equilibrium as well; that is, certain characteristics of the system are not changing. This is to be contrasted with a model proposed by Nucho in which transient analysis is fundamental.[1] The primary difference between these models is that the demand rate for new circuits is a function of the number of active circuits in the Nucho model, whereas it is considered to be an exogenous variable here. In the Nucho model, the variance to mean ratio of the number of active circuits increases indefinitely with time (since fluctuations tend to feed on themselves); in the model considered here this ratio remains constant. Another difference between the models is that the model described here allows an order to be for more than one circuit.

Here, we assume that (1) the arrivals of special-service circuit orders are given by a nonhomogeneous Poisson process with exponentially growing intensity, (2) each order is for a random number of circuits (a batch) with arbitrary distribution, and (3) the lifetime of an order is an exponentially distributed random variable, during which time the number of held circuits per order remains constant. Note that the last assumption implies that an order lifetime and a circuit lifetime have the same distribution.

We use three important parameters in special-services modeling, each with its own physical interpretation. These parameters may be described as growth rate, disconnect rate (per circuit), and batchiness.

The growth rate summarizes the rate at which the mean number of active circuits increases with time. It may be expressed in terms of proportion increase per unit of time; we denote it $\beta$. Thus the mean number of circuits at time $t$ is proportional to $e^{\beta t}$. We actually assume that connect activity grows at rate $\beta$, but it turns out that the number of active circuits, the total connect rate, and the total disconnect rate are all proportional to $e^{\beta t}$ in this model. Of course, for small growth rates or short periods of time, exponential growth is very close to linear growth.

The disconnect rate, denoted $\mu$, is the ratio of the number of disconnects per unit time (i.e., the total disconnect rate) to the number of active circuits. The mean circuit lifetime is then $1/\mu$. The distributions of circuit lifetimes have been shown to be well approximated by negative exponential distributions;[2] thus the disconnect rate does not vary with the age of a circuit.

The batchiness of the arrival process is related to the tendency of special service circuits to be ordered in multiples greater than one. We call the batchiness parameter $\nu$ and define it to be the ratio of the second moment to the first moment of the number of circuits in an order.

The ultimate goal of this modeling process is to provide a tool that can be used to predict special-services needs in the future. The model

contained herein should be very useful in this regard. One should remember that the underlying process is stochastic so that there is a fundamental uncertainty even if one has exact specification of the parameters of the model. The standard deviation of future requirements can be quite large compared to the mean for small circuit groupings, and this presents a major problem for provisioning at the most detailed level. This problem cannot be surmounted with a better model and/or additional data collection. The present analysis allows quantification of the fundamental uncertainty of forecasting, an insight which is difficult to obtain purely by statistical methods. The only possible method to further decrease relative uncertainty is to aggregate demand, or to obtain advance knowledge of connect or disconnect activity (sometimes called "deterministic events").

The rest of the paper is organized as follows: Section II summarizes the important results of the paper, giving formulae for the means and variances of the number of active circuits in the future, the total number of connects in a future interval, and the total number of disconnects in a future interval; and giving statistical methods to estimate the fundamental parameters of the model such as growth rate, disconnect rate, and batchiness. The reader not interested in the derivation of these results may stop at this point.

The predictions (summarized in Section II) of the model are derived in Section IV. These derivations are primarily substitutions into formulae given in Section III. Section III describes and analyzes a much more general model than the one described in this introduction (we refer to the latter simply as "the model"). We have chosen to introduce this generalized model for two reasons. First, the analysis required for the treatment of the generalized model is little different in complexity from that required for treatment of the specific model. Second, the general results of Section III allow rapid exploration of the consequences of changes in assumptions of the model. For example, one can explore the effects of linear growth of demand, or the super-exponential growth in demand which follows introduction of a new service. However, we do feel that the original assumptions are appropriate in most circumstances. Thus, the consequences of this model are the only ones summarized in Section II, and it is this specific model which is being verified with respect to the New Jersey Bell Telephone Co. database. Thus, Section III is provided for reference in case of non-typical special service applications.

Section V derives the statistical methods (summarized in Section II) for estimation of the fundamental parameters of the model. Section VI is a summary.

Appendix A gives background information on the compound Poisson random variable, and Appendix B gives background information on

the non-homogeneous Poisson process. These results are needed in Sections III and IV.

Table I presents values of a function useful in estimating growth (see Section II) and Table II lists the notation used in the paper.

## II. SUMMARY OF KEY RESULTS

This section provides a summary of the important results of the paper derived in Sections IV and V.

### *2.1 Churn*

Our model depends on three physical parameters: growth rate ($\beta$), disconnect rate ($\mu$), and batchiness ($\nu$). The meaning of these parameters is described in Section I. Another physical parameter is "churn," which has been defined in many different ways. For any reasonable definition, the churn is determined by the growth and disconnect rates of the model. We define the churn to be the minimum of the disconnect rate per circuit and the connect rate per circuit, and denote it by $\gamma$. With this definition, it can be shown [see (75)] that

$$\gamma = \min(\mu, \mu + \beta). \tag{1}$$

The values of churn under other definitions are also readily available. For example, if one defines churn to be the ratio of the average total connect rate to the average rate of change of net active circuits, then this value of churn is $(1 - \gamma)^{-1}$. Under still another definition, the churn equals $\mu/(\mu + \beta)$.

### *2.2 Mean and variance of total active circuits at a future time*

Here we give the mean $M(t)$ and the approximate variance $V(t)$ of the number of circuits in service at a given time $t$ in the future. The mean and the variance depend on the present (at time $t = 0$) number $k$ of circuits in service, the present instantaneous rate $D_o$ of circuit demand due to new orders, and the three key parameters described previously: $\beta$, $\mu$, and $\nu$. We give these two relationships below:

$$M(t) = ke^{-\mu t} + \frac{D_o}{\mu + \beta}(e^{\beta t} - e^{-\mu t}), \tag{2}$$

and

$$V(t) = \nu\left[ke^{-\mu t}(1 - e^{-\mu t}) + \frac{D_o}{\mu + \beta}(e^{\beta t} - e^{-\mu t})\right]. \tag{3}$$

It is interesting that (2) and (3) together imply the relationship

$$V(t) = \nu(M(t) - ke^{-2\mu t}), \tag{4}$$

which relates the variance of a forecast to the mean of the forecast, the number of circuits currently active, $k$, and the parameters $\nu$ and $\mu$.

### 2.3 Mean and variance of the total number of connected or disconnected circuits in the future

Similar results are available for the mean and variance of the total number of connected circuits (variables subscripted with a $C$) and the mean and variance of the total number of disconnected circuits (subscripted with a $D$) in an interval of length $t$ beginning immediately:

$$M_C(t) = \frac{D_o}{\beta}(e^{\beta t} - 1), \tag{5}$$

$$V_C(t) = \nu \frac{D_o}{\beta}(e^{\beta t} - 1) = \nu M_C(t) \tag{6}$$

$$M_D(t) = k(1 - e^{-\mu t}) + \frac{D_o \mu}{\beta(\mu + \beta)} e^{\beta t} + \frac{D_o}{\mu + \beta} e^{-\mu t} - \frac{D_o}{\beta}, \tag{7}$$

and

$$V_D(t) = \nu \left\{ k e^{-\mu t}(1 - e^{-\mu t}) + \frac{D_o \mu}{\beta(\mu + \beta)} e^{\beta t} + \frac{D_o}{\mu + \beta} e^{-\mu t} - \frac{D_o}{\beta} \right\}$$
$$= \nu(M_D(t) - k e^{-2\mu t}). \tag{8}$$

In this case, the total numbers of connected and disconnected circuits are dependent random variables.

We may also obtain the coefficient of correlation $\rho$ between the number of active circuits at different times

$$\rho[Y(t),\ Y(t + \tau)] = e^{-(\mu + \beta/2)\tau}, \tag{9}$$

where $Y(t)$ is the number of active circuits at time $t$.

### 2.4 Estimation of the model parameters

To use results such as (2) through (9), we must be able to estimate the parameters $\beta$, $D_o$, $\nu$, and $\mu$. These questions are addressed in Section V; we provide a brief summary here. Suppose that the system has been observed over the interval $[-\Theta, 0]$ and $n$ connect orders are observed at times $t_1, \ldots, t_n$. Form the statistic

$$S = \sum_{i=1}^{n} t_i / n\Theta + 1, \tag{10}$$

and then the maximum likelihood estimator $\hat{\beta}$ for the growth rate $\beta$ is

$$\hat{\beta} = \frac{1}{\Theta} f^{-1}(S), \tag{11}$$

where $f$ is the function given in (79). Values of $f^{-1}$ are available in Table I. Once $\hat{\beta}$ has been obtained from (11), the estimator $\hat{D}_o$ for the *instantaneous* present demand $D_o$ (assumed to be at the end of the interval of observation $[-\Theta, 0]$) is

$$\hat{D}_o = \frac{n\hat{\beta}}{1 - e^{-\hat{\beta}\Theta}} \hat{N}, \tag{12}$$

where $\hat{N}$ is an estimator for the average number of circuits per order and is equal to the average number of circuits actually observed per order. The estimator $\hat{\nu}$ for the batchiness $\nu$ of the order size is

$$\hat{\nu} = \frac{\sum_{k=1}^{\infty} k^2 i_k}{\sum_{k=1}^{\infty} k i_k}, \tag{13}$$

where $i_k$ is the observed number of existing orders of size $k$. The estimator $\hat{\mu}$ for the parameter $\mu$ can be obtained as the average disconnect rate for observed circuits

$$\hat{\mu} = \frac{m}{\tau}, \tag{14}$$

where $m$ is the total number of disconnects observed, and $\tau$ is the sum of the observed connection times for all circuits; $\mu$ can also be obtained from estimators of the churn and growth rate through the use of (1).

Estimation of these parameters from data supplied by New Jersey Bell Telephone Co. is being investigated. Estimates of the disconnect rate $\hat{\mu}$ by service family are available in the Reed and Smith paper,[2] in which it is shown that the lifetimes of special-service circuits are well approximated by exponential functions with means dependent on the service families.

## III. A GENERALIZED MODEL

This section treats a model that is more general than that which we propose for special-service activity in most cases. The analysis presented here will be applied to the specific model in Section IV.

### *3.1 Description of the generalized model*

We examine an arbitrarily defined category of special-service circuits (for example, circuits of a particular service family in a given

wire center) and divide the active circuits into independent groups. Possibly, each group is the demand from a single user, since it is reasonable that the activity of one user does not affect another. To facilitate this method of thinking we shall refer to the groups as "orders." Each order becomes nonzero for the first time at some point in time (referred to as the arrival or connect time of the order) and then has some history of changing size in some arbitrary manner before possibly becoming zero again indefinitely at some time (the departure or disconnect time of the order). The length of the interval between the arrival and departure of an order will be called the lifetime of the order. Obviously, the number of active circuits at any time equals the sum of the sizes of the existing orders at that time.

We assume that there is a large pool of customers (or potential orders) so that the arrival of an order has little effect on the potential arrival of others. Thus, the arrival of orders can be modeled by a nonhomogeneous Poisson process, whose intensity at time $t$ is given by some function $\lambda(t)$. For background on this process see Ross[3] or Karlin and Taylor.[4] Denote the probability that an arriving order at time $t$ is initially of size $m$ as $q_m(t)$, and let $P^*_{mn}(t, x)$ be the probability that an order arriving at time $t$ of initial size $m$ as becomes size $n$ at time $x \geq t$.

### 3.2 Distribution of the number of active circuits at a given time

Since the orders are noninterfering it can easily be seen (see Appendix B) that the number of orders of size $n$ at time $x$ is Poisson distributed with mean $\alpha_n(x)$, where

$$\alpha_n(x) = \sum_m \int_{-\infty}^{x} \lambda(t) q_m(t) P^*_{mn}(t, x) dt, \tag{15}$$

and that the numbers of orders of different sizes at time $x$ are independent of each other. If $Y(x)$ is the total number of active special-services circuits in the category of interest at time $x$, then $Y(x)$ has a compound Poisson distribution (see Appendix A), and

$$E[Y(x)] = \sum_{n=1}^{\infty} n\alpha_n(x), \tag{16}$$

and

$$\text{var}[Y(x)] = \sum_{n=1}^{\infty} n^2\alpha_n(x). \tag{17}$$

### 3.3 Distribution of future active circuits due to present orders

The transient behavior of this model is easily derived if one has knowledge of the distribution of *order sizes* at a given time. We treat

this case first and then consider the more difficult case where only the total number of *active circuits* at a given time is known. In either case, we will find the distribution of the number of active circuits at time $y$ resulting from the orders observed to be active at time $x$. The total circuits active at time $y$ is the sum of this with the number of circuits at time $y$ resulting from orders arriving between $x$ and $y$.

### *Case 1: Order sizes known*

Given an order is of size $n$ at time $x$, the conditional density that it arrived as an order of size $m$ at time $t$ is $\rho_{mn}(t, x)$, where

$$\rho_{mn}(t, x) = \frac{\lambda(t)q_m(t)P^*_{mn}(t, x)}{\alpha_n(x)} \tag{18}$$

and if several orders of size $n$ are present at $x$ their arriving times and sizes may be considered to be conditionally independent (see Appendix B). Thus an order of size $n$ at time $x$ becomes an order of size $l$ at time $y \geq x$ with probability $r_{nl}(x, y)$ where

$$r_{nl}(x, y) = \alpha_n^{-1}(x) \sum_{m=1}^{\infty} \int_{-\infty}^{x} \lambda(t)q_m(t)P^*_{mn}(t, x)q_{mnl}(t, x, y)dt, \tag{19}$$

and $q_{mnl}(t, x, y)$ is the conditional probability that an order arriving as size $m$ at time $t$ which is of size $n$ at time $x$ becomes size $l$ at time $y$. Note that $q_{mnl}$ is not available solely from $P^*$.

Equation (19) allows us to compute the distribution of the total number of circuits at time $y$ that were due to orders *observed* at time $x$, since all orders behave independently. Evaluating these distributions explicitly can be quite difficult. We can, however, easily evaluate the moments. Let $M_n(x, y)$ be the mean order size at time $y$ for an order observed to be size $n$ at time $x$, and let $V_n(x, y)$ be the mean order size at time $y$ for an order observed to be size $n$ at time $x$, and let $V_n(x, y)$ be the analogously defined variance. Then

$$M_n(x, y) = \sum_{l=1}^{\infty} l r_{nl}(x, y), \tag{20}$$

$$V_n(x, y) = \sum_{l=1}^{\infty} l^2 r_{nl}(x, y) - M_n^2(x, y). \tag{21}$$

If $i_n(x)$ is the number of orders of size $n$ observed at time $x$, and $M(x, y)$ and $V(x, y)$ denote the mean and variance of the number of circuits at time $y$ due to orders observed at time $x$, then

$$M(x, y) = \sum_n i_n(x)M_n(x, y), \tag{22}$$

and

$$V(x, y) = \sum_n i_n(x) V_n(x, y). \tag{23}$$

Note that there is a potential problem if orders can become size zero and then become nonzero later, since determination of $i_0$, the number of active orders of size 0, may be an impossible task.

***Case 2: Order sizes unknown***

We now examine the more difficult case where we observe the total number of active circuits at time $x$ (call this $k$), without observing the distribution of the order sizes. The conditional probability that there are $j_1$ orders of size 1, $j_2$ orders of size 2, etc., given that $k$ total circuits are observed at time $x$, written $\delta_{k,x}(j_1, j_2, \ldots)$, is easily found to be

$$\delta_{k,x}(j_1, j_2, \ldots) = \frac{\prod_i [\alpha_i(x)^{j_i}/j_i!]}{\sum_{j_1+2j_2+\cdots=k} \prod_i [\alpha_i(x)^{j_i}/j_i!]}, \tag{24}$$

provided that $j_1 + 2j_2 + \cdots = k$. Let the conditional first and second moment of the number of circuits at time $y$ due to orders observed at time $x$, given that a total of $k$ circuits were observed at time $x$, be $M_{k,x}(y)$ and $M^{(2)}{}_{k,x}(y)$ respectively. Then

$$M_{k,x}(y) = \sum E(J_i) M_i(x, y), \tag{25}$$

where $J_i$ is a random variable with the same distribution as the conditional number of orders of size $i$ at time $x$, so that the expectation is the expectation with respect to the probability distribution given in eq. (24). Also,

$$M^{(2)}_{k,x}(y) = \sum E(J_i) V_i(x, y) + E((\sum J_i M_i(x, y))^2), \tag{26}$$

where the expectation is in the same sense as before. Needless to say, these expectations with respect to the distribution in (24) are very difficult to evaluate for substantial $k$.

Things simplify somewhat if

$$M_i(x, y) = i\theta(x, y), \tag{27}$$

that is, if the conditional means are proportional to the size of the order. In this case, (25) and (26) give

$$M_{k,x}(y) = k\theta(x, y), \tag{28}$$

and

$$M^{(2)}_{k,x}(y) = \sum E(J_i) V_i(x, y) + k^2\theta^2(x, y), \tag{29}$$

so that

$$V_{k,x}(y) = \sum E(J_i) V_i(x, y), \tag{30}$$

where $V_{k,x}(y)$ denotes the conditional variance. Equation (30) can be approximated by using the following approximation which is intuitively reasonable for $k$ near $\sum i\alpha_i(x)$,

$$E(J_i) \approx k \frac{\alpha_i(x)}{\sum i\alpha_i(x)}. \tag{31}$$

In this case, (30) and (31) give the following useful approximation:

$$V_{k,x}(y) \approx k \frac{\sum \alpha_i(x) V_i(x, y)}{\sum i\alpha_i(x)}. \tag{32}$$

### 3.4 Distribution of future active circuits due to future orders

In section 3.3, we found the mean and the variance of the number of circuits at time $y$ from orders observed at time $x$. To obtain the total number of circuits at time $y$, we need to add to this the (independent) number of circuits due to orders arriving between time $x$ and time $y$. The number of orders of size $n$ at time $y$ that arrived between times $x$ and $y$ is easily seen to be Poisson with mean $\alpha_n(x, y)$, where

$$\alpha_n(x, y) = \sum_{m=1}^{\infty} \int_x^y \lambda(t) q_m(t) P^*_{mn}(t, y) dt, \tag{33}$$

and the number of orders of different sizes are independent of each other (see Appendix B). Thus, the number of circuits at time $y$ due to arrivals occurring between $x$ and $y$ has a compound Poisson distribution (see Appendix A) with mean and variance denoted $M^*(x, y)$ and $V^*(x, y)$, where

$$M^*(x, y) = \sum_n n\alpha_n(x, y), \tag{34}$$

and

$$V^*(x, y) = \sum_n n^2\alpha_n(x, y). \tag{35}$$

### 3.5 Mean and variance of future active circuits

To find expressions for the mean or variance of the total number of active circuits at time $y$, we merely add together the appropriate means or variances from the circuits active at time $y$ due to orders observed at time $x$ and from the circuits active at time $y$ due to arrivals between $x$ and $y$, since these are independent. For example, eqs. (28) and (34) give

$$M^T_{k,x}(y) = k\theta(x, y) + \sum_n n\alpha_n(x, y), \tag{36}$$

where $M^T_{k,x}(y)$ is the total mean number of circuits observed at time $y$ given $k$ circuits are observed at time $x$ [and assuming relationship (27)]. Also, eqs. (32) and (35) give the following approximation:

$$V^T_{k,x}(y) \approx k \frac{\sum \alpha_i(x) V_i(x, y)}{\sum i\alpha_i(x)} + \sum n^2 \alpha_n(x, y), \tag{37}$$

where $V^T_{k,x}(y)$ is the similarly defined variance.

### 3.6 Churn

We have previously defined churn as the minimum of the disconnect rate per circuit and the connect rate per circuit. Values of churn from other definitions are also easily obtained. We will here derive the churn, which happens to be a function of time in this case. To compute churn we need to know the probability measure for the individual order histories. Let $U_m(t, x)$ be the expected number of connects for an order of size $m$ arriving at time $t$ in the interval $[t, x]$ (thus $U_m(t, t) = m$). The expected total connect rate at time $x$, denoted $U(x)$, is then found to be:

$$U(x) = \frac{d}{dx}\left(\sum_m \int_{-\infty}^{x} \lambda(t) q_m(t) U_m(t, x) dt\right), \tag{38}$$

and similarly for the disconnects using the variable $D$,

$$D(x) = \frac{d}{dx}\left(\sum_m \int_{-\infty}^{x} \lambda(t) q_m(t) D_m(t, x) dt\right), \tag{39}$$

and thus we obtain the churn at time $x$, $\gamma(x)$:

$$\gamma(x) = \min\{D(x)/E[Y(x)],\ U(x)/E[Y(x)]\}, \tag{40}$$

where $E[Y(x)]$ is given by (16).

## IV. THE MODEL FOR SPECIAL-SERVICE CIRCUIT ACTIVITY

Here, we assume that the demand rate grows exponentially and that the behavior of orders is not dependent on the time of arrival. Specifically, we assume,

$$\lambda(t) = \lambda_o e^{\beta t}, \tag{41}$$

$$q_m(t) = q_m, \tag{42}$$

and

$$P^*_{mn}(t, x) = P_{mn}(x - t). \tag{43}$$

Later we will assume a specific form for $P_{mn}$.

Assumptions (41) through (43) are equivalent to:

1. exponential growth in the rate of new orders at rate $\beta$ (new orders occur as a nonhomogeneous Poisson process),
2. the probability that a new order is for $m$ circuits is $q_m$, and
3. an order initially for $m$ circuits requires a total of $n$ circuits after $z$ units of time with probability $P_{mn}(z)$. We will shortly further specify $P_{mn}$ to represent unchanging orders of exponential lifetime.

We now explore the consequences of (41) to (43) in the analysis presented in Section III. Substituting into (15) we find that the number of orders of size $n$ at time $x$ is Poisson distributed with mean $\alpha_n(x)$, where

$$\alpha_n(x) = \alpha_n e^{\beta x}, \tag{44}$$

and

$$\alpha_n = \lambda_o \sum_m q_m \int_o^\infty e^{-\beta y} P_{mn}(y) dy. \tag{45}$$

(The total number of circuits required at any time has a compound Poisson distribution, see Appendix A.) Thus, the mean and variance of the number of circuits at time $x$, $Y(x)$, are growing exponentially at the same rate, and the ratio remains fixed:

$$E[Y(x)] = e^{\beta x} \sum_{n=1}^{\infty} n\alpha_n, \tag{46}$$

$$\text{var}[Y(x)] = e^{\beta x} \sum_{n=1}^{\infty} n^2\alpha_n, \tag{47}$$

or

$$\text{var}[Y(x)] = \nu E[Y(x)], \tag{48}$$

where

$$\nu = \frac{\sum_{n=1}^{\infty} n^2\alpha_n}{\sum_{n=1}^{\infty} n\alpha_n}. \tag{49}$$

Further results are possible if the behavior for orders over time is specified. We assume that the order size does not change over its lifetime, which has a common distribution with c.d.f. $F$ independent of size. Later we will assume that $F$ is an exponential distribution. Although in practice the number of circuits per order does change with time, it is conceivable that this movement is relatively unimportant; or even if important, that the general form of eqs. (2) and (3)

will hold, although the parameter $\mu$ may then have a different physical meaning than we will associate here. In the model suggested here, $P_{mo}(y) = F(y)$; $P_{mm}(y) = 1 - F(y)$; $P_{mn}(y) = 0$, $n \neq 0$, $n \neq m$. In this case we may compute $\alpha_n$ more explicitly. Substituting into (45), we obtain

$$\alpha_n = q_n \left( \frac{\lambda_o}{\beta} [1 - \tilde{F}(\beta)] \right), \tag{50}$$

where

$$\tilde{F}(\beta) = \int_o^\infty e^{-\beta y} dF(y). \tag{51}$$

When the lifetimes are exponentially distributed with mean $1/\mu$, i.e. $F(x) = 1 - e^{-\mu x}$,

$$\alpha_n = q_n \lambda_o (\mu + \beta)^{-1}. \tag{52}$$

Also, the batchiness $\nu$ is related to the order-size distribution; substitution into (49) yields

$$\nu = \frac{\sum n^2 q_n}{\sum n q_n}. \tag{53}$$

The assumption that the order size does not change throughout its lifetime also allows more explicit representation of the mean and variance of the future requirements for circuits. Our development here parallels that of Section III. We first compute the probability that an observed order will change size during the period of observation. Recall that $q_{mnl}(t, x, y)$ is the conditional probability that an order is of size $l$ at time $y$ given that it was of size $n$ at time $x$ and arrived as size $m$ at time $t$. We easily obtain:

$$q_{mmm}(t, x, y) = \frac{\bar{F}(y - t)}{\bar{F}(x - t)}, \tag{54}$$

and

$$q_{mmo}(t, x, y) = 1 - q_{mmm}(t, x, y),$$

where

$$\bar{F}(x) = 1 - F(x),$$

and $q_{mml}(t, x, y) = 0$, $l \neq 0$, $l \neq m$. The value of $q$ is irrelevant for $n \neq m$.

We next find the probability that an order of size $n$ at time $x$ becomes of size $l$ at time $y$, which we denote $r_{nl}(x, y)$. Substitution into

(19) gives

$$r_{nl}(x, y) = 0, \qquad n \neq l, \qquad n \neq 0; \tag{55}$$

$$r_{nn}(x, y) = \bar{G}(y - x), \tag{56}$$

where

$$\bar{G}(t) = \frac{\int_o^\infty e^{-\beta z}\bar{F}(z + t)dz}{\int_o^\infty e^{-\beta z}\bar{F}(z)dz}; \tag{57}$$

and

$$r_{n0}(x, y) = 1 - \bar{G}(y - x).$$

Note that in the exponential-lifetime case, where $\bar{F}(z) = e^{-\mu z}$,

$$\bar{G}(y) = e^{-\mu y}. \tag{58}$$

We next find the mean and variance of the number of circuits in an order at time $y$, which was observed to be of size $n$ at time $x$, denoted $M_n(x, y)$ and $V_n(x, y)$, respectively. Substitutions of (55) and (56) into (20) and (21) give:

$$M_n(x, y) = n\bar{G}(y - x), \qquad \text{and} \tag{59}$$

$$V_n(x, y) = n^2\bar{G}(y - x)[1 - \bar{G}(y - x)]. \tag{60}$$

Notice that the conditional means are proportional to the size of the order, i.e., (59) implies (27).

We now focus on the mean and variance of the number of circuits at time $y$ due to orders which were observed at time $x$, given that $k$ circuits were observed at time $x$. These quantities are denoted $M_{k,x}(y)$ and $V_{k,x}(y)$ respectively. Equation (28) gives

$$M_{k,x}(y) = k\bar{G}(y - x). \tag{61}$$

We also conclude that, given the approximation in (32),

$$V_{k,x}(y) \approx k\bar{G}(y - x)[1 - \bar{G}(y - x)]\frac{\sum n^2 q_n}{\sum nq_n}, \tag{62}$$

thus

$$V_{k,x} \approx \nu[1 - \bar{G}(y - x)]M_{k,x}(y), \tag{63}$$

where use has been made of (53) and (61).

We next find the expected number of orders of size $n$ at time $y$ that arrived during the interval $(x, y)$ denoted $\alpha_n(x, y)$. Use of (3.3) yields

$$\alpha_n(x, y) = \lambda_o e^{\beta y} q_n \int_o^{y-x} e^{-\beta z} \bar{F}(z) dz, \tag{64}$$

where use is made of the fact $P^*_{mn}(t, x) = q_{mmn}(t, t, x)$, which follows from (54). When the lifetime distribution for orders is exponential, (64) becomes

$$\alpha_n(x, y) = \lambda_o e^{\beta y} q_n \left( \frac{1 - e^{-(\beta+\mu)(y-x)}}{\beta + \mu} \right). \tag{65}$$

The mean and variance of all circuits at time $y$ due to orders arriving in the interval $(x, y)$, $M^*(x, y)$ and $V^*(x, y)$, respectively, can be obtained by substitution of (64) into (34) and (35) yielding

$$M^*(x, y) = \lambda_o \sum n q_n e^{\beta y} \int_o^{y-x} e^{-\beta z} \bar{F}(z) dz, \tag{66}$$

and

$$V^*(x, y) = \nu M^*(x, y), \tag{67}$$

while for exponential lifetimes,

$$M^*(x, y) = \frac{D_o}{\beta + \mu} (e^{\beta t} - e^{-\mu t}), \tag{68}$$

where

$$D_o = \lambda_o e^{\beta x} \sum n q_n, \tag{69}$$

and

$$t = y - x.$$

Note that (61) and (68) [or (36)] give eq. (2), and (63) and (67) [or (37)] give (3), since the total number of active circuits at time $y$ is the sum of the number of active circuits due to orders present at time $x$ and the number of active circuits due to order arrivals between times $x$ and $y$, and these random variables are independent. Equations (5) through (9) can easily be derived by the methods described in the paper, although we omit the details here.

Next, turning our attention to churn for the specific model of this section, we find that the expected number of connects in the interval $[t, x]$ for an order arriving at time $t$ of size $m$, denoted $U_m(t, x)$, is given by

$$U_m(t, x) = m, \tag{70}$$

and similarly,

$$D_m(t, x) = mF(x - t), \tag{71}$$

where the variable $D$ represents disconnects. The total connect rate, total disconnect rate, and churn rate at time $x$, $U(x)$, $D(x)$, and $\gamma(x)$, respectively, can be obtained from (38) through (40), yielding

$$U(x) = \lambda_o e^{\beta x} \sum mq_m, \tag{72}$$

$$D(x) = \lambda_o e^{\beta x} \sum mq_m \hat{F}(\beta), \tag{73}$$

and

$$\gamma(x) = \gamma = \beta\hat{F}(\beta)/(1 - \hat{F}(\beta)), \qquad \beta \geqslant 0;$$

$$\gamma(x) = \gamma = \beta/(1 - \hat{F}(\beta)), \qquad \beta < 0. \tag{74}$$

In the special case where lifetimes are exponentially distributed,

$$\gamma = \mu, \qquad \beta \geqslant 0;$$

$$\gamma = \mu + \beta, \qquad \beta < 0. \tag{75}$$

## V. ESTIMATION OF THE PARAMETERS OF INTEREST

In this section, we describe the methodology that can be used to estimate the three key parameters of the model; $\beta$, the growth rate; $\mu$, the disconnect rate; and $\nu$, the batchiness.

### *5.1 Estimation of $\beta$*

Suppose that we wish to estimate $\beta$ on the basis of observed arrivals of orders, which by assumption occur according to a nonhomogeneous Poisson process with intensity $\lambda_o e^{\beta t}$. Suppose that the system is observed over the interval $[-\Theta, 0]$ and arrivals have been noted at times $t_1, \ldots, t_n$. We show how to obtain the maximum-likelihood estimator for $\beta$. (For a discussion of maximum-likelihood estimation, see any elementary book on statistics such as Mood & Graybill.)[5] The log-likelihood function, $\ln L(n, t_1, \ldots, t_n)$, is easily seen to be

$$\ln L(n, t_1, \ldots, t_n) = n \ln\lambda_o + \beta \sum_{i=1}^{n} t_i - \lambda_o \left(\frac{1 - e^{\beta\Theta}}{\beta}\right). \tag{76}$$

Differentiating with respect to $\lambda_0$ and $\beta$ we find the necessary conditions for a maximum:

$$n/\lambda_o = \frac{1 - e^{-\beta\Theta}}{\beta}, \tag{77}$$

$$\sum_{i=1}^{n} t_i - \frac{\lambda_o\Theta}{\beta} e^{-\beta\Theta} + \lambda_o \left(\frac{1 - e^{-\beta\Theta}}{\beta^2}\right) = 0. \tag{78}$$

Using (77) to eliminate $\lambda_o$ in (78), we obtain

$$S = \frac{xe^x - e^x + 1}{x(e^x - 1)} \equiv f(x), \tag{79}$$

where

$$S = \frac{\sum t_i}{n\Theta} + 1 \tag{80}$$

and

$$x = \beta\Theta. \tag{81}$$

The function $f$ defined in (79) can be seen to be strictly monotonic with range between 0 and 1. Therefore, eq. (79) allows us to solve for $\beta\Theta$ as $f^{-1}(S)$, where $S$ is the statistic defined in (80) equal to the proportion of the interval (*after* $-$ $\Theta$) at which the average time of arrival occurs. Thus, the maximum-likelihood estimator for $\beta$, written $\hat{\beta}$, is given by

$$\hat{\beta} = \frac{f^{-1}(S)}{\Theta}. \tag{82}$$

The function $f$ has the properties:

$$f(-\infty) = 0, f(0) = 1/2, f(\infty) = 1, \quad \text{and} \quad f(x) + f(-x) = 1.$$

Thus,

$$f^{-1}(0) = -\infty,$$
$$f^{-1}(1/2) = 0,$$
$$f^{-1}(1) = \infty,$$

and

$$f^{-1}(1/2 - x) = -f^{-1}(1/2 + x).$$

The function $f^{-1}$ is tabulated in Table I.

For small $x$, $f(x)$ may readily be expanded in the power series:

$$f(x) = 1/2\left[1 + (1/6)x - \frac{1}{360}x^3 \cdots\right]$$

so that

$$f^{-1}(1/2 + y) = 12y + 28.8y^3 \cdots. \tag{83}$$

Similarly, a large $f$ expansion yields

$$f^{-1}(1 - 1/y) \approx y - y^2e^{-y}. \tag{84}$$

We may also determine the mean and variance of the statistic $S$ given the correct parameter $\beta$ and the number of observed arrivals. It is well known that the distribution of the arrival times for a nonhomogeneous Poisson process, conditioned on a given number of arrivals

Table I—Values of the function $f^{-1}$ useful in estimating the growth rate $\beta$, and several approximations for the function [see eq. (79) and following]

| X | $f^{-1}(X)$ | 12X-6 | Approximation in (83) | Approximation in (84) |

| 0.92 | 12.4994 | | | 12.4994 |
| 0.94 | 16.6667 | | | 16.6667 |
| 0.96 | 25.0000 | | | 25.0000 |
| 0.98 | 50.0000 | | | 50.0000 |
| 1.00 | $\infty$ | | | $\infty$ |

in the interval, is the same as the order statistics from $n$ i.i.d. random variables with probability density proportional to the arrival rate. Thus $S$ has the distribution of the average of $n$ i.i.d. random variables, $Y_i$ on [0, 1] with density $g(\rho)$, where

$$g(\rho) = \frac{xe^{\rho x}}{e^x - 1}$$

and

$$x = \beta\Theta.$$

It is easily seen that

$$E(Y) = f(x) \tag{85}$$

and

$$\text{var}(Y) = \frac{1}{x^2} - \frac{1}{e^x + e^{-x} - 2}. \tag{86}$$

Equation (86) is valid if $x \neq 0$; when $x = 0$, $\text{var}(Y) = 1/12$, the limit

of (86) as $x$ goes to 0. The expression for the variance is symmetric in $x$ and takes its maximum value at $x = 0$.

Thus, for a given value of the growth rate $\beta$, and a (large) given number of observations $n$, the observed statistic $S$ is approximately normally distributed with mean $f(x)$ and variance less than or equal to $1/12n$. This observation can be readily translated into confidence intervals through the use of elementary statistical theory. For example, a 95-percent confidence interval for $f(x)$ (assuming normality of the statistic) is

$$S - 1.96 \sqrt{\frac{1}{12n}} \leq f(x) \leq S + 1.96 \sqrt{\frac{1}{12n}}, \tag{87}$$

which translates to

$$f^{-1}\left(S - 1.96 \sqrt{\frac{1}{12n}}\right) \leq \beta\Theta \leq f^{-1}\left(S + 1.96 \sqrt{\frac{1}{12n}}\right). \tag{88}$$

If $S$ is close to 0.5, then we can use $f^{-1}(x) \approx 12x - 6$ [see (83)] to obtain for the 95-percent confidence interval for $\beta\Theta$

$$\beta\Theta = 12S - 6 \pm \frac{6.79}{\sqrt{n}}. \tag{89}$$

### *5.2 Estimation of $\nu$*

There are several possible statistics for the measurement of the batchiness $\nu$. We shall take as our starting point eq. (49) which defines the batchiness in terms of the distribution of the order size at (any) point in time. This is preferable and is more robust than using the distribution of the order size on arrival, although the two happen to equal when order sizes do not change with time. Thus, if $\nu$ is to be estimated based on observation of the system at a given point in time at which $i_n$ orders of size $n$ are observed, then a reasonable estimator for $\nu$, which we write $\hat{\nu}$, is:

$$\hat{\nu} = \frac{\sum n^2 i_n}{\sum n i_n}. \tag{90}$$

When the number of circuits does change during the lifetime of an order, it is possible that the form of (3) still holds. In this case, it is likely that the parameter $\nu$ which multiplies each of the two terms in (3) is different. Equation (90) is a reasonable estimator for the multiplier of the second term. The multiplier of the first term should be estimated by other methods.

Table II—Notation

| | |
|---|---|
| $D_o$ | Present ($t = 0$) circuit demand rate due to new orders. |
| $D(x)$ | Expected total disconnect rate at time $x$. |
| $D_m(t, x)$ | Expected number of disconnects in the interval $[t, x]$ for an order of size $m$ arriving at time $t$. |
| $i_n(x)$ | Observed number of orders of size $n$ at time $x$. |
| $J_i$ | Conditional number of orders of size $i$ due to orders observed at time $x$ given that $k$ circuits were observed at time $x$. |
| $M(x, y)$ | Mean total number of circuits at time $y$ due to orders. |
| $M^*(x, y)$ | Mean of the total number of circuits at time $y$ due to orders arriving between $x$ and $y$. |
| $M^T_{k,x}(y)$ | Mean of the number of circuits at time $y$ given $k$ are observed at time $x$. |
| $M_{k,x}(y)$ | Conditional expectation of the number of circuits at time $y$ due to orders observed at time $x$ given that $k$ circuits are observed at time $x$. |
| $M^{(2)}_{k,x}(y)$ | Conditional second moment of the number of circuits at time $y$ due to orders observed. |
| $M_n(x, y)$ | Mean order size at time $y$ for an order observed to be of size $n$ at time $x$. |
| $P_{mn}(t)$ | Probability that an order of initial size $m$ becomes of size $n$, $t$ time units after arrival. |
| $P^*_{mn}(t, x)$ | Probability that an order arriving at time $t$ of initial size $m$ becomes of size $n$ at time $x$. |
| $q_m$ | $q_m(t)$ when there is no dependence on $t$. |
| $q_m(t)$ | Probability that an order at time $t$ is initially for $m$ circuits. |
| $q_{mnl}(t, x, y)$ | Conditional probability that an order arriving as size $m$ at time $t$ and of size $n$ at time $x$ becomes of size $l$ at time $y$. |
| $r_{nl}(x, y)$ | Probability that an order of size $n$ at time $x$ becomes an order of size $l$ at time $y$. |
| $U(x)$ | Expected total connect rate at time $x$. |
| $U_m(t, x)$ | Expected number of connects for an order of size $m$ arriving at time $t$ in the interval $[t, x]$. |
| $V(x, y)$ | Variance of the total number of circuits at time $y$ due to orders observed active at time $x$. |
| $V^*(x, y)$ | Variance of the total number of circuits at time $y$ due to orders arriving between $x$ and $y$. |
| $V^T_{k,x}(y)$ | Variance of the number of circuits at time $y$ given that $k$ are observed at time $x$. |
| $V_{k,x}(y)$ | Conditional variance of the total number of circuits at time $y$ due to orders observed at $x$ given that $k$ circuits are observed at time $x$. |
| $V_n(x, y)$ | Variance of order size at time $y$ for an order observed to be of size $n$ at time $x$. |
| $Y(x)$ | Total number of active special service circuits at time $x$. |
| $\alpha_n$ | Constant of proportionality for the exponential growth of $\alpha_n(x)$. |
| $\alpha_n(x)$ | Mean number of orders of size $n$ at time $x$. |
| $\alpha_n(x, y)$ | The number of orders of size $n$ at time $y$ which arrived between times $x$ and $y$. |
| $\beta$ | Growth rate. |
| $\gamma$ | Churn. |
| $\delta_{k,x}(j_1, j_2, \ldots)$ | Conditional probability that there are $j_1$ orders of size 1, $j_2$ orders of size 2, etc., at time $x$ given that $k$ total circuits are observed at time $x$. |
| $\theta(x, y)$ | Defined in (27). |
| $\Theta$ | Length of observation period. |
| $\lambda_o$ | Present ($t = 0$) arrival rate of orders. |
| $\lambda(t)$ | Instantaneous arrival rate of orders at time $t$. |
| $\mu$ | Disconnect rate (per circuit). |
| $\nu$ | Batchiness. |
| $\rho_{mn}(t, x)$ | The conditional probability density that an order arrived at time $t$ of initial size $m$ given that it is of size $n$ at time $x$. |

### 5.3 Estimation of $\mu$

The estimation of $\mu$ is relatively straightforward. The maximum-likelihood estimator is given in (14) and further details including estimated values by service family are given in Reed and Smith.[2]

### 5.4 Estimation of $D_o$

Equation (77) allows the MLE estimator of $\lambda_o$,

$$\hat{\lambda}_o = \frac{n\hat{\beta}}{1 - e^{-\hat{\beta}\Theta}}, \tag{91}$$

where the estimator $\hat{\beta}$ has been previously described in (82). The estimator of $D_o$ (the instantaneous demand at the end of the observation interval of length $\Theta$), $\hat{D}_o$ then is

$$\hat{D}_o = \lambda_o \hat{N}, \tag{92}$$

where $\hat{N}$ is an estimate of the average batch size. The previous expectation can be estimated from the order sizes at arrival epochs, or more crudely from the general distribution of order sizes at an arbitrary point of time.

Interestingly enough, $D_o/(\mu + \beta)$ can be estimated solely from the number of active circuits at a point of time. For simplicity, we assume that the orders are solely of size one, although the analysis could be repeated for other distributions. In this case, the following analysis is applicable.

Suppose that the number of active circuits at time $t$ is a Poisson random variable with mean $\lambda e^{\beta t}$. The time that the mean is between $x$ and $x + dx$ is $dx/x\beta$. The expected time that the mean is between $x$ and $x + dx$ and a total of $k$ active circuits are observed is $\frac{dx}{x\beta}\frac{x^k}{k!}e^{-x}$. Thus, if $k$ active circuits are observed, the conditional distribution of the mean (in our case this is $D_o/(\mu + \beta)$) has density proportional to $x^{k-1}e^{-x}$, or is a standard gamma random variable with $k$ degrees of freedom. This random variable has mean and variance equal to $k$. Thus, if $k$ circuits are observed, the conditional distribution of $D_o/(\mu + \beta)$ has mean $k$ and variance $k$, and is approximately normally distributed if $k$ is large. This information can be used to modify eqs. (2) and (3), to take into account the variability of $D_o/(\mu + \beta)$ to obtain:

$$M_k(t) = ke^{\beta t}, \tag{93}$$

and

$$V_k(t) = \nu k[e^{\beta t} - e^{-2\mu t}] + k[e^{\beta t} - e^{-\mu t}]^2, \tag{94}$$

where the subscript $k$ on the variables on the left-hand side indicates

conditional means and variances knowing $\beta$, $\mu$, and $\nu$ but not knowing $D_0$. Note that the variance-to-mean ratio is unbounded for increasing $t$, since errors in estimation of $D_0$ accumulate indefinitely.

## VI. SUMMARY

We have described a model for special-services activity useful in forecasting special-services requirements. It requires three physical characterizations of the process (growth rate, disconnect rate, and batchiness) and two instantaneous measurements (the current number of active circuits and the instantaneous rate of new connects). We give means and variances for the numbers of active circuits at a given point in the future and for the total number of connects or disconnects during a future period. The distribution of these variables can be computed by the methodology described in the paper. We also describe general techniques for estimation of the required parameters.

Work is being undertaken to verify and calibrate the model with the New Jersey Bell Telephone Co. database and will be reported elsewhere.

## APPENDIX A

### *The Compound Poisson Random Variable*

Briefly, a random variable is said to be a compound Poisson random variable if it can be thought of as the sum of a Poisson number of independent identically distributed positive integer-valued random variables. Thus $Y$ is a compound Poisson random variable if

$$Y = \sum_{i=1}^{N} X_i,$$

where $N$ is a Poisson random variable with mean $\alpha$, $N$ and the $X_i$ are

independent and

$$P\{X_i = n\} = p_n.$$

We have rather easily

$$E(Y) = \alpha E(X) = \alpha \sum np_n$$

$$\text{Var}(Y) = \alpha E(X^2) = \alpha \sum n^2 p_n.$$

An alternative (and equivalent) way of specifying a compound Poisson random variable is

$$Y = \sum_{i=1}^{\infty} iZ_i,$$

where

$Z_i$ are independent Poisson random variables with $E(Z_i) = \alpha p_i \equiv \alpha_i$. In this case it is convenient to think of $Z_i$ as the number of batches or orders of size $n$ that are aggregated to give the total number denoted $Y$.

## APPENDIX B

### *The Nonhomogeneous Poisson Process*

A process which counts events is a nonhomogeneous Poisson process (see, for example, Ross, Ref. 5) with intensity $\lambda(t) \geqslant 0$ if the number of events in the interval $[x, y]$ is a Poisson random variable with mean $\int_x^y \lambda(t)dt$, and the number of events in disjoint intervals are independent.

*Fact*: If events from a nonhomogeneous Poisson process are of two types, and an event at time $t$ is of Type 1 with probability $p(t)$, then the process which counts Type 1 events is a nonhomogeneous Poisson process with intensity $\lambda(t)p(t)$, and it is independent of the counting process which counts Type 2 events [which is a nonhomogeneous Poisson process intensity $\lambda(t)(1 - p(t))$].

*Fact*: Suppose that a nonhomogeneous Poisson process is observed over the interval $[x, y]$ and $n$ events are observed. If the times of these events are arranged in random order, their distribution is identical to that of $n$ independent identically distributed random variables whose density at $t$ is

$$\frac{\lambda(t)}{\int_x^y \lambda(z)dZ}$$

if $t \in [x, y]$ and is zero otherwise.

# TELBECC—A Computational Method and Computer Program for Analyzing Telephone Building Energy Consumption and Control

By P. B. GRIMADO*

(Manuscript received February 2, 1983)

Telephone Building Energy Consumption and Control (TELBECC) program has been developed to accurately and efficiently analyze environmental control and energy use in telephone company buildings. The program simulates various operational plans to determine the relative energy and cost savings. By analyzing the operation of the heating, ventilation, and air conditioning system as it regulates a changing environment, TELBECC calculates the heating and cooling load, dry-bulb temperature, and relative humidity in the building. The user specifies the building's dry-bulb temperature limits, which are the control variables for the program analysis. The simplified computational procedure of the program incorporates a recursive scheme using time series to perform the necessary calculations. The results of the computations can be obtained for different periods: the quarter hour, hour, day, or month. Energy consumption and control in several equipment buildings located in three different geographical areas have been analyzed by TELBECC. Analysis and comparison of the resulting data demonstrate the advantages of the program.

## I. INTRODUCTION

An ambitious energy-cost savings program has been instituted to reduce energy use in telephone company buildings. In recent years, telephone companies have saved energy mainly by redesigning and

retrofitting buildings to operate and maintain environmental control equipment at peak performance, to turn out unneeded lights, to reduce heating and cooling losses, and the like. Further energy and cost savings, although requiring additional capital investment, could be achieved through modification of environmental control systems, purchase of sophisticated microprocessors for more efficient control of building Heating, Ventilating, and Air conditioning (HVAC) systems, and installation of alternative energy sources, such as solar power and wind power. Before adopting any conservation plans that require appreciable capital investment, however, we should make a thorough economic evaluation. Such an evaluation can be carried out by correlating the changing operating characteristics of a building with selected energy conservation plans. This procedure would enable us to pinpoint the most economical operating strategies.

There are several commercially available computer programs to perform this type of analysis, such as DOE II, ESP, and BLAST;[1,2] most, however, are proprietary. These complex programs can analyze any of a broad spectrum of commercial, industrial, and residential buildings. But, because of their versatility, they require large computer systems, extensive data preparation, and high costs. The use of energy in the majority of telephone company equipment buildings, which are small, single-story structures varying in area from 1500 to 10,000 square feet, can be best evaluated by a more focussed computer program.

This paper describes a new computational method and computer program called Telephone Building Energy Consumption and Control (TELBECC). This program simulates building operations and quickly evaluates numerous energy conservation plans and cost-saving strategies under variable weather conditions [according to standard hourly Test Reference Year (TRY) weather data[3]]. The program can evaluate energy consumption for intermittent or proportional HVAC plant operation, economy cycle operation, enthalpy cycle operation, and wideband temperature operation with no heating or cooling between preset room temperature limits. Also, the program can calculate the optimum building orientation and U factor (heat transmission characteristics) of the outside walls and roof, chiller and heater plant size, dry-bulb temperature and Relative Humidity (RH) variations, and quantity of water required to maintain 20-percent minimum RH during economy cycle operations.

## II. PROGRAM DESCRIPTION

We can derive the heating or cooling load in an enclosed building from the following considerations:

1. Conduction of heat through the building walls and roof.

2. Permeation of outside air through the building envelope.
3. Internal heat generation from equipment, lights, and people.
4. Direct solar radiation through windows and skylights (fenestration).

Since most operating company equipment buildings have few windows, the program does not consider item 4 in the present version.

A Constant-Air-Volume (CAV) supply fan system typically controls the air temperature of a building. The building engineer normally sizes the fan system using the elementary steady-state heat balance, which takes into account the internal heat loads, outside air temperatures, and solar radiation in conjunction with the U factor of the building envelope. In general, this conservative approach produces fan systems that are oversized and therefore inefficient. To find a smaller, and perhaps more efficient, fan capacity, a TELBECC user selects different fan capacities for analysis by the program. The program generates data on the space temperatures, relative humidity, peak heating and chiller loads, and the hours of system operation for the different fan capacities that can be used to find an optimum air supply fan system.

For comfort, a limit is imposed on the difference between HVAC supply and return air temperatures. For cooling, this temperature difference is −20 degrees F; for heating, +40 degrees F. These default values may be overridden by the user. With an environmental dry-bulb temperature standard specified, the program computes the required operation of the HVAC.

The user can specify one of two basic ways to operate the HVAC: intermittent operation or proportional control. With intermittent operation, the HVAC does not supply any heating or cooling when the dry-bulb air temperature is within the wideband temperature range. Reaching or exceeding either wideband temperature limit activates the HVAC. The HVAC stays on and does not deactivate until the dry-bulb air temperature reaches 3 degrees F above the lower limit of the wideband temperature range for heating and 3 degrees F below the upper limit of the wideband temperature range for cooling. The TELBECC user can reset the numerical values of the throttling range if a different range is appropriate. The proportional control plan operates by continuously adjusting the supply and return air temperature difference in increments of 1 degree F to satisfy the instantaneous building heating or cooling load. This plan follows the building load to closely track the lower and upper limits of the wideband temperature range with essentially no throttling. When selecting a dual or extended wideband temperature standard (that is, one with different wideband limits for occupied and unoccupied times), the HVAC activates before occupancy in order to reach the preset temperature standard.

TELBECC calculates the heat added or removed by the HVAC

system in controlling the dry-bulb air temperature every quarter hour. In particular, when cooling is required, the sensible and latent loads on the chiller plant are simultaneously computed by incorporating any of three standard methods of fan system operation:

1. Conventional operation, which is chiller operation with no economizer.
2. Chiller operation with a dry-bulb economy cycle.
3. Enthalpy cycle.

In conventional operation, the minimum quantity of outside air needed for ventilation is circulated. This mode is also used as a benchmark for the program. The dry-bulb economy cycle uses outside air for cooling whenever the outside dry-bulb air temperature falls below the maximum value. The default value is 55 degrees F, but the user can reset the value. The enthalpy cycle checks the enthalpy of the inside air and the outside air. If the outside air enthalpy is lower, 100 percent outside air is circulated to reduce the load on the chiller regardless of the relative humidity. Otherwise, only the minimum quantity of outside air required for ventilation is circulated.

System control is based on dry-bulb air temperature and is not predicated on maintaining a particular value of relative humidity. Nevertheless, the program computes changes in relative humidity for the three methods of fan-system operation discussed above. The program summarizes the variation in relative humidity for the time period chosen by giving the number of hours the relative humidity is less than 10 percent, between 10 and 15 percent, between 15 and 20 percent, between 20 and 55 percent, between 55 and 60 percent, and greater than 60 percent.

In addition, since dry-bulb economy cycle operation generally calls for bringing in winter air with low humidity, the program calculates the quantity of water required for humidification. The operating company minimum standard of 20 percent RH in the inside air for dry-bulb economy cycle operation in winter is the basis for calculating the amount of water added to the air.

## III. TRANSIENT HEAT CONDUCTION THROUGH THE BUILDING ENVELOPE

Weather conditions influence the heating and cooling load of a building by heat conduction through the structural and decorative materials of the exterior walls and roof, as well as by permeation of outside air and direct absorption of solar radiation through window areas. Since, as previously mentioned, most operating company equipment buildings have few windows, only heat conduction and permeation are treated in the computer program. The program must account for the heat storage effects of the structure, as well as the daily and

seasonal variation of the outside air temperature and solar radiation. We can account for these influences on the building by considering the building envelope elements as one-dimensional flat slabs or plates. We then obtain a solution to a partial differential equation with time-dependent boundary conditions. A classical analytical solution of this equation[4] produces a set of equations that require an inordinate quantity of computational effort and time, rendering the whole idea of performing the analysis impractical and uneconomical. However, the analytical solution can be recast into a simpler, though effective, computational scheme with a method first introduced by Mitalas and Stephenson,[5] which is ideally suited to calculation by computer.

The inside-wall and roof-surface temperature $T_{BE}(t)$ and the air temperature of the building $T_a(t)$, which are dependent on time, determine the environmental load due to convection.* $T_{BE}(t)$ is represented in the form of the following time series:

$$T_{BE_t} = -\sum_{i=1}^{m-1} b_i T_{BE_{t-i}} + \sum_{i=1}^{m} a_i T_{O_{t-i-1}} + \sum_{i=1}^{m} a_i' T_{a_{t-i-1}}, \qquad (1)$$

where

$t$ = current time,
$T_{BE_t}$ = inside-wall temperature of the building at the current time,
$T_{BE_{t-i}}$ = inside-wall temperature of the building $i$ time units prior to $t$,
$T_{O_{t-i}}$ = outside sol-air temperature[6] $i$ time units prior to $t$, and
$T_{a_{t-i}}$ = air temperture of the building $i$ time units prior to $t$.

For hourly temperature calculations, the number of terms, $m$, will rarely exceed 5, and for quarter-hour calculations, $m$ will generally be less than 15. The recursive properties of the calculation make it extremely efficient and economical, especially when the operating characteristics of the building may need to be tracked for an entire calendar year. The coefficients $b_i$, $a_i$, and $a_i'$ in eq. (1) are determined from the thermophysical properties of the structure. Only six values are needed to uniquely specify these coefficients: wall thickness, wall U factor, wall-weight density, effective heat-transfer coefficient of the inside- and outside-wall surface, and the time interval between successive calculations. The appendix presents the mathematical procedure to evaluate these coefficients. Figures 1 and 2 show the mathematical and physical models for deriving the coefficients.

