly could be used to improve both precision and recall.

Of course, from our data we do not know how people can or do use multiple words, even without considering syntax. The popular balances of conjunction and disjunction are unknown, and spontaneous multiple guesses are no doubt not independent. But what sort of nonindependence is common? For example, do multiple terms tend to be more unrelated, or more redundant, than independence predicts? These questions must be explored before multiple-word systems can be theoretically evaluated, or optimized for the naive user.

The consideration of syntax leads to a whole new set of problems, those often encountered in Artificial Intelligence work on natural language understanding. We will not address them here.

### *4.8 Highlights*

In the previous sections we used the tables of observed word usage to explore various models of how systems could name, and thereby give access to, their contents. We devised six general schemes for assigning names to objects. To test the schemes, we approximated user behavior by sampling appropriately from the tables.

Thus, for example, we simulated what word a designer might assign to an object (pick from the table), what word a user might choose (pick again from the table), and looked at how frequently the two words were the same. The results were taken to indicate how well a set of spontaneously generated single names for objects can be expected to work for untrained users. This particular example was called the "armchair model." The table is, after all, only a compendium of many people's spontaneous armchair attempts to give the best possible names for these objects. Thus, sampling from the table mimics designers picking names from their armchairs.

We used this general technique to explore variants on our basic model of interaction, in which we assume the designer builds in certain connections between names and the system's objects or services. These names were in some cases purely random, and in other cases were a simulation of a designer's best armchair guess; in still other cases the names were chosen more systematically, with a goal of optimality. In all cases, we assume that the user must "guess" the right name because we are concerned with untutored users who do not know the system words. The user's choice of words was always mimicked by sampling from the tables.

Of the models and variations, summarized in Appendices A and C, perhaps the most important are:

(1b) "One name per object: weighted random"
(1c) "One name per object: optimized"
(6c) "M referents for every word: optimized."

The first of these (1b) was the so-called "armchair" naming method just described. Expected results from the armchair method are shown in Fig. 4 model (1b). Note that despite the fact that the four domains differ dramatically in content, data collection style, and subject population, the results are quite consistent. They are all low. Two people—the designer and the user—will come up with the same name only about 15 percent of the time.

These results indicate that the current practice is deficient; it guarantees that it will be difficult for people to tell machines what

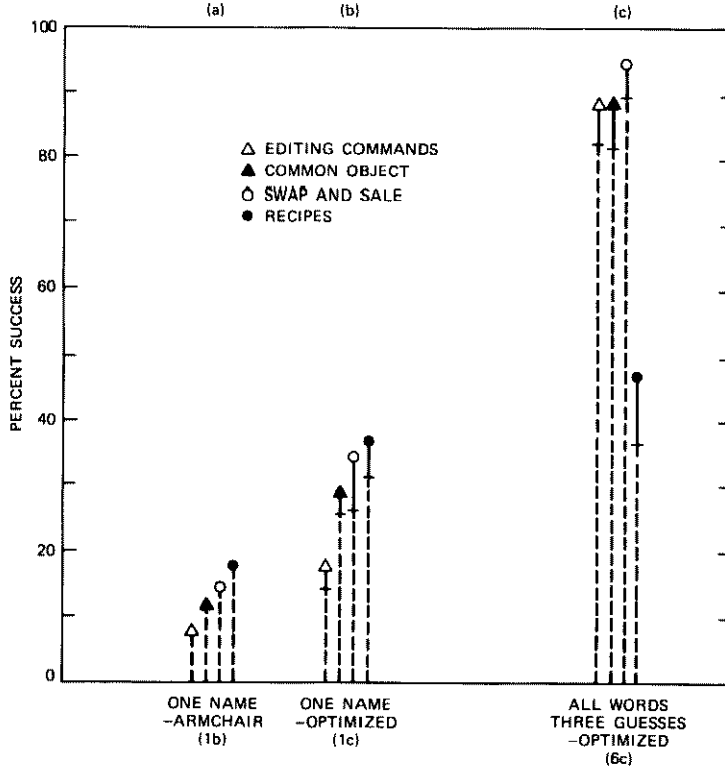

Fig. 4—Summary of expected success for three of the most important models presented. (a) "Armchair" model (1b); (b) Best possible single-name model (1c); (c) Model where the system recognizes all words and returns three guesses (6c).

they want, unless they already know what to say. Note that designers often have other, legitimate motives in assigning names—e.g., lack of ambiguity, memorability, or cuteness. But such naming practices only make the current problem worse; they lead to even less likely names.

The source of the problem is this. There are many names possible for any object, many ways to say the same thing about it, and many different things to say. Any one person thinks of only one or a few of the possibilities. Thus, designers are likely to think of names that few other people think of, not because they are perverse or stupid, but because everyone thinks of names that few others think of. Moreover, since any one person tends to think of only one or a few alternatives, it is not surprising that people greatly overrate the obviousness and adequacy of their own choices.

To improve performance of the "armchair" method we investigated whether experts in one of the content areas could pick better words. We had expert chefs choose key words for cooking recipes and found essentially no improvement: experts do not seem to do noticeably better picking terms from their armchairs than does anyone else (Section 4.1.4.2).

The next model of major interest (1c) substituted objective data for armchair suggestions. It used our data tables to identify the name that was most commonly used for each object. Thus, for example, for the operation we referred to as DELETE, the most commonly used term was "omit", with a frequency of 110, and that was the name used in this model. This empirical approach, occasionally advocated by human factors people, achieves the levels of expected success illustrated in Fig. 4 model (1c).

As discussed in Section 4.1.4.3, for statistical reasons we can only estimate certain upper and lower bounds on performance here. The lower one indicates how well one could do with a limited amount of empirical data from which to try to pick the best names. The upper one liberally estimates how well one could do with an infinite amount of data. The improvement over the armchair method is substantial, typically almost doubling the hit rate. This makes the point that the best name is a good bit better than the typical name. But it is also clear that even the best one is not very good.

It is critical tc note that these numbers represent the best one could possibly do by assigning a single name to each object. The problem is not solved by finding the right name. Different people, contexts, and motives give rise to so varied a list of names that no single name, no matter how well chosen, can do very well. Figure 5 is a plot of how many names are needed to account for a given percentage of the users' attempts, here for the common object data. (Here again we have the statistical estimation problem, so the boundary is double.) Note that

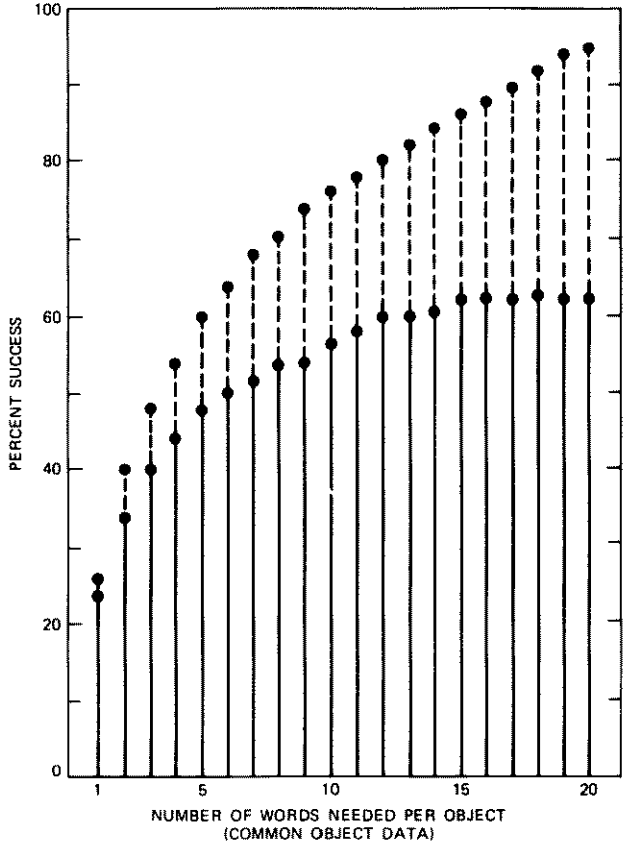

Fig. 5—A plot of how many different names (or "aliases") are needed for each object to account for a given percentage of success. This plot is based on data from the common object domain. The dashed lines indicate ranges.

even 15 words (word types or "aliases") per object account for only 60 to 80 percent of the words people apply. That is, even with 15 names stored per object, the computer will miss 20 to 40 percent of the time. The lesson clearly is that systems must recognize many, many names.

After considering several other models, we turned the problem around a bit. Instead of starting with system objects and looking for names, the new strategy was to begin with user's words and look for interpretations—that is, try to recognize every possible word that the users generate, and use empirical data to determine what they mean by that word.

We inject a cautionary note here: when word meanings are to be surmised from word usage data, there is always a risk that the same word may have been used in reference to several objects in the system.

In such a case, the system would not have a unique guess. (This was actually an implicit problem discussed for several of the earlier models.) In our simulations, we limited the system to returning just its single best (Model 5, Section 4.5) or best three (Model 6, Section 4.6) guesses as to what was wanted, given the word the user said. For discussion here we will mention only this last model (6c). The results in Fig. 4 show what can be achieved if all words are saved by the system, and it uses behavioral data to make the three best guesses as to what was meant. (Here too we can only present estimates of upper and lower bounds on performance.)

These results are encouraging. The big improvement is due primarily to the fact that the earlier methods, like most in current use, failed to recognize all the rare words. The unfortunate truth is that the majority of words used are "rare" words, and so it is a mistake not to reckon with them. Indeed, it turns out (see Section 4.3.4.3) that less common words tend to be more precise, more discriminating, and so are particularly valuable for the computer to know.

While we studied quite a wide variety of intermediate models, this last one really is the best. At the risk of belaboring the point, here it is summarized again. It requires: (1) the computer to keep all words that people use; (2) that data be collected on what users use each word to refer to; (3) that when someone uses a word, the computer goes to the data table and looks up the top few candidates to determine what its interpretation should be (what the word is most probably referring to); and (4) the computer presents the candidates to the user as a choice, since the interpretations may be in error. This model amounts, really, to a rich, empirically (i.e., behaviorally) defined cross index. Without it, performance is near abysmal, with it, potentially quite good.

Further improvements are shown to require the input of multiple words. This would entail means for representing and evaluating relations as well as reference, and matters of logic, syntax expression, and language comprehension. Detailed analyses of the complicated usability issues that would be involved are beyond the scope of this paper, but a number of related issues were addressed in Section 4.7.

## V. DISCUSSION

We have seen that the object referent of a word cannot be predicted with great accuracy from knowledge of its past referential use. The use of statistical data on reference behavior can improve the choice of a single name by roughly a factor of two over the common procedure, in which only a single designer-chosen word is stored as an entry point for each object. Even the best system input/output function of the general kind we have described, while adding another factor of two or

so to performance, can be expected to perform at well below perfect reliability. In this section, we touch on some of the reasons for this limitation and suggest some avenues for further exploration of better means for understanding object reference.

Obviously, one of the main difficulties in predicting an intended object from a provided word is synonymy. There are many different words that can refer to the same object. Even though the receiver may know several of them, the communicant (or user) may choose another. It is the long-tailed distribution of the word usage for objects, as illustrated in Fig. 1, that is the villain. Unfortunately, however, this is only a part of the problem. Indeed, our upper bound estimates assume that this problem does not exist, that we know every word that will be used, and with what probability each will be applied to every object. Still our best upper bound predictions are quite error prone. Another part of the problem is polysemy; each word means many different things and can refer to many different objects. In our observed data, words that were frequently used tended to be applied to several objects. Clearly, if a word is used for two or more objects, there is no way that we can guess from the use of that word which unique object is its referent. The more similar the objects in the domain, the more likely it is that a single word will include more than one in its scope (Section 4.5.4.2). In general, then, one might expect that the more similar the objects in a set seem to people, the more difficulty they will have in describing them uniquely and the more difficulty a receiver of their descriptions would have knowing to what they refer.

How might one interpret descriptions of objects more accurately? Observe that in the common object experiment, human subjects were able to make a single guess as to the intended object with over 80 percent success. This is well above any of our performance estimates for systems based on the statistical information in single-word input/output tables. How do people do this? What other sources of information, either in the input description or in the receiver's mind, are brought to bear? What is needed to build a system that would approach human capacities?

One possibility is that the limits we observed may be due to utilization of only a single word or phrase from the input. Perhaps if multiple words, or the combined meaning implied by conjunctions of several words and their syntactic order, were utilized, much better reference could be achieved. The conjunctive use of words primarily serves to more narrowly specify the object of discourse. This presumably increases the precision of reference and would reduce the chance that we would guess an incorrect object from a provided description. But, under models that assume the comprehender can return several guesses as to the likely object, the recall provided by a full description

would not necessarily be much greater than that provided by the unrestricted meaning of its most important word. However, if users can provide many independent words, each an essentially new attempt, the recall rate could be raised substantially, as Model 2 suggests. Thus, allowing longer, more complex specifications and learning how to understand them is one promising direction to be investigated.

Recall also that using experts to generate armchair key words did not work well, at least in the recipe data where we tested it. We also note that in informal demonstrations, programmer subjects do not fare well in providing a name for a program to be matched by other programmers. Similarly, there have been a number of studies of indexer reliability in bibliographic indexing.[14-18] These come from quite favorable circumstances, in which the index terms are chosen from restricted vocabularies and the indexers are highly trained. The chances of one indexer choosing the same categories as another, even under these circumstances, are usually disappointingly low. Thus, the chance that professional indexers will agree with the first word entered by an untrained user does not seem to offer a promising route.

A possibility for improvement that seems worthy of further investigation is the study of the structure of the conceptions or mental representations of the objects in a domain to be referenced. The polysemy aspect of the problem arises because two or more objects are not linguistically separable. If we could learn how to group such objects into "super-objects," then we could potentially improve at least our ability to predict which of these "super-objects" is being sought. Similarly, informal impressions from the swap-and-sale superordinate data suggest that certain levels of superordination give rise to more consistent naming than others. If means can be found to reveal and represent strong hierarchical structure in the concepts being named, then possibly one can choose the levels or nodes in such structure that are best represented as the objects to be found in a data set. These "super-objects" also might be more amenable to automatic reference by the means we have modeled.

We have generated statistics relevant to this hypothesis, in the double treatment given to the editing terms. The five objects in the Ed5 data are in fact "super-objects", made by condensing the 25 editing operation–text unit pairs into categories involving just the editing operation. A look back at the numbers involved shows a uniform superiority in the retrieval and discrimination of "super-objects" over that of the individual constituent objects. In part this is just because there are fewer objects to be dealt with, but our hypothesis is that performance is further enhanced by the lower overall similarity at the super-object level. Suppose a system were built to capitalize on this kind of situation, that is by first empirically discovering the lowest

level of subdivision of a given domain at which natural descriptive language is adequate. Freely chosen key-word entries might well be effective for specifying objects at this level. But the whole problem of retrieval would not yet be solved. Users who wanted to access particular subordinates of these super-objects would have to be provided with some further mechanism. A hybrid approach in which early stages of specification are done by freely chosen keys and later stages by menu selection seems a promising approach.

An especially important matter, which we have so far neglected, is the prior probabilities of a user's intending various objects. Our data have been aimed at estimation of the input/output pointer functions of words to objects, and were collected with equal numbers of occasions for nomination of key words for each object. In real life, and in a real system, people seek different objects with different frequencies, perhaps with steep distribution functions resembling Zipf's law.[9] Our ability to predict what object a person has in mind by a word could be greatly improved by taking into account its prior, unconditional likelihood of being sought. Again, our informal impressions from the kinds of descriptions provided in the common object data is that human describers and recipients take great advantage of such frequency information. For example, in specifying the Empire State Building as a tall building in midtown Manhattan, the describer probably assumes that the receiver would choose, from the large set of possible objects, the one that is most likely to be the object of specification.

It will also require further work to see how such information could be incorporated in an automated access system. A start would be to consider an adaptive system that keeps track of the frequency with which objects are sought (as well as the frequency with which the particular input is satisfied by a particular output). Then object prior-probability data could be combined with input/output conditional probability data, like that we have investigated, by the use of Bayes' rule.[19] This would almost certainly yield much better predictions than our models estimate, or any that are currently achievable in available systems. Such a scheme might also take advantage of individual differences in cases where the same people will use the system repeatedly.

There are still other plausible means for circumventing the limitations our models suggest. There are other kinds of data access devices, such as menu-driven systems, query languages, or natural language understanding systems. These approaches all have something to offer, and probably can overcome some of the deficiencies of the pure key-word entry method. But each also has problems of its own. For example, menus cannot list a very large number of alternatives at once, so the desirable feature of turning the recall or production

problem into comprehension and choice is limited. (Note also that in menus the user must understand the system's terse descriptions of objects, much as the system has to understand those of the user of key words.) When there are many objects, a menu system must use a successive search method that relies on some kind of hierarchical tree or other presentation of the relations among the objects. How to do this in a way that leads to correct user choices at each level, to good overall performance, and to acceptable convenience are unsolved issues. Query languages generally require users to input well-formed relational algebra or Boolean expressions that are unlike anything seen in the data specifications provided in our password study. Such expressions require the kind of logical thought that is known to be extremely difficult for ordinary people.[20] Natural language understanding systems, as so far implemented at least, have yet to deal adequately with the lexical reference problem. They have usually glossed over the issue by restricting themselves to very limited domains and limited lexical input, for which they can store a reasonably adequate "hand-tailored" synonym list. We suspect that when such systems are developed for use in real data applications they will have to solve the synonymy and polysemy problems in some of the same ways (e.g., by the use of statistical input/output tables and prior object probabilities that we have been suggesting here. It is probably a mistake to take a too naively optimistic view of the value of "natural language" input to a computer device. For example, although our human subjects were much better than our model automatic systems at predicting the referent of a description, it is not obvious that their success was based on being able to "understand" the natural language of the input, at least if this is taken to mean successful syntactic parsing, etc. We believe that it is also possible that human success is based largely on statistical knowledge of the likelihood of objects and the likely referents of words, and that this is a matter that could be incorporated into a system without it doing highly intelligent natural language understanding.

## VI. SUMMARY

The data we have collected on people describing objects have allowed us to estimate the likely performance of several mechanisms for understanding the references of words to information objects. We have found that input/output functions based on normative naming behavior of users will work much better than systems based on a single name provided by designers. We have also shown that a system that made several best guesses, and/or allowed the user to make several tries, and then returned a menu-like set of guesses to be chosen among, would substantially improve performance beyond current popular

methods. The best approach was to focus on what the user brings to the interaction, namely a great variety of words, and for each word have the system make one or more best guesses as to what the user meant.

But such a system for understanding references will still not perform nearly as well as a human receiver would. Thus, this model of the process of reference certainly does not fully capture what goes on in people's minds. Thus, we are clearly not yet ready to hazard a theory of how humans succeed as well as they do in this task, or to propose an automated method that would do as well or better. However, we believe that the evidence and analyses reviewed here lead to some promising suggestions for further exploration in both regards.

## APPENDIX A

### *Formal Model Structures*

In Table III below we present the formal structures for each of the six models studied. The constraints critical to the definition of each

Table III—Summary of constraints defining each model

| Model | Description | Words Used | | Objects Referenced | | Total Word-Object Pairs |
|---|---|---|---|---|---|---|
| | | Per Object | Total | Per Word | Total | |
| 1 | One name per object | **1** | $\leq R$ | $\leq C$ | **C** | $C$ |
| 2 | $M$ names per object | **M** | $\leq R$ | $\leq C$ | **C** | $M \times C$ |
| 3 | Distinct name for each object | **1** | **C** | **1 or 0** | **C** | $C$ |
| 4 | Distinct names, augmented with $M-1$ extra referents | $1 \leq n \leq M$ | **C** | **M or 0** | **C** | $M \times C$ |
| 5 | Recognize one referent for every word | $\leq C$ | **R** | **1** | $C$ | $R$ |
| 6 | $M$ referents for every word | $\leq C$ | **R** | **M** | $C$ | $M \times R$ |

Defining constraints for the models are in boldface. C = number of columns (objects), R = number of rows (words).

model are marked with asterisks. (Note that these constraints are to be met whenever possible, and for simplicity, the numbers below assume that this is always possible.)

## APPENDIX B

### *Evaluating the Pure Random Versions of the Models*

The success of any pure random model considered in this paper is given simply by the ratio of $t$, the number of cells included in the system mapping, to $RC$, the total number of cells in the matrix. To see this simply note that any structural constraints we might impose are only defined up to a permutation of the rows and columns. Thus, consider any table and its group, i.e., all its variants obtained by row and column permutations. The table that is the cell-wise total of all these tables must, for reasons of symmetry, be everywhere the same, and its grand total must be $t$ times the number of tables in the group. The success of any individual table is given by the dot product of the user and system matrices (treating the matrices as vectors, i.e., sum the products of corresponding cells). The total success for the group is the sum of these dot products for the members of the group. But the sum of the dot product of one vector with several others is the dot product of that vector with the sum of the others, so the total success for the group is just the dot product of the user matrix and the total matrix. But since the total matrix is uniform, and we divide by the size of the group, we conclude that the average matrix then is just $t/rc$ times the sum of user matrix. If the user matrix is in relative frequencies, the success is a probability.

## APPENDIX C

### *Summary of Recall Probabilities*

Table IV—Summary of recall probabilities

| Model | Description | Version | $M$ | Recall Probabilities Ed5 ($n$ = 5) | Ed25 ($n$ = 25) | CmOb ($n$ = 50) | Swap ($n$ = 64) | Recp ($n$ = 188) |
|---|---|---|---|---|---|---|---|---|
| 1 | One name per object | WGT | 1 | .074 | .106 | .117 | .142 | .182† |
| | | OPT | 1 | .151 | .194 | .257 | .258 | .312* |
| | | | | .271 | .322 | .329 | .353 | .419† |

Test subjects' abbreviations of command names and randomly selected English words were examined for production regularities. Abbreviation rules based primarily on a word's number of syllables were devised to capture regularities observed in people's productions. This rule set was compared to two simpler abbreviation rules—vowel deletion and truncation. In subsequent learning experiments, separate groups of subjects learned the rule-derived abbreviations for words, while other groups learned the most frequently given abbreviation for each word. Subjects who studied rule-derived abbreviations remembered substantially more of them when prompted with full words than did subjects who studied the most frequently given abbreviations. Moreover, the rule-based abbreviations were superior even for those for which the rule-produced and the most frequently produced abbreviations were identical. When the task was reversed (recall the source term given an abbreviation), performance was best for vowel deletion abbreviations and worst for the rule set abbreviations. We suggest that both memorability of abbreviations and the probability that people will spontaneously produce a "correct" abbreviation are increased by: (1) selecting abbreviations using a vowel deletion rule for one-syllable words and an acronym rule for multiple-word terms, as well as (2) allowing variable length truncations of words.

## I. INTRODUCTION*

Zipf[1] observed that in a number of languages frequently used words tend to be short. Further, this relation appears to be a causal one: as a word or phase increases in usage, it becomes shorter. Examples of word or phrase abbreviation are plentiful in English (e.g., "television" becomes "TV"). Abbreviating is particularly prevalent in government, corporations, and disciplines sharing a specialized vocabulary. Often the abbreviation process is so complete that the antecedent term is forgotten and only the abbreviation is retained (e.g., "cathode ray tube" becomes "CRT" or "light amplification by stimulated emission of radiation" becomes "laser"). Given the frequency and importance of this phenomenon, it seems reasonable to ask whether the process is systematic. That is, given a word or phrase, can one predict how it most likely will be abbreviated? If one could formulate abbreviation rules rooted in natural abbreviating behavior, would these abbreviations be "better" than abbreviations not suggested by behavioral data?

Discovering ways to generate abbreviations that are easy to learn and use has practical significance, since in many circumstances brevity is needed or desired. For instance, while infrequent users of a computer command language may be content to enter complete command names and arguments, frequent users often prefer terse command strings. To avoid typing long command strings, mechanisms should exist for abbreviating commands and their arguments.

There are some common ways to provide abbreviation facilities. One, truncation, allows the user to enter only as much of the command name (from the beginning to some point less than the whole word) as necessary to differentiate it from all other commands in the language. Another provides the user with standard system abbreviations. It is also possible to use both of these methods.

Selecting "good" abbreviations is a complicated problem. There is probably no single measure of an abbreviation's goodness, since there are some competing requirements to consider. For instance, one might want abbreviations in a system to be unique, easy to type, memorable, and natural (i.e., users who knew only the command would be more likely to produce this particular abbreviation than any other). However, some of these requirements are at odds with one another. Consider "easy to type" and "memorable." As Experiment II shows (see Section III), abbreviations produced by a simple vowel deletion rule are easy to remember or generate. Thus, given the command "journal,"

* Some of the material contained in this paper was presented at the 52nd Annual Meeting of the Midwest Psychological Association, St. Louis, May 1980 and the 52nd Meeting of the Eastern Psychological Association, New York City, April 1981.

subjects can generate the requisite vowel deletion abbreviation, "jrnl," with nearly perfect accuracy. However, this abbreviation is probably not easy to input, since the user must spell the whole word and omit every vowel. While we have no production data, it is likely that using a vowel deletion abbreviation rule for long words is no faster than entering the complete word. In fact, it may be slower in many cases.

Consider "easy to type" and "unique." Truncation produces abbreviations that seem easy to type (at least no more difficult to type than the whole word for a skilled typist and probably easier than the whole word for a nonexpert typist), particularly if one truncates to only a few letters. However, the likelihood of collisions among commands with truncation increases as the number of letters used decreases. If one requires uniqueness of abbreviations and has a truncation rule, the user must learn the minimum number of letters required to distinguish a particular command from all other commands. An additional burden may be imposed on the user if the command lexicon grows to include words whose truncations suddenly conflict with old abbreviations. If the lexicon is large enough, conflicts between abbreviations are bound to arise. One way to resolve conflicts in a rule-based system is to allow exceptions to the abbreviation rule. However, to what degree rule-generated systems can tolerate exceptions is an open issue worthy of future investigation. That is, at what point do exceptions to the rule render the rule worthless? It could well be that rules are useful only when there are relatively few or even no exceptions.

While each of these abbreviation requirements is important and critical from a design standpoint, the present study focuses on abbreviation naturalness and memorability. We examined abbreviations to determine how much regularity existed in those produced naturally. Next we incorporated the observed regularity into a set of abbreviation rules and compared the learning of rule-based abbreviations to the learning of the most frequently produced abbreviations for each word. The learning process was also reversed to include recalling of a word from its abbreviation, when the abbreviation was produced either by rules or by consensus.

## II. EXPERIMENT I: REGULARITIES IN NATURALLY PRODUCED ABBREVIATIONS

### *2.1 Introduction*

To determine how people abbreviate, we solicited abbreviations for a number of command terms. We then looked for regularities and the amount of agreement in these productions.

There were already data indicating that long and short words are abbreviated differently. Hodge and Pennington[2] examined how people

abbreviate words that varied in letter length. They observed that subjects used two principal mechanisms. One method, "contraction" (omitting word internal letters), tended to be used to abbreviate short words, whereas the other method, "truncation," was favored in abbreviating long words. However, they did not examine other linguistic properties of words associated with each of these strategies.

To examine abbreviations, we partitioned them into classes based on whether a particular abbreviation was an instance of a vowel deletion rule, a truncation rule, or an acronym formation rule. (Here acronyms are formed from multiple words, in which the first letter of each word is taken for the abbreviation; e.g., "cathode ray tube" becomes "CRT.") We examined whether the proportion of abbreviations accounted for by each rule varied with the number of syllables or words in the abbreviated term.

### *2.2 Method*

#### *2.2.1 Stimuli*

The vocabulary consisted of 81 command names and arguments that were to be used in a large computer system. Many of these terms, such as move, copy, and insert, are common to other computer systems. Others were unique to this particular application, such as usage billing number. The items varied from one to three words. Table I gives statistics for the commands and arguments used in the present study in terms of number of words and syllables and average number of vowels and consonants.

#### *2.2.2 Subjects*

There were two groups of subjects; one group consisted of 19 psychologists doing human factors work at Bell Laboratories, Holmdel, New Jersey, while the other set consisted of 30 adult females living in the Holmdel area. The Bell Laboratories employees volunteered their time; the other subjects were paid for participating.

#### *2.2.3 Procedure*

We gave each group a randomized list of the command terms and asked them to produce "a good abbreviation" for each, that is, one that would be easy to use and remember. Because the command list grew, the human factors psychologists saw a subset of 42 terms, whereas the other subjects saw 81 terms. The paid subjects produced the abbreviations and then performed a 30-minute text-editing task. After the intervening task, these subjects recalled as many of the command terms as they could. There was no free recall task for the psychologists.

### 2.3 Results and discussion

To determine the consistency with which subjects produced abbreviations, we examined the abbreviation that was most frequently produced for each item. Overall, the concurrence across the 81 terms was 37 percent; that is, on the average the most commonly produced abbreviation for each item comprised 37 percent of the abbreviations. There were no discernible differences between the psychologists and local residents in their abbreviations of the terms. The mean percentage concurrence was identical to the nearest percent for the two groups. The groups did not differ on other production measures, such as number of different abbreviations produced or the most commonly produced abbreviation. Consequently, data for the two groups were pooled in subsequent analyses.

Table II shows the average concurrence across items and the standard deviation both for all terms combined and separately by number of syllables. Concurrence decreased markedly as the number of syllables in a word increased and, correspondingly, the number of different abbreviations given for each term increased substantially. Thus, ab-

Table I—Composition of command names and arguments

| | Overall N = 81 | One-Syllable Words N = 15 | Two-Syllable Words N = 42 | Three-Syllable Words N = 12 | Four-Syllable Words N = 2 | Multiple Words N = 10 |
|---|---|---|---|---|---|---|
| Mean number of: | | | | | | |

| Average number of terms recalled | 3.25 | 4.87 | 3.20 | 2.50 | 2.00 | 2.20 |
| Standard deviation | (3.15) | | | | | |

breviation production was more homogeneous in simpler linguistic environments.

The one or two most frequently elicited abbreviations for each term were studied to determine whether abbreviating could be characterized by some "rule-governed" process. If one ignored the linguistic composition of the words, the abbreviation process appeared unorderly. However, if the terms were partitioned into three classes (monosyllabic, polysyllabic, and multiple words), there was some consistency within each class. By inspection there appeared to be three different rules operating in people's productions—vowel deletion (delete word internal vowels), truncation, and "acronym formation" (for multiple-word terms, select the first letter of each word).

We derived rules to account for the regularity observed in the abbreviating behavior. Table III shows the set of rules that appear to describe the data. The application of a particular rule depended on the number of syllables and/or number of words in the command term.

Table IV compares the proportion of abbreviations accounted for by the three different rules (truncation, vowel deletion, and the rule set from Table III) with the most frequently given abbreviation from each term ("popular"). We combined all truncations from the first letter to one less than the number of letters in a word. We defined vowel deletion as the deletion of all vowels following the first consonant in a word ("a," "e," "i," "o," "u," and "y," when it functioned as a vowel). It is important to remember in interpreting Table IV that popular abbreviations and those produced by the three rules are *not necessarily mutually exclusive.* For example, for one-syllable words there is a great deal of overlap between the rule set and vowel deletion. The rule set for one-syllable words is essentially a vowel deletion rule with only a few other features. However, there was no overlap between the truncated one-syllable abbreviations and the rule set or the vowel

Table III—Abbreviation rules

- Monosyllabic words:
  1. Take initial letter of the word and all subsequent consonants.
  2. Make adjacent double letters single.
  3. If more than four letters remain, retain the fifth letter if it is part of a functional cluster (such as *th, ch, sh, ph, ng*); otherwise, truncate from the right.
  4. Delete the fourth letter if it is silent in the word.
- Polysyllabic words:
  1. Take the entire first syllable.
  2. If second syllable starts with a consonant cluster, add it.
  3. If first syllable is a prefix (such as *de, re, in*) add the second syllable.
  4. Make final double consonants single.
  5. Truncate to four letters (but always retain entire first syllable).
- Multiple words:
  1. Retain the first letter of each word as the abbreviation.

Table IV—Proportion of abbreviations generated for each rule (variable length truncation, vowel deletion, rule set) compared with popular abbreviation for each term

| | Truncation | Vowel Deletion | Rule | Popular |
|---|---|---|---|---|
| | | Overall, N = 81 | | |
| Mean | 0.286 | 0.216 | 0.283 | 0.373 |
| Median | 0.286 | 0.143 | 0.267 | 0.367 |
| Standard error | 0.022 | 0.023 | 0.022 | 0.017 |
| | | One Syllable, N = 15 | | |
| Mean | 0.272 | 0.519 | 0.556 | 0.556 |
| Median | 0.233 | 0.533 | 0.533 | 0.533 |
| Standard error | 0.053 | 0.052 | 0.036 | 0.036 |
| | | Two Syllable, N = 42 | | |
| Mean | 0.313 | 0.192 | 0.208 | 0.358 |
| Median | 0.330 | 0.173 | 0.200 | 0.333 |
| Standard error | 0.025 | 0.024 | 0.023 | 0.018 |
| | | Three and Four Syllable, N = 14 | | |
| Mean | 0.408 | 0.077 | 0.247 | 0.317 |
| Median | 0.388 | 0.051 | 0.224 | 0.265 |
| Standard error | 0.040 | 0.020 | 0.056 | 0.088 |
| | | Multiple Words, N = 10 | | |
| Mean | 0.020 | 0.024 | 0.237 | 0.237 |
| Median | 0 | 0.027 | 0.173 | 0.173 |
| Standard error | 0.012 | 0.022 | 0.038 | 0.038 |

deletion set. For two-syllable words all rule set abbreviations were a subset of truncation abbreviations. In the case of multiple words, where an acronym formation rule applied, there was no overlap among the truncation, vowel deletion, and rule set.

Overall, truncation and the rule set were not significantly different from each other, but each was different from the most popular abbreviation (truncation vs. popular, $t_{80} = 3.507, p < 0.001$; rule vs. popular, $t_{80} = 5.316, p < 0.001$). For one-syllable and multiple words, the rule set was more often the same as people's natural abbreviations than was truncation. However, for two-, three-, and four-syllable words, truncation surpassed the rule set abbreviations.*

It is worth considering the results of allowing variable length truncation and the rule set abbreviations to be used in the same system. If both were allowed for this word set, what proportion of generated abbreviations would be subsumed? In this case the proportion equals 0.415 overall, 0.828 for one-syllable words, 0.313 for two-syllable words,

* In some cases the results of detailed statistical analysis are not presented. We have in all cases given variability estimates for each cell mean. For the most part, the differences among experimental conditions in all experiments were substantial and large relative to the observed variance.

0.408 for three- and four-syllable words, and 0.257 for multiple words. Thus, it is clear that allowing multiple abbreviations accounts for significantly more of the naturally produced abbreviations than any single abbreviation mechanism (truncation vs. combined rules, $t_{80} = 5.512$, $p < 0.001$; rule set vs. combined rules, $t_{80} = 9.846$, $p < 0.001$).

## III. EXPERIMENT II: LEARNING RULE-GENERATED VS. POPULAR ABBREVIATIONS

### *3.1 Introduction*

In the second experiment we examined whether learning a set of abbreviations generated by the rules was better than learning those abbreviations most frequently given by the subjects in Experiment I. That is, does placing abbreviations in an internally consistent set result in more memorable abbreviations than people's natural abbreviations?

### *3.2 Method*

#### *3.2.1 Materials*

The materials consisted of the 81 command terms and arguments from Experiment I and their abbreviations. There were two abbreviation conditions:

1. Rule Condition: The 81 abbreviations produced by the rule set shown in Table III.
2. Popular Condition: The most frequently given abbreviation for each of the 81 terms.

(Note that for 65 percent of the terms, the abbreviations were identical in the two conditions. That is, for the rule set 65 percent of the terms produced the same abbreviation as the one most frequently given by subjects in Experiment I.)

#### *3.2.2 Subjects*

We paid 44 high school students from the Murray Hill, New Jersey, area to participate. There were 23 subjects in the "rule" group and 21 subjects in the "popular" group.

#### *3.2.3 Procedure*

Subjects were randomly assigned to either the rule or the popular group. The task was paired-associate learning of the terms and their abbreviations. The rule subjects saw each term paired with the rule-generated abbreviation, whereas the popular group saw each term paired with the most frequently given abbreviation. Subjects in each group were given a randomized deck of 81 cards, each of which contained one term-abbreviation pair. Each subject received a different random order. Subjects studied each card for five seconds, and at the

sound of a buzzer, flipped to the next study card. During an intervening period of 20 minutes, subjects solved logic problems. Then they were given a list with only the terms and were asked to supply the abbreviations they had learned. If unsure, they were to make their best guess.

### *3.3 Results and discussion*

Table V shows the proportion of correct responses for the two experimental groups for all words combined, separately for the abbreviations that were identical for the two groups, and for those that were different for the two groups. It also shows the standard error of the mean calculated across terms. The difference between the rule and popular conditions was highly reliable ($p < 0.001$) in all three cases. Thus, learning an internally consistent set of abbreviations facilitated later recall or generation. (Note that if subjects implicitly or explicitly knew the rules, they should have been able to generate the correct abbreviation for a given term.)

We performed additional analyses to determine in which linguistic environments the rules most facilitated performance. Table VI shows the mean proportion correct as a function of experimental group for one-, two-, three-, and four-syllable words, and multiple words.

The ability of the abbreviation rules to predict the popular abbreviations was far from uniform across the syllable/word classes. For one-syllable words and multiple-word terms, the rule and popular abbreviations were identical. While there was still a recall advantage for the rule abbreviations, it was small and not statistically reliable. However, this was not the case for the other three word classes. Evidently, the abbreviation rules for one-syllable and multiple words are reasonably straightforward and either tacitly known or easily learned by subjects.

The rules and natural productions were in only moderate agreement

Table V—Proportion of abbreviations correctly recalled and/or generated as a function of experimental group

| | Rule | Popular |
|---|---|---|
| Overall (81 terms) | 0.70 | 0.54 |
| Standard error of the mean | 0.02 | 0.03 |
| Abbreviations same in two groups (53 terms) | 0.76 | 0.63 |
| Standard error | 0.03 | 0.03 |
| Abbreviation different in two groups (28 terms) | 0.54 | 0.37 |
| Standard error | 0.04 | 0.04 |

Table VI—Proportion correct in rule and popular conditions as a function of the linguistic class of term

| | One-Syllable Words N = 15 | Two-Syllable Words N = 42 | Three-Syllable Words N = 12 | Four-Syllable Words N = 2 | Multiple Words N = 10 |
|---|---|---|---|---|---|
| Mean proportion correct | | | | | |
| Rule group | 0.78 | 0.62 | 0.59 | 0.50 | 0.97 |
| Popular group | 0.73 | 0.42 | 0.45 | 0.44 | 0.91 |
| Proportion of items for which rule abbreviation and popular abbreviation were the same | 1.00 | 0.45 | 0.58 | 0.50 | 1.00 |

for two-, three-, and four-syllable words, and for these word classes, using the rules to produce abbreviations had the greatest facilitative effect on performance. One could presume that there is more variation in terms of linguistic composition for these classes. Owing to this complexity, people's internal abbreviation rules may be inconsistent, incomplete, and therefore, more variable. However, if rules are formulated for subjects, the subjects can use them to learn abbreviations.

### *3.4 Conclusions*

The results and conclusions to be drawn from Experiments I and II are relatively straightforward. First, the process by which we produce abbreviations is not entirely idiosyncratic, but is to a large degree regular. We derived abbreviation principles that characterized a majority of the most frequently elicited abbreviations for each term. The abbreviation rule produced abbreviations that were easier to learn than the most frequently produced abbreviations. There was a substantial advantage of learning abbreviations in a mutually consistent set, even when the abbreviation being learned *was the same* as would be frequently given by subjects. However, the generality of these results is limited, since the rules were derived from the same set of words that served as stimuli in the recall.

## IV. EXPERIMENT III: ABBREVIATION PRODUCTION AND LEARNING OF RANDOM WORDS

### *4.1 Introduction*

To test the generalizability of the rule set used in the previous experiment, we applied the rules to a random set of words selected to have the linguistic properties considered relevant in the rule set. A replication was needed, since it is possible that the terms used in the

command set studied in Experiments I and II have properties that differ in some unknown way from ordinary English words. A priori, it is conceivable that the command name words might be different semantically, phonetically, and grammatically from "ordinary" English words. Thus, to know whether rule-based abbreviations are better in general, the test words should be a random sample of words. Also, since the rules were generated from examining subjects' abbreviations of these words, the rule set may include conditions that are the result of idiosyncracies in the particular commands selected.

### *4.2 Method*

#### *4.2.1 Word selection*

A total of 200 English nouns and verbs were randomly selected from Kucera and Francis[3]. Words were either one ($N = 40$), two ($N = 80$), or three ($N = 80$) syllables. For the two- and three-syllable words, 40 had prefixes (e.g., "de," "dis," "pro," "post," and "mis"), while 40 did not.

#### *4.2.2 Production subjects*

Thirty-two paid Rutgers University undergraduates supplied abbreviations for the random words.

#### *4.2.3 Procedure*

The word set was randomly divided in half with half of the subjects supplying abbreviations for 100 words.

### *4.3 Production results*

We analyzed the data in the same way as in Experiment I. Tables VII and VIII show the proportion of abbreviation productions accounted for by variable length truncation, vowel deletion, the rule set, and the most frequently given abbreviation (popular). Table VII shows proportions for all words combined and separately for one-, two-, and three-syllable words. Note that the proportions in Table VII are reasonably close to those found in Experiment I.