We can validate this simplified computational approach by compar-

* Radiative interchange between inside building-wall surfaces is not included in the present version of the program.

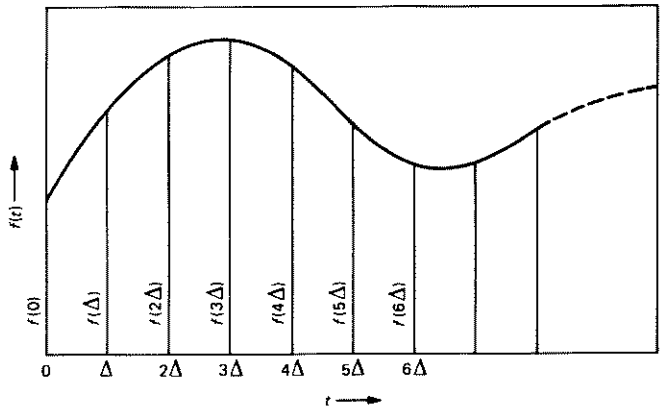

Fig. 1—Discrete and continuous functions.

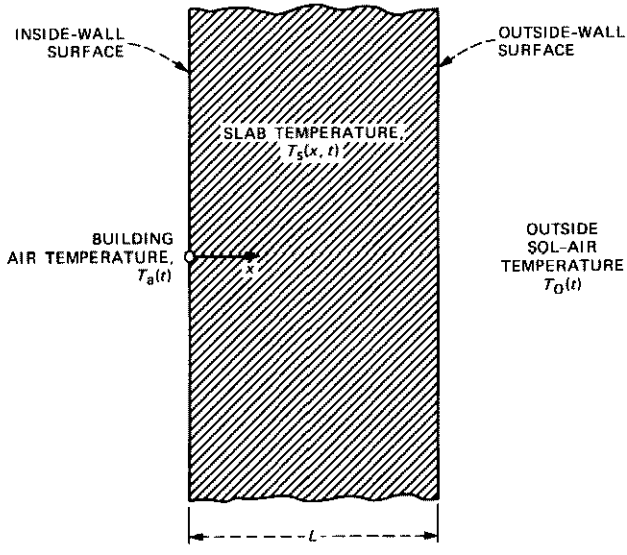

Fig. 2—Homogeneous flat slab.

ing it with an exact solution given in the literature.[7] We can see this in Figs. 3 and 4 for several values of the inside-wall dimensionless convective heat-transfer parameter $B_i \equiv h_i L/k$ and two limiting values of the outside-wall convective heat-transfer parameter $B_O \equiv h_O L/k$. In Fig. 3 the outside-wall convective heat transfer parameter $B_O = 0$; i.e., the surface $x = L$ is insulated. In Fig. 4 the solution corresponds to $B_O$ approaching $\infty$; i.e., the surface $x = L$ is maintained at a constant temperature. The initial and boundary conditions are indicated in the figures. The solid curves represent the exact condition given in Ref. 7,

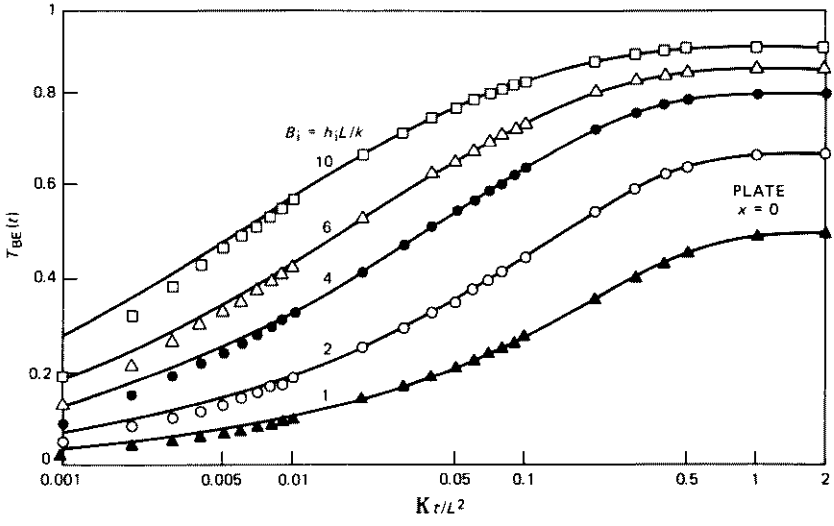

Fig. 3—Temperature response of front face of plate, $0 \leq x \leq L$, with back face $0 \leq x \leq L$, with back face $x = L$ maintained at $T_0 = 0$ degree F after sudden exposure to uniform-temperature convective environment $T_a = 1$ degree F at $x = 0$. Sampling interval $\Delta$ is one min.

and the dots represent the numerical values computed by the time series in eq. (1). The sampling interval for this example is $\Delta = 1$ min. or, in terms of dimensionless time, $k\Delta/L^2 = 0.001$. We can see that after some time has elapsed the exact solution and the time-series solution match identically. For the problem considered here at $t = 0$, the ambient convected temperature $T_a$ is suddenly raised from $T_a = 0$ to $T_a = 1$; i.e., the boundary condition is a step function. However, since the development of the time series assumes a linear variation between time intervals, as stated in the appendix, the solution resembles an initial ramp followed by a constant value, as shown in Fig. 5. Once the effect of the initial ramp input diminishes after about 10 sampling intervals, the solution coincides with the exact solution. This characteristic of the time series is not a problem here, since instantaneous changes of air temperatures inside and outside the building do not occur.

## IV. CALCULATION OF BUILDING AIR TEMPERATURE AND ENERGY USE

The air temperature of the building is obtained through the following equation for the heat balance within the building:

$$q_{air}(t) = q_{equipt}(t) + q_{lights}(t) + q_{people}(t) + q_{infiltration}(t) + q_{walls}(t) + q_{HVAC}(t), \quad (2)$$

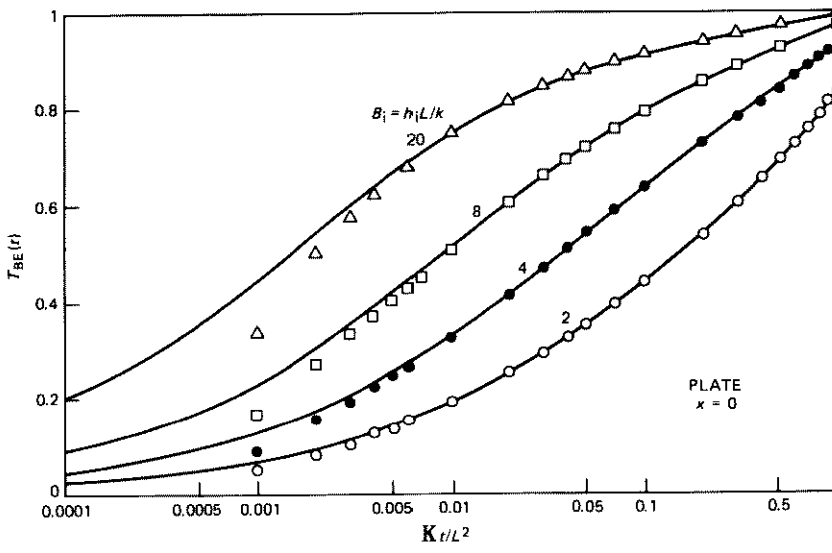

Fig. 4—Temperature response of front face of plate $0 \leq x \leq L$, with insulated back face $x = L$ after sudden exposure to uniform-temperature convective environment $T_a =$ 1 degree F at $x = 0$. Sampling interval $\Delta$ in one min.

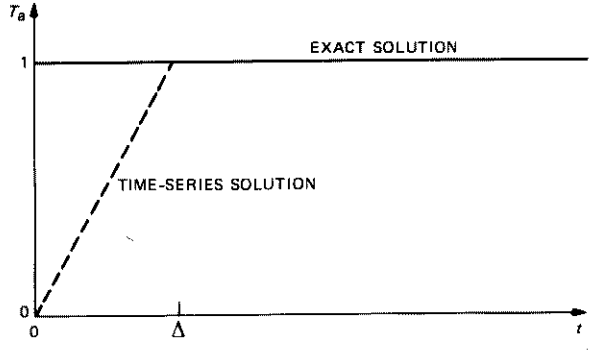

Fig. 5—Convection temperature environment at inside boundary surface $x = 0$.

where $q_{air}(t)$ (Btu/hr) represents the sensible thermal-energy convection rate of the inside air, resulting in a change in the overall dry-bulb air temperature. The other terms on the right represent the rate at which heat is convected to the air from the following: equipment heat dissipation; lighting; people; inadvertent infiltration of outside air; the exterior walls, floor, and roof of the building; and the building's HVAC control system.

To evaluate the air temperature $T_a(t)$ from eq. (2), each term is expressed as the difference in temperatures between the air and the

heat-convecting medium. We can determine $T_a(t)$ from the following differential equation:

$$\rho c v \frac{dT_a(t)}{dt} = H_{EL}A_{EL}[T_{EL}(t) - T_a(t)] + \rho cm[T_O(t) - T_a(t)] + H_{BE}A_{BE}[T_{BE}(t) - T_a(t)] + \rho cQ[DT_{SP}(t)], \quad (3)$$

where

$T_a(t)$ = average building dry-bulb air temperature;
$T_{EL}(t)$ = combined average temperature of the equipment, lights, and people;
$T_O(t)$ = outside dry-bulb air temperature;
$T_{BE}(t)$ = inside surface temperature of the building envelope;
$DT_{SP}(t)$ = difference between the air-supply temperature and the air temperature of the building;
$\rho$ = air density;
$c$ = air specific heat;
$v$ = volume of the building space;
$H_{EL}$ = heat-transfer coefficient between the air and equipment;
$A_{EL}$ = average surface area of equipment;
$m$ = rate at which outside air infiltrates the building;
$H_{BE}$ = heat-transfer coefficient between the building envelope and air;
$A_{BE}$ = surface area of the building envelope; and
$Q$ = air-supply rate of the HVAC system fan units.

Only one of the temperatures in eq. (3) is presumed known: the outside-air dry-bulb temperature, $T_O(t)$. The other four temperatures—$T_a(t)$, $T_{EL}(t)$, $T_{BE}(t)$, and $DT_{SP}(t)$—are coupled; therefore, additional equations are needed for their resolution.

We can consolidate our terms into two other equations. When we combined the heat gain generated by the equipment, lighting, and people into a single term for heat dissipation per unit of building floor area $W(t)$(W/ft$^2$), one additional equation can be written as

$$C_{EL} \frac{dT_{EL}(t)}{dt} = 3.41\ A_f W(t) + H_{EL}A_{EL}[T_a(t) - T_{EL}(t)], \quad (4)$$

where

$C_{EL}$ = heat capacity of the equipment, lights, and people;
$A_f$ = building floor area; and
$W(t)$ = combined heat dissipation of the equipment, lights, and people per unit of building floor area.

A third equation coupling the building envelope temperature $T_{BE}(t)$ and the building air temperature $T_a(t)$ is needed. A likely equation

would be the time series given by eq. (1). But before this can be applied, both eqs. (3) and (4) must also be recast in the form of time series. This is easily done by using the properties of the $z$ transform and the procedure already delineated in the appendix. The time-series solution of eqs. (3) and (4) assumes the form

$$T_{a_t} = sT_{a_{t-1}} + \left(\frac{\Delta\tau + s - 1}{\Delta t^2}\right)[\tau_{EL}T_{EL} + \tau_O T_O + \tau_{BE}T_{BE} + \tau_{SP}DT_{SP}]_t$$

$$+ \left(\frac{1 - s(\Delta\tau + 1)}{\Delta\tau^2}\right)[\tau_{EL}T_{EL} + \tau_O T_O + \tau_{BE}T_{BE} + \tau_{SP}DT_{SP}]_{t-1}, \quad (5)$$

and

$$T_{EL_t} = \hat{s}T_{EL_{t-1}} + \frac{(\Delta\hat{\tau} + \hat{s} - 1)}{\Delta\hat{\tau}^2}[\hat{\tau}_w W + \hat{\tau}_a T_a]_t$$

$$+ \frac{[1 - \hat{s}(\Delta\hat{\tau} + 1)]}{\Delta\hat{\tau}^2}[\hat{\tau}_w W + \hat{\tau}_a T_a]_{t-1}, \quad (6)$$

where

$\Delta$ = sampling time interval,
$\tau_{EL} = H_{EL}A_{EL}/\rho cv$,
$\tau_O = m/v$,
$\tau_{BE} = H_{BE}A_{BE}/\rho cv$,
$\tau_{SP} = Q/v$,
$\tau = \tau_{EL} + \tau_O + \tau_{BE} + \tau_{SP}$,
$s = \mathrm{EXP}(-\Delta\tau)$,
$\hat{\tau}_w = A_f/C_{EL}$,
$\hat{\tau}_a = H_{EL}A_{EL}/C_{EL}$,
$\hat{\tau} = \hat{\tau}_w + \hat{t}_a$, and
$\hat{s} = \mathrm{EXP}(-\Delta\hat{\tau})$,

and the subscripts $t$ and $t-1$ indicate that the temperature is evaluated at times $t = n\Delta$ and $t = (n-1)\Delta$.

The calculation of the humidity ratio in the space is also formulated in terms of a first-order linear differential equation in time similar to eqs. (3) and (4). This equation is also recast in the form of a time series [see eqs. (5) and (6)]. Knowing the humidity ratio and the dry-bulb air temperature, we can find the relative humidity by employing standard psychometric formulae.[6]

As previously noted in Section II, the system of eqs. (1), (5), and (6) permits controlling the dry-bulb air temperature in two basically different ways, intermittent operation and proportional control, and

determines the hours of operation. We use these equations for intermittent HVAC operation where we assume that the HVAC system holds the supply and return air-temperature difference constant at $DT_{SP} = -20$ degrees F whenever cooling is required and at $DT_{SP} = 40$ degrees F whenever heating is required. The hours of operation, and hence the total quantity of heat removed or added to satisfy the imposed dry-bulb temperature standard, can then be determined. For the proportional control plan, eqs. (1), (5), and (6) are also used to calculate not only the hours of HVAC operation but also the numerical value of the supply and return air-temperature difference $DT_{SP}(t)$, which in general varies continuously for this mode of control. The variation in time of the numerical value of $DT_{SP}(t)$ is determined by just satisfying the instantaneous building environmental load. When the HVAC system is activated, the proportional control plan closely follows the lower limit (for heating) or the upper limit (for cooling) of the building wideband temperature range.

Once $DT_{SP}(t)$ and the hours of operation are known, the program calculates the heat added or removed from the building by the HVAC system during every quarter hour and for whatever other period is of interest, e.g., monthly. As a corollary, we can estimate the environmental control system energy use, assuming the following HVAC system characteristics:

1. For chiller operation, a constant Coefficient Of Performance (COP) supplied by the user, together with the quantity of heat removed from the building air, characterizes its energy requirements.

Table I—Equipment buildings analyzed

| Energy Consumption and Control | | | | |
|---|---|---|---|---|
| | Wideband Temperature (°F) | | | |

Notes: Fan supply rate = 7400 CFM, ventilation = 150 CFM, wideband temperature limits for occupied and unoccupied times = 65° to 80°F, economizer temperature limit = 65°F, time period = 1 to 365 days, total hours = 8760.

2. For fan operation, fan power is calculated from the following equation:

$$\text{Fan power (kW)} = 2.487 \times 10^{-4} \times Q \times \Delta P, \tag{7}$$

where

$Q(CFM)$ = air flow delivered by the fan; and
$\Delta P$ = static pressure head of the fan in inches of water.

By multiplying the fan power by the total hours of fan operation, we can obtain the total energy use (kWh).

3. Humidification costs are based on supplying energy at the rate of 1000 Btu per pound of water added to the supply air stream. Costs are derived from the unit cost of energy, such as electricity ($/kWh), natural gas ($/1000 ft$^3$), and fuel oil ($/gal), which is supplied by the user. An 80 percent efficiency rate is assumed for these energy sources.

4. Heating costs are similarly calculated by the unit cost. An 80 percent efficiency rate is also used in these calculations.

## V. ILLUSTRATIVE EXAMPLES OF ENERGY CONSUMPTION AND CONTROL

Different geographic loctions of equipment buildings, dual or extended wideband temperature limits, and the method of HVAC control (intermittent or porportional) are considered in several variations. Table I gives this information along with some of the more salient building parameters. The results of the calculation are summarized by month in Tables II through VI for the cases specified in Table I. We assume here that a conventional cooling system, consisting of a chiller

Table IIb—Intermittent control of building space air temperature—New York City, case 1 in Table I

| | Number of Hours at Specified Relative Humidity (No Humidity Control) | | | | | |

Notes: Fan supply rate = 7400 CFM, ventilation = 150 CFM, wideband temperature limits for occupied and unoccupied times = 65° to 80°F, economizer temperature limit = 65°F, time period = 1 to 365 days, total hours = 8760.

and air-handling unit, provides cooling. By comparing the different cases, we find some interesting results.

Case 1 differs from case 2 in that the HVAC is intermittently controlled in case 1, but proportionally controlled in case 2. We see from Tables IIb and IIIb, for example, that the maximum cooling loads for both cases occur close in time [August 12 (day 224) and July 31 (day 212)]. However, the maximum cooling load of 13 tons for the proportional control plan (Table IIIa), which compares favorably with the load of 14.2 tons for the intermittent control plan (Table IIa), reduces the required size of the chiller plant by 9 percent. We would expect such a reduction from using a control sequence that follows the load closely and minimally overshoots the dry-bulb air temperature. Also, a control plan that matches the fan capacity to the load would compare favorably in energy use with on-off fan operation.

We can see in Table IIIa (in the column labeled "Space Temp") that the proportional control plan regulates the temperature to within one-tenth of a degree of the wideband temperature limit for the entire calendar year. For the economy cycle operation, the yearly electrical use of case 1 in Table IIb is 56,221 kWh, and that of case 2 in Table IIIb is 63,614 kWh. The chiller energy consumption for case 1, 37,522 kWh, is larger than that for use 2, 31,591 kWh. The proportional control plan, which modulates the air-supply temperature, requires the fan to run continuously at maximum power for the entire year. This maximum use of the fan creates larger overall energy requirements in spite of lower chiller energy use. However, a variable-air-volume system that modulates the fan supply rate to match loads should decrease the required fan power and significantly reduce total energy use.

Notes: Fan supply rate = 7400 CFM, ventilation = 150 CFM, wideband temperature limits for occupied times = 65° to 80°F, wideband temperature limits for unoccupied times = 60° to 85°F, economizer temperature limit = 65°F, time period = 1 to 365 days, total hours = 8760.

Tables IVa and IVb display monthly energy use for case 3 of Table I. Differing from case 1, this plan imposes dual wideband temperature limits. The wideband temperature limits for unoccupied times increase to 60 degrees F and 85 degrees F. Tables IVa and IVb show that this simple change with economy cycle operation reduces annual cooling energy use by 7 percent, from 56,222 kWh to 52,379 kWh. We can attribute this saving mainly to the lower chiller energy requirement, from 37,552 kWh to 34,237 kWh, and to a lesser extent to the smaller fan energy requirements, from 18,669 kWh to 18,141 kWh.

Tables V and VI show the results of the simulation for the buildings located in New Orleans and Phoenix, cases 4 and 5 of Table I. We can see that the maximum chiller load, 14.4 tons, is the same for these diverse locations. The total energy required in these buildings for economy cycle cooling is also nearly equal, 85,027 kWh and 85,123 kWh. Since the cooling load includes both sensible and latent energy, we can surmise from the degree-day totals that the dominant load on the system for Phoenix is sensible heat, and on that for New Orleans latent heat. The distribution of the relative humidity and the costs for humidification shown in Tables Vb and VIb tends to support these observations.

We can see the advantages in running the TELBECC program to compare different control plans. For example, although the intermittent control plan appears to use less energy overall, the proportional control plan actually reduces the size of the chiller plant by 9 percent in the same locale under similar conditions. The higher overall costs can be attributed to continuous operation of the fan, which, if operated to match the load, would consume much less power and make the

proportional control plan much more attractive. We can conclude that TELBECC has great potential for pinpointing significant energy reductions and cost savings before a building's HVAC system is purchased.

## VI. CONCLUSIONS

The TELBECC program analyzes more efficiently and quickly than any method used heretofore the possible telephone building environmental energy use and control options. To pinpoint the most economical energy-conservation plan, the program analyzes multiple plans at minimal cost and with minimal expenditure of time. The program calculates the energy consumed every quarter hour by the HVAC in regulating the environment under changing weather conditions. It computes the required energy from the physical characteristics of the building envelope, such as the U factor, internal heat generation, geographic location, orientation of the building, and the dry-bulb temperature standard. In order to make it feasible to calculate by computer, we employ a simplified recursive computation procedure using time series. For each of the illustrative problems in Tables II through VI, the procedure produced monthly projections; yet it took less than 40 seconds to calculate results on an IBM/3033 computer. From the examples, we see the advantages and disadvantages of both the intermittent and proportional control plans, as well as the significant savings obtained from increasing the range of the dual or

## APPENDIX

### *Calculating Inside-Wall Temperature Time Series Coefficients $b_i$, $a_i$, $a_i'$ of Eq. (1)*

The basis for computing the time-series coefficients is the $z$ transform,[8] a discrete function transformation. This transformation is applied to time functions sampled at regular intervals of time. The $z$ transform has the same role in discrete systems that the Laplace transform has in continuous systems analysis.

Let us consider a continuous function of time $f(t)$. When the function is sampled at regular intervals $\Delta$, the output consists of a train of pulses, as illustrated in Fig. 1. We defined the $z$ transform of this output as a polynomial in powers of $z^{-1}$ in the following:

$$f(0) + f(\Delta)z^{-1} + f(2\Delta)z^{-2} + f(3\Delta)z^{-3} + \cdots . \tag{8}$$

The successive outputs of the sampler are the coefficients of the successive powers of $z^{-1}$ in the $z$ transform.

A linear system is characterized when its response to an elementary input (such as a pulse, a unit step, or, as will be adopted here, a unit ramp) is ascertained. This is nothing more than obtaining a transfer function of the system. If both input and output of the system are expressed in terms of their $z$ transforms, the ratio of output/input is the $z$ transform of the system. If we assume that such a transfer function, $G(z)$, can be found and that it can be expressed as the quotient of two polynomials in $z^{-1}$, then

$$G(z) = \frac{N(z)}{D(z)} = \frac{a_0 + a_1z^{-1} + a_2z^{-2} + \cdots a_jz^{-j}}{b_0 + b_1z^{-1} + b_2z^{-2} + \cdots b_pz^{-p}}. \tag{9}$$

It follows that the $z$-transform of the output $O(z)$ resulting from an arbitrary input $I(z)$ is represented by

$$O(z) = G(z)I(z) \quad \text{or} \tag{10}$$

$$O(z)D(z) = N(z)I(z). \tag{11}$$

Since both sides of (11) are polynomials, the coefficients of the various powers of $z^{-1}$ must be the same on both sides of the equation. If, say, the coefficients of $z^{-n}$ are equated, eq. (11) yields

$$b_0O_n = a_0I_n + a_1I_{n-1} + a_2I_{n-2} + \cdots + a_jI_{n-j} - [b_1O_{n-1} + b_2O_{n-2} + \cdots + b_pO_{n-p}]. \tag{12}$$

The subscript $n$ on $O$ and $I$ indicates the value of the function at $t = n\Delta$; i.e., $O_n \equiv O(n\Delta)$, the coefficient of $z^{-n}$ in the $z$ transform of $O(z)$. This expression relates the output at any time $t = n\Delta$ to the input at that time and the input and output at earlier times. The coefficients $a_0, \cdots a_j$ and $b_0, \cdots b_p$ contain all the characteristics of

the system. With the properties of the $z$ transform described above, a method for determining the $z$ transform or time-series coefficients for the inside building wall temperature follows.

If we consider the outside building walls and roof structure as homogeneous flat slabs (Fig. 2), the temperature in the slab adheres to the following equations:

$$\kappa \frac{\delta^2 T_s}{\delta x^2} = \frac{\delta T_s}{\delta t},$$

$$T_s(x, 0) = 0,$$

$$k \frac{\delta T_s}{\delta x}(L, t) = -h_o[T_s(L, t) - T_o(t)],$$

$$k \frac{\delta T_s}{\delta x}(0, t) = h_i[T_s(0, t) - T_a(t)], \tag{13}$$

where

$T_s(x, t)$ (°F) = temperature in the slab,
$L$(ft) = slab thickness,
$k$(Btu/hr − ft − °F) = thermal conductivity,
$k \equiv \kappa/\rho c$(ft$^2$/hr) = diffusivity,
$\rho c$(Btu/ft$^3$) = volumetric heat capacity,
$h_o$(Btu/hr − ft$^2$ − °F) = outside-wall heat transfer coefficient,
$h_i$(Btu/hr − ft$^2$ − °F) = inside-wall heat transfer coefficient,
$T_o(t)$ = outside sol-air temperature, and
$T_a(t)$ = inside building air temperature.

It is convenient to use the Laplace transform

$$\bar{T}_s(x, p) = \int_0^\infty T_s(x, t) e^{-pt} dt$$

to eliminate the independent time variable $t$ in eq. (13). Then the solution for the inside wall surface ($x = 0$) temperature in terms of the transform parameter $p$ assumes the form:

$$\bar{T}_s(0, p) = \frac{h_i[kq \cosh(qL) + h_o \sinh(qL)]\bar{T}_a(p) + h_o kq \bar{T}_o(p)}{h_i[kq \cosh(qL) + h_o \sinh(qL)] + kq[kq \sinh(qL) + h_o \cosh(qL)]}, \tag{14}$$

where $q = (p/\kappa)^{1/2}$.

Letting $T_a(t)$ and $T_o(t)$ be unit ramp functions and inverting eq. (14) back to the real-time domain by using standard residue theory in the complex plane, the solution for $T_s(0, t)$, the temperature of the inside surface, is expressed as

$$T_s(0, t) = T_s^{(1)}(0, t) + T_s^{(2)}(0, t), \tag{15}$$

where $T_s^{(1)}(0, t)$ is the portion of the solution dependent on the outside sol-air temperature, and $T_s^{(2)}(0, t)$ the part dependent on the building space-air temperature. These temperatures are explicitly:

$$T_s^{(1)}(0, t) = B_O \left[ \frac{1}{B_i + B_O B_i + B_O} \left( t - \frac{L^2}{6\kappa} \frac{(3B_i + B_O B_i + 3B_O + 6)}{(B_i + B_O B_i + B_O)} \right) \right.$$

$$\left. - \frac{2L^2}{\kappa} \sum_{n=1}^{\infty} \frac{e^{-\alpha_n^2 \kappa t / L^2}}{\alpha_n^2 \{[(B_i + B_O B_i + B_i) - \alpha_n^2] \cdot \cos \alpha_n - \alpha_n (2 + B_O + B_i) \sin \alpha_n\}} \right], \tag{16}$$

and

$$T_s^{(2)}(0, t) = B_i \left[ \frac{1}{B_i + B_O B_i + B_O} \left( \frac{L^2}{6\kappa} (3 + B_O) \right. \right.$$

$$\left. \left. - \frac{L^2}{6\kappa} \frac{(1 + B_O)(3B_i + B_i B_O + 3B_O + 6)}{(B_i + B_O B_i + B_O)} + (1 + B_O)t \right) \right.$$

$$\left. - \frac{2L^2}{\kappa} \sum_{n=1}^{\infty} \frac{[\alpha_n \cos \alpha_n + B_O \sin \alpha_n] e^{-\alpha_n^2 \kappa t / L^2}}{\sigma_n^3 [(B_i + B_i B_O + B_O - \alpha_n^2] \cdot \cos \alpha_n - \alpha_n [2 + B_O + B_i] \sin \alpha_n} \right], \tag{17}$$

where $B_O = \dfrac{h_O L}{k}$, $B_i = \dfrac{h_i L}{k}$, and $\alpha_n$ are roots of the transcendental equation

$$\cot \alpha_n = \frac{\alpha_n^2 - B_O B_i}{\alpha_n (B_O + B_i)}, \qquad n = 1, 2, \cdots.$$

Equations (15) through (17) contain all the ingredients for forming the $z$-transform transfer functions for the inside-wall surface temperature. These are obtained by forming the ratio of output/input $z$ transforms as per eq. (9):

$$G^{(1)}(z) = \frac{T_s^{(1)}(0, z)}{T_O(z)} \quad \text{and} \quad G^{(2)}(z) = \frac{T_s^{(2)}(0, z)}{T_a(z)}. \tag{18}$$

$T_O(t)$ and $T_a(t)$ were taken as unit ramp functions, and therefore their $z$ transform from Ref. 8 is given as

$$T_O(z) = T_a(z) = \frac{\Delta}{z(1 - z^{-1})^2}. \tag{19}$$

The sampling interval is $\Delta$. The use of the input ramp function amounts to linear interpolation between the discrete values given by the $z$-transform coefficients.

The $z$ transforms of both $T_s^{(1)}(0, z)$ and $T_s^{(2)}(0, z)$ are similar in form and, with the aid of the table of $z$ transforms given in Ref. 8, can be expressed as

$$T_s^{(1,2)}(0, z) = \frac{A^{(1,2)}}{1 - z^{-1}} + \frac{B^{(1,2)}\Delta}{z(1 - z^{-1})^2} + \sum_{j=1}^{\infty} \frac{C_j^{(1,2)}}{1 - s_j z^{-1}}, \tag{20}$$

where

$$A^{(1)} = \frac{-B_O L^2}{6\kappa(B_i + B_O B_i + B_O)^2}(3B_i + B_O B_i + 3B_O + 6),$$

$$B^{(1)} = \frac{B_O}{B_i + B_O B_i + B_O},$$

$$C_j^{(1)} = -\frac{2L^2 B_O}{\kappa}\left(\frac{1}{\alpha_j^2\{[(B_i + B_O B_i + B_O) - \alpha_j^2] \cdot \cos\alpha_j - \alpha_j(2 + B_O + B_i)\sin\alpha_j\}}\right),$$

$$A^{(2)} = \frac{B_i}{B_i + B_O B_i + B_O}\left(\frac{L^2}{6\kappa}(3 + B_O) - \frac{L^2}{6\kappa}\frac{(1 + B_O)(3B_i + B_i B_O + 3B_O + 6)}{(B_i + B_O B_i + B_O)}\right),$$

$$B^{(2)} = \frac{B_i(1 + B_O)}{B_i + B_O B_i + B_O},$$

$$C_j^{(2)} = -\frac{2B_i L^2}{\kappa}\left(\frac{\alpha_j\cos\alpha_j + B_O\sin\alpha_j}{\alpha_j^3[(B_i + B_i B_O + B_O - \alpha_j^2)] \cdot \cos\alpha_j - \alpha_j(2 + B_O + B_i)\sin\alpha_j}\right), \quad \text{and}$$

$$s_j = e^{-\alpha_j^2 \Delta\kappa/L^2}$$

Equation (18) can now be expressed in the form of a ratio of polynomials in $z^{-1}$:

$$G^{(1,2)}(z) = \frac{N^{(1,2)}(z)}{D(z)}, \tag{21}$$

where, from the results of eqs. (19) and (20),

$$N^{(1,2)}(z) = \left(A^{(1,2)}\frac{z(1 - z^{-1})}{\Delta} + B^{(1,2)}\right)\prod_{j=1}^{\infty}(1 - s_j z^{-1}) + \frac{z(1 - z^{-1})^2}{\Delta}\sum_{n=1}^{\infty} C_n^{(1,2)}\prod_{j=n}^{\infty}(1 - s_j s^{-1}),$$

$$D(z) = \prod_{j=1}^{\infty}(1 - s_j z^{-1}).$$

Equation (21) is the form of eq. (9); consequently, the $b_i$ coefficients that are derived, as in eq. (12), from the coefficients of the polynomial $D(z)$ can be generated by a recursive scheme given as

$$b_0 = 1,\ b_i^{(1)} = 0,\ b_i^{(n+1)} = b_i^{(n)} - s_{i-n+1} b_{i-1}^{(n)}\ n = 1, \cdots N \qquad (22)$$

The number of $s_j$ terms needed to obtain the desired degree of accuracy for the $b_i$ coefficients is indicated by the index $n = N$, which in most instances should not exceed 20.

The $a_i$ and $a_i'$ coefficients in eq. (1) came from $N^{(1)}(z)$ and $N^{(2)}(z)$, respectively, by expanding these functions into polynomials in powers of $z^{-1}$; i.e.,

$$N^{(1)}(z) = a_1 z^{-1} + a_2 z^{-2} + \cdots$$

$$N^{(2)}(z) = a_1' z^{-1} + a_2' z^{-2} + \cdots$$

The desired coefficients are sorted out.

# Recursive Fixed-Order Covariance Least-Squares Algorithms

By M. L. HONIG*

(Manuscript received May 6, 1983)

This paper derives fixed-order recursive Least-Squares (LS) algorithms that can be used in system identification and adaptive filtering applications such as spectral estimation, and speech analysis and synthesis. These algorithms solve the sliding-window and growing-memory covariance LS estimation problems, and require less computation than both unnormalized and normalized versions of the computationally efficient order-recursive (lattice) covariance algorithms previously presented. The geometric or Hilbert space approach, originally introduced by Lee and Morf to solve the prewindowed LS problem, is used to systematically generate least-squares recursions. We show that combining subsets of these recursions results in prewindowed LS lattice and fixed-order (transversal) algorithms, and in sliding-window and growing-memory covariance lattice and transversal algorithms. The paper discusses both least-squares prediction and joint-process estimation.

## I. INTRODUCTION

Computationally efficient recursive Least-Squares (LS) algorithms have recently attracted attention in applications such as adaptive equalization,[1-4] echo cancellation,[5] and speech analysis and synthesis[6,7] because of their fast convergence properties when compared to older least-mean-square or gradient adaptation techniques.[8-10] Since the work on computationally efficient LS algorithms by Morf and others first appeared in Refs. 11 and 12, numerous papers have followed that produce computationally efficient algorithms that solve different types

of autoregressive LS estimation problems.[13-17] In general, these algorithms fall into four categories: (1) prewindowed recursive LS, (2) sliding-window recursive LS, (3) growing-memory covariance recursive LS, and (4) nonrecursive LS algorithms. Each of the first three categories has two subcategories: fixed-order, or transversal, algorithms; and order-recursive, or lattice, algorithms.

References 1 and 12 present a prewindowed LS algorithm that satisfies a transversal filter structure (fast Kalman algorithm). Subsequent Refs. 7, 18, and 19 describe prewindowed and growing-memory covariance LS algorithms that satisfy a lattice structure. Normalized prewindowed LS lattice algorithms that involve fewer recursions than the original unnormalized versions, and which have the important advantage that all internal variables are less than or equal to unity in magnitude are presented in the more recent Ref. 13. Reference 14 extends the normalized lattice algorithms to solve the sliding-window and growing-memory covariance LS problems. The recursive algorithms mentioned so far require order $N$ arithmetic operations per iteration to update the filter parameters, where $N$ is the order of the filter. A computationally efficient order-recursive algorithm that solves the set of linear equations for the covariance LS prediction problem has been presented in Ref. 11, and extended to the joint-process-estimation case in Ref. 17. These algorithms require order $N^2$ operations to compute the LS prediction coefficients and are nonrecursive in the sense that the solution generated at time interval $i$ is not used to generate the solution at time interval $i + 1$.

This paper attempts to unify and extend the previous work by (1) systematically generating all of the recursions needed to derive all of the previously mentioned algorithms, and (2) using these recursions to derive new recursive fixed-order sliding-window and growing-memory covariance LS algorithms. These new algorithms solve directly for the prediction- or autogressive-model coefficients, and involve significantly less computation than both the unnormalized and normalized versions of the order-recursive or covariance lattice algorithms presented in Ref. 14. In addition, in some applications it may be advantageous to work directly with the prediction- or autogressive-model coefficients, rather than the set of reflection coefficients produced by lattice algorithms. The algorithms mentioned in the previous paragraph, along with the new ones derived here, are obtained by appropriately arranging subsets of least-squares recursions. The geometric or Hilbert space approach originally used by Lee and Morf[20] to derive the prewindowed LS lattice algorithm is used to derive all of the basic least-squares recursions in a cohesive manner. In this paper, however, only scalar-valued data are considered.

The next section defines the sliding-window and growing-memory

covariance LS problems to be solved. Then Section III reviews the geometric approach to LS estimation. Fundamental order and time updates for the least-squares projection operator are given in Section IV, with derivations in Appendix A. In Section V these projection updates systematically derive least-squares recursions. Section VI gives fixed-order covariance algorithms and Section VII extends the preceding discussion to the joint-process-estimation case. Appendix B lists subsets of recursions in Sections V and VII that constitute other LS algorithms.

## II. PROBLEM STATEMENT

We start by defining a sequence of data values $y_0, y_1, \cdots, y_i$, where $i$ is the current time index. A linear least-squares *forward predictor* of order $n$ chooses the coefficients $f_{j|n}$ to minimize

$$\epsilon_f(i|n) = \sum_{m=i'}^{i} \left( y_m - \sum_{j=1}^{n} f_{j|n} y_{m-j} \right)^2, \tag{1}$$

where $i'$ to $i$ is the time window of interest. The coefficients $f_{j|n}$, $1 \leq j \leq n$, are called the forward-prediction coefficients. A linear least-squares *backward predictor* of order $n$ chooses the backward-prediction coefficients $b_{j|n}$, $1 \leq j \leq n$, to minimize

$$\epsilon_b(i|n) = \sum_{m=i'}^{i} \left( y_{m-n} - \sum_{j=1}^{n} b_{j|n} y_{m-j+1} \right)^2. \tag{2}$$

Minimization of (1) rather than (2) is generally desired for a given application. The forward and backward prediction problems stated above are closely related, however, and the LS algorithms to be presented use the backward prediction coefficients to solve for the forward prediction coefficients in a computationally efficient manner.

If, instead of estimating future values of the *same* process, we wish to estimate another related process $\{x_i\}$, the least-squares cost function becomes

$$\epsilon_x(i|n) = \sum_{m=i'}^{i} \left( x_m - \sum_{j=1}^{n} c_{j|n} y_{m-j+1} \right)^2, \tag{3}$$

where tap coefficients $c_{j|n}$ replace the prediction coefficients $f_{j|n}$ and $b_{j|n}$. The cost function (3) is relevant to joint-process-estimation problems such as channel equalization and echo cancellation. In the case of channel equalization, $y_i$ is the $i$th sample of the channel output, and $x_i$ is the $i$th channel symbol.

Setting the derivatives of the cost functions (1), (2), and (3) with respect to the prediction (tap) coefficients equal to zero results in the

following linear equations:

$$\Phi_{i'-1,i-1|n}\mathbf{f}(i|n) = \sum_{j=i'}^{i} y_j \mathbf{y}_{j-1|n}, \tag{4a}$$

$$\Phi_{i',i|n}\mathbf{b}(i|n) = \sum_{j=i'}^{i} y_{j-n}\mathbf{y}_{j|n}, \tag{4b}$$

and

$$\Phi_{i',i|n}\mathbf{c}(i|n) = \sum_{j=i'}^{i} x_j \mathbf{y}_{j|n}, \tag{4c}$$

where

$$\mathbf{f}^T(i|n) \equiv [f_{1|n} f_{2|n} \cdots f_{n|n}], \tag{5a}$$

$$\mathbf{b}^T(i|n) \equiv [b_{1|n} b_{2|n} \cdots b_{n|n}], \tag{5b}$$

$$\mathbf{c}^T(i|n) \equiv [c_{1|n} c_{2|n} \cdots c_{n|n}], \tag{5c}$$

$$\mathbf{y}_{j|n}^T \equiv [y_j y_{j-1} \cdots y_{j-n+1}], \tag{6}$$

and the covariance matrix

$$\Phi_{i',i|n} \equiv \sum_{j=i'}^{i} \mathbf{y}_{j|n}\mathbf{y}_{j|n}^T. \tag{7}$$

Suppose now that $i' = 0$, and that $y_0$ is the first available data sample. The least-squares solutions for **f**, **b**, and **c**, obtained by solving (4), are undefined since they depend on the unspecified data values $y - 1$, $y - 2$, $\cdots$, $y_{-n}$. The simplest, and perhaps most popular, technique for circumventing this problem is to assume all data values $y_j$, $j < 0$, are zero. The least-squares solutions resulting from this so-called prewindowed estimation are then well defined as long as the covariance matrix is nonsingular. In applications such as speech modelling, however, where estimates of the prediction coefficient vector $\mathbf{f}(i|n)$ are desired given relatively few data samples, prewindowed estimation may result in undesirable edge effects from assuming data is zero outside a given window. For these types of applications, it is desirable to estimate the prediction coefficients without any assumptions concerning the data outside the time window of interest.

Covariance least-squares estimation replaces the lower time limit $i'$ in (1), (2), and (3) by $n$, so that only known data values are used to compute the LS prediction (tap) coefficients. The improved estimates so obtained are not without cost, however. The resulting covariance LS algorithms derived in this paper and elsewhere[7] involve more computation than prewindowed LS algorithms. Notice that at each

iteration $i$, the prediction coefficients are computed from $i + 1$ data values. Because the number of data samples entering the least-squares computation grows with time, this type of estimation has been called growing-memory covariance estimation.[16]

Finally, another windowing technique that has attracted attention recently is the sliding-window technique, in which the lower time limit $i'$ in (1) and (2) is replaced by $i - M + n + 1$, and in (3) by $i - N + n$, where $M$ is a predetermined constant. At each iteration the least-squares prediction coefficients are therefore computed from a fixed number ($M$) of data samples. Notice that data samples outside the time window $i - M + 1$ to $i$ have no effect on the least-squares solution for $\mathbf{f}$, $\mathbf{b}$, and $\mathbf{c}$ at time $i$, i.e., they are totally forgotten. This is in contrast to more conventional exponential forgetting techniques that reduce the effects of past data samples in a more continuous fashion.[16] The sliding window is therefore useful in applications where the autoregressive model changes abruptly with time, or where undesirable transients periodically affect the data samples. In the former case, when the model parameters change, the sliding window eventually discards data values corresponding to previous model parameters. In the latter case, the sliding window eventually discards corrupted data values.

Computationally efficient recursive algorithms that solve the growing-memory covariance and sliding-window LS estimation problems will be derived in Sections V through VII. The next section develops the necessary mathematical background by reviewing the geometric interpretation of linear least-squares estimation.

## III. MATHEMATICAL BACKGROUND

Given two vectors $\mathbf{X}$ and $\mathbf{Y}$ having the same dimension $i$, the inner product of $\mathbf{X}$ and $\mathbf{Y}$ is defined to be

$$\langle \mathbf{X}, \mathbf{Y} \rangle \equiv \mathbf{X}^T \mathbf{W} \mathbf{Y}, \tag{8}$$

where $\mathbf{W}$ is some prespecified $i \times i$ weighting matrix. As an example, a typical weighting matrix is the exponential weighting matrix

$$\mathbf{W}_i = [1 \; w \; w^2 \; \cdots \; w^{i-1}]\mathbf{I}, \tag{9}$$

where $\mathbf{I}$ is the $i \times i$ identity matrix. For convenience, we will assume that $\mathbf{W}$ is the identity matrix. Modification of the results in this paper to the case where $\mathbf{W}$ is arbitrary is straightforward. The distance between two vectors $\mathbf{X}$ and $\mathbf{Y}$ with the same dimension is therefore the regular Euclidean distance,

$$d(\mathbf{X}, \mathbf{Y}) = \| \mathbf{Y} - \mathbf{X} \| \equiv \langle \mathbf{Y} - \mathbf{X}, \mathbf{Y} - \mathbf{X} \rangle^{1/2}. \tag{10}$$

The ($n$th order) projection of a vector $\mathbf{Y}$ onto a subspace (or

manifold) $M$, which is spanned by the $n$ vectors $\{\mathbf{X}_1, \mathbf{X}_2, \cdots, \mathbf{X}_n\}$, is denoted as $P_M\mathbf{Y}$. The orthogonal projection of $\mathbf{Y}$ onto $M$ is defined as

$$P_M^{\perp}\mathbf{Y} \equiv \mathbf{Y} - P_M\mathbf{Y}, \tag{11}$$

and is orthogonal to the subspace $M$. This implies that

$$\langle \mathbf{X}_j, \mathbf{Y} - P_M\mathbf{Y} \rangle = 0, \qquad \text{for} \quad j = 1, \cdots, n. \tag{12}$$

Since $P_M\mathbf{Y}$ lies in $M$, there exist constants, or regression coefficients $f_1, f_2, \cdots, f_n$ such that

$$P_M\mathbf{Y} = \sum_{j=1}^{n} f_j\mathbf{X}_j = \mathbf{S}\mathbf{f}, \tag{13}$$

where $\mathbf{S} = [\mathbf{X}_1 \cdots \mathbf{X}_n]$ and $\mathbf{f}^T = [f_1 \cdots f_n]$. Using (12) and (13), it is easy to show that

$$\mathbf{f} = (\mathbf{S}^T\mathbf{S})^{-1}\mathbf{S}^T\mathbf{X} \tag{14}$$

and

$$P_M\mathbf{Y} = \mathbf{S}(\mathbf{S}^T\mathbf{S})^{-1}\mathbf{S}^T\mathbf{Y}, \tag{15}$$

assuming $\mathbf{S}^T\mathbf{S}$ is nonsingular.

The linear least-squares estimate of $\mathbf{Y}$, based upon the vectors $\mathbf{X}_1, \cdots, \mathbf{X}_n$, is formed by choosing $f_1, \cdots, f_n$ such that

$$\| \underline{\epsilon} \|^2 \equiv \| \mathbf{Y} - \sum_{j=1}^{n} f_j\mathbf{X}_j \|^2 \tag{16}$$

is minimized. Differentiating this quantity with respect to $f_j$ and setting the result equal to zero gives

$$\hat{\mathbf{Y}} \equiv \sum_{j=1}^{n} f_j\mathbf{X}_j = P_M\mathbf{Y}, \tag{17}$$

and the vector of estimation errors,

$$\underline{\epsilon} = \mathbf{Y} - \sum_{j=1}^{n} f_j\mathbf{X}_j = P_M^{\perp}\mathbf{Y}. \tag{18}$$

We have identified the operator $P$ as a least-squares projection.

## IV. PROJECTION-OPERATOR UPDATE FORMULAS

In this section some fundamental relationships satisfied by the least-squares projection operator are presented. These projection updates fall into two main categories: order updates and time updates. Under time updates are two subcategories, forward and backward time updates. We point out in advance that a total of three projection-operator updates will be used throughout this paper: one order update, one

forward time update, and one backward time update. In addition, one forward and one backward time update for inner products will be needed.

### *4.1 Order updates*

Given two vectors, $\mathbf{Y}$ and $\mathbf{X}$, and a linear space $M$ spanned by the vectors $\mathbf{X}_1, \mathbf{X}_2, \cdots, \mathbf{X}_n$, all in $\mathbf{R}^i$, suppose we wish to calculate the least-squares estimate of $\mathbf{Y}$ based upon the vectors $\mathbf{X}_1, \cdots, \mathbf{X}_n$ and $\mathbf{X}$. In particular, we wish to find coefficients $a_j$, $j = 1, \cdots, n$, and $b$ such that $\| \mathbf{Y} - (\sum_{j=1}^{n} a_j \mathbf{X}_j + b\mathbf{X}) \|^2$ is minimized. From the discussion in the last section, we know that the least-squares estimate of $\mathbf{Y}$ is

$$\sum_{j=1}^{n} a_j \mathbf{X}_j + b\mathbf{X} = P_{\{M+\mathbf{X}\}}\mathbf{Y}, \tag{19}$$

where $\{M + \mathbf{X}\}$ denotes the space spanned by $M$ and $\mathbf{X}$. We can write the following orthogonal decomposition of the space $\{M + \mathbf{X}\}$,[21]

$$\{M + \mathbf{X}\} = M \oplus \{P_M^{\perp}\mathbf{X}\}. \tag{20}$$

By the Hilbert space projection theorem,[21] we have that for any vector $\mathbf{Y} \in \mathbf{R}^i$,

$$P_{\{M+\mathbf{X}\}}\mathbf{Y} = P_M\mathbf{Y} + P_{\{P_M^{\perp}\mathbf{X}\}}\mathbf{Y}. \tag{21}$$

Figure 1 illustrates this equation for the special case $n = 1$. The projection of $\mathbf{Y}$ onto the space spanned by two vectors $\mathbf{X}_1$ and $\mathbf{X}_2$ is shown as the sum of the two projections $P_{X_1}\mathbf{Y}$ and $P_{\{P_{X_1}^{\perp}\mathbf{X}_2\}}\mathbf{Y}$.

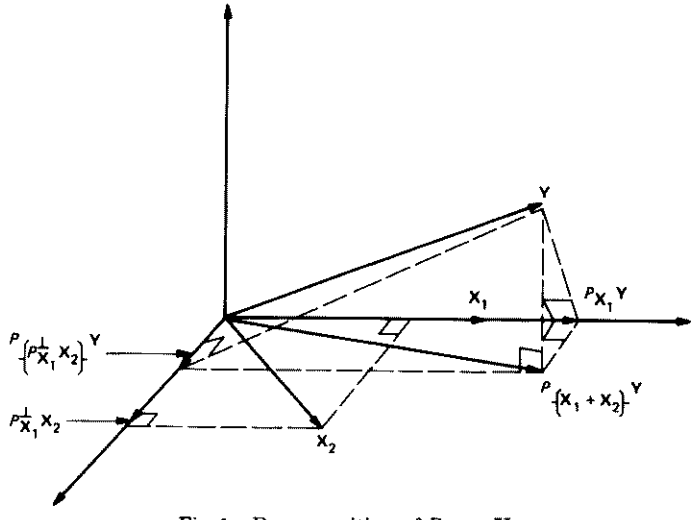

Fig. 1—Decomposition of $P_{\{\mathbf{X}_1+\mathbf{X}_2\}}\mathbf{Y}$.

Equation (21) constitutes a fundamental order update for the least-squares projection operator. The $(n+1)$st-order projection $P_{[M+\mathbf{X}]}$ is expressed as the sum of the $n$th order projection $P_M$ and the first order projection $P_{[P_M^{\perp}\mathbf{X}]}$. By subtracting both sides of (21) from $\mathbf{Y}$, we obtain the following order update for the *orthogonal* projection operator $P^{\perp}$,

$$P^{\perp}_{[M+\mathbf{X}]}\mathbf{Y} = P^{\perp}_{M}\mathbf{Y} - P_{[P^{\perp}_{M}\mathbf{X}]}\mathbf{Y}. \tag{22}$$

### 4.2 Forward time updates

The forward time updates derived in this section compute a least-squares projection at time $i$ given the same least-squares projection at time $i-1$. These recursions, when combined with the order recursions in the last subsection, can be used to derive prewindowed LS algorithms. We first consider the following vectors $\mathbf{X}_{i_0,i}$ and $\mathbf{Y}_{i_0,i}$, which are composed of data samples from time $i_0$ to $i$, i.e.,

$$\mathbf{X}^T_{i_0,i} = [x_i \; x_{i-1} \; \cdots \; x_{i_0}], \tag{23a}$$

and

$$\mathbf{Y}^T_{i_0,i} = [y_i \; y_{i-1} \; \cdots \; y_{i_0}]. \tag{23b}$$

For notational convenience, in this section only we will omit the lower time subscript on the data vectors and assume it to be $i_0$. Our objective is to compute the linear least-squares estimate of $\mathbf{Y}_i$, given $\mathbf{X}_i$ in terms of a least-squares estimate that does not use the most recent value $y_i$. With this in mind we define the unit vector

$$\mathbf{u}_i^T = [1 \; 0 \; \cdots \; 0 \; 0], \tag{24}$$

which has the same dimension as $\mathbf{Y}_i$, i.e., $\mathbf{u}_i \in \mathbf{R}^{i-i_0+1}$. Associated with $\mathbf{u}_i$ is the space spanned by $\mathbf{u}_i$, or the space of most recent data values, denoted as $U_i$. Note that $P_{U_i}\mathbf{Y}_i = y_i\mathbf{u}_i$. For notational convenience we define a tilde operator as follows,

$$\tilde{\mathbf{Y}}_i \equiv P^{\perp}_{U_i}\mathbf{Y}_i = [0 \; y_{i-1} \; y_{i-2} \; \cdots \; y_{i_0+1} \; y_{i_0}], \tag{25}$$

i.e., $\tilde{\mathbf{Y}}_i$ is the projection of $\mathbf{Y}_i$ onto the subspace of past data values.

The basic prediction problem is illustrated in Fig. 2, where $\mathbf{Y}_i$ is a vector having its endpoint in back of the plane of the paper and $\mathbf{X}_i$ has its endpoint in front of the plane of the paper. We are given the vector $\mathbf{X}_i$, from which the least-squares estimate of $\mathbf{Y}_i$, $P_{\mathbf{X}_i}\mathbf{Y}_i$, is to be recursively obtained. At time $i$ we therefore assume a regression coefficient $a$ computed at time $i-1$ (i.e., $P_{\mathbf{X}_{i-1}}\mathbf{Y}_{i-1} = a\mathbf{X}_{i-1}$, or equivalently, $P_{\tilde{\mathbf{X}}_i}\tilde{\mathbf{Y}}_i = a\tilde{\mathbf{X}}_i$), which we wish to modify using the most recent data values $y_i$ and $x_i$. Figure 2 therefore shows $P_{\mathbf{X}_i}\mathbf{Y}_i$ decomposed into the two vectors $a\mathbf{X}_i$ and $P_{\mathbf{X}_i}(\mathbf{Y}_i - a\mathbf{X}_i)$. Figure 3 illustrates the plane spanned by $\mathbf{X}_i$, $\tilde{\mathbf{X}}_i$, and $U_i$. Since ABC and ADE are similar

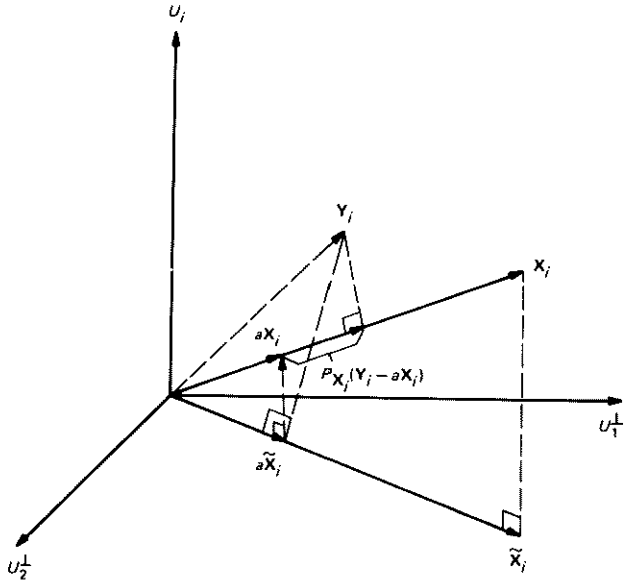

Fig. 2—Decomposition of $P_{\mathbf{X}_i}\mathbf{Y}_i$.

triangles,

$$\frac{\text{AB}}{\text{AD}} = \frac{\text{AC}}{\text{AE}} = a, \tag{26}$$

so that $\overline{\text{AC}} = a\mathbf{X}_i$. Figure 4 attempts to include vectors not shown in Fig. 2 and again illustrates the decomposition of $P_{\mathbf{X}_i}\mathbf{Y}_i$. (Only the endpoint of $\mathbf{Y}_i$ is in Fig. 4.)

Assume now that the vector $\mathbf{X}_i$ is replaced by the *subspace* $M_i$ spanned by the vectors $\mathbf{X}_{1,i}, \mathbf{X}_{2,i}, \cdots, \mathbf{X}_{n,i}$. Let

$$\mathbf{S}_i = [\mathbf{X}_{1,i}\ \mathbf{X}_{2,i}\ \cdots\ \mathbf{X}_{n,i}] \tag{27}$$

and

$$\tilde{\mathbf{S}}_i = [\tilde{\mathbf{X}}_{1,i}\ \tilde{\mathbf{X}}_{2,i}\ \cdots\ \tilde{\mathbf{X}}_{n,i}]. \tag{28}$$

We define the projection

$$P_{M_{i|i-1}}\mathbf{Y}_i \equiv \mathbf{S}_i[\tilde{\mathbf{S}}_i^T\tilde{\mathbf{S}}_i]^{-1}\tilde{\mathbf{S}}_i^T\tilde{\mathbf{Y}}_i = \mathbf{S}_i\mathbf{f}, \tag{29}$$

i.e., $P_{M_{i|i-1}}\mathbf{Y}_i$ lies in $M_i$, but uses regression coefficients computed at time $i-1$. Referring to Fig. 3, $P_{\mathbf{X}_{i|i-1}}\mathbf{Y}_i = a\mathbf{X}_i$. Appendix A shows that

$$P_{M_i}\mathbf{Y}_i = P_{M_{i|i-1}}\mathbf{Y}_i + P_{M_i}\mathbf{u}_i\langle \mathbf{u}_i, P_{M_i}^\perp\mathbf{Y}_i\rangle \sec^2\theta_i, \tag{30}$$

where

$$\sin^2\theta_i = \langle \mathbf{u}_i, P_{M_i}\mathbf{u}_i\rangle = \| P_{M_i}\mathbf{u}_i \|^2$$

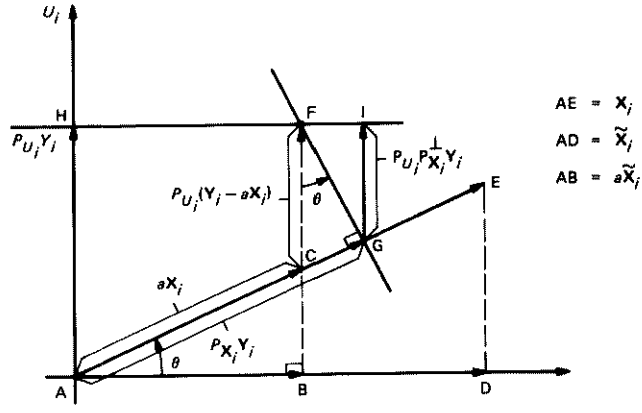

Fig. 3—Plane spanned by $\mathbf{X}_i$ and $\tilde{\mathbf{X}}_i$.

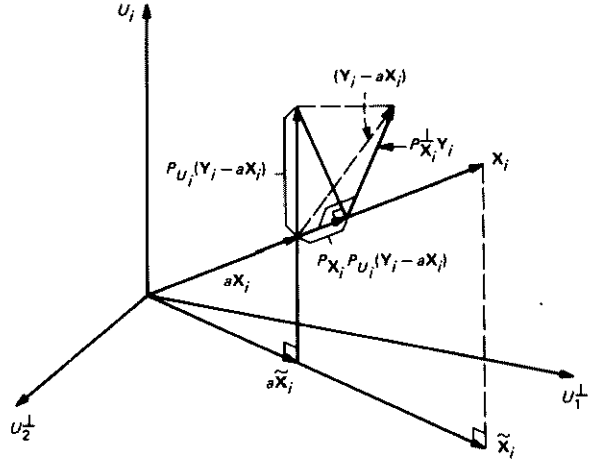

Fig. 4—Rotated view of Fig. 2.

$$= (\mathbf{u}_i^T\mathbf{S}_i)(\mathbf{S}_i^T\mathbf{S}_i)^{-1}(\mathbf{S}_i^T\mathbf{u}_i), \tag{31}$$

and

$$\sec^2\theta_i = \frac{1}{1 - \sin^2\theta_i}. \tag{32}$$

The variable $\theta_i$ can be interpreted as the angle between the spaces spanned by the matrices of basis vectors $\mathbf{S}_i$ and $\tilde{\mathbf{S}}_i$. Referring to Fig. 3, the angle $\theta$ is given by

$$\sin^2\theta = 1 - \frac{\|\tilde{\mathbf{X}}_i\|^2}{\|\mathbf{X}_i\|^2} = \frac{x_i^2}{\|\mathbf{X}_i\|^2}, \tag{33}$$

and measures the unexpectedness of the data received at time $i$. Notice that (33) can be rewritten as (31), where $M_i$ and $\mathbf{S}_i$ are replaced by $\mathbf{X}_i$.

We obtain the following time update for the orthogonal projection operator by subtracting both sides of (30) from $\mathbf{Y}_i$,

$$P_{M_i}^{\perp}\mathbf{Y}_i = P_{M_i|i-1}^{\perp}\mathbf{Y}_i - P_{M_i}\mathbf{u}_i\langle \mathbf{u}_i, P_{M_i}^{\perp}\mathbf{Y}_i\rangle \sec^2\theta_i. \tag{34}$$

One more relation that will be useful in the following section is a recursive equation for the inner product $\langle \mathbf{v}_i, P_{M_i}^{\perp}\mathbf{Y}_i\rangle$, where $\mathbf{v}_i$ is an arbitrary vector in $\mathbf{R}^{i-i_0+1}$. This recursion, which is derived in Appendix A, is

$$\langle \mathbf{v}_i, P_{M_i}^{\perp}\mathbf{Y}_i\rangle = \langle \tilde{\mathbf{v}}_i, P_{\tilde{M}_i}^{\perp}\tilde{\mathbf{Y}}_i\rangle + \langle \mathbf{u}_i, P_{M_i}^{\perp}\mathbf{v}_i\rangle\langle \mathbf{u}_i, P_{M_i}^{\perp}\mathbf{Y}_i\rangle \sec^2\theta_i, \tag{35}$$

where $\tilde{M}_i$ is the space spanned by $\tilde{\mathbf{S}}_i$.

### *4.3 Backward time updates*

Consider again the data vectors $\mathbf{X}_i$ and $\mathbf{Y}_i$ defined by (23). Suppose we wish to compute the linear least-squares estimate of $\mathbf{Y}_i$ given $\mathbf{X}_i$ in terms of a least-squares estimate that does not use the most *distant* or *past* values $y_{i_0}$ and $x_{i_0}$. Clearly, this problem can be solved in exactly the same fashion as the time-update problem stated at the beginning of the last section. By turning the vectors $\mathbf{Y}_i$ and $\mathbf{X}_i$ upside down, and assuming that $y_{i_0}$ and $x_{i_0}$ are the most recent samples, one can solve this problem by using time updates already derived. The same argument holds when $\mathbf{X}_i$ is replaced by the subspace $M_i$ spanned by vectors $\mathbf{X}_{1,i}, \mathbf{X}_{2,i}, \cdots, \mathbf{X}_{n,i}$. In this case we wish to calculate the projection $P_{M_i}\mathbf{Y}_i$ in terms of a projection onto the space spanned by the matrix of basis vectors $\mathbf{S}_i$ in which the *bottom row* has been replaced by zeros. This is in contrast to the previous time updates, which expressed $P_{M_i}\mathbf{Y}_i$ in terms of a projection onto the space spanned by $\mathbf{S}_i$ in which the *top* row has been replaced by zeroes (i.e., $\tilde{M}_i$).

In analogy with the notation defined in the last section, we define the unit vector

$$\mathbf{u}_{i_0}^T = [0\ 0\ \cdots\ 0\ 1] \in \mathbf{R}^{i-i_0+1}, \tag{36}$$

and the space spanned by $\mathbf{u}_{i_0}$ as $U_{i_0}$. We also define the following asterisk operator in analogy with the previous tilde operator,

$$\mathbf{Y}_i^* = P_{U_{i_0}}^{\perp}\mathbf{Y}_i = [y_i\ y_{i-1}\ \cdots\ y_{i_0+1}\ 0]^T. \tag{37}$$

Similarly,

$$\mathbf{S}_i^* = [\mathbf{X}_{1,i}^*\ \mathbf{X}_{2,i}^*\ \cdots\ \mathbf{X}_{n,i}^*]. \tag{38}$$

The projection of $\mathbf{Y}_i$ onto $M_i$ using regression coefficients computed from $\mathbf{S}_i^*$ is defined as

$$P_{M_{i_0|i_0+1}}\mathbf{Y}_i \equiv \mathbf{S}_i[\mathbf{S}_i^{*T}\mathbf{S}_i^*]^{-1}[\mathbf{S}_i^{*T}\mathbf{Y}_i]. \tag{39}$$

The regression coefficients that multiply the basis vectors of $M_i$ are in this case elements of the vector $[\mathbf{S}_i^{*T}\mathbf{S}_i^*]^{-1}[\mathbf{S}_i^{*T}\mathbf{Y}_i]$.

The derivation of (30) can be repeated with $\mathbf{u}_i$ replaced by $\mathbf{u}_{i_0}$, tildes replaced by asterisks, and $P_{M_{i|i-1}}$ replaced by $P_{M_{i_0|i_0+1}}$ to give the following projection decomposition,

$$P_{M_i}\mathbf{Y}_i = P_{M_{i_0|i_0+1}}\mathbf{Y}_i + P_{M_i}\mathbf{u}_{i_0}\langle \mathbf{u}_{i_0}, P_{M_i}^{\perp}\mathbf{Y}_i\rangle \sec^2\theta_i^*, \tag{40}$$

where

$$\begin{aligned}\sin^2\theta_i^* &= \| P_{M_i}\mathbf{u}_{i_0}\|^2 \\ &= (\mathbf{u}_{i_0}^T\mathbf{S}_i)(\mathbf{S}_i^T\mathbf{S}_i)^{-1}(\mathbf{S}_i^T\mathbf{u}_{i_0}) \\ &= \langle \mathbf{u}_{i_0}, P_{M_i}\mathbf{u}_{i_0}\rangle,\end{aligned} \tag{41}$$

and

$$\sec^2\theta_i^* = \frac{1}{1 - \sin^2\theta_i^*}. \tag{42}$$

Subtracting both sides of (40) from $\mathbf{Y}_i$ gives

$$P_{M_i}^{\perp}\mathbf{Y}_i = P_{M_{i_0|i_0+1}}^{\perp}\mathbf{Y}_i - P_{M_i}\mathbf{u}_{i_0}\langle \mathbf{u}_{i_0}, P_{M_i}^{\perp}\mathbf{Y}_i\rangle \sec^2\theta_i^*. \tag{43}$$

Finally, the following update for inner products is analogous to (35),

$$\langle \mathbf{v}_i, P_{M_i}^{\perp}\mathbf{Y}_i\rangle = \langle \mathbf{v}_i^*, P_{M_i^*}^{\perp}\mathbf{Y}_i^*\rangle + \langle \mathbf{u}_{i_0}, P_{M_i}^{\perp}\mathbf{v}_i\rangle\langle \mathbf{u}_{i_0}, P_{M_i}^{\perp}\mathbf{Y}_i\rangle \sec^2\theta_i^*. \tag{44}$$

This completes the presentation of projection-operator recursions needed to derive the least-squares recursions in Sections V and VII. All order updates for variables entering the least-squares algorithms to be presented can be derived from (22). Similarly, all forward and backward time updates for vectors entering these algorithms can be derived from (34) and (43), respectively, and all forward and backward time updates for inner products can be derived from (35) and (44), respectively.

## V. LEAST-SQUARES RECURSIONS

### *5.1 Notation*

Referring to the definition (23), a shift operator $z^{-j}$ is defined by

$$z^{-j}\mathbf{Y}_{i_0,i}^T = [y_{i-j}\ y_{i-j-1}\ \cdots\ y_{i_0-j}]. \tag{45}$$

Equations (1) and (2) can now be rewritten as

$$\epsilon_f(i\,|\,n) = \| \mathbf{Y}_{i_0+n,i} - \sum_{j=1}^{n} f_{j\,|\,n}(z^{-j}\mathbf{Y}_{i_0+n,i}) \|^2 \tag{46a}$$

and

$$\epsilon_b(i \mid n) = \| z^{-n}\mathbf{Y}_{i_0+n,i} - \sum_{j=1}^{n} b_{j\mid n}(z^{-j+1}\mathbf{Y}_{i_0+n,i}) \|^2, \tag{46b}$$

where $i'$ has been replaced by $i_0 + n$. A matrix of shifted data vectors is denoted as

$$\mathbf{S}_{i_0+n,i}(l, n) = [z^{-l}\mathbf{Y}_{i_0+n,i}\ z^{-l-1}\mathbf{Y}_{i_0+n,i} \cdots z^{-n}\mathbf{Y}_{i_0+n,i}], \tag{47}$$

where $l < n$. The space spanned by the columns of $\mathbf{S}_{i_0+n,i}(l, n)$, which is a subspace generated by past data values, is denoted as $M_{i_0+n,i}(l, n)$. For notational convenience we will omit the lower time index of $\mathbf{S}$ and $M$ and assume that it is always $i_0 + n$. Notice that we can write the covariance matrix defined by (7) as

$$\Phi_{i_0+n,i\mid n} = \mathbf{S}_i^T(0, n-1)\mathbf{S}_i(0, n-1). \tag{48}$$

Two types of updates exist for least-squares parameters: order updates and time updates. The time updates in this section generally fall into two categories. Given some LS parameter $\xi$ (i.e., the forward prediction vector $\mathbf{f}$ or the prediction residual), we wish to find (1) a recursion for $\xi$ computed from the data samples $\{y_{i_0}, y_{i_0+1}, \cdots, y_i\}$ in terms of $\xi$ computed from the data samples $\{y_{i_0}, y_{i_0+1}, \cdots, y_{i-1}\}$ (forward time update), and (2) a recursion for $\xi$ computed from the data samples $\{y_{i_0}, y_{i_0+1}, \cdots, y_i\}$ in terms of $\xi$ computed from the data samples $\{y_{i_0+1}, y_{i_0+2}, \cdots, y_i\}$ (backward time update). Associated with the variable $\xi$ is therefore an order index $n$ and the time indices of the data used in the least-squares computation. If the data values $\{y_{i_0}, y_{i_0+1}, \cdots, y_i\}$ are used to compute $\xi$, then the indices $i_0$ and $i$ must be specified. This is in contrast to the prewindowed case where only $i$ need be specified since $i_0$ is always zero.

Throughout the rest of this paper, the starting-time index of the generic parameter $\xi$ will appear as a subscript, and the current-time index will appear as a function argument. As an example $\xi_{i_0}(i \mid n)$ implies that the data values $\{y_{i_0}, y_{i_0+1}, \cdots, y_i\}$ are used to compute the $n$th order variable $\xi$. The following variables are needed to derive the LS algorithms in the next section:

1. Forward and backward prediction vectors [from (4)],

$$\mathbf{f}_{i_0}(i \mid n) = \Phi^{-1}_{i_0+n-1,i-1\mid n}[\mathbf{S}_i^T(1, n)\mathbf{Y}_{i_0+n,i}] \tag{49a}$$

and

$$\mathbf{b}_{i_0}(i \mid n) = \Phi^{-1}_{i_0+n,i\mid n}[\mathbf{S}_i^T(0, n-1)(z^{-n}\mathbf{Y}_{i_0+n,i})]. \tag{49b}$$

2. Forward and backward prediction residual vectors,

$$\mathbf{E}_{f,i_0}(i \mid n) \equiv \mathbf{Y}_{i_0+n,i} - \mathbf{S}_i(1, n)\mathbf{f}_{i_0}(i \mid n) \tag{50a}$$

and

$$\mathbf{E}_{b,i_0}(i \mid n) \equiv z^{-n}\mathbf{Y}_{i_0+n,i} - \mathbf{S}_i(0, n-1)\mathbf{b}_{i_0}(i \mid n). \tag{50b}$$

3. Forward and backward prediction residuals (scalars),

$$e_{f,i_0}(i \mid n) \equiv \langle \mathbf{u}_i, \mathbf{E}_{f,i_0}(i \mid n) \rangle = y_i - \mathbf{f}_{i_0}^T(i \mid n)\mathbf{y}_{i-1 \mid n} \tag{51a}$$

and

$$e_{b,i_0}(i \mid n) \equiv \langle \mathbf{u}_i, \mathbf{E}_{b,i_0}(i \mid n) \rangle = y_{i-n} - \mathbf{b}_{i_0}^T(i \mid n)\mathbf{y}_{i \mid n}. \tag{51b}$$

4. Forward and backward cost functions,

$$\epsilon_{f,i_0}(i \mid n) \equiv \| \mathbf{E}_{f,i_0}(i \mid n) \|^2, \qquad \epsilon_{b,i_0}(i \mid n) \equiv \| \mathbf{E}_{b,i_0}(i \mid n) \|^2. \tag{52}$$

5. PARtial CORrelation (PARCOR) coefficient,

$$k_{n,i_0}(i) \equiv \langle \mathbf{E}_{f,i_0+1}(i \mid n-1), \mathbf{E}_{b,i_0}(i-1 \mid n-1) \rangle. \tag{53}$$

6. Auxiliary variables, or gains,

$$\mathbf{g}_{i_0+1}(i \mid n) \equiv \Phi_{i_0+n,i \mid n}^{-1}\mathbf{y}_{i \mid n}, \tag{54a}$$

$$\mathbf{h}_{i_0+1}(i \mid n) \equiv \Phi_{i_0+n,i \mid n}^{-1}\mathbf{y}_{i_0+n \mid n}, \tag{54b}$$

$$\gamma_{i_0+1}(i \mid n) \equiv \langle \mathbf{u}_i, P_{M_i(0,n-1)}\mathbf{u}_i \rangle = \mathbf{y}_{i \mid n}^T\Phi_{i_0+n,i \mid n}^{-1}\mathbf{y}_{i \mid n}, \tag{55a}$$

$$\gamma_{i_0+1}^*(i \mid n) \equiv \langle \mathbf{u}_{i_0}, P_{M_i(0,n-1)}\mathbf{u}_{i_0} \rangle = \mathbf{y}_{i_0+n \mid n}^T\Phi_{i_0+n,i \mid n}^{-1}\mathbf{y}_{i_0+n \mid n}, \tag{55b}$$

and

$$\alpha_{i_0+1}(i \mid n) \equiv \langle \mathbf{u}_{i_0}, P_{M_i(0,n-1)}\mathbf{u}_i \rangle = \mathbf{y}_{i \mid n}^T\Phi_{i_0+n,i \mid n}^{-1}\mathbf{y}_{i_0+n \mid n}. \tag{55c}$$

Notice that

$$\mathbf{S}_i(0, n-1)\mathbf{g}_{i_0+1}(i \mid n) = P_{M_i(0,n-1)}\mathbf{u}_i; \tag{56a}$$

and

$$\mathbf{S}_i(0, n-1)\mathbf{h}_{i_0+1}(i \mid n) = P_{M_i(0,n-1)}\mathbf{u}_{i_0}; \tag{56b}$$

and that

$$\gamma_{i_0+1}(i \mid n) = \mathbf{g}_{i_0+1}^T(i \mid n)\mathbf{y}_{i \mid n}, \tag{57a}$$

$$\gamma_{i_0+1}^*(i \mid n) = \mathbf{h}_{i_0+1}^T(i \mid n)\mathbf{y}_{i_0+n \mid n}, \tag{57b}$$

and

$$\alpha_{i_0+1}(i \mid n) = \mathbf{g}_{i_0+1}^T(i \mid n)\mathbf{y}_{i_0+n \mid n} = \mathbf{h}_{i_0+1}^T(i \mid n)\mathbf{y}_{i \mid n}. \tag{57c}$$

Using the notation in the last section, the gains $\gamma$ and $\gamma^*$ are, respectively, $\sin^2\theta_i$ and $\sin^2\theta_i^*$ where $\theta_i$ and $\theta_i^*$ are, respectively, the angles between $M_i(0, n-1)$ and $\tilde{M}_i(0, n-1)$, and between $M_i(0, n-1)$ and $M_i^*(0, n-1)$.

At each time instant our objective is to minimize the cost functions

$\epsilon_{f,i_0}(i \mid n)$ and $\epsilon_{b,i_0}(i \mid n)$. From the discussion in Section III it follows that

$$\mathbf{E}_{f,i_0}(i \mid n) = P^{\perp}_{M_i(1,n)} \mathbf{Y}_{i_0+n,i} \tag{58a}$$

and

$$\mathbf{E}_{b,i_0}(i \mid n) = P^{\perp}_{M_i(0,n-1)}(z^{-n}\mathbf{Y}_{i_0+n,i}). \tag{58b}$$

The following variables, which are closely related to the prediction residuals, are also needed:

$$\begin{aligned}\mathbf{E}'_{f,i_0}(i \mid n) &\equiv P^{\perp}_{M_{i\mid i-1}(1,n)} \mathbf{Y}_{i_0+n,i} \\ &= \mathbf{Y}_{i_0+n,i} - \mathbf{S}_i(1,\ n)\mathbf{f}_{i_0}(i-1 \mid n),\end{aligned} \tag{59a}$$

and

$$\begin{aligned}\mathbf{E}'_{b,i_0}(i \mid n) &\equiv P^{\perp}_{M_{i\mid i-1}(0,n-1)}(z^{-n}\mathbf{Y}_{i_0+n,i}) \\ &= z^{-n}\mathbf{Y}_{i_0+n,i} - \mathbf{S}_i(0,\ n-1)\mathbf{b}_{i_0}(i-1 \mid n),\end{aligned} \tag{59b}$$

i.e., $\mathbf{E}'_f$ and $\mathbf{E}'_b$ are the forward and backward residual vectors obtained by using prediction vectors computed at the *previous* time interval. The top components of $\mathbf{E}'_{f,i_0}(i \mid n)$ and $\mathbf{E}'_{b,i_0}(i \mid n)$ are, respectively,

$$\begin{aligned}e'_{f,i_0}(i \mid n) &\equiv \langle \mathbf{u}_i,\ \mathbf{E}'_{f,i_0}(i \mid n)\rangle \\ &= y_i - \mathbf{f}^T_{i_0}(i-1 \mid n)\mathbf{y}_{i-1\mid n}\end{aligned} \tag{60a}$$

and

$$\begin{aligned}e'_{b,i_0}(i \mid n) &\equiv \langle \mathbf{u}_i,\ \mathbf{E}'_{b,i_0}(i \mid n)\rangle \\ &= y_{i-n} - \mathbf{b}^T_{i_0}(i-1 \mid n)\mathbf{y}_{i\mid n}.\end{aligned} \tag{60b}$$

The $n$th order forward prediction residual computed at time $i_0 + n$ using the tap vector $\mathbf{f}_{i_0}(i \mid n)$ is

$$\begin{aligned}e^*_{f,i_0}(i \mid n) &\equiv \langle \mathbf{u}_{i_0}, \mathbf{E}_{f,i_0}(i \mid n)\rangle \\ &= y_{i_0+n} - \mathbf{f}^T_{i_0}(i \mid n)\mathbf{y}_{i_0+n-1\mid n}.\end{aligned} \tag{61}$$

The forward residual vector at time $i$ using the forward prediction vector calculated from the data samples $\{y_{i_0+1},\ \cdots,\ y_i\}$ is

$$\begin{aligned}\mathbf{E}_{f,i_0\mid i_0+1}(i \mid n) &\equiv P^{\perp}_{M_{i_0\mid i_0+1}(1,n)} \mathbf{Y}_{i_0+n,i} \\ &= \mathbf{Y}_{i_0+n,i} - \mathbf{S}_i(1,\ n)\mathbf{f}_{i_0+1}(i \mid n).\end{aligned} \tag{62}$$

The variables $e^*_{b,i_0}(i \mid n)$ and $\mathbf{E}_{b,i_0\mid i_0+1}(i \mid n)$ are similarly defined.

Notice that the time indices associated with a residual vector change in accordance with the projection space, i.e.,

$$P^{\perp}_{M_i(1,n-1)} \mathbf{Y}_{i_0+n,i} = \mathbf{E}_{f,i_0+1}(i \mid n-1), \tag{63a}$$

and

$$P^{\perp}_{M_i(1,n-1)}(z^{-n}\mathbf{Y}_{i_0+n,i}) = \mathbf{E}_{b,i_0}(i-1\,|\,n-1). \tag{63b}$$

The recursions needed to derive the algorithms in the next section are now generated systematically. By appropriately defining the vectors and subspaces entering the projection order update (22), order updates are derived for all of the basic variables defined by (49) through (55). We then use the forward and backward time updates (34) and (43) to obtain forward and backward time updates for the basic vectors defined by (49), (50), and (54). Finally, the forward and backward time updates for inner products (35) and (44) are applied to $k_{n,i_0}(i)$, $\epsilon_{f,i_0}(i\,|\,n)$, and $\epsilon_{b,i_0}(i\,|\,n)$. It would take up too much space to explicitly define the vectors and subspaces that must be substituted in the projection update used to derive each recursion. Consequently, only the results are stated, with a few representative examples worked out in more detail.

### *5.2 Order updates*

The following order updates are obtained by using the projection order update (22) [or equivalently (21)]. The $l$th through the $m$th component of $\mathbf{f}_{i_0}(i\,|\,n)$ is denoted by $[\mathbf{f}_{i_0}(i\,|\,n)]_{l,m}$, and $[\mathbf{f}_{i_0}(i\,|\,n)]_j$ is the $j$th component of $\mathbf{f}_{i_0}(i\,|\,n)$. The same notation is used for the backward prediction vector $\mathbf{b}_{i_0}(i\,|\,n)$ and the gain vectors $\mathbf{g}_{i_0}(i\,|\,n)$ and $\mathbf{h}_{i_0}(i\,|\,n)$.

$$\mathbf{E}_{f,i_0}(i\,|\,n) = \mathbf{E}_{f,i_0+1}(i\,|\,n-1) - \frac{k_{n,i_0}(i)}{\epsilon_{b,i_0}(i-1\,|\,n-1)} \cdot \mathbf{E}_{b,i_0}(i-1\,|\,n-1), \tag{64a}$$

$$\mathbf{E}_{b,i_0}(i\,|\,n) = \mathbf{E}_{b,i_0}(i-1\,|\,n-1) - \frac{k_{n,i_0}(i)}{\epsilon_{f,i_0+1}(i\,|\,n-1)} \cdot \mathbf{E}_{f,i_0+1}(i\,|\,n-1), \tag{64b}$$

$$\epsilon_{f,i_0}(i\,|\,n) = \epsilon_{f,i_0+1}(i\,|\,n-1) - \frac{k^2_{n,i_0}(i)}{\epsilon_{b,i_0}(i-1\,|\,n-1)}, \tag{65a}$$

$$\epsilon_{b,i_0}(i\,|\,n) = \epsilon_{b,i_0}(i-1\,|\,n-1) - \frac{k^2_{n,i_0}(i)}{R_{f,i_0+1}(i\,|\,n-1)}, \tag{65b}$$

$$[\mathbf{f}_{i_0}(i\,|\,n)]_n = \frac{k_{n,i_0}(i)}{\epsilon_{b,i_0}(i-1\,|\,n-1)}, \tag{66a}$$

$$[\mathbf{f}_{i_0}(i\,|\,n)]_{1,n-1} = \mathbf{f}_{i_0+1}(i\,|\,n-1) - [\mathbf{f}_{i_0}(i\,|\,n)]_n \mathbf{b}_{i_0}(i-1\,|\,n-1), \tag{66b}$$

$$[\mathbf{b}_{i_0}(i\,|\,n)]_1 = \frac{k_{n,i_0}(i)}{\epsilon_{f,i_0+1}(i\,|\,n-1)}, \tag{67a}$$

$$[\mathbf{b}_{i_0}(i\,|\,n)]_{2,n} = \mathbf{b}_{i_0}(i-1\,|\,n-1) - [\mathbf{b}_{i_0}(i\,|\,n)]_1 \mathbf{f}_{i_0+1}(i\,|\,n-1), \tag{67b}$$

$$[\mathbf{g}_{i_0}(i\,|\,n+1)]_{n+1} = \frac{e_{b,i_0}(i\,|\,n)}{\epsilon_{b,i_0}(i\,|\,n)}, \tag{68a}$$

$$[\mathbf{g}_{i_0}(i\,|\,n+1)]_{1,n} = \mathbf{g}_{i_0+1}(i\,|\,n) - [\mathbf{g}_{i_0}(i\,|\,n+1)]_{n+1} \mathbf{b}_{i_0}(i\,|\,n), \tag{68b}$$

$$[\mathbf{g}_{i_0}(i\,|\,n+1)]_1 = \frac{e_{f,i_0}(i\,|\,n)}{\epsilon_{f,i_0}(i\,|\,n)}, \tag{69a}$$

$$[\mathbf{g}_{i_0}(i\,|\,n+1)]_{2,n+1} = \mathbf{g}_{i_0}(i-1\,|\,n) - [\mathbf{g}_{i_0}(i\,|\,n+1)]_1 \mathbf{f}_{i_0}(i\,|\,n), \tag{69b}$$

$$[\mathbf{h}_{i_0}(i\,|\,n+1)]_{n+1} = \frac{e^*_{b,i_0}(i\,|\,n)}{\epsilon_{b,i_0}(i\,|\,n)}, \tag{70a}$$

$$[\mathbf{h}_{i_0}(i\,|\,n+1)]_{1,n} = \mathbf{h}_{i_0+1}(i\,|\,n) - [\mathbf{h}_{i_0}(i\,|\,n+1)]_{n+1} \mathbf{b}_{i_0}(i\,|\,n), \tag{70b}$$

$$[\mathbf{h}_{i_0}(i\,|\,n+1)]_1 = \frac{e^*_{f,i_0}(i\,|\,n)}{\epsilon_{f,i_0}(i\,|\,n)}, \tag{71a}$$

$$[\mathbf{h}_{i_0}(i\,|\,n+1)]_{2,n+1} = \mathbf{h}_{i_0}(i-1\,|\,n) - [\mathbf{h}_{i_0}(i\,|\,n+1)]_1 \mathbf{f}_{i_0}(i\,|\,n), \tag{71b}$$

$$\gamma_{i_0}(i\,|\,n+1) = \gamma_{i_0+1}(i\,|\,n) + \frac{e^2_{b,i_0}(i\,|\,n)}{\epsilon_{b,i_0}(i\,|\,n)}, \tag{72a}$$

$$\gamma_{i_0}(i\,|\,n+1) = \gamma_{i_0}(i-1\,|\,n) + \frac{e^2_{f,i_0}(i\,|\,n)}{\epsilon_{f,i_0}(i\,|\,n)}, \tag{72b}$$

$$\gamma^*_{i_0}(i\,|\,n+1) = \gamma^*_{i_0+1}(i\,|\,n) + \frac{e^{*2}_{b,i_0}(i\,|\,n)}{\epsilon_{b,i_0}(i\,|\,n)}, \tag{73a}$$

$$\gamma^*_{i_0}(i\,|\,n+1) = \gamma^*_{i_0}(i-1\,|\,n) + \frac{e^{*2}_{f,i_0}(i\,|\,n)}{\epsilon_{f,i_0}(i\,|\,n)}, \tag{73b}$$

$$\alpha_{i_0}(i\,|\,n+1) = \alpha_{i_0+1}(i\,|\,n) + \frac{e_{b,i_0}(i\,|\,n) e^*_{b,i_0}(i\,|\,n)}{\epsilon_{b,i_0}(i\,|\,n)}, \tag{74a}$$

and

$$\alpha_{i_0}(i\,|\,n+1) = \alpha_{i_0}(i-1\,|\,n) + \frac{e_{f,i_0}(i\,|\,n) e^*_{f,i_0}(i\,|\,n)}{\epsilon_{f,i_0}(i\,|\,n)}. \tag{74b}$$

As an example, (64a) is derived from (22), where $M$ is replaced by $M_i(1, n-1)$, $\mathbf{X}$ is replaced by $z^{-n}\mathbf{Y}_{i_0+n,i}$, and $\mathbf{Y}$ is replaced by $\mathbf{Y}_{i_0+n,i}$.

By observing that $\mathbf{E}_{b,i_0}(i-1\,|\,n-1)$ is orthogonal to $M_i(1, n-1)$, it is clear that

$$\langle \mathbf{Y}_{i_0+n,i}, \mathbf{E}_{b,i_0}(i-1\,|\,n-1)\rangle = \langle \mathbf{E}_{f,i_0+1}(i\,|\,n-1), \cdot \mathbf{E}_{b,i_0}(i-1\,|\,n-1)\rangle = k_{n,i_0}(i). \tag{75}$$

Recursions (65) are obtained by taking norms of (64) respectively. The recursions (68) through (71) are obtained from (21), where $\mathbf{Y}$ is replaced by $\mathbf{u}_i$ and $\mathbf{u}_{i_0}$, respectively. Making the same substitutions in (21) and then taking inner products with $\mathbf{u}_i$ or $\mathbf{u}_{i_0}$ gives recursions (72) through (74).

### *5.3 Forward time updates*

The following forward time updates are obtained from the (orthogonal) projection operator forward time update (34):

$$\mathbf{E}_{f,i_0}(i\,|\,n) = \mathbf{E}'_{f,i_0}(i\,|\,n) - [P_{M_i(1,n)}\mathbf{u}_i]\,\frac{e_{f,i_0}(i\,|\,n)}{1-\gamma_{i_0}(i-1\,|\,n)}, \tag{76a}$$

$$\mathbf{E}_{b,i_0}(i\,|\,n) = \mathbf{E}'_{b,i_0}(i\,|\,n) - [P_{M_i(0,n-1)}\mathbf{u}_i]\,\frac{e_b(i\,|\,n)}{1-\gamma_{i_0+1}(i\,|\,n)}, \tag{76b}$$

$$\mathbf{f}_{i_0}(i\,|\,n) = \mathbf{f}_{i_0}(i-1\,|\,n) + \mathbf{g}_{i_0}(i-1\,|\,n)\,\frac{e_{f,i_0}(i\,|\,n)}{1-\gamma_{i_0}(i-1\,|\,n)}, \tag{77a}$$

$$\mathbf{b}_{i_0}(i\,|\,n) = \mathbf{b}_{i_0}(i-1\,|\,n) + \mathbf{g}_{i_0+1}(i\,|\,n)\,\frac{e_{b,i_0}(i\,|\,n)}{1-\gamma_{i_0+1}(i\,|\,n)}, \tag{77b}$$

$$\mathbf{h}_{i_0}(i\,|\,n) = \mathbf{h}_{i_0}(i-1\,|\,n) - \mathbf{g}_{i_0}(i\,|\,n)\,\frac{\alpha_{i_0}(i\,|\,n)}{1-\gamma_{i_0}(i\,|\,n)}, \tag{78}$$

$$\gamma^*_{i_0}(i\,|\,n) = \gamma^*_{i_0}(i-1\,|\,n) - \frac{\alpha^2_{i_0}(i\,|\,n)}{1-\gamma_{i_0}(i\,|\,n)}, \tag{79}$$

and

$$\alpha_{i_0}(i\,|\,n) = \mathbf{y}^T_{i|n}\mathbf{h}_{i_0}(i-1\,|\,n)[1-\gamma_{i_0}(i\,|\,n)]. \tag{80}$$

Equation (78) is obtained from (34), where $M_i$ is replaced $M_i(0, n)$ and $\mathbf{Y}_i$ is replaced by $\mathbf{u}_{i_0}$. Equations (79) and (80) are obtained by making the same substitutions in (34) and then taking inner products with $\mathbf{u}_{i_0}$ and $\mathbf{u}_i$, or by premultiplying (78) by $\mathbf{y}^T_{i_0+n-1|n}$ and $\mathbf{y}^T_{i|n}$, respectively. Taking the inner product of (76) with $\mathbf{u}_i$ and $\mathbf{u}_{i_0}$, respectively gives the following recursions:

$$e'_{f,i_0}(i\,|\,n) = \frac{e_{f,i_0}(i\,|\,n)}{1 - \gamma_{i_0}(i-1\,|\,n)}, \tag{81a}$$

$$e'_{b,i_0}(i\,|\,n) = \frac{e_{b,i_0}(i\,|\,n)}{1 - \gamma_{i_0+1}(i\,|\,n)}, \tag{81b}$$

$$e^*_{f,i_0}(i\,|\,n) = e^*_{f,i_0}(i-1\,|\,n) - e_{f,i_0}(i\,|\,n)\,\frac{\alpha_{i_0}(i-1\,|\,n)}{1 - \gamma_{i_0}(i-1\,|\,n)}, \tag{82a}$$

and

$$e^*_{b,i_0}(i\,|\,n) = e^*_{b,i_0}(i-1\,|\,n) - e_{b,i_0}(i\,|\,n)\,\frac{\alpha_{i_0+1}(i\,|\,n)}{1 - \gamma_{i_0+}(i\,|\,n)}. \tag{82b}$$

### *5.4 Backward time updates*

The following backward time updates are obtained from the projection operator backward time update (43):

$$\mathbf{E}_{f,i_0}(i\,|\,n) = \mathbf{E}_{f,i_0|\,i_0+1}(i\,|\,n) - [P_{M_i(1,n)}\mathbf{u}_{i_0}]\,\frac{e^*_{f,i_0}(i\,|\,n)}{1 - \gamma^*_{i_0}(i-1\,|\,n)}, \tag{83a}$$

$$\mathbf{E}_{b,i_0}(i\,|\,n) = \mathbf{E}_{b,i_0|\,i_0+1}(i\,|\,n) - [P_{M_i(0,n-1)}\mathbf{u}_{i_0}]\,\frac{e^*_{b,i_0}(i\,|\,n)}{1 - \gamma^*_{i_0+1}(i\,|\,n)}, \tag{83b}$$

$$\mathbf{f}_{i_0+1}(i\,|\,n) = \mathbf{f}_{i_0}(i\,|\,n) - \mathbf{h}_{i_0}(i-1\,|\,n)\,\frac{e^*_{f,i_0}(i\,|\,n)}{1 - \gamma^*_{i_0}(i-1\,|\,n)}, \tag{84a}$$

$$\mathbf{b}_{i_0+1}(i\,|\,n) = \mathbf{b}_{i_0}(i\,|\,n) - \mathbf{h}_{i_0+1}(i\,|\,n)\,\frac{e^*_{b,i_0}(i\,|\,n)}{1 - \gamma^*_{i_0+1}(i\,|\,n)}, \tag{84b}$$

$$\mathbf{g}_{i_0}(i\,|\,n) = \mathbf{g}_{i_0+1}(i\,|\,n) - \mathbf{h}_{i_0}(i\,|\,n)\,\frac{\alpha_{i_0}(i\,|\,n)}{1 - \gamma^*_{i_0}(i\,|\,n)}, \tag{85}$$

$$\gamma_{i_0}(i\,|\,n) = \gamma_{i_0+1}(i\,|\,n) - \frac{\alpha^2_{i_0}(i\,|\,n)}{1 - \gamma^*_{i_0}(i\,|\,n)}, \tag{86}$$

and

$$\alpha_{i_0}(i\,|\,n) = \mathbf{y}^T_{i_0+n-1|\,n}\mathbf{g}_{i_0+1}(i\,|\,n)[1 - \gamma^*_{i_0}(i\,|\,n)]. \tag{87}$$

Equation (85) is obtained by replacing $\mathbf{Y}_i$ by $\mathbf{u}_i$ in (43). Equations (86) and (87) are obtained by premultiplying (85) by $\mathbf{y}^T_{i|n}$ and $\mathbf{y}^T_{i_0+n-1|n}$, respectively. The following recursions are obtained by taking the inner product of (83) with $\mathbf{u}_i$, respectively:

$$e_{f,i_0+1}(i\,|\,n) = e_{f,i_0}(i\,|\,n) + e^*_{f,i_0}(i\,|\,n)\,\frac{\alpha_{i_0}(i-1\,|\,n)}{1 - \gamma^*_{i_0}(i-1\,|\,n)}, \tag{88a}$$

and

$$e_{b,i_0+1}(i \mid n) = e_{b,i_0}(i \mid n) + e^*_{b,i_0}(i \mid n) \frac{\alpha_{i_0+1}(i \mid n)}{1 - \gamma^*_{i_0+1}(i \mid n)}. \tag{88b}$$

The recursions that result from taking inner products with $\mathbf{u}_{i_0}$ will not be used and are therefore omitted.

### 5.5 Inner product updates

The following recursions are obtained from the forward time update for inner products (35):

$$k_{n,i_0}(i) = k_{n,i_0}(i-1) + e_{f,i_0+1}(i \mid n-1) e_{b,i_0}(i-1 \mid n-1) \cdot \frac{1}{1 - \gamma_{i_0+1}(i-1 \mid n-1)}, \tag{89}$$

$$\epsilon_{f,i_0}(i \mid n) = \epsilon_{f,i_0}(i-1 \mid n) + e^2_{f,i_0}(i \mid n) \frac{1}{1 - \gamma_{i_0}(i-1 \mid n)}, \tag{90a}$$

and

$$\epsilon_{b,i_0}(i \mid n) = \epsilon_{b,i_0}(i-1 \mid n) + e^2_{b,i_0}(i \mid n) \frac{1}{1 - \gamma_{i_0+1}(i \mid n)}. \tag{90b}$$

The following recursions are obtained from the backward time update for inner products (44):

$$k_{n,i_0}(i) = k_{n,i_0+1}(i) + e^*_{f,i_0+1}(i \mid n-1) e^*_{b,i_0}(i-1 \mid n-1) \cdot \frac{1}{1 - \gamma^*_{i_0+1}(i-1 \mid n-1)}, \tag{91}$$

$$\epsilon_{f,i_0}(i \mid n) = \epsilon_{f,i_0+1}(i \mid n) + e^{*2}_{f,i_0}(i \mid n) \frac{1}{1 - \gamma^*_{i_0}(i-1 \mid n)}, \tag{92a}$$

and

$$\epsilon_{b,i_0}(i \mid n) = \epsilon_{b,i_0+1}(i \mid n) + e^{*2}_{b,i_0}(i \mid n) \frac{1}{1 - \gamma^*_{i_0+1}(i \mid n)}. \tag{92b}$$

Equations (89) and (91) are obtained by using (35) and (44), where $\mathbf{v}_i$ is replaced by $\mathbf{Y}_{i_0+n,i}$, $\mathbf{Y}_i$ is replaced by $z^{-n}\mathbf{Y}_{i_0+n,i}$, and $M_i$ is replaced by $M_i(1, n-1)$, respectively. The previous set of recursions (64) through (92) are complete in the sense that any existing least-squares alogrithm can be derived by manipulating suitable subsets of these recursions.

## VI. RECURSIVE FIXED-ORDER COVARIANCE ALGORITHMS

### 6.1 *Sliding-window algorithm*

Combining (60), (61), (68) through (73), (77), (81a), (84), (90a), and (92a), gives the following sliding-window LS algorithm for the prediction coefficients. Where unspecified, the order of the variable is assumed to be $N$, the order of the least-squares filter. Also, the starting time index is denoted as $i_0$. If the sliding window contains $M$ data values, then $i_0 = i - M + 1$,

$$e'_{f,i_0}(i) = y_i - \mathbf{f}^T_{i_0}(i-1)\mathbf{y}_{i-1}, \tag{93a}$$

$$\mathbf{f}_{i_0}(i) = \mathbf{f}_{i_0}(i-1) + \mathbf{g}_{i_0}(i-1)e'_{f,i_0}(i), \tag{93b}$$

$$e_{f,i_0}(i) = e'_{f,i_0}(i)[1 - \gamma_{i_0}(i-1)], \tag{93c}$$

$$e^*_{f,i_0}(i) = y_{i_0+N} - \mathbf{f}^T_{i_0}(i)\mathbf{y}_{i_0+N-1}, \tag{93d}$$

$$\epsilon_{f,i_0}(i) = \epsilon_{f,i_0}(i-1) + e'_{f,i_0}(i)e_{f,i_0}(i), \tag{93e}$$

$$\mathbf{g}_{i_0}(i \mid N+1)]_1 = \frac{e_{f,i_0}(i)}{\epsilon_{f,i_0}(i)}, \tag{93f}$$

$$[\mathbf{g}_{i_0}(i \mid N-1)]_{2,N+1} = \mathbf{g}_{i_0}(i-1) - [\mathbf{g}_{i_0}(i \mid N+1)]_1\mathbf{f}_{i_0}(i), \tag{93g}$$

$$[\mathbf{h}_{i_0}(i \mid N+1)]_1 = \frac{e^*_{f,i_0}(i)}{\epsilon_{f,i_0}(i)}, \tag{93h}$$

$$[\mathbf{h}_{i_0}(i \mid N+1)]_{2,N+1} = \mathbf{h}_{i_0}(i-1) - [\mathbf{h}_{i_0}(i \mid N+1)]_1\mathbf{f}_{i_0}(i), \tag{93i}$$

$$\mathbf{f}_{i_0+1}(i) = \mathbf{f}_{i_0}(i) - \mathbf{h}_{i_0}(i-1)\frac{e^*_{f,i_0}(i)}{1 - \gamma^*_{i_0}(i-1)}, \tag{93j}$$

$$\epsilon_{f,i_0+1}(i) = \epsilon_{f,i_0}(i) - \frac{e^{*2}_{f,i_0}(i)}{1 - \gamma^*_{i_0}(i-1)}, \tag{93k}$$

$$e'_{b,i_0}(i) = y_{i-N} - \mathbf{b}^T_{i_0}(i-1)\mathbf{y}_i, \tag{93l}$$

$$\mathbf{b}_{i_0}(i) = \frac{\mathbf{b}_{i_0}(i-1) + e'_{b,i_0}(i)[\mathbf{g}_{i_0}(i \mid N+1)]_{1,N}}{1 - e'_{b,i_0}(i)[\mathbf{g}_{i_0}(i \mid N+1)]_{N+1}}, \tag{93m}$$

$$e^*_{b,i_0}(i) = y_{i_0} - \mathbf{b}^T_{i_0}(i)\mathbf{y}_{i_0+N}, \tag{93n}$$

$$\mathbf{g}_{i_0+1}(i) = [\mathbf{g}_{i_0}(i \mid N+1)]_{1,N} + [\mathbf{g}_{i_0}(i \mid N+1)]_{N+1}\mathbf{b}_{i_0}(i), \tag{93o}$$

$$\mathbf{h}_{i_0+1}(i) = [\mathbf{h}_{i_0}(i \mid N+1)]_{1,N} + [\mathbf{b}_{i_0}(i \mid N+1)_{N+1}\mathbf{b}_{i_0}(i), \tag{93p}$$

$$\gamma_{i_0+1}(i) = \frac{\gamma_{i_0}(i-1) + e_{f,i_0}(i)[\mathbf{g}_{i_0}(i \mid N+1)]_1 - e'_{b,i_0}(i)[\mathbf{g}_{i_0}(i \mid N+1)]_{N+1}}{1 - e'_{b,i_0}(i)[\mathbf{g}_{i_0}(i \mid N+1)]_{N+1}}, \tag{93q}$$

$$\gamma^*_{i_0+1}(i) = \gamma^*_{i_0}(i-1) + e^*_{f,i_0}(i)[\mathbf{h}_{i_0}(i \mid N+1)]_1 - e^*_{b,i_0}[\mathbf{h}_{i_0}(i \mid N+1)]_N, \tag{93r}$$

and

$$\mathbf{b}_{i_0+1}(i) = \mathbf{b}_{i_0}(i) - \mathbf{h}_{i_0+1}(i) \frac{e^*_{b,i_0}(i)}{1 - \gamma^*_{i_0+1}(i)}. \tag{93s}$$

The recursions (93m) and (93q) were not listed in the previous section, but are easily obtained by solving (77b) and (68b) simultaneously for $\mathbf{b}_{i_0}(i)$, and by substituting (68a), (69a), and (81b) into (72), and solving for $\gamma_{i_0+1}(i \mid n)$. Notice that all data samples in the sliding window $(y_{i-M+1}, \cdots, y_i)$ must be stored. This is also true of the order-recursive sliding-window algorithm presented in Ref. 14. If division is counted as multiplication, then the algorithm (93) requires $12N + 16$ multiplies and $12N + 12$ additions at each iteration. In contrast, the unnormalized sliding-window lattice predictor (see Appendix B) requires $16N$ multiplies and $10N$ additions per iteration, and the normalized lattice predictor[16] requires $30N$ multiplies, $18N$ additions, and $6N$ square roots per iteration.

Because sliding-window algorithms have finite memory, initialization for these algorithms is basically the same as for the prewindowed case, i.e., the data $y_i$ can be assumed to be zero for $i < 0$. After $M$ iterations, where $M$ is the window length, these data points are discarded. The algorithm (93) is therefore initialized by setting the gains $\gamma$ and $\gamma^*$, and the elements of the vectors **f**, **b**, **g**, and **h** equal to zero, and letting

$$\epsilon_{f,i_0}(0) = \delta, \tag{94}$$

where $\delta$ is chosen to ensure that the algorithm remains stable. It is easily verified that for time $i < M - N - 1$, where $M$ is the length of the sliding window, the algorithm (93) becomes a modified version of the prewindowed LS transversal (fast Kalman) algorithm.[1,22]

### 6.2 *Growing-memory covariance algorithm*

The following fixed-order growing-memory covariance algorithm is obtained by combining (60), (68b), (69), (77), (78), (80), (85), (87), and (90a). The lower index of the window $i_0$ is assumed to be zero. For notational convenience we define the following variables,

$$\beta_{i_0}(i \mid n) \equiv \frac{\alpha_{i_0}(i \mid n)}{1 - \gamma_{i_0}(i \mid n)} \tag{95a}$$

and

$$\beta^*_{i_0}(i \mid n) \equiv \frac{\alpha_{i_0}(i \mid n)}{1 - \gamma^*_{i_0}(i \mid n)}. \tag{95b}$$

Where unspecified, the lower time index and the order of the variables are equal to zero and $N$, respectively,*

$$e'_f(i) = y_i = \mathbf{f}^T(i-1)\mathbf{y}_{i-1}, \tag{96a}$$

$$\mathbf{f}(i) = \mathbf{f}(i-1) + \mathbf{g}(i-1)e'_f(i), \tag{96b}$$

$$e_f(i) = y_i - \mathbf{f}^T(i)\mathbf{y}_{i-1}, \tag{96c}$$

$$\epsilon_f(i) = \epsilon_f(i-1) + e_f(i)e'_f(i), \tag{96d}$$

$$[\mathbf{g}(i \mid N+1)]_1 = \frac{e_f(i)}{\epsilon_f(i)}, \tag{96e}$$

$$[\mathbf{g}(i \mid N+1)]_{2,N+1} = \mathbf{g}(i-1) - [\mathbf{g}(i \mid N+1)]_1\mathbf{f}(i), \tag{96f}$$

$$e'_b(i) = y_{i-N} - \mathbf{b}^T(i-1)\mathbf{y}_i, \tag{96g}$$

$$\mathbf{b}(i) = \frac{\mathbf{b}(i-1) + e'_b(i)[\mathbf{g}(i \mid N+1)]_{1,N}}{1 - e'_b(i)[\mathbf{g}(i \mid N+1)]_{N+1}}, \tag{96h}$$

$$\mathbf{g}_1(i) = [\mathbf{g}(i \mid N+1)]_{1,N} + [\mathbf{g}(i \mid N+1)]_{N+1}\mathbf{b}(i), \tag{96i}$$

$$\beta(i) = \mathbf{y}_i^T\mathbf{h}(i-1), \tag{96j}$$

$$\beta^*(i) = \mathbf{y}_{N-1}^T\mathbf{g}_1(i), \tag{96k}$$

$$\mathbf{g}(i) = \frac{\mathbf{g}_1(i) - \beta^*(i)\mathbf{h}(i-1)}{1 - \beta(i)\beta^*(i)}, \tag{96l}$$

and

$$\mathbf{h}(i) = \mathbf{h}(i-1) - \beta(i)\mathbf{g}(i). \tag{96m}$$

Notice that this algorithm can be applied only if $i > N$. Otherwise, the least-squares variables of order $N$ are undefined and cannot be used to compute the same least-squares variables at the successive time interval. Initialization of this algorithm can be performed, however, by using an order-recursive algorithm for $i < N$ to increase the order of the filter by one at each successive time iteration. An order-recursive algorithm for the prediction coefficients is obtained by combining (89), (66a), (67a), top components of (64a) and (64b), (66b), (67b), (65a) and (65b), (82a), (88a), (84a), (92a), (71), (73b), (72), and (74b). This algorithm is basically the same as the covariance lattice

* The author recently discovered that this algorithm has been independently derived in Ref. 23 using an algebraic approach.

algorithm presented in Refs. 7 and 19, except that additional order recursions for the prediction vectors **f** and **b** have been added. It is not explicitly stated in an effort to conserve space. Order-recursive computation of **f** and **b** requires order $N^2$ arithmetic operations per iteration, rather than order $N$ operations per iteration, as required by the fixed-order algorithm. Not all $N$ components of the vectors **f** and **b** need to be updated at each iteration for $i < N$, however. If data is first received at time $i = 0$, the recursions listed above can be used for $n = 0$ up to $n = i$. At time $i = N$ all of the variables that enter the fixed-order algorithm (96) have been computed by the order-recursive algorithm except for $\mathbf{g}(i)$, $\beta(i)$ and $\beta^*(i)$. The gain $\mathbf{g}(i)$ is the only variable needed at the next iteration of the fixed-order algorithm and can be computed by first using (96j) to calculate $\beta(i)$ and then using (96m) to solve for $\mathbf{g}(i)$.