Table VIII compares two- and three-syllable words with and without prefixes. The existence of a prefix decreased abbreviation agreement in the popular condition ($t_{79} = 2.790, p < 0.01$). Thus, prefixes affected production. However, it does not appear that prefix conditions in the rule set (as described in Table III) managed to capture any of the differences between words with and without prefixes. Abbreviation behavior was best represented by a truncation rule irrespective of whether the word had a prefix.

Table VII—Abbreviations generated for randomly selected English words

| | Truncation | Vowel Deletion | Rule Set | Popular |
|---|---|---|---|---|
| | | All words, N = 200 | | |
| Mean | 0.396 | 0.234 | 0.304 | 0.406 |
| Median | 0.375 | 0.188 | 0.312 | 0.312 |
| Standard error | 0.013 | 0.014 | 0.015 | 0.015 |
| | | One-Syllable Words, N = 40 | | |
| Mean | 0.228 | 0.483 | 0.473 | 0.512 |
| Median | 0.188 | 0.500 | 0.469 | 0.500 |
| Standard error | 0.027 | 0.033 | 0.034 | 0.027 |
| | | Two-Syllable Words, N = 80 | | |
| Mean | 0.382 | 0.245 | 0.274 | 0.374 |
| Median | 0.375 | 0.250 | 0.281 | 0.375 |
| Standard error | 0.018 | 0.017 | 0.019 | 0.015 |
| | | Three-Syllable Words, N = 80 | | |
| Mean | 0.493 | 0.099 | 0.250 | 0.383 |
| Median | 0.500 | 0.062 | 0.188 | 0.375 |
| Standard error | 0.019 | 0.008 | 0.024 | 0.017 |

## V. LEARNING RULE-BASED AND POPULAR ABBREVIATIONS FOR RANDOM WORDS

### *5.1 Method*

#### *5.1.1 Subjects*

A total of 90 paid adult recruits from the Holmdel area participated in the experiment.

#### *5.1.2 Procedure*

The procedure was identical to that reported in Experiment II with the exception that the interpolated task was underlining "important concepts" in a text-editing manual. There were three conditions. Thus, in separate conditions, each word was paired with (1) its rule set abbreviation, (2) its popular abbreviation, and (3) its vowel deletion abbreviation. There were 30 subjects in each of these three conditions.

### *5.2 Learning results*

Table IX shows the proportions and standard errors across words for each of the three groups. In each row each condition was significantly different from every other condition. (The largest matched-paired $t$ probability of occurrence was less than 0.02. However, this probability value is uncorrected, i.e., it does not take into account the number of post comparisons.) Thus, the ordering of generation or recall performance was best for the simple vowel deletion rule, second best for the rule set condition, and worst for the popular abbreviations.

Thus, the original results that rule-governed abbreviations were

Table VIII—Abbreviations generated for randomly selected two- and three-syllable words with and without prefixes

| | Truncation | Vowel Deletion | Rule Set | Popular |
|---|---|---|---|---|
| | | Two-Syllable Words, No Prefix (N = 40) | | |
| Mean | 0.425 | 0.259 | 0.326 | 0.411 |
| Median | 0.438 | 0.250 | 0.312 | 0.375 |
| Standard error | 0.028 | 0.025 | 0.030 | 0.021 |
| | | Two-Syllable Words, Prefix (N = 40) | | |
| Mean | 0.339 | 0.231 | 0.222 | 0.338 |
| Median | 0.312 | 0.188 | 0.250 | 0.312 |
| Standard error | 0.020 | 0.024 | 0.023 | 0.021 |
| | | Three-Syllable Words, No Prefix (N = 40) | | |
| Mean | 0.483 | 0.109 | 0.308 | 0.406 |
| Median | 0.500 | 0.094 | 0.344 | 0.375 |
| Standard error | 0.029 | 0.012 | 0.037 | 0.024 |
| | | Three-Syllable Words, Prefix (N = 40) | | |
| Mean | 0.503 | 0.089 | 0.192 | 0.359 |
| Median | 0.500 | 0.062 | 0.125 | 0.312 |
| Standard error | 0.024 | 0.012 | 0.029 | 0.025 |

better reproduced than abbreviations produced by consensus were strongly replicated. Note that a simple rule produced the best performance in this task. The vowel deletion rule appears to be a particularly easy rule for subjects to abstract. Thus, performance improved as the rules governing abbreviations became more straightforward.

## VI. EXPERIMENT IV: RECALLING THE SOURCE WORD GIVEN ITS ABBREVIATION

### *6.1 Introduction*

One of the anecdotal observations frequently made about new computer users is that they learn abbreviations for command terms without ever learning what some of the abbreviations mean. In this sense, the abbreviations represent an alternate name space. There is usually some care given to the choice of names for commands, devices, programs, etc, the assumption being that the use of appropriate names tends to make learning easier (but see Landauer, Galotti, and Hartwell[4], where random words assigned to text-editing functions were no easier or harder to learn or use than appropriate names). However, this care is not usually taken in choosing abbreviations. Most people's goal is to choose abbreviations that are easy to remember, given that the user remembers the right name in the first place. In this experiment we were interested in the decoding process: determining how well the abbreviations represented the words they abbreviated.

There is evidence that the decoding and encoding (determining an abbreviation, given a source word) are asymmetric processes. In par-

Table IX—Mean proportion of abbreviations recalled/produced correctly, given words

| | Popular | Rule Set | Vowel Deletion |
|---|---|---|---|
| Overall (200) | 0.466 | 0.650 | 0.811 |
| Standard error | 0.015 | 0.014 | 0.006 |
| 1-syllable (40) | 0.579 | 0.634 | 0.875 |
| Standard error | 0.029 | 0.023 | 0.011 |
| 2-syllable (80) | 0.428 | 0.622 | 0.815 |
| Standard error | 0.031 | 0.035 | 0.013 |
| 3-syllable (80) | 0.446 | 0.685 | 0.774 |
| Standard error | 0.039 | 0.032 | 0.011 |

ticular, rule-based abbreviation schemes are not as effective for decoding purposes as for encoding purposes. With a well-formed rule it is possible to produce the abbreviation accurately when given the word, but the converse is not true. That is, knowing the abbreviation rule and the abbreviation does not necessarily allow one to generate the correct source word.

Rogers and Moeller[5] compared decoding of conventional Navy sonar abbreviations and rule-based abbreviations (produced by truncation). (The subjects in their experiments were sonar operators.) Reaction time to decode the abbreviation was measured. When the scoring criteria were strict, the rule-based abbreviations were worse than the conventional military abbreviations. The difference was due primarily to conventional abbreviations giving a better indication of the endings of words.

Using two 20-word lexicons, Hirsh-Pasek, Niedelman, and Schneider[6] examined decoding in a wide variety of conditions: truncation to four letters, vowel deletion with truncation to four letters, minimum number of letters to distinguish, a phonics system, and user-supplied abbreviations. Vowel deletion and the phonics system produced the fewest number of errors, whereas minimum to distinguish produced the most. Truncation was only slightly worse in terms of errors (perhaps not significantly) than vowel deletion and phonics.

Ehrenreich and Porcu[7] compared decoding of abbreviations formed by vowel deletion and by truncation. There were no reliable differences between these two methods with liberal scoring procedures—65 percent and 57 percent correct, respectively. With stricter scoring criteria, truncation abbreviations were easier to decode (54 percent) than vowel deletion abbreviations (48 percent).

### *6.2 Method*

#### *6.2.1 Subjects*

We paid 90 residents from the Holmdel area to participate.

### 6.2.2 Procedure

We prepared cards using the 200 random English words used in Experiment III. One word and its abbreviation appeared on each card. There were three groups: one group learned popular abbreviations, another the rule set, and a third, the vowel deletion abbreviations. The procedure was the same as in previous experiments, except that after the 20-minute retention interval, subjects were given lists of *abbreviations* and asked to *write down the word* each represented.

### 6.3 Results and discussion

Table X compares the proportion of words recalled correctly in each of the three groups. Note that in Experiments II and III subjects recalled or produced abbreviations formed by the rule set more often than subjects who learned abbreviations arrived at by consensus. We attributed this improvement in performance to the fact that the existence of the rule lent some organization to the set of stimuli being learned. When we looked at ability to recall what the abbreviations represent, however, it appeared that the rule set seemed to interfere with subjects' ability to recall what the abbreviations stood for. Thus, there is an asymmetry between recalling the abbreviation from seeing the command term and recalling the command term from seeing its abbreviation. The superiority of the vowel deletion rule in this task is evident for all but the one-syllable words, and for this case the rule set is essentially a vowel deletion rule.

These results are somewhat at odds with those of Ehrenreich and Porcu.[7] First, in our experiment, the vowel deletion condition produced very high performance. Also, the overall level of performance was much higher in our study (79 percent here vs. 48 percent in the Ehrenreich and Porcu study). Ehrenreich and Porcu claim that when subjects produce words from vowel deletion abbreviations they are apt

Table X—Mean proportion of words recalled/produced correctly, given abbreviations

| | Popular | Rule Set | Vowel Deletion |
|---|---|---|---|
| Overall (200) | 0.626 | 0.467 | 0.788 |
| Standard error | 0.022 | 0.024 | 0.018 |
| 1-syllable (40) | 0.662 | 0.635 | 0.641 |
| Standard error | 0.046 | 0.050 | 0.052 |
| 2-syllable (80) | 0.628 | 0.500 | 0.799 |
| Standard error | 0.037 | 0.038 | 0.027 |
| 3-syllable (80) | 0.605 | 0.350 | 0.850 |
| Standard error | 0.035 | 0.034 | 0.024 |

to make spelling errors. People who misspell a word are more likely to err on a vowel than a consonant. Their terms were Army terms—ours random words; their subjects were Army personnel—ours primarily spouses of Bell Laboratories employees. These differences may have produced the resulting performance differences.

It would seem that vowel deletion should have produced the best results, since consonants carry more information than vowels and the abbreviations in this condition were longer than in the other two conditions (vowel deletion = 4.43 letters, standard deviation = 1.13; rule condition = 3.38 letters, standard deviation = 0.62; popular = 3.94 letters, standard deviation = 1.08). Thus, the results vary directly with the number of letters in the abbreviation alone.

In summary, there was a large asymmetry between the encoding results for the popular and rule condition in Experiment III and the decoding results in Experiment IV. Rule abbreviations were better than popular for remembering the abbreviation given the word, whereas popular abbreviations were better than rules for remembering the word given the abbreviation.

## VII. GENERAL DISCUSSION

While there is much variability in people's natural abbreviations, the process is far from random. People are most likely to abbreviate one-syllable words by deleting word-internal vowels, and multiword terms by deleting everything except the first letter of each word. Abbreviations of polysyllabic words are best characterized by truncation, that is, deleting letters from the end of the word. While these rules accounted for the majority of the most frequently generated abbreviations for each term, the proportion of all abbreviations covered by these rules was only about 0.30 in the two abbreviation production studies. Thus, there is much that people do when abbreviating that is idiosyncratic, variable, and not particularly amenable to rule-based descriptions.

We showed that if abbreviations are formed by applying rules derived from people's behavior, subjects can use these principles. Thus, subjects make use of the internal consistency of the set to learn the abbreviations. Performance with a set of rule-based abbreviations was better than with the corresponding set of most frequently produced abbreviations even when the two abbreviations were identical in the two conditions.

That people extract principles in complex stimuli is not a new finding. For instance Reber,[8,9,10] among others, has demonstrated that people's behavior when learning artificial languages in an experimental setting indicates that they have "learned" the grammatical rules of the language. However, very often they are unable to verbalize these rules

and seem unaware that they have extracted principles. It appears that rule formulation is often an automatic and unintentional process.

Throughout, we have explicitly assumed that rules based on behavior are better than arbitrary rules for abbreviation. One could argue that our own data contradict this assumption. That is, the vowel deletion rule used in Experiments III and IV produced the best performance in two tasks—recalling the abbreviation given the word and conversely recalling the word given the abbreviation. Don't the data then argue that one should abbreviate using vowel deletion? Yes, if the abbreviation is used to recall the term, that is, a decoding task. However, the ability to construct a correct abbreviation, given the word, is only one aspect of a good abbreviation. Another aspect that "abbreviate" itself denotes is that it should be short. Abbreviations produced by vowel deletion increase in length as the length of the source word increases, whereas abbreviations that people spontaneously produce and the ones produced by the rule set better maintain length constancy [e.g., a one-syllable word on the average is abbreviated to 3.4 letters in all conditions, whereas a three-syllable word is abbreviated to 5.2 letters (vowel deletion), 4.3 letters (popular), and 3.3 letters (rule)]. Thus, in terms of total number of keystrokes, the simple vowel deletion rule is least efficient.

A more serious failing for simple vowel deletion is that forming the abbreviation requires first producing the whole word, then systematically deleting the vowels, and finally outputting the remaining consonants. We suspect that this is difficult for long words. When a word is short, the entire word can be dealt with as a "chunk." For a single chunk it is probably not difficult to remove a vowel or two. Beyond simple, short words, the amount of mental bookkeeping increases. If one's goal is to enter command strings *quickly*, vowel deletion is probably not a serious candidate.

Truncation, on the other hand, has properties that make it the best abbreviation mechanism for polysyllabic words. Resulting abbreviations are short and easy to produce—the user does not need to pervert the assumed normal output strategies, just cut them short. It is a simple rule to teach[5–7] and users are most likely to abbreviate multisyllabic words in this way. Thus, it seems to have most of the desirable properties of an ideal abbreviation mechanism—natural, short abbreviations, easy to remember abbreviations, and easy to produce abbreviations. The one thing that may be sacrificed is uniqueness.

There have been suggestions on how to maintain uniqueness of abbreviations, which we now discuss. Many of the recommendations require the user to be flexible and relearn abbreviations from time to time, and some recommendations undermine the consistency of a rule-based set. Ehrenreich and Porcu[7] discuss two ways to resolve conflicts

among abbreviations: (1) use of alternate rules and (2) minimum number of characters to distinguish.

Using an alternate rule when conflicts exist has some serious problems. First, the user must know that there are two or more rules, and that one words most of the time, but when it doesn't, to use the alternate rules. Furthermore, the user has to know which one of the conflicting words requires which rule. The user doesn't know in advance when the primary rule will not work and, consequently, will probably have to learn by trial and error. When the number of exceptions to the primary rule is large, we suspect that the advantages gained by selecting abbreviations by rule will disappear. That is, the mixed rule set performance may approach or may even be worse than performance on abbreviations selected by consensus. However, the degree to which rule-based systems tolerate corruption warrants investigation.

In the case of minimum to distinguish, the user truncates to the number of characters required to differentiate that word for all other admissible words. For example, for "transport" and "transfer," the minimum to distinguish is in each case six characters—"transp" and "transf." There are a few problems worth noting with respect to minimum to distinguish. First, different words require different numbers of letters. Hirsch-Pasek et al.[8] have found in a paired-associates task that minimum to distinguish was more difficult to learn than the other abbreviation schemes they studied; truncation to four letters was the easiest. This may be only a relatively minor problem, which depends on the terms of the command set and the size of the lexicon. It could be dealt with by telling the user the minimum number of letters needed to distinguish all command names. However, a fixed minimum based on all commands will be unnecessarily long for many commands. The user could of course be told that fewer keystrokes will often suffice and learn the minimum to distinguish on a command-by-command basis. The second potential shortcoming occurs when new commands that produce collisions are introduced into the language. Truncations that worked previously are now ambiguous and require relearning. However, introducing software that informs the user of a conflict could solve these problems. If the input is ambiguous, the system could present the user with the collisions and ask the user to select one of the alternatives.

One way to minimize the likelihood of collisions is to make contextual information available to the system. For example, there may exist three words—"debug," "delete," and "define." If collisions were considered on the basis of the entire lexicon, three letters would be needed to differentiate these words. However, if "define" were a command while "debug" and "delete" were command options that occurred in

different environments, it could be the case that a "d" would suffice for either "debug" or "delete." Thus, if the command/option tables are structured hierarchically, such that a command points only to options meaningful in the context of that command, the potential range of conflicts is reduced from the entire command language to a small subset of the language.

In summary, considering all available evidence on producing abbreviations given command terms (encoding), truncation appears to be the best single abbreviation scheme. Truncation also best captures people's natural abbreviations in all environments except two—monosyllablic words and multiple-word terms. In these cases, we recommend using vowel deletion for the former and acronym formation for the latter. If, on the other hand, one's task requires generating full names, given abbreviations (decoding), vowel deletion abbreviations are better than other rule-based schemes.

# Designing and Evaluating Standard Instructions for Public Telephones

By C. J. KARHAN,* C. A. RILEY,† and M. S. SCHOEFFLER†

(Manuscript received July 30, 1982)

Difficulty finding and understanding information on public telephone instructions has led to problems using public telephones. To overcome these problems a new instruction card was designed. In this paper we discuss the information needs of the public telephone user, a conceptual solution to information presentation, a new standard instruction card design, and laboratory and field evaluations of the new design.

## I. INTRODUCTION

Many people have reported that placing a call from a public (pay) telephone is a problem. Individuals and consumer groups have complained to their telephone companies and even their public utility commissions. A major reason for this problem is the difficulty of finding and using information on public telephone instruction cards. In this paper we describe a series of studies conducted to develop standard instructions for public telephones that are easier to use.

### *1.1 The public telephone operating environment*

If all public telephones worked the same way, the task of designing

instructions would be easy. However, there is considerable variation in the operating procedures of public telephones in the Bell System. In addition, new public telephone services are being introduced or will be introduced soon. For example, at some public telephones the user must deposit coins equal to the cost of a local call before dialing any call (coin-first telephones). From the user's perspective, the coins work like a switch to turn on the telephone, and they are returned if no payment is required for the call. At other telephones no coins are needed to turn on the telephone, and a large class of calls, such as collect, credit card, emergency, and operator assistance, can be dialed without depositing any coins (dial-tone-first telephones). On some other telephones coins cannot be used at all (Charge-a-Call telephones). At most telephones, coins are deposited before a local call is dialed, but at some telephones coins are deposited after the person at the other end answers (post-pay telephones). From some telephones you can dial long distance calls; from others the operator must dial for you. From some telephones you can dial in your credit card number; from others you must tell your credit card number to the operator. In some areas you must dial "1" before long distance station-to-station calls; others require no prefix. Furthermore, there are many variations in the numbers for emergency help, directory assistance, and repair service.

Because of these variations, no single instruction card can be used for all public telephones. More importantly, because of these variations, even the most experienced public telephone users must sometimes consult the instructions to place a call correctly.

### *1.2 The need for standard instructions*

Prior to the standard developed from these studies, there was no standard for instruction card design in the Bell System. Various operating telephone companies have used different layouts, word choices, and color schemes to convey the same information. There are also variations within single telephone companies on the format and type of information included. Generally, telephones that operate differently, if only in minor respects, have instructions that vary in many ways that have nothing to do with operational differences. For example, instructions on how to place a long distance call may be different on a telephone where the initial deposit is 10 cents than on one where a 20-cent deposit is required, even though the dialing procedures are identical. There are also tremendous differences in the emphasis (location, color, and type size) placed on particular pieces of information. Finally, information is often provided in "telephonese."

The problem for users is not that all instruction cards are poorly

designed. While instruction cards in some locations may be particularly difficult to read and understand, the biggest problem for users is the inconsistency of design.

The use of a standard instruction card design for all public telephones should significantly reduce the problems of finding and understanding needed information. While identical instructions cannot be placed on all telephones because of differences in operating procedures, consistent language, graphics, and placement of information can be used. The information provided on the standard instruction card should match the information needs of the user. The instructions must be understandable, and the design should be attractive. A good design will help users; and, given a good design, a greater benefit for users will come from the universal application of this design.

### *1.3 Approach to the problem*

The new instruction card design and the studies that supported the development of that design are described in the sections that follow. First, we studied public telephone users to identify their information needs, how they used instructions, and the telephone terminology they used and understood. Based on this information we formed a model of the instruction user. Second, we developed a conceptual solution to the problem. Third, we presented this solution (along with detailed information about public telephone operating procedures) to graphic designers at Henry Dreyfuss Associates, who created designs for the instruction cards. Fourth, we evaluated and refined the designs in several phases. First we used our own and the designer's judgment, and then conducted a laboratory test, and, finally, a field test. During all phases of the project we consulted with the AT&T Public Services Marketing organization.

## II. THE INFORMATION USER

Before any attempts were made to design new instruction cards, we analyzed the information needs of the public telephone user.

### *2.1 Interview study*

A total of 500 users were interviewed in Arizona, Florida, and New Jersey. The individuals interviewed were approached following the completion of a call from a public telephone. They were asked to participate in a study of public telephone service. The individuals who agreed to participate were asked a series of questions about instruction use, such as: "Did you read the instruction card?" "Did you look at the instruction card?" "What information did you need?" "Did you find the information you needed?" They also were asked if they had

any difficulty finding or understanding information, and were asked to define several telephone terms, such as "collect call" and "dial-tone-first telephone."

Few of the people interviewed (about 10 percent) reported that they read the instruction cards. These individuals looked for procedural information necessary to place a specific call. This information included the cost of the initial deposit, when to deposit money, how to dial local calls and various types of long distance calls, and specific numbers, such as directory assistance or repair service.

Some respondents reported that they were unable to find information that they needed on the cards. In almost all of these cases, the individual was looking for more specific information than could ever be placed on the instruction card, such as the area code for Los Angeles, or the cost of a particular long distance call, or the telephone number of the local veterinarian.

Our interviews showed that people generally approach the instructions with particular questions in mind, and that the questions have two general forms. The first form is one in which a specific fact or procedure is needed. Examples are "How much does a local call cost?" or "How do I place a collect call?" The second form of question is asked by the more sophisticated telephone user who is already familiar with alternative operating procedures. This user might ask, "I know there are two kinds of telephones, one where I can dial long distance calls myself, and one where the operator dials all long distance calls; which type of telephone is this one?"

A few people look at the instructions without needing any specific information. These users may also be characterized, however, as having a question in mind before reading (looking at) the instructions, which can be phrased as, "Is there anything (new) here that I need to know about?"

Interview questions about terminology showed that telephone users generally understand terms referring to types of calls, such as collect, credit card, person-to-person, and station-to-station. However, language on instruction cards referring to the type of telephone, such as "dial-tone-first" telephone, was not understood.

## III. THE CONCEPTUAL SOLUTION

Most people do not read instructions on telephones; in fact, there are few circumstances in which anyone reads any instructions at all. (See Ref. 1 for a discussion of this issue.) Our goal was not to induce more people to read the instructions, but rather to make the instructions easier and more effective when they were read.

Our conceptual solution to instruction card design had several

components to simplify searching and understanding. The design should:

1. Provide the information that people need in words they understand.

2. Always place information about a particular aspect of a telephone's operating procedure in the same spatial location on the card. The card is thus like a form, with fields for each type of information. If there is no relevant information to be placed in the field, it should be left blank and not used for some other information.

3. Place frequently needed information on the upper card and detailed procedural information on the lower card.

4. Divide detailed information into related categories. Use the category labels to construct an index.

5. Provide visually obvious cues that are redundant with the text, e.g., colors, pictograms, and other symbols. This information should be visible at a glance and allow knowledgeable telephone users to answer the question "What type of telephone is this?" without reading the text. By systematically varying the visual characteristics of the instruction cards, telephones that have different operating procedures will have instructions that *look* different. Instruction cards on all telephones that operate the same way will look the same. Thus, information obtained at a glance can be informative. If the card "looks" different from cards the user is familiar with, then the instructions should be read.

6. As a final goal provide as much information as possible in a language-independent form to make the cards more usable by people who either do not read English or do so with difficulty.

## IV. THE NEW STANDARD DESIGN

Figures 1 to 3 show examples of the new instruction cards, designed according to the principles described in the section above, and revised based on the results of the study described in the following sections. (Space constraints prohibit illustration of the cards through all the design iterations.) Figure 1 is an instruction card for a telephone that requires a coin deposit before any calls can be dialed, and from which operator assistance is required for all long distance calls. Figure 2 is for a telephone from which credit card, collect, emergency, and other "free" calls can be made without depositing any coins; long distance calls can be dialed by the caller. Figure 3 shows an instruction card from a "Charge-a-Call" telephone, from which no coin-paid calls can be made.

### *4.1 Design features*

The instructions shown in Figs. 1 through 3 are for telephones that

**Local calls** Deposit 10¢ before dialing
**Long Distance** Dial 0
**Operator** will handle all Long Distance calls

**SOS dial 0** for Emergency help

KEENE N H EXP 5

| **Free calls** | **Directory Assistance** | Operator |
| | **Toll Free 800 Numbers** | Operator |

AREA TYPE 2 EXP 5 — Operator assisted rates apply to all toll calls from this telephone.

Fig. 1—Instruction card set for a telephone that requires a coin deposit before any call can be dialed, and from which the operator dials all long distance calls. Colored areas are tan.

differ considerably in operation; however, the common organization of the instructions is easily observed. Differences in visual appearance are also readily apparent. The features of the design are listed below:

1. Color: All instructions are printed on a white background; detailed instructions are in black type and emergency information is in red. Other colored sections—including the band across the top of the upper card, the "0+" and "1+" symbols, index headings and rules on the lower card—are color coded based on the basic operational procedure of the telephone. Telephones that require a coin deposit before any call can be dialed (coin-first) have tan instruction card coloring; telephones that do not require a coin for initial activation (dial-tone-first, including post-pay and Charge-a-Call) have blue instruction card coloring.

2. Upper-left symbols: Coin-first telephones have a white handset in a tan disk (coin); dial-tone-first telephones have a blue handset on a white background. The handset on the Charge-a-Call telephone has

**Local calls** Deposit 20¢ before dialing
**Long Distance** Dial all calls directly
0+ needed for Charge & Person-to-Person calls
1+ needed for Station-to-Station and Free calls

**SOS dial 0** for Emergency help
**SOS marque 0** para Emergencia

TSPS/DTF STERLING LOWER-EXP - 11 Operator assisted rates apply to all toll calls from this telephone.

Fig. 2—Instruction card set for a telephone from which credit card, collect, emergency, and other "free" calls can be made without depositing any coins, and from which long distance calls can be dailed by the caller.

a broken horizontal stripe, representing credit card and speed. The functional meaning of these symbols is explained in the text immediately to the right of the symbol.

3. Dial tone/deposit sequence pictograms: The pictograms in the upper right corner illustrate the sequence for listening for dial tone (depicted as a handset with waveform) and coin deposit. Numbers, as well as spatial position, show the sequence. The post-pay instruction card (not shown) has the additional modifier "Deposit only after answer" between the handset and the coin deposit. The disk representing the coin also contains the initial deposit rate (cost of a local call).

4. Summary instructions: Summary instructions for placing local and long distance calls are located directly below the colored band (for the two-card design). In the long distance case, these instructions are intended to be sufficient for the knowledgeable user to identify the

Fig. 3—Instruction card from a "Charge-a-Call" telephone.

general procedure. The "0+" and "1+" represent the prefixes required before dialing certain types of calls, when needed. The colored word "Operator" indicates that long distance calls cannot be dialed by the caller. Experienced users should be able to recognize the symbols at a glance, and identify the procedure without reading the instructions.

5. Emergency: "SOS" is the internationally recognized emergency symbol, and it is used to identify the number to dial for emergency assistance. Its red color makes it very salient. The use of a unique identifying color makes possible useful public relations messages in non-English-speaking communities. For example, the Chinese press in New York could carry a message stating (in Chinese) "If you need emergency help, dial the red number." Where dual language instructions are required by regulation, the SOS instruction can be repeated in the second language. Where separate numbers for fire, police, and ambulance are required, the SOS is supplemented with specific symbols (flames, a shield, and a cross) paired with each number.

6. Local instructions: The space directly under the dial tone/deposit symbols is reserved for locally varying instructions. Operating companies may use this space for special instructions or to publicize a new service.

7. Lower card: Specific dialing instructions and service numbers are listed on the lower instruction card. The major sections are divided by a colored rule, and each section has an index heading to simplify searching.

### *4.2 Preliminary design differences*

The instructions shown in Figs. 1 to 3 differ in several respects from the instructions used in the laboratory evaluation. Changes were made

based on the findings of that study, as we discuss in Section V. Briefly, the earlier designs differed from the new designs as follows: (1) There was no summary instruction for local calls; (2) the word "Operator" was not in color on the upper card for operator-dialed long distance calls; (3) all operator-dialed calls were combined into a category called "All other calls" on the lower instruction card; and (4) the local directory assistance number was listed in the same line as the heading "Directory Assistance" when that number was different from the "Within this area code" number. In addition, the handset with dial-tone pictogram and Charge-a-Call symbol were modified between the laboratory test phase and the field test.

## V. LABORATORY EVALUATION

### *5.1 Study goals*

The instruction cards were designed to satisfy two major goals. First, users should be able to search successfully and efficiently for the information they need. Second, knowledgeable users should be able to tell at a glance what services and procedures are available on a given telephone. The major purpose of the laboratory evaluation was to determine whether these design goals were met. We used an information search task to assess the new designs and identify needed improvements. The following questions were addressed:

1. Could users find the answers to questions about telephone operation?
2. Did users understand the information provided?
3. Were users able to find information quickly after some experience using standard instructions?
4. Did users understand the symbols and pictograms used on the instructions?
5. Did users infer the meaning of the redundant visual codes (e.g., color) that would allow them to get information at a glance?

In addition, several different formats were evaluated.

### *5.2 Method*

#### *5.2.1 Materials*

Three formats for the upper instruction card and two formats for the lower card were used. The same content and design elements described in the preceding section were used in each format. The only differences between the formats were in the arrangement of the information. The formats of the three upper cards were:

1. Horizontal: the design illustrated in Figs. 1 through 3.
2. Two-panel: the information contained in the stripe on the horizontal design was placed in a square patch on the left third of the

card; the other information was listed on the remaining two thirds of the card.

3. Three-panel: the left third was the same as in the two-panel design; the remaining space was divided into two equal sections by a blue or tan vertical bar. The center section contained long distance dialing and local information, and the right-hand section contained emergency information.

The formats of the two lower cards were:

1. Ruled: illustrated in Figs. 1 through 3.

2. Unruled: the colored lines separating categories were removed, the colored headings were placed directly above the listings for that category, and the listings were centered on the card.

Instructions for eight different telephones were created. The operating procedures and available services varied on the eight telephones. Three of the telephones had coin-first service, two had dial-tone-first, one had dial-tone-first/post-pay, and two had Charge-a-Call. Other operating differences, such as initial deposit rate, long distance dialing procedures, emergency numbers, directory assistance numbers (local and long distance), and repair numbers were systematically varied across the eight telephones. Only combinations of services and procedures that actually exist in the operating telephone environment were used. A set of instruction cards was constructed in each of the formats described above for each of the eight telephones. (For this study, upper and lower housing cards were designed for Charge-a-Call.)

#### *5.2.2 Experimental groups*

Seventy-two people (six groups of 12) participated in the study. Six conditions were formed by combining each set of upper instruction cards with each set of lower cards. Each group of participants saw cards from only one condition.

#### *5.2.3 Participants*

Participants were recruited from the Holmdel, New Jersey, vicinity. The 67 female and five male participants had a median age of 34 years, and a median education of one year of college. They were paid to participate.

#### *5.2.4 Procedure*

An information search task was used. Participants in the study were asked to answer many questions about the operating procedures of telephones, based on information obtained from the instructions. Errors in responding to questions indicated that information was not

found or understood. Response times to questions were measured to assess the efficiency of information search.

After the series of main questions were answered, participants were asked to answer a second set of questions. The instruction cards shown in this series had all text removed. Thus, the second set of questions measured incidental learning of the meaning of colors, symbols, and pictograms that occurred in the first part of the experiment. Finally, participants were asked to complete a questionnaire about overall ease of use and appearance of the instructions, as well as further questions about the colors, symbols, and pictograms.

The participants sat at a table that contained a response panel and a 50-cm-square rear projection screen. The viewing distance was two feet, approximately the viewing distance when reading instructions on a public telephone. The response panel contained four buttons, labeled "Ready," "Yes," "No," and "Don't Know." Participants were instructed to place their index fingers on the "Yes" and "No" buttons, and a thumb on "Ready." They were told to imagine that they were traveling, and that they would need to make numerous telephone calls from public telephones. Since telephones have different operating procedures, they would need to use the instructions on the telephones to answer questions before placing the calls.

Each trial began with the presentation of a slide containing a question, such as "Does a local call cost 20 cents?" The participants were told to study the question until they understood and remembered it, and then push the "Ready" button. Pushing the button started a sequence that turned off the question slide, and turned on a slide containing a picture of a telephone with instruction cards on it. The pictured telephone and instruction cards were shown at actual size. Participants were told to look for the answer to the question they had just seen on the instructions, and answer either "Yes" or "No." They were told that all answers were available in the instructions, but if they could not find it to answer "Don't Know."

The experiment was run under computer control; responses and response times were recorded. Response times were measured in milliseconds from the time the picture appeared on the screen until the response button was pressed. There were 96 trials separated by a 2-second intertrial interval, with a 1-minute break between blocks of 24 trials.

#### *5.2.5 Structure of the question series*

The questions came from eleven categories: cost of local calls, dial tone/deposit sequence, types of calls that require coin deposit, emergency numbers, long distance calls, calls requiring a "1" prefix, dialing of credit card numbers, possibility of coin use, directory assistance

numbers, repair service numbers, and the address of the telephone (provided on the experimental instruction cards). The 96 trial series contained eight questions from each category except emergency numbers and dial tone/deposit sequence, from which there were 12 questions. For half of the questions the correct answer was "Yes." Questions from each category were paired with each of the eight telephones, except where inappropriate (e.g., no questions about the dial tone/deposit sequence were asked about Charge-a-Call telephones). Question order and left-right position of the "Yes" and "No" buttons were counterbalanced.

Following the 96 questions, 16 questions were presented using the cards with text removed. Participants were told to try to figure out the answers based on the information remaining. Questions were from four categories, emergency numbers, types of calls requiring coin deposit, long distance dialing, and possibility of coin use.

### *5.3 Results*

#### *5.3.1 Main question series*

Mean response times were computed for each question category within each trial block (24 questions). An analysis of variance was done on these mean response times. Factors in the analysis were Upper Card Format, Lower Card Format, Trial Block, and Question Category.

No statistically significant ($p < 0.05$) differences in response times were observed between formats. The main effect of Trial Block was statistically significant ($p < 0.001$). Mean response times for trial blocks 1, 2, 3, and 4 were 13.4, 7.9, 6.3, and 5.8 seconds, respectively. Post hoc comparisons of the means showed that block 1 > block 2 = block 3 = block 4. Thus, participants responded more quickly to later questions, which indicates that they could find information more quickly once they had some experience using the cards.

The main effect of Question Category and the Question Category by Trial Block interaction were also statistically significant ($p < 0.001$). Mean response times differed widely across the different question categories. Slow response times, especially later in the question series, are an indication that users may be having difficulty finding or understanding information. In trial blocks 2 through 4, mean response times were relatively short (less than 6 seconds) for emergency numbers, possibility of coin use, repair numbers, cost of local call, and address; response times were slower (8 to 11 seconds) for "1" prefix for long distance, calls requiring coins, long distance dialing, dial tone/deposit sequence, directory assistance, and availability of credit card number dialing. Possible sources of difficulty will be discussed below.

The total number of errors in each trial block and in each question

category was computed for every subject. Both incorrect and "Don't Know" responses were counted as errors. The overall error percentage was 11.4 percent.

An Upper Card Format by Lower Card Format by Trial Block analysis of variance was done on the error data. Only the main effect of Trial Block was statistically significant. There were more errors in the first trial block (15.4 percent) than in the last three trial blocks (9.8 percent). The decrease shows the same facilitative effect of experience that was seen in the response time data.

An Upper Card Format by Lower Card Format by Question Category analysis of variance again showed only the main effect of Question Category statistically significant ($p < 0.001$). The pattern of errors is similar to the pattern of response times. The correlation between mean error rates and mean response times in the 11 categories was high, $r = 0.77$. High error rates are also an indication that users are having difficulty finding or understanding information on the instruction cards.

#### *5.3.2 Incidental learning question series*

The instruction cards used in this question series contained only the information that appears in color on the instruction cards. The purpose of this question series was to determine whether subjects had learned the meaning of this information during the main question series. All of the questions could be answered with the information available.

The total number of errors and mean response times were computed for each of the four question categories for every subject. An Upper Card Format by Lower Card Format by Question Category analysis of variance was done on the error data and on the response time data. In both analyses only the main effect of Question Category reached statistical significance. No differences between card formats were observed.

The questions on long distance calling ("Can you dial your own long distance calls?" or "Does the operator dial all long distance calls?") caused the most difficulty. The percentage of errors (58 percent) does not differ from the performance expected from guessing. The long distance category also elicited the highest percentage of "Don't Know" responses (7 percent). Clearly, the participants did not learn that the presence of the "0+" and sometimes "1+" symbols on the upper card indicated that long distance calls could be dialed, and that the absence of "0+" meant that the operator dials all long distance calls.

Performance on the other question categories was substantially better than what would be obtained by guessing, showing that some incidental learning had occurred. However, questions on the types of

calls that required coin deposit did have a fairly high (15 percent) error rate. The answers to these questions could be inferred from either the color of the card (blue or tan) or from the dial tone/deposit sequence.

The "SOS" emergency symbol was well understood. Responses were fast and few errors were made.

#### *5.3.3 Questionnaire results*

The questionnaire contained four rating-scale items. The instructions were rated on the ease of finding needed information, the ease of understanding the words in the instructions, the overall ease of understanding the instructions, and the attractiveness of the instructions. The responses were scored from 0 to 5, where 5 was the most positive response. An Upper Card Format by Lower Card Format analysis of variance was done on the ratings for each item. No statistically significant differences between formats were found for any item. Overall, participants rated the ease of finding needed information between "somewhat easy" and "easy" (mean rating 3.6), the ease of understanding words between "easy" and "very easy" (4.3), the overall ease of understanding between "somewhat easy" and "easy" (3.7), and the attractiveness between "somewhat attractive" and "attractive" (3.6).

When asked if any information seemed to be missing from the instructions, the majority of participants responded negatively (67 percent). Of the people responding affirmatively, most of the comments were about the lack of information on placing local calls or about the dial tone/deposit sequence. A few general comments were made, such as "Instructions too wordy," or "Instructions not detailed enough." Similarly, the majority of participants did not report any specific problems understanding the instructions in response to an open-ended probe. The problems that were reported were also about the lack of information on local calls, and confusion about when to deposit coins. In addition, some people were confused about the "0+" and "1+" symbols.

The majority of participants gave no suggestions for improving the instructions. Some general suggestions were made, such as "Make the instructions simpler," or "Make the instructions easier to understand." A few participants commented on the small size of the print. Most suggestions, however, concerned the variety of procedures described on the instructions. The most frequent comment was "Make the instructions the same on all telephones." The nature of the comments made by these participants implied that some thought the operating procedures were determined by the instructions, rather than the reverse.

In the last section of the questionnaire the participants were asked to explain the meaning of the colors and symbols. Most of the participants did not learn the meaning of the blue and tan colors but did learn the meaning of the Charge-a-Call symbol. Ninety-six percent of the participants correctly explained the meaning of "SOS," and most of these recalled that the "SOS" symbol was red.

The "0+" and "1+" on the upper instruction card were generally explained as "Dial 0 (1) and then the number." However, a third of the participants said that "0+" meant "Dial the operator" or "Operator dials long distance." A number of the participants who said that "1+" was for direct-dialed long distance also stated that "0+" was for operator-dialed long distance. Certainly these participants had not learned the distinction between 0+ and 1+ dialing.

The symbol sequence for the dial tone/dial/deposit coin sequence was confusing in some cases. The symbol sequence for coin-first operation was understood by 79 percent of the participants. In contrast, there was some confusion about the meaning of the dial-tone-first symbols. Fifty-four percent of the respondents correctly answered either "Dial tone first" or "No coins needed for dial tone." However, a third of the participants confused the typical dial-tone-first case (deposit coins before dialing local calls) with the post-pay procedure. This pattern of responses is consistent with the general confusion over the dial tone/coin deposit/dialing procedures observed in the experiment.

### *5.4 Discussion of problems and recommendations for improvement*

The major findings in this study relate to the content of the instructions, not the formats.

The highest overall error rate in the main question series occurred on questions about directory assistance numbers. There were two major sources of difficulty. First, the listing for local directory assistance appeared in the same line as the heading, and was hard to find. Since no separate listing for "Local" was made on some of the instructions, the participants tended to infer that the number for "Within this Area Code" was always the local number. This problem was subsequently remedied by adding a separate line for "Local" on the lower instruction card. The other confusion has no obvious solution. The participants expressed confusion over the need for separate listings for "Local" and "Within this Area Code." The confusion may stem in part from the fact that all participants were from New Jersey, where only a single number is used for directory assistance within an area code.

The dial tone/deposit sequence questions contained two subsets of

questions. One subset contained questions about the temporal sequence of hearing the dial tone and depositing a coin, the other about the temporal sequence of depositing a coin and dialing a call. The problems occurred in the latter subset. Forty-eight percent of the participants responded that coins were deposited after answer for the typical (pre-pay) dial-tone-first case. Some people appeared to equate the pre-pay and post-pay dial-tone-first telephones. The post-pay telephone is uncommon (except in a few areas outside of New Jersey), so participants may have been confused about the two types of telephones. The cards tested in this experiment contained no written instructions on how to place local calls. Based on the difficulty seen in this area, some statement about when to deposit coins on local calls appeared warranted.