Derivation of initial conditions for the order-recursive initialization routine is significantly more complicated than for the sliding-window algorithm. This is because for $i = n$, the matrix $\Phi_{n,i|n}$ is guaranteed to be singular, and hence all variables are technically undefined. Reference 14 gives a convenient solution to this startup problem. By using a generalized inverse of a singular or nonsingular matrix, the least-squares projection operator $P$, given by (15), can be defined even when the matrix $\mathbf{S}^T\mathbf{S}$ is singular. If this generalized inverse is defined appropriately, it can be shown that the projection updates in Section IV hold even when the covariance matrix is singular. This implies that all of the recursions listed in the last paragraph that constitute the order-recursive initialization routine can be used starting from $i = 0$ with the following initial conditions:

$$\mathbf{f}(0\,|\,0) = \mathbf{b}(0\,|\,0) = \mathbf{f}_1(-1\,|\,0) = \mathbf{h}(-1\,|\,0) = \mathbf{0}, \tag{97a}$$

$$k_n(-1) = 0, \qquad 1 \leq n \leq N, \tag{97b}$$

$$\gamma(-1\,|\,0) = \gamma^*(-1\,|\,0) = \alpha(-1\,|\,0) = 0, \tag{97c}$$

and

$$e_f^*(0\,|\,n) = \begin{cases} y_0 & \text{for} \quad n = 0 \\ 0 & \text{for} \quad n > 0. \end{cases} \tag{97d}$$

At each iteration $i < N$,

$$e_f(i\,|\,0) = e_b(i\,|\,0) = y_i \tag{97e}$$

and

$$\epsilon_f(i\,|\,0) = \epsilon_b(i\,|\,0) = \epsilon_f(i-1\,|\,0) + y_i^2. \tag{97f}$$

Counting division as multiplication, the algorithm (96) requires

$11N + 7$ multiplies and $11N + 1$ additions per iteration. To compare, the unnormalized growing-memory lattice predictor (see Appendix B) requires $22N$ multiplies and $12N$ additions per iteration. The normalized lattice algorithm requires $30N$ multiplies, $18N$ additions, and $6N$ square roots per iteration. We point out that the fixed-order covariance algorithm specified by (96) is not unique. In particular, equation (96c) can be replaced by (81a). The extra recursion (93q) must be added to compute $\gamma$, however. This type of modification has been applied to the fast Kalman algorithm, and has resulted in improved numerical properties.[22]

## VII. EXTENSIONS TO JOINT-PROCESS ESTIMATION

The algorithms presented so far solve the LS prediction problem wherein the sums (1) and (2) are minimized. In applications such as channel equalization, echo and noise cancellation, and adaptive line enhancement, two processes, $\{x_j\}$ and $\{y_j\}$, are given, and our objective is to estimate the $\{x_j\}$ process in terms of the $\{y_j\}$ process. The vector of estimation errors is denoted as

$$\begin{aligned}\mathbf{E}_{x,i_0+1}(i \mid n) &\equiv \mathbf{X}_{i_0+n,i} - \sum_{j=0}^{n-1} c_{j+1\mid n}(z^{-j}\mathbf{Y}_{i_0+n,i}) \\ &= \mathbf{X}_{i_0+n,i} - \mathbf{S}_i(0,\, n-1)\mathbf{c}_{i_0+1}(i \mid n), \end{aligned} \tag{98}$$

where $\mathbf{X}_{i_0,i}$ is defined by (23a), $\mathbf{c}_{i_0+1}(i \mid n)$ is the $n$-dimensional vector of regression coefficients at time $i$ used to estimate $\mathbf{X}_{i_0+n,i}$ [given by (4c)] where $i' = i_0 + n$), and the lower time subscript of $\mathbf{E}_x$ and $\mathbf{c}$ denotes the time index of the starting value from the $y$ sequence (i.e., $y_{i_0+1}$), which is used in the least-squares computation. Our objective is to choose $\mathbf{c}_{i_0+1}(i \mid n)$ such that

$$\epsilon_{x,i_0+1}(i \mid n) \equiv \| \mathbf{E}_{x,i_0+1}(i \mid n) \|^2 \tag{99}$$

is minimized. The discussion in Section III implies that

$$\mathbf{E}_{x,i_0+1}(i \mid n) = P^{\perp}_{M_i(0,n-1)}\mathbf{X}_{i_0+n,i}. \tag{100}$$

We now use the projection recursions in Section IV to derive order and time updates for $\mathbf{E}_{x,i_0}(i \mid n)$ and $\mathbf{c}_{i_0}(i \mid n)$. Details are again omitted since they are basically the same as before. Combining recursions in this section with the prediction algorithms of the last section results in recursive algorithms that solve the LS joint-process-estimation problem.

The following notation, which is analogous to the notation in Section 5.1, is first defined:

1. Cross-correlation coefficient,

$$k^{(x)}_{n+1,i_0}(i) \equiv \langle \mathbf{X}_{i_0+n,i},\, \mathbf{E}_{b,i_0}(i \mid n) \rangle$$
$$= \langle \mathbf{E}_{x,i_0+1}(i \mid n),\, \mathbf{E}_{b,i_0}(i \mid n) \rangle. \tag{101}$$

2. Current residual (scalar),

$$e_{x,i_0}(i \mid n) = \langle \mathbf{u}_i,\, \mathbf{E}_{x,i_0}(i \mid n) \rangle$$
$$= x_i - \mathbf{c}^T_{i_0}(i \mid n)\mathbf{y}_{i \mid n}. \tag{102}$$

3. Past residual (scalar),

$$e^*_{x,i_0+1}(i \mid n) = \langle \mathbf{u}_{i_0},\, \mathbf{E}_{x,i_0+1}(i \mid n) \rangle$$
$$= x_{i_0+n} - \mathbf{c}^T_{i_0+1}(i \mid n)\mathbf{y}_{i_0+n \mid n}. \tag{103}$$

4. Oblique residual

$$e'_{x,i_0}(i \mid n) \equiv x_i - \mathbf{c}^T_{i_0}(i-1 \mid n)\mathbf{y}_{i \mid n}. \tag{104}$$

The following order recursions are obtained from (22):

$$\mathbf{E}_{x,i_0}(i \mid n+1) = \mathbf{E}_{x,i_0+1}(i \mid n) - \frac{k^{(x)}_{n+1,i_0}(i)}{\epsilon_{b,i_0}(i \mid n)}\, \mathbf{E}_{b,i_0}(i \mid n), \tag{105}$$

$$\epsilon_{x,i_0}(i \mid n+1) = \epsilon_{x,i_0+1}(i \mid n) - \frac{k^{(x)2}_{n+1,i_0}(i)}{\epsilon_{b,i_0}(i \mid n)}, \tag{106}$$

$$[\mathbf{c}_{i_0}(i \mid n+1)]_{n+1} = \frac{k^{(x)}_{n+1,i_0}(i)}{\epsilon_{b,i_0}(i \mid n)}, \tag{107a}$$

and

$$[\mathbf{c}_{i_0}(i \mid n+1)]_{1,n} = \mathbf{c}_{i_0+1}(i \mid n) - [\mathbf{c}_{i_0}(i \mid n+1)]_{n+1}\mathbf{b}_{i_0}(i \mid n). \tag{107b}$$

Derivation of the following forward time updates involves a straightforward application of (34) and (35), where $\mathbf{Y}_i$ is replaced by $\mathbf{X}_{i_0+n,i}$ and $M_i$ is replaced by $M_i(0, n-1)$:

$$\mathbf{c}_{i_0}(i \mid n) = \mathbf{c}_{i_0}(i-1 \mid n) + e'_{x,i_0}(i \mid n)\mathbf{g}_{i_0}(i \mid n), \tag{108}$$

$$k^{(x)}_{n+1,i_0}(i) = k^{(x)}_{n+1,i_0}(i-1) + e_{x,i_0+1}(i \mid n)e_{b,i_0}(i \mid n)\, \frac{1}{1 - \gamma_{i_0+1}(i \mid n)}, \tag{109}$$

$$\epsilon_{x,i_0}(i \mid n) = \epsilon_{x,i_0}(i-1 \mid n) + e^2_{x,i_0}(i \mid n)\, \frac{1}{1 - \gamma_{i_0}(i \mid n)}, \tag{110}$$

$$e^*_{x,i_0}(i \mid n) = e^*_{x,i_0}(i-1 \mid n) - e_{x,i_0}(i \mid n)\, \frac{\alpha_{i_0}(i \mid n)}{1 - \gamma_{i_0}(i \mid n)}, \tag{111}$$

and

$$e'_{x,i_0}(i \mid n) = \frac{e_{x,i_0}(i \mid n)}{1 - \gamma_{i_0}(i \mid n)}. \tag{112}$$

Similarly, the following backward time updates are obtained from (43) and (44):

$$\mathbf{c}_{i_0}(i \mid n) = \mathbf{c}_{i_0+1}(i \mid n) + \mathbf{h}_{i_0}(i \mid n) \frac{e^*_{x,i_0}(i \mid n)}{1 - \gamma^*_{i_0}(i \mid n)}, \tag{113}$$

$$e_{x,i_0+1}(i \mid n) = e_{x,i_0}(i \mid n) + e^*_{x,i_0}(i \mid n) \frac{\alpha_{i_0}(i \mid n)}{1 - \gamma^*_{i_0}(i \mid n)}, \tag{114}$$

$$k^{(x)}_{n+1,i_0+1}(i) = k^{(x)}_{n+1,i_0}(i) - e^*_{x,i_0+1}(i \mid n) e^*_{b,i_0}(i \mid n) \frac{1}{1 - \gamma^*_{i_0+1}(i \mid n)}, \tag{115}$$

and

$$\epsilon_{x,i_0+1}(i \mid n) = \epsilon_{x,i_0}(i \mid n) - e^{*2}_{x,i_0}(i \mid n) \frac{1}{1 - \gamma^*_{i_0}(i \mid n)}. \tag{116}$$

Combining (104), (108), (103), and (113) (in that order) with the fixed-order sliding-window algorithm (93) gives the corresponding sliding-window joint-process-estimation algorithm. Adding these additional recursions results in a total computational complexity of $16N + 17$ multiplies and $16N + 13$ additions per iteration. This should be compared with $23N$ multiplies and $14N$ additions per iteration required by the unnormalized sliding-window lattice joint-process estimator. Initialization of these additional recursions is accomplished in a fashion analogous to the prediction recursions. In particular, the data $y_i$ and $x_i$ is assumed to be zero for $i < 0$, and $\mathbf{c}_{i_0}(-1 \mid n) = \mathbf{0}$.

The fixed-order growing-memory algorithm (96) is extended to the joint-process-estimation case by adding the recursions (104) and (108). The order-recursive prediction algorithm listed in Section 6.2 is extended to the joint-process-estimation case by adding the recursions (105) (top component only), (109), (107), (111), and (113). In each case the variable $i_0 = 0$. Adding (104) and (108) to (96) results in a total computational complexity of $13N + 7$ multiplies and $13N + 1$ additions per iteration. This should be compared with $28N$ multiplies and $16N$ additions per iterations required by the growing-memory covariance lattice joint-process estimator. The following accomplishes the initialization of the additional recursions for the order-recursive algorithm:

$$k^{(x)}_n(-1) = 0, \qquad 1 \leq n \leq N, \tag{117a}$$

$$\mathbf{c}(-1 \mid n) = \mathbf{0}, \qquad 0 \leq n \leq N, \tag{117b}$$

and

$$e_x^*(0 \mid n) = \begin{cases} x_0 & \text{for } n = 0 \\ 0 & \text{for } n > 0. \end{cases} \tag{117c}$$

The fixed-order algorithm is initialized by using the order-recursive algorithm for $i < N$.

## VIII. CONCLUSIONS

We have presented new fixed-order algorithms that recursively solve the sliding-window and growing-memory covariance least-squares estimation problems. The fixed-order growing-memory algorithm requires approximately one half the number of multiplies and divides required by the analogous unnormalized order-recursive or lattice algorithm. The fixed-order sliding-window algorithm requires approximately 70 percent of the number of multiplies and divides required by the analogous lattice algorithm. These fixed-order algorithms also help complete the list of computationally efficient LS algorithms currently available. In particular, each type of windowing technique that has been proposed for the LS computation (i.e., prewindowed, growing-memory covariance, and the sliding window) has resulted in both computationally efficient fixed-order and order-recursive algorithms. The order-recursive algorithms offer the advantage of being able to dynamically choose the order of the autoregressive model, while the fixed-order algorithms require less computation.

Associated with the algorithms mentioned in this paper are performance issues such as the relative convergence speed of each algorithm given different types of stationary and nonstationary random inputs, and the evaluation of finite word-length effects. As an example, the relative performance improvement offered by LS covariance algorithms over LS prewindowed algorithms has yet to be ascertained in applications where the prediction coefficients must be estimated from relatively few data samples. These issues will play a crucial role in determining the practical value of the LS algorithms presented in this paper.

## APPENDIX A

### *Derivation of (30)*

We wish to prove (30). By definition,

$$P_{M_i|i-1}\mathbf{Y}_i = P_{\tilde{M}_i}\mathbf{Y}_i + P_{U_i}P_{M_i|i-1}\mathbf{Y}_i, \tag{118}$$

where $\tilde{M}$ is the subspace spanned by the column vectors of $\tilde{\mathbf{S}}_i$. Projecting both sides of (118) onto $M_i$ gives

$$P_{M_i}P_{M_i|i-1}\mathbf{Y}_i = P_{M_i}P_{\tilde{M}_i}\mathbf{Y}_i + P_{M_i}P_{U_i}P_{M_i|i-1}\mathbf{Y}_i. \tag{119}$$

Now $P_{M_i|i-1}\mathbf{Y}_i$ lies in $M_i$, and hence

$$P_{M_i}P_{M_i|i-1}\mathbf{Y}_i = P_{M_i|i-1}\mathbf{Y}_i. \tag{120}$$

Also,

$$P_{M_i}P_{\tilde{M}_i}\mathbf{Y}_i = \mathbf{S}_i(\mathbf{S}_i^T\mathbf{S}_i)^{-1}(\mathbf{S}_i^T\tilde{\mathbf{S}}_i)(\tilde{\mathbf{S}}_i^T\tilde{\mathbf{S}}_i)^{-1}\tilde{\mathbf{S}}_i^T\mathbf{Y}_i$$

$$= \mathbf{S}_i(\mathbf{S}_i^T\mathbf{S}_i)^{-1}\tilde{\mathbf{S}}_i^T\mathbf{Y}_i$$

$$= P_{M_i}(\mathbf{Y}_i - P_{U_i}\mathbf{Y}_i). \tag{121}$$

Combining (118) through (121) gives

$$P_{M_i}\mathbf{Y}_i = P_{M_{i|i-1}}\mathbf{Y}_i + P_{M_i}P_{U_i}P^{\perp}_{M_{i|i-1}}\mathbf{Y}_i$$

$$= P_{M_{i|i-1}}\mathbf{Y}_i + (P_{M_i}\mathbf{u}_i)\langle \mathbf{u}_i,\ P^{\perp}_{M_{i|i-1}}\mathbf{Y}_i\rangle. \tag{122}$$

Subtracting both sides of (122) from $\mathbf{Y}_i$, and then taking inner products of both sides with $\mathbf{u}_i$ gives

$$\langle \mathbf{u}_i,\ P^{\perp}_{M_i}\mathbf{Y}_i\rangle = \langle \mathbf{u}_i,\ P_{M_{i|i-1}}\mathbf{Y}_i\rangle[1 - \langle \mathbf{u}_i,\ P_{M_i}\mathbf{u}_i\rangle]. \tag{123}$$

Combining (122) and (123), and using the definition (31) gives (30). [Ref. 24 gives a purely geometric proof of (30) for the case where $M_i$ is spanned by one vector (as illustrated in Fig. 2).]

To derive the inner product update (35), we first rewrite (34) as

$$P^{\perp}_{M_i}\mathbf{Y}_i = P^{\perp}_{U_i}P^{\perp}_{M_{i|i-1}}\mathbf{Y}_i + P_{U_i}P^{\perp}_{M_{i|i-1}}\mathbf{Y}_i - P_{M_i}\mathbf{u}_i\langle \mathbf{u}_i, P^{\perp}_{M_i}\mathbf{Y}_i\rangle\sec^2\theta_i$$

$$= P^{\perp}_{U_i}P^{\perp}_{\tilde{M}_i}\mathbf{Y}_i + \mathbf{u}_i\langle \mathbf{u}_i,\ P^{\perp}_{M_{i|i-1}}\mathbf{Y}_i\rangle - P_{M_i}\mathbf{u}_i\langle \mathbf{u}_i,\ P^{\perp}_{M_i}\mathbf{Y}_i\rangle\sec^2\theta_i$$

$$= P^{\perp}_{U_i}P^{\perp}_{\tilde{M}_i}\mathbf{Y}_i + P^{\perp}_{M_i}\mathbf{u}_i\langle \mathbf{u}_i,\ P^{\perp}_{M_i}\mathbf{Y}_i\rangle\sec^2\theta_i. \tag{124}$$

Taking the inner product of both sides with $\mathbf{v}_i$ and using the fact that

$$\langle \mathbf{v}_i,\ P^{\perp}_{M_i}\mathbf{u}_i\rangle = \langle \mathbf{u}_i,\ P^{\perp}_{M_i}\mathbf{v}_i\rangle \tag{125}$$

gives (35).

## APPENDIX B

### *Other Recursive Least-Squares Algorithms*

The recursions in Section V and VII are complete in the sense that any of the existing computationally efficient LS prediction or joint-process-estimation algorithms can be derived from suitable subsets of these recursions. The purpose of this appendix is to illustrate this point by listing the recursions that enter the prewindowed LS transversal (fast Kalman) and lattice algorithms, the unnormalized sliding-window and growing-memory covariance lattice algorithms,[14] and the nonrecursive LS algorithm presented in Refs. 11 and 17. The list of recursions presented below does not completely describe each algorithm. For example, initialization is not discussed. Consistent steady-state algorithms can be formulated, however, by choosing the time indices and order of the variables in each recursion appropriately. The

following algorithms apply to the more general joint-process-estimation case (eliminating the recursions from Section VII gives the analogous prediction algorithm):

1. Prewindowed transversal (fast Kalman) algorithm:[1] (60a), (77a), (51a), (90a), (69), (60b), (93m), (68b), (104), and (108).
2. Prewindowed lattice algorithm* (See Refs. 18 and 16): (89), (64a)† and (64b), (65a) and (65b), (72a), (109) and (105).
3. Sliding-window lattice algorithm:[14,16] (89), (64a) and (64b), (65a) and (65b), (72a), (73a), (91), (109), (105), and (115).
4. Growing-memory covariance lattice algorithm:[14,16] (89), (64a) and (64b), (65a) and (65b), (82a), (88a), (92a), (72b) and (72a), (73b), (74b), (109), (105), (111), and (114).
5. Nonrecursive LS algorithm:[11,17]

The following set of recursions, which represents a modified version of the algorithm presented in Ref. 17, can be used to compute $\mathbf{f}(i \mid N)$, $\mathbf{b}(i \mid N)$, and $\mathbf{c}(i \mid N)$, given by (4), in an order-recursive fashion starting with first-order least squares variables at time $i$. Initialization consists of computing these first-order variables via the definitions given in Section V.

(78) (for computing $\mathbf{h}(i-1 \mid n)$), (85) (for computing $\mathbf{g}_1(i \mid n)$), (79), (86), (84a), (77b), (92a), (90b), (53), (66), (67), (65a) and (65b), (51b), (61), (68), (71), (57c), (72a), (73b), (103), (113), (101), (107).

Assuming that the covariance matrix $\Phi_{N,i|N+1}$ has been computed, a more convenient form for (53) is

$$\begin{aligned} k_n(i) &= \langle \mathbf{Y}_{n,i},\ \mathbf{E}_b(i-1 \mid n-1) \rangle \\ &= \mathbf{Y}_{n,i}^T [z^{-n}\mathbf{Y}_{n,i} - \mathbf{S}_i(1,\ n-1)\mathbf{b}(i-1 \mid n-1)] \\ &= R_n - \sum_{j=1}^{n-1} R_{n-j}[\mathbf{b}(i-1 \mid n-1)]_j, \end{aligned} \tag{126}$$

where $R_j = \mathbf{Y}_{n,i}^T(z^{-j}\mathbf{Y}_{n,i})$, and is the $(1,\ j+1)$st element of $\Phi_{n,i|n+1}$. Equation (101) can be similarly modified.

# On the Average Product of Gauss-Markov Variables

By B. F. LOGAN, Jr.,* J. E. MAZO,* A. M. ODLYZKO* and L. A. SHEPP*

(Manuscript received April 8, 1983)

Let $x_i$ be members of a stationary sequence of zero mean gaussian random variables having correlations $Ex_ix_j = \sigma^2\rho^{|i-j|}$, $0 < \rho < 1$, $\sigma > 0$. We address the behavior of the averaged product $q_m(\rho, \sigma) \equiv Ex_1x_2 \cdots x_{2m-1}x_{2m}$ as $m$ becomes large. Our principal result when $\sigma^2 = 1$ is that this average approaches zero (infinity) as $\rho$ is less (greater) than the critical value $\rho_c = 0.563007169\ldots$. To obtain this we introduce a linear recurrence for the $q_m\cdot(\rho, \sigma)$, and then continue generating an entire sequence of recurrences, where the $(n + 1)$-st relation is a recurrence for the coefficients that appear in the $n$th relation. This leads to a new, simple continued fraction representation for the generating function of the $q_m(\rho, \sigma)$. The related problem with $\tilde{q}_m(\rho, \sigma) = E|x_1 \cdots x_m|$ is studied via integral equations and is shown to possess a smaller critical correlation value.

## I. INTRODUCTION

The problem that we consider in this paper is as follows: Let $\{x_i\}_1^\infty$ be a stationary sequence of zero mean, gaussian random variables with covariances

$$\rho_{ij} \equiv Ex_ix_j = \sigma^2\rho^{|i-j|},\ 0 < \rho < 1,\ \sigma > 0; \quad i, j = 1, 2, \cdots, \quad (1)$$

where $E(\cdot)$ denotes mathematical expectation. What is the behavior of

$$q_m(\rho, \sigma) \equiv Ex_1x_2 \cdots x_{2m-1}x_{2m} \tag{2}$$

as $m$ becomes large?

In other words, the product in (2) is formed from samples of a gauss-markov process that are taken at regular intervals. Only an even number of samples is considered in (2) since an odd number would result in a zero average.

Originally, the problem was conceived as a simple model for averages of multiplicative structures having infinite memory between the factors of the product. Such products arise in the analysis of learning curves for many adaptive systems, and for these problems one encounters products whose factors are noncommuting matrices. We felt that the analysis of a simple problem, such as that described above, would serve as a valuable guide to what results might be achievable for more realistic situations. However as one may readily imagine, as soon as the problem described in (1) and (2) was written down it became of interest in its own right, consisting as it does of a simple question about long familiar quantities.

Our principal result is that for large $m$ the behavior of the average product $q_m(\rho, \sigma)$ in (2) depends on the relationship of $\rho$ to a critical value, $\rho_c = \rho_c(\sigma)$. If $\rho < \rho_c$, then $q_m(\rho, \sigma)$ will approach zero exponentially fast; if $\rho > \rho_c$, $q_m(\rho, \sigma)$ approaches infinity exponentially fast; finally, if $\rho = \rho_c$, $q_m(\rho, \sigma) \to q_\infty(\sigma)$. We find for $\sigma = 1$, $\rho_c(1) = 0.563007169391816 \cdots$, and $q_\infty(1) = 0.50900853 \ldots$. A plot of $\rho_c(\sigma)$ is given in Fig. 1. All of these results were obtained from a continued fraction representation for the generating function

$$Q(z, \rho, \sigma) = \sum_{m=0}^{\infty} q_m(\rho, \sigma) z^m. \tag{3}$$

Since $q_m(\rho, \sigma) = \sigma^{2m} q_m(\rho, 1)$, we have

$$Q(z, \rho, \sigma) = Q(z\sigma^2, \rho, 1), \tag{4}$$

so it is without loss of generality that we will set $\sigma = 1$, $Q(z, \rho) = Q(z, \rho, 1)$, and $q_m(\rho) = q_m(\rho, 1)$. By introducing a sequence of generating functions, we show in Section II that

$$Q(z, \rho) = \cfrac{1}{1 - \cfrac{\rho z}{1 - \cfrac{2\rho^3 z}{1 - \cfrac{3\rho^5 z}{1 - \ddots}}}} \tag{5}$$

The value $\rho_c^{(\sigma)}$ is then the smallest $\rho$ for which $Q(\sigma^2, \rho) = \infty$, while the value $q_\infty(\sigma)$ is the limit as $z \to 1$ of $(1 - z)Q(z\sigma^2, \rho_c)$.

Since methods are as interesting as results, Section III presents another approach involving integral equations for discussing the $q_m(\rho)$ behavior. Although this method is not rigorously justified for the present problem due to a non-hermitian kernel, it is applicable to a

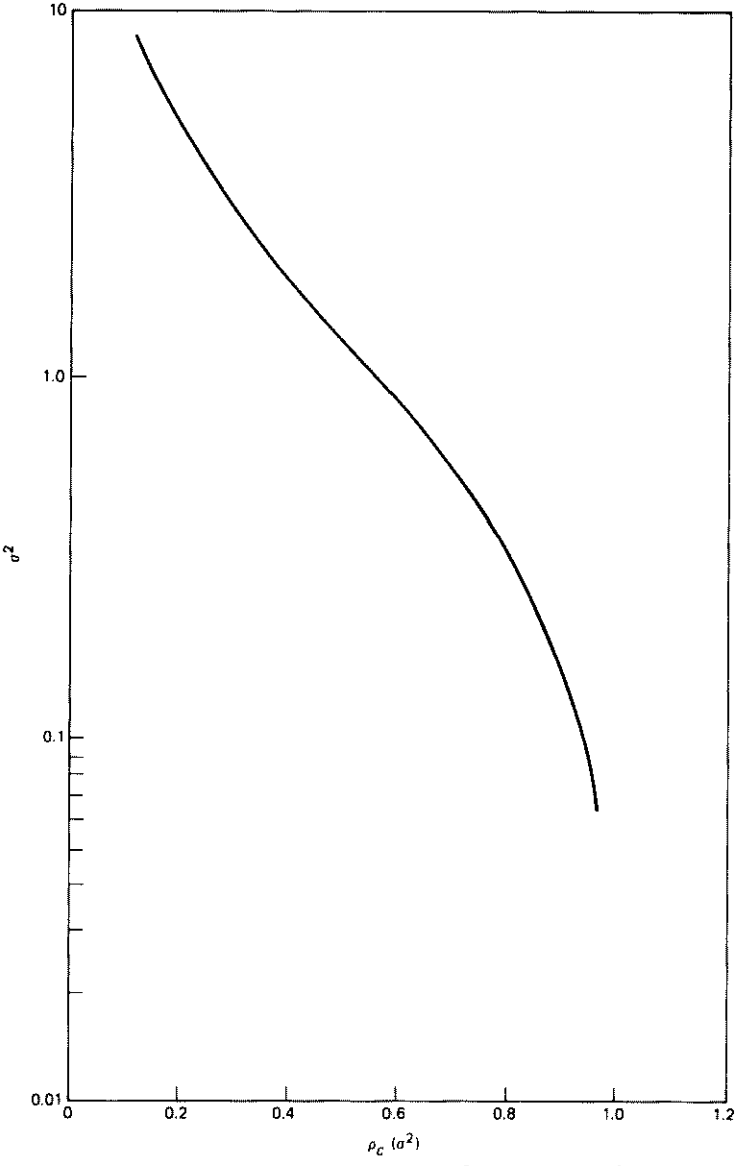

Fig. 1—Critical correlation value $\rho_c(\sigma^2)$ vs. variance $\sigma^2$.

related problem, the behavior of $E|x_1 \cdots x_m|$ as $m \to \infty$ [still assuming (1)]. Using the integral equation we show that $\bar{\rho}_c$, the critical value of $\rho$ for this new problem, is strictly smaller than the $\rho_c$ defined above. This is of interest since it shows that the behavior of $q_m(\rho)$ is determined both by how large $|x_1 \cdots x_{2m}|$ is on the average, and by the extent of cancellation between positive and negative values of $q_m$.

Although we do not give the details here, it is not difficult to show that for all $\rho < 1$, $q_m(\rho)$ approaches zero with probability one as $m$ becomes large.

## II. LINEAR RECURRENCES AND GENERATING FUNCTIONS

Given $2m$ zero-mean jointly gaussian random variables $x_i$ of unit variance and correlations $Ex_ix_j = \rho_{ij}$, then a known formula[1] states that

$$Ex_1 \cdots x_{2m} = \sum_{\substack{\text{all} \\ \text{pairs}}} \rho_{i_1 i_2} \rho_{i_3 i_4} \cdots \rho_{i_{2m-1} i_{2m}}, \tag{6}$$

where the unordered set $\{i_1, \cdots, i_{2m}\}$ is equal to the unordered set $\{1, 2, \cdots, 2m\}$. The sum in (6) is over all distinct, unordered pairs of subscripts. That is, we do not count twice terms which differ only by interchanging the values within one or more subscript pairs, nor do we count twice terms which differ only by permuting subscript pairs. Thus there are $(2m)!/(2^m m!)$ terms in the sum (6).

If we denote permutations of $2m$ objects by $\sigma(i)$: $i \to \sigma(i)$, $i = 1, 2, \cdots, 2m$, then a succinct way of writing (6) when (1) holds is

$$q_m(\rho) = \frac{1}{2^m m!} \sum_{\sigma \in S_{2m}} \rho^{\sum_{j=1}^{m} |\sigma(2j) - \sigma(2j-1)|}, \tag{7}$$

the sum in (7) being over all $(2m)!$ permutations of $S_{2m}$, the group of permutations of $2m$ symbols. Formula (7) shows immediately that $q_m(\rho) > 0$ if $\rho > 0$.

Now define $q_0(\rho) = 1$ and write

$$q_m(\rho) = \sum_{s=1}^{m} b_s(\rho) q_{m-s}(\rho), \qquad m = 1, 2, \cdots. \tag{8}$$

We evaluate a few of the $b_s(\rho)$, writing for convenience $b_i(\rho) = b_i$, $q_i(\rho) = q_i$. The evaluation is done from (8) by explicitly evaluating the $q_m(\rho)$ as needed. A partial list of $b_i(\rho)$ follows:

$$b_1 = \rho$$

$$b_2 = 2\rho^4$$

$$b_3 = 4\rho^7 + 6\rho^9$$

$$b_4 = 8\rho^{10} + 24\rho^{12} + 18\rho^{14} + 24\rho^{16}$$

$$b_5 = 16\rho^{13} + 72\rho^{15} + 108\rho^{17} + 150\rho^{19} + 144\rho^{21} + 96\rho^{23} + 120\rho^{25}. \tag{9}$$

Equation (9) suggests the possibility that, for small $\rho$, only a few terms in (8) would need to be kept for an accurate description of $q_m(\rho)$. For example, keeping only one term yields

$$q_m = \rho q_{m-1}, \tag{10}$$

or $q_m = \rho^m$. Since $Ex_1x_2 = \rho$, this approximation corresponds to treating the successive pairs of gaussian variables which determine $q_m(\rho)$, via (2), as independent. The next step after (10) would be to write

$$q_m = b_1 q_{m-1} + b_2 q_{m-2}. \tag{11}$$

This equation, involving $b_2$ as well, would be a correction to the "independence assumption," but one involving only up to fourth-order correlations, since, from (8) the highest average appearing in $b_2$ is $E(x_1x_2x_3x_4)$. Further corrections are obtained by including more terms of (8), with higher order correlations entering.†

Assuming the $b_i(\rho)$ to be known, the natural procedure would be to "solve" (8) using generating functions. We define these as follows: if $y_0, y_1, y_2, \cdots$ is a bounded sequence of numbers, then the generating function, $Y(z)$, of the sequence is defined for complex $z$, $|z| < 1$, by

$$Y(z) = \sum_{i=0}^{\infty} y_i z^i. \tag{12}$$

Given $Y(z)$, the $y_i$ are, in principle, uniquely determined. We assume that the reader is familiar with the use of generating functions. If not, consult Chapters XI and XIII of Feller.[2]

We define $b_0(\rho) = 0$, $q_0(\rho) = 1$, and call the generating functions of the $b_i(\rho)$, and $q_i(\rho)$ sequences $B(z; \rho)$ and $Q(z; \rho)$, respectively. The $\rho$ dependence is explicitly indicated.

If we multiply (8) by $z^m$ and sum from $m = 1$ to $\infty$ (treating $q_m = 0$, $m < 0$ and $b_m = 0$, $m < 0$), we obtain the basic relation

$$Q(z; \rho) = \frac{1}{1 - B(z; \rho)}. \tag{13}$$

Equation (13) thus allows us to determine, in principle, the $q_m$ from the $b_m$. In particular, we have

†The above interpretation prompts us to advocate consideration of the ideas represented by (8) for analyzing more complex multiplicative structures, particularly when connections to some sort of independence approximation are a natural thing to seek.

$$\sum_{m=1}^{\infty} q_m(\rho) = Q(1; \rho) = \frac{1}{1 - B(1; \rho)}, \tag{14}$$

and the critical value $\rho_c$ will be given by the equation

$$B(1; \rho_c) = \sum_{1}^{\infty} b_k(\rho_c) = 1. \tag{15}$$

Although we could work with the $b_m(\rho)$ themselves, a more convenient approach for finding $\rho_c$ numerically is to set up a continued fraction representation for the generating functions $Q(z; \rho)$, or equivalently, $B(z; \rho)$. It is this approach that we follow now.

Recall (8) defining $b_s(\rho)$. Since these $b_s$ coefficients are a numerical sequence themselves, we can use the same reasoning that took us from the $q_k$ to the $b_s$ and use it to suggest going from the $b_s$ to a new set of coefficients, $b_k^{(2)}$, via the following recurrence

$$b_k(\rho) = \sum_{s=1}^{k} b_s^{(2)}(\rho) b_{k-s}(\rho), \qquad k = 2, 3, \cdots, \tag{16}$$

where we define $b_0(\rho) = 0$. The recurrence (16) yields

$$B(z; \rho) = \frac{b_1(\rho) z}{1 - B^{(2)}(z; \rho)}, \tag{17}$$

$B^{(2)}(z; \rho)$ being the generating function for the $b_k^{(2)}(\rho)$. To continue this procedure with a uniform notation, we define

$$\begin{aligned} b_s^{(1)}(\rho) &= b_s(\rho) \\ b_0^{(m)}(\rho) &= 0, \qquad m = 1, 2, \cdots \end{aligned} \tag{18}$$

and write

$$b_k^{(m)}(\rho) = \sum_{s=1}^{k} b_s^{(m+1)}(\rho) b_{k-s}^{(m)}(\rho), \qquad \begin{matrix} m = 1, 2, \cdots \\ k = 2, 3, \cdots \end{matrix}. \tag{19}$$

The corresponding sequence of generating functions are related by

$$B^{(m)}(z; \rho) = \frac{b_1^{(m)}(\rho) z}{1 - B^{(m+1)}(z; \rho)}. \tag{20}$$

We use this repeatedly in (13) and obtain the continued fraction representation†

† The fact that this continued fraction does not terminate implies that $Q(z; \rho)$ is not a rational function of $z$, and thus one cannot find a (finite-order) difference equation for the $q_m(\rho)$. See Ref. 3, Theorem 99.1, p. 400.

$$Q(z,\rho)=\cfrac{1}{1-\cfrac{b_1^{(1)}z}{1-\cfrac{b_1^{(2)}z}{1-\cfrac{b_1^{(3)}z}{1-\ddots}}}} \tag{21}$$

In (21) we have, for simplicity, written $b_1^{(m)}(\rho)=b_1^{(m)}$.

A relation which will be used later to aid in finding the $b_1^{(m)}$ follows by setting $k=2$ in (19), to obtain

$$b_1^{(m+1)}(\rho)=\frac{b_2^{(m)}(\rho)}{b_1^{(m)}(\rho)}. \tag{22}$$

We can calculate some of the $b_1^{(m)}(\rho)$ using the partial list of the $b_k(\rho)$ given in (9) to derive several $b_s^{(m)}(\rho)$ from (19). Using (22) we then obtain

$$\begin{aligned} b_1^{(1)} &= \rho \\ b_1^{(2)} &= 2\rho^3 \\ b_1^{(3)} &= 3\rho^5 \\ b_1^{(4)} &= 4\rho^7 \\ b_1^{(5)} &= 5\rho^9. \end{aligned} \tag{23}$$

The obvious guess that

$$b_1^{(m)}=m\rho^{2m-1}, \qquad m=1,2,\cdots \tag{24}$$

follows from a direct proof of the continued fraction given in the appendix. Assuming (24) to hold yields the simple representation

$$Q(z;\rho)=\cfrac{1}{1-\cfrac{\rho z}{1-\cfrac{2\rho^3 z}{1-\cfrac{3\rho^5 z}{1-\ddots}}}} \tag{25}$$

The accurate numerical value

$$\rho_c=0.563007169391816\cdots \tag{26}$$

was obtained by using this representation along with (14) and (15).

When $\rho = \rho_c$,

$$q_\infty = \lim_{k\to\infty} q_k(\rho_c) = \frac{1}{\sum_1^\infty k b_k(\rho_c)}. \tag{27}$$

Using the computed value of $\rho_c$ and the definition of the $b_k(\rho)$, we found numerically that

$$q_\infty = 0.50900853 \cdots. \tag{28}$$

It was quite surprising to us that $Q(z, \rho)$ turned out to be a new, but simple, continued fraction.

## III. INTEGRAL EQUATION METHOD

The purpose of this section is to introduce the integral equation method and to show that $\tilde{\rho}_c < \rho_c$, where $\tilde{\rho}_c$ is the critical correlation value for the related problem involving $E|x_1 \cdots x_n|$.

We begin by developing an expression for $Ex_1 \cdots x_n$. We have, from the Markov property of the $x_i$ sequence,

$$Ex_1 \cdots x_n = \int \cdots \int x_n p(x_n|x_{n-1}) \cdots x_1 p(x_1|x_0)\phi(x_0)dx_0 \cdots dx_n, \tag{29}$$

where

$$\phi(x) = \frac{1}{\sqrt{2\pi}} \exp(-x^2/2) \tag{30}$$

is the standard normal density and

$$p(y|x) = \frac{1}{\sqrt{2\pi(1-\rho^2)}} \exp[-(y-\rho x)^2/2(1-\rho^2)] \tag{31}$$

is the generic form of the conditional densities occurring in (29). Define a kernel $K(x, y)$ by

$$K(x, y) = yp(y|x),$$

$$Kf(x) = \int_{-\infty}^{\infty} K(x, y)f(y)dy.$$

Then (29) may be written in the inner product notation of Hilbert Space

$$Ex_1 \cdots x_n = (K^n \underline{1}, \phi), \tag{32}$$

where $\phi$ is the normal density (30), $\underline{1}$ is the unit constant function,

and $K^n$ is the $n$th iterated kernel. Now assume, heuristically, that $K^n$ has the usual expansion

$$K^n(x, y) = \sum_{j=1}^{\infty} \lambda_j^n \psi_j(x)\psi_j(y) \tag{33}$$

in terms of eigenfunctions $\psi_j(x)$ and eigenvalues $\lambda_j$ of $K$. Then $Ex_1 \cdots x_n$ would remain bounded, if, and only if, the largest eigenvalue $\lambda_1 = \lambda_1(\rho)$ is less or equal to one; thus $\lambda_1(\rho_c) = 1$ would determine $\rho_c$. Unfortunately there is no general eigenexpansion theory available for $K$ since it is not symmetric and is not symmetrizable.

Fortunately symmetry holds for the integral equation method when one expresses $E|x_1 \cdots x_n|$ via kernels. Define, in analogy to (32),

$$\bar{K}(x, y) = |y| p(y|x). \tag{34}$$

If we further define

$$J(x, y) = \frac{h(x)}{h(y)} \bar{K}(x, y), \tag{35}$$

where

$$h(x) = \sqrt{|x|} \exp(-x^2/4), \tag{36}$$

then

$$J(x, y) = \frac{1}{\sqrt{2\pi(1 - \rho^2)}} \sqrt{|xy|} \exp\left[-\frac{1}{4}\frac{1 + \rho^2}{1 - \rho^2}(x^2 + y^2)\right] \cdot \exp\left[\frac{\rho xy}{1 - \rho^2}\right] \tag{37}$$

is a symmetric kernel.

As in (29),

$$\begin{aligned} E|x_1 \cdots x_n| &= \int \cdots \int \bar{K}(x_{n-1}, x_n)\bar{K}(x_{n-2}, x_{n-1}) \\ &\qquad \cdots \bar{K}(x_0, x_1)\, \phi(x_0) dx_0 \cdots dx_n \\ &= \int \cdots \int dx_0 \cdots dx_n\, J(x_0, x_1) \\ &\qquad \cdots J(x_{n-1}, x_n) \frac{h(x_n)}{h(x_0)} \phi(x_0) \\ &= \left(J^n h, \frac{\phi}{h}\right). \end{aligned} \tag{38}$$

Since $J$ is symmetric and square-integrable, it is a Hilbert-Schmidt kernel and so has a discrete spectrum. Further its maximum eigenvalue, $\lambda$, is given by

$$\lambda = \sup_f \frac{(Jf, f)}{(f, f)}. \tag{39}$$

Since $J(x, y) \geq 0$, we see that the maximum eigenfunction $g = g(x)$ is nonnegative and $\lambda > 0$ as well. Further since $h$ and $\phi/h$ are nonnegative, $(h, g) > 0$ and $(\phi/h, g) > 0$ so that $E|x_1 \cdots x_n| = (J^n h, \phi/h) \to \infty$ if and only if $\lambda > 1$.

Define $f_\alpha$ by

$$f_\alpha(x) = \sqrt{|x|}\exp(-\alpha x^2/4), \tag{40}$$

and note that from (39),

$$\lambda > (Jf_\alpha, f_\alpha)/(f_\alpha, f_\alpha). \tag{41}$$

Now

$$(f_\alpha, f_\alpha) = \int |x|\exp(-\alpha x^2/2)dx = 2/\alpha \tag{42}$$

and

$$(Jf_\alpha, f_\alpha) = \frac{1}{\sqrt{2\pi(1-\rho^2)}} \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} |xy| \cdot \exp\left[-\frac{c}{2}(x^2+y^2) + \frac{\rho xy}{1-\rho^2}\right] dxdy, \tag{43}$$

where

$$c = \frac{1}{2}\left(\frac{1+\rho^2}{1-\rho^2} + \alpha\right). \tag{44}$$

Set $y = xu$ and integrate over $x$ to obtain

$$(Jf_\alpha, f_\alpha) = \frac{4}{\sqrt{2\pi(1-\rho^2)}} \int_{-\infty}^{\infty} \frac{|u|du}{(c(1+u^2) - \beta u)^2},$$

$$\beta = \frac{2\rho}{1-\rho^2}. \tag{45}$$

Using Ref. 4 (p. 68, 2.175) we evaluate the last integral as

$$(Jf_\alpha, f_\alpha) = \frac{4}{\sqrt{2\pi(1-\rho^2)}}\left[\frac{4}{\Delta} + \frac{4\beta}{\Delta^{3/2}}\tan^{-1}\frac{\beta}{\sqrt{\Delta}}\right],$$

$$(\Delta = 4c^2 - \beta^2. \quad (46)$$

Setting $\alpha = 0.5$, $\rho = 0.55$, we find that $c = 1.18369$, $\beta = 1.57706$, $\Delta = 3.11738$, $(Jf_\alpha, f_\alpha) = 4.0824$, $(f_\alpha, f_\alpha) = 4$, so that $\lambda > 1.012$. Thus for $\rho = 0.55$, $E|X_1 \cdots X_n| \to \infty$, and $\bar{\rho}_c < 0.55$. We have seen that $\rho_c > 0.563$ so the claim is proven.

## APPENDIX

### *Combinatorial Derivation of Continued Fraction*

In this appendix we give a direct combinatorial proof of the continued fraction representation (25) of $Q(z, \rho)$. This derivation is complete in itself, but we preferred the method of the text for showing where the continued fraction comes from. Our starting point is the formula (7). Let us define, for $\sigma \in S_{2m}$,

$$V(\sigma) = \sum_{i=1}^{m} |\sigma(2i) - \sigma(2i-1)|. \quad (47)$$

For $1 \leq k \leq m$, let

$$\begin{aligned} S(m, k) = \{\sigma \in S_{2m} : &\sigma(2m) = 2m, \\ &\sigma(2m-2) = 2m-1, \\ \sigma(2m-4) = 2m-2, &\cdots, \\ &\sigma(2m-2k+2) = 2m-k+1\}. \end{aligned} \quad (48)$$

For $k = 0$, we adopt the convention that $S(m, 0) = S_{2m}$. We also define

$$u(m, k) = \frac{1}{2^{m-k}(m-k)!}\sum_{\sigma \in S(m,k)} \rho^{V(s)}, \quad (49)$$

so that $u(m, 0) = q_m$. (We take $u(0, 0) = q_0 = 1$, and $u(m, k) = 0$ for $k < 0$ and $k > m$.) Our key result is:

*Lemma. If* $m \geq 1$, $k \geq 0$, *then*

$$u(m, k) = k\rho^{2k-1}u(m-1, k-1) + u(m, k+1). \tag{50}$$

*Proof.* We will prove this for $1 \leq k \leq m-1$, as the other cases are easy. Let

$$S' = \{\sigma \in S(m, k): 2m-k \in \{\sigma(2m-1), \sigma(2m-3), \cdots, \sigma(2m-2k+1)\}\},$$
$$S'' = S(m, k) - S'. \tag{51}$$

If $\sigma \in S''$, we construct a permutation $\sigma^* \in S(m, k+1)$ by changing the action of $\sigma$ on four letters in such a way that $V(\sigma) = V(\sigma^*)$ and $\sigma^*(2m-2k) = 2m-k$. To define $\sigma^*$ precisely, let $p$ and $r$ be such that $\{r, 2m-k\} = \{\sigma(2p-1), \sigma(2p)\}$. Then, if we associate to $\sigma$ the vector $A(\sigma) = (\sigma(1), \sigma(2), \cdots, \sigma(2m))$, the vector $A(\sigma^*)$ is obtained from $A(\sigma)$ by interchanging the pairs $\{\sigma(2m-2k-1), \sigma(2m-k)\}$ and $\{r, 2m-k\}$ so as to keep the same ordering in the first pair, but possibly reversing it in the second, so as to have $\sigma^*(2m-2k) = 2m-k$. As an example, if $m = 5$, $k = 3$, and $A(\sigma) = (7, 2, 4, 1, 6, 8, 3, 9, 5, 10)$, then $A(\sigma^*) = (4, 1, 2, 7, 6, 8, 3, 9, 5, 10)$. It is clear that $\sigma^* \in S(m, k+1)$ and $V(\sigma^*) = V(\sigma)$. Moreover, every $\tau \in S(m, k+1)$ can be represented in exactly $2(m-k)$ ways as $\tau = \sigma^*$, $\sigma^* \in S''$. Therefore,

$$\frac{1}{2^{m-k}(m-k)!} \sum_{\sigma \in S''} \rho^{V(\sigma)} = u(m, k+1). \tag{52}$$

Suppose now that $\sigma \in S'$. Then $2m-k = \sigma(2m-2r+1)$ for some $r$, $1 \leq r \leq k$. We now define a permutation $\sigma' \in S(m-1, k-1)$ as follows: In $A(\sigma)$, delete $a = \sigma(2m-2r+1)(= 2m-k)$ and $b = \sigma \cdot (2m-2r+2)$ and reduce the remaining entries that are between $a$ and $b$ by 1, and those that are larger than $\max(a, b) = a$ by 2. As an example, if $m = 5$, $k = 3$, and $A(\sigma) = (2, 1, 6, 3, 5, 8, 7, 9, 4, 10)$, then $A(\sigma') = (2, 1, 6, 3, 5, 7, 4, 8)$. The resulting vector clearly equals $A(\sigma')$ for some $\sigma' \in S(m-1, k-1)$, and each $\tau \in S(m-1, k-1)$ has exactly $k$ such representations. Further, $V(\sigma)$ equals the sum of (i) $V(\sigma')$, (ii) $a-b$ for the pair that was dropped, (iii) 2 for each of the $r-1$ pairs $(\sigma(2m-2j+1), \sigma(2m-2j+2))$ for $1 \leq j \leq r-1$, since in each such pair $\sigma(2m-2j+2) > a$, $\sigma(2m-2j+1) < b$, and finally (iv) 1 for each of the $k-r$ pairs $(\sigma(2m-2j+1), \sigma(2m-2j+2))$, $r+ \leq j \leq k$, since in each of them $\sigma(2m-j+1) < b$, $b < \sigma(2m-2j+2) < a$. Hence,

$$V(\sigma) = V(\sigma') + a - b + 2(r-1) + k - r. \tag{53}$$

But $a = 2m-k$ and $b = \sigma(2m-2r+2) = 2m-r+1$ from the definitions of $S(m, k)$, so

$$V(\sigma) = V(\sigma') + 2k - 1. \tag{54}$$

Hence, we have

$$\frac{1}{2^{m-k}(m-k)!}\sum_{\sigma\in S'}\rho^{V(\sigma)} = k\rho^{2k-1}u(m-1,\,k-1), \tag{55}$$

which proves the lemma.

We now can use the recurrence of the Lemma to derive the continued fraction expansion of the generating function. Let

$$f_k = f_k(z) = \sum_{m=0}^{\infty} u(m,\,k)z^m, \qquad k = 0,\,1,\,\cdots,$$

which for the moment we regard as formal power series in $z$. Then the Lemma gives us

$$f_1 = f_0 - 1, \tag{56}$$

and for $k \geqslant 2$,

$$\begin{aligned} f_k &= \sum_m u(m,\,k-1)z^m - (k-1)\rho^{2k-3}\sum_m u(m-1,\,k-2)z^m \\ &= f_{k-1} - (k-1)\rho^{2k-3}zf_{k-2}. \end{aligned} \tag{57}$$

Relations (56) and (57) show that for $k \geqslant 0$,

$$f_k = s_k f_0 - r_k, \tag{58}$$

where $s_0 = s_1 = 1$, $r_0 = 0$, $r_1 = 1$, and for $k \geqslant 2$ both $s_k$ and $r_k$ satisfy the recurrence

$$x_k = x_{k-1} - (k-1)\rho^{2k-3}zx_{k-2}.$$

Hence the quotients $r_k/s_k$ are the partial quotients of the continued fraction $R(z,\,\rho)$ on the right side of (25), and $s_k$ and $r_k$ converge as $k \to \infty$ to power series (in $z$) $s(z,\,\rho)$ and $r(z,\,\rho)$, respectively, for which

$$R(z,\,\rho) = \frac{r(z,\,\rho)}{s(z,\,\rho)}. \tag{59}$$

On the other hand, since $f_k$ starts with a term involving $z_k$, we conclude that $f_k$ converges to 0 in the ring of formal power series as $k \to \infty$. Therefore, from (58),

$$f_0 = \frac{r(z,\,\rho)}{s(z,\,\rho)} = R(z,\,\rho). \tag{60}$$

Since $f_0 = Q(z,\,\rho)$, we obtain the relation (25), at least in the ring of formal power series in $z$. However, the continued fraction (25) is clearly a meromorphic function of $z$ for $\rho$ fixed, $0 < \rho < 1$, and it is analytic at 0. Hence (25) holds as an equality among meromorphic functions, and we can obtain from this the exponential decrease of the $q_m(\rho)$ for $\rho < \rho_c$ and the exponential increase for $\rho > \rho_c$.

# Series Solutions of Companding Problems

By B. F. LOGAN, Jr.*

(Manuscript received March 10, 1982)

A formal power series solution (i) $x(t) = \sum_1^\infty m^k x_k(t)$ is given for the companding problem (ii) $Bf\{x(t)\} = my(t)$, $B\{x(t)\} = x(t)$, where $B$ is the bandlimiting operator defined by $Bg = (Bg)(t) = \int_{-\infty}^{\infty} g(s)[\sin \lambda(t-s)]/[\pi(t-s)]ds$ and $f(t)$ has a Taylor series with $f(0) = 0, f'(0) \neq 0$. Expressions for the $x_k$ are given in terms of the coefficients of $f$, and operations on $y$, and in a different form in terms of the coefficients of the inverse function $\phi$, $\phi\{f(x)\} = x$. A series development is given for a bandlimited $z(t)$, $Bz = z$, such that the solution of (ii) is given by $x = B\phi(z)$. Also a series development is given for the "approximate identity", $x \doteq B\phi\{Bf(x)\}$, where $x = x(t)$, $Bx = x$, which is shown to be a good approximation to $x$ for fairly linear $f(x)$, not necessarily having a Taylor series expansion. As an example of one application of the results, a few terms are given for correction of the "inband" distortion arising in envelope detection of "full-carrier" single-sideband signals. The results should prove useful in correcting small distortions in other transmission systems. Finally, it is shown that the formal series solution (*i*) actually converges for sufficiently small $|m|$. This involves proving that the companding problem (*ii*) has a unique solution for arbitrary complex-valued $y(t)$ and complex $m$ of sufficiently small magnitude, the solution $x(t; m)$ being, for each $t$, an analytic function of the complex variable $m$ in a neighborhood of the origin. It is a curious fact, as shown by an interesting example, that the series (*i*) may converge for values of $m$ for which it is not a solution of (*ii*).

## I. INTRODUCTION

Suppose $x(t)$ is a bandlimited signal whose Fourier transform vanishes outside the interval $[-\lambda, \lambda]$. If such a signal is instantaneously

distorted by a nonlinear (companding) function $f(x)$, the distorted signal $f\{x(t)\}$ will, in general, have frequency components outside the interval $[-\lambda, \lambda]$. If the out-of-band components of the distorted signal are removed by ideal low-pass filtering, the result is a bandlimited signal $y(t)$ whose Fourier transform agrees with that of $f\{x(t)\}$ over $(-\lambda, \lambda)$. How, and under what conditions, may $x(t)$ be recovered from $y(t)$? When the signals are real-valued, this is known as the *companding problem* of Landau and Miranker (Refs. 1 and 2), hereafter referred to as the *r.v. companding problem.* Before stating their result, and our purpose, we introduce some notation.

The symbol $\mathscr{B}_2(\lambda)$ will denote the subspace of $L_2 = L_2(-\infty, \infty)$ whose elements are those (square-integrable) functions whose Fourier transforms vanish outside $[-\lambda, \lambda]$. Associated with this subspace is the *bandlimiting operator* $B_\lambda$, defined for $g$ in $L_2$ by

$$B_\lambda g = (B_\lambda g)(t) = \int_{-\infty}^{\infty} g(s) \frac{\sin \lambda(t-s)}{\pi(t-s)}\, ds.$$

The Fourier transforms of $g$ and $B_\lambda g$ agree over $(-\lambda, \lambda)$, the transform of the latter vanishing outside $[-\lambda, \lambda]$. In the language of Hilbert space, $B_\lambda g$ is the projection of $g$ on $\mathscr{B}_2(\lambda)$, being the best approximation to $g$ in the subspace $\mathscr{B}_2(\lambda)$. In case $g$ belongs to $\mathscr{B}_2(\lambda)$, we have

$$B_\lambda g = g.$$

It follows that

$$B_\lambda^n g = B_\lambda g, \qquad g \text{ in } L_2, \qquad n = 1, 2, \cdots.$$

The operator $B_\lambda$ may be applied also to functions belonging to $L_p$, $1 \leq p < \infty$; i.e., to functions $g$ satisfying

$$\|g\|_p = \left\{\int_{-\infty}^{\infty} |g(t)|^p dt\right\}^{1/p} < \infty \quad (1 \leq p < \infty).$$

Here the notation $\|g\|_p$ designates the norm of $g$ in $L_p$, or simply the $L_p$-norm of $g$. The space $L_\infty$ consists of those functions $g$ whose magnitude is bounded on the real line, their norm $\|g\|_\infty$ being the "essential supremum" of $|g(t)|$, which for functions we will be dealing with here, is simply the maximum value of $|g(t)|$. The operator $B_\lambda$ may not be applied to an arbitrary bounded function, since the associated integral may not converge. However, the integral may converge conditionally for a large class of functions; in particular, $B_\lambda g = g$, for any constant function $g$.

The operator $B_\lambda$ is a "contraction" operator on $L_2$; i.e.,

$$\|B_\lambda g\|_2 \leq \|g\|_2,$$

with equality attaining only for $g$ in $\mathscr{B}_2(\lambda)$. This follows from Parseval's theorem and the definition of $B_\lambda$.