The same confusion appeared to affect the results in the category of calls requiring coin deposit. Most of the errors occurred on the question "Do you need to deposit any coins to make a local call?" Thirty-eight percent said "No." The additional written instruction described above should also help this problem.

The questions about long distance calling can also be divided into two subsets, one about whether customers can dial their own long distance calls, and the other about the specific digits to dial for long distance calls. Most errors occurred in the latter category, on telephones from which long distance calls were dialed by the operator. These instructions had no specific instructions for long distance on the lower card, just a listing for "All other calls" (Dial the Operator). Some improvement should be obtained if these instructions contained all categories, even though the instruction in every case is "Dial the Operator."

On the incidental learning question series, participants were asked whether long distance calls could be dialed. The answers to these questions had to be inferred from the "0+" and "1+" symbols. If these symbols were present, then long distance calls could be dialed; the absence of a symbol implied that the operator dialed the calls. The problem may have occurred because this upper card information was never used in the main question series. However, the problem may have occurred because of the lack of a positive indicator for operator-dialed long distance. The subsequent addition of such a cue should make the information on the upper card clearer.

Errors were made on 19 percent of the questions about the need for a 1 prefix on direct-dialed station-to-station long distance calls. These errors are hard to interpret since the prefix is not used in New Jersey. The other category that caused some confusion was about customer-dialed credit card numbers. As in the case of the 1 prefix, this information was explicitly stated on the lower instruction card when

appropriate; however, the new procedure was not familiar to New Jersey residents.

In summary, the improvements recommended were:

1. Add a separate line for "Local" directory assistance.
2. Add a written instruction on when to deposit coins for local calls on the upper card; the heading should be "Local calls" and be placed above "Long distance calls."
3. Add a symbol for "Operator dialed long distance" to contrast with the "0+" and "1+" symbols in the long distance section of the upper card.
4. Remove the heading "All other calls" from the lower card and replace it with the same headings used on the other cards "Charge and Person-to-person calls" and "Station-to-station calls."

These changes were incorporated into the instructions used in the subsequent field evaluation. The choice of format (horizontal and ruled) used in the final design was made by AT&T Public Services Marketing and the designer.

## VI. FIELD EVALUATION

The major purpose of the field study was to assure that the instruction card design, modified based on laboratory results, was acceptable to telephone users, and that telephone users could use the instructions to find needed information. Because the overall success of the new instructions depends on the use of standard instructions throughout the Bell System, we could not expect to show all the advantages of the new instructions.

### *6.1 Field trial sites*

The field trial of the proposed standard instruction cards was conducted in Illinois Bell Telephone (IBT) Company and New York Telephone (NYT) Company at three sites in each company: a major city airport, a large suburban shopping center, and a small, self-contained city. The sites were selected so that a variety of public telephone users would be exposed to the trial instructions: travelers, local residents, local callers, long distance callers, credit card callers, etc. In addition, a second shopping center was selected in each company. The new cards were not installed at the second shopping center.

A broad range of services and procedures was available at these sites. Among the variations in operating procedures were telephones requiring an initial deposit for all calls, telephones requiring a deposit only for coin-paid calls, and Charge-a-Call telephones. At some locations callers could dial their own long distance calls, at others operator assistance was required. At some locations a "1" prefix was required on calls to other area codes; on others it was not required.

### 6.2 Instruction card content

The information on the trial cards was the same as the information on the instructions they replaced, although some changes were made to conform to the new standards. The changes mainly involved the removal of specific place names. For example, on the existing instructions at Roosevelt Field shopping center in NYT, long distance dialing instructions were given for "Nassau and Suffolk" and "All other places." These specific names were replaced by the general, but equivalent, instructions for "Within this Area Code" and "Outside this Area Code."

### 6.3 Interview study

Interviews were conducted at selected public telephones in December 1979 (three months after card installation in New York, two months after installation in Illinois). People who had just used a public telephone were interviewed face-to-face by professional interviewers. The interviewer asked a series of questions about the call just made and the use of the instructions, then showed instruction cards identical to the ones on the telephone just used and asked a series of questions about how to place various types of calls. The interviews addressed the following areas:

—Did people look at the cards?
—What information was needed?
—Was the information easy to find?
—Was the information easy to understand?
—Could people find and report dialing instructions correctly for various types of calls?
—What was the overall judgment of the appearance of the card?
—Could people understand the pictograms used on the cards?
—Did people understand the meaning of "SOS?"

A total of 650 interviews were conducted at trial locations, 100 at each of the trial sites, plus an additional 50 interviews at Charge-a-Call telephones at O'Hare International airport. Two hundred additional interviews were conducted at the two shopping centers where the original instruction cards had been left in place. The locations provided a comparison of telephone users' acceptance of and problems using the trial cards. Since the advantage of the new cards depends upon their use in all locations, and since the old cards were familiar to the users, this comparison is not intended to be the proof that the new cards are better.

### 6.4 Interview results

For the following discussion, the normal approximation to the

difference between two observed and independent proportions was used to test the significance of the differences between results from the trial and nontrial shopping centers.

Less than 25 percent of the people interviewed reported looking at or reading the instructions cards at any location except at the Charge-a-Call telephones, where 63 percent of those interviewed reported reading the instructions. Charge-a-Call telephones look different from regular coin telephones; 88 percent of the Charge-a-Call users who read the instructions reported doing so to find out how to use the telephone, or because the telephone looked new or different. No significant differences were found between the number of interviewees who looked at or read the instructions at the trial and nontrial shopping centers.

The people interviewed reported needing a variety of types of information. The types of information requested were: how to use the telephone; how much money to deposit; how to make collect, credit card, or person-to-person calls; how to dial long distance; and what numbers to dial for service calls. Ninety percent of those interviewed who reported reading the instructions said that the information they needed was easy to find; 94 percent reported that the information was easy to understand. No significant differences were found between the trial and nontrial shopping centers.

Interviewees were asked to use a set of instructions cards identical to the cards on the telephone they had just used to find and report dialing instructions for the following types of calls: police emergency, local directory assistance, collect, and coin-paid station-to-station long distance calls. In all cases, most of those interviewed were able to correctly report the dialing procedures. Most of the errors occurred when the interviewee reported a dialing procedure that would be correct in other settings, for example, reporting "911" as the police emergency number at a location where "0" was the correct response. This type of error was made in both trial and nontrial locations. No significant problems in finding or understanding dialing instructions were identified with the new instructions. The interviewees had no trouble in finding the emergency information associated with the "SOS" symbol.

Pictograms were used on the upper instruction card to represent the dial tone/deposit sequence. The numerals "1." and "2." were used to indicate the sequence.* A coin-like disk indicated both the action of depositing and the amount of the local call deposit. A handset with an

* A separate study conducted by M. L. Viets reported that sequential steps should be indicated by numbers followed by a dot. Omitting the dot led people to interpret 1 and 2 as magnitudes rather than as ordinal steps in a sequence.

expanding waveform indicated the concept "listen for dial tone." Overall, a high percentage of interviewees (88 percent) were able to provide a correct or partially correct meaning for the dial tone/deposit pictograms. Thirty-nine percent gave correct responses that included the correct meaning of both pictograms and the correct action sequence. The remainder gave responses that included correct meanings for some of the elements.

Interviewees were asked to rate the overall appearance of the instruction cards on a six-point scale ranging from very attractive (a rating of 1) to very unattractive (a rating of 6). Overall, the trial cards were rated attractive; the median response was 2 at all locations except the New York shopping center, where the median response was 3 (somewhat attractive). The median rating of the cards at the Illinois nontrial location was 3; at the New York nontrial location the median response was 2.

Interviewees were also asked an open-ended question about their overall reaction to the instruction cards. Most of the comments were positive; however, about 20 percent of the respondents had some criticism of the instructions. The most common complaints were that the print was too small, the appearance of the card was cluttered, and the color unattractive. Overall, 9 percent of the trial location respondents complained about the print size (10-point type). In Illinois, the nontrial cards were dual-language cards. All instructions were printed in both English and Spanish. This required the use of smaller print (8-point type) than on a single-language card. Thirteen percent of the respondents at the Illinois nontrial location complained about the size of the print, and 13 percent more complained about the use of Spanish, indicating that it made the instructions harder to read. Overall, 6 percent of the trial location respondents complained that the cards were cluttered (too much information); however, less than 1 percent of the airport respondents had this complaint, compared to 11 percent in the small cities and shopping centers. Generally, public telephone users in the cities and shopping centers made local calls, and had little need for most of the information on the instruction cards. Seven percent of those who saw tan cards complained about the color of the cards; less than 1 percent disliked the blue cards.

### *6.5 Field trial conclusions*

The proposed standard public telephone instruction cards were acceptable to users. They were rated as easy to use. Telephone users were able to use the trial instructions at least as well as the nontrial instructions, and no major problems were detected. The new card establishes a standard that satisfies users' needs.

## VII. CONCLUSIONS

Based on the results of the laboratory evaluation and on the reception of the new instructions cards in the field, AT&T Public Services recommended to all Bell Operating Companies (BOCs) that the new instruction cards be used on all public telephones. The new cards have been introduced in most BOCs. In addition, the new design was made available to the Independent Telephone Companies for use in preparing their instruction cards. We anticipate that the widespread use of the new standard instructions will make public telephones easier to use.

# A Study of the Match Between the Stylistic Difficulty of Technical Documents and the Reading Skills of Technical Personnel

By E. U. COKE* and M. E. KOETHER*

(Manuscript received November 24, 1981)

The reading grade level of a sample of Bell System technical documents was assessed using the Flesch Reading Ease Index, which estimates the reading skill needed to cope with a document's writing style. The reading skills of two groups of Bell System craft and management trainees were also estimated from their performance on a standardized reading test. We found that most of these employees had sufficient reading skill to deal with the writing styles of the sample documents. This observed match between readers and documents resulted because most of our students were proficient readers, not because the documents' writing styles were easy. We compared the reading skills of students as they entered and completed training to see whether less able students were eliminated during training. Results did not support training selection as an explanation of our readers' proficiency. While results indicated that many Bell System employees have the reading skills necessary to cope with the technical documents they read, others may find that the writing styles of technical documents are real barriers to success on the job. We can identify a document that may place an undue burden on its readers by estimating the likelihood of a mismatch between the document's readability and the reading skills of its users.

## I. INTRODUCTION

How well technical documents communicate with their readers depends in part on the style in which they are written, since the *way* ideas are expressed can influence how easily they are understood. Readers may find a document particularly difficult to read when its writing style places an undue burden on their reading skill. For example, use of words that are unfamiliar to readers can obscure a document's message. Also, a document can be unclear if ideas are embedded in sentences whose syntax is too complex for its readers. Other characteristics of style are described elsewhere in this issue of the *Journal*.[1]

The stylistic difficulty of written communication can be appraised with the help of readability formulas.[2,3] These formulas predict the reading difficulty that may result from a document's writing style but not from its content, organization, or format. Readability formulas estimate the reading skill needed to cope with a document's writing style, as manifested in the writer's choice of surface structures. A readability index is calculated from measures of text features that are thought to be indicators of stylistic difficulty. For example, many formulas use the average length of a text's words and sentences to calculate readability. These two text measures, word length and sentence length, function primarily as indicators of the lexical and syntactic difficulty of the text. In English, shorter words are likely to be more familiar to readers than longer words, since shorter words tend to occur more frequently. Shorter sentences are apt to be easier for readers to process than longer sentences because shorter sentences tend to be less complex syntactically.

While readability indexes are often derived from relatively simple formulas, they can provide useful estimates of sytlistic difficulty.[4] For example, readability indexes tend to agree with human judgments of text difficulty,[5] and it is usually less time-consuming and costly to calculate a readability index than to collect human judgments of reading ease. Readability indexes have also been shown to predict behavioral measures of reading ease, such as reading rate[2,6] or duration of eye fixations,[7] in experimental settings. The readability level of documents has also been related to their effective use in work situations[8,9] and will be discussed later in this section.

Readability formulas have their limitations. Formulas only provide estimates of the stylistic difficulty of texts. These formulas are derived from correlations between text measures related to style and measures of reading difficulty such as comprehension test scores. Almost all formulas have been developed using a multiple regression technique to select the linear combination of stylistic measures that best predicts the scaled difficulty levels of a set of texts. Most of the commonly

used readability formulas, such as the Flesch and Dale-Chall formulas, produce estimates that are accurate to within ±1 reading grade level.[10] The Kincaid formula[11] is slightly less accurate, having a standard error of 1.41 as compared to the Flesch, which has a standard error of 0.81.[12]

Readability formulas are often criticized because editorial revisions that produce acceptable readability indices do not necessarily result in a more readable text.[3,13,14] For example, shortening words or sentences will lower a text's readability index without necessarily making it easier to read. This should not be surprising since readability formulas are derived from *correlations* between measurable text attributes and readers' performance on comprehension tests.[3] As pointed out in the preceding paragraphs, easily quantifiable text features such as sentence length gain their predictive power by indexing underlying contributors to text difficulty that are less easily quantified. Some of the important *determinants* of reading difficulty, such as syntactic complexity and the use of the passive voice, are discussed elsewhere in this issue of the *Journal*.[1]

Just how much difficulty a particular group of readers will have with a document's style depends on their level of reading skill. If a given reader's skill matches or exceeds that required by a document, its writing style alone is not likely to cause trouble for that reader, even though the document's subject matter may be difficult. Conversely, a reader with more limited skill is likely to find that the document's writing style alone presents a challenge.[2–4] By comparing a document's readability index (an estimate of stylistic difficulty) with an estimate of reading skill, we can predict the difficulty a reader might be expected to have with a document's writing style. An estimate of overall reading competence can be obtained from a person's performance on a standardized reading test. These tests sample a reader's behavior on tasks that have been found to discriminate between skilled and unskilled readers.

Estimation of the match between a document's readability and the reading skills of its audience can be helpful in evaluating the effectiveness of technical writing that contains job-related information. Many companies, such as the Bell System, rely heavily on written communication to support job performance. When the writing style of a job-related document is too difficult for its users, job performance may suffer in a number of ways. Studies have investigated the consequences of this mismatch between document style and reading skill. Jobs may take longer than usual to perform because needed information is hard to access.[9] Errors may increase because the descriptions of work procedures are unclear.[8] Perplexed readers may turn to co-workers for help, thus reducing their co-workers' productivity.[9]

In the present study, the match between the readability of docu-

ments and the reading skills of readers was estimated for a large sample of Bell System technical documents. These documents are a major source of information about the operation and maintenance of equipment. The readability of these documents was measured by computer and compared with the reading skills of two groups of Bell System employees who use the documents. Levels of reading skill were estimated from the employees' scores on a reading test.

## II. METHOD

### *2.1 Readability survey*

#### *2.1.1 Documents*

Readability measures were obtained for the text of Bell System technical documents called Bell System Practices (BSPs). These documents are a major source of information about the operation and maintenance of equipment. They are used throughout the system by both craft and management personnel. There are well over 250,000 BSPs so only a sample of these documents were analyzed. Most of these BSPs are typeset under computer control and consequently were available in computer-readable form.

The BSPs selected for analysis were those likely to be used frequently. To meet this goal, documents were chosen from three important areas of company activity—outside plant, customer equipment, and *ESS** switching equipment. The BSPs dealing with outside plant and customer equipment were taken in a random fashion from handbooks provided to craft personnel for use on the job. The BSPs about electronic switching systems were chosen in a random fashion from those describing the operation of two different systems, 1 *ESS* and 2 *ESS* switching equipment. Table I shows the number of BSPs analyzed from each category of company activity. Altogether, readability indices were obtained for 140 BSPs consisting of a total of 378,359 words.

#### *2.1.2 Readability measure*

The Flesch Reading Ease Index[12] was chosen to measure readability. The formula for calculating this index, given in Table II, uses two features of a text to predict stylistic difficulty: (1) the average length of a text's words in syllables, and (2) the average length of its sentences in words. These two measures function primarily as indicators of the lexical and syntactic difficulty of a passage. Available evidence[2–4] suggests that formulas using these simple word and sentence measures are satisfactory predictors of the stylistic difficulty of texts. The

* Trademark of Western Electric.

Table I—Number of BSPs in the readability survey from each category of company activity

| Category | Number of BSPs | Total Number of Words |
|---|---|---|
| Outside plant | 49* | 101,162* |
| Customer equipment | 48* | 83,927* |
| ESS maintenance | 50 | 213,373 |

* Seven BSPs that were in both the outside-plant and customer-equipment handbooks were included in the totals for both categories.

Table II—Formula for the Flesch Reading Ease Index and the algorithm for converting a vowel count to a syllable estimate

1. Flesch Reading Ease Index (FL):

   $FL = 206.84 - 84.6\ WL - 1.015\ SL$

   Where
   WL* is the average length of a word in syllables
   SL is the average length of a sentence in words

2. Algorithm for estimating the syllables (SYL) in a sample of words

   $SYL = 0.998\ VOW - 0.343\ W$

   Where
   VOW is total vowels (aeiouy)
   W is total words

* WL = SYL/W.

Kincaid formula[11] also uses these two measures and is the basis for the Writer's Workbench advisory on readability.[1] The Flesch formula was chosen for the present survey because it has been more widely used than the Kincaid formula and has been shown to be one of the most accurate predictors of readability.[10]

The Flesch Index ranges from 0 to 100 with a higher index representing a more readable text. A Flesch Index can also be expressed as a reading grade level, which is the average school grade of readers who would be expected to score 75 percent on a comprehension test for the reading material. Originally, a point on the Flesch Index scale corresponded to one-tenth of a grade,[12] but Flesch found that his formula underestimated the reading grade level of more difficult passages. He proposed a nonlinear relationship between the Flesch Index and reading grade level,[15] and this relationship is used in the present study to assign a reading grade level to an index value.

The Flesch Index was calculated by computer,[16,17] since the BSPs were in computer-readable form. A program was written to compute average sentence length for (complete) sentences in the text of the BSPs. The program was able to exclude tables, headings, and titles

that were flagged in the text. To calculate the average length of a word in syllables (WL), the program estimated the number of syllables in a word sample from a count of the number of vowels in that sample. This vowel count was then converted to syllables using the formula[18] shown in Table II.

When syllables are estimated from a vowel count, the presence of words without vowels, such as abbreviations, acronyms, and numbers, may be a problem. Their inclusion in the computer's estimate of syllables can lead to an underestimation of average word length and a consequent underestimation of reading difficulty. This is a problem when analyzing technical documents. In some of the BSPs selected for the present survey, over 11 percent of the words did not contain vowels. One solution to this problem is to base the syllable estimate on words that conform to the syllable estimation algorithm's assumption that a word contains at least one vowel. This solution was adopted in the present study and has been implemented in the Writer's Workbench. Only nonnumeric words with at least one vowel were used in the estimation of syllables from a vowel count. This solution seemed to work. Flesch Indexes were computed using hand counts of syllables for 16 BSPs that had a large number of words without vowels. These manually produced indexes were compared with computer-produced indexes. When words without vowels were omitted from the computer estimation of syllables, 11 of the 16 texts were assigned the same reading grade levels by the computer-produced and manually produced indexes. When words without vowels were included in the syllable estimation, only 4 of the 16 BSPs were classified at the same readability level by the computer-produced and manually produced indexes. This solution finds precedence in Flesch's suggestion[12] that counts of syllables be based on words whose pronunciation is unambiguous.

### *2.2 Reading skills survey*

#### *2.2.1 Reading test*

The reading skills of Bell System personnel were estimated from their performance on a standardized, commercially produced reading test, the Nelson-Denny Reading Test, Form D.[19] This test had been standardized by giving it to a sample of over fifteen thousand high school students, representing the student population of the United States in 1972. The test performance of students in this sample was used to estimate the reading skill represented by a test score. Level of reading skill is often expressed as a score's reading grade level. A test score is assigned a reading grade level that corresponds to the *average* educational level of students who made that test score in the standardization sample. Thus, a reader's reading grade level is the school grade for which his or her test score is typical. It should be emphasized

here that the educational level of a person and the reading grade level of his or her test score are not identical.

The Nelson-Denny Reading Test was chosen for three reasons: (1) it can be given in a reasonably short period of time, (2) it covers a range of reading abilities appropriate for Bell System employees, and (3) it was well constructed according to standards for norm-referenced tests.[20]

The Nelson-Denny Test is composed of a vocabulary test and a comprehension test. The vocabulary test contains 100 multiple-choice items consisting of a sentence stem and four words that can complete the sentence. The comprehension test consists of 36 multiple-choice questions that relate to five short prose passages. Readers work on the vocabulary test for 10 minutes and on the comprehension test for 20 minutes.

Performance on the test is expressed as a total score. This score is the sum of two subscores: (1) the number of correct vocabulary items, and (2) the number of correct comprehension items multiplied by two. The reading grade equivalents for total scores are given in the Examiner's Manual of the Nelson-Denny Test.[19] In terms of accuracy, the total score has a standard error of measurement* of about 5.7.[19] Translated into reading grade level, this standard error is approximately a 0.5 reading grade level.

In the present study, total scores were used in all statistical computations. However, the results were also presented as reading grade equivalents of test scores. Reading grade levels were used because: (1) they are often a more meaningful way of expressing reading skill, and (2) the readability of the technical documents was expressed as reading grade levels.

#### *2.2.2 Subjects*

The Nelson-Denny Reading Test was given to 471 technical management employees and 210 craft employees. Both groups were students at Bell System training centers. The management students were taking a variety of technical courses covering such diverse subjects as switching systems, data management, building engineering, and finance. The craft students were taking the final course in an *ESS* switching equipment training program that involves approximately 700 hours of training.

These employees were chosen because they were likely to use doc-

* The consistency of a test can be expressed in terms of the standard error of measurement. Approximately two-thirds of the hypothetical "true" scores on a test would lie within one standard error of measurement from a score obtained on the test.

uments such as the BSPs sampled in the readability survey. In addition, students at the training centers are more readily available for testing than are employees in work situations.

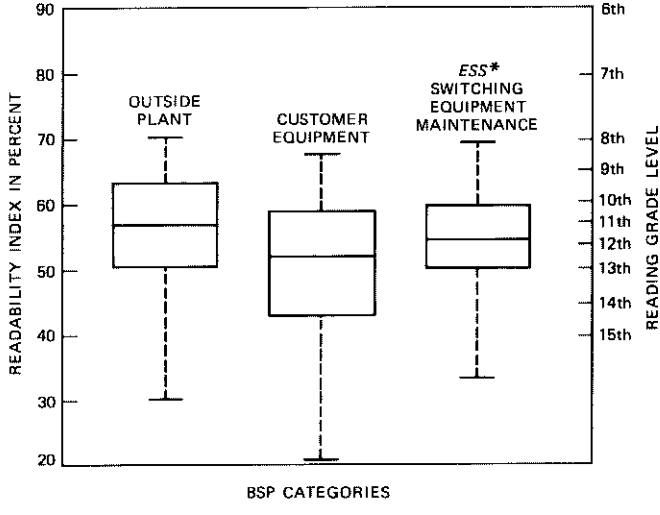
Each student took the Nelson-Denny Test and filled out a questionnaire requesting information about his or her age, sex, years of formal education, job level, years of service in the Bell System, and region of the country in which he or she worked. The study was conducted in the students' classrooms in groups ranging from 10 to 30 students. All students in the selected classes participated in the study although they were not required to do so. To ensure the anonymity of the participants, each student used a number to identify all test material and the questionnaire.

## III. RESULTS

### *3.1 Readability survey*

Figure 1 shows the distributions of Flesch Indexes for BSPs in each of the three categories: outside plant, customer equipment, and *ESS* maintenance. The distribution for each category is displayed as a box plot. The ends of a box are drawn at the upper and lower quartiles of the distribution, while the bar across the box represents the median. The extremes of the distribution are plotted as horizontal lines joined to the box by dashed lines.

Figure 1 suggests that considerable reading skill is required to cope with the writing styles of many BSPs. Thirty-three percent of all the



*TRADEMARK OF WESTERN ELECTRIC.

Fig. 1—The distributions of readability for the three categories of BSPs.

BSPs sampled had Flesch Indexes below 50. An appreciation of the stylistic difficulty of these BSPs can be gained by comparing their readability levels with those obtained by Flesch[12] for some representative magazine articles. Flesch found that academic journals such as the *American Scholar* or the *Yale Review* had Flesch Indexes ranging from 30 to 50, while quality magazines such as the *New Yorker* had Indexes ranging from 50 to 60. Over half of the customer-equipment BSPs were comparable to academic journals in their level of stylistic difficulty. The writing style of three-quarters of the *ESS* switching equipment maintenance BSPs was at least as difficult as that of quality magazines. In terms of required reading skill, the writing style of one-third of the BSPs would be likely to cause difficulty for readers with skills below the 13th reading grade level. The writing style of over half the documents (63 percent) would be likely to cause difficulty for those employees reading below the 11th reading grade level.

### *3.2 Reading skills survey*

#### *3.2.1 Reader characteristics*

The questionnaires provided information about the students who took the reading test. Sixty-five percent of the technical management students were first-level management, 27 percent were second-level management, and the remaining 8 percent were third- (4 percent) and fifth- (4 percent) level management. As Table III shows, the technical management students represented a broader range of age, education, and years of service than did the craft students. The two groups differed primarily in educational level. More technical management

Table III—Age, formal education, and years of service

| | | Percentage of Students | |
|---|---|---|---|
| | | Technical Management | Craft |
| Age Level | 20–29 | 26 | 29 |
| | 30–39 | 39 | 52 |
| | 40–49 | 24 | 14 |
| | 50 or older | 11 | 5 |
| Educational Level | Some high school | 1 | 3 |
| | High school grad | 30 | 55 |
| | Some college | 29 | 36 |
| | College grad | 26 | 6 |
| | Some grad school | 14 | |
| Years of Service | 1–5 | 19 | 9 |
| | 6–10 | 26 | 49 |
| | 11–20 | 30 | 30 |
| | over 20 | 25 | 12 |

students (69 percent) than craft students (42 percent) had continued on to college after graduating from high school. There were also more women among the technical management students (30 percent) than among the craft students (9 percent).

### *3.2.2 Reading scores*

The cumulative probability distributions of total scores on the Nelson-Denny Reading Test are shown in Fig. 2 for each group of students. The reading grade equivalents of test scores appear at the top of the figure. The median, upper, and lower quartiles of the distributions are also shown. The maximum total score is 172, while the highest reading grade level that can be assigned to a score is 15.

Test scores indicate that, on the average, both groups of students were competent readers. Mean scores were 81 and 94 for craft and technical management students, respectively. For comparison, the Nelson-Denny manual[19] gives mean scores for samples of freshmen, sophomores, juniors, and seniors in college. These scores were 75, 85, 93, and 98, respectively. Over half the craft and technical management students had test scores at or above the 14th (college sophomore) reading grade level. The reading grade levels of the mean scores were 14.0 and 14.9 for craft and technical management students, respectively, and this difference between student groups was greater than would be expected by chance ($t = 3.24$, $df = 671$, $p < 0.05$).

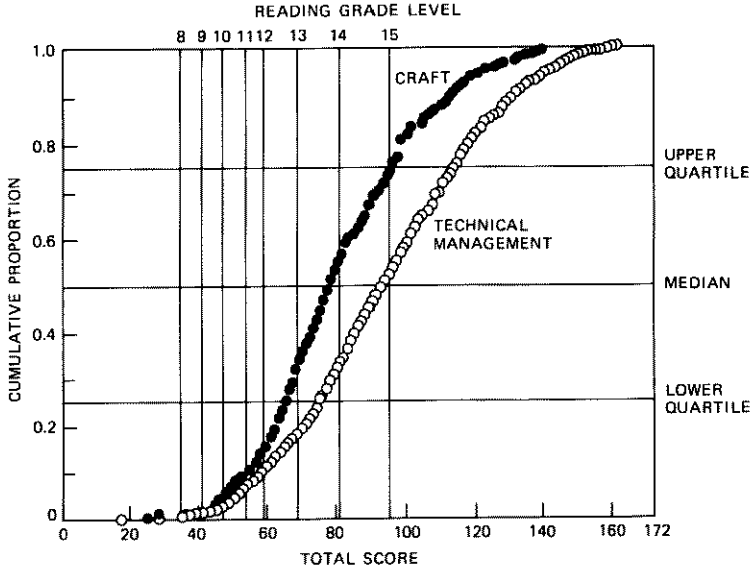


Fig. 2—Cumulative frequency distributions of reading test scores showing the median, upper, and lower quartiles of distributions.

### 3.3 *Estimating the stylistic difficulty of BSPs*

An estimate of the difficulty a group of readers may have with the writing style of a specific document can be made by finding the proportion of readers whose reading grade levels on a reading test are below the reading grade level of the document. If a document's reading grade level is 12, for example, and one third of its users have reading skills below the 12th reading grade level, then the likelihood of a mismatch is 0.33 (e.g., the probability that the users' reading skills will be below the 12th reading grade level).

This likelihood of a mismatch between audience and document can be extended to a set of documents. In this case, two measures are needed for each reading grade level represented by the set of documents:

1. The proportion of documents in the set whose reading grade levels are greater than a specified reading grade level (that is, the proportion of documents likely to be difficult for readers at that grade level);

2. The proportion of readers in the group at that reading grade level.

The likelihood of a mismatch is the sum of the products of these two estimates over all reading grade levels. This likelihood is the probability that a member of the audience will select a document from the set that exceeds his or her reading grade level.

The likelihood of a mismatch between BSPs and the technical management and craft students were calculated from the information in Table IV. This table shows the proportion of BSPs whose reading grade levels exceeded each level in the table. Also shown are the

Table IV—Proportions for calculating the likelihood of a mismatch between BSPs and two employee groups

| Reading Grade Level | Proportion of Difficult BSPs | Proportion at Each Reading Grade Level | |
|---|---|---|---|
| | | Technical Management | Craft |
| below 7.0 | 1.00 | 0.00 | 0.01 |
| 7.0–7.9 | 0.99 | 0.00 | 0.00 |
| 8.0–8.9 | 0.90 | 0.01 | 0.01 |
| 9.0–9.9 | 0.74 | 0.01 | 0.02 |
| 10.0–10.9 | 0.63 | 0.04 | 0.05 |
| 11.0–11.9 | 0.44 | 0.04 | 0.05 |
| 12.0–12.9 | 0.33 | 0.06 | 0.15 |
| 13.0–13.9 | 0.20 | 0.16 | 0.26 |
| 14.0–14.9 | 0.11 | 0.19 | 0.18 |
| 15 or greater | 0.00 | 0.49 | 0.27 |

proportion of technical management and craft students at each reading grade level.

The likelihoods of a mismatch between BSPs and the student audiences was 0.14 for technical management students and 0.20 for craft students. This result suggests that technical management students were likely to have some difficulty with the writing style of about 14 percent of the BSPs in the sample, and craft students with about 20 percent. These estimates of difficulty suggest that the mismatch between students and BSPs is not great, but we do not really know how to interpret such results. For one thing, the Flesch Reading Ease Index assumes 75-percent reading comprehension. For technical documents, such as these BSPs, comprehension closer to 100 percent is probably desirable. In addition, although losses in job efficiency may result when employees have difficulty with a document, simplifying its writing style can be both costly and time-consuming. At present we know that it is useful to match documents to readers but we don't know how to calculate the benefits and costs involved in achieving this match.

## IV. DISCUSSION

The results of the present study suggest that the writing style of many Bell System documents used on the job and in training requires considerable reading skill. Yet, the reading skill levels of the majority of the employees we tested matched or exceeded the estimate of required reading skill provided by the readability analysis. Our two samples of Bell System employees appeared to have fewer people with limited reading skills than might be expected from their educational levels. This was especially so for the craft students who had an average reading grade level (level 14—college sophomore) that was two grade levels *above* their average educational level (level 12—high school graduate).

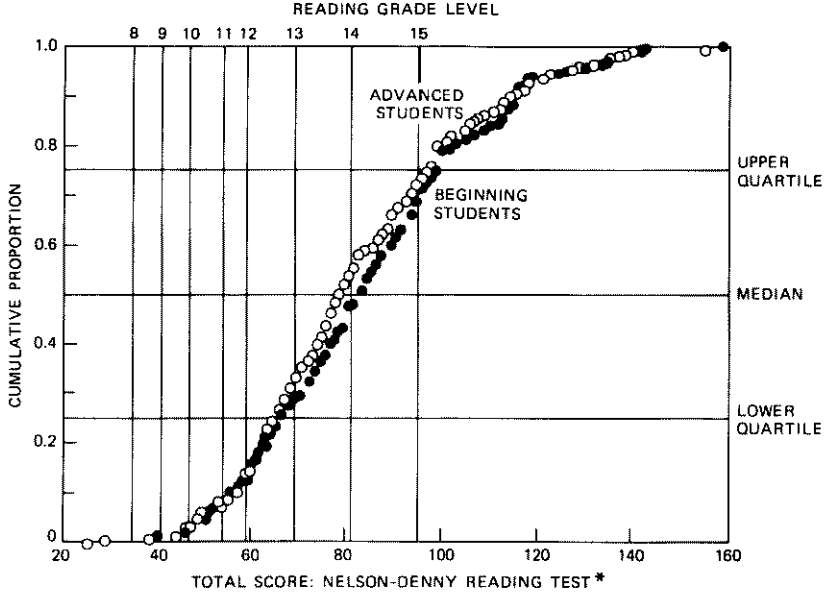
A number of selection factors may have acted to make our sample of Bell System employees such able readers. One of these factors may have been the documents that these students read during training. The craft students we tested had successfully completed a series of courses (approximately 700 hours of training) that required the use of highly technical documents, including BSPs. These technical documents may have acted as selective filters, tending to eliminate students with limited reading skills. This explanation assumes that students who have reading difficulties or who are averse to reading difficult documents will tend to leave training. If our filter explanation is correct, we would expect to find proportionately more skilled readers among students who were about to complete training than among students who were starting a training sequence. We explored this filter

explanation by comparing the reading-test performance of craft students who were just beginning an *ESS* switching equipment training sequence with students who were about to complete this sequence.

The Nelson-Denny Reading Test and a questionnaire were administered to 160 craft employees who were enrolled in introductory *ESS* switching equipment courses given at the training centers of several operating companies. Their performance was compared with that of the 210 craft students discussed earlier (Fig. 2), who were finishing their last course in the ESS training sequence.

The distributions of total scores on the reading test are shown in Fig. 3 for the beginning and advanced students. There was little difference between these two groups in their performance on the reading test. These results do not support the contention that training documents tend to filter out less able readers during *ESS* training, but rather they suggest that our sample of Bell System craft students was not biased by selective factors during *ESS* switching equipment training. Thus, their level of reading skill is likely to be representative of Bell System craft employees with similar training.

Training documents may not have worked as filters because of the procedures for selecting employees who enter *ESS* switching equip-



*MAXIMUM SCORE IS 172

Fig. 3—Cumulative distributions of reading test scores for advanced and beginning students.

ment training. These procedures, themselves, may lead to the choice of able readers. Operating companies undoubtedly choose their more able employees for *ESS* training because it is expensive and time-consuming. In addition, all those who start *ESS* training must complete a mini-course that helps to select employees who are likely to do well in *ESS* switching equipment self-instructional training. Even the perceived mental demands of operating and maintaining a complex switching system may discourage employees with limited intellectual skills. Although *ESS* trainees are not chosen explicitly for their reading skills, all the factors mentioned above could lead to the selection of competent readers as trainees.

## V. CONCLUSION

In the present study, the reading skills of the majority of employees we tested were likely to be matched to the reading demands made by the writing styles of the majority of the technical documents they read. This match resulted because so many of the employees were proficient readers and not because the documents were easy to read. In many technical areas, such as *ESS* switching equipment, readers may have more reading skill than would be expected on the basis of their education. One implication of this finding is that demographic information about education may not be sufficient to predict an audience's level of reading skill. More direct estimates of reading skill may be needed, such as the Nelson-Denny Reading Test.

Although we found a reasonable match in grade levels between documents and readers in the present study, this does not ensure that the documents are easy to read. Documents can be identified as difficult but not necessarily as easy to read, because the readability index does not include such important determinants of difficulty as organization, content, or format. For this reason, our findings should not discourage Bell System writers from writing as clearly and simply as possible. For many employees, the writing styles of technical documents may be a real barrier to success on the job. Screening devices that combine information about the readability of documents and the reading skills of their audiences, such as the likelihood of a mismatch, can help identify documents that may be too difficult for their intended readers.

## VI. ACKNOWLEDGMENTS

We are grateful to E. Z. Rothkopf for his helpful comments and suggestions and Western Electric at Winston-Salem, North Carolina, for providing us with the BSPs. We also wish to thank the management and instructors at the Bell System Center for Technical Education,

Lisle, Illinois, and the Bell System Technical Center, Dublin, Ohio, for their assistance. J. A. Leedy of Network Operations Training at AT&T and the management and instructors at the following Training Centers also lent us their assistance: Plant Training Center, Pennsylvania Bell; Birmingham Training Center, South Central Bell; Decatur Training Center, Southern Bell; Houston Training Center and St. Louis Training Center, Southwestern Bell.

# Toward Bell System Applications of Automatic Speech Recognition

By J. E. HOLMGREN*

(Manuscript received July 30, 1982)

Advances over the past few years in the field of Automatic Speech Recognition (ASR) have brought more attention to potential Bell System applications of this technology. Before reaching the point of ASR implementation, several human factors problems have to be overcome. This paper describes the central human factors issues, then summarizes the initial steps at Bell Laboratories in attempting to deal with those issues. Findings from observations of customers speaking credit card numbers to operators are described, followed by summaries of three studies investigating control of the speech of ASR system users.

## I. INTRODUCTION

The potential of Automatic Speech Recognition (ASR) in telecommunication applications has long been recognized,[1] but until recently the state of ASR technology did not warrant effort beyond the existing laboratory activity. In the past few years, ASR has emerged from the laboratory into commercial use. Several systems are now available providing speaker-dependent word recognition.[2] Such a system must be trained by each user before it can recognize that user's speech.

Permission to reproduce or republish any other portion of this paper must be obtained from the Editor.

Most of these systems require isolated speech in the sense that each vocabulary item must be spoken with a short silent interval preceding and following each word, although a few systems allowing connected speech are now available.[2] Speaker-dependent systems have been applied primarily in industrial settings that require hands-free data entry, such as inspection and quality control.

Speaker-dependent ASR systems are inappropriate for many attractive telecommunications applications. Instead, speaker-independent systems, which need no prior training by users, are required. Various network operator services, such as credit card calling and directory assistance, are examples of applications in this category. Through the use of ASR, such services could be automated and used from any telephone that has access to the existing network. A few isolated-speech, speaker-independent ASR systems are already in use in the United States and Japan. They provide service to selected groups of users in applications such as private network call-routing and banking. Laboratory work is under way to develop a connected-speech, speaker-independent ASR capability.[3]

The use of ASR in universally accessible services raises many human factors questions. This paper summarizes Bell Laboratories initial human factors work leading toward the first network applications of speaker-independent ASR. Our work began in the context of considering the use of ASR in one particular network service: credit card calling. Today, most credit card calls require giving a credit card number (CCN) to an operator. A new service known as Calling Card Service (CCS) automates the handling of credit card calls from *Touch-Tone** telephones by allowing customers to enter their CCNs on the *Touch-Tone* telephone number pad. However, calls from rotary telephones must still be handled by operators. ASR would allow automation of all credit card calls.

Our first step in investigating the credit card application was to identify the critical human factors issues that require attention. Several of these issues are common to almost all potential network applications of speaker-independent ASR. A description of the common issues provides perspective on our subsequent human factors work.

## II. THE CENTRAL HUMAN FACTORS ISSUES

Issues that surround the user-system dialog were selected as the focus of the work reported here. Although the other issues are only touched on in this paper, they are no less important to any successful network application of ASR.

### 2.1 User-system dialog

For the foreseeable future, ASR systems will be limited by several aspects of human speech, such as the vocabulary they can recognize, the maximum rate of speech they can handle, their ability to ignore extraneous words and sounds, and the accuracy of recognition per spoken vocabulary item. Thus, care must be taken in the design of any user-system dialog to overcome these limitations.

#### 2.1.1 Instructions

Appropriate instructions are needed to control the speaking rate and vocabulary that untrained speakers use when they encounter an ASR system for the first time. These instructions also must allow experienced users to proceed without unnecessary delay.

#### 2.1.2 Feedback

While current ASR systems are achieving impressive recognition accuracy for limited vocabularies, their accuracy is less than that of a human listener. Therefore, many applications, particularly those where errors are costly, require feedback to the user to ensure correct recognition by the ASR system. For many attractive telecommunications applications of ASR, user input will consist primarily of strings of digits (e.g., telephone numbers or credit card numbers). Several digit feedback provisions are possible. For instance, feedback could be given after each digit, after each group of digits, or after entry of the entire number. The optimal method depends on the nature of the application and the recognition accuracy of the ASR system.

#### 2.1.3 Error correction

Methods are needed that allow users to correct both their own speaking errors and, when feedback is given, recognition errors on the part of the ASR system. Again, several options are available and the optimal method for each application is unclear.

#### 2.1.4 Problem speakers

No matter how good an ASR system may be, there will always be some speakers whose speech cannot be reliably recognized by the system. Any service incorporating ASR will have to provide for some type of alternate treatment for such individuals; this will often mean transfer to an operator or attendant. Detection of problem speakers early in the dialog and swift alternate treatment will be necessary to ensure both service efficiency and customer satisfaction. The best way to detect these speakers has not yet been established.

### *2.2 Isolated vs. connected speech*

Connected speech is preferable to isolated speech for use as input to an ASR system. However, when speaker-independent ASR systems that accept connected speech become available for use, isolated input will still be more accurately recognized. For this reason, in any application of ASR it will be necessary to decide whether the trade-off between the greater ease of use of connected speech and the greater accuracy of isolated speech favors the former or the latter.

### *2.3 Vocabulary choice and expansion*

User and system considerations may often conflict when a vocabulary is selected for any given application of ASR. The most appropriate vocabulary for the speaker may be particularly difficult for the ASR system. For instance, while spoken, spelled input might be a natural way to specify a name to a directory assistance system, the spoken alphabet is a singularly difficult vocabulary for any ASR system to accept.[4] Words in a vocabulary such as the international word-spelling alphabet (Alpha, Bravo, Charlie, etc.) would be much more accurately recognized by machine, but much less convenient for most users. Closely related to vocabulary selection is the problem of vocabulary expansion. Careful selection of new vocabulary items is necessary because adding new words to a vocabulary may change the system's performance on the original set of words.

### *2.4 Integration of* Touch-Tone *service with ASR*

For any network service using ASR, a large percentage of the customers will be calling from *Touch-Tone* telephones. Thus, it is necessary to consider the possibility of mixed *Touch-Tone* telephone and voice input to an automated service. This raises several questions regarding integration of the two, such as whether to provide both input options at every point in a service, whether to encourage the use of one option over the other, how to make voice input compatible in some sense with *Touch-Tone* telephone input when both are available, etc.

### *2.5 Template construction*

In an ASR system templates represent the words to be recognized in a given application. Template construction is in many respects the most critical hurdle in applying speaker-independent ASR because it is largely the quality of those templates that determines the recognition accuracy of the system across the population of users.[5] Template considerations are included here because of the human factors problems involved in building the speech database needed to construct them.

### *2.6 System evaluation*

The performance of a speaker-independent ASR system in any application depends not only on the characteristics of the system but also on the vocabulary used in the application, the set of templates constructed for that vocabulary, the transmission conditions, and the characteristics of the spoken input. Therefore, evaluating the adequacy of a system in an application involves more than simply obtaining some overall measure of recognition accuracy. Information will be needed about variation in recognition accuracy across segments of the user population, across vocabularies, and across transmission conditions. Other critical aspects of performance will be system response time and the rate of false recognition for words outside the application vocabulary.

## III. TSPS OBSERVATION STUDY

To study user-system dialog issues in the application of ASR to credit card calling we gathered data from customers speaking their credit card numbers to Traffic Service Position System (TSPS) operators, who handle all nonautomated credit card traffic. Such data were needed to identify any customer behavior changes necessary to interact successfully with an ASR system.

The particular aspects of customer speaking behavior that we investigated were:

1. Customer segmenting of CCNs. Segmenting, as used here, refers to the tendency of most customers to break a CCN into spoken segments by pausing briefly after speaking a group of three or four digits. Segmenting is important because the per-item recognition accuracy of speaker-independent ASR systems that can accept connected speech is likely to be highly sensitive to the number of items in a connected sequence.
2. Customer vocabulary (e.g., "zero" versus "oh," "hundred" versus "zero zero," etc.).
3. Occurrence of words or sounds other than those used to give the CCN.
4. Frequency of customer mistakes in speaking the CCN and spontaneous correction of those mistakes.
5. Frequency of operator requests for repetition of a portion or all of the CCN. Our interest in this stems from the fact that reliable system performance is possible only when the customer corrects system-recognition errors using feedback from the ASR system; thus, it is useful to have information on the current frequency of operator-requested repetitions.
6. Speaking rates distribution for current customers.

### 3.1 Summary of results

#### 3.1.1 Number of observations

A total of 3040 credit card calls were observed at three different TSPS offices, 1157 in Milwaukee, 742 in Louisville, and 1141 in Boston. The relatively low number of observations for Louisville reflects a low overall credit card call volume during the observation period. Since the card numbers for the observed calls at each site were not recorded, the number of distinct CCNs among the 3040 calls is not known.

#### 3.1.2 Segmentation of the spoken CCN

The majority of CCNs were spoken in consecutive segments of 3, 3, 4, and 4 digits. Of all observations, 69 percent fell in this category. This is not surprising, since the format of most CCNs is NPA NXX XXXX XXXX and in the three operating companies visited the number is printed on the credit card with that segmenting.

The next most common segmentation was 3 3 4 3 1, used in 17 percent of the observations. The frequency of this segmentation probably reflects carryover from the previous 10-digit-plus-one-letter format used for CCNs up until two months before data collection. In most cases, the new 14-digit numbers were constructed from existing CCNs by adding an initial NPA and changing the terminal letter to a digit. Thus, despite the fact that the new number was printed on the credit card with the 3 3 4 4 segmentation, customers accustomed to speaking their old number with a 3 4 3 1 segmentation carried that habit over to the new number.

Only four percent of the observed numbers were spoken with the digits run together. A number was classified as run together if five or more digits were spoken without an intervening pause. This was the third most common segmentation category. The remaining 10 percent of the calls were distributed among several infrequently occurring segmentation categories.

#### 3.1.3 Variation in vocabulary

Regarding the use of "zero" or "oh" when speaking the digit zero, 29 percent of the 3040 spoken CCNs contained a spoken "zero," 51 percent contained a spoken "oh," 9 percent contained both "zero" and "oh," and 11 percent contained neither. It is interesting that customers frequently say both "zero" and "oh" while speaking a single CCN. While figures are not available on the proportion of observed CCNs that contain multiple occurrences of the digit zero, it is evident that the percentage of multiple zero calls involving the use of both "zero" and "oh" is considerably greater than nine percent.

When speaking the CCN, customers used words outside the single-

digit vocabulary in only eight percent of all calls. Almost all of these calls involved some combination of three types of multiple-digit utterances. The most common type was a two-digit combination such as "fifty-six," "eighty-eight," "thirteen," etc. The next most common type was the phrase "double zero" or "double oh" for the digit combination 00, usually when the 00 was the leading pair of a segment. The word "hundred," usually used for a terminal 00 in a segment, was the third most common type.

#### *3.1.4 Extraneous vocalizations*

There were relatively few occurrences of extraneous vocalizations from the customer. Less than two percent of all calls included such events. The most commonly used word was "dash," spoken between segments of the CCN. This occurred because some operating companies print the CCN on the credit card with dashes between segments.

#### *3.1.5 Customer correction of errors*

The customer corrected an error in the spoken CCN before any request for repetition from the operator on less than three percent of all calls. The most common error was to leave off the area code when giving the CCN. Since the requirement to give the area code had been in force for less than three months at the time these data were collected, customers were still adjusting to the new CCN format.

#### *3.1.6 Operator requests for repetition*

The operator asked the customer to repeat some or all of the CCN on less than six percent of all calls. Usually the operator requested repetition of all 14 digits. This occurred because the operator can collect any number of digits entered on the TSPS console number pad only by cancelling all entered digits and beginning again. The three most common reasons for requesting repetition were operator keying errors, the operator misunderstanding or not hearing the customer, and the customer forgetting to give the area code.

#### *3.1.7 Customer speaking rates*

Customer speaking rates are of interest only for those calls on which the CCN was entered in a manner otherwise consistent with the constraints likely to be placed on users of any connected-speech, speaker-independent ASR system. Examining these calls allows one to determine if credit card customers were speaking too quickly for ASR systems when their spoken input was acceptable in all other respects. A call was classified as acceptable if it had the following characteristics:

1. Only single-digit words were spoken.

2. No extraneous vocalizations occurred.
3. The customer did not make an error in entry.
4. The operator did not request a repetition.

An operator may request repetition of a CCN, even though the input was acceptable to an ASR system. However, to be conservative, these calls were excluded from the acceptable set, which contained 80 percent of all calls.

As a function of location, the mean speaking time for a CCN is 5.16 seconds in Milwaukee, 5.33 seconds in Louisville, and 5.09 seconds in Boston. Although the variation among these means is small, an analysis of variance shows it to be statistically significant ($F = 11.79$, $p < 0.001$). The mean speaking times for males and females are nearly identical, being 5.17 seconds and 5.19 seconds, respectively.

The performance of connected-speech, speaker-independent ASR systems is likely to fall off rapidly as the rate of speaking connected strings increases beyond about 2.5 words per second.[6] For this reason, speaking rates within connected strings of digits are of more interest than total speaking times for CCNs. To compute a speaking rate for each call, the total speaking time was corrected for the pauses occurring between segments. This correction was made by assuming that for any speaker, the duration of such pauses was roughly equal to that speaker's mean speaking time per digit. Based on the listening experience of the two data collectors, this appears to be a reasonable assumption. The appropriate estimate of speaking rate for a call is therefore given by the following expression:

$$\text{Rate} = (14 + s)/t,$$

where $s$ is the number of intersegment pauses and $t$ is the total speaking time for the CCN. The value of $s$ was based on the segmentation judgment made by each data collector on each call. Calls for which the digits were judged to be run together present problems for this rate estimate. Any call having five or more digits run together should fall in this category, so the number of intersegmental pauses is not constant within the category. For simplicity, it was assumed (based on the data collectors' observations) that the average number of pauses in a call classified as run together was one, so $s$ was set to that value.

The distribution of speaking rates is given in Fig. 1, where, for 94.2 percent of the acceptable calls, the speaking rate was greater than 2.5 digits per second.

### *3.2 Implications for customer behavior*

The above findings indicate two areas where the modal customer-speaking behavior is likely to require modification before customers

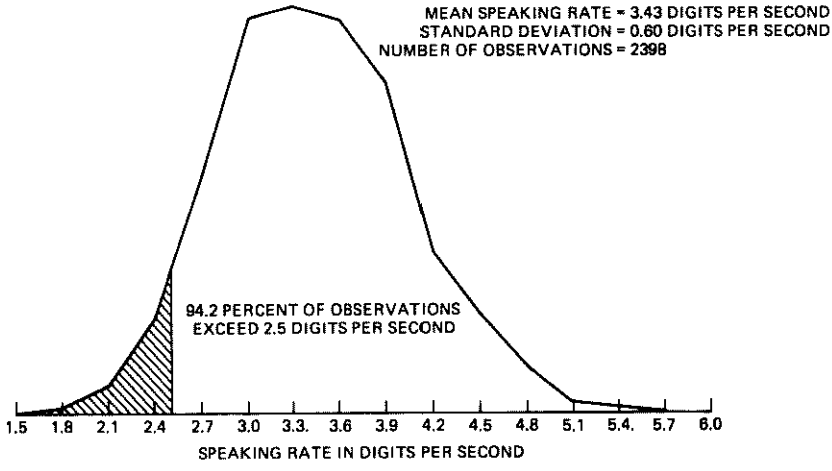

Fig. 1—Distribution of speaking rate for calls classified as acceptable.

could successfully interact with a speaker-independent, connected-speech ASR system. First, assuming that any such system will have considerably more difficulty recognizing "oh" than "zero" (due to the relatively small amount of energy in a spoken "oh" and to coarticulation effects), customers may have to learn to say "zero" in place of "oh". Second, assuming that 2.5 digits per second represent an approximate maximum acceptable speaking rate, most customers will have to lower their rates. Some means is needed of getting all customers under the critical rate without lowering the rate for many of them too much. In other words, both the mean and variance of the speaking rate distribution need to be decreased.

While these data provide some useful baseline information about spoken digit strings in a field environment, generalization of the findings to other situations must be done carefully. The CCN is a long, highly familiar number and credit card customers are experienced callers. Input characteristics may differ for shorter, less familiar digit strings or for a less experienced user population. Also, there are several important questions that could not be addressed in this study. For instance, while there were no important differences among locations on any of the variables investigated, the possibility remains that variation in speaker accent will present critical problems for any ASR system. Questions such as this cannot be answered without testing a system on actual speech samples from a field environment.

Despite its limited scope, this study was useful in guiding subsequent human factors work. The studies reported below followed directly from the questions produced by these data.

## IV. CONTROL OF USER SPEECH

Having determined the speech characteristics of customers giving numbers to operators, we conducted a series of three studies designed to investigate methods of eliciting spoken numbers from users of automated network services that would be acceptable to ASR systems. These studies are summarized below.

### *4.1 Simulation study*

The first study of the series involved a laboratory simulation of a connected-speech, speaker-independent ASR system in CCS. Each of the 30 subjects in the study was given a credit card with a 14-digit number printed with 3 3 4 4 segmentation. Subjects were then instructed to make a series of between 24 and 36 credit card calls that required voice entry of the credit card number to the simulated ASR system.

#### *4.1.1 Prompts and feedback*

After dialing a ten-digit number, most subjects heard a tone followed by a brief pause, then the following prompt:

> Please speak your credit card number in groups of four digits or less. Please wait for the numbers to be repeated back to you before speaking the next group. If the numbers are repeated incorrectly, say the word "error." Then when you hear the tone, repeat the last group of numbers spoken. Listen again for the response and then proceed with the next group of numbers. At the tone, please begin speaking your credit card number.

A similar prompt was used for another group of subjects that was not given feedback of the spoken digit groups. The instructions for this group included the phrase "say zero instead of oh." This phrase was not included when feedback was provided because we wanted to see the effect of feeding back "zero" when the subject said "oh." The subjects did not know that digit recognition was done by a human who keyed in the spoken segments of the number, triggering voice feedback of the spoken digits to those subjects selected to receive feedback.

We attempted to implicitly control speaking rate by means of the rate at which feedback was given; digits were fed back at either 2.50 or 1.25 digits per second. To investigate the effect of system recognition error rate on user input, two different digit recognition error rates of 1.8 percent and 5.4 percent were simulated. Each subject experienced at least two different combinations of feedback rate and error rate.

#### *4.1.2 Summary of results*

Subjects were initially told that once they thought they no longer needed to hear the prompt they could begin to speak after the first

tone. The typical subject would listen to the prompt on the first one or two calls, then begin to speak after the first tone on all subsequent calls. Despite the length of the prompt and the limited exposure to it, subjects had little difficulty following the instructions. All subjects in the feedback condition corrected errors smoothly and consistently. There were very few departures from the digit vocabulary (0.1 percent of all calls) and subjects nearly always used proper segmentation (99.8 percent of all calls).

While all subjects not given feedback followed the instruction to say "zero" instead of "oh," the feedback "zero" less successfully induced subjects who received feedback to say "zero". The proportion of those subjects saying "zero" on the first call was 0.3; this increased to 0.7 by the twelfth call.

The mean speaking rate across all conditions was 2.58 digits per second. While this rate is lower than the rate of 3.43 digits per second observed in the field, the speaking rate did not vary significantly as a function of either feedback (none, slow, fast) or system error rate. Subjects in the feedback conditions did lower their speaking rate slightly (by 0.2 digit per second) when correcting a system recognition error, but then returned to the higher rate on the next call. Thus, under the conditions of this study, user speaking rate was not sensitive to feedback, either in terms of feedback rate or recognition error rate. However, it should be noted that the simulated-recognition error rates in this study were independent of a subject's speaking rate. In a real ASR system, the system error rate would increase with increasing user speaking rate, possibly making users more sensitive to feedback.

### *4.2 Telephone prompt study*

The simulation study showed that some aspects of subjects' speech could be effectively controlled (at least in a laboratory setting) with simple prompting. However, the instructions in that study did not attempt to control speaking rate. Therefore, the next study concentrated on the speaking rate problem. Instead of bringing subjects into a laboratory stimulation to evaluate prompts, we chose to contact subjects by phone in their own work environments and ask for their cooperation in a very brief experiment that required them to simply say their own home phone numbers, including the area codes. Participants heard one of a set of recorded prompts and responded by speaking their numbers. All subjects were employees at Bell Laboratories in Holmdel, New Jersey. Spoken home telephone numbers provided a stronger test of our ability to control speaking rate, since a highly familiar number is likely to be spoken more rapidly than an unfamiliar one.

#### 4.2.1 Candidate prompts

Table I gives the four components from which six prompts were composed. Three of the prompts began with Component 1 in Table I; one of these was completed by adding only Component 2, while the other two were completed by adding both Component 2 and either the first or second sentence of Component 3. The remaining three prompts were the same as the above three, except that Component 1 was omitted.

This set of six prompts allowed separate evaluation of the effect on subjects of knowing that they were speaking to a machine and the effect of specific instruction on how to speak. The first sentence of Component 3 in Table I (rate instruction) was designed simply to lower the speaking rate; the second (isolation instruction) was designed to elicit isolated speech. Absence of either of those two sentences from the prompt provided a control condition. A total of 60 subjects provided data on these prompts, 10 for each of the 6 prompts.

#### 4.2.2 Summary of results

Table II gives the mean speaking rate for each prompt, corrected for intersegment pauses. A $3 \times 2$ analysis of variance showed that informing subjects that they were speaking to machines significantly lowered speaking rates ($F = 6.04$, $p < 0.03$). Also, specific instruction about how to speak significantly affected speaking rate ($F = 7.83$, $p < 0.01$). The interaction between the machine information and specific instruction conditions was not significant ($F = 0.51$).

One other instruction evaluated in an early phase of this study deserves mention. This instruction was worded as follows:

> At the tone, please speak your telephone number. Say "zero" instead of "oh." Speak at the following rate: [Recorded voice speaking, "One, two, three (pause) four, five, six"].

This instruction produced the lowest mean speaking rate (1.31 digits per second) of any prompt evaluated. Prior to playing the prompt, the experimenter told the subjects that they would speak to a machine, instead of including that information as part of the prompt.

As can be seen in Table II, even when no machine information and no specific rate instruction is given, the speaking rate is still considerably lower than that observed in the field study. As in the simulation study, this probably occurred because the subjects knew they were

Table I—Components of telephone study prompts

| |
|---|
| 1. This is a machine which recognizes human speech. |
| 2. At the tone, please speak your telephone number. Say zero instead of oh. |
| 3. Speak slowly and distinctly. |
| OR |
| Pause briefly after each digit. |

Table II—Speaking rates in the telephone prompt study (digits/s)

| | Machine Information | |
|---|---|---|
| Instruction | Absent | Present |
| Control | 2.41 | 2.04 |
| Rate | 2.18 | 1.54 |
| Isolation | 1.56 | 1.36 |

participating in an experiment and were making a special effort to speak clearly. That special effort cannot be expected in an actual service environment. Nonetheless, the results clearly show that simple instructions can considerably lower the speaking rate.

Beyond the fact that the isolation instruction lowered user speaking rates, it is of interest to know if it also succeeded in eliciting isolated speech. Although the speech given in response to the instruction sounded adequately isolated to the listener, the data were not recorded in a form that allowed a more thorough treatment of the isolation question. This question is directly addressed in the next study.

### *4.3 Speech isolation study*

Up to this point, the reported work has focused primarily on issues surrounding connected-speech recognition. For reasons related to a larger, ongoing ASR project, the focus of our human factors work now shifted to the problem of eliciting speech acceptable to an isolated speech recognition system. We wanted to see whether it was possible, through the use of prompts alone, to obtain isolated speech from subjects. While it is possible to force isolation through the use of a pacing cue or feedback after each spoken item, such techniques tend to produce slower input from the user than is required by the ASR system. Particularly in applications involving entry of long digit strings (such as credit card numbers), experienced users may find paced entry tedious. We adapted the procedure used in the previous study to the current needs. Besides attempting to develop in this study an initial prompt that would produce isolated speech, we also investigated the use of a reprompt to be used if the speech given in response to the initial prompt was not adequately isolated. Each of 90 subjects (60 Bell Laboratories employees and 30 from the surrounding community) heard one of a set of prompts over the telephone and responded with their home telephone numbers. Because of the concerns of the larger project, subjects were asked to give their numbers without the area codes.

#### *4.3.1 The initial prompt*

Based on the results of the previous study, we selected two variations

of each of two prompts for evaluation as the initial prompt. The candidates were:

1. At the tone, please say your number. Pause briefly between digits.
2. At the tone, please say your number. Pause briefly after each digit.
3. At the tone, please say your number. Pause between digits, like this. (Recorded voice speaking, "One, two, three")
4. At the tone, please say your number, as follows: (Recorded voice speaking "One, two, three")

The phrase "say zero instead of oh" was not used because reliable recognition of "oh" by an isolated speech system is not as difficult as it would be with a connected speech system, due to the absence of coarticulation effects. Also, in an attempt to keep the prompts as short as possible, we did not include a sentence telling customers that they would speak to a machine.

#### *4.3.2 The reprompt*

To evaluate the effect of a second attempt, a subject whose speaking time did not exceed 5.0 seconds on the first attempt received a second prompt, as follows:

We're sorry, would you please say your number again, but pause longer between digits.

#### *4.3.3 Evaluation of isolation*

Since the central question in this study was whether subjects were producing isolated speech, we needed a definitive test of isolation. This was provided by recording subjects' speech on analog tape and sending the tapes to the Bell Laboratories Acoustics Research Department at Murray Hill, New Jersey, where they were processed for end-point detection. Of primary interest were the number of isolated segments detected in each subject's speech. Since subjects spoke their own seven-digit home telephone numbers, seven segments should be detected on a number spoken with correctly isolated speech.

#### *4.3.4 Summary of results*

After gathering data from 40 subjects, 10 for each prompt, it was evident that Prompt 4 was unacceptable. Four of the ten subjects hearing this prompt responded with three digits or expressed confusion. Prompt 4 was therefore eliminated from further consideration. Data were then collected from an additional 30 subjects, 10 for each remaining prompt. After an initial evaluation of these data, 20 more subjects were added to better discriminate between Prompts 1 and 2.

For Prompt 1, 17 of the 30 subjects took longer than 5.0 seconds to say their telephone numbers on the first attempt and were therefore

not given the reprompt. The end-point detector found seven isolated segments in 14 of those 17 first attempts and six segments in each of the remaining two (one was missing from the tape). Of the 13 subjects given the reprompt, seven segments were detected on the first attempt for two subjects and on the second attempt for 12. The speech level was too low to segment on the second attempt of the remaining subject.

For Prompt 2, 22 of the 30 subjects were not given the reprompt. Of these, 18 achieved perfect isolation as determined by the end-point detector. Five segments were detected for two subjects, six for another, and again one subject was missing from the tape. None of the eight subjects given the reprompt spoke seven isolated segments on the first attempt. Six of the eight spoke perfectly isolated digits after the reprompt. One of the remaining two gave three segments and the other gave four.

For Prompt 3, 19 of the 20 subjects were not given the reprompt. Of these, 14 were determined to have spoken seven isolated digits. One spoke seven digits in six segments and another in five. The end-point detector found five digits in five segments for two subjects, with the speech level on the remaining two digits being too low to segment. For a third subject, there were six isolated digits, plus one with too low a level. The one subject given the reprompt spoke six segments on the first attempt and seven on the second.

The results of this study are an encouraging indication that the combination of an initial prompt with a reprompt can be effective in eliciting isolated speech. The differences in effectiveness among the initial prompts are not large, but are in favor of Prompt 3. However, since that prompt is considerably longer than either of the others, use of one of the comparable shorter prompts is preferable in any real application.

## V. CONCLUSION

The work reported above represents the initial human factors steps toward eventual use of ASR in Bell System network applications. That effort has been concentrated on those human factors questions surrounding the user-system dialog. As indicated in Section II of this paper, there are many other human factors issues that must be faced before any network application of speaker-independent ASR will be possible. However, our work on those remaining issues is beyond the scope of this paper. Also beyond the present scope are those potential telecommunications applications of both speaker-dependent and speaker-independent ASR outside the network. This broader range of applications raises several human factors questions in addition to those considered here.

## VI. ACKNOWLEDGMENTS

Several people deserve thanks for their contributions to the work summarized here. H. Holinka assisted in all of the studies. L. Chapman, a visiting student from the University of Texas at El Paso, helped plan and collect data for the laboratory simulation. T. M. Gruenenfelder was responsible for analysis of the data from that study. M. L. Viets was heavily involved in all phases of the telephone prompt and speech isolation studies. C. J. Karhan served as primary coordinator for the project of which the speech isolation study was a part. I would also like to thank L. R. Rabiner and J. G. Wilpon of the Acoustics Research Department at Bell Laboratories for evaluating the isolation of the recorded speech. Finally, special thanks are due E. A. Youngs, who initiated the human factors effort reported here and has been a constant source of ideas and encouragement.

## AUTHOR

**John E. Holmgren,** B. S. (Psychology), 1965, University of Wisconsin; Ph.D. (Mathematical Psychology), 1970, Stanford University; Bell Laboratories, 1979–1982; American Bell, 1982—. In the Human Factors Department at Bell Laboratories, Mr. Holmgren worked on potential applications of automatic speech recognition. His other major responsibility was in the area of audiographics teleconferencing. In July 1982, Mr. Holmgren transferred to American Bell, where he is a Group Supervisor in AIS Net 1000 Research and Development. Member, Psychonomic Society.

# New Functions for Technology

This section describes the *UNIX*™ Writer's Workbench software, its philosophy (L. T. Frase), the programs (N. H. Macdonald), and people's response to the programs (P. S. Gingrich). The programs do many things that an editor does when proofreading and commenting on a paper, and they have stimulated much public interest. The programs have been discussed on the *Today* show, and in articles in *Time*, *Discover*, and other magazines and newspapers. Why are the programs so interesting? Part of the answer is that they relieve us from the drudgery of proofreading. But part of the answer is also that such programs come close to helping as a human would, without the embarrassment of personal criticism.

# The *UNIX*™ Writer's Workbench Software: Philosophy

By L. T. FRASE*

(Manuscript received December 17, 1981)

Technology has dramatically increased the number and complexity of written documents. The Bell System spends over $100,000,000 annually on technical documents, with much effort devoted to review and revision. The *UNIX*™ Writer's Workbench programs assist documentation by automating copy editing and proofreading tasks. These programs deliver detailed measures and comments about text readability, punctuation, word use, abstractness, and other features. Authors use the system to evaluate draft documents, and many feel the programs improve their writing skills. The programs have been used for quality control and text research, and in writing courses. This paper discusses principles used in system development, introduces the two following papers, and suggests possible uses for automated language analysis aids.

## I. INTRODUCTION

Massive growth in the number of documents and in the sophistication needed to understand technical language has created challenges for many organizations, outside and within the Bell System. The Naval Air Systems Command, for instance, supplies technical manuals

for 135 aircraft. There are over 25,000 manuals, totaling 3,000,000 pages. In 1950, the manuals for one aircraft contained fewer than 2,000 pages; today, the manuals for one aircraft contain nearly 300,000 pages.[1] In the Bell System, there are over 100 general categories of documents. Just one of these categories, the Bell System Practices, contains 400 broad document categories, with 35,000 active titles. Current issues are routinely distributed to 45,000 locations. But number of pages is not the only concern. In some states, if documents are relevant to the physical or financial well-being of individuals, laws dictate how difficult the language of a text may be. Recent "plain language" legislation, passed by six states, allows courts to rewrite texts that are unclear.[2]

The telecommunications industry, along with others, is faced with two substantial problems: (1) how to manage a large number of documents, and (2) how to make them understandable. Review and evaluation of technical documents is costly, time-consuming, subjective, and often tedious. Mechanized aids for reviewing documents, although not relieving humans of responsibility for document quality, can simplify and speed the documentation process. Efforts elsewhere in Bell Laboratories address the problem of managing a large number of documents.[3,4] The *UNIX** Writer's Workbench software was designed to help improve quality.

Until recently, document technology has consisted of two parallel, but separate, lines of work. The first consists of experimental research on what makes text easy or difficult to understand. This work, reflected in psychological and linguistic research, includes studies of the effects of text format, wording, and graphic displays.[5] The second line of work includes more intuitive or prescriptive bases for writing and text design. This involves the expertise of text and graphics designers,[6] such as technical editors and layout specialists, as well as rhetorical traditions that specify writing standards.[7] Both knowledge bases, one derived from experimental research and the other from nonexperimental sources, provide useful guidelines for effective text design.

Unfortunately, text researchers and designers have not always worked closely together. Psychological theories of what makes a document difficult to understand often seem oversimplified to designers, and designers' intuitions and prescriptions often seem vague to researchers. Designers have been concerned with creating good documents, while researchers have been trying to understand problems of text comprehension.

The use of computers for language analysis is beginning to stimulate

---

* Trademark of Bell Laboratories.

integration of technical knowledge from research and design areas. McMahon, Cherry, and Morris,[8] for instance, have shown how language analysis, such as vocabulary analysis or assigning parts of speech to words, can be done easily and accurately by computer. Humans find those tasks difficult and tedious. Models of decision processes used by experts have been incorporated into programs that make design recommendations, such as the most suitable column width to use for a particular text.[9] Knowledge-based expert systems,[10] developed by researchers in artificial intelligence, provide additional ways of expressing, in computer-readable language, expertise derived from different disciplines. Development of the Writer's Workbench system has required, and continues to encourage, this contact between different disciplines. The programs recognize the validity of principles derived from research and the validity of principles derived from intuition and practical experience. Hence, they help bring research and application closer together.

The Writer's Workbench system provides a simple set of commands that deliver many assessments needed in documentation work. These include editorial comments on punctuation, word use, spelling, and text abstractness, along with analyses of grammatical parts of speech and calculations of overall text readability (expressed as reading grade levels). The programs combine work done by the Computing Science Research Center and the Human Performance Engineering Department of Bell Laboratories.

Using routines already developed for *UNIX* software, such as spelling and parts of speech analysis programs, developers were able to build programs that expanded and went beyond existing facilities. For portability, the wide distribution of *UNIX* operating systems in Bell Laboratories was an advantage. An early version of the programs was tried on several *UNIX* systems for four months before the first general release within Bell Laboratories. During those months, program efficiency, outputs, and options were modified in response to user feedback. Although current versions of the programs incorporate further enhancements and pruning of esoteric programs, the system architecture has remained the same.

Text to be analyzed must be stored in the computer. Some authors prefer to compose text on line; others have it entered by clerical staff. Text should contain standard formatting commands, for instance, commands that define headings and other special elements. To analyze a text, the user logs in to the system and issues a command name followed by the name of the file that contains the text. The program then executes, prints analyses, and perhaps suggests changes to improve the text. Currently, the programs are appropriate for proofreading and stylistic analyses of expository and descriptive prose, but not

for procedural documents consisting entirely of lists or abbreviated step-by-step directions.

The Writer's Workbench system is limited by the text features that the programs can recognize, and also by our understanding of the relation of text features to reading difficulty. For instance, one program recognizes when the first word in a sentence is not capitalized; it is more difficult to develop a program that can recognize when important content is missing. Currently, the programs do not use linguistic parsing algorithms; they cannot "understand" the subject and object of a sentence, for example, as humans would. Nevertheless, the richness and variety of feedback delivered by the programs are different enough from commonly encountered word and text processing systems that we find it useful to refer to these expanded capabilities as "language processing" functions. Hence, we have used this terminology here and in the following two papers, perhaps as much to remind ourselves of what remains to be done as to characterize the current programs.

## II. DESIGN PRINCIPLES

Six specific principles, reviewed below, guided Writer's Workbench program development. The principles provide a context for the detailed program descriptions in the paper that follows this.[11] To summarize, the principles assume that language analysis programs should be rational, diverse, evaluative, modifiable, specific, and informative.

### *2.1 Expert knowledge base*

The Writer's Workbench programs are *rational* in the sense that they are based on research or expert consensus that justifies the relevance of program information for text comprehension or use. Some program outputs are based on psychological research, showing, for instance, that passive sentences are more difficult to understand than active sentences.[11] Other programs are based on advice from writing and style experts.[7,12] For instance, standard punctuation usage is evaluated by some programs. Knowledge about the features of good writing is scattered among disciplines; hence, no single discipline is entirely adequate for formulating language analysis programs. Currently, we have drawn from rhetorical and psychological literature to provide text assessments that people commonly use in document evaluation. To do more, contributions from artificial intelligence and related fields are required. In addition, since not all features of document design can be clearly supported by research or expert opinion,[13] programs contain messages directing users to information sources that explain certain evaluations.

### *2.2 Program diversity*

Written communication is so complex that single measures, such as an overall index of text readability, can draw an author's attention away from other important text characteristics. Therefore, we wanted to provide *diverse* measures so users would think about a constellation of features. For instance, one program delivers over 40 measures of text characteristics, some measuring word characteristics, others measuring sentence characteristics.

We assume that authors have diverse needs, which cannot be foreseen entirely. Hence, the Writer's Workbench system contains many programs and options that can be used, or not, as an author desires. The diversity of programs works as a structured system to let users explore characteristics of words (such as syllables), sentences (such as length in words), or paragraphs (such as beginning and ending sentences).

### *2.3 Relative judgments*

A text is good or bad depending on whether it is adequate for a particular task or audience. *Evaluative* judgments about a document usually relate to some standard of excellence. The Writer's Workbench system makes such comparisons explicit. Measures from one document are compared to measures obtained from other documents. For instance, evaluative comments about the readability of a text can be based on statistics derived from training or technical memoranda judged to be of high quality. The author is warned when the text being analyzed departs significantly from the standard documents. Ability to compare documents to various standards emulates an important component of human text judgments, and it is a distinctive feature of the Writer's Workbench system.

### *2.4 User modifications*

Since it is not possible to anticipate the documentation needs of all users, programs should be *modifiable*. Three aspects of the programs can be adjusted by the user—standards, input, and output. For instance, one program calculates statistics for variables derived from texts supplied by an author. These statistics can then be used as standards to evaluate features of the author's subsequent texts, such as percentage of passive sentences. Other programs allow adding or deleting words or phrases that are detected by spelling and word usage dictionaries. In addition, input can be modified to include or exclude lists from analyses, and output format and length can be changed by appending simple descriptors to commands.

### *2.5 Text location*

For authors to review exactly where language may have gone awry in a text, *specific* text locales must be identified. For instance, printing an average measure of sentence length is less useful for an author than printing sentences that exceed a specified length. Early work on identifying troublesome text locales for a reader was done by Koether and Coke.[14] Command options in the Writer's Workbench system provide summary statistics or review sentences that violate certain standards, such as length or word use. In the latter case, line numbers show where offending text can be found. This level of specificity is necessary if programs are to speed text revision.

### *2.6 Information resources*

The Writer's Workbench system is intended to be *informative* rather than to make rigid decisions. Text statistics should be interpreted cautiously, and we suspect they will be used most effectively when an author can get advice related to those statistics. The Writer's Workbench system provides guidance, using information files, about word use, punctuation, and other features. Brief explanatory comments are also given in programs, with information about how to obtain more information.

## III. RATIONALE AND DESIGN

"*UNIX*™ Writer's Workbench Software: Rationale and Design,"[11] describes program architecture, and discusses at length the literature behind programs and their options. Current literature on writing is rich in descriptions of text patterns that characterize faulty expression,[15] and contains descriptions of actions that a writer can take to correct those faults. These patterns and actions, which are the bases for program measures and recommended revisions, are described in the first part of the next paper. Next, the individual programs and their options are described. The programs are divided into those that proofread, those that comment on style, and those that comment on organization. Finally, features that help people use the programs—human factors issues—are surveyed.

## IV. RESULTS OF A FIELD STUDY

The Writer's Workbench system has been used in Bell Laboratories for over three years; currently it runs on over 100 *UNIX* systems. Bell Laboratories users have responded favorably to the programs, and many believe the programs improve writing skills.[16]

Of course, there are many environments in which language analysis programs might be used. "*UNIX*™ Writer's Workbench Software:

Results of a Field Study,"[17] describes data collected from program trials conducted outside Bell Laboratories. The two outside locations included one human factors organization and one technical writing organization. The groups were engaged in different writing tasks and the staffs had different computer experience.

According to the field study, authors liked the detailed computer suggestions about how to revise their texts, and they were better able to detect errors with program help than without it.

## V. CONCLUSIONS

The Writer's Workbench programs do not do everything humans do when evaluating text. They cannot determine whether important content is missing, nor do they assess format features or the meaning of texts, as humans would. Nevertheless, the programs speed editing, and they help detect features that authors might otherwise miss.

Language analysis programs have many uses. Components of the Writer's Workbench system have been used for research; for instance, to derive general quantitative descriptions of text style and to relate these styles to text difficulty.[18] They have also been used, by various groups at Bell Laboratories, to help develop technical documents for new software systems and for writing technical memoranda. Programs could be used to obtain management information, for example, to monitor changes in documents across time, and to determine the match between skills of readers and the texts they must read.[19] Finally, the programs can be used for instruction to provide detailed feedback to students about the characteristics of their writing, or by an instructor to evaluate the effects of instruction on student writing.

The Writer's Workbench programs have recently been used as an adjunct to a technical writing course sponsored by the Bell Laboratories Education Center. Such programs could be especially useful to authors whose native language is other than English. Use of language analysis programs in research, development, management, and instruction will no doubt grow as these programs increase in diversity and sophistication.

## VI. ACKNOWLEDGMENTS

Programs created by L. L. Cherry contributed much to the development of the Writer's Workbench system. She also helped with program enhancements. W. Vesterman, of Rutgers University, stimulated early work on stylistic and diction programs. S. A. Keenan made important contributions to program development and documentation, as well as to Writer's Workbench system trials. J. L. Collymore, M. L. Fox, and M. F. Poller also contributed to development, and exchanges with W. F. Fox and J. J. Dever were helpful.

# The *UNIX*™ Writer's Workbench Software: Rationale And Design

By N. H. MACDONALD*

(Manuscript received December 17, 1981)

The *UNIX*™ Writer's Workbench software is a set of computer programs that help with two stages of document production: evaluation and editing. These programs analyze prose documents and suggest improvements. There are several types of programs: those that proofread, analyze style, and reformat the text in new ways, and those that provide information about the English language. This paper first describes the rhetorical and psychological writing principles that underlie the Writer's Workbench programs. It then describes the major Writer's Workbench programs and how they judge writing, based on these writing principles. Finally, it presents the human factors principles used in the design and development of the Writer's Workbench system.

## I. INTRODUCTION

The previous paper in this issue of the *Journal*[1] pointed out the growing need for automated language processing, that is, for tools to help authors write clearly and understandably. Such tools are especially important for technical writing where the content is precise and a reader's failure to understand the text can be costly.[2] This paper

describes how the *UNIX** Writer's Workbench software attempts to meet this need.

The first major section of this paper describes the principles of good writing that are incorporated into the Writer's Workbench programs. Many of these principles are supported by research showing that, indeed, different writing styles make a difference to the reader. The next section describes the major Writer's Workbench programs and relates them to the principles. The last major section describes the user considerations that guided the design of the Writer's Workbench programs.

## II. SOME PRINCIPLES OF GOOD WRITING STYLE

This section presents some principles of good writing style. Research suggests that text that violates these principles is more difficult to comprehend. These principles belong to the word, sentence, paragraph, or document level, but of course, some principles overlap categories.

### *2.1 Word level*

There are several word level principles besides the obvious ones such as using and spelling words correctly.

#### *2.1.1 Wordiness*

Style guides usually advise writers to avoid hackneyed, empty, or frequently misused phrases, such as "at this point in time" and "notwithstanding the fact that."

#### *2.1.2 Definite, specific, concrete language*

Strunk and White[3] remark that "the surest way to arouse and hold the attention of the reader is by being specific, definite, and concrete." They illustrate this principle by this pair of sentences, the first vague, the second concrete:

> A period of unfavorable weather set in.
> It rained every day for a week.

Psychological research on memory and the imageability (ability to create an image) of words suggests that texts with many abstract words will be more difficult to remember, and presumably to understand, than texts with concrete words.[4-8]

#### *2.1.3 Word frequency and length*

Coleman reported a high negative correlation between the average

* Trademark of Bell Laboratories.

frequency of content words in a passage and its difficulty to readers.[9] That is, texts made up of many infrequent words are difficult to comprehend. He also found that difficult passages contained more letters, syllables, and morphemes per word. Since frequency and length are highly correlated,[10] these two effects are possibly one effect. In keeping with these findings, Klare recommends Anglo-Saxon-based words over Latin-based words in English since the Latin form is usually longer, as in "go" versus "proceed."[11]

### *2.2 Sentence level*

There are several obvious sentence-level principles, for instance, using correct punctuation and correct grammar. Some of the less obvious or more subjective principles are described below. These are not principles of right or wrong, but rather of better or worse.

#### *2.2.1 Passive voice*

One of the biggest writing problems, particularly in scientific writing, is the overuse of the passive voice. Historically the passive voice was used to indicate the objectivity of science and the scientist. The scientist did not state, "I found that. . .," but rather, "It was found that. . . ." This usage was dogma; as Einstein said, "When a man is talking about scientific subjects, the little word 'I' should play no part in his exposition."[12]

One problem with the passive voice in scientific materials is that its use has spread from obscuring "I" and "we" to many other cases as well, e.g.,

> A variable-gain control is included in this circuit.

Scientific objectivity is still served by stating:

> This circuit includes a variable-gain control.

Perhaps because of a change in scientists' perceptions of their role,[13] or perhaps because of the difficulty of the passive style, many scientists and scientific editors[14,15] now recognize and even promote the use of the active voice, including the use of first-person pronouns.