Applying Schwarz's inequality to the integral equation denoted by $B_\lambda g = g$, we obtain the useful inequality

$$\|g\|_\infty \leq \sqrt{\lambda/\pi}\, \|g\|_2, \qquad g \quad \text{in} \quad \mathscr{B}_2(\lambda).$$

Also, it is easy to show from the integral equation that

$$\lim_{t\to\pm\infty} g(t) = 0, \qquad g \quad \text{in} \quad \mathscr{B}_2(\lambda).$$

We shall also make use of the *high-pass operator* $H_\lambda$, defined by

$$H_\lambda = I - B_\lambda,$$

where $I$ is the identity operator. $H_\lambda$ is an identity operator for functions $h$ of $L_2$ whose Fourier transforms vanish over $(-\lambda, \lambda)$, and it is also a contraction operator on $L_2$,

$$\|H_\lambda g\|_2 \leq \|g\|_2,$$

with equality attaining only for $H_\lambda g = g$, i.e., for $B_\lambda g = 0$. (In these operational equations, 0 is interpreted as the null function.)

It is clear from the operator definitions and the associated Fourier transform relations that any function $f$ in $L_2$ has the decomposition

$$f = g + h,$$

where

$$g = B_\lambda f, \qquad h = H_\lambda f.$$

Since $\lambda$ will be fixed throughout the paper, we will, except where emphasis is desired, simply write $B$, $H$, and $\mathscr{B}_2$ for $B_\lambda$, $H_\lambda$, $\mathscr{B}_2(\lambda)$, respectively.

Now, using our notation, we may state the important result of Landau and Miranker as follows:

*Theorem* (Landau and Miranker): *Let $f(x)$ be a real-valued function of the real variable $x$, satisfying*

(*i*) $f(0) = 0$

(*ii*) $0 < m_1 \leq f'(x) \leq m_2 < \infty, \qquad (-\infty < x < \infty).$

*Then to each real-valued $y$ in $\mathscr{B}_2$ there corresponds a unique $x$ in $\mathscr{B}_2$, also real-valued, satisfying*

(*iii*) $Bf(x) = y.$

*The solution $x$ of (iii) may be obtained as the limit of the sequence of approximants $\{x_n\}$ defined iteratively by*

(*iv*) $x_{n+1} = x_n - cB\{f(x_n) - y\},$

*provided only that $x_1$ is a real-valued function in $\mathscr{B}_2$ and the real constant $c$ is so chosen that*

(v) $\max_x |1 - cf'(x)| \leq r < 1.$

The beauty of this result is that, under the hypotheses on $f$, every (r.v.) $y$ in $\mathscr{B}_2$ has the representation (*iii*) where $x$ is a unique (r.v.) function in $\mathscr{B}_2$. In some r.v. companding problems of interest, $f(x)$ may not be defined outside some interval and/or the condition on $f'(x)$ may not be satisfied over the whole real axis, but rather over some interval including the origin. Then the conclusion will apply only to $y$ of sufficiently small norm. In such cases, the companding problem has two essentially different interpretations. The first is the *recovery problem*: $y$ is known to be of the form (*iii*); recover $x$. The second is the *design problem*: $y$ is a prescribed (desired) signal; find $x$, if possible, so that $y$ is given by (*iii*). In this case, one is faced with the problem of determining for what $y$ the problem has a solution.

The speed of covergence of the iterative solution of Landau and Miranker is a matter of practical concern. They show that

$$\| x_{n+1} - x_n \|_2 \leq r \| x_n - x_{n-1} \|_2.$$

Then the constant $c$ in (v) should be chosen to make $r$ as small as possible. Assuming that equality may attain on both sides in (*ii*), one should choose

$$c = \frac{2}{m_1 + m_2}, \qquad \text{giving} \quad r = \frac{m_2 - m_1}{m_2 + m_1}.$$

Thus rapid convergence is assured if $(m_2/m_1)$ is not much larger than 1. If this is not the case, a large number of iterations are, in general, required to obtain a close approximation to the solution of the problem. In a practical implementation of the iterative scheme of solution (Ref. 1), the ideal bandlimiting operator is replaced by an approximate operator, incurring a certain delay, in addition to (eventually) significant spectral distortions, with the result that the sequence $\{x_n\}$ will not converge to the solution $x$. Thus, in practice, the number of iterations to be performed is limited both by practical and theoretical considerations. The conclusion is that good approximate solutions to companding problems may be conveniently obtained in practice only in those cases where the companding function $f(x)$ is fairly linear over the range of $x(t)$.

We should remark at this point that there is only one known (nonlinear) r.v. companding problem (see Ref. 3) admitting of an explicit noniterative solution; viz.,

$$B\{\log(1 + x)\} = y, \qquad x > -1, \qquad x \text{ in } \mathscr{B}_2,$$

which has a solution if, and only if, the function†

† Here we are applying the $B$ operator to a function not in $L_2$, the proper interpretation being $w = 1 + B\{-1 + \exp(\cdot)\}$.

$$w(t) = B\{\exp\ 1/2[\,y(t) + \hat{y}(t)]\},$$

where $\hat{y}$ is the Hilbert transform of $y$, extends as a function zero-free in the upper half-plane, which will be the case if $\| y \|_2$ is sufficiently small. Then the solution is given by

$$x(t) = |\,w(t)\,|^2 - 1.$$

Motivated by the above considerations, pure curiosity, and the fact that in many cases of practical interest the companding function and/or its inverse can be well approximated by a polynomial of low degree over the range of interest, we are led to consider the case where the companding function has a Taylor series expansion, allowing the possibility of developing a corresponding series solution to the problem. To obtain the terms (1st order, 2nd order, etc.) in the series solution it is convenient to multiply $y$ by a scalar parameter $m$, and consider the problem

$$Bf(x) = my \tag{1}$$

to be solved for $x$ in $\mathscr{B}_2$, given $y$ in $\mathscr{B}_2$, for companding functions

$$f(x) = \sum_1^\infty b_k x^k, \qquad |\,x\,| < R_0 \tag{2}$$

$$b_1 \neq 0.$$

For sufficiently small $|\,x\,|$, $f$ will have an inverse $\phi$,

$$x = \phi\{f(x)\}$$

$$\phi(y) = \sum_1^\infty a_k y^k, \qquad |\,y\,| \leq R_0^*. \tag{3}$$

We assume that the solution $x = x(t; m)$ of (1) has a series expansion in the parameter $m$,

$$x(t; m) = \sum_1^\infty m^k x_k(t), \tag{4}$$

where the $x_k(t)$, aptly described as $k$th order corrections, (not to be confused with the Landau-Miranker approximants) depend only on $y(t)$ and $f$. Presumably, in cases of small distortion, a few terms of the series would give a satisfactory approximation to the solution.

Explicit expressions for the first five of the $x_k(t)$ are given in the sequel, first in formulas involving the coefficients of $\phi$, and next, the coefficients of $f$, together with certain operations on $y$. These formulas reveal how the Fourier transforms of the $x_k(t)$ may be calculated from the Fourier transform of $y(t)$, if this be given.

Next, we find a series development of $z$ in $\mathscr{B}_2$,

$$z(t) = z(t; m) = \sum_1^\infty m^k z_k(t) \tag{5}$$

such that the solution to (1) is given (presumably for sufficiently small $|m|$) by

$$x = B\phi(z). \tag{6}$$

We find that $z_1 = y$, $z_2 = 0$, and in case $a_2$ in (3), or $b_2$ in (2), vanishes, we have, in addition, $z_3 = z_4 = 0$. That is, under certain conditions, $z \doteq my$, implying that $B\phi\{Bf(x)\}$ is an "approximate identity" ($\doteq x$) for $x$ in $\mathscr{B}_2$, especially if $f$ is odd and fairly linear, or if $x(t)$ is a predominantly low-frequency function.

To further investigate the approximate identity, we introduce the parameter $m$ again, and obtain expressions for $u_k$ in

$$B\phi\{Bf(mx)\} = \sum_1^\infty m^k u_k, \qquad x \text{ in } \mathscr{B}_2. \tag{7}$$

To see how interchanging $f$ and $\phi$ affects the approximate identity, we compare $u_k$ with $v_k$ in

$$Bf\{B\phi(mx)\} = \sum_1^\infty m^k v_k, \qquad x \text{ in } \mathscr{B}_2. \tag{8}$$

As expected from the series development of $z$, we find $u_1 = v_1 = x$, and $u_2 = v_2 = 0$. Further comparisons [with the same $m$ in (7) and (8)] should be made for the case $f'(0) = \phi'(0) = 1$. For this case, we find $u_3 = v_3 = 2b_2^2 B(x \cdot Hx^2)$, which may be small if $b_2$ is small or if $Hx^2$ is small. In case $b_2 = 0$, we find $u_k = v_k = 0$ for $k = 2, 3, 4$, and $u_5 = v_5 = 3b_3^2 B(x^2 \cdot Hx^3)$.

These series developments of the approximate identity suggest that it would be useful in obtaining an approximate solution to the r.v. companding problem for fairly linear companding functions, not necessarily having a Taylor series expansion, but merely satisfying $f(0) = 0$ and

$$0 < m_1 \leqslant f'(x)\ m_2 < \infty, \qquad (-\infty < x < \infty). \tag{9}$$

Compelled by this suggestion, we digress in the Appendix to show for such $f$ that

$$\| x - B\phi\{Bf(x)\} \|_2 \leqslant \gamma \| x \|_2, \qquad x \text{ in } \mathscr{B}_2, \tag{10}$$

where

$$\gamma = \frac{\epsilon^2}{4(1+\epsilon)}, \qquad \epsilon = \frac{m_2}{m_1} - 1.$$

(Note that $\gamma = 1/8$ for $m_2/m_1 = 2$.) Thus in many companding

problems, $B\phi(y)$, involving only one filtering operation, would be an adequate approximation to the solution $x$. We go on to define an iterative procedure, involving both $f$ and its inverse $\phi$, obtaining approximants converging to $x$ for $\gamma < 1$, offering an alternative to the solution of Landau and Miranker in cases where $(m_2/m_1) < 3 + 2\sqrt{2}$. In any case, $B\phi(y)$ is suggested as a good choice for $x_1$ in their iterative solution. We note, in leaving this topic, that the inequality (10) is invariant to the interchange of $f$ and its inverse $\phi$.

Returning to the series solution, we apply the results to the problem of compatible single-sideband transmission (Ref. 4), obtaining a few terms for correction of the "in-band" distortion arising in envelope detection of "full-carrier" single-sideband signals.

Although the original intent of the work here was to obtain expressions for the first few terms of the series solution (4), supposedly adequate for correcting small distortions, the mathematical question naturally arises in the end as to whether the series actually converges for sufficiently small $|m|$ (or equivalently, for $|m| = 1$ and $\|y\|_2$ sufficiently small), or whether it is merely an asymptotic series. It is indeed a pertinent mathematical question, since the expressions for the $x_k(t)$ were obtained by purely formal manipulations of power series and application of the operators $B$ and $H$. The resulting expressions become progressively cumbersome and complicated, with no obvious general form, offering no possibility of establishing (from them) bounds on $|x_k(t)|$ which would ensure convergence of the series. The remainder of the paper is addressed to the problem of establishing the convergence of the series.

If we suppose in the r.v. companding problem that the series converges for real-valued $m$ of sufficiently small magnitude, then it would also converge for similar complex $m$, suggesting that the companding problem [for fixed $y(t)$] would have a solution for all complex $m$ of sufficiently small magnitude. This, in turn, suggests that the problem would have a solution for arbitrary *complex-valued* $y(t)$ in $\mathscr{B}_2$ and all complex $m$ of sufficiently small magnitude, depending on $f$ and the norm of $y$. That this is a fact has been established previously (Ref. 3) only for complex-valued $y(t)$ whose Fourier transforms vanish outside $[0, \lambda]$, (or $[-\lambda, 0]$), the Fourier transform of the solution $x(t)$ having the same property. In this case (with $m = 1$), the solution is given by $x = B\phi(y)$ for $y$ of sufficiently small norm; i.e., in case the Fourier transform of $x(t)$ vanishes outside $[0, \lambda]$, (or $[-\lambda, 0]$) the "approximate identity" is an exact identity,

$$x = B\phi\{Bf(x)\} = \phi\{f(x)\}$$

for $x$ of sufficiently small norm. This result can be explained, roughly, by the fact that nonlinear (analytic) distortion of such $x(t)$ does not

produce both "sum and difference" frequency components, but only "sum" components.

In order to prove that the series solution actually converges for sufficiently small $|m|$, we show that the companding problem (1), where $y(t)$ is an arbitrary *complex-valued* function in $\mathscr{B}_2$, has a solution $x(t; m)$ for all complex $m$ of sufficiently small magnitude, this solution being, for each fixed $t$, an anaytic function of the complex variable $m$, from which it follows that the solution has a Taylor series expansion in $m$; i.e.,

$$x(t;m) = \sum_1^\infty m^k x_k(t), \qquad |m| < m_0. \tag{11}$$

To obtain this result, we first have to establish for the complex-valued (c.v.) companding problem the analogue of A. Beurling's uniqueness theorem (see Ref. 1) for the r.v. companding problem.

We then examine in detail a specific problem illustrative of the theory and some of its nuances; viz., the problem (taking $\lambda = 2$ for convenience)

$$B\left\{\frac{x}{1-x}\right\} = m\,\frac{\sin 2t}{2t} \tag{12}$$

for which the solution is (at least for sufficiently small $|m|$)

$$x = x(t;m) = 2\beta\,\frac{\sin 2t}{2t} - \beta^2\left(\frac{\sin t}{t}\right)^2, \tag{13}$$

where

$$\beta = m/(2 + m).$$

The rather surprising revelation of this example is that, although the series expansion in $m$ of $x(t;m)$ converges, uniformly in $t$, for $|m| < 2$, it is not a solution of (12) for all such $m$. Furthermore, one might reasonably assume that (13) is a solution of (12) for all $m$ other than $-2$, but this is not true either. As an illuminating exercise, we determine precisely the set of $m$ for which (13) is a solution of (12).

## II. THE INVERSE SERIES METHOD

To obtain a series solution to (1), we first think of recovering from $y(t)$ the out-of-band components of $f\{x(t)\}$, so that we might apply the inverse function $\phi$ to the whole in order to recover $x(t) = x(t;m)$. We have

$$f\{x(t)\} = my(t) + h(t), \tag{14}$$

where $h(t) = h(t;m)$ is some unknown "high-pass" function satisfying

$$Bh(t) = 0 \tag{15}$$

and hence

$$x(t) = \phi\{my(t) + h(t)\}. \tag{16}$$

It is convenient at this point to introduce the high-pass operator defined by

$$H = I - B, \tag{17}$$

where $I$ is the identity operator. Thus applying $H$ to (16) we have

$$H\phi\{my(t) + h(t)\} = 0. \tag{18}$$

We would like to solve (18) for $h(t)$, which we think of as small in cases of interest.

Now we assume that

$$\phi(y) = \sum_1^\infty a_k y^k \quad \text{for sufficiently small} \quad |y|, \tag{19}$$

$$a_1 \neq 0$$

and that in (16)

$$h(t) = h(t;m) = \sum_2^\infty m^k h_k(t), \qquad Hh_k = h_k, \qquad k \geqslant 2, \tag{20}$$

$$x(t) = x(t;m) = \sum_1^\infty m^k x_k(t), \qquad Bx_k = x_k, \qquad k \geqslant 1, \tag{21}$$

where $h_k(t)$ and $x_k(t)$ do not depend on $m$.

We want to expand $\phi\{my(t) + h(t)\}$ as a power series in $m$. To do this it is convenient to write

$$my(t) + h(t) = \sum_1^\infty m^k h_k(t), \tag{22}$$

where we identify

$$y(t) = h_1(t) \quad \text{in} \quad \mathscr{B}_2. \tag{23}$$

Then we write

$$\phi\left\{\sum_1^\infty m^k h_k(t)\right\} = F(m;t) = \sum_1^\infty m^k F_k(t). \tag{24}$$

For convenience we suppress the variable $t$ and write simply $x_k$, $h_k$, $F_k$. In terms of the coefficients $a_k$ in

$$\phi(y) = \sum_{1}^{\infty} a_k y^k,$$

we find, equating coefficients of $m^k$ in (24),

$$F_1 = a_1 h_1 \tag{25.1}$$

$$F_2 = a_1 h_2 + a_2 h_1^2 \tag{25.2}$$

$$F_3 = a_1 h_3 + a_2(2h_1 h_2) + a_3 h_1^3 \tag{25.3}$$

$$F_4 = a_1 h_4 + a_2(2h_1 h_3 + h_2^2) + a_3(3h_1^2 h_2) + a_4 h_1^4 \tag{25.4}$$

$$F_5 = a_1 h_5 + a_2(2h_1 h_4 + 2h_2 h_3) + a_3(3h_1^2 h_3 + 3h_1 h_2^2) + a_4(4h_1^3 h_2) + a_5 h_1^5 \tag{25.5}$$

$$F_6 = a_1 h_6 + a_2(2h_1 h_5 + 2h_2 h_4 + h_3^2) + a_3(3h_1^2 h_4 + 6h_1 h_2 h_3 + h_2^3) + a_4(4h_1^3 h_3 + 6h_1^2 h_2^2) + a_5(5h_1^4 h_2) + a_6 h_1^6 \tag{25.6}$$

$$F_7 = a_1 h_7 + a_2(2h_1 h_6 + 2h_2 h_5 + 2h_3 h_4) + a_3(3h_1^2 h_5 + 6h_1 h_2 h_4 + 3h_1 h_3^2 + 3h_2^2 h_3) + a_4(4h_1^3 h_4 + 12h_1^2 h_2 h_3 + 4h_1 h_2^3) + a_5(5h_1^4 h_3 + 10h_1^3 h_2^2) + a_6(6h_1^5 h_2) + a_7 h_1^7 \tag{25.7}$$

$$F_8 = a_1 h_8 + a_2(2h_1 h_7 + 2h_2 h_6 + 2h_3 h_5 + h_4^2) + a_3(3h_1^2 h_6 + 6h_1 h_2 h_5 + 6h_1 h_3 h_4 + 3h_2^2 h_4 + 3h_2 h_3^2) + a_4(4h_1^3 h_5 + 12h_1^2 h_2 h_4 + 6h_1^2 h_3^2 + 12h_1 h_2^2 h_3 + h_2^4) + a_5(5h_1^4 h_4 + 20h_1^3 h_2 h_3 + 10h_1^2 h_2^3) + a_6(6h_1^5 h_3 + 15h_1^4 h_2^2) + a_7(7h_1^6 h_2) + a_8 h_1^8 \tag{25.8}$$

$$F_9 = a_1 h_9 + a_2(2h_1 h_8 + 2h_2 h_7 + 2h_3 h_6 + 2h_4 h_5) + a_3(3h_1^2 h_7 + 6h_1 h_2 h_6 + 6h_1 h_3 h_5 + 3h_1 h_4^2 + 3h_2^2 h_5 + 6h_2 h_3 h_4 + h_3^3) + a_4(4h_1^3 h_6 + 12h_1^2 h_2 h_5 + 12h_1^2 h_3 h_4 + 12h_1 h_2^2 h_4 + 12h_1 h_2 h_3^2 + 4h_2^3 h_3) + a_5(5h_1^4 h_5 + 20h_1^3 h_2 h_4 + 10h_1^3 h_3^2 + 30h_1^2 h_2^2 h_3 + 5h_1 h_2^4) + a_6(6h_1^5 h_4 + 30h_1^4 h_2 h_3 + 20h_1^3 h_2^3) + a_7(7h_1^6 h_3 + 21h_1^5 h_2^2) + a_8(8h_1^7 h_2) + a_9 h_1^9 \tag{25.9}$$

$$F_{10} = a_1 h_{10} + a_2(2h_1 h_9 + 2h_2 h_8 + 2h_3 h_7 + 2h_4 h_6 + h_5^2) + a_3(3h_1^2 h_8 + 6h_1 h_2 h_7 + 6h_1 h_3 h_6 + 6h_1 h_4 h_5 + 3h_2^2 h_6 + 6h_2 h_3 h_5 + 3h_2 h_4^2 + 3h_3^2 h_4) + a_4(4h_1^3 h_7 + 12h_1^2 h_2 h_6$$

$$+ 12h_1^2h_3h_5 + 6h_1^2h_4^2 + 12h_1h_2^2h_5 + 24h_1h_2h_3h_4 + 4h_1h_3^3$$
$$+ 4h_2^3h_4 + 6h_2^2h_3^2) + a_5(5h_1^4h_6 + 20h_1^3h_2h_5 + 20h_1^3h_3h_4$$
$$+ 30h_1^2h_2^2h_4 + 30h_1^2h_2h_3^2 + 20h_1h_2^3h_3 + h_2^5) + a_6(6h_1^5h_5$$
$$+ 30h_1^4h_2h_4 + 15h_1^4h_3^2 + 60h_1^3h_2^2h_3 + 15h_1^2h_2^4)$$
$$+ a_7(7h_1^6h_4 + 42h_1^5h_2h_3 + 35h_1^4h_2^3) + a_8(8h_1^7h_3$$
$$+ 28h_1^6h_2^2) + a_9(9h_1^8h_2) + a_{10}h_1^{10}. \tag{25.10}$$

In general the coefficient of $a_m$ in the expansion of $F_n$ consists of sums of products of the $h_k$ corresponding to partitions of $n$ into $m$ parts. The coefficient of the product is $m!$ divided by the product of the factorials of the exponents of the $h_k$ (the multinomial theorem). For example, in $F_{10}$ the coefficient of $a_5$ is found by writing down the partitions of 10 into 5 parts and proceeding thus (see Table 24.2, Ref. 5):

| | | | |
|---|---|---|---|
| $1^4, 6$ | $\rightarrow$ $h_1^4h_6$ | coef. $= 5!/4!$ | $= 5$ |
| $1^3, 2, 5$ | $h_1^3h_2h_5$ | $5!/3!$ | $= 20$ |
| $1^3, 3, 4$ | $h_1^3h_3h_4$ | $5!/3!$ | $= 20$ |
| $1^2, 2^2, 4$ | $h_1^2h_2^2h_4$ | $5!/2!2!$ | $= 30$ |
| $1^2, 2, 3^2$ | $h_1^2h_2h_3^2$ | $5!/2!2!$ | $= 30$ |
| $1, 2^3, 3$ | $h_1h_2^3h_3$ | $5!/3!$ | $= 20$ |
| $2^5$ | $h_2^5$ | $5!/5!$ | $= 1.$ |

Now we may obtain a formal series solution (21) by successively solving for the $h_k$ by requiring

$$HF_k(t) = 0, \qquad k = 1, 2, \cdots \tag{26}$$

and setting

$$x_k(t) = BF_k(t) = F_k(t), \qquad k = 1, 2, \cdots. \tag{27}$$

Recall that $h_1 = y$, the given bandlimited (low-pass) function, and all the other $h_k$ are high-pass functions.† We have $Hh_k = h_k$, $k \geq 2$ and

$$HF_1 = a_1Hh_1 = 0 \tag{28.1}$$
$$HF_2 = a_1h_2 + a_2Hh_1^2 = 0$$
$$h_2 = -\frac{a_2}{a_1}Hh_1^2 \tag{28.2}$$

† Actually, for $k \geq 2$, $h_k$ is a bandpass function whose Fourier transform vanishes over $(-\lambda, \lambda)$ and outside $[-k\lambda, k\lambda]$. This can be seen from (28.1)–(28.k).

$$HF_3 = a_1h_3 + 2a_2H(h_1h_2) + a_3Hh_1^3 = 0$$

$$h_3 = \frac{2a_2^2}{a_1^2} H(h_1 \cdot Hh_1^2) - \frac{a_3}{a_1} Hh_1^3 \tag{28.3}$$

$$HF_4 = a_1h_4 + a_2(2H(h_1h_3) + Hh_2^2) + 3a_3H(h_1^2h_2) + a_4Hh_1^4 = 0$$

$$h_4 = -\frac{4a_2^3}{a_1^3} H[h_1 \cdot H(h_1 \cdot Hh_1^2)] + \frac{2a_2a_3}{a_1^2} H(h_1 \cdot Hh_1^3)$$
$$- \left(\frac{a_2}{a_1}\right)^3 H[(Hh_1^2)^2] + \frac{3a_2a_3}{a_1^2} H(h_1^2 \cdot Hh_1^2) - \frac{a_4}{a_1} Hh_1^4 \tag{28.4}$$

$$HF_5 = a_1h_5 + a_2[2H(h_1h_4) + 2H(h_2h_3)] + a_3[3H(h_1^2h_3)$$
$$+ 3H(h_1h_2^2)] + 4a_4H(h_1^3h_2) + a_5Hh_1^5 = 0$$

$$h_5 = \frac{8a_2^4}{a_1^4} H\{h_1 \cdot H[h_1 \cdot H(h_1 \cdot Hh_1^2)]\} - \frac{4a_2^2a_3}{a_1^3} H[h_1 \cdot H(h_1 \cdot Hh_1^3)]$$
$$+ \frac{2a_2^4}{a_1^4} H[h_1 \cdot (Hh_1^2)^2] - \frac{6a_2^2a_3}{a_1^3} H[h_1 \cdot H(h_1^2 \cdot Hh_1^2)]$$
$$+ \frac{2a_2a_4}{a_1^2} H(h_1 \cdot Hh_1^4) + \frac{4a_2^4}{a_1^4} H[(Hh_1^2) \cdot H(h_1 \cdot Hh_1^2)]$$
$$- \frac{2a_2^2a_3}{a_1^3} H[(Hh_1^2) \cdot Hh_1^3] - \frac{6a_2^2a_3}{a_1^3} H[h_1^2 \cdot H(h_1 \cdot Hh_1^2)]$$
$$+ \frac{3a_3^2}{a_1^2} H(h_1^2 \cdot Hh_1^3) - \frac{3a_2^2a_3}{a_1^3} H[h_1 \cdot (Hh_1^2)^2]$$
$$+ \frac{4a_2a_4}{a_1^2} H(h_1^3 \cdot Hh_1^2) - \frac{a_5}{a_1} Hh_1^5. \tag{28.5}$$

Now replacing $h_1$ by $y$ we have from (25), (27), and (28)

$$x_1 = BF_1 = a_1y \tag{29.1}$$

$$x_2 = BF_2 = a_2By^2 \tag{29.2}$$

$$x_3 = BF_3 = 2a_2B(yh_2) + a_3By^3$$
$$= -\frac{2a_2^2}{a_1} B(y \cdot Hy^2) + a_3By^3 \tag{29.3}$$

$$x_4 = BF_4 = a_2(2B(yh_3) + Bh_2^2) + 3a_3B(y^2h_2) + a_4By^4$$
$$= \frac{4a_2^3}{a_1^2} B[y \cdot H(y \cdot Hy^2)] - \frac{2a_2a_3}{a_1} B(y \cdot Hy^3)$$

$$+\frac{a_2^3}{a_1^2}B(Hy^2)^2-\frac{3a_2a_3}{a_1}B(y^2\cdot Hy^2)+a_4By^4 \tag{29.4}$$

$$\begin{aligned}x_5=BF_5&=a_2[2B(yh_4)+2B(h_2h_3)]+3a[B(y^2h_3)+B(yh_2^2)]\\&\quad+4a_4B(y^3h_2)+a_5By^5\\&=-\frac{8a_2^4}{a_1^3}B\{y\cdot H[y\cdot H(y\cdot Hy^2)]\}+\frac{4a_2^2a_3}{a_1^2}B[y\cdot H(y\cdot Hy^3)]\\&\quad-\frac{2a_2^4}{a_1^3}B[y\cdot H(Hy^2)^2]+\frac{6a_2^2a_3}{a_1^2}B[y\cdot H(y^2\cdot Hy^2)]\\&\quad-\frac{2a_2a_4}{a_1}B(y\cdot Hy^4)-\frac{4a_2^4}{a_1^3}B[(Hy^2)\cdot H(y\cdot Hy^2)]\\&\quad+\frac{2a_2^2a_3}{a_1^2}B[(Hy^2)\cdot(Hy^3)]+\frac{6a_2^2a_3}{a_1^2}B[y^2\cdot H(y\cdot Hy^2)]\\&\quad-\frac{3a_3^2}{a_1}B(y^2\cdot Hy^3)+\frac{3a_2^2a_3}{a_1^2}B[y\cdot(Hy^2)^2]\\&\quad-\frac{4a_2a_4}{a_1}B(y^3\cdot Hy^2)+a_5By^5.\end{aligned} \tag{29.5}$$

If in (29) we replace the $H$ operator by $I-B$ and collect terms we obtain

$$x_1=a_1y \tag{30.1}$$

$$x_2=a_2By^2 \tag{30.2}$$

$$x_3=\frac{2a_2^2}{a_1}B(y\cdot By^2)+\left(a_3-\frac{2a_2^2}{a_1}\right)By^3 \tag{30.3}$$

$$\begin{aligned}x_4&=\frac{4a_2^3}{a_1^2}B[y\cdot B(y\cdot By^2)]-\left(\frac{4a_2^3}{a_1^2}-\frac{2a_2a_3}{a_1}\right)B(y\cdot By^3)\\&\quad+\frac{a_2^3}{a_1^2}B(By^2)^2-\left(\frac{6a_2^3}{a_1^2}-\frac{3a_2a_3}{a_1}\right)B(y^2\cdot By^2)\\&\quad+\left(a_4-\frac{5a_2a_3}{a_1}+\frac{5a_2^3}{a_1^2}\right)By^4\end{aligned} \tag{30.4}$$

$$\begin{aligned}x_5&=\frac{8a_2^4}{a_1^3}B\{y\cdot B[y\cdot B(y\cdot By^2)]\}+\left(\frac{4a_2^2a_3}{a_1^2}-\frac{8a_2^4}{a_1^3}\right)B[y\cdot B(y\cdot By^3)]\\&\quad+\left(\frac{6a_2^2a_3}{a_1^2}-\frac{12a_2^4}{a_1^3}\right)B[y\cdot B(y^2\cdot By^2)]+\frac{2a_2^4}{a_1^3}\end{aligned}$$

$$\cdot B[y\cdot B(By^2)^2] + \left(\frac{3a_2^2a_3}{a_1^2} - \frac{6a_2^4}{a_1^3}\right) B[y\cdot(By^2)^2]$$

$$+ \left(\frac{2a_2a_4}{a_1} - \frac{10a_2^2a_3}{a_1^2} + \frac{10a_2^4}{a_1^3}\right) B(y\cdot By^4) + \frac{4a_2^4}{a_1^3} B[(By^2)$$

$$\cdot B(y\cdot By^2)] + \left(\frac{6a_2^2a_3}{a_1^2} - \frac{12a_2^4}{a_1^3}\right) B[y^2\cdot B(y\cdot By^2)]$$

$$+ \left(\frac{2a_2^2a_3}{a_1^2} - \frac{4a_2^4}{a_1^3}\right) B[(By^2)\cdot(By^3)]$$

$$+ \left(\frac{3a_3^2}{a_1} - \frac{12a_2^2a_3}{a_1^2} + \frac{12a_2^4}{a_1^3}\right) B(y^2\cdot By^3)$$

$$+ \left(\frac{4a_2a_4}{a_1} - \frac{20a_2^2a_3}{a_1^2} + \frac{20a_2^4}{a_1^3}\right) B(y^3\cdot By^2)$$

$$+ \left(a_5 - \frac{6a_2a_4}{a_1} + \frac{21a_2^2a_3}{a_1^2} - \frac{14a_2^4}{a_1^3} - \frac{3a_3^2}{a_1}\right) By^5. \tag{30.5}$$

Note that if $y$ belongs to $\mathscr{B}_2(\lambda/n)$, then $By^k = y^k$ for $k = 1, 2, \cdots, n$. In this case we will have $x_n = a_n y^n$. So the sum of all coefficients in the expressions for $x_n$ must be $a_n$. If $\phi$ is an odd function these formulas simplify considerably. It is rather curious that if $a_2 = 0$, $a_3 \neq 0$, the coefficient of $B(y^3\cdot By^2)$ vanishes, whereas the coefficient of $B(y^2\cdot By^3)$ does not. The coefficients in (30) are more simply expressed in terms of the coefficients in the power series for $f$ as we see below.

## III. FORWARD SERIES METHOD

We can also solve (1) in the "forward" direction by writing

$$Bf(mx_1 + m^2x_2 + m^3x_3 + \cdots) = my, \tag{31}$$

where

$$f(x) = \sum_1^\infty b_k x^k. \tag{32}$$

Then applying the expansion (24) and (25) to $f(\sum m^k x_k)$ we have, equating coefficients of $m^k$,

$$Bb_1x_1 = y \tag{33.1}$$

$$Bb_1x_2 + Bb_2x_1^2 = 0 \tag{33.2}$$

$$Bb_1x_3 + Bb_2(2x_1x_2) + Bb_3x_1^3 = 0 \tag{33.3}$$

$$Bb_1x_4 + Bb_2(2x_1x_3 + x_2^2) + Bb_3(3x_1^2x_2) + Bb_4x_1^4 = 0 \tag{33.4}$$

$$Bb_1x_5 = Bb_2(2x_1x_4 + 2x_2x_3) + Bb_3(3x_1^2x_3 + 3x_1x_2^2)$$
$$+ Bb_4(4x_1^3x_2) + Bb_5x_1^5 = 0. \tag{33.5}$$

Then solving (33) successively for $x_k$, $(Bx_k = x_k)$, we have

$$x_1 = y/b_1 \tag{34.1}$$

$$x_2 = -\frac{b_2}{b_1^3}By^2 \tag{34.2}$$

$$x_3 = \frac{2b_2^2}{b_1^5}B(y\cdot By^2) - \frac{b_3}{b_1^4}By^3 \tag{34.3}$$

$$x_4 = -\frac{4b_2^3}{b_1^7}B[y\cdot B(y\cdot By^2)] + \frac{2b_2b_3}{b_1^6}B(y\cdot By^3)$$
$$-\frac{b_2^3}{b_1^7}B(By^2)^2 + \frac{3b_2b_3}{b_1^6}B(y^2\cdot By^2) - \frac{b_4}{b_1^5}By^4 \tag{34.4}$$

$$x_5 = \frac{8b_2^4}{b_1^9}B\{y\cdot B[y\cdot B(y\cdot By^2)]\} + \frac{4b_2^4}{b_1^9}B[(By^2)\cdot B(y\cdot By^2)]$$
$$+\frac{2b_2^4}{b_1^9}B[y\cdot B(By^2)^2] - \frac{4b_2^2b_3}{b_1^8}B[y\cdot B(y\cdot By^3)]$$
$$-\frac{6b_2^2b_3}{b_1^8}B[y\cdot B(y^2\cdot By^2)] - \frac{2b_2^2b_3}{b_1^8}B[(By^2)\cdot(By^3)]$$
$$-\frac{6b_2^2b_3}{b_1^8}B[y^2\cdot B(y\cdot By^2)] - \frac{3b_2^2b_3}{b_1^8}B[y\cdot(By^2)^2]$$
$$+\frac{2b_2b_4}{b_1^7}B(y\cdot By^4) + \frac{4b_2b_4}{b_1^7}B(y^3\cdot By^2)$$
$$+\frac{3b_3^2}{b_1^7}B(y^2\cdot By^3) - \frac{b_5}{b_1^6}By^5. \tag{34.5}$$

These correspond to the solutions for the $h_k$ in (28) with $H$ and $B$, and $a$'s and $b$'s interchanged, except here $x_1 = y/b_1$ as compared by $h_1 = y$ in (28). They agree with the formulas in (30) according to the identities in reversion of series (see 3.6.25, Ref. 5)

$$a_1b_1 = 1 \tag{35.1}$$

$$a_1^3b_2 = -a_2 \tag{35.2}$$

$$a_1^5b_3 = 2a_2^2 - a_1a_3 \tag{35.3}$$

$$a_1^7b_4 = 5a_1a_2a_3 - a_1^2a_4 - 5a_2^3 \tag{35.4}$$

$$a_1^9 b_5 = 6a_1^2 a_2 a_4 + 3a_1^2 a_3^2 + 14a_4^2 - a_1^3 a_5 - 21a_1 a_2^2 a_3 \tag{35.5}$$

$$a_1^{11} b_6 = 7a_1^3 a_2 a_5 + 7a_1^3 a_3 a_4 + 84a_1 a_1^3 a_3 - a_1^4 a_6 - 28a_1^2 a_2 a_3^2 - 42a_2^5 - 28a_1^2 a_2^2 a_4 \tag{35.6}$$

$$a_1^{13} b_7 = 8a_1^4 a_2 a_6 + 8a_1^4 a_3 a_5 + 120a_1^2 a_2^3 a_4 + 180a_1^2 a_2^2 a_3^2 + 132a_2^6 - a_1^5 a_7 - 36a_1^3 a_2^2 a_5 - 72a_1^3 a_2 a_3 a_4 - 12a_1^3 a_2 a_3 a_4 - 12a_1^3 a_3^3 - 330a_1 a_1^4 a_3. \tag{35.7}$$

Of course the $a$'s and $b$'s may be interchanged in (35). Actually the expressions for $x_k$ in (34) are analogous in a way to the coefficients $a_k$ expressed in terms of the $b_k$ as given by (35) (with the $a$'s and $b$'s interchanged). That is, if it were not for the $B$ operator in eq. (33.k), we would have simply $x_k = a_k y^k$ according to the determining equations for the inverse coefficients. Because of the $B$ operator, successive solutions for the $x_k$ generate powers of $y$ interposed with $B$ operators and powers of $\{B(\cdot)\}$ in all combinations so that, for example, in $x_5$ we have a number of terms with coefficients $b_2^2 b_3 / b_1^8$ that combine only when $B$ is replaced by $I$ to give $-21 b_2^2 b_3 y^5 / b_1^8$, corresponding to the last term in (35.5). Note if all the $b_k = 1$, the sum of the integer coefficients in $x_n$ is $(-1)^{n+1}$ as this is the case $y = f(x) = x/(1 - x)$, $x = \phi(y) = y/(1 + y)$. Note also that in the expression (34.5) for $x_5$, for example, there are five groups of functions with common "$b$" coefficients. These combine with certain weights, depending only on the coefficients of $f(x)$, to give $x_5$. Similarly, in the expression (29.5) obtained from the inverse function, there are again five groups of functions with common "$a$" coefficients that combine with certain weights, still depending only on the coefficients of $f(x)$, to give $x_5$. The interesting and rather puzzling fact is that the groups are not identical but overlap.

## IV. A SOLUTION OF THE FORM $x(t) = B\phi\{x(t)\}$, $z$ in $\mathscr{B}_2$

For the solution to (1) we have $x = \sum_1^\infty m^k x_k$, where according to (25) and (29), we have

$$x_1 = a_1 y$$

$$x_2 = a_1 h_2 + a_2 y^2 = a_2 B y^2$$

$$x_3 = a_1 h_3 + 2a_2 y h_2 + a_3 y^3 = 2a_2 B(y h_2) + a_3 B y^3.$$

Since

$$\phi(my) = a_1 my + a_2 m^2 y^2 + a_3 m^3 y^3 + \cdots,$$

we see that $x = B\phi(my) + \mathscr{O}(m^3)$, $m \to 0$. Then setting $m = 1$ (with $y$ sufficiently small) we can conclude that

$$x = B\phi(y) + \mathscr{O}(y^3), \qquad y \to 0. \tag{36}$$

At least as $y \to 0$, $B\phi(y)$ is a better approximation than $\phi(y) = x + \mathscr{O}(y^2)$. Also $B\phi(y)$ could be a good approximation to $x$ without $y$ being small, as would be the case if $y$ were a predominately low-frequency function (compared with its top frequency). This suggests that given $y$ in (1) we determine a bandlimited function $z$, perhaps close to $y$, such that the solution to (1) is given by

$$x = B\phi(z). \tag{37}$$

To determine a series solution for $z$ we set

$$z = \sum_1^\infty z_k m^k, \qquad Bz_k = z_k \tag{38}$$

and expand $\phi(z)$ in a power series in $m$:

$$\phi(mz_1 + m^2 z_2 + m^3 z_3 + \cdots) = \sum_1^\infty m^k F_k. \tag{39}$$

The $F_k$ are given by (25) with $z_k$ replacing $h_k$. The difference now is that the $F_k$ are bandlimited to $[-k\lambda, k\lambda]$, i.e., $\phi(z)$ is not bandlimited (in general) with $z$ in $\mathscr{B}_2$. However, we must have

$$BF_k = x_k, \tag{40}$$

where in terms of operations on $y$ the $x_k$ are given conveniently by (29). We have

$$Ba_1 z_1 = x_1 = a_1 y \tag{41.1}$$

$$B(a_1 z_2 + a_2 z_1^2) = x_2 = a_2 B y^2 \tag{41.2}$$

$$B(a_1 z_3 + 2a_2 z_1 z_2 + a_3 z_1^3) = x_3 = -\frac{2a_2^2}{a_1} B(y \cdot Hy^2) + a_3 B y^3 \tag{41.3}$$

$$\begin{aligned} B[a_1 z_4 + a_2(2z_1 z_3 + z_2^2) + a_3(3z_1^2 z_2) + a_4 z_1^4] &= x_4 \\ &= \frac{4a_2^3}{a_1^2} B[y \cdot H(y \cdot Hy^2)] - \frac{2a_2 a_3}{a_1} B(y \cdot Hy^3) \\ &\quad + \frac{a_2^3}{a_1^2} B(Hy^2)^2 - \frac{3a_2 a_3}{a_1} B(y^2 \cdot Hy^2) + a_4 B y^4 \end{aligned} \tag{41.4}$$

$$\begin{aligned} &B[a_1 z_5 + a_2(2z_1 z_4 + 2z_2 z_3) + a_3(3z_1^2 z_3 + 3z_1 z_2^2) \\ &\quad + a_4(4z_1^3 z_2) + a_5 z_1^5] = x_5 = -\frac{8a_2^4}{a_1^3} B\{y \cdot H[y \cdot H(y \cdot Hy^2)]\} \\ &\quad + \frac{4a_2^2 a_3}{a_1^2} B[y \cdot H(y \cdot Hy^3)] - \frac{2a_2^4}{a_1^3} B[y \cdot H(Hy^2)^2] \end{aligned}$$

$$+\frac{6a_2^2a_3}{a_1^2}B[y\cdot H(y^2\cdot Hy^2)]-\frac{2a_2a_4}{a_1}B(y\cdot Hy^4)$$

$$-\frac{4a_2^4}{a_1^3}B[(Hy^2)\cdot H(y\cdot Hy^2)]+\frac{2a_2^2a_3}{a_1^2}B[(Hy^2)\cdot(Hy^3)]$$

$$+\frac{6a_2^2a_3}{a_1^2}B[y^2\cdot H(y\cdot Hy^2)]-\frac{3a_3^2}{a_1}B(y^2\cdot Hy^3)$$

$$+\frac{3a_2^2a_3}{a_1^2}B[y\cdot(Hy^2)^2]-\frac{4a_2a_4}{a_1}B(y^3\cdot Hy^2)+a_5By^5. \tag{41.5}$$

Solving these equations successively for $z_k$ we find

$$z_1=y \tag{42.1}$$

$$z_2=0 \tag{42.2}$$

$$z_3=-\frac{2a_2^2}{a_1^2}B(y\cdot Hy^2) \tag{42.3}$$

$$z_4=\frac{4a_2^3}{a_1^3}B[y\cdot H(y\cdot Hy^2)]-\frac{2a_2a_3}{a_1^2}B(y\cdot Hy^3)+\frac{a_2^3}{a_1^3}B(Hy^2)^2$$
$$-\frac{3a_2a_3}{a_1^2}B(y^2\cdot Hy^2)+\frac{4a_2^3}{a_1^3}B[y\cdot B(y\cdot Hy^2)]. \tag{42.4}$$

The first and last terms in (42.4) combine ($H+B=I$) to give $\frac{4a_2^3}{a_1^3}B(y^2\cdot Hy^2)$, which then combines with the fourth term to give

$$z_4=\frac{a_2}{a_1^3}(4a_2^2-3a_1a_3)B(y^2\cdot Hy^2)-\frac{2a_2a_3}{a_1^2}B(y\cdot Hy^3)$$
$$+\frac{a_2^3}{a_1^3}B(Hy^2)^2 \tag{42.4a}$$

$$z_5=-\frac{8a_2^4}{a_1^4}B\{y\cdot H[y\cdot H(y\cdot Hy^2)]\}$$
$$-\frac{8a_2^4}{a_1^4}B[y\cdot B(y^2\cdot Hy^2)]+\frac{a_3}{a_1^3}(4a_2^2-3a_1a_3)B(y^2\cdot Hy^3)$$
$$+\frac{a_2^2}{a_1^4}(3a_1a_3-2a_2^2)B[y\cdot(Hy^2)^2]$$
$$+\frac{4a_2}{a_1^3}(3a_2a_3-a_1a_4)B(y^3\cdot Hy^2)-\frac{2a_2a_4}{a_1^2}B(y\cdot Hy^4)$$

$$-\frac{4a_2^4}{a_1^3}B[(Hy^2)\cdot H(y\cdot Hy^2)]+\frac{2a_2^2a_3}{a_1^3}B[(Hy^2)\cdot(Hy^3)]. \tag{42.5}$$

The expressions for the third- and fourth-order terms, $z_3$ and $z_4$, are quite simple, owing to the fact that $z_1 = y$, $z_2 = 0$. Note in eq. (41.n) the "diagonal" term $a_nBz_1^n$ on the left is cancelled by the term $a_nBy^n$ appearing in $x_n$ on the right. Also in case $a_2 = 0$ we have

$$z_1 = y \tag{43.1}$$

$$z_2 = 0 \tag{43.2}$$

$$z_3 = 0 \tag{43.3}$$

$$z_4 = 0 \tag{43.4}$$

$$z_5 = -\frac{3a_3^2}{a_1^2}B(y^2\cdot Hy^3). \tag{43.5}$$

## V. THE APPROXIMATE IDENTITY

The series development in the previous section suggests that as a practical expedient one might take

$$x \doteq B\phi(y) = B\phi\{Bf(x)\} \doteq \phi\{f(x)\} = x.$$

That is, what appears to be the naive thing to do may in fact be quite good, especially for odd functions $\phi$ (or $f$) that are not severely nonlinear. The interposition of the bandlimiting operator between a nonlinear function and its inverse and then subsequent bandlimiting is an interesting "approximate identity" that we examine further in the Appendix. One might ask how the interchange in the order of a particular function and its inverse in the transformation affects the approximate identity. The series expansion of the approximate identity may shed some light on the general problem. To keep track of the various orders, it is convenient to introduce the parameter $m$ as before. We have

$$Bf(mx) = \sum_1^\infty m^k b_k Bx^k, \tag{44}$$

$$\phi\{Bf(mx)\} = \sum_1^\infty m^k F_k, \tag{45}$$

where the $F_k$ are given by (25) with $b_kBx^k$ replacing $h_k$, and $Bx = x$. Thus,

$$F_1 = a_1b_1x = x \tag{46.1}$$

$$F_2 = a_1b_2Bx^2 + a_2b_1^2x^2 \tag{46.2}$$

$$F_3 = a_1b_3Bx^3 + 2a_2b_1b_2x\cdot Bx^2 + a_3b_1^3x^3 \tag{46.3}$$

$$\begin{aligned} F_4 = {} & a_1b_4Bx^4 + 2a_2b_1b_3x\cdot Bx^3 + a_2b_2^2(Bx^2)^2 \\ & + 3a_3b_1^2b_2x^2\cdot Bx^2 + a_4b_1^4x^4 \end{aligned} \tag{46.4}$$

$$\begin{aligned} F_5 = {} & a_1b_5Bx^5 + 2a_2b_1b_4x\cdot Bx^4 + 2a_2b_2b_3(Bx^2)\cdot(Bx^3) \\ & + 3a_3b_1^2b_3x^2\cdot Bx^3 + 3a_3b_1b_2^2x\cdot(Bx^2)^2 \\ & + 4a_4b_1^3b_2x^3\cdot Bx^2 + a_5b_1^5x^5. \end{aligned} \tag{46.5}$$

Now we set

$$B\phi\{Bf(mx)\} = \sum_1^\infty m^k u_k, \tag{47}$$

where

$$u_k = BF_k. \tag{48}$$

Now note in (46) that if all the terms in $BF_k$ involving $x$ were of the form $Bx^k$ then $BF_k$ would vanish identically for $k \geq 2$ because $\phi\{f(x)\} = x$. So we will introduce the high-pass operator $H = I - B$ to collect the terms $Bx^k$ that cancel. For example, to collect terms $Bx^3$ in $BF_3$ we write

$$B(x\cdot Bx^2) = B(x^3 - x\cdot Hx^2) = Bx^3 - B(x\cdot Hx^2).$$

Thus,

$$u_1 = BF_1 = x \tag{49.1}$$

$$u_2 = BF_2 = a_1b_2Bx^2 + a_2b_1^2Bx^2 = 0 \tag{49.2}$$

$$\begin{aligned} u_3 = BF_3 &= a_1b_3Bx^3 + 2a_2b_1b_2B(x\cdot Bx^2) + a_3b_1^3Bx^3 \\ &= a_1b_3Bx^3 + 2a_2b_1b_2B(x^3 - x\cdot Hx^2) + a_3b_1^3Bx^3 \\ &= -2a_2b_1b_2B(x\cdot Hx^2) \end{aligned} \tag{49.3}$$

$$\begin{aligned} u_4 = BF_4 &= a_1b_4Bx^4 + 2a_2b_1b_3B(x\cdot Bx^3) + a_2b_2^2B(Bx^2)^2 \\ &\quad + 3a_3b_1^2b_2B(x^2\cdot Bx^2) + a_4b_1^4Bx^4 \\ &= a_1b_4Bx^4 + 2a_2b_1b_3B(x^4 - x\cdot Hx^3) + a_2b_2^2B(x^2 - Hx^2)^2 \\ &\quad + 3a_3b_1^2b_2B(x^4 - x^2\cdot Hx^2) + a_4b_1^4Bx^4 \\ &= -2a_2b_1b_3B(x\cdot Hx^3) - (2a_2b_2^2 + 3a_3b_1^2b_2)B(x^2\cdot Hx^2) \\ &\quad + a_2b_2^2B(Hx^2)^2 \end{aligned} \tag{49.4}$$

$$
\begin{aligned}
u_5 = BF_5 &= a_1b_5Bx^5 + 2a_2b_1b_4B(x\cdot Bx^4) \\
&\quad + 2a_2b_2b_3B[(Bx^2)\cdot(Bx^3)] \\
&\quad + 3a_3b_1^2b_3B(x^2\cdot Bx^3) + 3a_3b_1b_2^2B[x\cdot(Bx^2)^2] \\
&\quad + 4a_4b_1^3b_2B(x^3\cdot Bx^2) + a_5b_1^5Bx^5 \\
&= a_1b_5Bx^5 + 2a_2b_1b_4B(x^5 - x\cdot Hx^4) \\
&\quad + 2a_2b_2b_3B[(x^2 - Hx^2)\cdot(x^3 - Hx^3)] \\
&\quad + 3a_3b_1^2b_3B(x^5 - x^2\cdot Hx^3) \\
&\quad + 3a_3b_1b_2^2B[x\cdot(x^2 - Hx^2)^2] + 4a_4b_1^3b_2B(x^5 - x^3\cdot Hx^2) \\
&\quad + a_5b_1^5Bx^5 \\
&= -2a_2b_1b_4B(x\cdot Hx^4) - (2a_2b_2b_3 + 3a_3b_1^2b_3)B(x^2\cdot Hx^3) \\
&\quad - (2a_2b_2b_3 + 6a_3b_1b_2^2 + 4a_4b_1^3b_2)B(x^3\cdot Hx^2) \\
&\quad + 2a_2b_2b_3B[(Hx^2)\cdot(Hx^3)] + 3a_3b_1b_2^2B[x\cdot(Hx^2)^2]. \qquad (49.5)
\end{aligned}
$$

Now in order to assess the symmetry or lack of symmetry in interchanging $\phi$ and $f$ we can use the identities (35) to express the mixed coefficients of $u_n$ in terms of the $b_k$ or the $a_k$ alone. We have

$$u_1 = x \qquad (50.1)$$

$$u_2 = 0 \qquad (50.2)$$

$$u_3 = {}_3C_1B(x\cdot Hx^2) \qquad (50.3)$$

$$u_4 = {}_4C_1B(x\cdot Hx^3) + {}_4C_2B(x^2\cdot Hx^2) + {}_4C_3B(Hx^2)^2 \qquad (50.4)$$

$$
\begin{aligned}
u_5 &= {}_5C_1B(x\cdot Hx^4) + {}_5C_2B(x^2\cdot Hx^3) + {}_5C_3B(x^3\cdot Hx^2) \\
&\quad + {}_5C_4B[(Hx^2)\cdot(Hx^3)] + {}_5C_5B[x\cdot(Hx^2)^2], \qquad (50.5)
\end{aligned}
$$

where

$${}_3C_1 = -2a_2b_1b_2 = \frac{2b_2^2}{b_1^2} = \frac{2a_2^2}{a_1^4} \qquad (50.3a)$$

$${}_4C_1 = -2a_2b_1b_3 = \frac{2b_2b_3}{b_1^2} = \frac{2a_2a_3}{a_1^5} - \frac{4a_2^3}{a_1^6} \qquad (50.4a)$$

$${}_4C_2 = -(2a_2b_2^2 + 3a_3b_1^2b_2) = -\frac{4b_2^3}{b_1^3} + \frac{3b_2b_3}{b_1^2} = -\frac{2a_2^3}{a_1^6} + \frac{3a_2a_3}{a_1^6}$$

$${}_4C_3 = a_2b_2^2 = -\frac{b_2^3}{b_1^3} = \frac{a_2^3}{a_1^6}$$

$$
{}_5C_1 = -2a_2b_1b_4 = \frac{2b_2b_4}{b_1^2} = -\frac{10a_2^2a_3}{a_1^7} + \frac{2a_2a_4}{a_1^6} + \frac{10a_2^4}{a_1^8} \tag{50.5a}
$$

$$
{}_5C_2 = -(2a_2b_2b_3 + 3a_3b_1^2b_3) = -\frac{4b_2^2b_3}{b_1^3} + \frac{3b_3^2}{b_1^2}
$$

$$
= (2a_2^2 - a_1a_3)(2a_2^2 - 3a_1a_3)/a_1^8
$$

$$
{}_5C_3 = -(2a_2b_3 + 6a_3b_1b_2^2 + 4a_4b_1^3b_2)
$$

$$
= \frac{8b_2^4}{b_1^4} - \frac{12b_2^2b_3}{b_1^3} + \frac{4b_2b_4}{b_1^2} = \frac{4a_2^4}{a_1^7} - \frac{8a_2^2a_3}{a_1^7} + \frac{4a_2a_4}{a_1^3}
$$

$$
{}_5C_4 = 2a_2b_2b_3 = -\frac{2b_2^2b_3}{b_1^3} = \frac{2a_2^2a_3}{a_1^7} - \frac{4a_2^4}{a_1^8}
$$

$$
{}_5C_5 = 3a_3b_1b_2^2 = \frac{6b_2^4}{b_1^4} - \frac{3b_2^2b_3}{b_1^3} = \frac{3a_2^2a_3}{a_1^7}.
$$

Now if we interchange the order of $\phi$ and $f$ in (45) and write

$$
Bf\{B\phi(mx)\} = \sum_1^\infty m^k v_k, \tag{51}
$$

we obtain the $v_k$ by replacing $u_k$ by $v_k$ in (49.k) and then interchanging the $a$'s and $b$'s. We have $u_1 = v_1 = x$ and $u_2 = v_2 = 0$. We should compare $u_k$ and $v_k$, $k \geqslant 3$, for $f'(0) = 1 = a_1 = b_1$. Then we have

$$
u_k = v_k \qquad k = 1, 2, 3. \tag{52}
$$

But we have, for example (with $a_1 = b_1 = 1$),

$$
u_4 = 2b_2b_3B(x\cdot Hx^3) + (3b_2b_3 - 4b_2^3)B(x^2\cdot Hx^2) - b_2^3B(Hx^2)^2 \tag{53.1}
$$

$$
v_4 = (2b_2b_3 - 4b_2^3)B(x\cdot Hx^3)
$$

$$
+ (3b_2b_3 - 2b_2^3)B(x^2\cdot Hx^2) + b_2^3B(Hx^2)^2. \tag{53.2}
$$

If, however, $b_2 = 0$ ($a_2 = 0$) we have

$$
u_k = v_k = 0, \qquad k = 2, 3, 4, \tag{53.3}
$$

and if $a_1 = b_1 = 1$,

$$
u_5 = v_5 = 3b_3^2B(x^2\cdot Hx^3). \tag{53.4}
$$

In case $b_2 = b_4 = b_6 = 0$, ($a_2 = a_4 = a_6 = 0$), we have

$$
u_7 = \frac{3b_3b_5}{b_1^2}B(x^2\cdot Hx^5) + \left(\frac{5b_3b_5}{b_1^2} - \frac{9b_3^3}{b_1^3}\right)B(x^4\cdot Hx^3)
$$

$$
- \frac{3b_3^3}{b_1^3}B[x\cdot(Hx^3)^2], \tag{54}
$$

where the coefficients expressed in terms of the $a$'s are

$$\frac{3b_3b_5}{b_1^2} = \frac{3a_3a_5}{a_1^8} - \frac{9a_3^3}{a_1^9},$$

$$\frac{5b_3b_5}{b_1^2} - \frac{9b_3^3}{b_1^3} = \frac{5a_3a_5}{a_1^8} - \frac{6a_3^3}{a_1^9} - \frac{3b_3^3}{b_1^3} = \frac{3a_3^3}{a_1^9}.$$

So we do not have, in general, $u_7 = v_7$ for odd functions $f(x)$ with $f'(0) = 1$.