Why should we avoid the passive voice? The rhetoric books describe it as "dron[ing] like nothing under the sun," wordy and unclear,[16] and less direct and less vigorous[3] than the active voice. It may indeed be all those things, but in addition, psychological research has shown that the active versions of a sentence are recalled better[17] and verified faster.[18] Scientific texts written in the third person passive, as "It was concluded that . . ." are remembered less well and appreciated less than the same content written in the active voice.[19]

Kirkman[20] took samples of scientific papers and rewrote the content in six different styles. He asked scientists and engineers to rate which version they found "most comfortable to read, easiest to grasp and simplest to digest." In three different surveys, he found they preferred "direct, active writing, with a minimum of specialist vocabulary, a judicious mixture of personal and impersonal constructions, short and uncomplicated sentences and liberal paragraphing."

These data do not imply that passive voice should never be used; at times it is preferable to

1. Emphasize the object of the sentence
2. Vary the rhythm of the text
3. Avoid naming an unimportant actor.

EXAMPLE: The mail was delivered.

However, the passive voice should be restricted to the useful and necessary cases, rather than used widely and indiscriminately.

#### *2.2.2 Nominalizations*

Nominalizations are nouns that have been created from verbs. They usually end in "ion," "ment," "ence," or "ance," e.g., "transformation," "establishment," and "admittance." The empirical case against using nominalizations is strong. Coleman[21] found that individual sentences without nominalizations were remembered better than their nominalized forms. A multiple-choice comprehension test on content failed to show a significant difference between the two versions. But on a memory task, subjects required significantly more exposures to memorize sentences containing two nominalizations than to memorize the same content written in active-verb form.

In a later experiment, Coleman[17] investigated ten different types of nominalizations and their active versions. He found that for those pairs of sentences in which the active version was phrased in two clauses and the nominalized version in one, the active was memorized more quickly. For example

ACTIVE: If he discusses the reason for the price-change, it will be appreciated.

NOMINALIZED: His discussion of the reason for the price-change will be appreciated.

Coleman[21] took passages from a psychology text and rewrote all the nominalizations, passive sentences, and adjectivalizations (verbs formed from adjectives) into active sentences. (Coleman[17] found no difference between adjectivalizations and their active forms.) He found

that students answered correctly 25 percent more questions from the rewritten texts than from the originals. In a similar experiment, subjects were asked to write the passages immediately after reading them. Subjects recalled the simplified passages significantly better than the originals.

#### *2.2.3 Expletives*

In grammar, the term expletive refers to a syllable, word, or phrase that adds no information. In particular "expletives" are words such as "it" or "there," which anticipate a later word or phrase. Thus, in "There are three solutions to this puzzle," "There" is an expletive anticipating "solutions."

Many times such expletives can be deleted, e.g., "This puzzle has three solutions," although sometimes they cannot, e.g., "It is raining." Although no research demonstrates that expletives make text more difficult, Brogan[22] argues that when the expletive deemphasizes the main verb inappropriately, the sentence should be changed. For instance,

> It is this necessity that adds to their complexity.

can be changed to

> This necessity adds to their complexity.

making "adds" more salient.

### *2.3 Paragraph level*

#### *2.3.1 Readability*

The readability or reading grade score for a text predicts how many years of schooling a reader would need to understand it. (Units other than years of schooling are sometimes used.) The prediction is usually based on the length of the words in the text and the length of the sentences. Different readability formulas calculate the lengths differently and weight the factors differently.

As we mentioned in the previous section, the length of a word (highly related to its frequency) predicts its difficulty. Sentence length is related to sentence type, with complicated sentences usually containing more words than simple ones. Readability formulas predict reasonably well the difficulty of the text, not because sentence length and word length cause reading difficulty, but because they are highly correlated with features such as complexity and frequency, which do.

As with any predictor, these formulas can be fooled. The Dale-Chall formula[23] takes vocabulary items into consideration, but most formulas

do not and will provide incorrect readability scores for nonsense text. All the formulas will give the same values for text with the sentences input backwards or forwards. But, in general, the formulas give a reasonable prediction of text difficulty when presented with naturally written text.

Unfortunately, research has shown[11] that the comprehensibility of the text is not necessarily improved, although the reading grade score is, by simply shortening words and sentences. The best way to improve the comprehensibility of a text is to rewrite it following the principles of good writing.

#### *2.3.2 Variation*

In writing, as in most fields of endeavor, moderation is best. The previously described principles are not absolutes; some passives and nominalizations are reasonable, and in fact, variation in sentence length, structure, and type is necessary to make writing interesting and keep the reader's attention.[13] There are other more important reasons to vary sentence type, which usually varies length as well.

Writing instructors suggest that less important ideas should be grammatically subordinated to more important ones so that the grammatical structure emphasizes the logical structure. Two simple sentences can be joined by using a "that" clause or an adverb, such as "although," to subordinate one to the other. The less important sentence should be in the subordinate clause after the "that" clause or adverb. For example, the following sentences:

1. The short, simple sentence is the most comprehensible form for an individual sentence.
2. Overusing such sentences may make a document seem disjointed.

can be combined:

> Although the short, simple sentence is the most comprehensible form for an individual sentence, overusing such sentences may make a document seem disjointed.

The combined sentence subordinates sentence (1) to sentence (2), thus emphasizing that the information in sentence (2) is more important than that in sentence (1).

### *2.4 Document level*

#### *2.4.1 Organization*

Most books on writing recommend that the first sentence of each paragraph present the topic of the paragraph or else provide a transition from the previous paragraph into a new topic.[3,13] If, for most paragraphs, the first sentence reflects the topic, then these sentences give the reader a reliable signpost to the meaning. Headings also provide signposts to topics and topic changes. A paper with good

headings and topic sentences can be skimmed easily and quickly, and even the person who reads every word will find it easier to follow.

#### *2.4.2 Audience considerations*

Style books strongly advise writers to know their audience and to write for them. This is particularly important for materials such as instruction manuals, which the reader needs to understand. Writing for the reader extends from questions of vocabulary and sentence structure to content and organization. For content and organization, Flower[24] gives particularly thorough advice.

## III. PROGRAMS

Until recently, students of writing could use only books and teachers to help them. This has slowly been changing with the advent of computer programs to do some of the work. Most programs, however, have focused solely on checking and correcting spelling.[25] Several readability indices have also been automated, but in general, wire services, magazines, newspapers, and businesses still do not analyze their text with the computer, although it is often stored and edited in a computer.

Although not yet in widespread use, several text analysis systems do exist. Besides the Writer's Workbench programs[26,27] to be described here, other systems include EPISTLE,[28] an IBM project still in the research stage; JOURNALISM,[29] a University of Michigan system that provides feedback to journalism students; and CRES,[30] a Navy system to help improve the quality of technical manuals and training materials. The EPISTLE system is a business office system that will abstract the contents of incoming letters but will also correct grammatical errors in outgoing letters. JOURNALISM provides some proofreading, but because it is programmed with specific knowledge about the articles it evaluates, it is able to comment on the organization and content as well. CRES calculates the readability score for the text, flags uncommon and misspelled words and long sentences, and suggests simple replacements for difficult words and phrases.

The rest of this section describes some of the Writer's Workbench programs, focusing on those that most strongly reflect the principles discussed in Section II.

### *3.1 Proofreading: proofr*

The most useful Writer's Workbench programs are in some ways the least interesting. Every writer can use proofreading help, since as we become more familiar with a piece of writing we become poorer at spotting errors in it.

The proofreading program, proofr, invokes five separate programs.

A three-line example of input text and its proofr output are shown in Fig. 1. Each of these five programs can be run individually, but are more conveniently run as a package. When run separately, some of the programs have capabilities not found when they are run as part of proofr. Each separate program will be discussed in turn.

### *3.1.1 Spelling: spellwwb*

The spellwwb program, a spelling checker based on the *UNIX* system spell program,[31] allows users to have a personal dictionary of words.

```
INPUT:    Our report, "The Basic Fundamentals of Organizatonal Complexity",
          is enclosed.  Please send any recomended changes at your
          earliest convenience. thanks.

PROOFR    ********** SPELLING **********
OUTPUT:   Possible spelling errors in examplefile are:

          Organizatonal                recomended

          If any of these words are spelled correctly, later type
                    spelladd word1 word2 ... wordn
          to have them added to your spelldict file.

          ********** PUNCTUATION **********

          The punctuation in examplefile is first described.

          2 double quotes and 0 single quotes
          0 apostrophes
          0 left parentheses and 0 right ones

          The program next prints any sentence that it thinks is incorrectly
          punctuated and follows it by its correction.

          line 1
          OLD: Our report, "The Basic Fundamentals of Organizatonal Complexity",
          NEW: Our report, "The Basic Fundamentals of Organizatonal Complexity,"

          PHRASE                    SUBSTITUTION

          at your earliest convenience: use "soon" for " at your earliest convenience"
          basic fundamentals: use "fundamentals" for " basic fundamentals"

          ********** SPLIT INFINITIVES **********

          For file examplefile:

          No split infinitives found
```

Fig. 1—Input to and output from proofr program.

The program searches the input text and prints all words that are not in its dictionary or the user's dictionary.

In addition, the spellwwb program can be used interactively to correct spelling errors. The spellwwb program prompts the user with each possibly misspelled word. Responding to each, the user can:

1. Find all lines on which it appears in the file
2. Invoke another program to try to determine the correct spelling
3. Tell the program how to change the spelling
4. Leave it as it is
5. Save it in a personal dictionary of correct words.

The user can also specify that certain misspellings always be changed. For instance, a poor speller might store the correction "relevant" for "relevent." Then spellwwb makes all specified corrections and updates the user's personal spelling file.

#### *3.1.2 Punctuation: punct*

The punct program searches for simple punctuation errors. It recommends changes to:

1. Move commas and periods to the left of double quotes, and move semicolons and colons to the right of double quotes
2. Capitalize the first letter of sentences
3. Balance double and single quotes and parentheses.

The program enforces straightforward rules, not ones that require judgment, such as deciding whether a comma or semicolon is the appropriate mark. When punct finds an error, it prints the original line, followed by its correction of the line.

Some of the rules punct enforces are unfamiliar to many people, such as the relative position of double quotation marks with other marks of punctuation. Nevertheless, they are accepted standards of American English. The punct program directs a user who has made punctuation errors to use the program punctrules, which provides a list of pertinent punctuation rules. The user, thus, has easy access to reference information, which can be used to decide whether the suggested changes are appropriate.

#### *3.1.3 Consecutive occurrences of the same word: double*

Using context line editors for editing text increases the chance of having the same word twice in a row. The double program locates consecutive occurrences of the same word, which can be split across two lines.

#### *3.1.4 Wordy phrasing: diction*

The diction program, described by Cherry,[32] searches a text file for phrases that writing experts have classified as wordy or frequently

misused. The latest version of its dictionary also contains some phrases that may reflect a sexual bias. The program prints sentences containing such phrases and surrounds them with stars and brackets (*[ ]*). It then recommends substitutions for these phrases. For instance, for the phrase, "bring to a conclusion," it recommends using "conclude," "end," or "finish."

Users should have the flexibility of tailoring the word list to their environment. In general, "end," "stop," or "finish" may be good choices for "terminate," but for many people writing about software, "terminate" is the appropriate word. Such a user can direct the program to stop searching for "terminate" by creating a personal dictionary. Having a private dictionary of extra terms and suppressed terms increases the usefulness of the diction program.

#### *3.1.5 Split infinitives: splitinf*

The splitinf program uses a "parts of speech" analysis program, parts,[33] to find infinitives that are split by adverbs. Such split infinitives as in "to quickly decide" are the most common type. Since users may be unfamiliar with this error, those whose papers contain split infinitives are told to use splitrules, which will print grammatical information about split infinitives.

### *3.2 Stylistic analyses*

The stylistic analysis programs provide information whose interpretation is less concrete than that given by the proofreading programs. Hence, the information is more difficult to use; following the advice faithfully can require a considerable amount of time.

#### *3.2.1 Tabular stylistic information: style*

The style program,[32] based on parts, provides 71 numbers describing the stylistic features of a text. The most important variables it reports are several readability indices (described more fully by Cherry[32]), information on the average length of the words and sentences, the distribution of sentence lengths, the grammatical types of sentences used, e.g., simple and complex, the percentage of verbs in the passive voice, the percentage of nouns that are nominalizations, and the number of sentences that begin with expletives.

The style output for this article, shown in Fig. 2, is more useful for research on the style of documents, however, than for helping inexperienced writers improve their writing style. The style table is difficult for many writers to interpret because

1. Users may not know the meaning of some terms, e.g., "expletive" and "nominalization."
2. Users frequently do not know whether the numerical values

```
readability grades:

```

Fig. 2—Style program output for this paper.

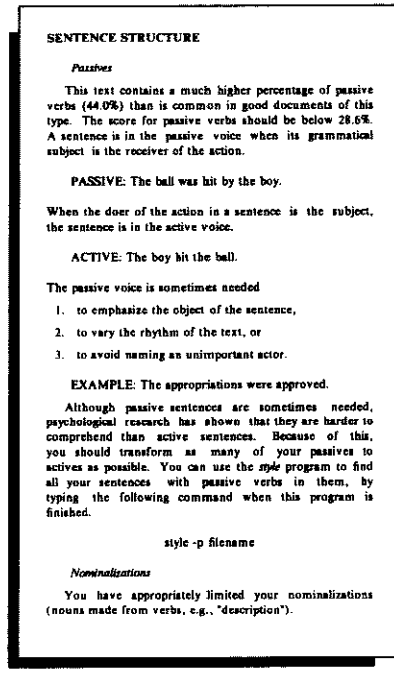
should be high or low, even for terms that are probably familiar, such as "complex sentence."

3. Users who know enough to minimize or maximize the use of some construction still do not know what numerical value is appropriate.

### *3.2.2 Interpreted stylistic analysis: prose*

The prose program goes beyond the style program by providing the style statistics and an interpretation as well. The prose program compares the style values of the user's text against a set of standards and describes the differences in a two-to-three page output written in English sentences. A section of prose output is shown in Fig. 3.

Several sets of standards for comparison are available since texts are written for different types of readers and for different purposes. Users select which set of standards should be used in the interpretation of their text. Currently there are built-in standards for technical papers and prose training materials. These standards were set as follows. Department heads in the Bell Laboratories basic research area were asked to identify the best technical writers in their departments. These people were, in turn, asked to identify their best written technical documents (content aside). This process yielded twenty-eight documents. An editor in a Bell Laboratories training department provided 34 documents that he judged to be particularly well written. The technical and training documents were then run through the style program. The means and standard deviations of each of the style



SENTENCE STRUCTURE

*Passives*

This text contains a much higher percentage of passive verbs (44.0%) than is common in good documents of this type. The score for passive verbs should be below 28.6%. A sentence is in the passive voice when its grammatical subject is the receiver of the action.

PASSIVE: The ball was hit by the boy.

When the doer of the action in a sentence is the subject, the sentence is in the active voice.

ACTIVE: The boy hit the ball.

The passive voice is sometimes needed

1. to emphasize the object of the sentence,
2. to vary the rhythm of the text, or
3. to avoid naming an unimportant actor.

EXAMPLE: The appropriations were approved.

Although passive sentences are sometimes needed, psychological research has shown that they are harder to comprehend than active sentences. Because of this, you should transform as many of your passives to actives as possible. You can use the *style* program to find all your sentences with passive verbs in them, by typing the following command when this program is finished.

style -p filename

*Nominalizations*

You have appropriately limited your nominalizations (nouns made from verbs, e.g., "description").

Fig. 3—Section of prose program output for a poor paper.

variables were computed for each document set. These means and standard deviations now make up the standard for that document type. When the value of a user's variable is more than one standard deviation from the mean of that standard, prose recommends changes. The mkstand program can be used to create additional standards from a set of documents. This flexibility allows any writing group to tailor the standards for its particular audience.

If any of the input text's values is more than one standard deviation from the selected standard, prose explains why this may make the document hard to comprehend and how to rewrite the text to remove the problem. If scores on a variable are acceptable, and the variable is an important one, prose tells the user that the text achieved an appropriate score.

### *3.2.3 Stylistic problems in context: findbe*

Although the style program can isolate individual sentences that contain passive verbs, expletives, or nominalizations, it is frequently difficult to know which sentences to change and how to change them without seeing the surrounding context. The findbe program automates part of a prescription for revision given by Lanham, who tells the

revisor to circle all forms of the verb "to be" and to try to replace them.[34,35] This advice agrees with some of the information presented earlier since "to be" occurs with passives, e.g.,

The difficulty of the passive voice *IS disregarded* by many writers.

with many nominalizations, e.g.,

Coleman's *discussion* of nominalizations *IS* comprehensive.

and with expletives, e.g.,

*There ARE* many ways to avoid expletives.

The findbe program underlines and capitalizes all forms of "to be." The text is then formatted as usual, providing the user with a paper that is easy to read, since all sentences are in context and problem areas are highlighted. This turns out to be a useful way of looking at the first draft of a paper.

#### *3.2.4 Checking text abstractness: abst*

The abst program[36] indexes the conceptual abstractness of the input text. Abstractness is defined here as the percentage of words in the text that also occur on a list of 314 words rated as abstract in psychological research.

When the percentage of abstract words is over 2.3 percent, the program suggests that concrete examples be introduced to make the document more understandable. (This cutoff was derived from the collection of good documents used to develop the prose standards.) The abstract words found in the text are saved in a file for the user to review.

### *3.3 Organization*

#### *3.3.1 Judging organization: org*

The organization of a text is important since an appropriate structure makes it more comprehensible. For a computer program to analyze the organization of a text fully, it would need to abstract the content. Without a parser for English, or some other way of interpreting the meaning of a text, our programs cannot give feedback on the quality of the content and organization.

The org program, however, was designed to give a writer a different perspective on a text as an aid in evaluating its organization. The program formats the text and preserves headings and paragraph

boundaries, but prints only the first and last sentence of each paragraph.

For writers who follow the traditional topic sentence and concluding sentence format for paragraphs, the output can be a good abstract of the paper. Even for writers with a more casual style, seeing the overall structure of a long paper can help to improve it.

## IV. USER CONSIDERATIONS

In discussing human-computer interactions, two issues should be considered: the ease of using the programs and the quality of the computer's responses.[37] This section will describe how the Writer's Workbench system attempts to optimize both aspects of the interaction.

### *4.1 User interactions*

#### *4.1.1 Program power*

Perhaps the most important organizational decision made was to design the Writer's Workbench system hierarchically. One command, wwb, runs the most commonly used programs, the proofreading program, proofr, and the English-language stylistic program, prose. The wwb program is easily remembered as the acronym for the Writer's Workbench system, and so the casual user of the system finds the system simple to access.

For the experienced user of the Writer's Workbench programs, proofr and prose can be used individually, as can the separate components of proofr, thus allowing such users all the power they need. For one program, proofr, there is an alternate spelling, proofer, because based on the pronunciation it was often misspelled this way.

Many of the programs allow users to have their own dictionaries to tailor the output. Rather than requiring the users to type the names of the dictionaries as part of the command line, these programs use a particular file if it exists. Of course, users can still override this when they choose. Furthermore, commands were created to add words to these dictionaries, rather than requiring the users to edit them and keep them in sorted order. Thus, casual users can create personal spelling dictionaries and access them automatically with just two commands.

#### *4.1.2 Documentation*

For new users, there is now a substantial amount of paper documentation that describes the programs, how to use them, and their relation to good writing. But because users frequently do not own the paper documentation or do not have it near them, there are many on-line aids as well.

As with all *UNIX* system commands there are manual pages for each Writer's Workbench program, which are helpful to experienced *UNIX* system users. For the casual user, there is an on-line introductory system, which describes the uses of each Writer's Workbench program command.

Two other commands give on-line help. The wwbinfo command provides a list of all the commands and their functions. The wwbhelp command takes a key word as an argument and lists all the programs that have anything to do with that key word. These are words such as the following: "syllable," "prose," "passive," "sentence," and "organization."

Each Writer's Workbench program can also be run with a "flags" option, which prints that program's format and options. Further, since many of the programs have default options, these options are also echoed back with the user-specified options, as described in Section 4.2.2.

Finally, the output of many of the programs suggests other programs that would be useful. These suggestions are based on the analyses of the input text, and can thus remind users of programs that are useful for that text. For instance, users with spelling errors are told how to add correctly spelled words to their personal spelling dictionary, and the prose output suggests other appropriate programs. For example, users with too many passives are told how to find all sentences with passive verbs by using the style program.

### *4.2 Computer responses*

What users have to remember and what they have to type are certainly important variables to consider when evaluating a system. But the quality of the messages the computer provides is also important.

#### *4.2.1 Output length*

The Writer's Workbench programs have attracted many new *UNIX* system users. For such users, the traditional "silence" of *UNIX* system commands is unfriendly,[38] e.g., if the spell command finds no misspelled words it simply stops, and the user receives a prompt (not a pat on the back). This silence is exactly what the regular *UNIX* system user wants, as McIlroy states, "Canned chitchat, like the plastic announcements on airplanes, may please newcomers, but it annoys old hands."[39] The obvious problem is that regular and casual users share machines, and what is right for one is frustrating for the other.

The first versions of most of the Writer's Workbench programs were verbose, irritatingly so, for experienced *UNIX* system users. We added "-s" options (for short) to most programs, which removed the

chitchat and most of the "pats on the back." Recently, we changed all the programs so that users can specify once what length of output they want in the future. Since expert users are best able to change this default, users who do not specify any length receive the long version.

#### *4.2.2 Feedback*

The Writer's Workbench programs inform the user when the program has started. Even experienced users may want reassurance that everything is proceeding on a heavily loaded system. Most commands echo the command line and include any options that were not chosen by the user but came about through default. This gives users a record of the exact command run; it may also remind them that they do not want a particular default, and it may alert them to options they did not know existed.

The Writer's Workbench programs cannot correct incorrect entries, but they try to provide complete, informative, and accurate error messages.

### *4.3 Needed improvements*

To date, proofr is a major proofreading package, geared toward users who print the output on paper and make any recommended changes themselves. Since the output refers to a text problem by labeling it with the line number in the unformatted file, a user who has someone else type the text and only has the formatted output does not find these line numbers useful. For users with CRT display terminals, the output can be too lengthy to fit in the terminal's memory so that by the end of the program the first part of the output has disappeared. This makes it difficult to notice all the problems and change them.

We are currently designing two new versions of the proofr program. A version for word processing center customers will provide all the proofreading comments superimposed on the formatted output. For CRT users, we plan a completely interactive version, which will move linearly through the file and display possible corrections for the user to accept or ignore.

## V. SUMMARY

This paper described some principles of good writing and some experimental results that show that readers prefer writing that embodies these principles and find it easier to understand. The paper then described a set of computer programs called the *UNIX* Writer's Workbench software. These programs help a writer isolate problems with general style as well as with individual sentences, phrases, and words. The final section of the paper described some of the human

factors principles that guided the design of the programs. The following paper in this journal[40] will describe the reception of the Writer's Workbench programs at Bell Laboratories and at two trial locations.

# The *UNIX*™ Writer's Workbench Software: Results of a Field Study

By P. S. GINGRICH*

(Manuscript received December 17, 1981)

This paper describes a study in which the *UNIX*™ Writer's Workbench software was used by writers to analyze and revise the texts they wrote. For ten weeks, two groups of writers were observed: those for whom writing was their principal activity, and others for whom writing was only one of their responsibilities. These participants used the Writer's Workbench programs to produce documents related to their jobs. The results indicate that both types of writers can use the programs without changing their accustomed modes of operating. Writers found the programs helpful; they liked the immediate feedback the programs provided and the detailed suggestions on how to revise their texts. In addition, when editing prepared texts, writers found more errors using Writer's Workbench output than when they had no output available. Finally, participants thought they spent less time editing their documents when they used the Writer's Workbench programs, although total time spent on writing and editing did not change.

## I. INTRODUCTION

The *UNIX*† Writer's Workbench software was developed in two major stages. The first version of the system contained 23 programs

ranging from those that searched for proofreading errors to those that summarized stylistic features. These programs were used within Bell Laboratories for nearly a year, during which time data were collected on patterns of program use. A second, expanded version was then developed to reflect the experience gained from the first version.

To date, there is little formal evidence about user interaction with Writer's Workbench programs. We monitored the program on eight *UNIX* systems and observed that the programs were used most when they first became available, and then later they were used on a constant, but less frequent basis, amounting to an average of six to seven program runs per week per user. Informal discussions with users indicated that the peaks in use were due to users experimenting with a variety of input texts, good and poor, to evaluate the potential of the programs. Once they understood the potential, use dropped to a more normal level.

The present study examined the way experienced writers at two Bell System locations used the Writer's Workbench programs as a tool in performing their jobs. We were interested in examining how using the programs affected people's attitudes toward the system, the documents they write, and their modes of writing.

The Writer's Workbench programs provide feedback about many characteristics of writing. But do writers want the feedback? Which programs are used most often? Does using the programs make a difference in the way people write or in their attitudes about what constitutes good writing? How might the programs be modified to make them more useful to writers? This study was the first attempt to address these issues systematically.

## II. FIELD STUDY

### *2.1 Background of the participants*

Fourteen participants from each of two Bell System locations took part in the study. The 14 participants in Group 1 were course developers and instructors with a mean of 10.5 years service in the Bell System, and most had been in their current jobs between one and three years. Forty-three percent of the Group 1 participants had completed four years of college. Before the study began, these participants said they spent about 75 percent of their time writing and editing documents.

Of the 14 participants in Group 2, 11 were technical staff and 3 were clerks. For the technical participants, writing documents was only one of many job responsibilities; prior to the study, they reported spending about one-third of their time writing and editing documents. They also helped to design, develop, and assess systems. The three clerks were included because they processed documents for three managers

from whom we collected data. The technical participants had a mean of 13.6 years service in the Bell System, and most had been in their current jobs between one and three years. Sixty percent of these participants had completed four years of college, and half of those had master's degrees. All three managers had completed four years of college; none of the clerks had.

The two groups of writers differed in their approaches to writing documents and their knowledge of the *UNIX* operating system. Group 1 participants were more knowledgeable about the *UNIX* system and more inclined to compose, edit, and complete drafts on the terminal without the services of clerks. Such differences between groups could lead to different patterns of using the Writer's Workbench system.

### *2.2 Design of the study*

#### *2.2.1 Trial procedures*

The study included two days of training, a one-week period for practice using the Writer's Workbench programs, and 10 weeks of using the programs in normal work activities.

During the two-day training sessions, participants completed questionnaires, learned about the Writer's Workbench system, and then used the programs. After we trained the participants, we tested them for mastery of 11 important concepts of the Writer's Workbench system, including characteristics of a document's style, specific program functions, and program options. Our training successfully conveyed the hierarchical arrangement of the major Workbench commands and the most frequently used options. Participants did have difficulty, however, in naming specific commands for given functions, perhaps because they had not yet used all the commands. All the commands, however, were explained during training.

After the training was completed, participants were encouraged to explore the Writer's Workbench programs during one week of warm-up before the official on-line record keeping began. We provided structured exercises that participants could use to run each program, as well as a handbook that contained a tutorial introduction to the Writer's Workbench programs, and documentation describing each program.

For the next 10 weeks participants used the Writer's Workbench programs. We gave them guidelines, which suggested primary programs to run on each document they wrote, and we encouraged them to use additional programs as well.

#### *2.2.2 Data collection instruments*

*2.2.2.1 Questionnaires.* Participants completed questionnaires before the study began, at the midpoint, and after the study ended.

These questionnaires gathered demographic information about the participants, assessed their attitudes toward computers, and determined characteristics of their type of work and mode of writing. Some questions recurred on two or three of the questionnaires to measure changes in attitudes and modes of operating.

*2.2.2.2 On-line data collection.* Every time a Writer's Workbench program was run, the program automatically recorded its name, the date and time, who ran it, and the name of the text file it analyzed. Some programs, such as the prose analysis programs,[1,2] also saved data about the text characteristics. We used this information to describe program use across time and also to note changes in text files.

In addition, an interactive program prompted users to rate the helpfulness of each program's output on a five-point scale. These data were collected to determine users' opinions of how well the programs analyzed each text file.

*2.2.2.3 Revision tasks.* During the study, participants completed four document revision tasks, which involved editing in ten minutes a 300-word passage containing planted errors. Each participant edited the four different passages once. Each passage appeared equally often in the following sessions:

Session 1. Edit one passage before training begins (no Writer's Workbench program output).

Session 2. Edit one passage immediately after training (no Writer's Workbench program output).

Session 3. Edit one passage at the end of the study. (Appropriate Writer's Workbench program output was attached to each passage.)

Session 4. Edit one passage three weeks after the end of the study (no Writer's Workbench program output).

These revision tasks provided a controlled environment in which to compare the participants' ability to improve a text at various stages of the study.

*2.2.2.4 Interviews with participants.* Each participant was interviewed for 25 minutes at the end of the study. We asked 11 general questions to elicit the participants' comments on how they used the Writer's Workbench programs and what they liked most and least about the system.

### *2.3 Results*

#### *2.3.1 User acceptance of the programs*

We examined user acceptance of the Writer's Workbench programs in several ways. Program use was recorded automatically, and following each use, participants rated the helpfulness of the output. In interviews, participants also reported what they liked least and best

about the system. We found no significant difference in the way the two groups of participants used the programs or their acceptance of them. Consequently, their data were combined in most of the following sections.

*2.3.1.1 Program use.* Although the way participants used the programs varied greatly, on the average they ran about six programs a week.

Table I shows the number of times each program was run during each week of the study. The wwb program, along with its two components proofr and prose, and the spellwwb program were run most often. Use of the programs diminished over the course of the study, but use of the informational "help" programs, such as punctrules and wwbinfo, dropped to zero some weeks before the end of the study. It seems that participants used the "help" programs only as they learned about the Writer's Workbench programs.

*2.3.1.2 Helpfulness ratings.* Participants rated the helpfulness of the output each time they ran a Writer's Workbench program and generally found the programs helpful. The average rating was 3.8 on a scale of 1 (not helpful) to 5 (very helpful). The wwb and prose programs, those most frequently used by Group 1 and Group 2, respectively, had average ratings of 4.0 and 3.7 on the helpfulness scale. Table II shows the mean rating for each program by group.

*2.3.1.3 What participants liked best.* During the final interviews and on questionnaires, many participants said that the Writer's Workbench programs were most valuable because they gave immediate, objective criticisms on concrete problems in their text. They liked the advice from the proofr component because they found it accurate and complete.

For the prose component, participants reported that they felt the advice was objective and specific, but they often were not sure of how to make the changes it suggested. Nevertheless, many participants reported that the stylistic information from prose was an improvement over the often vague advice and subjective opinions of human reviewers.

Participants commented on three other general aspects of the Writer's Workbench system. First, it saved time (both by the speed with which it reviewed text and by eliminating delays caused by looking for a colleague to review the document). Second, it was completely private, giving the writer a chance to improve the document before anyone else saw it. Third, participants reported they were more aware of principles of good writing and of how to change their style to suit the purpose and audience of a particular document.

*2.3.1.4 What participants liked least.* Two criticisms of the programs surfaced during final interviews and from questionnaire responses.

| Average (Total) | 3.6 | 559 | 4.0 | 578 |

* NR means no rating.
NOTE: The number of ratings does not agree with the number of programs run shown in Table V because participants did not begin rating program output until after the warm-up week. Also, some end data was not incorporated from the last week.

First, some participants reported that they found it difficult to apply the advice they received from the prose and diction programs. They either were unfamiliar with the principle the program checked or were unsure of how the principle was being evaluated.

Participants also criticized the length of some program outputs. For example, some said that for the wwb command, the default output was too long and wwb − s output was too short. An output of intermediate length was suggested.

### *2.3.2 Effects on documents*

What effects does using the Writer's Workbench programs have on the documents produced? Do writers locate more errors using Writer's Workbench output to edit a document? Does using the programs for

a period of time later enable writers to edit more effectively on their own?

***2.3.2.1 Revision tasks.*** Results from the revision tasks show how the participants' ability to improve a document differed at various stages of the study. The revision tasks were completed: (1) before the study, (2) after training, (3) after 10 weeks of using the Writer's Workbench programs, and (4) three weeks after the study ended. Output from the Writer's Workbench programs was available only in the third session.

Passages used in the revision tasks were adapted from stories in the *Bell Laboratories Record* and traced the development of new Bell System operations. The average length of the passages was 300 words. Table III describes the twenty errors planted in each of the four passages.

Of the nine categories of inserted errors shown in Table III, the Writer's Workbench programs cannot provide feedback on using a word that looks like the correct word (category g), mistyping one word that produces another (category h), and making a mistake in the agreement of subject and verb (category i).

Table IV shows the results of the revision tasks. More errors were detected in Session 3 than in any other session. Having the Workbench output available improved performance compared both with where the user had no experience with it (Sessions 1 and 2) and where the user

Table III—Type and number of errors in each revision passage

| Type | Number of Error(s) | Item |
|---|---|---|
| a | 4 | Spelling errors, which were not legitimate words and would be found by the spell program |
| b | 2 | Punctuation errors that the punct program could identify |
| c | 6 | Wordy phrases included in the diction phrase dictionary |
| d | 1 | Immediate repetition of a word |
| e | 1 | Split infinitive |
| f | 3 | Instances of sexist language |
| g | 1 | Case of a word substituted for another that looked similar |
| h | 1 | Misspelled word that was a proper English word and would not be found by the spell program |
| i | 1 | Case of subject verb disagreement |

Table IV—Proportion of errors detected for each session*

| | Session 1 | Session 2 | Session 3 | Session 4 |
|---|---|---|---|---|
| Mean | 0.271 | 0.275 | 0.408 | 0.309 |
| Standard error | 0.006 | 0.007 | 0.007 | 0.007 |
| Number | 21 | 21 | 21 | 21 |

Session 3 vs Session 1—$t_{(20)} = 3.35, p < 0.005$
Session 3 vs Session 2—$t_{(20)} = 3.41, p < 0.005$
Session 3 vs Session 4—$t_{(20)} = 2.49, p < 0.05$

* Data are reported for those 21 participants who completed all four sessions.

had employed the Writer's Workbench system in the past but did not have its output available while proofreading (Session 4).

The data are broken down by category in Fig. 1. We see from this figure, which shows the percentage of detected errors for each session (bars 1 to 4) for each category, that Session 3 is clearly distinct from the others.

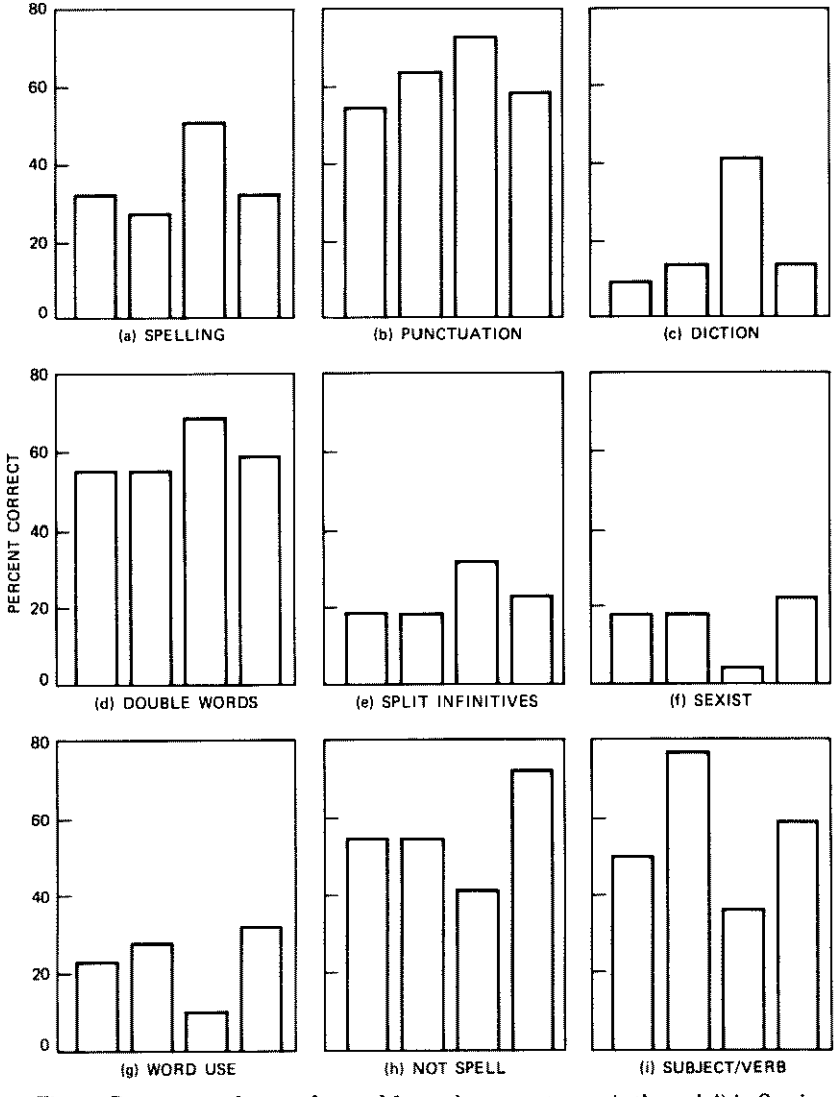

Fig. 1—Percentage of errors detected for each error category (a through i) in Sessions 1 through 4: (a) spelling errors; (b) punctuation errors; (c) wordy diction; (d) double words; (e) split infinitives; (f) sexist language; (g) incorrect word use; (h) spelling errors not found by spell program; and (i) subject/verb disagreement.

We included the errors in categories g, h, and i because we wanted to determine whether the participants had become so dependent on the Writer's Workbench analysis that they would fail in Session 3 to notice the errors that it does not find. The results of Session 3 support this supposition; participants found many of the Writer's Workbench errors and overlooked others.

It appears that participants used the time in Session 3 to find and mark the errors given by the Writer's Workbench programs, but did not have a chance to proofread the paper for other errors. Indeed, several participants remarked that they spent their time reviewing the output and locating the corresponding error in the passage, rather than proofreading the passage as a whole. As a result they may have run out of time. This seems likely in view of the low rate of marking sexist usage, the output for which came last in the collection of Writer's Workbench program outputs given to participants. As Fig. 1f shows, participants marked far fewer sexist usages in Session 3 than in any other session. Even so, overall performance was best in Session 3.

#### *2.3.3 Effects on writers' activities*

The writers completed questionnaires on how the Writer's Workbench programs influenced the way they prepared documents and assessed their stylistic features.

***2.3.3.1 Mode of writing.*** The questionnaires asked participants how they write: Do they write on-line or on paper? Do they make their changes on-line or on paper? As we described above, before the study began participants in Groups 1 and 2 differed in their methods of writing and editing. To test whether their methods changed during the study, we performed a 2 × 3 (group × time) analysis of variance on each of these two items. (The range of responses to both questions represented the degree of involvement with a terminal during the task of either writing or editing. A value of 1 represented the most direct involvement with the terminal and a value of 4 represented the least.) Again, time (pre-, mid-, and post-study) was the within-subject repeated measure; and group (Group 1 or Group 2) was the grouping factor. The results show only a significant group effect for the writing method [$F(1,15) = 7.32$, $p < 0.05$], as well as for the editing method [$F(1,15) = 21.0$, $p < 0.001$]. Participants in Group 1 were less likely to have a clerk do the terminal work for them ($M = 1.43$ for writing and $M = 1.19$ for editing) than were participants in Group 2 ($M = 2.47$ for writing and $M = 2.37$ for editing). There were no significant time effects or time × group interactions.

***2.3.3.2 Estimates of stylistic features.*** We wanted to know whether using the Writer's Workbench programs would affect the way participants evaluated the stylistic errors in their documents. The pre-,

mid-, and post-questionnaires included questions about nine features of writing style that are measured by the Writer's Workbench programs. Participants estimated whether their draft documents typically had

—too few
—the right amount
—too many instances

of each feature, or they indicated that they could not evaluate the amount by saying either

—there was no right or wrong answer, or
—they could not answer the question.

The most marked difference was in how participants evaluated their proportion of passive sentences before and after the study. Before the study, about 85 percent of the Group 1 participants said there was no right or wrong number of passives sentences, or said they could not answer. After the study, no one answered in either of those categories; half thought they had too many passive sentences in their drafts, and half thought they had the right number. Before the study, more than 50 percent of Group 2 said they either had the right number of passive sentences, or they could not answer. By the end of the study, 60 percent of Group 2 thought they either had too many, or too few, passive sentences.

### *2.4 Discussion*

Participants were able to use the programs frequently, liked them, and found the output helpful. By reviewing the results of the different measures together, we come to a clearer understanding of what effects the Writer's Workbench programs have on writers.

First, the data on program use reveal that, on the average, participants ran six Writer's Workbench programs per week. (This figure is comparable to data collected from Bell Laboratories *UNIX* systems we have monitored in the past.) Over time, there was a reduction in the total number of programs run, possibly because the novelty of using the programs wore off, or because of the cyclical nature of the documentation process. Writing a document generally entails collecting information, organizing it, and then writing, editing, and revising. Participants may have confined their use of the Writer's Workbench programs to the first stage of the editing process and to the final version. In addition, documentation efforts vary with the phases of product development; thus, the activities that the Writer's Workbench programs can support are cyclical. Observing program use over a much longer time period, perhaps a year, would give a clearer understanding of the long-term frequency of use, one less subject to seasonal cycles of writing demands.