## VI. APPLICATION TO COMPATIBLE SINGLE-SIDEBAND TRANSMISSION

The mathematical problem of compatible single-sideband transmission was formulated in Ref. 4. Given a signal $y(t)$ in $\mathscr{B}_2$ the problem is to determine $m$ such that the equation

$$B\{\sqrt{(1 + s(t))^2 + \hat{s}(t)^2}\} = my(t) + 1 \tag{55}$$

has a solution $s(t)$ in $\mathscr{B}_2$. In (55) $\hat{s}(t)$, sometimes called the quadrature signal, is the Hilbert transform of $s(t)$, and $B$ is operating on the envelope of the single-sideband signal. The idea is to transmit a single-sideband signal that is compatible with receivers designed for double-sideband (AM) reception. Setting

$$2s(t) + s^2(t) + \hat{s}^2(t) = x(t), \tag{56}$$

we may write (55) as

$$Bf\{x(t)\} = my(t), \tag{57}$$

where

$$f(x) = \sqrt{1 + x} - 1, \qquad x \geqslant -1. \tag{58}$$

Then $s(t)$ may be found from the solution $x(t)$ of (57). (This requires factoring $1 + x(t)$ in the form $g(t)\bar{g}(t)$, where the bandwidth of $g$ is half the bandwidth of $x$.) Then with $y = f(x)$ we have for the inverse

$$x = \phi(y) = 2y + y^2. \tag{59}$$

Setting

$$x = \sum_1^\infty m^k x_k, \tag{60}$$

we have from (29) with $a_1 = 2$, $a_2 = 1$, $a_k = 0$ for $k \geqslant 3$,

$$x_1 = 2y \tag{61.1}$$

$$x_2 = By^2 \tag{61.2}$$

$$x_3 = -B(y \cdot Hy^2) \tag{61.3}$$

$$x_4 = B[y \cdot H(y \cdot Hy^2)] + 1/4B(Hy^2)^2 \tag{61.4}$$

$$x_5 = -B\{y \cdot H[y \cdot H(y \cdot Hy^2)]\} - 1/4B[y \cdot H(Hy^2)^2] - 1/2B[(Hy^2) \cdot H(y \cdot Hy^2)]. \tag{61.5}$$

Replacing $H$ by $I - B$ we have from (30) the alternate forms

$$x_3 = B(y \cdot By^2) - By^3 \tag{61.3a}$$

$$x_4 = B[y \cdot B(y \cdot By^2)] - B(y \cdot By^3) + 1/4B(By^2)^2 - 3/2B(y^2 \cdot By^2) + 5/4By^4 \tag{61.4a}$$

$$\begin{aligned} x_5 = {} & B\{y \cdot B[y \cdot B(y \cdot By^2)]\} - B[y \cdot B(y \cdot By^3)] \\ & - 3/2B[y \cdot B(y^2 \cdot By^2)] + 1/4B[y \cdot (By^2)^2] \\ & - 3/4B[y \cdot (By^2)^2] + 5/4B(y \cdot By^4) \\ & + 1/2B[By^2) \cdot B(y \cdot By^2)] \\ & - 3/2B[y^2 \cdot B(y \cdot By^2)] - 1/2B[(By)^2 \cdot (By^3)] \\ & + 3/2B(y^2 \cdot By^3) \\ & + 5/2B(y^3 \cdot By^2) - 7/4By^5. \end{aligned} \tag{61.5a}$$

The factoring of $1 + x$ can be avoided by developing a series solution for $s$, $Bs = s$. We have

$$x = 2s + s^2 + \hat{s}^2$$

$$x = mx_1 + m^2x_2 + m^3x_3 + \cdots.$$

Then setting

$$s = ms_1 + m^2s_2 + m^3s_3 + \cdots \tag{62}$$

$$\hat{s} = m\hat{s}_1 + m^2\hat{s}_2 + m^3\hat{s}_3 + \cdots, \tag{63}$$

we have

$$s^2 = m^2s_1^2 + m^3 2s_1s_2 + m^4(2s_1s_3 + s_2^2) + m^5(2s_1s_4 + 2s_2s_3) + \cdots \tag{64}$$

$$\hat{s}^2 = m^2\hat{s}_1^2 + m^3 2\hat{s}_1\hat{s}_2 + m^4(2\hat{s}_1\hat{s}_3 + \hat{s}_2^2) + m^5(2\hat{s}_1\hat{s}_4 + 2\hat{s}_2\hat{s}_3) + \cdots. \tag{65}$$

Note that if $s$ belongs to $\mathscr{B}_2(\lambda)$, then the Fourier transform* of $(s + i\hat{s})$ vanishes outside $[0, \lambda]$ and that of its complex conjugate $(s - i\hat{s})$

*Here the Fourier transform of $\hat{s}$ is $-i(sgn\omega)S(\omega)$ where $S(\omega)$ is the Fourier transform of $s$.

vanishes outside $[-\lambda, 0]$. Thus the Fourier transform of $e^{-i\lambda t/2}(s + i\hat{s})$ vanishes outside $[-(\lambda/2), \lambda/2]$. It follows that the Fourier transform of $s^2 + \hat{s}^2$ vanishes outside $[-\lambda, \lambda]$, and hence that the sums of the coefficients of $m^n$ in (64) and (65) are functions whose Fourier transforms vanish outside $[-\lambda, \lambda]$.

Now we can solve successively for $s_k$. It is convenient to introduce the Hilbert transform (Quadrature) operator $Q$

$$\hat{g} = Qg \tag{66}$$

to indicate the "hat" of complicated expressions.

Equating coefficients of $m_k$ in

$$x = 2s + s^2 + \hat{s}^2,$$

we have

$$s_1 = x_1/2 = y \tag{67.1}$$

$$\begin{aligned} s_2 &= 1/2x_2 - 1/2(s_1^2 + \hat{s}_1^2) \\ &= 1/2By^2 - 1/2(y^2 + \hat{y}^2), \end{aligned} \tag{67.2}$$

which may be written, using $Bs_2 = s_2$, as

$$s_2 = -1/2B\hat{y}^2 \tag{67.2a}$$

$$\begin{aligned} s_3 &= 1/2x_3 - (s_1 s_2 + \hat{s}_1 \hat{s}_2) \\ &= -1/2B(y \cdot Hy^2) + 1/2yB\hat{y}^2 + 1/2\hat{y} \cdot QB\hat{y}^2. \end{aligned} \tag{67.3}$$

Here we may write

$$yB\hat{y}^2 = y \cdot \hat{y}^2 - y \cdot H\hat{y}^2$$

and then use $Bs_3 = s_3$ to obtain

$$\begin{aligned} s_3 &= -1/2B(y \cdot Hy^2) - 1/2B(y \cdot H\hat{y}^2) + 1/2B(y \cdot \hat{y}^2) + 1/2B(\hat{y} \cdot QB\hat{y}^2) \\ &= -1/2B[y \cdot H(y^2 + \hat{y}^2)] + 1/2B(y \cdot \hat{y}^2) + 1/2B(\hat{y} \cdot QB\hat{y}^2). \end{aligned}$$

Then since $H(y^2 + \hat{y}^2) = 0$, we have

$$s_3 = 1/2\ B(y \cdot \hat{y}^2) + 1/2\ B(\hat{y} \cdot QB\hat{y}^2) \tag{67.3a}$$

$$\begin{aligned} s_4 &= 1/2\ x_4 - (s_1 s_3 + 1/2\ s_2^2) - (\hat{s}_1 \hat{s}_3 + 1/2\ \hat{s}_2^2) \\ &= 1/2\ B[y \cdot H(y \cdot Hy^2)] + 1/4\ B(Hy^2)^2 \\ &\quad - 1/2\ yB(y \cdot \hat{y}^2) - 1/2\ \hat{y}QB(y \cdot \hat{y}^2) \\ &\quad - 1/8\ (B\hat{y}^2)^2 - 1/8\ (QB\hat{y}^2)^2. \end{aligned} \tag{67.4}$$

There appears to be no simplification here. One may prefer the alternate expression (61.4a) for $x_4$ to eliminate the $H$ operator. Note

that $QB$ can be replaced by the bandlimiting quadrature operator $\hat{B}$ where

$$\hat{B}g = (\hat{B}g)(t) = \int_{-\infty}^{\infty} g(s) \frac{1 - \cos \lambda(t - s)}{\pi(t - s)} \, ds. \tag{68}$$

## VII. THE COMPLEX-VALUED COMPANDING PROBLEM

The c.v. companding problem is considerably more complicated than the r.v. companding problem, even for the same analytic companding function. For example, if

$$f(x) = \tan^{-1} x + \epsilon x, \qquad (\epsilon > 0),$$

we know from the Landau-Miranker theory that the r.v. companding problem

$$Bf(x) = y$$

has a unique solution $x$ in $\mathscr{B}_2$ corresponding to every real-valued $y$ in $\mathscr{B}_2$. However, in the case of complex-valued $y$, this may not be true because $x$ must then take complex values which, if the norm of $y$ is not restricted, may be singularities of $f$. In addition, we are confronted with the problem of establishing the uniqueness of the solution, which may require still more severe restrictions on the norm of $y$.

Beurling's uniqueness proof (see Ref. 1) for the r.v. companding problem is elegant and simple: Suppose $f(x) = \mathscr{O}(|x|)$, $|x| \to 0$, and is monotone increasing, and further that

$$Bf(x_1) = y \qquad \text{and} \qquad Bf(x_2) = y,$$

with $x_1$, $x_2$, (and $y$) in $\mathscr{B}_2$. Then $f(x_1)$ and $f(x_2)$ belong to $L_2$ and $B\{f \cdot (x_1) - f(x_2)\} = 0$, i.e., the Fourier transform of $\{f(x_1) - f(x_2)\}$ vanishes over $(-\lambda, \lambda)$, and therefore $\{f(x_1) - f(x_2)\}$ must be orthogonal to $(x_1 - x_2)$. But this is impossible unless $x_1 \equiv x_2$, for otherwise $(x_1 - x_2) \cdot \{f(x_1) - f(x_2)\}$, which is everywhere non-negative, will be positive everywhere on the real axis, except at the isolated zeros (if any) of $(x_1 - x_2)$.

For establishing uniqueness in the c.v. companding problem, it would seem that the weakest analogue of monotocity should be "schlichtness" of $f$, i.e., that $x$ should be confined to a region, where $f(x_1) = f(x_2)$ implies $x_1 = x_2$. This suffices to establish uniqueness of the solution in the special case where $x$ has a one-sided Fourier transform, but we are not able to see that it suffices in the general case. We can establish the following analogue of Buerling's theorem, where, without loss of generality, we assume $f'(0)$ is positive.

*Theorem* 1: *Suppose* $f(0) = 0$, $f'(0) > 0$, *and* $f(z)$ *is analytic in a convex region* $G$ *including the origin, wherein*

$$Re\{f'(z)\} > 0.$$

*If $x_1(t)$ and $x_2(t)$ belong to $\mathscr{B}_2$ and are confined to $G$ for all real $t$, then*

$$Bf(x_1) = y \qquad \text{and} \qquad Bf(x_2) = y$$

*imply*

$$x_1(t) \equiv x_2(t).$$

*Proof of Theorem* 1: Since $G$ is convex, any two points $x_1$ and $x_2$ in $G$ can be connected by a straight line segment in $G$. Suppose $(x_1 - x_2) = re^{i\theta}$, where $r > 0$. Then integrating $f'$ along the connecting line segment, we have

$$f(x_1) - f(x_2) = e^{i\theta} \int_0^r f'(x_2 + se^{i\theta})ds,$$

and hence

$$\operatorname{Re} \frac{f(x_1) - f(x_2)}{x_1 - x_2} = \operatorname{Re} \frac{1}{r} \int_0^r f'(x_2 + se^{i\theta})ds > 0.$$

In case $x_1 \to x_2$, the limit is $\operatorname{Re} f'(x_2) > 0$.

Now $\{f[x_1(t)] - f[x_2(t)]\}$ belongs to $L_2$ and must be orthogonal to all members of $\mathscr{B}_2$, in particular to $\{x_1(t) - x_2(t)\}$; i.e., setting

$$P(t) = (\bar{x}_1 - \bar{x}_2)\{f(x_1) - f(x_2)\} = |x_1 - x_2|^2 \frac{\{f(x_1) - f(x_2)\}}{x_1 - x_2},$$

the integral of $P(t)$ must vanish. However, we see that the real part of $P(t)$ is non-negative everywhere on the real axis, and vanishes only where $x_1 = x_2$. Since the integral of $P$ is zero, its real part vanishes a.e. Thus the function $\{x_1(t) - x_2(t)\}$ in $\mathscr{B}_2$ vanishes a.e., and hence everywhere. □

Now we can establish that the c.v. companding problem,

$$Bf(x) = y,$$

will have a solution $x$, which will take values in a disk centered on the origin, wherein $\operatorname{Re}\{f'(z)\} > 0$, provided $\|y\|_2$ is sufficiently small. Then the uniqueness of the solution follows from Theorem 1.

An objectionable, but inherent, feature of companding problems (as formulated here) is that a restriction on $\|y\|_\infty$ is not sufficient to give a corresponding restriction on $\|x\|_\infty$. We can, however, establish that $\|x\|_2$ will be small if $\|y\|_2$ is small, and hence that $\|x\|_\infty$ will be small, according to the inequality (given in the introduction) for a function $g$ in $\mathscr{B}_2(\lambda)$,

$$\|g\|_\infty \leq \sqrt{\lambda/\pi}\,\|g\|_2. \tag{69}$$

In the sequel, we assume, for convenience and without loss of generality, that $f'(0) = 1$,

$$f(z) = z + \sum_{2}^{\infty} b_k z^k, \qquad |z| < R_0, \tag{70}$$

where $R_0$ (perhaps $\infty$) is the radius of convergence of the series. We exclude the trivial case $f(z) = z$, and define

$$M(r) = \max_{|z|=r} |f'(z) - 1| \leqslant \sum_{2}^{\infty} k|b_k| r^{k-1}, \qquad r < R_0, \tag{71}$$

which increases steadily from 0 to $\infty$, allowing us to define $p$ uniquely by

$$M(p) = 1. \tag{72}$$

Then it is clear that

$$\mathrm{Re}\{f'(z)\} > 0 \qquad \text{for} \quad |z| < p. \tag{73}$$

We are now able to establish the following result.

*Theorem* 2: *Let $y(t)$ be any complex-valued function in $\mathscr{B}_2 = \mathscr{B}_2(\lambda)$, satisfying*

$$\sqrt{\lambda/\pi}\, \|y\|_2 \leqslant \max_{0<r<p} \{r[1 - M(r)]\} = r_0[1 - M(r_0)]. \tag{74}$$

*Then the companding problem*

$$Bf(x) = y$$

*has a unique solution $x = x(t)$ in $\mathscr{B}_2$.*

*Proof of Theorem* 2: We can use the method of Landau and Miranker to obtain a Cauchy sequence $\{x_n\}$ converging to the solution $x$, provided we restrict $\|y\|_2$, in the end, to be sufficiently small that all the approximants satisfy $|x_n| < p$.

Assuming the norm of $y$ to be sufficiently small, we take

$$x_1 = y = By, \tag{75}$$

which should be a good approximation to $x$ for small $y$. Then we set, following Landau and Miranker,

$$x_{n+1} = x_n + y - Bf(x_n), \qquad n \geqslant 1, \tag{76}$$

so that, by induction, $Bx_n = x_n$, i.e., $x_n$ belongs to $\mathscr{B}_2$. We have, writing the same equation for $n - 1$ and subtracting,

$$\begin{aligned} x_{n+1} - x_n &= x_n - Bf(x_n) - \{x_{n-1} - Bf(x_{n-1})\} \\ &= B[x_n - f(x_n) - \{x_{n-1} - f(x_{n-1})\}]. \end{aligned} \tag{77}$$

Now we write

$$f(x_n) - x_n - \{f(x_{n-1}) - x_{n-1}\} = \int_{x_{n-1}}^{x_n} \{f'(z) - 1\}dz. \tag{78}$$

Then assuming that

$$|x_n| \leq r < p \qquad \text{for all} \quad n \geq 1 \tag{79}$$

[and all $t$, suppressed in the notation $x_n = x_n(t)$] we have in (78)

$$\left| \int_{x_{n-1}}^{x_n} \{f'(z) - 1\}dz \right| \leq M(r)\,|x_n - x_{n-1}|, \tag{80}$$

where

$$M(r) < M(p) = 1.$$

Substituting in (77) the inequality (80) for the magnitude of the function in (78), we obtain

$$\|x_{n+1} - x_n\|_2 \leq M(r)\,\|x_n - x_{n-1}\|_2. \tag{81}$$

So, under the assumption (79), $\{x_n\}$ forms a Cauchy sequence converging to $x$ in $\mathscr{B}_2$ [cf. Landau, Ref. 1]. It follows from (76) that

$$Bf(x) = y. \tag{82}$$

Now we would like to see how large $\|y\|_2$ may be in order that (79) hold, giving the conclusion in (82). We write

$$x_n = x_1 + (x_2 - x_1) + (x_3 - x_2) + \cdots + (x_n - x_{n-1}) \tag{83}$$

from which follows

$$\|x_n\|_2 \leq \sum_1^n \|x_k - x_{k-1}\|_2, \tag{84}$$

where

$$x_1 = y \qquad \text{and} \qquad x_0 = 0.$$

Applying (81) to (84), we have

$$\|x_n\|_2 \leq \frac{1 - \alpha^n}{1 - \alpha}\,\|y\|_2, \tag{85}$$

where $\alpha = M(r) < 1$, provided (79) holds. This will be the case, according to (69), if

$$\|x_n\|_2 \leq \sqrt{\pi/\lambda}\,r \qquad \text{for all} \quad n \geq 1, \tag{86}$$

which, in turn, will hold if in (85) we have

$$\sqrt{\pi/\lambda}\ \|y\|_2 \leq r[1 - M(r)]. \tag{87}$$

Here we are free to take the maximum over $r$. Thus the problem will have a solution $x$ satisfying the hypotheses, provided the norm of $y$ satisfies

$$\sqrt{\pi/\lambda}\ \|y\|_2 \leq \max_{0<r<p}\{r(1 - M(r)\} = r_0[1 - M(r_0)], \tag{88}$$

and the solution is unique according to Theorem 1. □

We note that if (88) is satisfied, then the solution $x$ satisfies, according to (85) and (69),

$$\|x\|_\infty \leq r_0 < p. \tag{89}$$

So, in fact, the restriction (88) on the norm of $y$ is too severe. We obtain a slightly better result later, using a different method.

We now wish to show that if $y_1$ and $y_2$ are close to each other, then the corresponding solutions, $x_1$ and $x_2$, are also close to each other.

*Lemma: Let $y_1$ and $y_2$ satisfy the hypotheses on $y$ in Theorem 2. Then the solutions of*

$$Bf(x_1) = y_1 \qquad \textit{and} \qquad Bf(x_2) = y_2$$

*satisfy*

$$\|x_1 - x_2\|_2 \leq \frac{\|y_1 - y_2\|_2}{1 - M(r_0)} \leq 2\sqrt{\pi/\lambda}\ r_0 \tag{90}$$

$$\|x_1 - x_2\|_\infty \leq \sqrt{\pi/\lambda}\ \frac{\|y_1 - y_2\|_2}{1 - M(r_0)} \leq 2r_0. \tag{91}$$

*Proof of the Lemma*: We have

$$x_1 - x_2 = y_1 - y_2 - B[f(x_1) - x_1 - f(x_2) + x_2], \tag{92}$$

giving

$$\|x_1 - x_2\|_2 \leq \|y_1 - y_2\|_2 + \|B[\cdot]\|_2 \leq \|y_1 - y_2\|_2 + \|[\cdot]\|_2. \tag{93}$$

Also, since, according to (89),

$$|x_1| \leq r_0 < p \qquad \text{and} \qquad |x_2| \leq r_0 < p,$$

we have from (78) and (80),

$$\|f(x_1) - x_1 - f(x_2) + x_2\|_2 \leq M(r_0)\|x_1 - x_2\|_2, \tag{94}$$

which with (93) gives

$$\|x_1 - x_2\|_2 \leq \frac{\|y_1 - y_2\|_2}{1 - M(r_0)}. \tag{95}$$

This, with (69) and the assumptions on $y_1$ and $y_2$, establishes the lemma. □

With this Lemma and Theorem 2 we can show that the problem

$$Bf\{x(t;m)\} = my(t),$$

for fixed $y$ in $\mathscr{B}_2$, has a unique solution in $\mathscr{B}_2$ for all complex $m$ of sufficiently small magnitude, the solution $x(t; m)$ being a continuous function of the complex variable $m$ in a certain disk centered on the origin. To establish for each $t$ that $F(m;t) = x(t;m)$ is an analytic function of $m$ in that disk, we show that $F(m)$ has a derivative (nondirectional) there. Working with the derivative we are able to improve on Theorem 2. It is convenient now to set $\sqrt{\lambda/\pi}\,\|y\|_2 = 1$ so that $|y(t)| \leqslant 1$.

*Theorem* 3: *Let $y(t)$ be any complex-valued function in $\mathscr{B}_2 \equiv \mathscr{B}_2(\lambda)$ satisfying*

$$\sqrt{\lambda/\pi}\,\|y\|_2 = 1.$$

*Then the problem*

$$Bf\{x(t;m)\} = my(t)$$

*has a unique solution $x(t;m)$ in $\mathscr{B}_2$ for all complex $m$ satisfying*

$$|m| \leqslant \alpha(p) = \int_0^p [1 - M(r)]dr, \tag{96}$$

*where $M(r)$ and $p$ are defined in* (71) *and* (72). *Furthermore, for each fixed real $t$, $x(t;m)$ is an analytic function of $m$, $|m| \leqslant \alpha(p)$, and hence, since $x(t; 0) \equiv 0$,*

$$x(t;m) = \sum_1^\infty m^k x_k(t), \qquad |m| \leqslant \alpha(p), \qquad (-\infty < t < \infty) \tag{97}$$

*where the $x_k(t)$ depend only on $y(t)$ and $f$.*

We note, before proving Theorem 3, that in Theorem 2, $0 < r_0 < p$, and in Theorem 3

$$\alpha(p) = \int_0^{r_0} [1 - M(r)]dr + \int_{r_0}^p [1 - M(r)]dr,$$

where $M(r)$ increases from 0 to 1 over $(0, p)$. Thus

$$\int_0^{r_0} [1 - M(r)]dr > r_0[1 - M(r_0)],$$

and hence

$$r_0[1 - M(r_0)] < \alpha(p) < p. \tag{98}$$

Then, according to Theorem 3, the c.v. companding problem

$$Bf(x) = y$$

has solutions for $y$ of larger norm than specified in Theorem 2.

*Proof of Theorem* 3: We first consider the solutions $x_1 = x(t;m_1)$, $x_2 = x(t;m_2)$, corresponding to $y_1 = m_1 y(t)$, $y_2 = m_2 y(t)$, where

$$m_2 = m_1 + \epsilon, \qquad \epsilon = |\epsilon| e^{i\theta} \tag{99}$$

and

$$|m_1| + |\epsilon| \leq r_0[1 - M(r_0)], \tag{100}$$

so that Theorem 2 and the Lemma apply.

We have

$$y_2 - y_1 = \epsilon y(t), \tag{101}$$

and hence, from the Lemma,

$$\| x_2 - x_1 \|_2 \leq \frac{|\epsilon|}{1 - M(r_0)} \cdot \| y \|_2 = \frac{|\epsilon| \sqrt{\pi/\lambda}}{1 - M(r_0)}. \tag{102}$$

Now

$$B\{f(x_2) - f(x_1)\} = \epsilon y, \tag{103}$$

which we rewrite as

$$\frac{x_2 - x_1}{\epsilon} = y - B\left\{\frac{f(x_2) - f(x_1) - (x_2 - x_1)}{\epsilon}\right\}. \tag{104}$$

We intend to let $\epsilon \to 0$ (with any argument) and show that the quantity on the left tends to a limit, independent of $\arg(\epsilon)$; viz., $F'(m_1;t)$, where

$$F'(m;t) = \frac{\partial}{\partial m} x(t;m), \qquad |m| \leq r_0[1 - M(r_0)]. \tag{105}$$

From (78), (80), and (102) we have

$$\| f(x_2) - f(x_1) - (x_2 - x_1) \|_2 \leq M(r_0) \| x_2 - x_1 \|_2 \leq \frac{|\epsilon| \sqrt{\pi/\lambda} M(r_0)}{1 - M(r_0)}. \tag{106}$$

So

$$\frac{f(x_2) - f(x_1) - (x_2 - x_1)}{\epsilon} \quad \text{belongs to} \quad L_2. \tag{107}$$

We also have from (102), or the Lemma,

$$\| x_2 - x_1 \|_\infty \leq \frac{|\epsilon|}{1 - M(r_0)}. \tag{108}$$

Thus we may write

$$x_2 = x_1 + \epsilon u, \tag{109}$$

where

$u = u(t;m_1, \epsilon)$ belongs to $\mathscr{B}_2$ and $|u|$

$$= \mathscr{O}(1) \quad \text{as} \quad \epsilon \to 0. \tag{110}$$

Then

$$f(x_2) - f(x_1) = f(x_1 + \epsilon u) - f(x_1)$$
$$= \epsilon u f'(x_1) + \mathscr{O}(\epsilon^2 u^2).$$

So (104) may be rewritten as

$$u = y - B\{uf'(x_1) - u + \mathscr{O}(\epsilon u^2)\}. \tag{111}$$

Now letting $\epsilon \to 0$ and replacing $m_1$ by $m$ and $x_1$ by $x(t;m)$, we obtain, setting $u(t;m, o) = u(t;m)$, the equation

$$u(t;m) = y(t) - B\{u(t;m)[f'\{x(t;m)\} - 1]\}, \tag{112}$$
$$|m| \leq A < r_0[1 - M(r_0)].$$

Here we make the identification

$$u(t;m) = F'(m;t) = \frac{\partial}{\partial m} x(t;m), \qquad |m| \leq A \tag{113}$$

by verifying that (112) has a solution $u(t;m)$ in $\mathscr{B}_2$, in fact, for $|m|$ larger than $r_0[1 - M(r_0)]$. We observe, since $x(t;0) \equiv 0$, and $f'(0) = 1$, that

$$u(t;0) = y(t). \tag{114}$$

Actually, we can obtain better estimates for $|x(t;m)|$ by integrating its partial derivative from 0 to $m$.

We consider the equation for $u$,

$$u = y - B\{u \cdot [f'(x) - 1]\}, \tag{115}$$

assuming $x = x(t; m)$ is known and satisfies

$$\| x \|_\infty \leq r < p, \tag{116}$$

so that

$$|f'(x) - 1| \leq M(r) < M(p) = 1. \tag{117}$$

Using this inequality in (115) we obtain

$$\| u \|_2 \leq \| y \|_2 + M(r) \| u \|_2, \tag{118}$$

or

$$\| u \|_2 \leq \frac{\| y \|_2}{1 - M(r)} = \frac{\sqrt{\pi/\lambda}}{1 - M(r)}. \tag{119}$$

The last inequality implies that (115) has a solution $u$ in $\mathscr{B}_2$ (obtained iteratively), in fact, for $\| x \|_\infty < p$, since $M(r) < 1$ for $r < p$. We note further that the inequality (119) is crude, with equality possible only for $r = 0$, for we cannot have

$$| f'\{x(t;m)\} - 1 | \equiv M(r), \qquad (-\infty < t < \infty)$$

unless $x(t;m) \equiv 0$. Therefore, in (115) we have

$$\| B\{u[f'(x) - 1]\|_2 < M(r) \| u \|_2 \quad \text{for} \quad 0 < \| x \|_\infty \leq r < p.$$

So we have strict inequality in (119) for $0 < r < p$. Hence,

$$\| u \|_\infty < \frac{1}{1 - M(r)} \quad \text{for} \quad 0 < \| x \|_\infty \leq r < p. \tag{120}$$

Now let us set

$$m = \alpha e^{i\theta}, \qquad \alpha > 0 \tag{121}$$

and

$$r(\alpha) = \max_\theta \| x(t;\alpha e^{i\theta}) \|_\infty. \tag{122}$$

We want to see how large we can make $\alpha$, say $\alpha(p)$, and have $r(\alpha) < p$. Using (120) in

$$x(t;m) = \int_0^m u(t;\xi) d\xi, \tag{123}$$

we obtain the inequality

$$r(\alpha) < \int_0^\alpha \frac{d\xi}{1 - M[r(\xi)]}, \qquad 0 < \alpha \leq \alpha(p). \tag{124}$$

Then, after defining

$$s(\alpha) = \int_0^\alpha \frac{d\xi}{1 - M[s(\xi)]}, \qquad 0 < \alpha \leq \alpha(p), \tag{125}$$

it is clear, since $M(r)$ is an increasing function of $r$, that we will have

$$r(\alpha) < s(\alpha), \qquad 0 < \alpha \leq \alpha(p). \tag{126}$$

Differentiating (125) with respect to $\alpha$, we obtain the simple equation

$$s'(\alpha)\{1 - M[s(\alpha)]\} = 1,$$

or, considering $\alpha$ as a function of $s$,

$$\frac{d\alpha}{ds} = 1 - M(s).$$

Thus

$$\alpha(s) = \int_0^s [1 - M(r)]dr, \qquad 0 < s \leqslant p. \tag{127}$$

We have $s(\alpha(p)) = p$ and $r(\alpha) < s(\alpha)$ for $\alpha > 0$. So we will have

$$\| x(t;m) \|_\infty < p \quad \text{for} \tag{128}$$

$$| m | \leqslant \alpha(p) = \int_0^p [1 - M(r)]dr. \tag{129}$$

According to (120) and (128), the partial derivative $u(t;m)$ will exist for $| m |$ somewhat larger than $\alpha(p)$. This completes the proof of Theorem 3. □

## VIII. AN ILLUSTRATIVE EXAMPLE

It will be shown in a future paper that the r.v. companding problem

$$B\left\{\frac{x}{1 - x}\right\} = y, \qquad x < 1, \qquad x, y \text{ in } \mathscr{B}_2(\lambda), \tag{130}$$

is equivalent to finding the reproducing kernel for a certain Hilbert space of bandlimited functions. The specific problem with $\lambda = 2$ (for convenience) and

$$y = m \frac{\sin 2t}{2t} \tag{131}$$

is quite easily solved. For real $m > -2$, the solution is

$$x(t;m) = 2\beta \frac{\sin 2t}{2t} - \beta^2 \left(\frac{\sin t}{t}\right)^2, \tag{132}$$

where

$$\beta = m/(2 + m).$$

We need not be concerned here with the derivation of this solution, as we will later show directly that it satisfies

$$B\left\{\frac{x(t;m)}{1 - x(t;m)}\right\} = m \frac{\sin 2t}{2t} \tag{133}$$

for all $m$ in a certain region of the complex plane, but for no other $m$.

We know from Theorem 3 that (133) has a unique solution for sufficiently small $|m|$, and that the solution is an analytic function of $m$. It follows that (132) is the solution of (133) for all complex $m$, $|m| < |m_0|$, for some $|m_0| > 0$. Since $m = -2$ is the only point where $x(t;m)$ is not analytic, we might suppose $|m_0| = 2$. The series expansion of $x(t;m)$ certainly converges (uniformly in $t$) for all $|m| < 2$, but it is not a solution of (133) for all such $m$. For example, we have

$$x\left(\pm \frac{\pi}{2};m\right) = -\left(\frac{2\beta}{\pi}\right)^2$$

and

$$m = \frac{2\beta}{1-\beta}.$$

Then for $\beta = \pm i\pi/2$, we have

$$m = \frac{-2}{1 \pm i\dfrac{2}{\pi}}, \quad \text{and} \quad x\left(\pm \frac{\pi}{2};m\right) = 1.$$

Therefore, the meromorphic function of $t$,

$$f\{x(t;m)\} = \frac{x(t;m)}{1 - x(t;m)}$$

will have poles at $t = \pm \pi/2$ for $m = -2/(1 \pm i2/\pi)$. Thus we have here an example, $|m| < 2$, for which (132) is not a solution of (133). However, it is, according to Theorem 3, for all $m$ satisfying $|m| \leqslant 3 - 2\sqrt{2}$. This, as it turns out, is an overly conservative upper bound for $|m|$.

We now turn to the problem of determining precisely those $m$ for which (132) is a solution of (133).

First we can easily show that the r.v. problem has no solution for $m \leqslant -2$ by convolving both sides of (133) with $1/\pi K(t)$, where $K(t) = (\sin t)^2/t^2$. The result is

$$\int_{-\infty}^{\infty} \frac{x(s;m)}{1 - x(s;m)} \cdot \frac{1}{\pi} K(t-s)ds = \frac{m}{2} K(t). \tag{134}$$

Since $x/(1-x) > -1$, and $K(t) \geqslant 0$, we have

$$\int_{-\infty}^{\infty} \frac{x(s;m)}{1 - x(s;m)} \cdot \frac{1}{\pi} K(t-s)ds > -\frac{1}{\pi} \int_{-\infty}^{\infty} K(t)dt = -1$$

This gives, setting $t = 0$ in (134),

$$m > -2. \tag{135}$$

Now to proceed towards our stated goal, we first write

$$1 - x(t;m) = \left(1 - \beta e^{it} \frac{\sin t}{t}\right)\left(1 - \beta e^{-it} \frac{\sin t}{t}\right). \tag{136}$$

Then in order for $x(t;m)$ to be a solution of the problem, the Fourier transform of the function

$$h(t;m) = \frac{x(t;m)}{1 - x(t;m)} - m \frac{\sin 2t}{2t} \tag{137}$$

must vanish over $(-2,2)$. With a bit of manipulation we arrive at the expression

$$h(t;m) = g(t;m) + g(-t;m), \tag{138}$$

where

$$g(t;m) = \frac{-\beta^2}{1 - \beta} \frac{e^{2it}\left(1 - e^{it} \dfrac{\sin t}{t}\right)}{2it\left(1 - \beta e^{it} \dfrac{\sin t}{t}\right)} \tag{139}$$

and

$$\beta = \frac{(m/2)}{1 + (m/2)} \neq 1.$$

We now introduce the complex variable $\tau = t + iu$, and observe that

$$|g(t + iu;\, m)| = \mathscr{O}\left\{\frac{e^{-2u}}{|t + iu|}\right\}, \qquad u \to +\infty. \tag{140}$$

Then if the denominator satisfies the condition,

$$\left(1 - \beta e^{i\tau} \frac{\sin \tau}{\tau}\right) \textit{ is zero-free} \quad \text{for} \quad u \geqslant 0, \tag{141}$$

it is easy to see (by contour integration in the upper half-plane) that

$$G(\omega;m) = \int_{-\infty}^{\infty} g(t;m)e^{-i\omega t}dt = 0 \quad \text{for} \quad \omega < 2. \tag{142}$$

On the other hand, if the function in (141) has zeros $\tau_k$ in the upper half plane $u > 0$, (it must have no real zeros in order for $g$ to have a Fourier transform) we will have, by the calculus of residues,

$$G(\omega;m) = \sum_1^n c_k e^{-i\omega\tau_k}, \qquad c_k \neq 0, \tag{143}$$

where $n$, depending on $\beta$, is finite, since it is clear that the function in (141) can have only a finite number of zeros in the upper half-plane. Since the Fourier transform of $h(t;m)$ is given by

$$H(\omega, m) = G(\omega;m) + G(-\omega;m) \tag{144}$$

it will vanish over $(-2,2)$ if, and only if, the condition (141) is satisfied.

Now the values taken by $e^{i\tau} \sin \tau/\tau$ in the upper half-plane, $u \geqslant 0$ are precisely those values on the boundary and interior of the cardioid-like region whose boundary is described parametrically by

$$e^{it} \frac{\sin t}{t}, \qquad -\pi \leqslant t \leqslant \pi.$$

(Some values are taken more than once.) Then $x(t;m)$ will be a solution to the problem except for those values of $m$ such that $1/\beta$ is a point on the boundary or in the interior of the cardioid-like region. By the mapping

$$m = \frac{2}{\frac{1}{\beta} - 1},$$

$x(t;m)$ is a solution to the problem for precisely those (finite) $m$ lying in the region to the right of the boundary line described parametrically by

$$m = \frac{2}{e^{it} \frac{\sin t}{t} - 1}, \qquad -\pi \leqslant t \leqslant \pi. \tag{145}$$

This region (see Fig. 1) includes the half-plane $\mathrm{Re}\{m\} \geqslant -4/3$, its boundary indenting more to the left near the real axis, having a cusp at its leftmost point, $m = -2$, where it is tangent to the real axis. It is found that the distance from the origin to the boundary is minimal (see circle in Fig. 1) at the point $m_0$ and its conjugate, where

$$\begin{aligned} m_0 &= (-2 + \xi) + i\xi, \\ \xi &= \frac{1}{t_0} \doteq .4895273114 \doteq (2.42786943)^{-1}, \end{aligned} \tag{146}$$

$t_0$ is the smallest positive root of $\sin t/t = \cos t + \sin t$,

$$|m_0| = \frac{\sqrt{2}}{\sin t_0} \doteq 1.58781760, \ \arg\{m_0\} = \frac{\pi}{4} + t_0.$$

So $|m_0|$ is the largest number such that $x(t;m)$ is a solution for *all* $m$

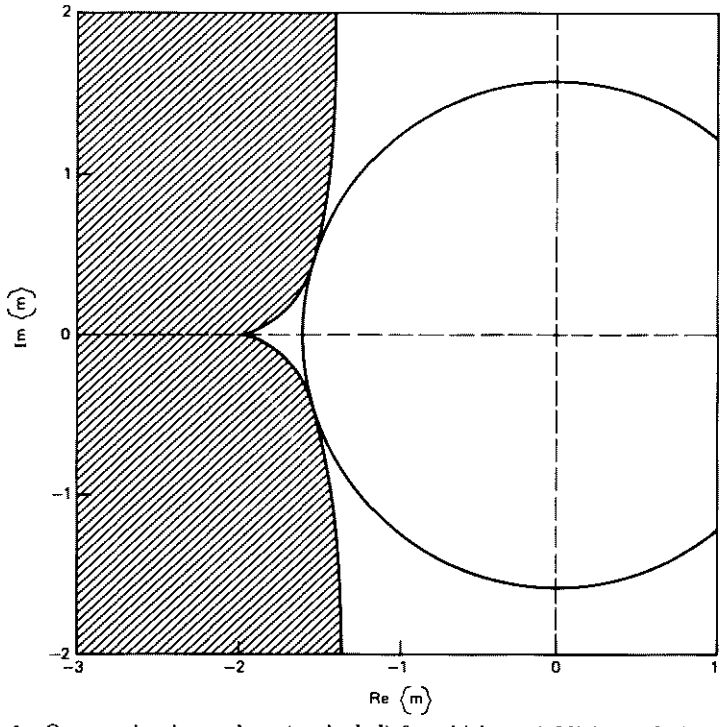

Fig. 1—Open region in $m$-plane (unshaded) for which eq. (132) is a solution of eq. (133). Shown is the largest disk (centered on the origin) contained in the region.

satisfying $|m| < |m_0|$. Also,

$$|m_0| = \min_t R_0(t),$$

where $R_0(t)$ is the radius of convergence of the series

$$\frac{x(t;m)}{1 - x(t;m)} = m \frac{\sin 2t}{2t} + m^2 h_2(t) + m^3 h_3(t) + \cdots,$$

the minimum occurring for $t = \pm t_0$.

## IX. CONCLUSION

The expressions for the $n$th order components $x_n(t)$ of the series solution to the companding problem become so complicated that, for practical purposes, only the first few are of interest. These should be useful in correcting small distortions in nonlinear transmission systems which fit the companding model. It would appear that the corrections applied internally to the inverse function (the $z_k$ in Section V) would be more effective for correcting larger distortions, especially if the lower frequency components are predominant in the signals. In

this connection, the simpler "approximate identity" should be quite effective for correcting small to moderate distortions of a more general nature, as evidenced by the inequality given in the appendix. Experimental evidence of the effectiveness of these correction schemes would be desirable.

The question of the convergence of the series solution is a matter of little practical concern, but the fact that it does attaches more mathematical significance to the results. To settle this question we had to show that the complex-valued companding problem has solutions for functions of sufficiently small norm. This generalizes the result for functions of one-sided spectra; and whether or not the general result will ever find practical application, it is an interesting addition to a theory, though still incomplete in many respects. For example, it is doubtful that the condition that $x(t)$ be confined to a convex region $G$ where $\mathrm{Re}\{f'\} > 0$ is a necessary condition for uniqueness of the solution. In this connection, one could probably use analytic continuation arguments to show that the specific problem examined in Section VIII has solutions only for those values of $m$ for which the (particular) solution given is the only solution, this being unique for sufficiently small $|m|$, and being an analytic function of $m$ having no branch points. Also there is the difficult question of determining for what $y(t)$ the companding problem has a solution, where particular interest is attached to the real-valued problem with analytic companding functions. It can be shown for the case $f(x) = x/(1 - x)$, $x < 1$, that the problem has a solution for every (r.v.) $y$ in $\mathscr{B}_2$ satisfying $y > -1$. This suggests (conjecture) that the r.v. companding problem with $f(x) = x/(1 - x^2)$, $-1 < x < 1$, has a solution for every (r.v.) $y$ in $\mathscr{B}_2$, or more generally for monotone $f(x)$ defined on $(-1, 1)$ having singularities as strong as poles at $\pm 1$. In general, it is not enough for $f(x)$ to increase from $-\infty$ to $+\infty$ over its range of definition in order to draw the same conclusion; e.g., $f(x) = \log(1 + x)$, $x > -1$. The questions raised here are certainly worthy of future consideration.

In connection with the series solution, one naturally inquires whether an explicit formula (albeit complicated and involving partitions of various kinds) can be given for the general term $x_n$. Perhaps the combinatorics experts will consider this question.

We note that the solution $x = B\phi(y)$, valid for $y$ (of sufficiently small norm) whose Fourier transforms vanish outside $[0, \lambda]$, is verified by the fact that in (29.n) the expression reduces to $x_n = a_n B y^n$, the other terms vanishing because $B$ is operating on functions whose Fourier transforms vanish over $(-\infty, \lambda)$. The same reduction occurs in the expression (34.n), because, in this case, $B$ is operating on functions whose Fourier transforms vanish over $(-\infty, 0)$ and agree over $[0, \lambda]$; i.e.,

$$B[\cdots] = By^n$$

holds for each term in (34.n), the sum of all the coefficients being $a_n$.

Some interesting identities are obtained by equating the expressions for $x_n$ in the series solution of the general problem to those obtained from the explicit solution (given in the introduction) to the special problem

$$B \log(1 + x) = my,$$

which involve $\hat{y}$, the Hilbert transform of $y$, which does not appear in the more general expressions. For example, we find from (34.3) that $x_3$ in the series solution of this problem is given by

$$x_3 = 1/2B(y \cdot By^2) - 1/3By^3,$$

and, from the series expansion of the explicit solution, by

$$x_3 = 1/8yB(y^2 - \hat{y}^2) - 1/8B(y\hat{y}^2) + 1/24\,By^3 + 1/4\hat{y}B(y\hat{y}).$$

It is an interesting exercise to show directly that these two expressions are identical.

Finally, since truly bandlimited signals exist only as mathematical abstractions, some attention should be given to developing a mathematical theory of practical companding problems,

$$\int_{-\infty}^{\infty} f\{x(s)\}k(t - s)ds = y(t),$$

where $k(t)$ is the (absolutely-integrable) impulse response of a practical low-pass filter, so that the theory may be extended to signals that are merely bounded. Here one may not be interested, for various reasons, in the exact solution of this problem but, instead, a compromise problem, where the equation is nearly satisfied with both $x(t)$ and $y(t)$ being close to bandlimited functions. For example, in many cases $f\{x(t)\}$ is given (say) by an $n$th order differential operator acting on $y(t)$. Then the (exact) solution $x(t) = \phi\{f(x)\}$ may be far from a bandlimited function. However, if $y(t)$ is close to a bandlimited function there should be an approximate solution which is also close to a bandlimited function. A case in point is found in Landau's simulation of the iterative solution of the companding problem (Ref. 2), where, in fact, the equation he was obtaining approximate solutions to was the case $y(t) = k(t)$, (approximately bandlimited) for which the unique solution is (a multiple of) the Dirac delta function.

## X. ACKNOWLEDGMENT

I am grateful to H. J. Landau for helpful discussions, to J. C.

Lagarias for aid in preparation of the manuscript, and to A. M. Odlyzko for the production of Fig. 1.

## APPENDIX

Suppose $f(x)$ is a monotone increasing function of the real variable $x$, satisfying

$$(i) \qquad f(0) = 0$$

$$(ii) \qquad 0 < m_1 \leqslant f'(x) \leqslant m_2 < \infty, \qquad (-\infty < x < \infty).$$

Then $f$ has an inverse $\phi$

$$(iii) \qquad x = \phi\{f(x)\}, \qquad (-\infty < x < \infty),$$

satisfying, since $1 = f'(x)\phi'\{f(x)\}$,

$$(iv) \qquad 0 < \frac{1}{m_2} \leqslant \phi'(y) \leqslant \frac{1}{m_1} < \infty, \qquad (-\infty < y < \infty).$$

Now let $x = x(t)$ be any function in $\mathscr{B}_2$. We wish to establish

$$\| x - B\phi\{Bf(x)\}\|_2 \leqslant \gamma \| x \|_2, \tag{147}$$

where $$\gamma = \frac{\epsilon^2}{4(1 + \epsilon)}, \qquad \epsilon = \frac{m_2}{m_1} - 1.$$

Set

$$y(t) = y = Bf(x). \tag{148}$$

Then

$$f(x) = y + h, \qquad Bh = 0. \tag{149}$$

Now set

$$x_1 = B\phi(y) \tag{150}$$

so that, since $x = \phi(y + h) = Bx = B\{\phi(y + h)\}$,

$$x - x_1 = B\{\phi(y + h) - \phi(y)\}. \tag{151}$$

Since $|\phi(y+h)-\phi(y)| \leq \frac{1}{m_1} h$, we see that

$$\|\phi(y+h)-\phi(y)\|_2 \leq \frac{1}{m_1}\|h\|_2$$

and hence that

$$\|x-x_1\|_2 \leq \frac{1}{m_1}\|h\|_2,$$

but we can improve this inequality by writing

$$\phi(y+h)-\phi(y) = \int_y^{y+h} \{\phi'(\xi)-\alpha\}d\xi + \alpha h, \tag{152}$$

where

$$\alpha = \frac{1}{2}\left(\frac{1}{m_1}+\frac{1}{m_2}\right).$$

Then, since

$$|\phi'(\xi)-\alpha| \leq \frac{1}{2}\left(\frac{1}{m_1}-\frac{1}{m_2}\right), \tag{153}$$

we have

$$\phi(y+h)-\phi(y) = u + \alpha h, \tag{154}$$

where $u = u(t)$ and

$$|u| \leq \frac{1}{2}\left(\frac{1}{m_1}-\frac{1}{m_2}\right)|h|. \tag{155}$$

Thus

$$x - x_1 = B(u+\alpha h) = Bu, \tag{156}$$

and hence

$$\|x-x_1\|_2 \leq \|u\|_2 \leq \frac{1}{2}\left(\frac{1}{m_1}-\frac{1}{m_2}\right)\|h\|_2. \tag{157}$$

Now we need an inequality of the form $\|h\|_2 \leq c\|x\|_2$. We have

$$h = Hf(x), \tag{158}$$

where $H = I - B$ is the high-pass operator. So, clearly

$$\|h\|_2 \leq \|f(x)\|_2 \leq m_2\|x\|_2.$$

We can improve this inequality by setting

$$v(t) = v = f(x) - \beta x, \tag{159}$$

where

$$\beta = 1/2(m_1+m_2).$$

Then

$$|v| \leq 1/2(m_2 - m_1)|x|, \tag{160}$$

and, since $Hx = 0$,

$$h = Hf(x) = H\{f(x) - \beta x\} = Hv. \tag{161}$$

Hence

$$\|h\|_2 \leq \|v\|_2 \leq 1/2(m_2 - m_1)\|x\|_2. \tag{162}$$

This, with (157) gives

$$\|x - x_1\|_2 \leq \frac{1}{4}\left(\frac{1}{m_1} - \frac{1}{m_2}\right)(m_2 - m_1)\|x\|_2 = \gamma\|x\|_2, \tag{163}$$

which is the result (147). The number $\gamma$ in the inequality is invariant under the interchange of $\phi$ and $f$ in the approximate identity (147), as we would expect from using only (*ii*) and (*iv*).

So $x_1 = B\phi\{Bf(x)\}$ is a good approximation to $x$ if $\gamma$ is small. The manipulations leading to the inequality (163) suggest an iterative scheme for solving, given $y$ in $\mathscr{B}_2$,

$$BF(x) = y, \qquad x \text{ in } \mathscr{B}_2, \tag{164}$$

provided $\gamma < 1$, which will be the case if $(m_2/m_1) < 3 + 2\sqrt{2}$.

We set

$$x_n = B\phi(y + h_{n-1}), \qquad n \geq 1, \tag{165}$$

where

$$\mathrm{h}_n = \mathrm{Hf}(\mathrm{x}_n), \qquad \mathrm{n} \geq 0, \tag{166}$$

and $\mathrm{x}_0 = \mathrm{h}_0 = 0,$

giving $\mathrm{x}_1 = \mathrm{B}\phi(\mathrm{y})$ as in (150).

Now we wish to show that

$$\|x - x_n\|_2 \leq \gamma^n\|x\|_2, \qquad n \geq 1. \tag{167}$$

We have

$$x - x_n = B\{\phi(y + h) - \phi(y + h_{n-1})\}. \tag{168}$$

Following the previous pattern we write

$$\phi(y + h) - \phi(y + h_{n-1}) = u_n + \alpha(h - h_{n-1}), \tag{169}$$

where

$$u_n = \int_{y+h_{n-1}}^{y+h} \{\phi'(\xi) - \alpha\}d\xi,$$

and hence

$$|u_n| \leqslant \frac{1}{2}\left(\frac{1}{m_1} - \frac{1}{m_2}\right)|h - h_{n-1}|. \tag{170}$$

Then

$$x - x_n = B\{u_n + \alpha(h - h_{n-1})\} = Bu_n, \tag{171}$$

giving

$$\|x - x_n\|_2 \leqslant \frac{1}{2}\left(\frac{1}{m_1} - \frac{1}{m_2}\right)\|h - h_{n-1}\|_2. \tag{172}$$

Now

$$h - h_{n-1} = H\{f(x) - f(x_{n-1})\}, \quad n \geqslant 1, \quad \text{with } x_0 = h_0 = 0. \tag{173}$$

Here we write

$$\begin{aligned} f(x) - f(x_{n-1}) &= \int_{x_{n-1}}^{x} \{f'(\xi) - \beta\}d\xi + \beta(x - x_{n-1}) \\ &= v_n + \beta(x - x_{n-1}), \end{aligned} \tag{174}$$

where

$$|v_n| \leqslant \frac{m_2 - m_1}{2}|x - x_{n-1}|. \tag{175}$$

Then

$$h - h_{n-1} = H\{v_n + \beta(x - x_{n-1})\} = Hv_n, \tag{176}$$

giving, with (175),

$$\|h - h_{n-1}\|_2 \leqslant \frac{m_2 - m_1}{2}\|x - x_{n-1}\|_2. \tag{177}$$

This, with (172), gives

$$\|x - x_n\|_2 \leqslant \gamma\|x - x_{n-1}\|_2, \tag{178}$$

whence follows, with $x_0 = 0$,

$$\|x - x_n\|_2 \leqslant \gamma^n\|x\|_2, \qquad n \geqslant 1. \tag{179}$$

Note that there is a bonus attached to $x_1 = B\phi(y)$, in that only one filtering operation is required to obtain it. Thereafter, two filtering operations are required to obtain $x_n$ from $y$ and $x_{n-1}$.

# Bandwidth-Conserving Independent Amplitude and Phase Modulation

By B. F. LOGAN, Jr.*

(Manuscript received March 26, 1982)

Given two baseband signals $f(t)$ and $g(t)$, suitably restricted in amplitude and bandlimited to $[\lambda, \mu]$ and $[-\mu, -\lambda]$, $0 < \lambda < \mu < \infty$, it is shown how to generate a carrier signal, $s(t) = A(t)\cos\{ct + \phi(t)\}$, bandlimited to $[c - \beta, c + \beta]$ and $[-(c + \beta), -(c - \beta)]$, where $\beta$ need be only sightly larger than $\mu$, and such that $f(t)$ and $g(t)$ may be recovered by bandlimiting $\log A(t)$ and $\phi(t)$, respectively. The restriction $\lambda > 0$, i.e., that the baseband signals be bandpass, is not essential but it is a practical constraint in approximating the required operations. Also a modification is given for conserving bandwidth in case the signals $f(t)$ and $g(t)$ are of disparate bandwidths.