Even when program use declined over time, the programs were still rated as helpful. The average helpfulness rating was 3.8 on a scale from 1 (not helpful) to 5 (very helpful). The use of programs was more strongly determined by individual needs than by our recommendations. For example, use of the acro program, which locates and prints all acronyms in a document, was highly recommended in the study guidelines. Yet, users in Group 1 did not find this program helpful (2.7 helpfulness rating) because it gave them too much output. Hence, no one used it after the third week of the study. The participants did, however, continue to use the programs that took the tedium out of editing, such as the proofreading programs. That the participants continued to use many of the programs indicates that they found these programs helpful.

The results of the revision tasks clearly show that the programs are helpful in locating errors when the person is under pressures of time. Using the Writer's Workbench system in Session 3, participants found significantly more errors in the same amount of time than in the other sessions. To produce their typical error-free final products, participants would need to spend far more editing time without Writer's Workbench system than with it. The results of the Session 4 revision tasks also show that one must use Writer's Workbench programs continually to get this benefit; it is not enough to have used them in the past. The computer is just much better at finding certain errors than our participants were. However, we do not know whether error types not located by the programs would tend to be missed by the human proofreader more or less often as a result.

When we look at how using Writer's Workbench programs affects a writer's mode of writing, we see few changes. Those who used clerks to type their texts before the study continued to do so during the study. Those who typed their texts themselves continued to do so. Participants did not need to change how they wrote to use the Writer's Workbench programs effectively, nor did it increase or decrease the personal contact individuals had with terminals.

In the current study, we were limited in the degree of control we could impose on the participants. There were no rewards for using the Writer's Workbench programs and incorporating the suggestions into later drafts, nor were there any punishments for not using them. We could not control how much or how little participants wrote during the 10-week trial. We had no independent judges to evaluate the quality of the documents produced with the aid of the Writer's Workbench programs, nor did we have comparable people writing comparable texts without the aid of the programs so we could compare our participants' texts. Thus, we were limited in the issues we could address.

Currently, studies with university English composition students are addressing some of the unanswered questions. In composition classes, students are using the Writer's Workbench program output to edit and revise their essays. Instructors and independent judges will evaluate the essays and compare the quality of these essays to those of control students not using the Writer's Workbench programs. In addition, these new studies include unskilled writers rather than experienced adult writers, which will allow us to determine whether using the system helps students learn how to write better. These findings will enable us to evaluate more fully the effectiveness of the Writer's Workbench programs.

## III. ACKNOWLEDGMENTS

I want to thank the people who contributed to the work of the study reported here. Nina Macdonald conducted the activities for participants in Group 1. Once the study began, Stacey Keenan monitored both sites and analyzed much of the data. Mary Fox summarized responses from hours of taped interviews. Merle Poller assisted in developing the questionnaires. I also want to thank those who participated in the Writer's Workbench system study.

# Stabilized Biasing of Semiconductor Lasers

By R. G. SWARTZ* and B. A. WOOLEY*

(Manuscript received December 10, 1982)

In this paper we analyze the design of biasing and control circuits for semiconductor lasers in a generalized context based on an idealized laser characteristic. In particular, we address three major design considerations: whether to bias the laser above or below threshold, how to stabilize the optical output levels independent of variation in the average output power, and to what degree the output levels can be stabilized relative to various circuit and device parameters. Results of our study indicate that to eliminate from the optical output any dependence on either variation in laser device characteristics or the dc average of the input signal, feedback control of both the prebias and modulation current is necessary.

## I. INTRODUCTION

Within the past few years digital lightwave communication systems have become a practical reality. Several systems have been demonstrated for both interoffice trunk transmission and the subscriber plant.[1-4] In these applications optical fiber systems have the advantages of inherently large bandwidths and electrical isolation.

High-bit-rate lightwave systems commonly use semiconductor laser diodes as the optical sources. The diodes are threshold devices whose characteristics depend on both age and operating temperature. As a consequence, large variations in the light output of the lasers will occur unless special measures are taken to properly bias and modulate these devices.

Several circuits for biasing and digitally modulating injection lasers have been reported. To ensure modulation of the laser output at the highest possible rates, these circuits typically dc bias the laser near its threshold. A modulation current is then superimposed on this bias to switch between the high and low light outputs. The circuits described to date commonly used negative feedback control of the bias current to stabilize the laser light output. In some early circuits the feedback stabilizes the average optical output of the laser. For this method to be successful, the digital input codes must exhibit a fixed on-off ratio (constant average value). More recent laser driver circuits employ balancing compensation of the modulation signal and purport to allow arbitrary on-off ratio digital codes.[5-8]

In this paper we consider the design of laser biasing and control circuits in a generalized context. Within this context we address three major design considerations: the choice of biasing the laser above or below threshold, how to stabilize the output independently of the nature of the laser modulation, and to what degree the laser output levels can be readily stabilized relative to various circuit and device parameters. Initially, we consider the stabilization obtainable by means of the approach adopted in a recently described monolithic laser driver, wherein feedback stabilization of the laser bias current is augmented by a simple balancing compensation of the modulation signal.[7] Following this analysis, we examine the benefits of using modulation current compensation.

## II. FEEDBACK BIAS STABILIZATION

Figure 1 shows the luminosity versus current characteristic assumed for heterojunction lasers in this analysis. This relation can be characterized by three parameters: the threshold current, $I_T$, the subthreshold differential slope efficiency, $\eta_1$, and the above-threshold slope efficiency, $\eta_2$. (The variables used are defined at the back of this paper.) These parameters analytically approximate the characteristic of Fig. 1 by the piecewise linear relationships

$$L = \eta_1 I_L, \qquad I_L \leqslant I_T \tag{1}$$

and

$$L = \eta_1 I_T + \eta_2 (I_L - I_T), \qquad I_L \geqslant I_T, \tag{2}$$

where $L$ is the luminosity (or light output intensity) of the laser.

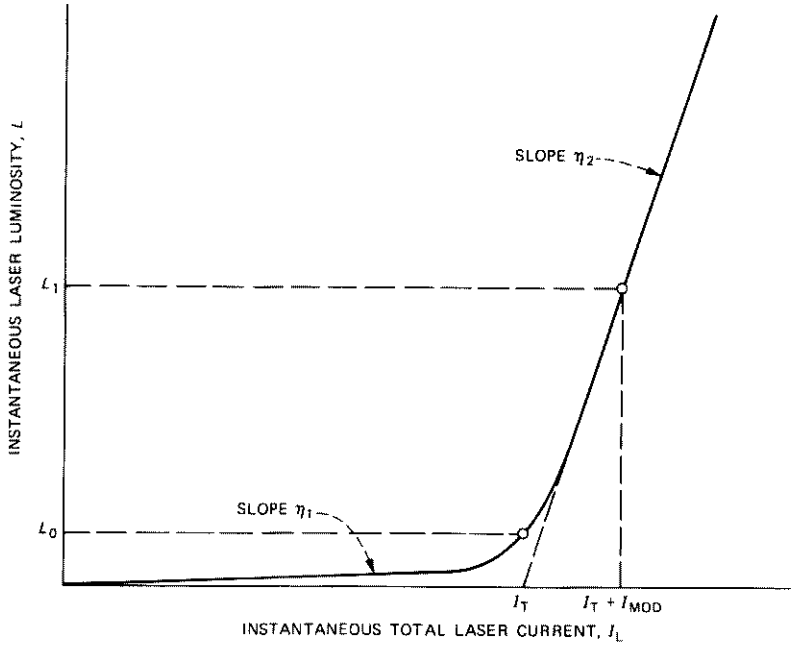

Fig. 1—The luminosity versus current relationship for an injection laser.

Figure 2 is a generalized circuit diagram for a recently reported integrated laser driver employing feedback stabilization.[7] In this circuit the laser is biased near its threshold by a prebias current $I_A$. Added to this bias is a modulation current, $I_M$, which switches the laser between its ZERO and ONE light output levels ($L_0$ and $L_1$). The prebias current is stabilized by a negative feedback loop comprising the laser, a photodetector, a reference current ($I_B$), a low-pass filter ($C_A$), and a current amplifier ($A$). The photodetector generates a current proportional to the optical output of the laser, typically by monitoring the light emitted from its rear face. The photodetector current ($I_D$) is compared to the reference current at the summing node, $S$, and the resulting current difference is then low-pass filtered and amplified to generate the prebias current. Because the modulation current, $I_M$, will alter the dc component of the laser output, the current $I_X$ is added to node $S$ to cancel this influence, as described below.

It is assumed throughout the analysis that:

1. The differential slope efficiency of the laser is much greater above threshold than below, i.e., $\eta_2 \gg \eta_1$.

2. As a consequence of the filtering provided by $C_A$, the response time of the feedback loop is long in comparison with the time constants of modulation-related parameters. It is also required, however, that the feedback loop response time be much shorter than the time

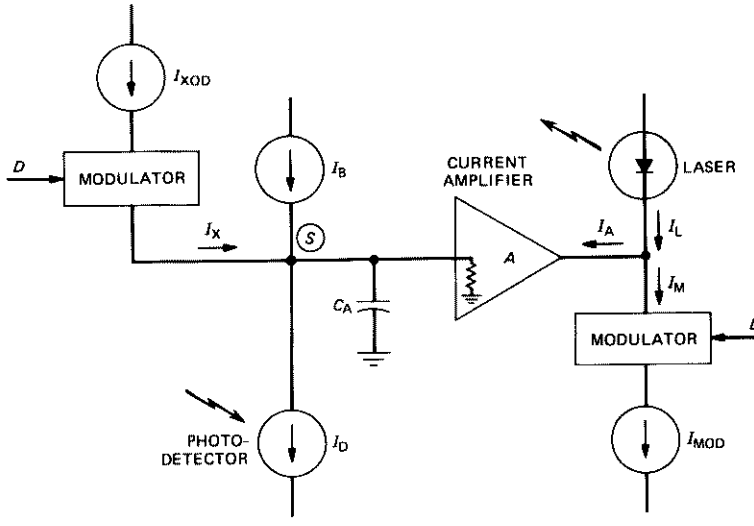

Fig. 2—A laser driver employing feedback stabilization of bias current.

constants of the laser parameter drift that occurs as a consequence of aging or changes in environment.

In the circuit of Fig. 2, the instantaneous laser current, $I_L$, is given by the sum of the prebias current and the instantaneous modulation current

$$I_L = I_A + I_M, \tag{3}$$

where

$$I_M = DI_{MOD} \tag{4}$$

and $D$ is the binary data signal driving the modulator ($D = 0$ or 1). In Fig. 2, the capacitor, $C_A$, serves to average the summation of currents feeding the input to amplifier $A$. Thus,

$$I_A = A_I(I_B + \bar{I}_X - \bar{I}_D) \tag{5}$$

where $A_I$ is the amplifier current gain, and $\bar{I}_X$ and $\bar{I}_D$ are the dc components (averages) of the balance and detector currents, respectively.

The output of the photodetector in Fig. 2 is assumed to be related to the laser light output by a proportionality factor, $f$. Thus, the average detector output current is given in terms of the average laser luminosity by

$$\bar{I}_D = f\bar{L}. \tag{6}$$

The laser light levels $L_0$ and $L_1$ are defined such that $L_0 \triangleq L$ when $D = 0$ and $L_1 \triangleq L$ when $D = 1$. It therefore follows that

$$\bar{L} = \bar{D}(L_1 - L_0) + L_0 \tag{7}$$

and then from (6) and (7) that

$$\bar{I}_D = f[\bar{D}(L_1 - L_0) + L_0]\,. \tag{8}$$

Implicit in this equation is the assumption that time delays in the responses of the laser and photodetector are negligible.

Inserting (8) into (5) and observing that $\bar{I}_X = \bar{D}I_{XOD}$ leads to the relationship

$$I_A = A_I\{I_B + \bar{D}I_{XOD} - f[\bar{D}(L_1 - L_0) + L_0]\}\,. \tag{9}$$

This result, together with the relationship between the laser luminosity ($L$) and current ($I_L$), as represented by (1) and (2), will next be used to determine the laser light output levels, $L_0$ and $L_1$. However, to proceed with this analysis we must first determine whether the laser is prebiased above threshold or below. This distinction, which seems minor at first glance, has important implications for the ultimate stability of the optical output. We first consider the above-threshold case.

### *2.1 Above-threshold prebiasing ($I_{L0} \geq I_T$)*

From eq. (3) and the definition of $L_0$ and $L_1$ it follows that

$$I_{L0} = I_A \tag{10a}$$

and

$$I_{L1} = I_A + I_{MOD}. \tag{10b}$$

For the case where the laser is biased above threshold ($I_{L0} \geq I_T$), it thus follows from (2) that

$$L_0 = \eta_2(I_A - I_T) + \eta_1 I_T \tag{11a}$$

and

$$L_1 = \eta_2(I_A + I_{MOD} - I_T) + \eta_1 I_T\,. \tag{11b}$$

Substitution of (11) into (9) leads to the result

$$I_A = A_I\{I_B + \bar{D}I_{XOD} - f[\eta_2\bar{D}I_{MOD} + \eta_2(I_A - I_T) + \eta_1 I_T]\}\,. \tag{12}$$

This expression can be solved for $I_A$ to obtain

$$I_A = \frac{A_I[I_B + (k_2 - k_1)I_T] + A_I\bar{D}(I_{XOD} - k_2 I_{MOD})}{1 + A_I k_2}\,, \tag{13}$$

where the laser-photodetector current efficiencies $k_1$ and $k_2$ are defined as $k_1 \triangleq f\eta_1$ and $k_2 \triangleq f\eta_2$.

Equations (11) and (13) can be now used to determine the light output levels for the laser:

$$L_0 = \frac{\eta_2 A_I I_B + (\eta_1 - \eta_2) I_T}{1 + A_I k_2} + \frac{A_I \bar{D} \eta_2 (I_{XOD} - k_2 I_{MOD})}{1 + A_I k_2} \tag{14a}$$

and

$$L_1 = L_0 + \eta_2 I_{MOD} . \tag{14b}$$

The quantity $A_I k_2$ represents the loop gain of the bias feedback loop. In a proper design the loop gain is necessarily very large ($A_I k_2 \gg 1$). Under this condition, together with the assumption that $\eta_2 \gg \eta_1$, we can simplify the expressions for the laser light output to

$$L_0 = \frac{1}{f}\left[I_B - \frac{I_T}{A_I}\right] + \frac{\bar{D}}{f}(I_{XOD} - k_2 I_{MOD}) \tag{15a}$$

$$L_1 = L_0 + \eta_2 I_{MOD} . \tag{15b}$$

The balance current, $I_X$, is incorporated in the circuit of Fig. 2 for the purpose of eliminating the dependence of the laser light levels on $\bar{D}$, the dc component of the data input signal. This is accomplished to first order by choosing $I_{XOD} = k_2 I_{MOD}$ so as to eliminate the second term in (15a). However, a dependence on $\bar{D}$ will reappear as a consequence of changes in the above-threshold conversion efficiency, $k_2$, that results from the drift of $\eta_2$ with time. In particular, if $I_{XOD}$ is chosen to balance the circuit at some initial time when $\eta_2 = \eta_2^0$,

$$I_{XOD} = f \eta_2^0 I_{MOD} , \tag{16}$$

and if $\Delta\eta_2$ is defined to represent the subsequent drift in $\eta_2$,

$$\Delta\eta_2 \triangleq \eta_2 - \eta_2^0 , \tag{17}$$

then it follows from eqs. (15) through (17) that the laser output levels can be expressed as

$$L_0 = \frac{1}{f}\left[I_B - \frac{I_T}{A_I}\right] - \bar{D} I_{MOD}(\Delta\eta_2) \tag{18a}$$

and

$$L_1 = L_0 + \eta_2 I_{MOD}. \tag{18b}$$

A principal function of the feedback loop in Fig. 2 is to eliminate the dependence of the optical output on the laser threshold current. However, there remain in (18) terms dependent on $I_T$, and we now consider their relative importance. Assume the laser is biased near threshold so that $I_{L0} \approx I_T$. Then, if the drift in $\eta_2$ is small so that $I_{XOD} = f\eta_2^0 I_{MOD} \approx f\eta_2 I_{MOD}$, it follows from (10a) and (13) that

$$I_{L0} \approx \frac{A_I[I_B + (k_2 - k_1) I_T]}{1 + A_I k_2} \approx I_T . \tag{19}$$

Thus,

$$\frac{I_T}{A_I} \approx \frac{I_B}{1 + A_I k_1}. \tag{20}$$

The quantity $A_I k_1$ is the *subthreshold* loop gain of the feedback loop, and if this gain is large ($A_I k_1 \gg 1$), then

$$\frac{I_T}{A_I} \ll I_B. \tag{21}$$

Therefore, the threshold current dependent terms in (18) are negligible. Thus, under the conditions that the feedback loop gain is large both above and below threshold ($A_I k_2 \gg A_I k_1 \gg 1$), the laser light output levels can be expressed simply as

$$L_0 \approx \frac{I_B}{f} - \bar{D} I_{MOD}(\Delta\eta_2) \tag{22a}$$

$$L_1 \approx \frac{I_B}{f} - \bar{D} I_{MOD}(\Delta\eta_2) + \eta_2 I_{MOD}. \tag{22b}$$

We can draw a number of conclusions with regard to above-threshold biasing from the results expressed in (22):

1. The laser light output levels, $L_0$ and $L_1$, are to first order independent of the subthreshold slope efficiency, $\eta_1$, and the threshold current, $I_T$.

2. If the above-threshold slope efficiency, $\eta_2$, is constant ($\Delta\eta_2 = 0$), the light output levels are independent of the data signal dc component, $\bar{D}$.

3. If $\eta_2$ drifts as a function of time or changes in environment, the light levels $L_0$ and $L_1$ will exhibit some dependence on $\bar{D}$.

4. In a proper design of the circuit represented by Fig. 2, the feedback loop gain must be large below, as well as above, the laser threshold.

### *2.2 Subthreshold prebiasing ($I_{L0} \leq I_T$)*

When the laser is biased below threshold, it is necessarily the case that $I_{L0} = I_A \leq I_T$ and that $I_{L1} = I_A + I_{MOD} > I_T$; it therefore follows from (1), (2), and (10) that

$$L_0 = \eta_1 I_A \tag{23a}$$

and

$$L_1 = \eta_2(I_A + I_{MOD} - I_T) + \eta_1 I_T. \tag{23b}$$

Substitution of (23) into (9) then leads to the expression

$$I_A = A_I(I_B + \bar{D}I_{XOD} - f\{\eta_1 I_A + \bar{D}[\eta_2 I_{MOD} + (\eta_2 - \eta_1)(I_A - I_T)]\}) \quad (24)$$

and this result can be solved for $I_A$ to obtain

$$I_A = \left[\frac{A_I}{1 + A_I k_1 + \bar{D}A_I(k_2 - k_1)}\right] \cdot \{I_B + \bar{D}[I_{XOD} - k_2 I_{MOD} + (k_2 - k_1)I_T]\}, \quad (25)$$

where $k_1 \triangleq f\eta_1$ and $k_2 \triangleq f\eta_2$.

As is the case for above-threshold biasing, the loop gain of the feedback circuit should be large both above and below the laser threshold ($A_I k_2 \gg 1$ and $A_I k_1 \gg 1$). Under these conditions, together with the assumption $\eta_2 \gg \eta_1$, (25) simplifies to

$$I_A \simeq \left(\frac{1}{k_1 + \bar{D}k_2}\right)\{I_B + \bar{D}[I_{XOD} - k_2(I_{MOD} - I_T)]\}. \quad (26)$$

To eliminate the dependence of the optical output levels on $\bar{D}$, $I_{XOD}$ must be chosen so as to remove the dependence of $I_A$ on $\bar{D}$. However, for subthreshold biasing a dependence on $\bar{D}$ will reappear in the event of drift in any of the laser parameters $\eta_2$, $\eta_1$, or $I_T$. If $\eta_1^0$, $\eta_2^0$ and $I_T^0$ denote the values of $\eta_1$, $\eta_2$, and $I_T$ at the time when $I_{XOD}$ is initially adjusted to cancel out the $\bar{D}$ dependence of $I_A$, then from (24) the appropriate value of $I_{XOD}$ is

$$I_{XOD} \simeq k_2^0\left(\frac{I_B}{k_1^0} + I_{MOD} - I_T^0\right), \quad (27)$$

where $k_1^0 = f\eta_1^0$, $k_2^0 = f\eta_2^0$, and we have assumed that $\eta_2^0 \gg \eta_1^0$ and $A_I k_1 \gg 1$. For this choice of $I_{XOD}$ the initial value of $I_A$ is simply

$$I_A^0 \simeq \frac{I_B}{k_1^0}. \quad (28)$$

The expression for $I_A$ at some time following the initialization of $I_{XOD}$ is obtained by substituting (27) into (26), with the result

$$I_A = \left(\frac{1}{k_1 + \bar{D}k_2}\right)\left\{I_B\left(\frac{k_1^0 + \bar{D}k_2^0}{k_1^0}\right) + \bar{D}\,[k_2 I_T - k_2^0 I_T^0 - (k_2 - k_2^0)I_{MOD}]\right\}. \quad (29)$$

It then follows from (23) and (29) that for subthreshold prebiasing, and under the assumption of large feedback loop gain both above and below the laser threshold, the light output levels are given by

$$L_0 = \left(\frac{\eta_1}{\eta_1 + \bar{D}\eta_2}\right)\left\{\frac{I_B}{f}\left(\frac{\eta_1^0 + \bar{D}\eta_2^0}{\eta_1^0}\right)\right.$$
$$\left. + \bar{D}[\eta_2 I_T - \eta_2^0 I_T^0 - (\eta_2 - \eta_2^0) I_{MOD}]\right\} \tag{30a}$$

and

$$L_1 = \left(\frac{\eta_2}{\eta_1 + \bar{D}\eta_2}\right)\left\{\frac{I_B}{f}\left(\frac{\eta_1^0 + \bar{D}\eta_2^0}{\eta_1^0}\right)\right.$$
$$\left. + I_{MOD}(\eta_1 + \bar{D}\eta_2^0) - \eta_1 I_T - \bar{D}\eta_2^0 I_T^0\right\}. \tag{30b}$$

From these complex expressions, as compared to the simple results obtained in (22) for above-threshold biasing, we can draw the following conclusions with respect to subthreshold biasing:

1. The laser light output levels are not stabilized against individual variations in any of the parameters characterizing the laser ($\eta_1$, $\eta_2$, and $I_T$).

2. The light output levels will exhibit a dependence on the data signal average, $\bar{D}$, if changes occur in any one of the laser parameters.

### III. MODULATION CURRENT COMPENSATION

As we demonstrated in Section 2.1, if the laser is prebiased above its threshold current, the circuit of Fig. 2 effectively stabilizes the optical output against variations in both the laser's subthreshold slope efficiency, $\eta_1$, and its threshold current, $I_T$. However, the light output levels remain sensitive to the above-threshold slope efficiency, $\eta_2$, and, as a consequence, to the average value of the input data, $\bar{D}$. One means of eliminating this remaining sensitivity is to compensate for changes in $\eta_2$ through control of the modulation source current, $I_{MOD}$. This approach has, in fact, already been proposed in specific designs.[6,8]

As in Section 2.1 we assume that the laser is prebiased above threshold ($I_{L0} \geq I_T$) so as to eliminate sensitivity of the optical output to $\eta_1$ and $I_T$. It is then apparent from (15) that the sensitivity of the light output levels to $\eta_2$ and $\bar{D}$ can be eliminated if the source current $I_{MOD}$ can be continuously adjusted so as to hold the product $\eta_2 I_{MOD}$ constant. This can be accomplished by deriving a signal proportional to the difference between the ZERO and ONE light levels, and then using negative feedback to control $I_{MOD}$ in a manner that stabilizes this difference. After a signal is obtained proportional to the difference $L_1 - L_0$, $I_{MOD}$ is generated as

$$I_{MOD} = I_{REF} - \gamma(L_1 - L_0), \tag{31}$$

where $\gamma$ is a constant characterizing the feedback loop controlling $I_{MOD}$, and $I_{REF}$ is a modulation reference, or "baseline", current.

From (11) it follows that for above-threshold biasing

$$L_1 - L_0 = \eta_2 I_{MOD}. \tag{32}$$

Upon substituting this expression into (31) and then solving for $I_{MOD}$, we obtain

$$I_{MOD} = \frac{I_{REF}}{1 + \gamma\eta_2} \simeq \frac{I_{REF}}{\gamma\eta_2} \quad \text{for} \quad \gamma\eta_2 \gg 1. \tag{33}$$

In this equation the term $\gamma\eta_2$ represents the loop gain of the negative feedback loop controlling $I_{MOD}$ and should necessarily be much greater than unity.

If we substitute (33) in (14) we obtain the following expressions for the laser light output levels:

$$L_0 = \frac{\eta_2 A_I I_B + (\eta_1 - \eta_2) I_T}{1 + A_I k_2} + \left(\frac{A_I \bar{D} \eta_2}{1 + A_I k_2}\right)\left(I_{XOD} - \frac{k_2 I_{REF}}{\gamma\eta_2}\right) \tag{34a}$$

and

$$L_1 = L_0 + \frac{I_{REF}}{\gamma}. \tag{34b}$$

If, as in Section 2.1, we assume that $\eta_2 \gg \eta_1$, $A_I k_2 \gg 1$ and $A_I k_1 \gg 1$, then, recognizing that $k_2 = f\eta_2$, it follows from (34) that

$$L_0 \approx \frac{I_B}{f} + \frac{\bar{D}}{f}\left(I_{XOD} - \frac{f I_{REF}}{\gamma}\right) \tag{35a}$$

and

$$L_1 = L_0 + \frac{I_{REF}}{\gamma}. \tag{35b}$$

It is apparent from (35) that the sensitivity of $L_0$ and $L_1$ to $\eta_2$ has been successfully eliminated. As in Section 2.1 the remaining dependence on $\bar{D}$ can be removed by the appropriate choice of $I_{XOD}$, namely,

$$I_{XOD} = \frac{f I_{REF}}{\gamma}. \tag{36}$$

The expressions for the ZERO and ONE light output levels then reduce to the very simple form

$$L_0 = \frac{I_B}{f} \tag{37a}$$

and

$$L_1 = \frac{I_B}{f} + \frac{I_{REF}}{\gamma}. \tag{37b}$$

Clearly these levels are now, to first order, independent of the laser parameters $\eta_1$, $\eta_2$, and $I_T$ and the dc component of the data signal, $\bar{D}$.

Compensation of the modulation source current as described below can be implemented as illustrated in Fig. 3. Following the approach of Gruber, et al.,[6] the circuit of Fig. 2 is modified by the inclusion of high-speed buffers (B1 and B2), positive (B3) and negative (B4) peak detectors, and a summing amplifier (B5). The current $I_{MOD}$ is developed at the output of the summing amplifier and is proportional to $L_1 - L_0$. The secondary negative feedback loop controlling $I_{MOD}$ will act to hold $L_1 - L_0$ constant.

The modulation current feedback loop will have a characteristic response time. Consistent with our assumption that $I_{MOD}$ is a parameter that changes slowly with respect to the response of the prebias

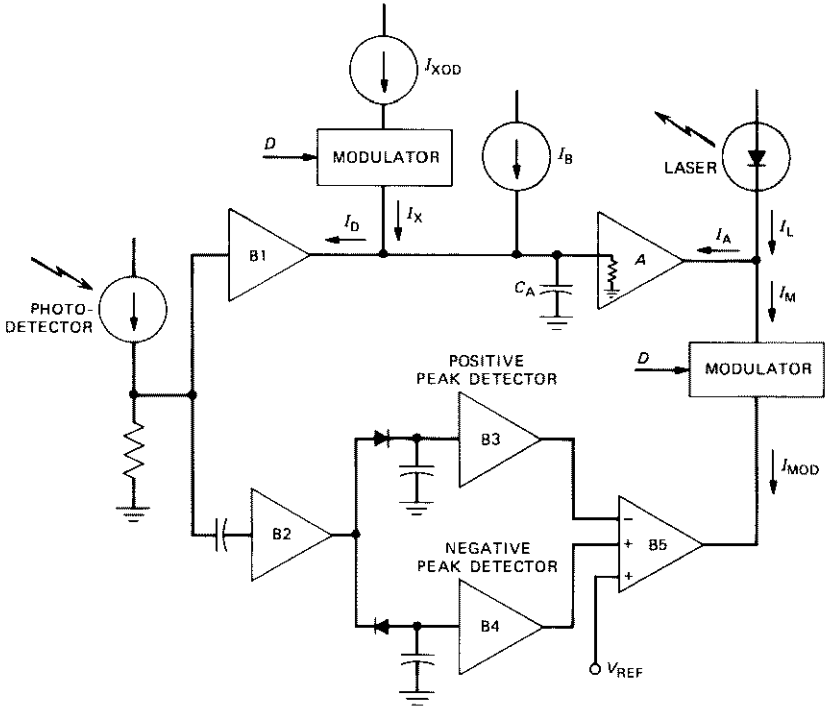

Fig. 3—An improved laser driver incorporating feedback control of both bias and modulation currents. Light output levels are set independently of laser parameters.

current feedback loop, the secondary feedback loop should respond slowly in comparison with the feedback controlling $I_A$.

## IV. CONCLUSION

This paper has presented an analysis of a generalized method of negative feedback stabilized biasing and modulation of semiconductor lasers. Our objective was to evaluate the effectiveness of the stabilization and determine the critical feedback loop parameters. The analysis considered not only the direct influence of variations in $\eta_1$, $\eta_2$, and $I_T$, but also the effect of changes in the average modulation signal and the issue of biasing the laser above or below threshold.

For the more simple bias schemes reported to date, we showed that the laser light levels are susceptible to variation in any of the laser parameters when the laser is dc biased below threshold. When the laser is biased above threshold, only changes in $\eta_2$ affect the light output.

We also analyzed a method of stabilizing the difference $L_1 - L_0$ and thereby fixing laser light output independent of variations in any laser or modulation parameters. To maintain this independence the laser must, of course, be prebiased to remain above threshold under all expected conditions. Moreover, the optical output will still be sensitive to changes in the photodetector light-to-current conversion factor, $f$.

## LIST OF VARIABLES

### *Device parameters*

- $\eta_1$ laser subthreshold differential slope efficiency
- $\eta_2$ laser above-threshold differential slope efficiency
- $I_T$ laser threshold current
- $f$ photodetector light-to-current conversion factor
- $k_1$ laser-photodetector subthreshold conversion efficiency $\triangleq f\eta_1$
- $k_2$ laser-photodetector above-threshold conversion efficiency $\triangleq f\eta_2$

### *Modulation-related (rapidly changing) parameters*

- $D$ digital signal data (ONE or ZERO)
- $I_L$ instantaneous total laser current
- $I_M$ instantaneous modulation current: 0 or $I_{MOD}$
- $I_X$ instantaneous balance current: 0 or $I_{XOD}$
- $I_D$ instantaneous photodetector output current
- $L$ instantaneous laser luminosity

### *Nominally DC (slowly changing) parameters*

- $\bar{D}$ average (dc) value of digital signal data
- $I_{L0}$ logic ZERO laser current

$I_{L1}$ logic ONE laser current
$I_{MOD}$ modulation source current
$I_{XOD}$ balance source current
$L_0$ logic ZERO laser luminosity
$L_1$ logic ONE laser luminosity
$I_B$ bias current
$I_A$ amplifier output current $\triangleq$ laser prebias current $= I_{L0}$

# Empirical Evaluation of Profile Variations in an MCVD Optical Waveguide Fiber Using Modal Structure Analysis

By A. CARNEVALE* and U. C. PAEK†

(Manuscript received November 15, 1982)

This paper presents a computer modeling evaluation of the effect on mode propagation of typical perturbations in the refractive index profile produced as a result of the MCVD process. Certain profile variations were eliminated, singly and/or collectively, and the resultant changes in modal structure analyzed. The most important factor in the deterioration of the bandwidth is the presence of a refractive index dip at the core center. Small shifts in the level of dopant were seen to broaden pulse shapes and thus reduce bandwidth. Much less effect on bandwidth is associated with the ripples in the profile, as is also true for dips in refractive index below the index of the cladding near the core-cladding interface. A perpendicular rise, or step, in index of refraction at the core-cladding interface reduces the number of altered modes near the cladding.

## I. INTRODUCTION

In a previous paper[1] we reported on calculation of the modal structure as a function of wavelength ($\lambda$) of an optical waveguide produced by the Modified Chemical Vapor Deposition (MCVD) process using an exact numerical procedure. This technique[2] has been used extensively to investigate various theoretical aspects of optical waveguide propagation.[3-6] We observed excessive splitting and scattering in the

effective indices ($N_e$) and the group indices ($N_g$), which lead to a reduction of the bandwidth (BW) at any particular $\lambda$.[1] We concluded that the profile variations inherent in the MCVD process were responsible for the reduction of the BW. This paper analyzes in detail the same profile considered there.

The profile is shown in Fig. 1. The data, obtained by the laser beam refraction method,[7] indicates the change in refractive index ($\Delta N_r$) as a function of the unnormalized radius (r). $\Delta N_r = 0$ corresponds to the cladding, in this case, $SiO_2$. The major deviations (imperfections) of this MCVD profile from a power law ($\alpha$) profile are common to most profiles produced by the MCVD process. These include:

1. Region A in the plot, usually referred to as "BURNOFF" or "BURNOUT", which indicates a precipitous reduction in the refractive index at the core center. This reduction is believed to be due to the vaporization of dopant components, such as $GeO_2$, during the high-temperature collapse phase of the process.

2. Region B, which extends over most of the profile, containing what are generally called "RIPPLES", whose width and amplitude

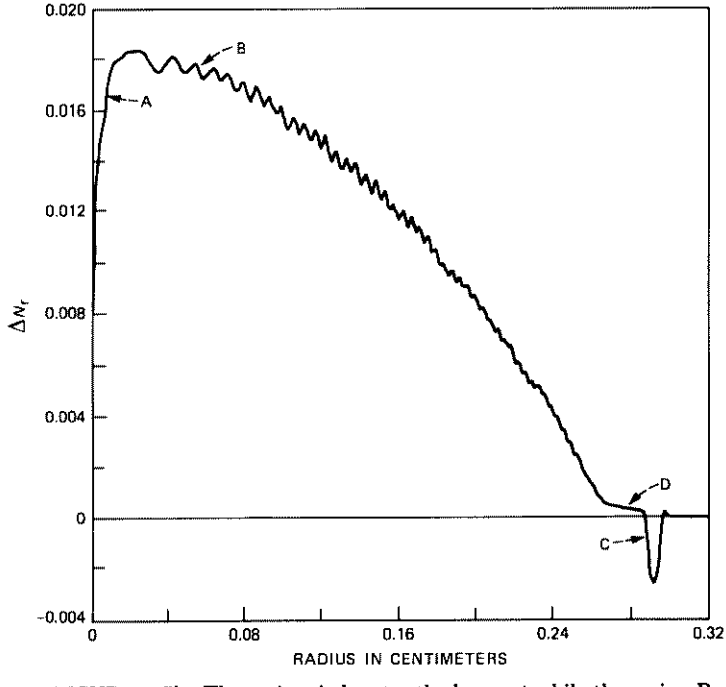

Fig. 1—MCVD profile. The region A denotes the burnout while the region B, which extends over most of the profile, shows the characteristic ripples referred to in the text. Regions C and D refer to the dip and the step, respectively. The radius data are not normalized.

increase toward the core center. These ripples are a direct result of the compositional gradient across the MCVD layer, burnoff of $GeO_2$ at the surface of the layer, and the finite number of discrete layers of changing composition (typically 50).

3. The sharp "DIP", C, near the core-cladding interface caused by the use of an index-reducing dopant in the deposited barrier layer, in this case, boron. In some special cases this "depressed cladding" feature can have a greater width than shown.

4. The "STEP", D, at the cladding.

The above deviations constitute the major obvious perturbations of the MCVD profile from an ideal profile. More subtle deviations, which are usually ignored, will be seen later in this report.

## II. METHOD

It was deemed necessary and sufficient to find the effective indices and the group indices for the:

1. Meridional modes $TE_{0,q}$, and $TM_{0,q}$
2. Helical modes $HE_{1,q}$, and $EH_{1,q}$ over some wavelength region of interest.

The subscripts above denote the angular and radial mode number (m, q) respectively. Thus we conducted the modeling process at 11 specific wavelengths itemized below in Table I.

### *2.1 "As is" case*

Initially, $N_e$ and $N_g$ of the modal groups at $m = 0$ and $m = 1$, were obtained for each of the $\lambda$'s listed in Table I, operating on the MCVD profile as it exists; i.e., on an "as is" basis. Figure 2 shows examples of the distribution of $N_g$ vs $N_e$ for $\lambda = 0.82$ (a), 1.32 (b), and 1.55 (c) $\mu$m, respectively. We note the counterclockwise rotation of the data as a function of increasing $\lambda$; this rotation has been commented on in our early work.[4] The profile was shown to remain constant with $\lambda$, but the group index vs effective index changes in this manner owing to the dependence of bandwidth on $\alpha$.

We further note the clear separation (splitting) of the $HE$ modes ($\Delta$) from all other modes (O, ●); this separation decreases as $\lambda$ increases. The two groups appear to be moving roughly in parallel but

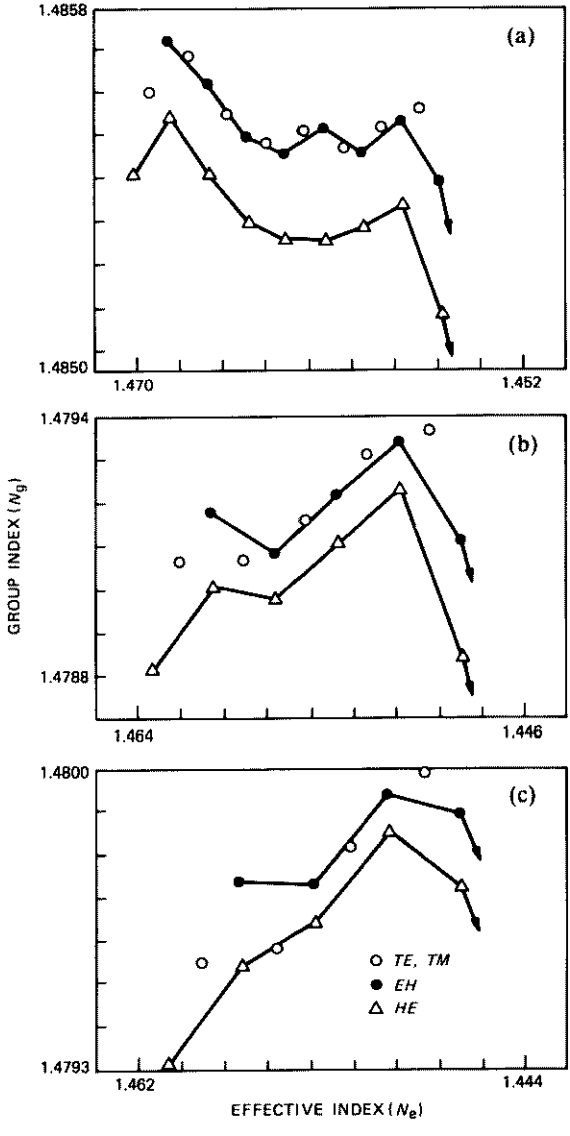

Fig. 2—$N_g$ vs $N_e$—"as is" case. (a) $\lambda = 0.82$ μm. (b) $\lambda = 1.32$ μm. (c) $\lambda = 1.55$ μm.

displaced in time. This can result in two or more peaks, depending on any mode mixing, in the output pulse of the fiber, and a reduction in the BW at any λ. BW reduction would be more severe at short λ's, where the splitting is greater. Last, we observed the drop-off (lower $N_g$) of those high-order modes near the cladding. These modes have been altered because of their proximity to the cladding. The plots of

Fig. 2 can be compared to the ideal case of a power law profile using the computed $\alpha$, $\Delta N$, and $r$ derived from the MCVD profile.[1] A plot of $N_g$ at each $\lambda$ results in a shape similar to those shown in the MCVD plot by (○, ●); i.e., other than the *HE* (Δ) modes.

### 2.2 *"No ripple or dip" case*

To analyze the effect of the MCVD imperfections on the modal structure, each was removed separately. Our first step was to remove the ripple in the section (B) between the burnout (A) and the step (D) in Fig. 1. Past experience in $\alpha$ curve fitting to MCVD profiles indicated that rarely can one fit section $B$ with a single $\alpha$. Because we did not want to destroy any short-term (local) variations in $\Delta N$ and/or $\alpha$, we partitioned the $B$ region into eight equal radial segments, and fitted each segment with a least squares parabola. We then used the fitted curve as the profile in each segment. The index of refraction data shown in Fig. 1 is collected at a number of discrete points and is generally not a continuous curve.

Next, the dip (C) was removed by connecting the end points with a two-point straight line, thus making the step (D) continuous. This correction caused negligible change in the spectrum and so for brevity we eliminated the ripple and dip in one operation.