## I. INTRODUCTION

Double-sideband amplitude modulation is wasteful of bandwidth, but it offers the advantage of envelope detection (with full carrier). A simple way to utilize the same bandwidth in transmitting two independent signals, $f(t)$ and $g(t)$, is the so-called in-phase and quadrature modulation

$$S_1(t) = f(t)\cos ct - g(t)\sin ct,$$

where synchronous demodulation is required to recover $f$ and $g$. A modification that allows $f$ to be recovered (approximately) by envelope detection is

$$S_2(t) = \{1 + f(t)\}\cos ct - g(t)\sin ct.$$

Permission to reproduce or republish any other portion of this paper must be obtained from the Editor.

The envelope of $S_2(t)$ is

$$A_2(t) = \sqrt{\{1 + f(t)\}^2 + g^2(t)}.$$

Then if $g$ is made small (compared to $\min\{1 + f(t)\}$), we have

$$A_2(t) \cong 1 + f(t).$$

The phase of $S_2$ (i.e., the part due to signals) is

$$\phi_2(t) = \tan^{-1} \frac{g(t)}{1 + f(t)} \cong \frac{g(t)}{1 + f(t)}.$$

So making $g$ small allows envelope and phase detection to be used so as to approximately recover $f$ and $g$ (multiplying the phase output by the envelope output).

A still further modification is

$$S_3(t) = \{1 + x_1(t)\}\cos ct - \{1 + x_2(t)\}\sin ct,$$

where $x_1$ and $x_2$ are both small. The envelope of $S_3$ is

$$A_3(t) = \sqrt{(1 + x_1)^2 + (1 + x_2)^2} = \sqrt{2 + 2x_1 + 2x_2 + x_1^2 + x_2^2}$$
$$\cong \sqrt{2}\left(1 + \frac{x_1 + x_2}{2}\right).$$

The phase of $S_3$ is

$$\phi_3(t) = \tan^{-1} \frac{1 + x_2}{1 + x_1} \cong \frac{\pi}{4} + \frac{x_2 - x_1}{2}.$$

So if

$$\frac{x_1 + x_2}{2} = f \quad \text{and} \quad \frac{x_1 - x_2}{2} = g,$$

i.e.,

$$x_1 = f + g$$
$$x_2 = f - g,$$

then envelope and phase detection of $S_3$ will give (approx.) the desired independent signals $f$ and $g$.

An exact result of this type may be obtained using log of the envelope, rather than the envelope, and then *bandlimiting* the phase and log of the envelope to obtain the desired independent signals $f$ and $g$. A slight increase in bandwidth is required to allow a guard band in the filtering operations. Also $|f|$ and $|g|$ cannot be too large if the increase in bandwidth is to be small. The basic theory is that of

Exponential Single-Sideband Modulation (ESSB) developed in Ref. 1.

## II. THE EXACT METHOD

We assume that the desired signals, $f$ and $g$, are bounded band-pass signals whose Fourier transforms vanish (in the sense detailed in Ref. 1) outside $[\lambda, \mu]$ and $[-\mu, -\lambda]$, $0 < \lambda < \mu < \infty$, which then (automatically) have bounded Hilbert transforms, $\hat{f}$ and $\hat{g}$. The band-pass assumption is not essential to the theory, but affords important practical simplifications in approximating the Hilbert transform operations as well as in effecting the subsequent analytic exponential modulation.

Now suppose $z_1(t)$ and $z_2(t)$ are bandlimited "analytic signals" whose Fourier transforms vanish outside $[0, \beta]$ and which signals are zero-free in the upper half-plane with

$$|z_{1,2}(t + iu)| \geq \epsilon \quad \text{for} \quad u \geq 0, \qquad -\infty < t < \infty. \tag{1}$$

Then $\log z_1$ and $\log z_2$ are analytic and bounded in the upper half-plane, and hence their Fourier transforms vanish over $(-\infty, 0)$.

Writing

$$z_1(t) = A_1(t)e^{i\phi_1(t)}, \qquad A_1 = |z_1| \tag{2}$$

$$z_2(t) = A_2(t)e^{i\phi_2(t)}, \qquad A_2 = |z_2|, \tag{3}$$

we have

$$\log z_1(t) = \log A_1(t) + i\phi_1(t) \tag{4}$$

$$\log z_2(t) = \log A_2(t) + i\phi_2(t). \tag{5}$$

Under further assumptions on $z$, e.g.,

$$z_{1,2}(t + iu) = 1 + 0(e^{-\lambda u}), \qquad u \to \infty, \tag{6}$$

$\log A$ and $\phi$ will be Hilbert transform pairs:

$$\phi_1(t) = \log^{\wedge} A_1(t), \qquad \log A_1(t) = -\hat{\phi}_1(t) \tag{7}$$

$$\phi_2(t) = \log^{\wedge} A_2(t) \qquad \log A_2(t) = -\hat{\phi}_2(t). \tag{8}$$

Now we consider the product

$$z_1(t)\overline{z_2(t)} = A_1(t)A_2(t)e^{i[\phi_1(t)-\phi_2(t)]},$$

where the bar denotes the complex conjugate. The F.T. (Fourier transform) of $z_1(t)$ vanishes outside $[0, \beta]$ and the F.T. of $\overline{z_2(t)}$ vanishes outside $[-\beta, 0]$. Therefore, the F.T. of $z_1(t)\overline{z_2(t)}$ vanishes outside $[-\beta, \beta]$. Then we form the signal

$$s(t) = \text{Re } e^{ict} z_1(t)\overline{z_2(t)}$$
$$= A(t)\cos\{ct + \phi(t)\}, \tag{9}$$

where $c > \beta$,

$$A(t) = A_1(t)A_2(t) \tag{9a}$$

$$\phi(t) = \phi_1(t) - \phi_2(t), \tag{9b}$$

and the spectrum of $s(t)$ is confined to $[c - \beta, c + \beta]$ and $[-c - \beta, -c + \beta]$.

We require

$$\mathbf{B}_{\mu,\alpha}\{\log A(t)\} = f(t) \tag{10}$$

$$\mathbf{B}_{\mu,\alpha}\{\phi(t)\} = g(t), \tag{11}$$

where $\mu < \alpha < \beta$, and, in general, $\mathbf{B}_{p,q}$ is any bandlimiting operator [with passband $(-p, p)$ and cut-off frequency $\pm q$] defined by

$$\mathbf{B}_{p,q}\{x(t)\} = \int_{-\infty}^{\infty} x(s)K_{p,q}(t - s)ds \tag{12}$$

and

$$\overset{>}{K}_{p,q}(\omega) = \int_{-\infty}^{\infty} K_{p,q}(t)e^{-i\omega t}dt = 1, \qquad -p < \omega < p$$
$$= 0, \qquad |\omega| > q. \tag{12a}$$
$$0 < p < q < \infty. \tag{12b}$$

The definition of $\overset{>}{K}_{p,q}(\omega)$ in the cut-off region $(p, q)$ and $(-q, -p)$ is not important, but $\overset{>}{K}_{p,q}(\omega)$ must be sufficiently smooth to give

$$\int_{-\infty}^{\infty} |K_{p,q}(t)|\,dt < \infty \tag{12c}$$

so that $\mathbf{B}_{p,q}\{x(t)\}$ is defined for any bounded $x(t)$.

Writing (10) as

$$\mathbf{B}_{\mu,\alpha}\{\log A_1(t) + \log A_2(t)\} = f(t)$$

and taking Hilbert transforms of both sides of (10) and (11), using (7) and (8), we have

$$\mathbf{B}_{\mu,\alpha}\{\phi_1(t) + \phi_2(t)\} = \hat{f}(t) \tag{13}$$

$$\mathbf{B}_{\mu,\alpha}\{\phi_1(t) - \phi_2(t)\} = g(t) \tag{14}$$

or

$$\mathbf{B}_{\mu,\alpha}\{\phi_1(t)\} = \tfrac{1}{2}\{\hat{f}(t) + g(t)\} \tag{15}$$

$$\mathbf{B}_{\mu,\alpha}\{\phi_2(t)\} = \tfrac{1}{2}\{\hat{f}(t) - g(t)\}, \tag{16}$$

which according to (7) and (8) is equivalent to

$$\mathbf{B}_{\mu,\alpha}\{\log A_1(t)\} = \tfrac{1}{2}\{f(t) - \hat{g}(t)\} \tag{17}$$

$$\mathbf{B}_{\mu,\alpha}\{\log A_2(t)\} = \tfrac{1}{2}\{f(t) + \hat{g}(t)\}. \tag{18}$$

Setting

$$h_1(t) = \tfrac{1}{2}\{f(t) - \hat{g}(t)\}; \qquad \hat{h}_1(t) = \tfrac{1}{2}\{\hat{f}(t) + g(t)\}, \tag{19}$$

$$H_1(t) = h_1(t) + i\hat{h}_1(t), \tag{19a}$$

$$h_2(t) = \tfrac{1}{2}\{f(t) + \hat{g}(t)\}; \qquad \hat{h}_2(t) = \tfrac{1}{2}\{\hat{f}(t) - g(t)\}, \tag{20}$$

$$H_2(t) = h_2(t) + i\hat{h}_2(t), \tag{20a}$$

the four equations (15), (16), (17), and (18) are equivalent to the two equations, implying (6),

$$\mathbf{B}_{\mu,\alpha}\{\log z_1(t)\} = H_1(t) \tag{21}$$

$$\mathbf{B}_{\mu,\alpha}\{\log z_2(t)\} = H_2(t), \tag{22}$$

where $H_1$ and $H_2$ are given "analytic" band-pass signals whose Fourier transforms vanish outside the single interval $[\lambda, \mu]$ and $z_1$ and $z_2$ are bandlimited "analytic" signals whose Fourier transforms vanish outside the single interval $[0, \beta]$. The problem of finding $z_1$ and $z_2$ has been solved (see Ref. 1):

$$z_1(t) = \mathbf{B}_{\alpha,\beta}\{\exp H_1(t)\} \tag{23}$$

$$z_2(t) = \mathbf{B}_{\alpha,\beta}\{\exp H_2(t)\}, \tag{24}$$

where $\mathbf{B}_{\alpha,\beta}$ is any bandlimiting operator with passband $(-\alpha, \alpha)$ and cut-off frequency $\pm\beta$.

Now $z_1$ and $z_2$ given by (23) and (24) satisfy (21) and (22), *provided* $z_1(\tau)$ and $z_2(\tau)$, $\tau = t + iu$, are zero free in the upper half-plane $u > 0$. The filter characteristic $\overset{>}{K}_{\alpha,\beta}(\omega)$ in the cut-off region $(\alpha, \beta)$ becomes important, but not critical, in this respect. From theoretical considerations the linear cut-off characteristic is desirable (see Ref. 1):

$$\overset{>}{K}_{\alpha,\beta}(\omega) = \frac{\beta - \omega}{\beta - \alpha}, \qquad \alpha < \omega < \beta. \tag{25}$$

For a given $\alpha$ and $\beta$, and a smooth cut-off characteristic, $z_1$ and $z_2$ will be zero free in the upper half-plane provided $|H_1|$ and $|H_2|$ are not too large. In practice this means that the levels of $f$ and $g$ must not be

too large if $\alpha$ and $\beta$ are not much larger than $\mu$, the top signal frequency, i.e., in the bandwidth conserving case. The results in Ref. 1 may be used as a rough guide. For example, if $\alpha$ is only slightly larger than $\mu$ and $\beta/\alpha = 1.1$ (relatively sharp cut-off), then $z_1$ and $z_2$ will be zero free in the upper half-plane if $|H_1|$ and $|H_2|$ are less than 0.6. (See the appendix for a modification of signals $f$ and $g$ of disparate bandwidths.)

## III. IMPLEMENTATION

The block diagram of an implementation is shown in Fig. 1. The transmitter is shown in Fig. 1a. The inputs are labeled $f(t + T)$ and $g(t + T)$ to account for a delay $T$ incurred in the Hilbert transform filters. The delay $T$ need not be more than one or two periods of the lower signal frequency $\lambda$ to obtain a good approximation to the Hilbert transforms, $\hat{f}(t)$ and $\hat{g}(t)$. (The inputs $f(t + T)$ and $g(t + T)$ must be delayed accordingly to obtain $f(t)$ and $g(t)$.) The signals $f(t)$, $\hat{f}(t)$, $g(t)$, and $\hat{g}(t)$ are summed to obtain

$$h_1 = \tfrac{1}{2}(f - \hat{g})$$

$$\hat{h}_1 = \tfrac{1}{2}(\hat{f} + g)$$

$$h_2 = \tfrac{1}{2}(f + \hat{g})$$

$$\hat{h}_2 = \tfrac{1}{2}(\hat{f} - g)$$

in accord with (19) and (20). (The gain factor of the summing networks, shown as 1/2, may be any constant, which may be simply reflected as a gain factor on the inputs.) Then these outputs are fed to two analytic exponential modulators that furnish outputs

$$X_1 = e^{h_1}\cos \hat{h}_1 = \mathrm{Re}\{\exp H_1\}$$

$$Y_1 = e^{h_1}\sin \hat{h}_1 = \mathrm{Im}\{\exp H_1\}$$

$$X_2 = e^{h_2}\cos \hat{h}_2 = \mathrm{Re}\{\exp H_2\}$$

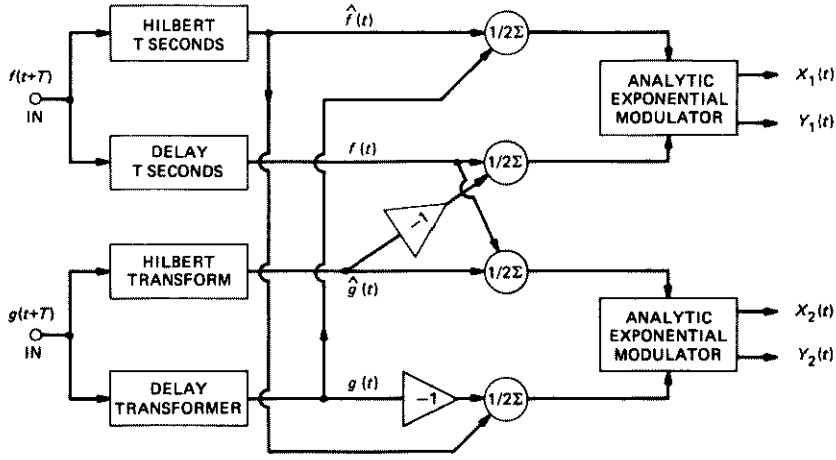
$$Y_2 = e^{h_2}\sin \hat{h}_2 = \mathrm{Im}\{\exp H_2\}.$$

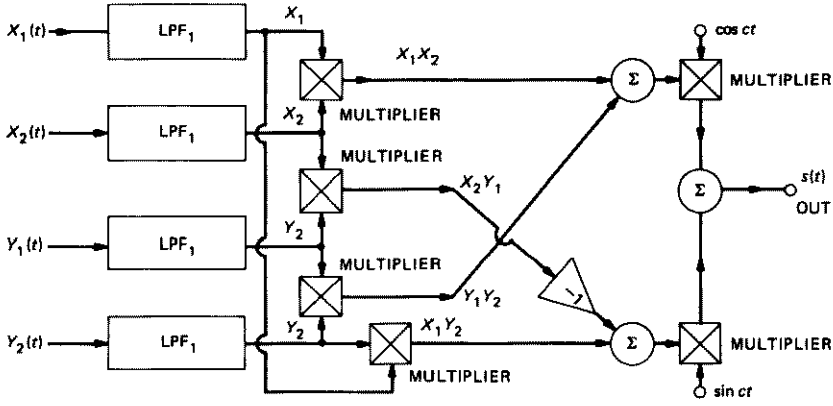
A feedback circuit for accomplishing the analytic exponential modulation is described in Ref. 2. The outputs of the modulators are then bandlimited with identical low-pass filters $\mathrm{LPF}_1$ having the characteristic shown in Fig. 2a to obtain

$$x_1 = \mathrm{Re}\{z_1\}, \qquad y_1 = \mathrm{Im}\{z_1\}$$

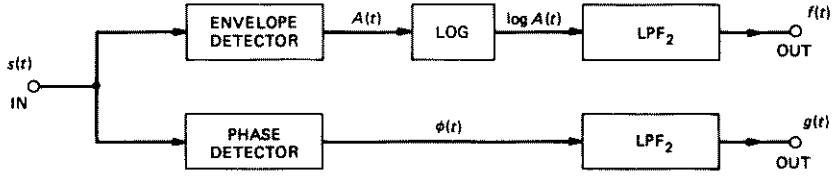
$$x_2 = \mathrm{Re}\{z_2\}, \qquad y_2 = \mathrm{Im}\{z_2\}.$$

These outputs are then combined to form





(a)



(b)

Fig. 1a—Transmitter.
Fig. 1b—Receiver.

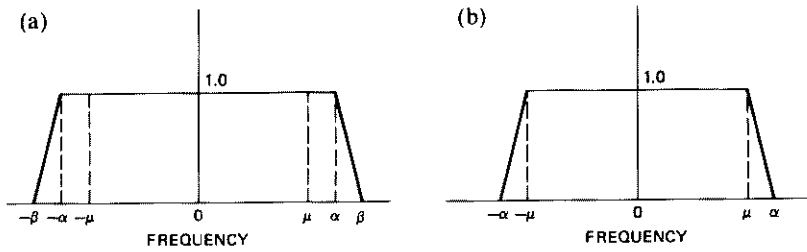


Fig. 2a—Characteristic of $LPF_1$.

Fig. 2b—Characteristic of $LPF_2$.

$$\begin{aligned} s(t) &= \mathrm{Re}\{[x_1(t) + iy_1(t)][x_2(t) - iy_2(t)]e^{ict}\} \\ &= \mathrm{Re}\{[x_1x_2 + y_1y_2 + i(y_1x_2 - y_2x_1)]e^{ict}\} \\ &= (x_1x_2 + y_1y_2)\cos ct - (y_1x_2 - y_2x_1)\sin ct \\ &= A(t)\cos\{ct + \phi(t)\}. \end{aligned}$$

The signal $s(t)$ is then transmitted to the receiver, Fig. 1b, where an envelope detector is used to obtain the envelope $A(t)$, which is then fed to a device having a logarithmic characteristic to furnish the output $\log A(t)$. This output is then filtered with $LPF_2$ to obtain $f(t)$. A phase detector, e.g., a phase-locked loop, is used to detect the phase $\phi(t)$, which is subsequently filtered with another $LPF_2$ to obtain $g(t)$. The characteristic of the filters $LPF_2$ is shown in Fig. 2b.

Note that $\phi(t)$ is high pass with lower frequency $\lambda$; so $\phi(t)$ may be recovered from $\{\phi'(t) + c\}$, if desired.

## APPENDIX

### *Modification for Signals of Disparate Bandwidths*

Note that the bandwidth of the transmitted signal is the sum (or twice the sum, counting positive and negative frequencies) of the bandwidths of the analytic signals $z_1(t)$ and $z_2(t)$, which need be only slightly larger than the sum of the bandwidths of the analytic signals $H_1(t)$ and $H_2(t)$. Owing to the linear combinations in (19) and (20), the bandwidths of $H_1(t)$ and $H_2(t)$ will be the same, equal to the larger of the bandwidths of $f(t)$ and $g(t)$. In case the bandwidth of, say, $g(t)$ is (considerably) larger than that of $f(t)$, the bandwidth of the transmitted signal may be reduced by setting

$$H_1(t) = f(t) + i\hat{f}(t) \tag{26}$$

$$H_2(t) = g(t) + i\hat{g}(t). \tag{27}$$

Here we assume that the Fourier transforms of $H_1(t)$ and $H_2(t)$ vanish outside the intervals $[\lambda, \mu_1]$ and $[\lambda_2, \mu_2]$, respectively. Now we set

$$z_1(t) = \mathbf{B}_{\alpha_1,\beta_1}\{\exp H_1(t)\}, \qquad \mu_1 < \alpha_1 < \beta_1 \tag{28}$$

$$z_2(t) = \mathbf{B}_{\alpha_2,\beta_2}\{\exp H_2(t)\}, \qquad \mu_2 < \alpha_2 < \beta_2, \tag{29}$$

where $\beta_1$ and $\beta_2$ need be only slightly larger than $\mu_1$ and $\mu_2$ (respectively), the top frequencies of $f(t)$ and $g(t)$ (respectively). The Fourier transform of $z_1(t)\overline{z_2(t)}$ now vanishes outside the interval $[-\beta_2, \beta_1]$, which is smaller than would obtain in the previous scheme. Thus the Fourier transform of the transmitted signal,

$$s(t) = \operatorname{Re} e^{ict} z_1(t)\overline{z_2(t)}, \qquad c > \beta_2 \tag{30}$$

vanishes outside the interval $[c - \beta_2, c + \beta_1]$ (and its reflection about the origin). The price paid for the saving in bandwidth is another Hilbert transform operation required in separating the signals at the receiver.

We have

$$s(t) = A(t)\cos[ct + \phi(t)], \tag{31}$$

where

$$A(t) = |z_1(t)z_2(t)|$$

$$\phi(t) = \phi_1(t) - \phi_2(t).$$

Then, assuming as before that $z_1$ and $z_2$ are zero free in the upper half-plane, we have

$$L(t) = \log A(t) = L_1(t) + L_2(t), \tag{32}$$

where $L_1(t) = \log |z_1(t)|$, $L_2(t) = \log |z_2(t)|$ and $L(t)$ is related to $\phi(t)$ by

$$\phi(t) = \phi_1(t) - \phi_2(t) = \hat{L}_1(t) - \hat{L}_2(t) \tag{33}$$

$$\hat{\phi}(t) = \hat{\phi}_1(t) - \hat{\phi}_2(t) = -L_1(t) + L_2(t). \tag{34}$$

In accord with (28) and (29) and the zero-free hypothesis, we have (as shown in Ref. 1)

$$\mathbf{B}_{\mu_1,\alpha_1}\{L_1(t)\} = f(t) \tag{35}$$

$$\mathbf{B}_{\mu_2,\alpha_2}\{L_2(t)\} = g(t) \tag{36}$$

To obtain $L_1(t)$ and $L_2(t)$ from $\log A(t)$ and $\phi(t)$, we need the Hilbert transform $\hat{\phi}(t)$, where according to (32) and (34),

$$L_1(t) = \tfrac{1}{2} \log A(t) - \tfrac{1}{2}\hat{\phi}(t) \tag{37}$$

$$L_2(t) = \tfrac{1}{2} \log A(t) + \tfrac{1}{2}\hat{\phi}(t). \tag{38}$$

However, to recover $f(t)$ and $g(t)$, we may use a modified version of $\hat{\phi}(t)$. We define

$$\hat{\phi}_{\lambda,\mu}(t) = \mathbf{H}_{\lambda,\mu}\{\phi(t)\}, \tag{39}$$

where $\mathbf{H}_{\lambda,\mu}$ is a modified (e.g., band-pass) Hilbert transform operator defined by

$$\mathbf{H}_{\lambda,\mu}\{\phi(t)\} = \int_{-\infty}^{\infty} h_{\lambda,\mu}(t - x)\phi(x)dx \tag{40a}$$

$$h_{\lambda,\mu}(\omega) = \int_{-\infty}^{\infty} h_{\lambda,\mu}(t)e^{i\omega t}dt = -i \operatorname{sgn} \omega, \tag{40b}$$

$$\text{for} \quad 0 < \lambda \leqslant |\omega| \leqslant \mu.$$

Now $\phi_1(t)$ and $\phi_2(t)$ are high-pass functions with lower frequencies $\lambda_1$ and $\lambda_2$ (respectively). Thus, if we require

$$0 < \lambda \leqslant \min(\lambda_1, \lambda_2), \qquad \mu \geqslant \max(\mu_1, \mu_2), \tag{41}$$

then we have

$$f(t) = \tfrac{1}{2}\mathbf{B}_{\mu_1,\alpha_1}\{\log A(t) - \hat{\phi}_{\lambda,\mu}(t)\} \tag{42}$$

$$g(t) = \tfrac{1}{2}\mathbf{B}_{\mu_2,\alpha_2}\{\log A(t) + \hat{\phi}_{\lambda,\mu}(t)\}. \tag{43}$$

## AUTHOR

**Benjamin F. Logan, Jr.,** B.S. (Electrical Engineering), 1946, Texas Technological College; M.S., 1951, Massachusetts Institute of Technology; Eng.D.Sc. (Electrical Engineering), 1965, Columbia University; Bell Laboratories, 1956—. While at MIT, Mr. Logan was a research assistant in the Research Laboratory of Electronics, investigating characteristics of high-power electrical discharge lamps. Also at MIT he engaged in analog computer development at the Dynamic Analysis and Control Laboratory. From 1955 to 1956 he worked for Hycon-Eastern, Inc., where he was concerned with the design of airborne power supplies. He joined Bell Laboratories as a member of the Visual and Acoustics Research Department, where he was concerned with the processing of speech signals. Currently, he is a member of the Mathematical Research Department. Member, Sigma Xi, Tau Beta Pi.

# Theory of Program Testing—An Overview

By R. E. PRATHER*

(Manuscript received January 18, 1983)

In this paper, we provide a detailed survey of the various approaches to program testing that have been proposed in recent years. Particular attention is given to a discussion of the developing theory of program testing and to the decomposition of the testing problem into the program graph construction, test path selection, and test case generation phases. Examples are included to illustrate the different testing strategies. Comparisons are made from one method to another, all in a uniform terminology and notation, to facilitate an understanding of various combinations of strategies that might lead to a more workable testing methodology.

## I. INTRODUCTION

The general goal of software testing is to affirm the quality of a program through systematic exercising of the code in a carefully controlled environment. The execution of a program test scheme should validate an expected prespecified behavior, ideally serving to demonstrate the absence of program errors. Considering the difficulty of obtaining actual proofs of program correctness, program testing

may be the only effective means for assuring the quality of software systems of nontrivial complexity.

The state of the art in software testing as of a decade ago is broadly surveyed in the book by Hetzel,[1] representing an ad hoc approach at best. During the intervening years, computer programming methodology has made great strides toward improving the quality of our product. And yet, software testing has remained a kind of "black art", only vaguely understood by its practitioners. Happily, this situation is changing. The development of the beginnings of a theory of testing are well under way, and the more recent literature shows great promise for brighter days ahead. Some of these ideas are discussed in a new book by Myers,[2] and further elaboration can be found in the survey papers by Miller.[3-6]

In this overview, we summarize in detail the more recent literature on software testing and present the more important results in a uniform framework, style, and notation. We hope that this perspective will help to focus attention on the more viable alternatives and to point the way toward the most promising directions for future research and development.

## II. GENERAL THEORY—THE FUNCTIONAL APPROACH

The first attempt to describe a generalized theory of testing is found in the work of Goodenough and Gerhart,[7,8] A related study is that of Hamlet.[9] In the former, a *program* is viewed as a function $F{:}D \rightarrow R$ over an *input domain* $D$ with values in an *output range* $R$. The program *specification* can also be viewed as a function $G{:}D \rightarrow R$, whether completely specified or not. For testing purposes, we must compare $F(d)$ with $G(d)$ for selected inputs $d$ in $D$. Though such an exhaustive test is not feasible in general, we say that the program $F$ is *correct* if we have

$$F(d) = G(d) \text{ (for all } d \text{ in } D),$$

recognizing that this is simply a theoretical notion, one not necessarily capable of direction verification.

In any practical setting, we will only be able to examine the behavior of the program for a few selected input values. Realizing this, we say that a *test* for the program $F$ is a (finite) subset $T$ of $D$. Recalling the 'goal of software testing,' $T$ is said to be an *ideal test* (for $F$) if

$$\text{success}(T) \Rightarrow \text{correct}(F),$$

i.e., if $F(t) = G(t)$ for $t$ in $T$ implies the same for all $t$ in $D$. Note that the successful execution of an ideal test would constitute a proof of correctness. Given the difficulty in finding proofs of correctness, however, we should not be surprised to learn that ideal tests, in this

sense, are difficult to discover. (We note that the 'trivial' ideal test, the exhaustive one with $T = D$, though easily stated is ordinarily unmanageable in size.)

As a matter of fact, we would prefer not to 'discover' our tests at all, but to have them 'selected' on the basis of some sensible criterion. Formally, a *test selection criterion* (for a program $F$) is a (true-false) predicate $C$ over the subsets of $D$. Following Goodenough and Gerhart once again, such a criterion $C$ is *reliable* (for $F$) if

$$C(T1) \text{ and } C(T2) \Rightarrow \text{success}(T1) = \text{success}(T2),$$

and, on the other hand, $C$ is said to be *valid* (for $F$) if

$$\sim\text{correct}(F) \Rightarrow \sim\text{success}(T)$$

for some $T$ satisfying $C(T)$. In general, reliability refers to the consistency with which results will be produced within the selection criterion, whereas validity refers to the ability to produce meaningful results, regardless of their consistency.

It is clear that these notions of reliability and consistency are quite strong. Perhaps the most convincing statement to this effect is given by the following:

*Theorem (Goodenough and Gerhart): If C is reliable and valid, then C(T) implies that T is an ideal test.*

On the other hand, Weyuker and Ostrand[10] have argued that these notions are not strong enough, referring as they do to a particular program. If the same ideas are extended, however, so as to apply "uniformly" over all programs $F$, then one obtains the following:

*Theorem (Weyuker and Ostrand): If C is uniformly reliable and uniformly valid, then C(T) implies that $T = D$, i.e., T is an exhaustive test.*

Surely this carries the original ideas too far. And in fact, the theorem can be understood to say, "If nothing is known about the errors in the program, a test criterion is guaranteed ideal (in the sense of Goodenough and Gerhart) if and only if it selects the entire input domain." What is probably needed to arrive at a more practical alternative is a weakening of the Goodenough and Gerhart theory. This is the general thrust of Hamlet's work, but results along these lines thus far are less than satisfactory, showing perhaps more promise toward applications to program maintenance than to testing. The interested reader should consult Ref. 9 for details.

A test selection criterion $C$ should outline the properties of a program that must be exercised to constitute a "thorough" test, ideally one whose successful execution implies an error-free program. Following Goodenough and Gerhart once again, we may suppose that $C$ is described as a finite set $\{c\}$ of *test predicates* (i.e., logical conditions on

the input data), and we then choose $T$ subject to the condition(s):

$$C(T) \Leftrightarrow \begin{array}{l}\text{for all } c \text{ in } C, \text{ there is } t \text{ in } T \text{ with } c(t) \\ \text{for all } t \text{ in } T, \text{ there is } c \text{ in } C \text{ with } c(t).\end{array} \qquad (*)$$

In words, every test predicate belonging to $C$ should be satisfied by at least one test datum $t$ in $T$, and conversely, every $t$ in $T$ must satisfy at least one test predicate.

It is suggested that the test predicates be derived from the program specifications—this is the essence of the *functional approach* (or "black box" approach) to testing. But the claim is made[7] that to have a reasonable chance of constituting a reliable criterion, $C$ must be composed of test predicates satisfying (at least) the following set of conditions:

*Condition 1:* Every individual branching condition in the program must be represented by an equivalent test predicate.

*Condition 2:* Every potential termination condition (e.g., error, overflow, etc.) must be represented by a corresponding test predicate.

*Condition 3:* The range of every variable appearing in a test predicate must be partitioned into classes that are "treated in the same way" by the program.

*Condition 4:* Every condition relevant to the proper functioning of the program that is implicit in the program specification or of one's knowledge of the program must be represented by a corresponding test predicate.

*Condition 5:* The test predicates must be "independent," in that all data satisfying a particular test predicate must exercise the same path in the program and must test the same branch conditions.

We note that only the second and fourth of these conditions are of a "functional" nature. The others are "structural," that is, relating more to the topology of the underlying flowchart. It would seem, therefore, that any reasonable testing strategy should address both points of view.

Consider the following example, the often cited problem of classifying triangles:

Specification:

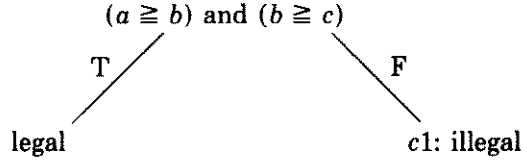
*Input:* Three positive integers $a \geqq b \geqq c$.

*Output:* An indication as to whether:

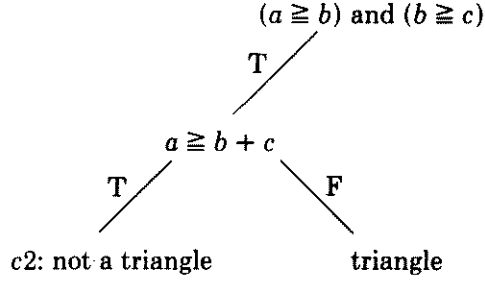
1. They do not represent the sides of a triangle
2. They are the sides of an equilateral triangle
3. They are the sides of an isosceles triangle
4. They are the sides of a scalene right triangle
5. They are the sides of a scalene obtuse triangle
6. They are the sides of a scalene acute triangle.

This problem is especially well suited to the "functional" approach.

Since the whole purpose of the problem is to classify its input domain, there is an obvious specification-based derivation of test predicates. We may first divide the universe of triples $(a, b, c)$ into legal and illegal forms:



For the legal entries, we may further distinguish two cases:



and the triangles may then be subdivided into six subclasses:

$c3 : (a = b)$ and $(b = c)$ equilateral
$c4 : (a = b)$ and $(b > c)$ isosceles
$c5 : (a > b)$ and $(b = c)$ and $(a < b + c)$ isosceles
$c6 : (a > b)$ and $(b > c)$ and $(a*a = b*b + c*c)$ right scalene
$c7 : (a > b)$ and $(b > c)$ and $(a*a < b*b + c*c)$ acute scalene
$c8 : (a > b)$ and $(b > c)$ and $(a*a > b*b + c*c)$ and $(a < b + c)$ obtuse scalene.

If we set $C = \{c(i) : i = 1 \text{ to } 8\}$ and choose one triple from each input subdomain, we may obtain the test set:

$t1 = (1, 2, 3)$
$t2 = (14, 6, 4)$
$t3 = (1, 1, 1)$
$t4 = (2, 2, 1)$
$t5 = (3, 2, 2)$
$t6 = (5, 4, 3)$
$t7 = (6, 5, 4)$
$t8 = (4, 3, 2).$

Such a test set will automatically satisfy $(*)$ and the test selection criteria will more than likely meet Conditions 2 and 4 above. But we have no guarantee that the "structural" conditions 1, 3, 5 will be met, since we haven't looked at the program!

Weyuker and Ostrand[10,11] have made the cogent suggestion that the input domain be partitioned *both* on the basis of the specification-driven, program-independent properties mentioned above, and on the structural properties of the program as well. It seems that this is the only way to meet all five of the Goodenough and Gerhart conditions, and to thus have a chance of approaching a reliable test selection criterion $C = \{c\}$ defined by a set of test predicates.

Suppose we add a sixth (implicit) condition to the five that are outlined above, namely:

*Condition 6:* The test predicates must be "complete" in that every input of the domain $D$ must satisfy (exactly—see condition 5) one of the test predicates.

Then Conditions 5 and 6 ensure that $C = \{c\}$ defines a partition

$$\kappa = \{C\}$$

on the input domain. When we concentrate only on the problem specifications, as above, we obtain the *problem partition* consisting of *problem domains* $C$. Having a completed version of the program in hand, we may speak as well of a *path partition*

$$\pi = \{P\}$$

of the same domain $D$, where each *path domain* $P$ comprises a class of inputs that traverse the same path through the program. Thus, the path partition separates $D$ into classes of inputs that are treated the same way by the program, whereas the problem partition separates $D$ into classes that should be treated the same.

There is no assurance that these two partitions will coincide, nor is it necessary that they do. But ultimately (or at least, hopefully), the program and its algorithm all derive from the original problem specification, so we should not expect the two paritions to differ markedly. On the other hand, those differences that do exist are fruitful places to look for errors! Recognizing this, Weyuker and Ostrand have suggested that the problem and path partitions be intersected, yielding a finer partition

$$\sigma = \kappa \wedge \pi = \{C \cap P\} = \{S\}$$

of nonoverlapping subdomains $S$ of the domain $D$, and they further suggest that this be used as the ultimate test selection criterion, choosing one test case from each subdomain as before.

In the terminology of Weyuker and Ostrand,[10,11] a subdomain $S$ of $D$ is said to be *revealing* (of errors) if

$$\text{success}(s \text{ in } S) \Rightarrow \text{correct}(F, S),$$

i.e., if the successful execution of any input from $S$ implies correctness

of the program over the whole subdomain. Since the inputs of a subdomain $S$ (in the intersection above) should be and in fact are treated the same by the program, the hope is extended that these are, in essence, the revealing subdomains. A successful execution of one test datum from each of the subdomains $S$ then implies (or at least suggests) the correctness of the program over the whole domain.

Consider the "triangle classification problem" once again, and suppose we are presented with the program (flowchart) of Fig. 1 as

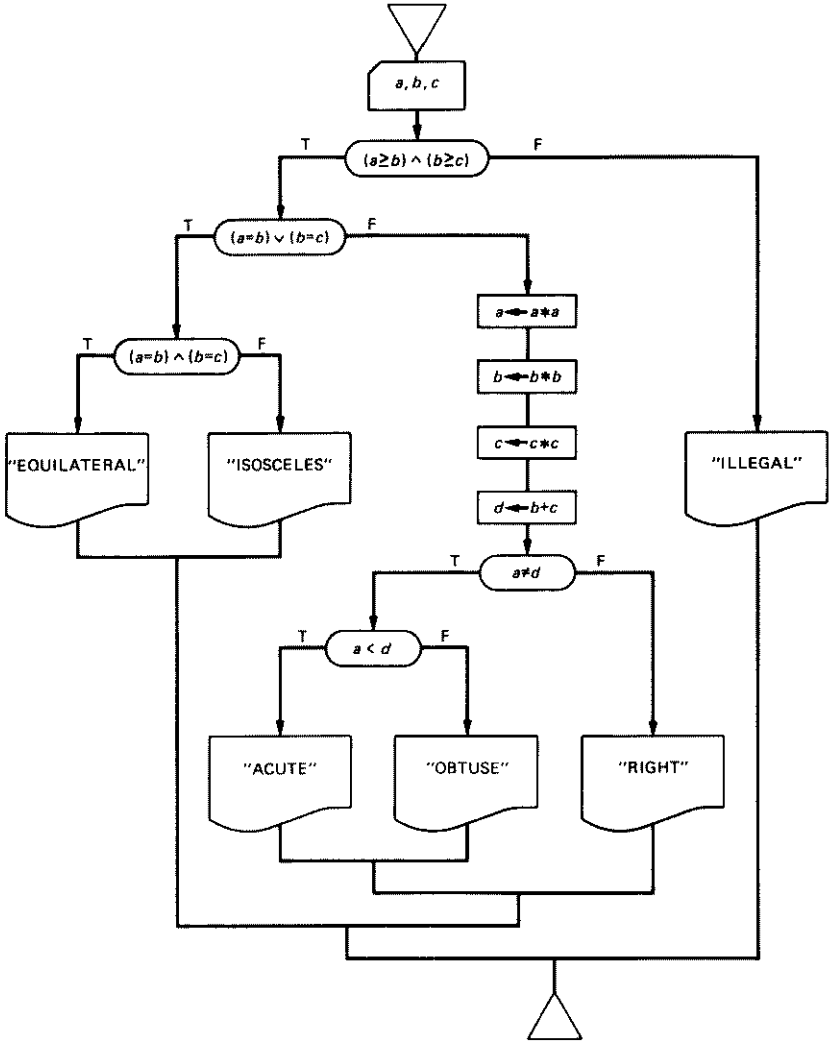


Fig. 1—Flowchart for classifying triangles.

representing a solution to the problem. There are six paths through the program, as described by the conjunctions of branch conditions defined by each path, as follows:

$p1 : \sim[(a \geqq b) \text{ and } (b \geqq c)] = (a < b) \text{ or } (b < c)$
$p2 : (a > b > c) \text{ and } (a*a = b*b + c*c)$
$p3 : (a > b > c) \text{ and } (a*a < b*b + c*c)$
$p4 : (a > b > c) \text{ and } (a*a > b*b + c*c)$
$p5 : (a \geqq b \geqq c) \text{ and } [(a = b) \text{ or } (b = c)] \text{ and } \sim[(a = b) \text{ and } (b = c)]$
$= (a = b > c) \text{ or } (a > b = c)$
$p6 : a = b = c.$

Intersecting the six corresponding path domains $P[i]$ ($i = 1$ to 6) with the eight earlier problem domains $C[i]$ results in a partition $\{S\}$ of nine subdomains characterized as follows:

$S1 = C1 = C1 \cap P1 : (a < b) \text{ or } (b < c)$
$S2 = C2 \cap P4 : (a > b > c) \text{ and } (a \geqq b + c)$
$S3 = C2 \cap P5 : (b = c) \text{ and } (a \geqq b + c)$
$S4 = C3 = C3 \cap P6 : a = b = c$
$S5 = C4 = C4 \cap P5 : a = b > c$
$S6 = C5 = C5 \cap P5 : (a > b = c) \text{ and } (a < b + c)$
$S7 = C6 = C6 \cap P2 : (a > b > c) \text{ and } (a*a = b*b + c*c)$
$S8 = C7 = C7 \cap P3 : (a > b > c) \text{ and } (a*a < b*b + c*c)$
$S9 = C8 = C8 \cap P4 : (a > b > c) \text{ and } (a*a > b*b + c*c)$
$\text{and } (a < b + c)$

in very close agreement with the problem partition $\{C\}$ obtained earlier.

The problem we are discussing has a rather precise functional specification so that we would expect that the problem and path partitions might nearly coincide. Nevertheless, there is a slight discrepancy, and in place of the test datum $t2 = (14, 6, 4)$ we would now have to choose two, say (14, 6, 4) and (3, 1, 1). A test of the resulting nine data points would then reveal two errors, as shown in Table I below.

Table I—Test of nine data points

| Domain | Test Data | Correct Output | Actual Output |
|---|---|---|---|
| $S1$ | (1, 2, 3) | Illegal | illegal |
| $S2$ | (14, 6, 4) | Not a triangle | obtuse |
| $S3$ | (3, 1, 1) | Not a triangle | isosceles |
| $S4$ | (1, 1, 1) | Equilateral | equilateral |
| $S5$ | (2, 2, 1) | Isosceles | isosceles |
| $S6$ | (3, 2, 2) | Isosceles | isosceles |
| $S7$ | (5, 4, 3) | Right | right |
| $S8$ | (6, 5, 4) | Acute | acute |
| $S9$ | (4, 3, 2) | Obtuse | obtuse |

The programmer has failed to take account of those situations where $a \geqq b + c$ (not a triangle). And our test criteria are able to detect such errors. In fact, so detailed is the specification for this example that a test set based on the problem partition alone would have served equally well.

In spite of the obvious relevance of the ideas presented here, particularly those of Weyuker and Ostrand, a good deal of work remains to be done to apply the theory to a wide class of programs. One of the more important tasks is to find more systematic methods for constructing the problem partition. This will not be easy, since finding a good problem partition is quite similar to the task of creating the program itself. It is suggested, however, that the development of formal specification languages would be helpful here, particularly if such developments are made with a specification-driven testing methodology in mind, along the lines presented here.

An equally important consideration when thinking of applying the above theory to larger programs is that of obtaining the domains of the path partition. How are the paths to be described, generated, and selected with programs of increasing size and complexity? It is certainly clear that our one example is misleading in this respect. We had only a small number of paths to consider, whereas a typical program of any size will have a very large number of paths, most likely an infinity of paths, owing to the presence of loops. If our test is still to be finite, how do we then choose paths judiciously? How are they described? And most importantly, how do we generate test cases that will traverse these paths, if indeed this is possible? These are some of the questions that we begin to address in the following sections.

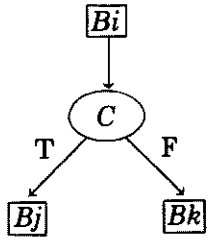
## III. GENERAL THEORY—THE STRUCTURAL APPROACH

In a *structural approach* to the theory of testing, a program $F$ is represented by a "skeleton" of its underlying flowchart, a directed graph symbolizing the flow of control. This point of view is advanced most effectively in the extremely lucid survey paper by Huang.[12] We should keep in mind, however, that the flowchart graph must be an accurate representation of the program flow in the code itself. Ordinarily, this is ensured through the use of a "tool" that automatically generates the flowgraph from the source program listing.

Using Huang's terminology,[12-14] a *program block* is a maximal sequence of program statements having the property that if the first member of the sequence is executed, then all other statements in the sequence will also be executed. A *program graph* $F = (V, E)$ is then a directed graph with vertex set $V$ and edge set $E$, where each vertex is associated with a program block and in which there are pairs of edges:

$(i, j)$ labeled by the condition $C$
$(i, k)$ labeled by the condition $\sim C$

according as the flowchart segment:



encountered for blocks *Bi*, *Bj*, and *Bk*. (For convenience, we permit an empty block as a vertex in good standing, e.g., for treating an "if ··· then ···" statement with vacuous "else" clause.) It is further assumed that the graph has a single entry point, the *start vertex*, and a single exit point, the *stop vertex*, and that every vertex lies on some path from 'start' to 'stop.'

A *path* in a (program) graph is defined in the usual way, as a sequence of edges

$$p = e1, e2, \cdots, en,$$

though we ordinarily assume as well that we begin the sequence at 'start' and end at 'stop.' Each such path has an associated *path predicate*

$$P = P1 \wedge \cdots \wedge Pn$$

written as a conjunction of the individual interpreted branch condition labels on the edges $e$, as discussed below (see Section V). The path predicates $P$ are to be identified in one-to-one correspondence with the path domains of the previous section. Thus we may write (somewhat ambiguously):

$$D = \cup P \quad \text{for} \quad P = \{d \text{ in } D : P(d)\}$$

so that the program function $F : D \rightarrow R$ is a union of functions $F(P)$: $P \rightarrow R$ restricting $F$ to the individual path domains $P$.

In structured testing, we examine the program (as a digraph) and we seek to choose a finite set of paths that will cover the program with a certain degree of thoroughness. It is then hoped that test data causing the program to be successfully executed when traversing these paths are sufficient to warrant our confidence in the program's correctness. The theoretical underpinnings of such a testing plan have been studied by Howden,[15–18] who relates his work to the earlier study by Goodenough and Gerhart.[7] Rather than speaking of a "test criteria," however, Howden refers to a *testing strategy*, as a uniform computable function

$$(F : D \rightarrow R) \xrightarrow{H} (T, \text{ subset of } D)$$

that associates with each program $F$ a finite test set $T$ of $D$. $H$ is said to be an *ideal strategy* if each $T = H(F)$ is an ideal test (for every program $F$). As is so often the case with testing theory, the first result is of a negative character:

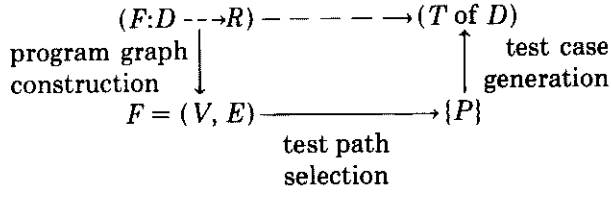
*Theorem (Howden): An ideal testing strategy does not exist.*

Nevertheless, Howden was able to show that "path testing" can be a reliable approach, at least for detecting certain types of errors. He takes the view that the program being treated is a member of a class of programs differing only as to whether they are correct, and for which the incorrect programs have errors of various (known) types. His objective was then to find, if possible, a restricted set of programs for which certain forms of structured testing (i.e., path testing) would be reliable. Typical of Howden's results is that which assumes that the error in a program does not change its control flow, i.e., that the set of path domains is not affected.

*Theorem (Howden): Path testing is a reliable method for distinguishing correct from incorrect programs, as long as the errors of incorrect programs do not affect the path partition.*

Of course, there are theoretical limitations in applying results such as this, since Howden has in mind our choosing one test datum from each path domain $P$, and these may be infinite in number. On the other hand, he has also devised a classification of error types that can be expected to lead to new insights into the testing problem generally. The reader should consult Howden's work (particularly Refs. 16 and 17) for further detail.

In a practical test setting, we require that the subset $T$ of $D$ be finite. Moreover, if we are speaking of a "path testing strategy," the above schema will be decomposed into the three-stage process,



summarized as follows:

1. Program graph construction
2. Test path selection
3. Test case generation.

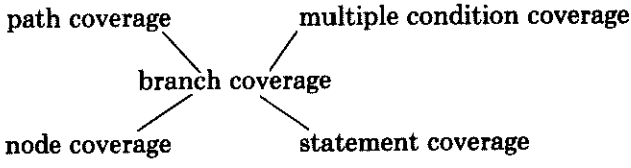
The first phase of the process, to construct the program graph from a source code listing, is fairly straightforward, and for most of the conventional programming languages, e.g., FORTRAN, Pascal, etc., such implementations are already in existence.

As a matter of fact, implementations of testing tools are in various stages of development for treating the entire process outlined above (e.g., see Clarke[19]). But, as we shall see, there are serious problems associated with the latter stages of any proposed implementation along these lines. There are many alternative strategies to choose from, and seemingly, none of these is best for all situations. All we can do at this point is to outline the several alternatives and comment on their general suitability. We begin by introducing the various path selection criteria, continuing this discussion in the next section. The last, and perhaps the most difficult, of our three subprocesses, the generation of test data, is treated in Section V.

There are, as we have indicated, a number of path selection criteria that can be used in attempting to devise a testing strategy that will provide a reasonable coverage of a program graph. Among these criteria are:

1. *Statement coverage*: Execute all statements (blocks) in the graph.
2. *Node coverage*: Encounter all decision node entry points in the graph.
3. *Branch coverage*: Encounter all exit branches of each decision node in the graph.
4. *Multiple condition coverage*: Achieve all possible combinations of condition outcomes at each decision node of the graph.
5. *Path coverage*: Traverse all paths in the graph.

These five strategies are related in their strength of coverage as shown below:



with the weaker criteria at the bottom and the stronger criteria at the top.

As an example illustrating the differing requirements of these criteria, consider the flowchart segment (program graph) shown in Fig. 2. In order to achieve node coverage, the single test:

$$abe\text{: } A = 2, B = 1, X = 1$$

will suffice (but it will not achieve statement coverage because the assignment $X \leftarrow X/A$ will not have been executed). On the other hand, the single test:

$$ace\text{: } A = 2, B = 0, X = 3$$

will be sufficient for complete statement coverage (and node coverage

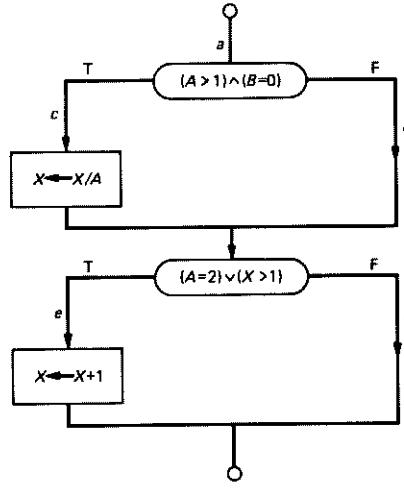


Fig. 2—Flowchart segment illustrating coverage criteria.

as well). For branch coverage, however, at least two tests would be required, e.g.,

$$acd\text{: } A = 3, B = 0, X = 3$$
$$abe\text{: } A - 2, B = 1, X = 1.$$

In the multiple condition coverage criterion, there are 2*2 + 2*2 or 8 outcomes to achieve in combination for the two simple conditions at each decision node. These may be satisfied, for example, by the selection of four separate tests, e.g.,

$$ace\text{: } A = 2, B = 0, X = 4$$
$$abe\text{: } A = 2, B = 1, X = 1$$
$$abe\text{: } A = 1, B = 0, X = 2$$
$$abd\text{: } A = 1, B = 1, X = 1.$$

The first test satisfies the conditions $A > 1, B = 0$ in the first decision and $A = 2, X > 1$ in the second decision. The second test ensures that $A > 1, B \neq 0$ for the first decision and $A = 2, X \leqq 1$ for the second decision. Further analysis shows that all eight combinations are achieved. For the path coverage criterion to be met, we again require four tests, e.g.,

$$ace\text{: } A = 2, B = 0, X = 4$$
$$acd\text{: } A = 3, B = 0, X = 3$$
$$abe\text{: } A = 1, B = 0, X = 2$$
$$abd\text{: } A = 1, B = 1, X = 1.$$

Note, however, that this test set would not satisfy the multiple condition coverage criterion.

It is clear that "statement coverage" and "node coverage" are in themselves rather weak strategies for testing, representing necessary but by no means sufficient criteria for a reasonable structural test. The "branch coverage" criterion, however, implies the other two (as seen in the diagram above) and has come to be regarded as a minimal standard of achievement in structure-based testing. The stronger criteria of "multiple condition coverage" and "path coverage" are difficult to achieve in a program of any complexity. In fact, the path testing criterion is usually relaxed to the extent that only "equivalence classes" of paths are represented. In a program of any size, particularly in the presence of program loops, there is a virtual infinity of paths through the program graph. Two paths are then considered "equivalent" if they differ only in their number of loop traversals. One then chooses only one representative from each such equivalence class in devising a test set. But still, this *modified path coverage* criterion is difficult to achieve in practice.

A survey of the literature shows that there is little common agreement as to what would be considered as an 'adequate' structural test criterion. As we have noted, the "branch coverage" criterion has been widely recognized as a basic measure of testing thoroughness. This is evidenced by the fact that most of the major software testing tools in existence or in development do indeed include some provision for achieving this particular test goal. The disagreement seems to be in deciding how much more (or less) is needed beyond this basic requirement to entitle a structural testing strategy to be considered adequate.

If total branch coverage is indeed used as a measure of testing thoroughness, a simple calibration scheme can be invoked, using a set of *software counters.* One "prepares" the program for testing by inserting counters at appropriate points in a modified copy of the program, and after running through the test set, one can determine the degree of thoroughness from a listing of the resulting counter values. This is the method of *test instrumentation.* We first define a *decision to decision* (DD) *path* of a program to be a sequence of a statements leading from a decision box (or the "start" node) to a decision box (or the "stop" node), having no intervening decisions. To determine whether every branch of our program has been encountered at least once (branch coverage) in our testing, it is sufficient to insert a counter at the 'head' of each DD path.