One example, which is typical of all $\lambda$'s tested, is given in Fig. 3 at $\lambda = 0.6328$ $\mu$m. Figure 3a is the modal display on an as is basis, while Fig. 3b is the result for no ripple or dip. The as is plot is consistent with those $\lambda$'s shown in Fig. 2, i.e., the rotation of the data, the drop-off of the high-order modes, and, most important, the splitting of *HE* from all other modes. The relatively short $\lambda$ of 0.6328 $\mu$m makes the $N_e$ and $N_g$ very sensitive to the short-term variations in the profile. We see the development of some jagged peaks and depressions in the display as we approach the cladding. Since it is the high-order modes that are most affected, imperfections in the profile near the cladding are most likely responsible for the development of these sharp features. It could be the step D, or as seems more likely, a shift in $\alpha$ or $\Delta N$ in the latter part of section B in the profile. Identification of the parameter responsible ($\Delta N$ or $\Delta\alpha$) is difficult. In any case, a change in either results in shifting $N_g$ in the same direction. We can see two pronounced shifts at $r = 18$ and $r = 22$ in Fig. 1. If we examine the fine structure of the profile, we can detect other such shifts over the full range of the radius. Although these shifts appear to be small, they can cause large changes in the eigenvalues and, thereby, in $N_g$. We can therefore associate the ragged appearance of $N_g$ in our plots with very small changes in $\Delta N_r$.

Elimination of the ripple and the dip (Fig. 3b) reduces the scatter of the data and lessens the effect of the shifts in $\Delta N$, probably because

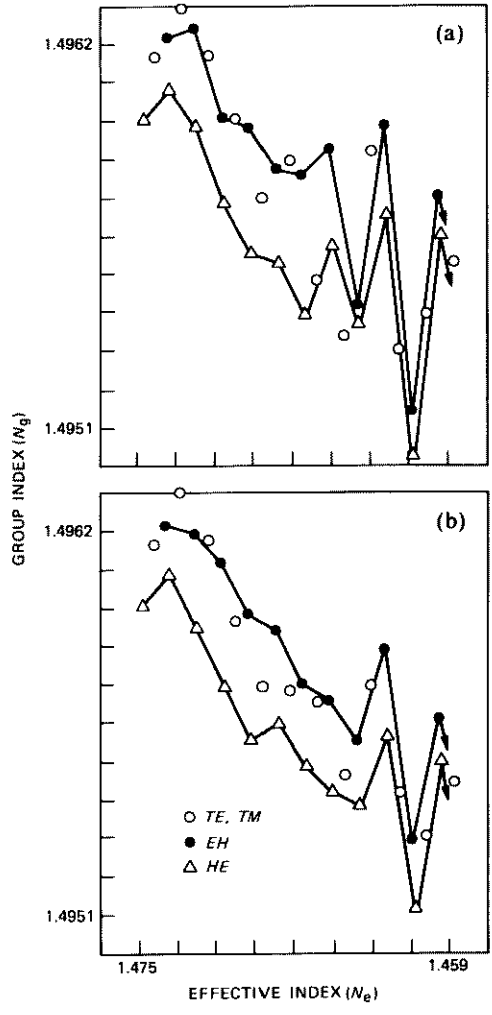

Fig. 3—Plot of $N_g$ vs $N_e$ for $\lambda = 0.6328$ $\mu$m. (a) "As is" case. (b) Ripple and dip removed.

it acts as a smoothing mechanism. However, it does not eliminate or reduce the separation of the *HE* modes and therefore is not the major cause of reduced BW resulting from this profile. The data in Figs. 3a and b appear to have approximately the same slope, but the slope in Fig. 3b is more clearly defined, probably as a result of the smoothing action.

### *2.3 "No burnout" case*

The next MCVD deviation eliminated was the dip in the index of refraction at the core center, i.e., the burnout region (A) in Fig. 1. To

accomplish this, we found the maximum $\Delta N$ in the profile and extended it in a horizontal line to the core center. The rest of the profile was kept intact, thus preserving the original ripples, dip, and step. Figure 4 shows the results at $\lambda = 1.23$ $\mu$m. Figure 4a shows the results on an as is basis, while Fig. 4b shows the case without burnout.

The as is result at this $\lambda$ is again consistent with our earlier results. At this longer $\lambda$, $N_e$ and $N_g$ are much less sensitive to the short-term variations in the profile, which is evident in the relatively smooth plot of $N_g$ vs $N_e$ as compared to the same plot (Fig. 3a) at $\lambda = 0.6328$ $\mu$m.

The elimination of the burnout (Fig. 4b) has removed the displacement in time of the *HE* modes and all modal groups are now traveling together. This remarkable result was observed at all $\lambda$'s (see Table I) tested. Except for considerations of $\alpha$ optimum ($\alpha_{opt}$), the burnout appears to be of paramount significance in the deterioration, or optim-

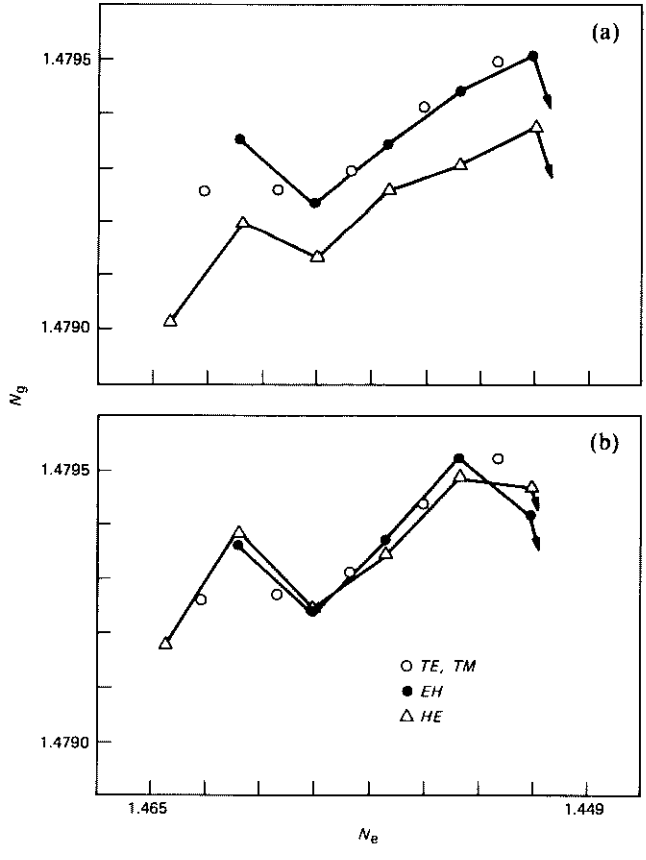

Fig. 4—$N_g$ vs $N_e$ for $\lambda = 1.23$ $\mu$m. (a) "As is" case. (b) "No burnout" case.

ization, of the BW. We should realize that the burnout region in this MCVD profile is much less than that seen in most MCVD profiles.

### *2.4 "Inverted burnout" case*

Because of the previous results we decided to investigate a phenomenon sometimes seen in MCVD profiles. This defect can occur as a result of overcompensation of dopant in attempting to reduce or eliminate burnout. A study of some MCVD profiles[8] in which this defect was present indicated that we could simulate this characteristic by simply inverting the burnout. We found the difference of $\Delta N$ from the maximum $\Delta N$ and added this difference to the maximum, over the burnout region A in Fig. 1.

Figure 5 shows one result at $\lambda = 1.20$ $\mu$m, which was typical of all

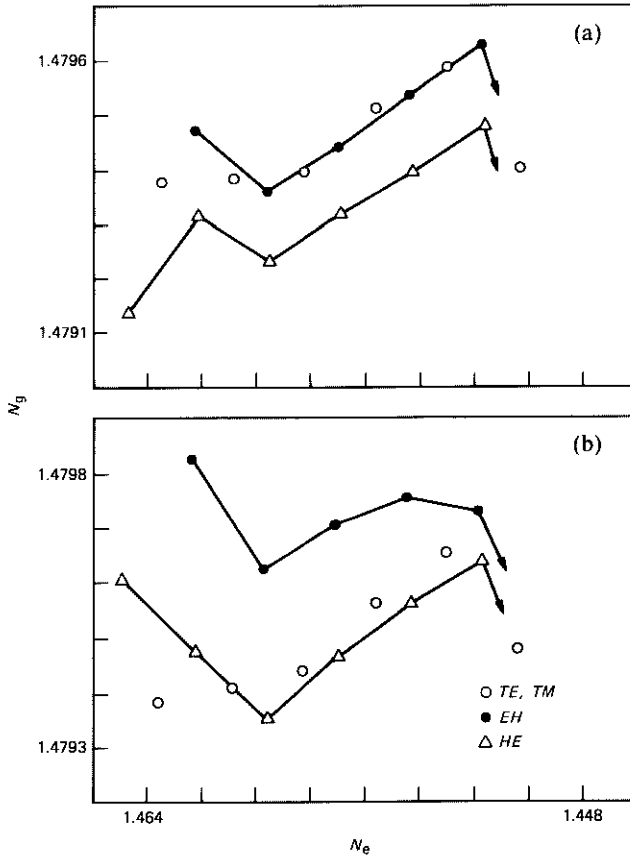

Fig. 5—$N_g$ vs $N_e$ for $\lambda = 1.20$ $\mu$m. (a) "As is" case. (b) "Inverted burnout" case.

λ's tested. Figure 5a is the modal display on an as is basis (which includes the burnout), and Fig. 5b is the result for the inverted burnout (overcompensation).

The as is result is consistent with our previous observations on similar spectra at other λ's.

Inverting the burnout (Fig. 5b) has displaced the *EH* modes from all the rest, and further, this displacement is much greater than the burnout effect, and thus is far more serious than burnout in the decrease of the BW. Our calculations indicate that if both burnout and overcompensation are present simultaneously (which has been observed at times), both splittings would also occur, i.e., the two effects would not be cancelled). Thus we would expect three or more peaks, depending on mode mixing, in the output pulse of the fiber.

### *2.5 "No step" case*

One last perturbation in the MCVD profile remains to be examined, namely, the step (D) near the cladding. We used the least squares fitted curve for the ripple section of the profile nearest the step. We eliminated the step D (and also the dip C) by using the derived equation to extrapolate paired values of $r$, $\Delta N_r$ to the cladding. At $\Delta N_r = 0$, the radius is then renormalized to 25 $\mu$m. One comprehensive result is given in Fig. 6 at $\lambda = 0.70$ $\mu$m, where all plots are on identical scales and are called:

1. As is
2. No ripple or dip
3. No ripple, dip or burnout
4. No ripple, dip, burnout, or step.

The as is modal display (A) is consistent with our previous observations at other λ's on this basis. We see the separation of the *HE* modes due to the burnout and the increased sensitivity to the short-term variations in this profile at this relatively short λ. We note the development of the sharp features in the distribution as we approach the cladding; this is very similar to the comparable spectrum (Fig. 3a) at $\lambda = 0.6328$ $\mu$m.

Removing the ripple and dip (Fig. 6b) provides the same smoothing mechanism previously cited (see Fig. 3b for example).

Figure 6c is the modal distribution realized when the ripple, dip, and burnout have been removed, retaining the step. We see that all modes are now travelling together (no *HE* separation), and that we are now approaching the distribution to be realized for an ideal profile, except for the short-term shifts in $\Delta N_r$ in the profile.

Figure 6d is the modal distribution obtained when the ripple, dip, burnout, and step have been eliminated. This distribution represents the closest approach to an ideal profile. The severe drop-off in $N_g$ of

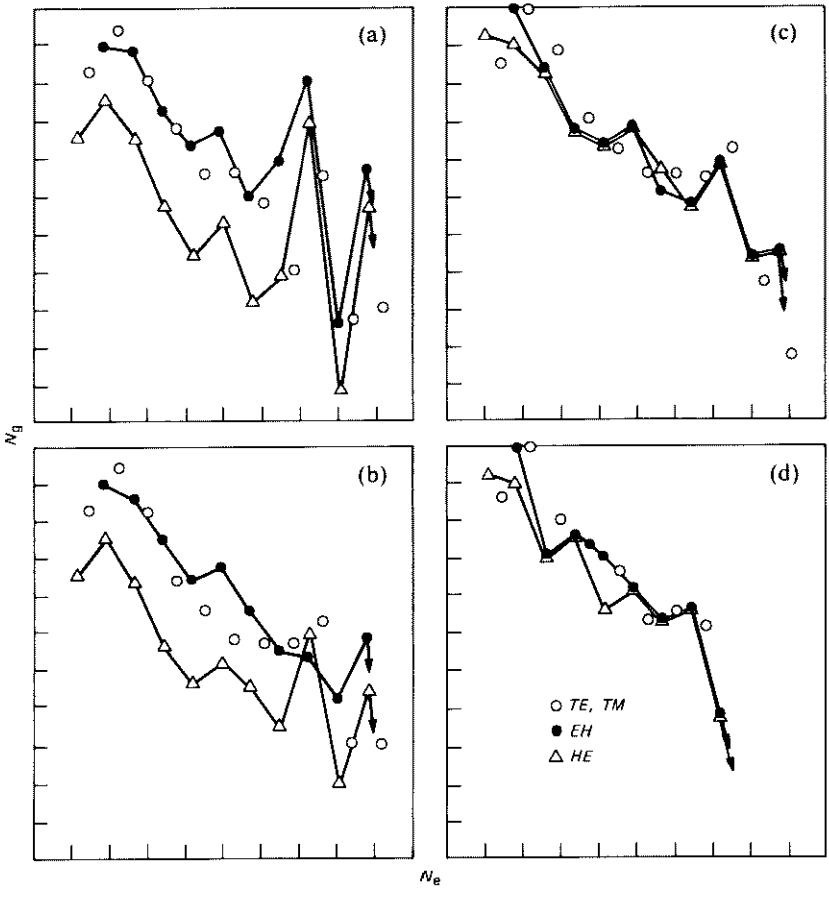

Fig. 6—$N_g$ vs $N_e$ for $\lambda = 0.70$ $\mu$m (Scales are identical in all sections). (a) "As is" case. (b) No ripple or dip case. (c) No ripple, dip, or burnout (step is in). (d) No ripple, dip, burnout, or step.

the high-order modes can lead to a reduction of the BW. Thus we see that the step is beneficial when we are attempting to optimize the BW. Note that there are many more modes in the distribution (Fig. 6c) than there are in our closest approach to an ideal profile (Fig. 6d). In this example, the step will introduce approximately 75 more modes to the distribution as compared to the ideal profile. Figure 7 uses data obtained at $\lambda = 0.6328$ $\mu$m (A) and $\lambda = 1.32$ $\mu$m (B) to show the steps beneficial effect. Each plot represents the results for the MCVD profile with the ripple, dip, burnout, and step removed. The solid line represents $N_g$ values for an ideal profile using the computed values of $\alpha$, $\Delta N$, and $r$ derived from the MCVD profile, at each $\lambda$. The dashed line indicates the path taken by the high-order modes, which have been

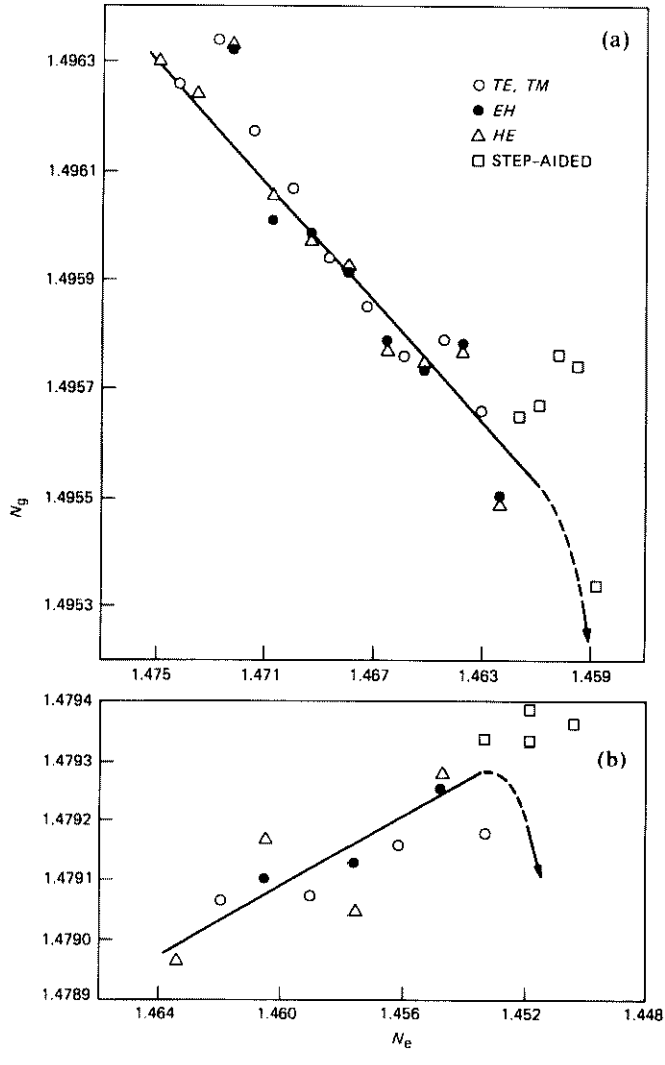

Fig. 7—$N_g$ vs $N_e$. The solid line depicts an ideal profile using the pertinent parameters derived from the MCVD profile. (a) $\lambda = 0.6328$ $\mu$m. (b) $\lambda = 1.32$ $\mu$m.

altered by their proximity to the cladding. The filled squares in each plot show the $N_g$ of some of these altered modes if the step is retained. Since this is the region of high modal density, the squares represent an addition of $\approx$100 modes to the modal distribution at $\lambda = 0.6328$ $\mu$m and $\approx$50 additional modes at $\lambda = 1.32$ $\mu$m. These additional modes can only be helpful when we are trying to optimize BW at any $\lambda$. We can now predict that the BW at these two $\lambda$'s would be a function of the slope of the line.[4]

## III. DISCUSSION

In our earlier work,[4] we have established that for a fixed profile that is a function of $\alpha$, $\Delta N$, and $r$, a least squares linear fit of $N_g$ vs $N_e$, ignoring the high-order modes, will show an increasing slope for increasing $\lambda$. At a given $\lambda$, we have defined $\alpha_{opt}$ as that $\alpha$ which produces a slope of zero. A slope of zero will generate the minimum spread in $N_g$, in the group velocities ($V_g$), and of course, in the delay times. Using that criterion we can see[1] that this MCVD fiber should have an optimum operating wavelength ($\lambda_0$) of about 1.00 $\mu$m. Independent BW measurements[9] have established a BW performance of $\approx$1.5 GHz·km over the range

$$1.06\ \mu\text{m} \leq \lambda \leq 1.35\ \mu\text{m}$$

with a maximum of $\approx$2 GHz·km at $\lambda = 1.23\ \mu$m. We have reproduced the output pulse displays from this work in Fig. 8. In this figure the number in each plot is the $\lambda$ in $\mu$m at which the distribution was obtained. A study of these distributions shows at least two peaks (broadening) at the short $\lambda$'s, which appear to merge as $\lambda$ increases. In all the pulses we see the common characteristic of a trailing tail. This tail is generated by the slowest modes in the modal distribution; at $\lambda = 0.7\ \mu$m (Fig. 6a) these would be the *low-order* modes, while at $\lambda = 1.55\ \mu$m (Fig. 2c) these would be the *high-order* modes. In Fig. 7, we have shown that the step at the core-cladding interface slows down the modes by raising the group indices. We have not attempted to derive the optimal step to optimize the BW for this profile. The reader should bear in mind that *all* modes will also be slowed down by increasing $\alpha$.

In the "as is" section of this report (Section 2.1) we have seen that the burnout displaces the *HE* modes from all other modes and that the two modal groups will travel in parallel but be displaced in time. This will lead to at least two peaks in the output pulse shapes. Further, we have noted that the displacement in time will decrease as a function of increasing $\lambda$. This naturally suggests that the two peaks should merge (depending on instrumental resolution) in the output pulse of $\lambda$ is increased (see Fig. 8).

## IV. REDUCTION OF DATA

We now consider the separation of the various modal groups at several $\lambda$'s (Table I) for the three conditions:

1. As is (includes burnout)
2. Inverted burnout (overcompensation)
3. No burnout,

and, for 2 and 3 above, the rest of the profile remains unaltered. Thus we are concerned here only with the index of refraction dip at the core

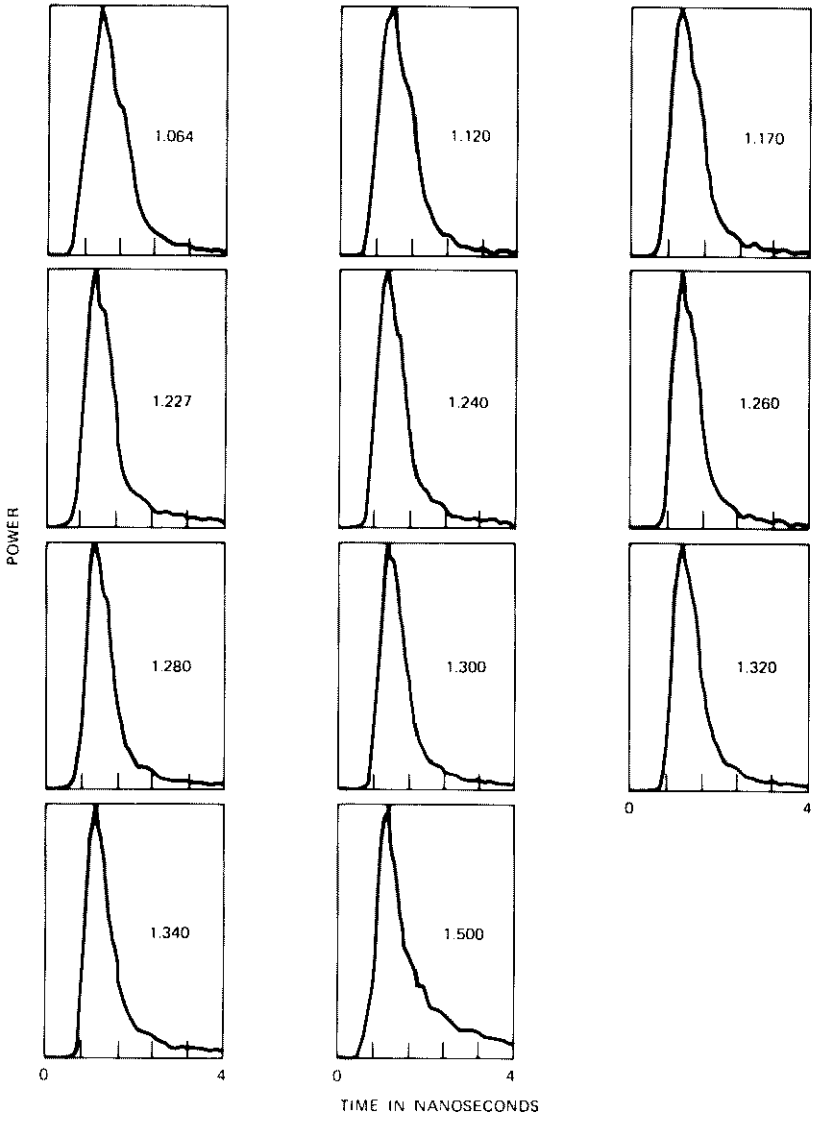

Fig. 8—Power vs time, as a function of the λ (μm) listed in each plot, for the specific MCVD fiber used in this study. Reprinted here, with permission, from Ref. 9.

center. We have previously stated that the separation of the modal groups appears to decrease for increasing λ, and this is true for 1 and 2 above. No such pattern was detected for the no burnout case. To codify these results over the range of λ's listed in Table I, we did the following.

At all λ's tested (Table I, Figs. 2a through 6a) we could generate at

least five distinct *EH-HE* splittings. We therefore found the average splitting ($\overline{\Delta N}_g$) over the first five such splittings at all λ's for each of the three cases listed above. These results are displayed in Fig. 9 as a function of λ. In the figure, the curves are defined as follows:

(A) Inverted burnout—*EH* modes separated from and moving slower than the comparable *HE* modes;

(B) As is—i.e., with burnout. *HE* modes separated from and moving faster than the comparable *EH* modes;

(C) No burnout—no real separation of modal groups—probably a random fluctuation about some relatively small average;

and 30 on the $\overline{\Delta N}_g$ axis is ≈1 ns.

Overcompensation (Curve A) is about 50 percent more deleterious in inducing splitting and is always worse in that respect than the burnout (Curve B). Further, if both phenomena are present, then the

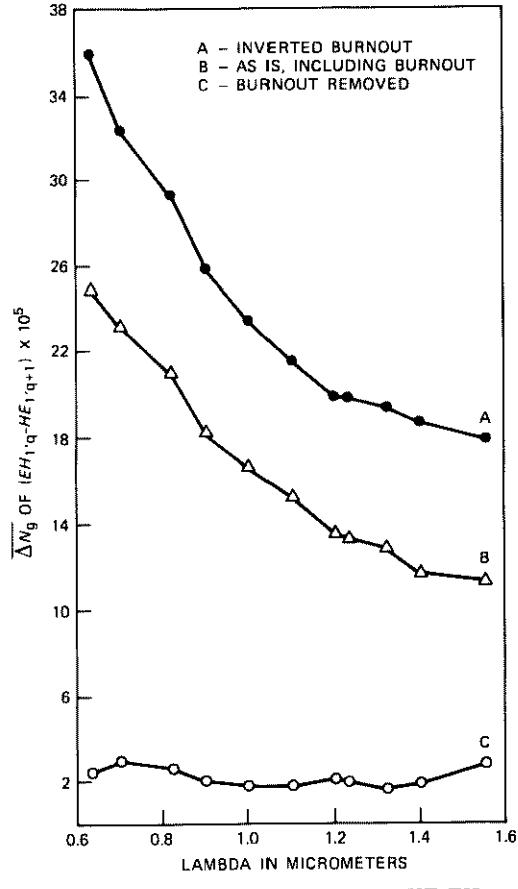

Fig. 9—The average splitting of $N_g$ for the first five *HE-EH* modes, plotted as a function of λ, for the MCVD profile. The measurement 30 on the y axis is ≈1 ns.

total splitting is the sum of the two curves. Three distinct peaks (or more) can be produced in the output pulse of the fiber, and these modal groupings might be, among others:

1. *HE*
2. *EH*
3. *TE, TM*
4. MIXED (*HE, EH*).

In practice, preform makers[8] do not consider preforms that show significant overcompensation for fiber drawing. Experience has shown that this perturbation in the profile yields poor BW in drawn fibers.

Removal of the burnout (Curve C) has reduced the splitting of the *EH-HE* modes to a minimum that is constant over the full range of λ's investigated. This residual splitting can now be attributed to the perturbations still present in the profile, ripple, dip, and short-term $\Delta N_e$, $\Delta\alpha$ variations, etc. If this condition could be realized in practice, i.e., burnout eliminated, the BW at each λ would be a function of $\alpha_{opt}$.[4]

In our computational method,[2] we obtain the eigenvalues ($N_e$) at three closely spaced wavelengths, where

$$\lambda_1 < \lambda_2 < \lambda_3,$$

and $\lambda_2$ is the operating wavelength. The eigenvalues are inserted in the numerical derivative to obtain the group indices for $\lambda_2$ by

$$N_{g2} = N_{e2} - \lambda_2 \left| \frac{N_{e1} - N_{e3}}{\lambda_1 - \lambda_3} \right|.$$

Errors in the determination of $N_e$ can be cancelled or amplified in the above formula. Thus we chose to obtain the average splitting in effective index ($\overline{\Delta}\overline{N}_e$) only at $\lambda_2$. The analogous display to Fig. 9 for $\overline{\Delta}\overline{N}_e$ is given in Fig. 10. In the figure, curves A, B, and C have the same connotation as before. We observe qualitatively the same trends for $\overline{\Delta}\overline{N}_e$ as for $\overline{\Delta}\overline{N}_g$ in Fig. 9. This information may be of some use to those computational methods[10] that calculate $N_g$ directly from $N_e$.

## V. CONCLUSION

We have examined the effect of various perturbations on the BW of an MCVD prepared fiber. We conclude that the primary reason for the deterioration of the BW in the MCVD as is profile is caused by the severe change in refractive index at the core center. This defect produces modal groupings that are displaced in time by as much as 0.5 ns, more or less, depending on the operating wavelength ($\lambda_0$). Short λ's are particularly sensitive to this defect, but even for longer λ's, the burnout will seriously affect attempts to maximize the BW. If burnout is minimized or eliminated in the MCVD process, we believe the next most important goal should be to optimize $\alpha$ at $\lambda_0$. Eliminating local

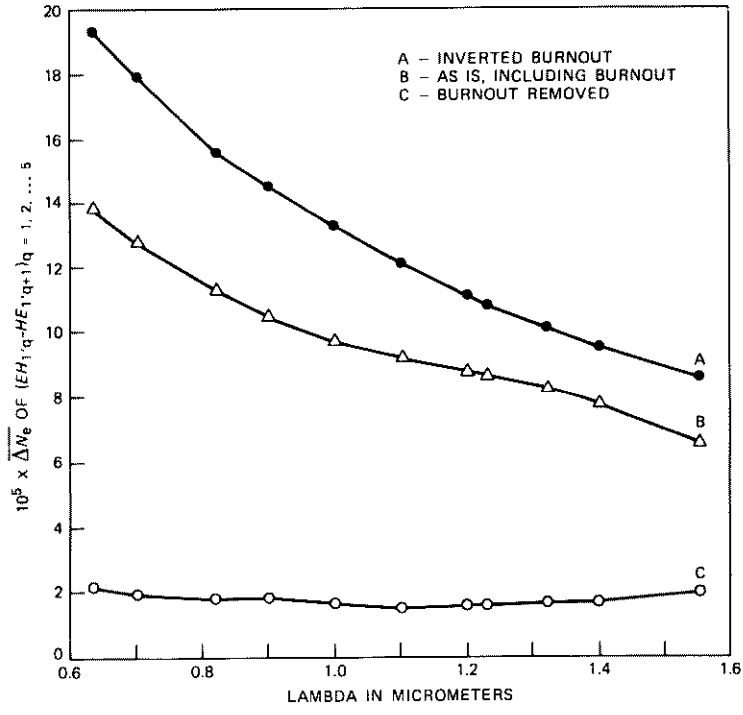

Fig. 10—Same as Fig. 9, except this is for the effective indices at the plotted λ.

shifts in $\Delta N$ would be the next priority, followed by reducing the amplitude of the ripples. This last is probably the least harmful in causing deterioration of BW. The step at the core-cladding interface appears to be beneficial in that it significantly *reduces* the number of high-order modes that have been altered by their proximity to the cladding. The works of Vassel[11] suggest that a perpendicular rise in the index of refraction at the core-cladding interface will have the same effect as the step (D) in Fig. 1.

In theory,[1,4] this MCVD fiber should have a maximum BW at $\lambda_0 \approx 1.00\ \mu m$. The experimental $\lambda_0$ was determined[9] to be 1.23 μm, and this shift to the longer $\lambda_0$ was verified by the statistical study conducted in Ref. 1. In an ideal profile, the governing factor for the optimization of BW is the determination of $\alpha_{opt}$ for $\lambda_0$.[4] In the MCVD profile this criterion has been overridden by the excessive broadening of the output pulse induced by the burnout causing the theoretical $\lambda_0$ to shift longer λ's. Even at longer λ's the effect of the burnout on BW is significant and may preclude the optimization of BW beyond the present state of the art.

Optimization of BW, based on optimum parameters ($\alpha_{opt}$, $\Delta N_{opt}$, etc.) derived from theoretical (ideal) concepts, will have limited appli-

cation to MCVD fibers. This limited applicability can explain to a great extent why workers in the field endeavoring to optimize BW utilizing concepts based on the theory cannot reproduce these bandwidths.

The literature is replete with studies of the effects on BW caused by disturbances in the profile such as burnoff, ripple, and steps in the index of refraction at the core-cladding interface. Most of these studies (including the present work) describe a cause and effect relationship. We are not aware of any study correlating these effects in terms of local changes in the $\alpha$ value, which the burnoff and/or ripples cause, resulting in a deterioration of the BW.

In our most recent work, we have tried to determine the fundamental cause of mode splitting. In this project we believe we have been successful. The fundamental cause of mode splitting is easily applied to the width and depth of the burnoff, and to the width (variable or otherwise), amplitude, and frequency of the ripples. The project is incomplete at this time.

# A Comparison of Line Difference Predictions for Time-Frequency Multiplexing of Television Signals

By R. L. SCHMIDT*

(Manuscript received January 27, 1983)

Studies are presented of a scheme utilizing time-frequency multiplexing (TFM) to multiplex two television signals on a microwave radio channel. This scheme transmits alternate lines of the television signal at full bandwidth, along with a differential signal for the remaining lines. The differential signal is derived by subtracting the true value of each picture element from a prediction for that value based on surrounding elements located in the transmitted lines. This differential signal is then placed on a carrier, and frequency multiplexed with the baseband signal. In this way, two television lines of information can be transmitted in one line time, allowing a second similarly constructed signal to be transmitted during the vacated line. Thus, the television signals will be time interleaved on a line-to-line basis. This paper describes the comparison of two different prediction algorithms used to construct the line-differential signal. Time and frequency domain analyses were carried out on the computer and then verified with hardware testing.

## I. INTRODUCTION

Recently, a time-frequency multiplexing (TFM) system was described[1] as a method for multiplexing two National Television System Committee (NTSC) color television signals onto a single microwave radio channel. This system proposes to transmit alternate

lines of a television signal at full bandwidth, and the remaining lines by means of a band-limited line-differential signal formed by using a prediction obtained from adjacent, full bandwidth lines. This differential signal is then placed on a carrier and frequency multiplexed with a full bandwidth television line. In this way two lines are sent in one line period, and, by time multiplexing, two pictures can be sent on a single microwave radio channel.

The reconstructed picture in the receiver is then a combination of alternate lines of full bandwidth video, and lines regenerated from the prediction and the band-limited line-differential signal. Consequently, a more accurate prediction would require less differential signal information. Stated another way, better picture quality can be attained for a given bandwidth limitation of the differential signal. The proposed differential signal band limiting for the TFM system is 3 MHz, and, within this constraint, an improved prediction would allow the transmission of more detailed pictures.

The originally proposed system had a prediction based on an average of adjacent picture elements of the same color subcarrier phase, from the previous and upcoming lines (Fig. 1). These elements were chosen because we did not have to take into account the color subcarrier, making this prediction the simplest to implement. However, since the prediction elements had to be of the same color subcarrier phase, they were not the elements closest to the element being predicted. This would create a larger differential signal on sharp vertical edges. This paper refers to this prediction as $XP_1$, and its associated differential signal as $XDIF_1$.

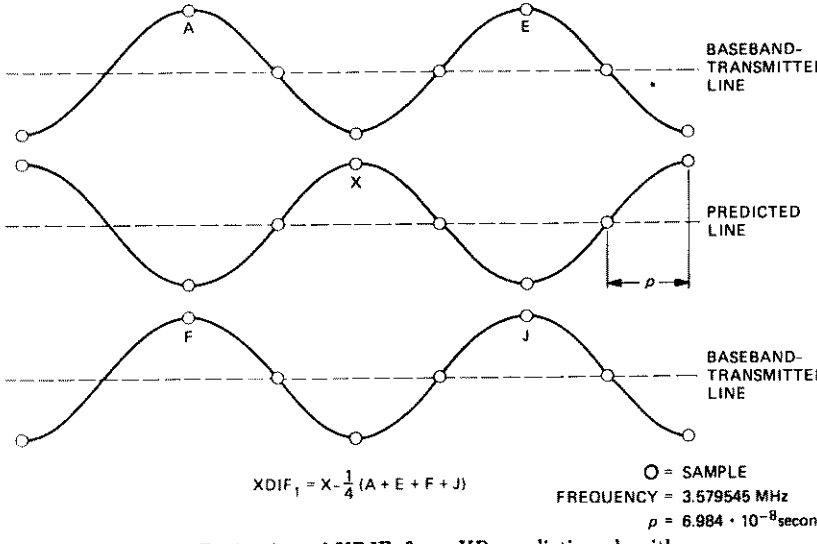

Fig. 1—Derivation of $XDIF_1$ from $XP_1$ prediction algorithm.

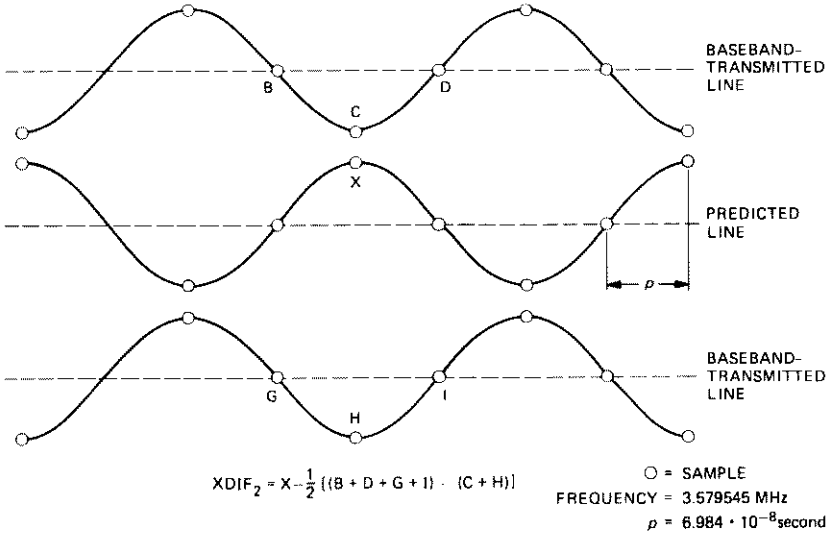

Fig. 2—Derivation of $XDIF_2$ from $XP_2$ prediction algorithm.

It was conjectured that picture quality would improve if we chose a line difference prediction that used the picture elements from the previous and upcoming lines closer to the coded element (Fig. 2), thus improving the resolution of the predicted value on vertical edges. Here we refer to this prediction as $XP_2$ and its associated differential signal as $XDIF_2$.

## II. TIME DOMAIN ANALYSIS

The complexity of the baseband signal, and its quasi-periodic nature, would make analysis of the network response to an average video signal tedious and not very informative. However, since line-to-line correlation is high, some typical waveforms can be looked at and yield useful results.

Since there is a high content of color subcarrier in a typical television waveform, the differential signal should be small for that frequency. This criterion is met for both line difference predictions, and is shown in Appendix A to be zero for any flat field of constant color.

Appendix B shows that if there is color change from one line to the next the worst case differential signal will be the same for both predictions, with the amplitude being an average of the amplitudes of the two color sine waves for the adjacent lines. However, the worst case for each predictor does not occur at the same color subcarrier phase angle.

Along a horizontal line, color changes are almost always accompanied by luminance changes, and, since the bandwidth of the lumi-

nance is much higher than that of the chrominance, the effect of chrominance distortions will be secondary. With regard to luminance changes, three different waveforms are used to demonstrate the difference between the two prediction algorithms. The first waveform considered is the standard $2T$ pulse[2] shown in Fig. 3. This is a sine squared function, and is assumed repetitive from line-to-line. Calculations were done with a computer using the same general approach as shown in Appendices A and B. The results in Fig. 4 show that $XDIF_2$ (dotted line) has a reduced amplitude for both positive and negative directional peaks. In addition, the negative peaks are of shorter duration, resulting in less energy. Although this implies a slightly higher bandwidth, the magnitude of the band-limited signal for $XDIF_2$ is substantially less, indicating a more accurate reconstructed signal in the receiver, with less dependence on the differential signal.

The next waveform considered is the rising edge of the standard bar pulse[2] shown in Fig. 5. This function is represented a follows:

$$f(t) = \begin{cases} 0 & t < 0 \\ 6.4 \cdot 10^6 t & 0 \leq t \leq 156.25 \text{ ns} \\ 1 & t > 156.25 \text{ ns.} \end{cases}$$

Again, line-to-line repetition is assumed, and Fig. 6 shows the response of the two different algorithms. It can be seen that although the amplitudes of both differential signals are the same, the width is less for $XDIF_2$, resulting in less energy. Since the line-differential

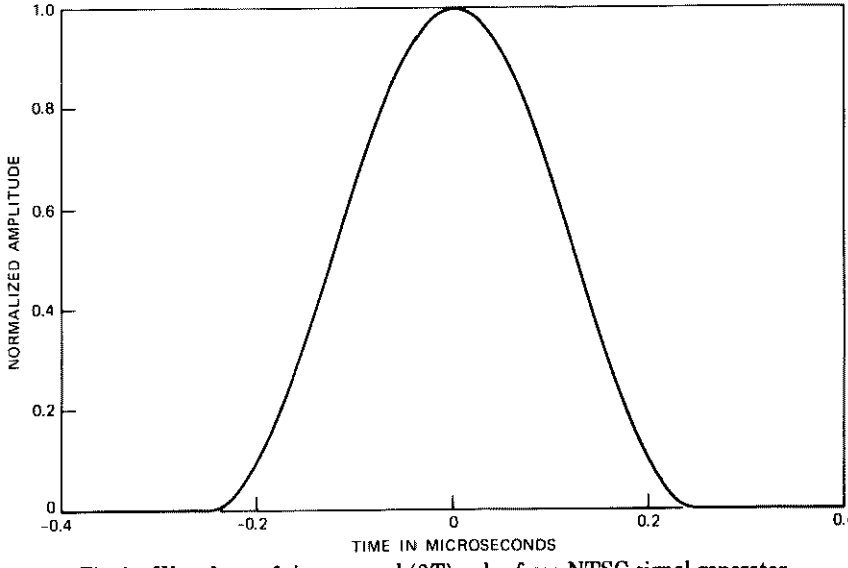

Fig. 3—Waveform of sine squared ($2T$) pulse from NTSC signal generator.

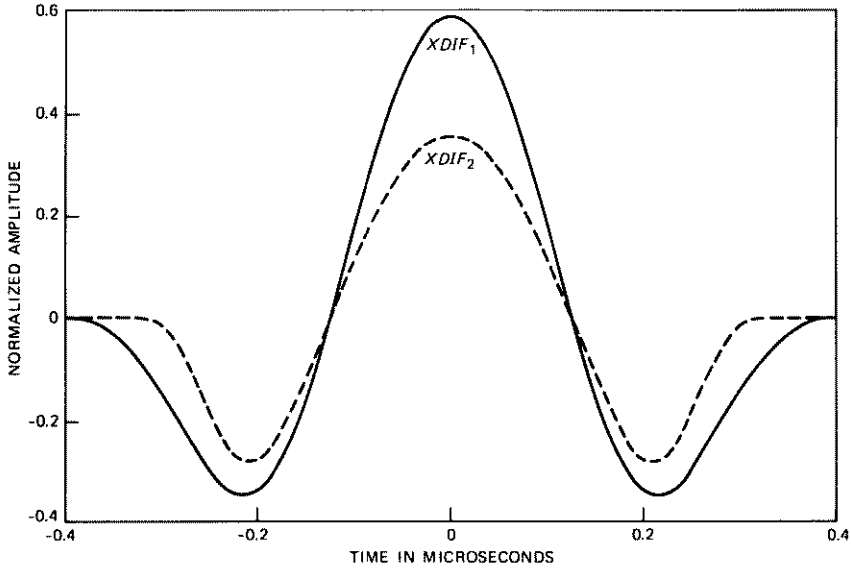

Fig. 4—Differential signal response of both algorithms to sine squared pulse.

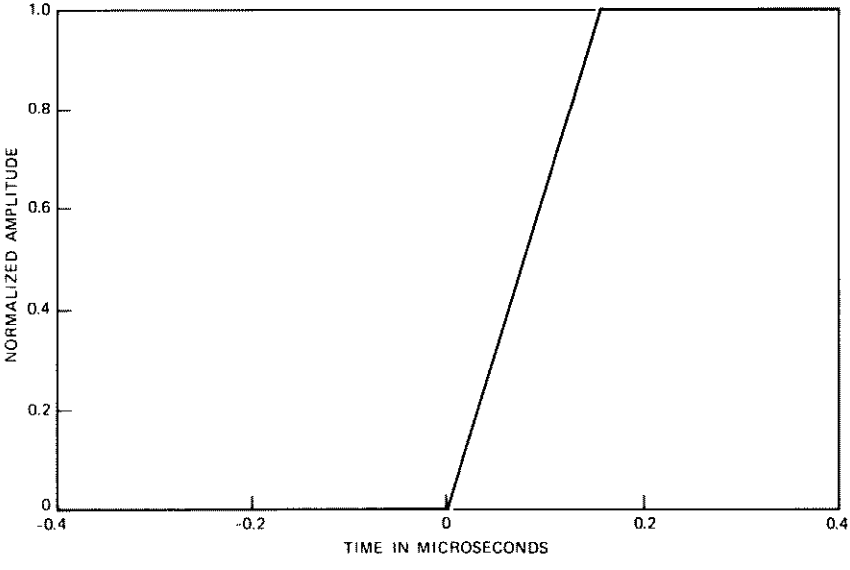

Fig. 5—Rising edge of bar pulse from NTSC signal generator.

signal in the proposed system is band limited to 3 MHz, this will again result in a smaller signal after filtering, with the same advantages as in the previous example.

The next and final waveform evaluated is a raised cosine function

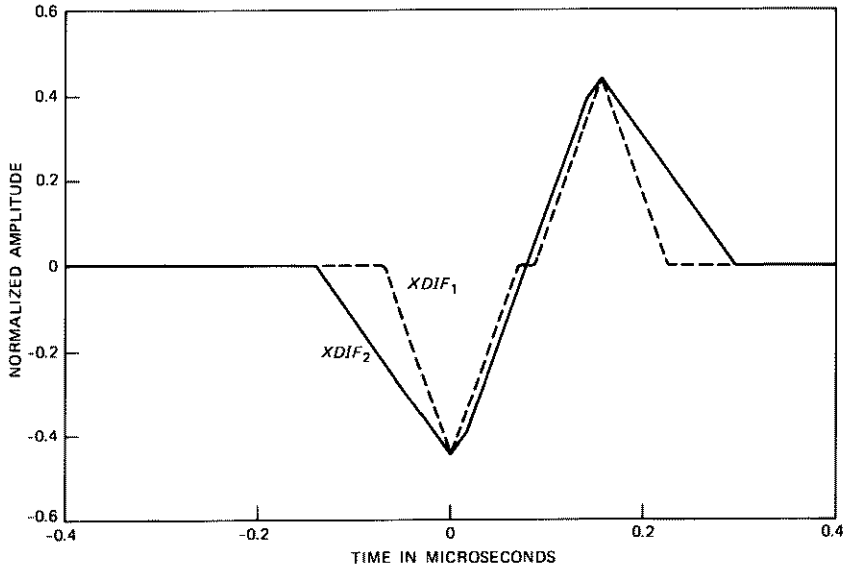

Fig. 6—Differential signal response of both algorithms to rising edge of bar pulse.

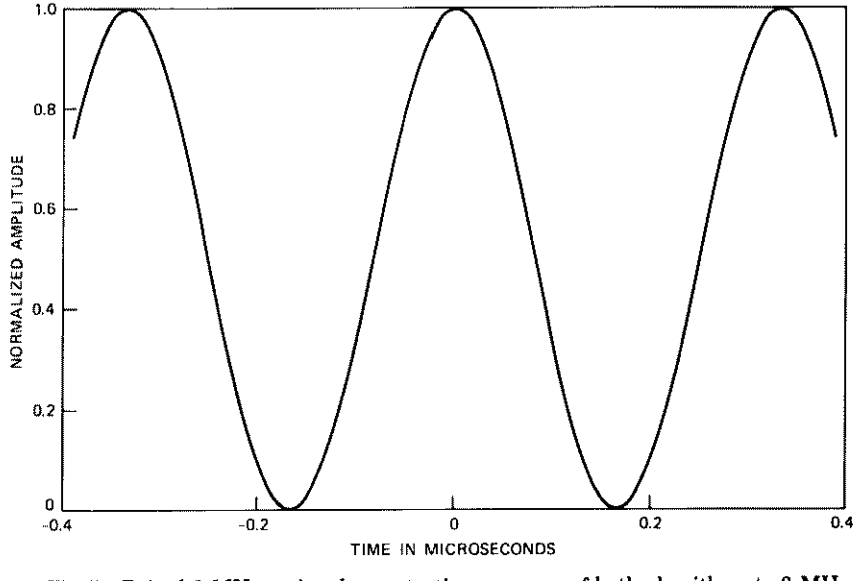

Fig. 7—Raised 3-MHz cosine demonstrating response of both algorithms to 3-MHz section of multiburst test signal.

at a frequency of 3 MHz, shown in Fig. 7. We chose this frequency because it is the intended maximum bandwidth of the differential signal. This would correspond to the fourth burst of the standard multiburst pattern[2] except that, for convenience, the amplitude is set to unity. Again, line-to-line repetition of the signal was assumed, and it can be seen in Fig. 8 that there is a 20-percent decrease in signal amplitude with $XDIF_2$. This again indicates a better reconstruction of the signal in the receiver with the available full bandwidth information.

## III. FREQUENCY DOMAIN ANALYSIS

Before going into the analysis of the two predictors in the frequency domain, it will be useful to look at the frequency spectrum of a typical video signal.

It is well known[3] that the energy of a typical video luminance signal is concentrated on the harmonics of the horizontal or line sweep frequency $F_H$ (≈15734 Hz). This means that most of the luminance energy of the video signal is distributed at multiples of $F_H$ along the frequency axis. The chrominance information also peaks at line frequency intervals, and, by placing the color subcarrier $F_c$ at an odd multiple of half the line frequency, i.e., $F_c = 455/2 \cdot F_H$, the chrominance information will be interleaved with luminance information peaks.

Chrominance information bandwidth is approximately 1.5 MHz, but, with the composite signal band-limited to 4.2 MHz, it results in

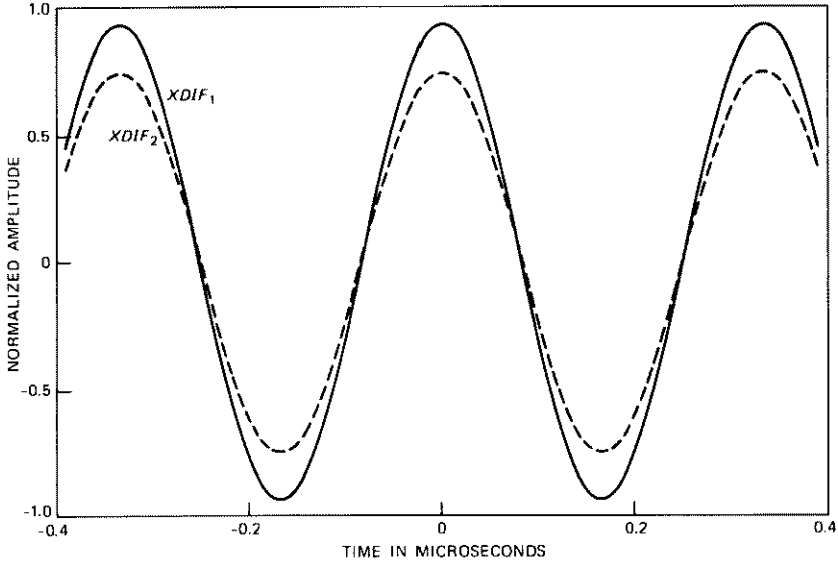

Fig. 8—Differential signal response of both algorithms to 3-MHz raised cosine.

a chrominance bandwidth of 1.5 MHz below the color subcarrier and 0.5 MHz above. Figure 9 shows the spectrum of a chrominance-modulated linear ramp test pattern. Figure 9a is the 0- to 4-MHz spectrum that shows the luminance information at low frequencies and the chrominance centered about $F_c = 3.579 \cdots$ MHz. Figure 9b shows the fundamental and the first nine harmonics of the line frequency, and Fig. 9c shows the color subcarrier and the line multiples on either side of it. It can be seen in this third photograph, also, that the luminance information (which peaks halfway between the chrominance peaks) is much lower than the chrominance at this frequency for this waveform.

The ideal frequency response of the linear system that produces the differential signal would then require that the differential signal be zero at even intervals of half the line frequency for the lower frequencies, and zero at odd intervals of half the line frequency for frequencies around the color subcarrier. Where the transition from odd to even intervals of half the line frequency should occur is not exactly defined, but it should not be lower than the lowest chrominance component, i.e., color subcarrier frequency minus the chrominance bandwidth, or approximately 2.08 MHz. In fact, the ideal value is picture dependent and, more exactly, would depend on the relationship between the luminance high-frequency content and the chrominance information content.

## IV. FREQUENCY DOMAIN COMPARISON

It is well known from circuit theory that, in a linear system with input $x(t)$, output $y(t)$, and impulse response $h(t)$,

$$Y(j\omega) = H(j\omega) \cdot X(j\omega),$$

where uppercase letters designate Fourier Transforms. Since the time relationship of the differential predictors is known, the frequency domain representation of the network $H(j\omega)$ can be found easily, and this process is shown in Appendix C for both the original and the new predictors.

With the results of these simple calculations, a program was written to plot the network response $|H(j\omega)|$. Figures 10 and 11 show the 0- to 100-kHz response of the original and new differential signal networks, respectively. It can be seen that both signals are zero for the line frequency and its harmonics. Since this is where most of the incoming signal energy is concentrated, both of these algorithms should behave well in this regard.

Figures 12 and 13 show the response of the two algorithms in a 100-kHz interval centered around the color subcarrier. It can be seen that both algorithms are zero at the color subcarrier and are again periodic

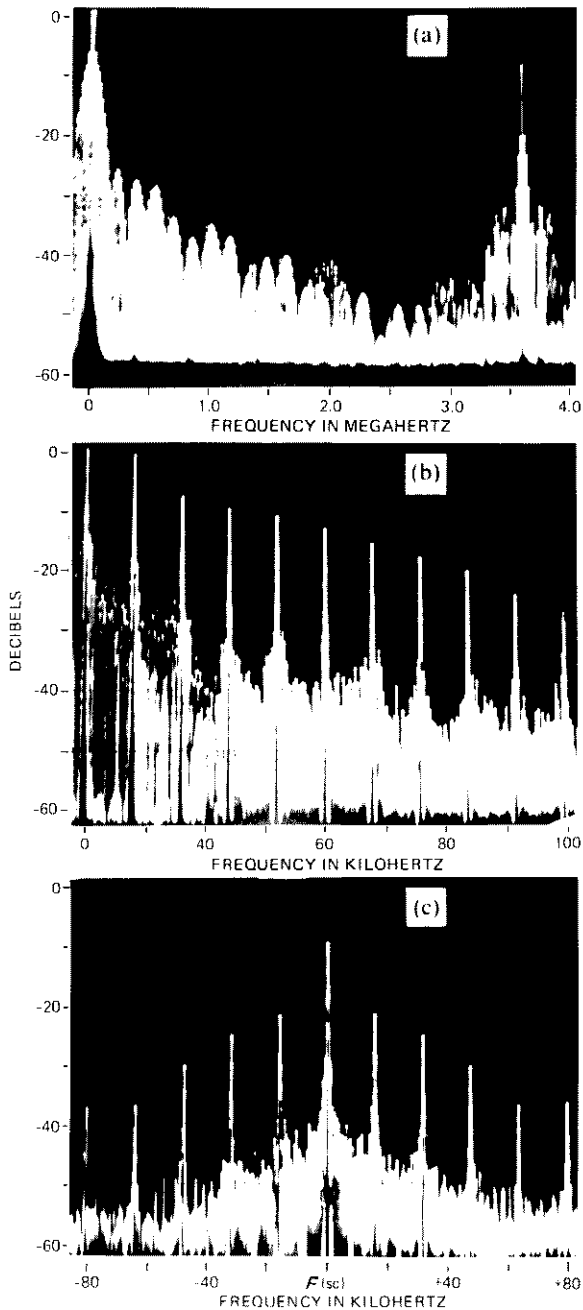

Fig. 9—Spectrum of chrominance-modulated linear ramp test pattern: (a) from 0 to 4.2 MHz; (b) from 0 to 100 kHz, with peaks at even multiples of half the line frequency; and (c) over a 100-kHz band centered around color subcarrier, with peaks at odd multiples of half the line frequency.

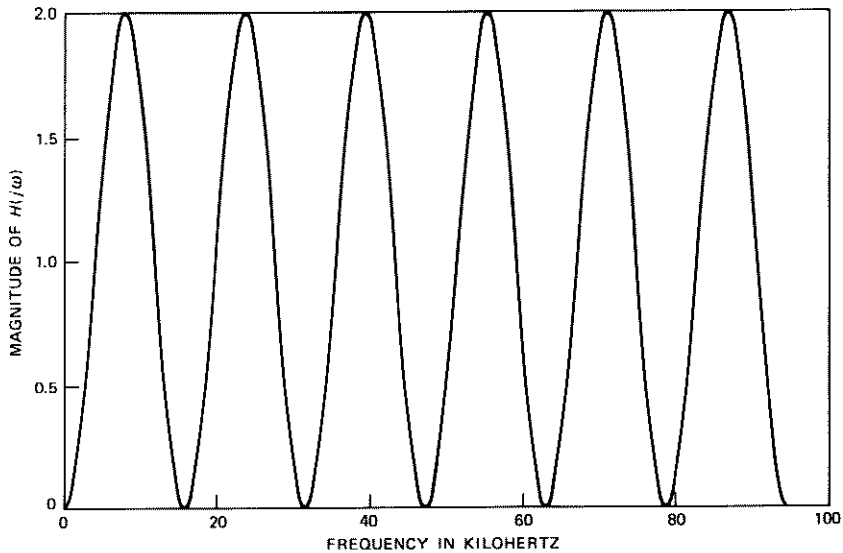

Fig. 10—Calculated differential signal spectrum of $XP_1$ algorithm from 0 to 100 kHz.

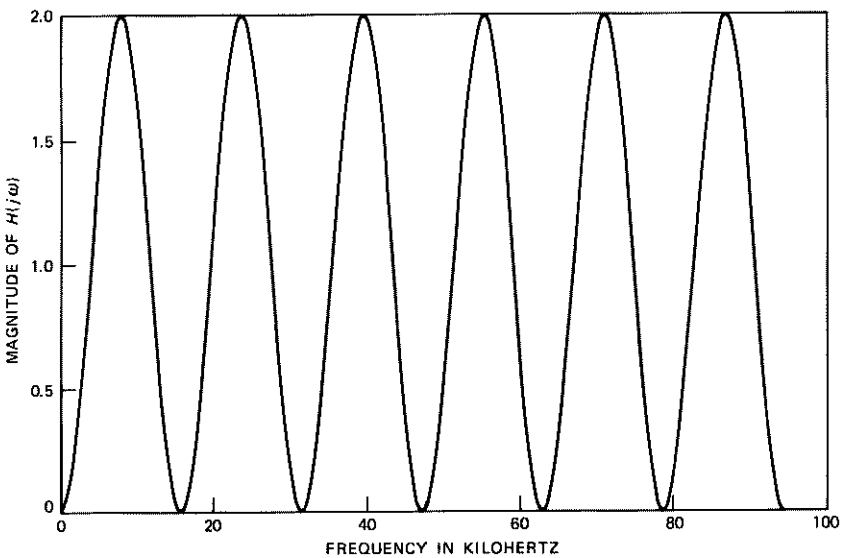

Fig. 11—Calculated differential signal spectrum of $XP_2$ algorithm from 0 to 100 kHz.

at a line rate. Since this corresponds to the high-energy chrominance portions of the incoming signal for this part of the spectrum, both algorithms should again behave well.

The difference in the response of the two algorithms can be seen,

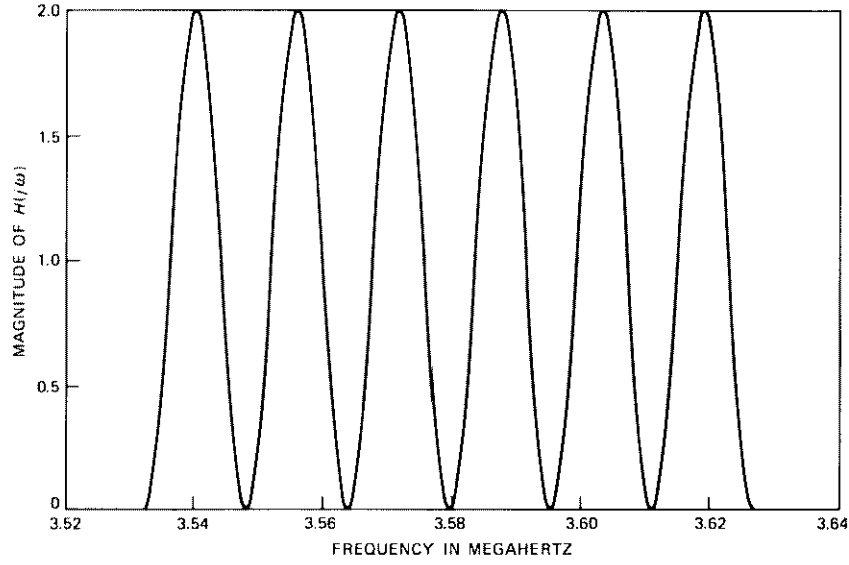

Fig. 12—Calculated differential signal spectrum of $XP_1$ algorithm for 100-kHz window centered around color subcarrier.

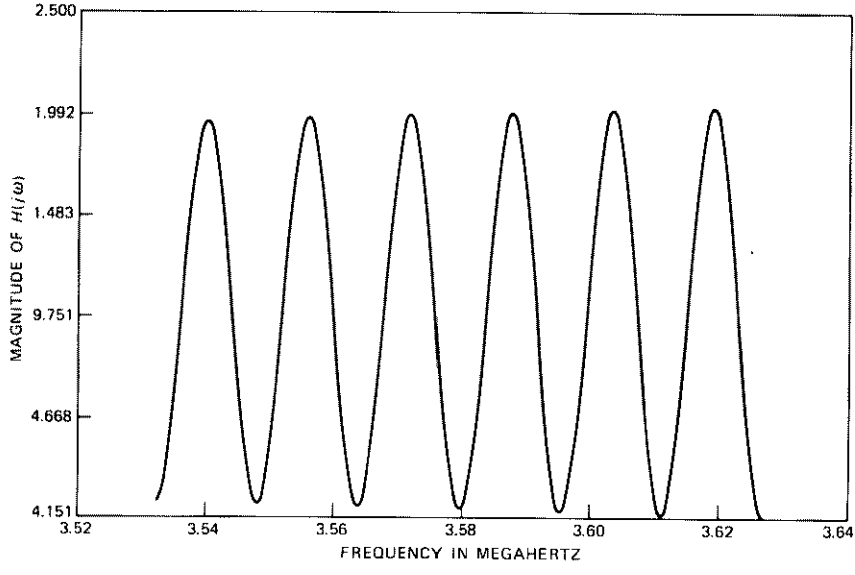

Fig. 13—Calculated differential signal spectrum of $XP_2$ algorithm for 100-kHz window centered around color subcarrier.

however, in Figs. 14 and 15. In these figures the differential signal response is plotted from 0 to 3 MHz, and the oscillatory response pattern is shown with the sine wave minimum values falling on even multiples of half the line frequency in the lower part of the spectrum, and at odd multiples of half the line frequency in the upper part.

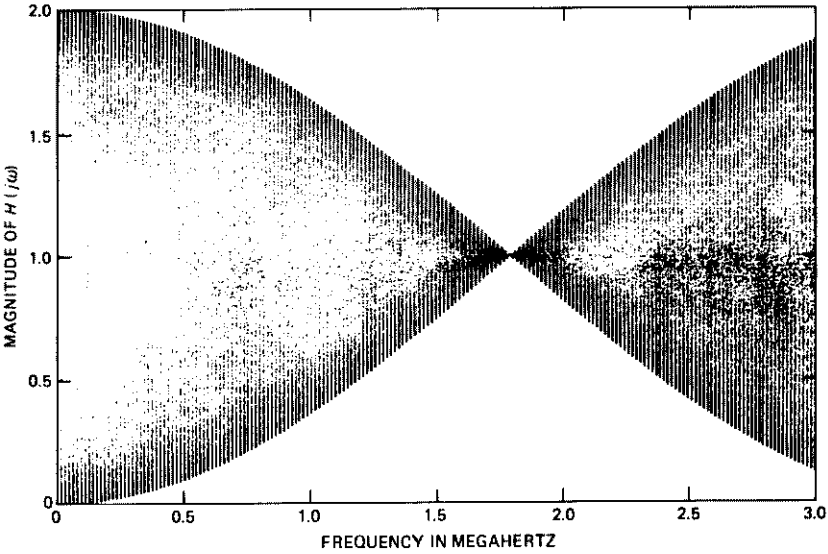

Fig. 14—Calculated differential signal spectrum of $XP_1$ algorithm from 0 to 3 MHz.

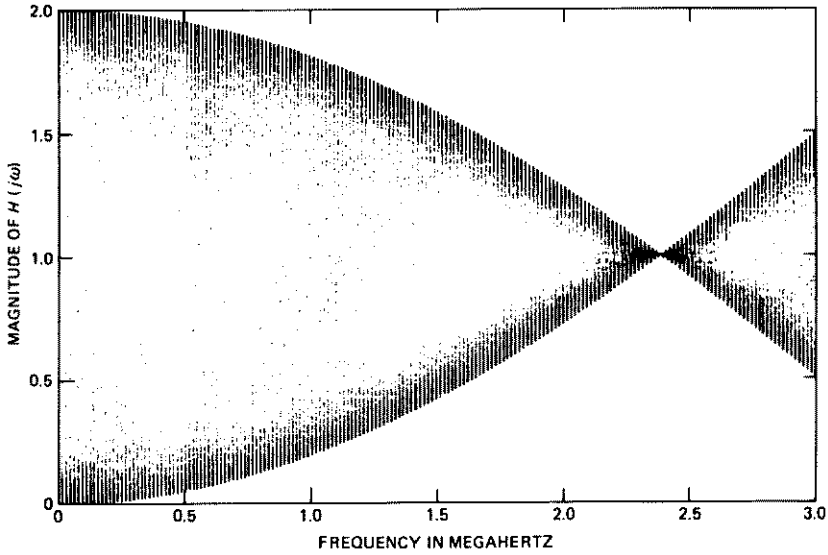

Fig. 15—Calculated differential signal spectrum of $XP_2$ algorithm from 0 to 3 MHz.

Because the lower limit of the chrominance information bandwidth is 2.08 MHz, we can see that the $XDIF_1$ transition is too soon (at about 1.8 MHz). This results in a greater than unity gain for the luminance information in this region and, therefore, a poorer prediction with no resulting savings in chrominance information because it is out of band. The $XDIF_2$ signal, however, is below unity for luminance response until 2.38 MHz, giving a better luminance prediction over an additional 500 kHz of bandwidth. This gives a poorer line difference prediction for the upper 300 kHz of the chrominance band, but since a fast chrominance change is almost always accompanied by a luminance change, the loss should be offset by an improvement in luminance response. Figure 16 plots the envelope for the luminance response and shows that the $XDIF_2$ signal will be lower throughout this whole region, indicating a better line difference prediction. These plots cross over at the color subcarrier, but that is of no concern since the differential signal will be band limited to 3 MHz in the proposed system.

## V. HARDWARE VERIFICATION OF RESULTS

To verify these results, a Tektronix test signal generator was modified so that a sweep generator signal could be added to the flat field test pattern. In this way the system could be analyzed with a full field sine wave input. The differential signal was then put into a spectrum

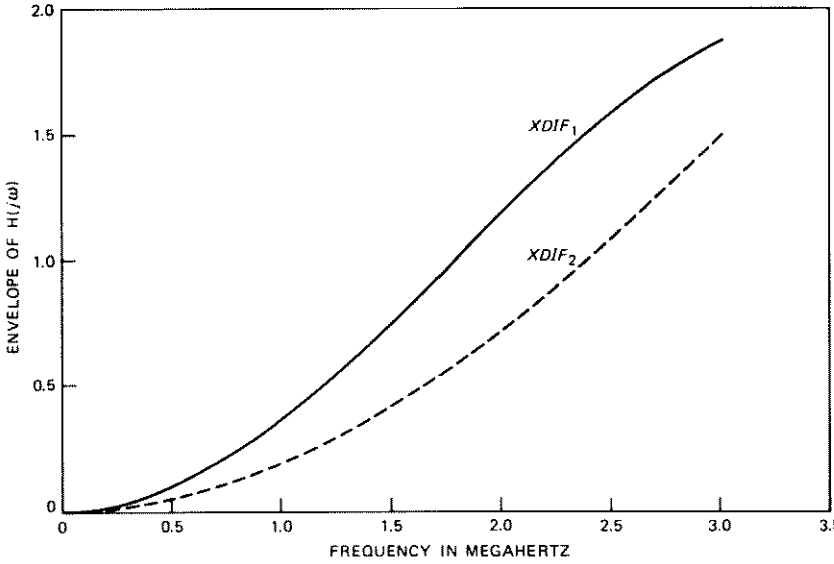

Fig. 16—Envelope of differential signal frequency response for $XP_1$ and $XP_2$, with samples taken at even multiples of half the line frequency.

analyzer. Figure 17 shows photographs of the 0- to 100-kHz spectrum and the 0- to 3-MHz spectrum. The response of the network is identical to the computed values shown in Figs. 10 through 16.

Time domain measurements were also made to verify the results of the analysis of this paper. The measurements were made with the full field pulse bar test pattern from the NTSC test signal generator. The differential signal output was band limited to 3 MHz, which resulted in some deviation from the calculated ideal results. Figures 18a and 18b show the response of the two algorithms to the sine squared pulse. A slight spreading of the signal caused by filtering can be seen, but otherwise the results are quite close to the ideal calculations. Figures 18c and 18d then show the response to the 156.25-ns ramp (bar pulse). Here again the high resolution of the ideal waveforms is lost because of filtering, but the predicted decrease in amplitude is clear.

Subjective tests were then carried out to determine if any degradation in picture quality was visible with either line difference prediction

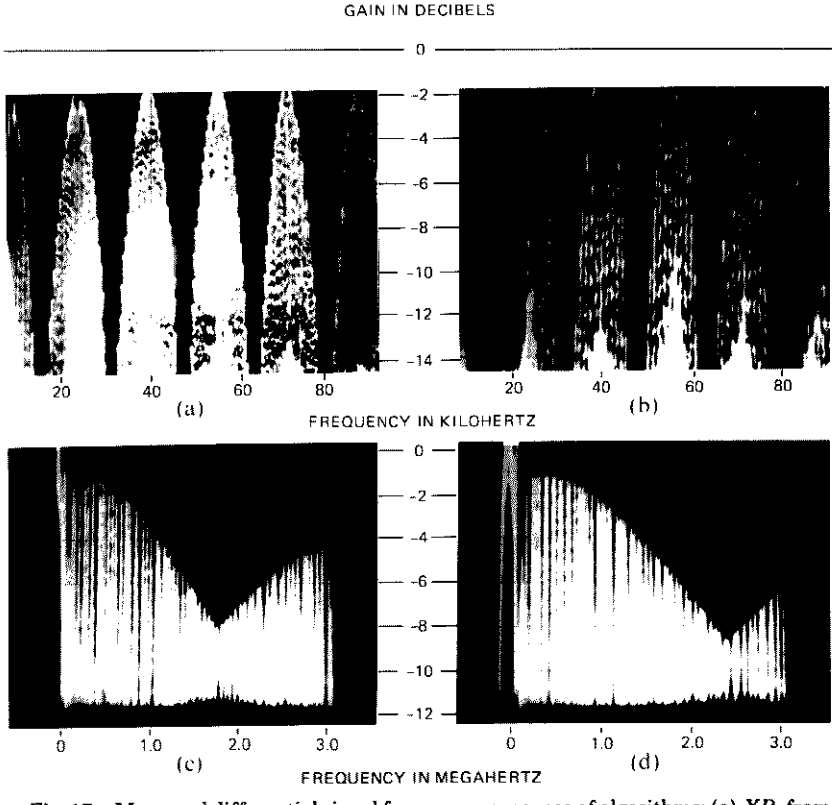

Fig. 17—Measured differential signal frequency responses of algorithms: (a) $XP_1$ from 0 to 100 kHz, (b) $XP_2$ from 0 to 100 kHz, (c) $XP_1$ from 0 to 3 MHz, and (d) $XP_2$ from 0 to 3 MHz.

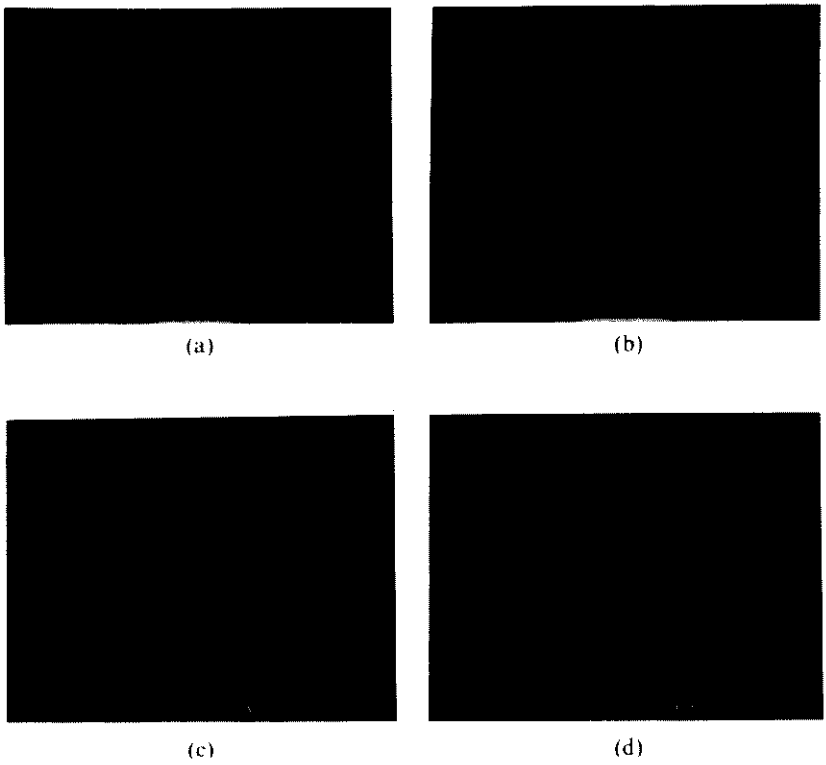

Fig. 18—Measured differential signal time domain responses of both algorithms to the sine for (a) $XP_1$ and (b) $XP_2$. Same responses to rising edge of the bar pulse for (c) $XP_1$ and (d) $XP_2$.

algorithm. To minimize distortion contributions from other hardware sources, so that contributions from the algorithm would be the primary cause of degradation, the TFM hardware was simplified. The band-limited differential signal and the time-multiplexed baseband signals from the transmitter were sent on individual coaxial cables to the receiver. This avoided signal degradations from the frequency multiplexing operation, and also transmission system degradations, leaving only the analog baseband amplifiers and two analog-to-digital-to-analog conversions as additional sources of degradation. Both the transmitter and the receiver use eight-bit pulse code modulation (PCM) for their digital processing, so that these additional contributions should be small in comparison with the differential signal band limiting. A block diagram of the test configuration is shown in Fig. 19.

Several video signals were evaluated using a stringent comparison between the reconstructed video signals and one which is unimpaired except for the two analog-to-digital conversions. The signals were switched on the same television monitor during the vertical blanking

intervals so that switching transitions were only visible when coding caused degradation. A toggle switch in both the transmitter and receiver allowed selection of either algorithm. The television monitor used for this evaluation did not contain a comb filter, so there is a possibility that some degradation caused by coding was masked by the luminance component band limiting. However, since both algorithms were evaluated with the same constraints, this did not appear to be a problem.

Results showed that with normal off-the-air video signals both algorithms performed well, and neither one produced any visible degradation. However, with electronically generated test patterns and text, the degradation of high-frequency signals, such as the $2T$ pulse, the multiburst pattern, and character edges, was less severe with the new algorithm.

## VI. CONCLUSIONS

Subjective tests verified the results of this analysis. Thus, the quality of a picture using the band-limited differential signal is improved with the new algorithm. The implementation is somewhat more difficult than the original one and requires only the addition of two more arithmetic stages. It is, therefore, a practical and desirable change to make in the system.

## APPENDIX A

### *Comparison of Differential Signal Responses to a Constant Color, Flat Field Luminance Video Signal*

Consider a uniform flat field of some color for the $XP_1$ algorithm shown in Fig. 1:

$$XDIF_1 = X - 1/4(A + E + F + J).$$

Let $X = U \cos(2\pi F_c t)$, where $F_c$ = the color subcarrier frequency. Then, since it is a uniform flat field,

$$A = E = F = J = U \cos(2\pi F_c t) = X.$$

Therefore,

$$XDIF_1 = 0 \qquad \text{for all } t.$$

For the $XP_2$ prediction shown in Fig. 2 with the same $X$ as above,

$$XDIF_2 = X - [1/2(B + D + G + I) - 1/2(C + H)].$$

Letting $\omega_c = 2\pi F_c$ we have

$$B = G = U \cos\left(\omega_c t + \frac{\pi}{2}\right),$$

$$D = I = U \cos\left(\omega_c t - \frac{\pi}{2}\right),$$

and

$$C = H = U \cos(\omega_c t + \pi);$$

therefore

$$\begin{aligned} XDIF_2 &= U \cos(\omega_c t) - \frac{U}{2}\left[2 \cos\left(\omega_c t + \frac{\pi}{2}\right)\right. \\ &\qquad \left. + 2 \cos\left(\omega_c t - \frac{\pi}{2}\right) + 2 \cos(\omega_c t)\right] \\ &= U \cos(\omega_c t) - U[-\sin(\omega_c t) + \sin(\omega_c t) + \cos(\omega_c t)] \\ &= U \cos(\omega_c t) - U \cos(\omega_c t) \\ &= 0 \qquad \text{for all } t. \end{aligned}$$

## APPENDIX B

### *Comparison of Differential Signal Responses to an Adjacent Line Color Change, Flat Field Luminance Video Signal*

Now consider a color change with no corresponding luminance change from one line to the next. The change will be considered between lines two and three of the prediction area, although calculations would be identical for a change from line one to two. Let $U$ = magnitude of the first color, $V$ = magnitude of the second color, and $\omega_c = 2\pi F_c$. Then for the $XP_1$ predictor,

$$\begin{aligned} XDIF_1 &= U \cos(\omega_c t) - \left[\frac{U}{2} \cos(\omega_c t) + \frac{V}{2} \cos(\omega_c t + \phi)\right] \\ &= \frac{U}{2} \cos(\omega_c t) - \frac{V}{2} \cos(\omega_c t + \phi), \end{aligned}$$

where the worst case would be for $\phi = \pi$, giving

$$XDIF_1 = \frac{U + V}{2} \cos(\omega_c t).$$

For the $XP_2$ predictor,

$$XDIF_2 = U\cos(\omega_c t) - \frac{1}{2}\left[U\cos\left(\omega_c t + \frac{\pi}{2}\right) + U\cos\left(\omega_c t + \frac{\pi}{2}\right) + V\cos(\omega_c t + \phi) + V\cos(\omega_c t + \pi + \phi) - U\cos(\omega_c t + \pi) - V\cos\left(\omega_c t + \frac{\pi}{2} + \phi\right)\right]$$

$$= U\cos(\omega_c t) - \frac{1}{2}[V\cos(\omega_c t + \phi) - V\cos(\omega_c t + \phi) + U\cos(\omega_c t) + V\sin(\omega_c t + \phi)]$$

$$= U\cos(\omega_c t) - \frac{U}{2}\cos(\omega_c t) - \frac{V}{2}\sin(\omega_c t + \phi)$$

$$= \frac{U}{2}\cos(\omega_c t) - \frac{V}{s}\sin(\omega_c t + \phi),$$

where the worst case will occur when $\sin(\omega_c t + \phi)$ equal $-\cos(\omega_c t)$ or at $\phi$ equal to $-\frac{\pi}{2}$, giving

$$XDIF_2 = \frac{U + V}{2}\cos(\omega_c t),$$

which is the same as for $XDIF_1$.

## APPENDIX C

### *Transfer Function Derivation for Both Prediction Algorithms*

Knowing the time relationship of the picture elements, we can find the Fourier Transform of the impulse responses of the differential signal algorithms. Let $p = 1$ picture element with a duration of $6.98412 \cdot 10^{-8}$ second. Then $910p = 1$ line $= 6.3555 \cdot 10^{-5}$ second.

For the $XP_1$ predictor:

$$XDIF_1(t) = X(t) - \frac{1}{4}[X(t + 908p) + X(t + 912p) + X(t - 908p) + X(t - 912p)],$$

$$XDIF_1(j\omega) = X(j\omega) - \frac{1}{4}[X(j\omega)e^{-j\omega 908p} + X(j\omega)e^{-j\omega 912p} + X(j\omega)e^{+j\omega 908p} + X(j\omega)e^{j\omega 912p}]$$

$$= X(j\omega)\left\{1 - \frac{1}{4}\left[e^{908pj\omega} + e^{-908pj\omega} + e^{912pj\omega} + e^{-912pj\omega}\right]\right\}$$

$$= X(j\omega)\left\{1 - \frac{1}{2}\left[\cos(908p\omega) + \cos(912p\omega)\right]\right\}$$

$$= X(j\omega)\cdot H(j\omega),$$

with

$$H(j\omega) = 1 - \tfrac{1}{2}[\cos(908p\omega) + \cos(912p\omega)].$$

Now for the $XP_2$ predictor:

$$\begin{aligned} XDIF_2(t) = X(t) &- \{1/2[X(t-911p) + X(t-909p) + X(t+909p) \\ &+ X(t+911p)] - 1/2[X(t-910p) + X(t+910p)]\}, \\ XDIF_2(j\omega) = X(j\omega) &- \{1/2[X(j\omega)e^{+911pj\omega} + X(j\omega)e^{+909pj\omega} \\ &+ X(j\omega)e^{-909pj\omega} + X(j\omega)e^{-911pj\omega}] \\ &- [X(j\omega)e^{910pj\omega} + X(j\omega)e^{-910pj\omega}]\} \\ = X(j\omega)\{1 &- [(e^{909pj\omega} + e^{-909pj\omega}/2) + (e^{911pj\omega} + e^{-911pj\omega}/2) \\ &- (e^{910pj\omega} + e^{-910pj\omega}/2)]\} \\ = X(j\omega)\{1 &- [\cos(909pj\omega) + \cos(911pj\omega) - \cos(910pj\omega)]\}. \end{aligned}$$

Therefore,

$$H(j\omega) = 1 + \cos(910pj\omega) - \cos(909pj\omega) - \cos(911pj\omega).$$