Consider the classical flowchart solution (Fig. 3) to the problem of computing $z =$ "$x$ to the power $y$". Here, there are five DD paths:

*abc, d, efhi, gfhi, jk*

and we therefore insert our software counters at the points *a, d, e, g,*

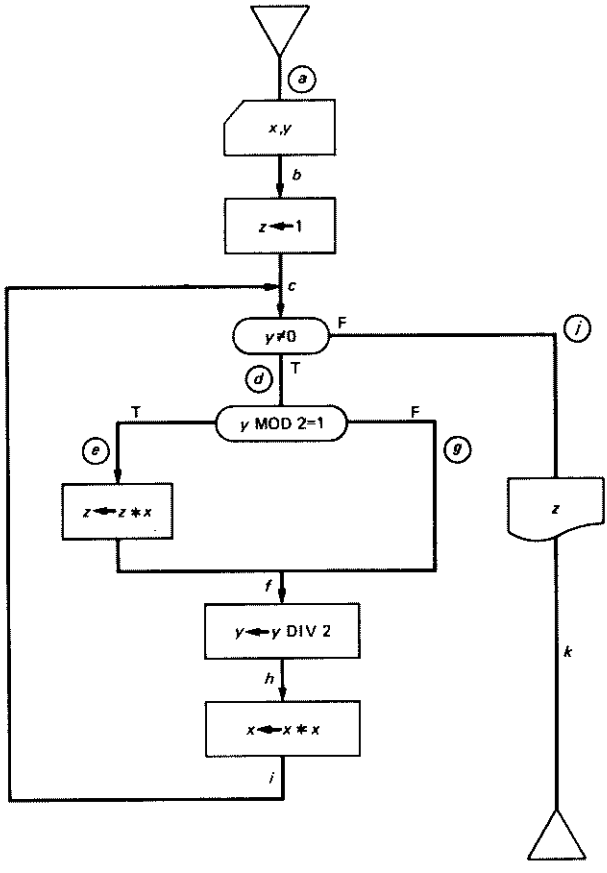

Fig. 3—Flowchart for computing $x^y$.

$j$, as shown. If we have run two test cases as shown in the table below,

| $x$ | $y$ | $a$ | $d$ | $e$ | $g$ | $j$ |
|---|---|---|---|---|---|---|
| 10 | 0 | 1 | 0 | 0 | 0 | 1 |
| 20 | 1 | 1 | 1 | 1 | 0 | 1 |

we would find that 'counter $g$' has not yet been activated. Inspection of the flowchart then shows that we need a test to traverse the path $a$, $b$, $c$, $d$, $g$, etc., requiring $y \neq 0$, $y \bmod 2 \neq 1$. So we may use $x = 24$ and $y = 2$, say, as an additional test case, thus ensuring complete branch coverage. Ideally, this latter phase, directing the tester to the area of untested code, would also be automated.

Of course, we would like to automate as much of the testing methodology as possible, recalling the three-stage process mentioned earlier. On the other hand, in lieu of a complete mechanization, the testing

instrumentation scheme presented here can be of great help in isolating areas in need of further testing. Furthermore, it can be argued that for the little extra cost entailed, it is a worthwhile investment in any testing process, fully automated or not. [Parenthetically, we might note as an indication of the expense associated with the development of testing tools generally, that a package that does little more than "test instrumentation," as described here, has been announced recently (Computer, May 1982) by Management and Computer Services, selling for $12,000.00!.] It may be that some other criterion than "branch coverage" is being used as a measure of test thoroughness. It is still good practice to be concerned as to what extent this standard measure is being met. Moreover, it is reasonable to suppose that the "instrumentation concept," as exemplified here, might generalize to settings where other thoroughness criteria are being used.

## IV. TEST PATH SELECTION

As we have indicated, there are a number of criteria that can be used in selecting program paths to achieve an adequate testing coverage. But the question then becomes: How do we automatically generate a collection of paths meeting a given criterion? The literature is somewhat "hazy" on this point. Perhaps the most explicit treatment of the problem is that of Paige,[20–22] in reference to programs built up from a strict adherence to the structured programming methodology. In fact, we know of no more general approach to the problem, one that would handle structured or unstructured code in relation to the whole spectrum of path selection criteria.

Recall that a *structured program* F is one that has been built up inductively from certain "simple statements" as a base (typically, the assignment, input and output statements, and procedure calls), using only the three familiar constructs:

1. *Sequence:* begin $P1$; $P2$; $\cdots$ ; $Pn$ end
2. *Selection:* if $C$ then $P$ else $Q$
3. *Repetition:* while $C$ do $P$

for structured (but possibly themselves compound) statements $Pi$, $P$, $Q$, respectively. The resulting program graph $F = (V, E)$ is then of a correspondingly restricted form, greatly facilitating the path analysis problem. Perhaps collapsing sequences of simple statements to a single block (graph node), one may then use a "regular expression" $r(F)$ to characterize the program flow, associating

1. The '$\cdot$' operator to sequences
2. The '+' operator to selections
3. The (Kleene) '*' operator to repetitions,

respectively.

For example, if $F$ is the (structured) program graph shown in Fig.

4, we have

$$r(F) = a(b(d + e)(k + 1) + c(f + g(h(i + j))^*m))$$

as the corresponding regular expression. Note the loop $(h(i + j))^*$ resulting from a "while" statement.

We have mentioned earlier, in reference to the modified path coverage criterion, how an equivalence relation is often used to obtain a finite representation of the path alternatives in the presence of loops. Accordingly, if we make the substitution $x^* = x + 1$ (1 = null) in the regular expression $r(F)$, we acknowledge that a loop is either executed or not. Multiplying out so as to obtain a "sum of products" expression, one then obtains the desired collection of paths satisfying the modified path coverage criterion, e.g.,

| | |
|---|---|
| *abdk* | *acf* |
| *abdl* | *acghim* |
| *abek* | *acghjm* |
| *abel* | *acgm* |

in reference to the program graph of Fig. 4. On the other hand, it does not appear that this technique can be extended to handle unstructured programs.

But if we continue to deal with a structured program graph, we can describe a method for deriving a minimum number of paths sufficient to meet the "branch coverage" criterion. We assign a set of paths $S(r)$ to each regular expression $r = r(F)$ inductively, as follows. We let $S(a) = \{a\}$ for each simple statement $a$, and then, assuming that $S(r)$

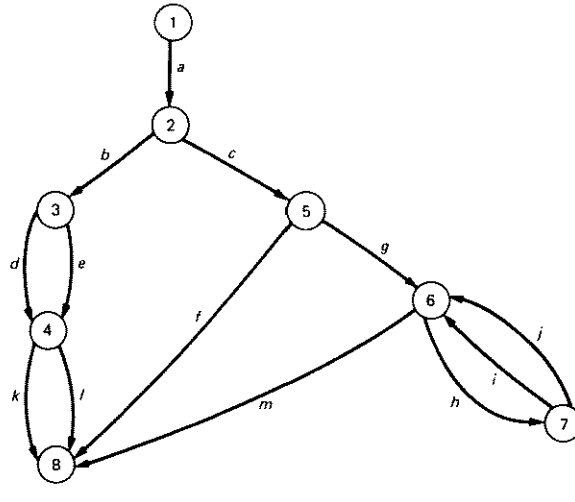

Fig. 4—Structured program graph illustrating modified path coverage criterion.

and $S(t)$ have been defined, for regular expressions $r$ and $t$, we set:

1. $S(r \cdot t) = S(r) \cdot S(t)$
2. $S(r + t) = S(r) \cup S(t)$
3. $S(r^*) = S(r)^*$.

Here, $S(r)^*$ is the singleton set obtained by concatenating (in any order) all of the paths in $S(r)$, and similarly, the set product $S(r) \cdot S(t)$ is obtained by concatenating paths in $S(r)$ with those in $S(t)$—but retaining only enough products so that each of the factors from $S(r)$ and $S(t)$ are represented. It follows that

1. $|S(r \cdot t)| = \max\{|S(r)|, |S(t)|\}$
2. $|S(r + t)| = |S(r)| + |S(t)|$
3. $|S(r^*)| = 1$.

By way of illustration, in considering once again the example from Fig. 4, we may compute:

$$S(i + j) = \{i, j\}$$
$$S(h(i + j)) = \{hi, hj\}$$
$$S((h(i + j))^*) = \{hihj\}$$
$$S(g(h(i + j))^*m) = \{ghihjm\},$$

etc., and finally,

$$S(r) = \{abdk, abel, acf, acghihjm\},$$

yielding four paths that together cover all of the branches of the program.

Once again, as in the case of the previous algorithm, there seems to be no easy extension of this technique that would handle unstructured programs as well. However, a general *upper bound* is readily available regarding the number of paths necessary for total branch coverage. Whether our program is structured or not, we make the observation that if a test path reaches a particular node of the program graph, then it must exit this node through one of the (two) branches leaving the node. If the graph $F$ has $e$ edges and $n$ nodes, it follows that

$$v(F) = e - (n - 2) = e - n + 2$$

is an upper bound on the number of paths necessary to achieve total branch coverage. Coincidentally, this is the formula for McCabe's *cyclomatic complexity measure*,[23] a figure that has proved to be useful in estimating overall "program complexity". At the same time, the graph theoretic derivation of a program's "independent" circuits (paths) yields a branch covering of paths, $v(F)$ in number—though generally somewhat in excess of the minimum number of paths that would be required. In the context of our running example, we have

$v(F) = 13 - 8 + 2 = 7$ and a corresponding set of *basis paths*:

$$\begin{array}{ll} acf & acgm \\ abdk & acghim \\ abek & acghjm. \\ abel & \end{array}$$

Note that the single path *abdl* from our "path coverage" list that is not present here is itself a linear combination of paths already listed. Note as well that we obtain seven paths here, whereas we know from the preceding analysis that four paths will suffice (for branch coverage).

The whole notion that McCabe's *basis of program paths* should constitute a goal of program testing has attracted considerable attention, and we feel obliged to comment on this point. Perhaps this is best done by listing what we think are the pros and cons to the approach. On the positive side, we cite the following:

1. The method is sufficiently general as to be applicable to both structured and unstructured programs.
2. The resulting "basis" does indeed ensure total branch coverage.
3. The paths of a basis are feasibly computable, using standard graph theoretic techniques.

On the other hand, these aspects must be counterbalanced with the following:

1. A single basis is not uniquely determined—there are many, and we must make a choice.
2. The number $v(F)$ of paths in a basis can greatly exceed the minimum number of paths required to achieve branch coverage.
3. The notion that, in some sense, *every* path in the program graph is accounted for by our having selected a basis is somewhat specious.

Note that we do not comment here on the inadequacies of McCabe's $v(F)$ as a measure of overall program complexity—we leave this discussion to a separate paper. On the other hand, the arguments for and against the use of the associated "basis of program paths" as a testing strategy are inconclusive at best, particularly in comparison with the "level paths" of Paige[21,22] that we now describe.

In a program graph $F = (V, E)$, a *level-0 path* is a simple (acyclic) path from "start" to "stop". In effect, these paths trace the "fall through" conditions in the program. Then, inductively, a *level-i path* ($i > 0$) is a simple path (perhaps a circuit) that begins and ends on nodes of a path of lower level, but has none of its other nodes previously appearing on paths of a lower level. Intuitively, the level-$i$ paths for $i > 0$ account for program loops of increasing nesting level and for feedback paths, etc., in the case of an unstructured program.

Considering our earlier structured program graph (Fig. 4) and the

unstructured program graph of Fig. 5, we tabulate the respective level-$i$ paths as shown in Tables II and III.

In any case, we are able to say that a given level-$(i + 1)$ path is "associated with" a certain level-$i$ path according as the given path begins and ends on nodes of the parent path. This relationship orders the level paths in a tree-like structure, in such a way that one can readily construct test paths that again effect a total branch coverage. In so doing, only level paths that associate can be combined to form a program test path. Thus, for example, in the case of the program graph of Fig. 4 above, we may construct the path *acghihjm* as the linear combination:

$$acghihjm = (6) + (7) + (8)$$

using the notation in Table II.

It is clear that the level paths of a program graph span the space of

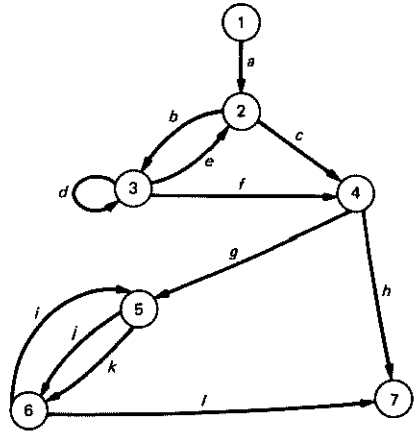

Fig. 5—Unstructured program graph.

Table II—Level-$i$ paths for structured program graph (see Fig. 4)

| Level | Level Paths | $V[i]$ | $E[i]$ |
|---|---|---|---|
| −1 | | {1, 8} | 0 |
| 0 | (1) *abdk*<br>(2) *abdl*<br>(3) *abek*<br>(4) *abel*<br>(5) *acf*<br>(6) *acgm* | {2, 3, 4, 5, 6} | {*a*, *b*, *c*, *d*, *e*, *f*, *g*, *k*, *l*, *m*} |
| 1 | (7) *hi*<br>(8) *hj* | {7} | {*h*, *i*, *j*} |

Note: The sets $V[i]$ and $E[i]$ of vertices and edges at level-$i$ are useful in the computation of the level-$(i + 1)$ paths.

Table III—Level-$i$ paths for unstructured program graph (see Fig. 5)

| Level | Level Paths | $V[i]$ | $E[i]$ |
|---|---|---|---|
| −1 | | {1, 7} | 0 |
| 0 | (1) *acgjl*<br>(2) *acgkl*<br>(3) *abfgjl*<br>(4) *abfgkl*<br>(5) *ach*<br>(6) *abfh* | {2, 3, 4, 5, 6} | {*a*, *b*, *c*, *f*, *g*, *h*, *j*, *k*, *l*} |
| 1 | (7) *d*<br>(8) *e*<br>(9) *i* | 0 | {*d*, *e*, *i*} |

Note: The sets $V[i]$ and $E[i]$ of vertices and edges at level-$i$ are useful in the computation of the level-$(i + 1)$ paths.

program paths. But taken together, they do not usually constitute a basis. Thus, again in Fig. 4 above, we have eight-level paths, whereas we know from our previous analysis that this graph has rank $v = 7$. On the other hand, Paige's level paths have a definite uniqueness, an advantage over the notion of a basis as developed by McCabe, and leading to a graduated *level path testing strategy* as follows:

1. First test all level-0 paths—in effect, keeping all loops in the "nonexecuting" mode.
2. Next test all level-1 paths, reaching them through their associated level-0 paths, etc.

The result is a highly structured testing strategy where segments of the program are treated in successive layers of nesting depth.

The level path testing strategy provides for a rather exhaustive treatment of a program's path structure at successive depths of nesting. In this sense, the approach has a potential thoroughness rivaling that of the "modified path coverage" criterion. On the other hand, Paige's strategy is readily applicable to both structured and unstructured programs. At the same time, his method lends itself to a convenient algorithmic solution,[22] though one must be prepared to compute all simple paths (or circuits) between various identified pairs of nodes, along edges not previously used—most likely requiring the use of a "depth first search" strategy. Except for this computational difficulty, the approach is quite orderly; it provides for a more thorough testing than simple branch coverage, and it compares favorably against McCabe's "basis of program paths" in that:

1. The level paths are uniquely determined.
2. The number of level paths will exceed $v(F)$.
3. The notion that somehow every path in the program graph is accounted for by our successive treatment of its levels has a good deal more credibility.

In conclusion, it must be noted that all of the methods we have discussed for selecting program test paths are subject to one overriding criticism. There is absolutely no assurance that the paths selected will be *feasible*, i.e., executable with an appropriate choice of input data. We suggest that this problem becomes more serious (and is surely more difficult to analyze) in the case of paths selected in an attempt to minimize the number required for branch coverage. Paige's "level path" strategy would seem to be easier to handle in this respect, since we build up paths from the simple to the more complex, starting with those that are more likely to be feasible.

## V. TEST CASE GENERATION

The whole question of path feasibility is related to the "test case generation" problem. This is the one remaining phase to be discussed of the three that were outlined in the rectangular problem-decomposition paradigm of Section III. Considering the question of feasibility, however, we can see that it is difficult to so trichotomize the automation of the overall testing program. Though useful as a paradigm, we must admit that this partition of the problem is overly idealistic in relation to the real world of program testing that we are likely to encounter.

Suppose we have selected a set of program paths because they meet one or another of the test coverage criteria, or for whatever reason. There still remains the problem of generating corresponding test cases that will drive the program through the indicated paths. This again turns out to be a nontrivial (and in some cases, unsolvable) problem. All we can do at this point is to summarize the approaches that have been taken by researchers in the field and to give a few suggestions that might aid in developing a workable methodology.

Perhaps the most comprehensive treatment of the problem is that of Clarke.[19,24,25] Consider a single path $p$ from "start" to "stop" through a program $F = (V, E)$, again viewed as a directed graph. We intend to show how $p$ may be characterized as a *path predicate*, i.e., a logical condition

$$P = P1 \wedge P2 \wedge \cdots \wedge Pn$$

expressed as a conjunction of "interpreted" branch conditions derived from the labels on the edges of $F$. Inductively, we may think of $p$ as having developed as a sequence of "partial paths:"

$$p(k) = (v[0] = \text{start}, v[1], \cdots, v[k])$$

leading from "start" to some intermediate vertex $v(k)$ on the way to

"stop". Correspondingly, we may give an inductive derivation of the path predicate, writing $P(0) = \text{true}$ and

$$P(k) = P(k-1) \wedge ibp(v[k-1], v[k]),$$

where the latter conjunct is the *interpreted branch predicate* associated with the transition from vertex $v[k-1]$ to $v[k]$. More precisely, $ibp(e)$ for an edge $e$ labeled with the Boolean condition $C$ will be computed by substituting (in $C$) the current "symbolic values" of all variables according to their updating along the partial path $p(k)$.

For example, consider the flowchart solution (Fig. 6) for estimating the point where a function $f$ takes on its maximum value. For the path

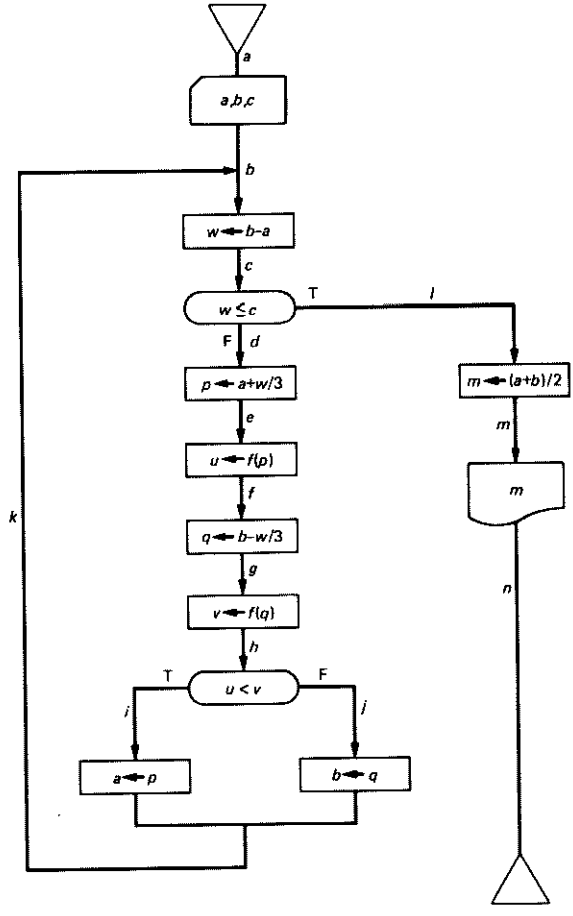

Fig. 6—Flowchart for estimating the point where a function is maximized.

$p = abclmn$, we compute

$$\begin{aligned} P(0) &= \text{true} \\ P(1) &= P(0) \wedge \text{true} = \text{true} \\ P(2) &= P(1) \wedge \text{true} = \text{true} \\ P(3) &= P(2) \wedge (b - a \leqq c) = (b - a \leqq c) \\ P(4) &= P(3) \wedge \text{true} = (b - a \leqq c) \end{aligned}$$

and finally,

$$P = P(5) = P(4) \wedge \text{true} = (b - a \leqq c),$$

noting that it was necessary to substitute $a - b$ for $w$ in the condition for traversing edge 1 because of the earlier assignment statement.

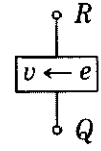
In general, this process of continually updating the symbolic values of program variables as we proceed along a path is called *symbolic execution* (or *symbolic evaluation*). The data descriptions generated in symbolic execution provide a precise representation of the changing *program state*. Initially, the program state is the three-place vector:

$$\begin{aligned} \text{state} &= [\text{start, values (start), pathpred (start)}] \\ &= (\text{start, } (\perp, \perp, \cdots, \perp), \text{true}), \end{aligned}$$

where "values" tabulates the symbolic values of all program variables ($\perp$ = undefined), and "pathpred" stores the inductively generated path predicate $P$ as described earlier. Symbolic names are assigned (in "values") to input variables whenever a read statement is encountered on the program path. Throughout the symbolic evaluation, all symbolic representations of variable and branch predicate values are then expressed in terms of these symbolic names, as representatives of input values. In particular, as one encounters an assignment statement ($v \leftarrow e$), the symbolic value of the program variable $v$ is updated (as in the example above) through substitution of the symbolic value of the expression $e$. In this way, "state" and especially the "values" vector will provide a continually updated snapshot of the program's development along the path. Moreover, the final value of the "pathpred" component of "state" provides the logical conjunction described above.

This path predicate $P$ defines a corresponding (path) subdomain of the input space $D$, and by the nature of the symbolic evaluation technique, $P$ is expressed as a set of conditions on the input variables alone. To generate a test case (of input data) that will cause the program to traverse the path $p$, it is then only necessary to find input values that satisfy all of these conditions. As we might expect, however, this is often easier said than done.

Before discussing this problem in any detail, it is better that we first describe an alternative to the above approach, one that proceeds in reverse—from the end of the path to its beginning. This technique, known appropriately as *backward substitution*, is best described in the survey paper by Huang.[12] To traverse a path $p$, certain conditions must be met, i.e., the set of branch conditions ($C$ or $\sim C$) along the path must be satisfied as they are encountered. On the other hand, suppose that an assignment statement ($v \leftarrow e$) intervenes, between "start" and the predicate $Q$, the latter representing a given branch condition (though modified by "partial backward substitution" as we are now describing). In the following flowchart segment:



if we want $Q$ to be true after the assignment ($v \leftarrow e$) has been executed, then the predicate $Q(v \leftarrow e)$ must be satisfied prior to its execution. Here, $Q(v \leftarrow e)$ is the predicate obtained by substituting the expression $e$ for each occurrence of $v$ in $Q$ [and we speak of $Q(v \leftarrow e)$ as the predicate obtained by *dragging* $Q$ *backward* through the indicated assignment statement]. It follows that the conjunction

$$R \wedge Q(v \leftarrow e)$$

is necessary for our passage along the edge with condition $R$ (through the assignment) and then to satisfy $Q$.

Altogether, if we want the specific path $p$ to be traversed in a program's execution, then we must drag each of its edge conditions backward to "start", and the conjunction of all resulting predicates must be satisfied by the corresponding test case of input data. Note once again that we obtain in this way a corresponding path predicate:

$$P = P1 \wedge P2 \wedge \cdots \wedge Pn,$$

i.e., a conjunction of modified branch conditions, each expressed in terms of the input variables to the program.

Consider once again the example of Fig. 6, and suppose we wish to traverse the path *abcdefghikclmn*. The listing shown below traces the dragging of the three necessary branch conditions backward along this

path:

| | | | |
|---|---|---|---|
| $l$ | $w \leqq c$ | | |
| $c$ | $w \leqq c$ | | |
| $k$ | $b - a \leqq c$ | | |
| $i$ | $b - p \leqq c$ | $u < v$ | |
| $h$ | $b - p \leqq c$ | $u < v$ | |
| $g$ | $b - p \leqq c$ | $u < f(q)$ | |
| $f$ | $b - p \leqq c$ | $u < f(b - w/3)$ | |
| $e$ | $b - p \leqq c$ | $f(p) < f(b - w/3)$ | |
| $d$ | $b - (a + w/3) \leqq c$ | $f(a + w/3) < f(b - w/3)$ | $\sim(w \leqq c)$ |
| $c$ | $b - (a + w/3) \leqq c$ | $f(a + w/3) < f(b - w/3)$ | $\sim(w \leqq c)$ |
| $b$ | $b - a - (b - a)/3 \leqq c$ | $f(a + (b - a)/3) < f(b - (b - a)/3)$ | $\sim(w \leqq c)$ |
| $a$ | $b - a - (b - a)/3 \leqq c$ | $f(a + (b - a)/3) < f(b - (b - a)/3)$ | $\sim(w \leqq c)$ |

One finally obtains the conjunction of three predicates:

$$P1 : b - a - (b - a)/3 \leqq c$$
$$P2 : f(a + (b - a)/3) < f(b - (b - a)/3)$$
$$P3 : \sim(b - a \leqq c)$$

all expressed in terms of the inputs $a$, $b$, $c$ (and the "called" function $f$). For purposes of comparison, the reader may try to compute an equivalent predicate using the symbolic execution method.

In an overall comparison of these two methods, one can identify an obvious "trade-off." With backward substitution, we avoid the costly storage facility needed for the continuous updating of all the symbolic program variable values. On the other hand, an important advantage accrues to the symbolic execution method, one that is not available for the backward substitution technique. Namely, we are more easily able to determine whether a given path is (or will be) feasible. And we can make the determination early in the symbolic evaluation. We need only check that the inductively generated predicates $P(k)$ are noncontradictory, as far as they go. We begin with $P(0)$ = true—certainly there is no contradiction here. Then, in the expression for $P(k)$ in terms of $P(k - 1)$, we have only to see whether $ibp(v[k - 1], v[k])$ contradicts $P(k - 1)$. If so, $P(k)$ and hence $P$ itself is contradictory, and the path $p$ is infeasible. Otherwise, we keep going. Note, in comparison, that with the backward substitution method, we wouldn't know whether a path was feasible until all of the calculation (of $P$) was completed—a definite disadvantage.

One must note, however, that all such "logical satisfiability" problems as we are now beginning to consider are exceedingly difficult to handle in practice. We include here the satisfiability question that results from the use of the "backward substitution" technique or the forward "symbolic evaluation" method, whichever is used. At the

conclusion of the backward substitution, we have a system of constraints on the inputs to the problem, and unless these constraints can be "solved" for the input data, we don't have a test case at all. The same may be said for the forward symbolic execution, except for the slight advantage that we can be determining the satisfiability (or lack thereof) as we go.

Huang, in his survey paper,[12] presents a systematic approach for handling the satisfiability problem, and we now outline the major features of his plan. The simplifying assumption is made that the path predicate takes the form:

$$P = P1 \wedge P2 \wedge \cdots \wedge Pn,$$

where the $Pi$ are nonnegated atomic expressions:

$$d\ R\ e$$

with $d$, $e$ arithmetic expressions in the input variables and $R$ one of the six relational operators: $<, \leqq, =, \langle\rangle, \geqq, >$. Such a system of atomic logical expressions can readily be rewritten in the *prenex normal form*:

$$(Ex1)(Ex2) \cdots (Exn)(x1 = e1) \wedge (x2 = e2) \wedge \cdots \wedge (xn = en),$$

where the $E$'s are "existential quantifiers" on auxiliary variable $x$'s, and the new expressions (the $e$'s) are differences of $d$, $e$ above, sufficient to transform any inequalities to equalities. The inequalities are, in effect, shifted to the auxiliary variables, thereby serving to normalize the solution space. Thus, in place of the inequality $2(b - a)/3 \leqq c$ at the end of the table above, we would have $(Ex1 \geqq 0)[x1 = c - 2(b - a)/3]$. Altogether, the three inequalities of that problem are similarly transformed, and we have instead the prenex normal form:

$$(Ex1 \geqq 0)(Ex2 \geqq 0)(Ex3 > 0)$$

$$\begin{aligned} x1 &= c - 2(b - a)/3 \\ x2 &= b + 2a - 6 \\ x3 &= b - a - c, \end{aligned}$$

one that is somewhat easier to handle.

From this point, standard techniques of linear algebra can be used to further transform the system into one where a minimum number of variables are involved. Thus, in the case of our running example, we can simplify the system so as to finally obtain:

$$\begin{aligned} &(Ex1 \geqq 0)(Ex2 \geqq 0)(Ex3 > 0) \\ &\quad 3x1 - x2 + 3x3 = 6 - 3a. \end{aligned}$$

From here, one may "guess" a solution, e.g., $x1 = x2 = 0$ and $x3 = 0.1$

say. One thereby obtains:

$$a = 1.9$$
$$b = 2.2$$
$$c = 0.2,$$

an input set that will cause the program to traverse the path *abcdefghikclmn* in Fig. 6, as originally required.

If we are going to have to "guess" a solution to the feasibility question in the end, however, the outright "trial and error" approach of Ramamoorthy et al.[26] offers an attractive alternative. One makes the assumption, as before, that the path predicate $P$ is expressed as a logical conjunction:

$$P = P1 \wedge P2 \wedge \cdots \wedge Pn,$$

where each of the $Pi$ is a constraint on the program's input variables. Moreover, it is assumed that the input variables have been ordered as $v[1], v[2], \cdots, v[m]$. With each variable $v[i]$, we associate a set $S[i]$ of conjuncts from $P$, namely:

$$S[i] = \{Pj : \text{only } v[1], \cdots, v[i] \text{ occur in } Pj\}$$

and these sets are then used as the basis for the "trial and error" algorithm shown in Fig. 7.

Assuming that values have been found for $v[1], \cdots, v[i-1]$ satisfying all the conjuncts in $S[1], \cdots, S[i-1]$, we either solve for $v[i]$ or randomly choose $v[i]$, depending on whether the set $S[i]$ contains an equality relation in $v[i]$. We then substitute this value in the conjuncts of $S[i]$. Should we thereby arrive at a contradiction, we "backtrack" to the iteration $i-1$, generating a different value for $v[i-1]$. Otherwise, we go ahead to the iteration $i+1$. If the complete iteration on $i$ concludes successfully, we arrive thereby at a "satisfiable" test case for the input variables of the program; otherwise we do not. Note that the "key" to the method is the fact that at each stage $i$, only the variable $v[i]$ has not yet been resolved. Note, however, that the loop at the right of Fig. 7 must include some criterion for deciding that "enough" random numbers have been tried in the current iteration. But however this is decided, it must be conceded that such an approach as presented here has much to offer in its favor, particularly considering the difficulty of the "satisfiability" question in general.

The authors[26] provide an example of the use of their algorithm on the "triangle classification problem" considered earlier. More generally, they suggest that the method has proven to be successful in treating a much wider class of problems. We would note further that the method could conceivably be applied to the "running satisfiability" questions that arise in the use of the "symbolic execution" technique.

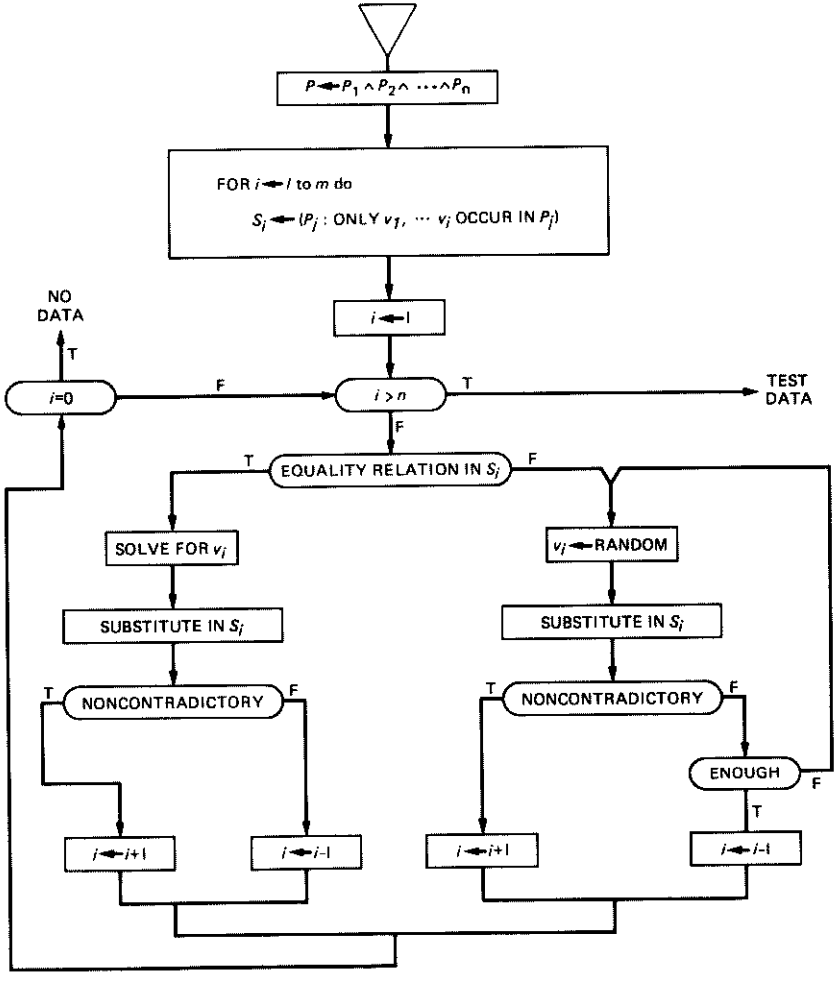


Fig. 7—Trial and error algorithm for solving the satisfiability problem.

In fact, it seems that this "trial and error" approach has a definite place—at least as a method of last resort, to be used as a component of any overall testing methodology.

Without some technique such as this, we are forced to rely on the extremely costly and not wholly reliable methods of "mathematical programming," particularly those routines that are designed to generate solutions to systems of inequalities. We cannot always assume that our systems are linear, in spite of the assumptions made by some authors. And in the absence of such an assumption, the problem is quite a difficult one, generally beyond the capability of the packages that are currently available.

Recognizing this, a most unusual and quite promising approach has been suggested by Kundu.[27] The idea is to combine the "test path selection" and "test case generation" phases of the solution, using the previous test case(s) $t[k]$ to help in determining the next test case $t[k+1]$. The result is a sequence of determinations:

$$(t[0]\rightarrow)p[0]\rightarrow t[1]\rightarrow p[1]\rightarrow \cdots$$

starting from an initial test case $t[0]$, chosen at random. The method is as follows:

1. Analyze $t[k]$: Execute the program with input $t[k]$, and determine its execution path $p[k]$. Then perform a (partial) symbolic execution of $p[k]$, so as to determine (an approximation to) its path predicate $P[k]$.
2. Select next test case: Determine the next test case $t[k+1]$ so that it violates at least one constraint in each of the path predicates $P[j]$, for $j < k$.

We are thus assured that each new test care $t[k+1]$ causes the program to traverse a genuinely new path, different from all those previously chosen.

In comparison with the previous methods we have discussed, Kundu reverses the roles of the test paths and the test data. The path $p[k]$ is determined from $t[k]$ in order to guide the next test case $t[k+1]$ away from previous paths. That is, $p[k]$ is not used for finding an input that corresponds to that path itself. Therein lies the novelty of the approach.

Moreover, Kundu's method is definitely not designed with any specific measure of test thoroughness in mind. (He asserts that no good measures of testedness are available, anyway.) It is clear, however, that one could easily augment his procedure with test instrumentation devices, as discussed earlier, for the purpose of assuring that some standard test coverage criterion (e.g., branch coverage) has been met.

The primary advantage of Kundu's method is easily understood. Consider the constraint on $t[k+1]$ as described in (2) above, i.e.,

$$t[k+1] \text{ not in } P[1] \cup P[2] \cup \cdots \cup P[k].$$

It is clear that the "forbidden region" for $t[k+1]$ thus represents only a small portion of the total input domain $D$ (see Fig. 8). This is so because the number of test cases generated in the testing activity is very small compared with the total number of executable paths in the program. Intuitively, the determination of the required $t[k+1]$ should thus be relatively easy. And for the same reason, the determination of a test datum in a given path domain (as is required in the usual strategy) should be more difficult. Kundu (see Ref. 27, pp. 176–177)

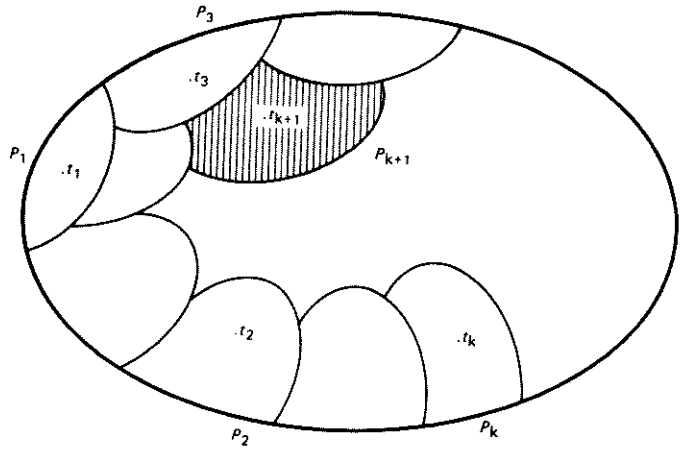

Fig. 8—Illustration of the forbidden region for selecting test cases.

gives a more detailed account of this reasoning, and the thrust of his argument is quite compelling. The reader may wish to consult Kundu's article for these additional details.

## VI. CONCLUDING REMARKS

We have attempted to describe the many interesting and varied approaches to the program testing problem. Whereas no single approach to the problem may hold all the answers, it seems that there are enough good ideas around as to suggest the feasibility of a workable methodology, based on one or another combination of the strategies that have been advanced to date.

It must be remembered, however, that the thrust of our presentation, and, indeed, the main thrust in the literature has been toward the "unit test" level, where smaller programs are encountered. Thus, the ideas we have presented are, at the present time, feasible only in the case of programs of limited size. To think that we are nearing the point where we are ready to apply all of these techniques to the testing of an entire operating system or a compiler would be to miss the point completely. Nevertheless, our study has shown that indeed a start has been made.

We have tried to present a reasonably balanced survey of the recent contributions to the research literature on software testing methodology. It is perhaps likely that one or more worthwhile studies have escaped the author's attention, and therefore, their omission from this survey should not reflect on their importance to the development of the field. Moreover, the author can only hope that the studies that have been cited here have been presented in their best light. Limita-

tions of time and space have prevented a more complete treatment of these works, and for this, apologies to the authors are in order. At the same time, this author would like to acknowledge the use of the many cogent examples from the literature cited, hoping as well that these and other contributions have been faithfully reported.

In conclusion, the author would like to thank W. H. Leung, K. A. Gluck, and N. H. Petschenik for their most helpful comments in reviewing an earlier draft of the manuscript.

# Parallel Fault Simulation Using Distributed Processing*

By Y. H. LEVENDEL,† P. R. MENON,† and S. H. PATEL†

(Manuscript received June 3, 1983)

This paper presents a method of performing fault simulation of digital logic circuits using a special-purpose computer with distributed processing. The architecture for true value simulation presented in an earlier paper can also be used for parallel fault simulation. The special-purpose computer consists of inexpensive microprocessors interconnected by either a time-shared parallel bus or a cross-point matrix. The cross-point matrix provides higher performance than the time-shared parallel bus. The performance of the proposed simulator is better by over two orders of magnitude than traditional logic fault simulation performed on a general-purpose computer. The power of the simulator is proportional to the number of microprocessors over a certain range.

## I. INTRODUCTION

Fault simulation is an important part of the logic circuit design process. It is a means of determining the behavior of a logic circuit in the presence of each one of a predefined set of faults.

One of the most common uses of fault simulation is in determining the set of faults detected by a proposed test sequence, i.e., its fault coverage. Adequate fault coverage (usually greater than 90 percent of single stuck faults) is necessary to guarantee that the test sequence will detect most of the manufacturing defects.

Permission to reproduce or republish any other portion of this paper must be obtained from the Editor.

In test pattern generation, fault simulation is used to determine the faults that are detected by the tests already generated so they can be removed from consideration. A yet undetected fault is then selected as a target for the next test. Additional faults detected by a newly generated test may be determined by simulation. Thus, fault simulation is used frequently as a part of the test generation process.

Fault simulation is also used to construct fault dictionaries for fault isolation. Other uses of fault simulation include the evaluation of test point effectiveness and the evaluation of self-checking circuitry. Effective test points are essential for factory testing. It is much cheaper and easier to locate and repair failures during manufacture than it is in the field. Also, good self-checking circuitry makes it easier to isolate faults in the field.

Currently, fault simulation is carried out on large general-purpose computers. This method has seen some use in large-scale integrated (LSI)* designs, but suffers from excessive run time at current levels of integration. Its applicability to very large-scale integration (VLSI) is doubtful, at least in the manner that it is currently used.[1] There is a need for more sophisticated and cost-effective fault simulators as very large simulation time and costs will result when dealing with circuits of VLSI complexity (more than 100,000 gates on a single chip).

## II. PARALLEL FAULT SIMULATION

A number of different algorithms have been developed for performing fault simulation efficiently on general-purpose computers. Among these the best known and widely used are the parallel,[2] deductive,[3] and concurrent[4] methods. All these methods attempt to simulate the effects of a number of individual faults simultaneously. This paper will consider the use of the parallel fault simulation algorithm in the special-purpose simulation hardware architecture developed in Ref. 5.

In parallel fault simulation the fault-free circuit and several different faulty circuits are processed simultaneously. The number of faulty circuits simulated in parallel is normally constrained by the number of bits in the host computer word. One bit of the computer word represents the signal value on a line in the fault-free circuit, while the remaining bits represent values on the same line in the presence of different single faults. Word-oriented operations performed on the host computer imply that the fault-free and faulty circuits are handled simultaneously and in exactly the same manner.

The output fault word of a gate is computed by simple word-oriented logic operations on the input fault words. The logic operations performed on the fault words correspond to the logic operation performed

* Acronyms and abbreviations are defined in the Glossary at the back of this article.

by the gate. Faults are injected using predefined masks. A stuck at 1 fault on a lead is injected by ORing the fault word with a mask containing a 1 in the bit position for the faulty value and 0's elsewhere. Similarly, a stuck at 0 fault can be injected by ANDing the fault word with a mask containing a 0 in the bit position for the faulty value and 1's elsewhere.

Two logic values are not sufficient for accurate logic simulation. Since each bit position in the computer word can represent only a logical 0 or 1, more than one bit per signal is required for multiple-value simulation.[6] In this case more than one word is required. For three-value representation two bits are required to represent each signal and, therefore, two computer words are required for representing a set of fault-free and faulty values. Since a pair of words are used to represent a signal, some sort of coding method is required to implement parallel simulation. A commonly used method of coding denotes one of the words as the 0-word and the other word as a 1-word. Let $i_0$ represent the $i$th bit in the 0-word and $i_1$ represent the $i$th bit in the 1-word. Then the $i_0i_1 = 01$ combination represents a logical 1, the $i_0i_1 = 10$ combination represents a logical 0, the $i_0i_1 = 00$ combination represents an unknown, and the $i_0i_1 = 11$ combination is unused. Simple word-oriented operations are still sufficient for performing the parallel simulation. This coding is the same as that in Ref. 7. Faults are injected in the 0-word and the 1-word using a 0-mask and a 1-mask, respectively. This injection is also done using simple logic operations. The method for simulating three logic values can be extended to any number of logic values by coding them using a sufficient number of bits.[8] Only three-valued simulation is considered in this paper.

The most widely used method of parallel simulation is the *event-driven* method. Event-driven simulation means that an element is not simulated unless there is a change in one of its input fault words. The main operations performed in an event-driven simulation are processing of active elements and scheduling changes to occur in future. The scheduling is done on a timing wheel. A *timing wheel* is a list structure in which events are chained together in the order they are to occur. In parallel fault simulation an element is considered to be *active* if the fault word associated with its output changes. The fault word is considered changed even if only one of its bits changes. All the values (i.e., the whole fault word) are propagated even if only one of the values changes.

Since the number of faults simulated at one time is restricted by the length of the host computer word, multiple passes through the simulator are necessary to simulate a large number of faults. It is possible to reduce the number of passes by using extra computer words

and simulating more faults during one pass. For example, 64 computer words can be used to simulate (two-value simulation) 1024 faults on a computer with a word size of 16 bits. The string of values in the set of computer words representing the fault-free and faulty signal values on a line will be called the *value vector.* The configuration of the value vector is shown in Fig. 1. The value vector consists of $L_p$ word pairs for three-value simulation. Two bits at the same position in the two words of a pair represent the signal value of one faulty circuit. Simulating $L_p$ word pairs at a time is better than making $L_p$ passes through the simulator since the overhead involved in the fanout search associated with each pass is saved. (However, as we will see in Section 6.1, some of these savings are lost due to increased activity as the number of faults per pass increases.) The number of words used in the value vector is usually constrained by the space requirements of the computer.

During simulation, operations are performed on value vectors by considering word pairs. Thus, the time required to perform an operation on the value vector is proportional to the number of word pairs used in the value vector. For example, if there are several word pairs in a value vector, then faults are injected one word pair at a time.

The whole value vector is considered active if any of the values in the vector changes. Furthermore, all the word pairs are propagated even if only one word pair changes. An element is considered *active* if the value vector associated with its output is active.

## III. CONCURRENCY IN FAULT SIMULATION

At least three types of concurrencies exist in fault simulation of logic circuits. The first type of concurrency occurs in the actual simulated hardware, the second type occurs in the simulation algo-

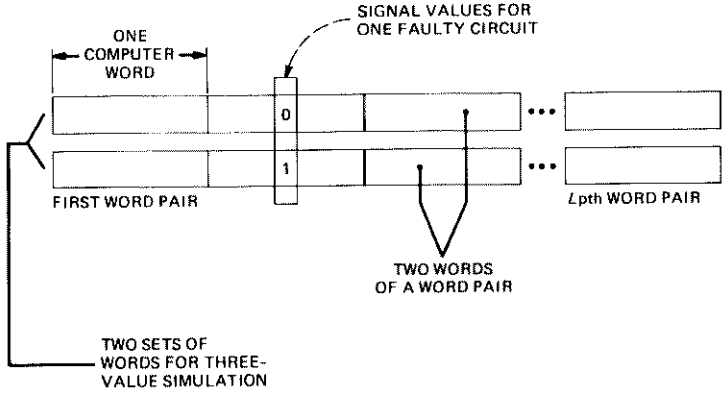

Fig. 1—Value vector configuration.

rithm, and the third type occurs in the form of fault activity. The first two types of concurrencies also occur in true value simulation of logic circuits and have been discussed in an earlier paper.[5]

The concurrency occurring in the actual simulated hardware can be called *logic circuit concurrency.* Utilizing this type of concurrency leads to distributed processing with identical processors performing identical tasks. The architecture for true-value simulation developed by Levendel et al.[5] and Denneau et al.[9–11] takes advantage of this type of concurrency.

The concurrency occurring in the simulation algorithm can be called *algorithm concurrency.* This concurrency is indirectly due to the concurrency occurring in the actual simulated hardware. Since several elements can be simultaneously active and a sequence of steps is to be performed for each active element, they can be processed in a pipeline fashion. Utilizing this type of concurrency leads to functional partitioning of tasks among several processors and a pipelined architecture. The architecture for true-value simulation developed by Barto and Szygenda[12] and Abramovici et al.[13] takes advantage of this type of concurrency.

For efficient fault simulation, a number of faults are simulated simultaneously in software-based simulators. This leads to *fault activity concurrency,* which can be utilized in special-purpose hardware for fault simulation.

This paper extends the architecture for true-value simulation described in Ref. 5 to fault simulation using the parallel method. The architecture takes advantage of the parallelism due to logic circuit concurrency and fault activity concurrency. The main difference between true-value simulation and fault simulation is in the algorithm executed by the individual processing units.

## IV. SPECIAL-PURPOSE ARCHITECTURE

The simulator consists of one master and a number of slaves (processors) interconnected by a communication structure (Fig. 2). The communication structure is used as a medium for transferring data between the slaves and between the slaves and the master. The communication structure can be either a time-shared parallel bus or a cross-point matrix. The circuit to be simulated is partitioned into subcircuits and each subcircuit is simulated in a separate processor. Subcircuits in different processors become active as signal values proceed from the primary inputs to primary outputs. As simulation progresses, data are transferred between subcircuits as the logic values on the signal connections between two subcircuits change. These data are transported across the communication structure. Typical data sent across the data path consist of element information and changed value

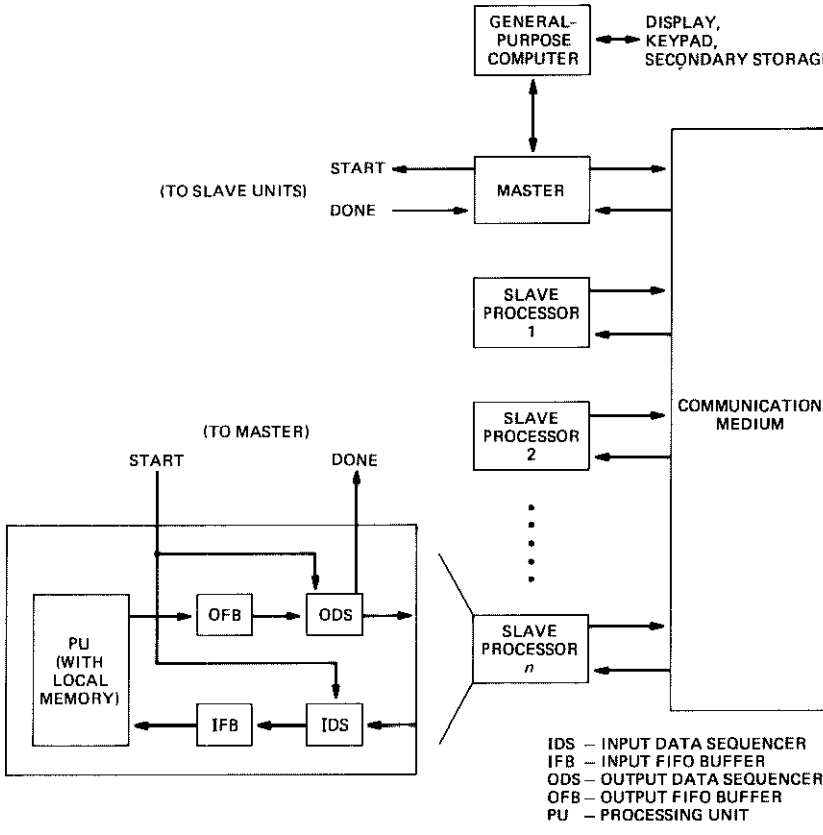

Fig. 2—Multiprocessor-based digital logic simulator.

vectors. The architecture of the simulator has been described in detail in the previous paper.[5] A summary of the architecture description is presented in Appendix A for completeness.

The overall architecture for true-value simulation is applicable to fault simulation since the algorithms for the two types of simulations are the same except that fault simulation requires:

1. Carrying of faulty signal values in addition to true-value signals (more than one word may be used to allow representation of a larger number of faulty signals)
2. Fault injection using masks
3. Multiple passes if the fault set is large.

The processing time per pass will be higher for fault simulation due to the extra processing required for injecting faults and manipulating multiple-word pairs in a value vector. The latter requirement applies only when the value vector contains more than one word pair. As far as communication between the processors is concerned, the data

transferred between the processors are greater than those transferred for true-value simulation, since the signal values require one or more complete words in addition to a word for the element number.

## V. ARCHITECTURE EVALUATION

The processing time per simulation cycle and the communication times using a time-shared parallel bus and a cross-point matrix are estimated first. These results are then used for selecting the communication structure. A multiple-bus communication structure is also discussed in this section.

### *5.1 Processing time $t_p$*

The average number of active elements per processor during a simulation cycle for true-value simulation is given by $kN/n$, where $N$ is the average number of active elements per simulation cycle during true-value simulation, $n$ is the number of processors in the multiprocessor simulator, and $k$ is the average unbalance factor representing the extra active elements per processor during a simulation cycle due to nonideal partitioning.[5] Ideal partitioning will cause an equal number of elements to be active in all the processors during all simulation cycles. However, because of some imbalance such as the fanout of all active elements during one simulation cycle not feeding equally into all the processors, some processors will have more active elements than the others during some simulation cycles. The average number of active elements per processor during a fault simulation cycle can be written as $kN_f/n$, where $N_f$ is the average number of active elements per simulation cycle in one pass during fault simulation. The value of $N_f$ is expected to be larger than $N$. Indeed, experimental runs on the Logic Analyzer for Maintenance Planning (LAMP) simulator[14] show that the overall activity (total number of active elements) during parallel fault simulation increases by a factor of about 2 for 16 faults per pass and by about 3.5 for 1024 faults per pass compared to true-value simulation. These results are averaged over several runs made using both combinational and sequential circuits with sizes ranging from 420 gates to 1912 gates. The number of faults simulated ranged from 1020 faults for the 420-gate circuit to 5046 faults for the 1912-gate circuit. The LAMP simulator is based on the deductive method. A mapping mechanism from deductive simulation activity to parallel simulation activity was implemented to predict the results for parallel simulation.

During one simulation cycle the following major operations occur in the given order:

1. Using the current list of events, list $L_t$ of the timing wheel (Fig.

11 in Appendix B), update, and find fanout of the elements whose outputs changed during the current simulation cycle.

2. Using the next list $L_{t+1}$ of the timing wheel, prepare external events to be transmitted to other processors for the next time interval.

3. From data in the Input FIFO Buffer (IFB) (sent by other processors), update and find fanout of the elements active during the current simulation cycle.

4. Evaluate the fanout of active elements (this includes fault injection).

5. Schedule on timing wheel elements whose output changes.

The detailed algorithm is given in Appendix C.

Let $t_a$ be the time required to process one active element. The average processing time per processor during one simulation cycle is then given by:

$$t_p = \frac{kN_f}{n} t_a.$$

Assume a microprogrammable microprocessor (e.g., Am2900 series) for each slave unit processing unit (PU) and the following operation times (150 ns cycle time): memory-to-memory move = 1.2 $\mu$s, memory-to-register move = 0.6 $\mu$s, and memory-to-memory logical AND/OR operation = 1.5 $\mu$s. Using these major microprocessor operations, the execution time for each operation in the parallel simulation algorithm described in Appendix C can be estimated. For example, obtaining each fanout of an updated element (after the fanout list has been accessed) takes one memory-to-register instruction and moving the element number to the Output FIFO Buffer (OFB) takes one memory-to-memory instruction. The processing times per active element for the various steps of the algorithm are shown in Table I, where $f_i$ is the average fan-in, $f_o$ is the average fan-out, and $L_p$ is the number of word pairs in the value vector.

The total processing time per element during one simulation cycle is the sum of all the expressions in Table I:

$$t_a = 9.6 + 8.7L_p + 3f_o + 3f_iL_p - \frac{(2.4 + 7.2L_p)}{f_o} \mu s.$$

Taking typical values of $f_i$ and $f_o$ to be 2 and an unbalance factor of $k = 1.1$, the processing time for a simulation cycle becomes:

$$t_p = (15.8 + 12.2L_p) \frac{N_f}{n} \mu s. \quad (1)$$

### *5.2 Communication time $t_c$*

The value of $t_c$ will depend on the type of communication structure.

Table I—Simulation cycle timings for parallel simulation

| Step | Expression ($\mu$s) |
|---|---|
| Update data from timing wheel | $\frac{(1.8 + 2.4f_o)}{f_o}$ |
| Prepare external events for next time interval | $\frac{(f_o - 1)(6.6 + 3.6L_p)}{f_o}$ |
| Update data from IFB | $\frac{(f_o - 1)(1.2 + 3f_o + 3.6L_p)}{f_o}$ |
| Evaluate schedule | $2.4 + 1.5L_p + 3f_iL_p + \left(\frac{3.6}{f_o}\right)$ |

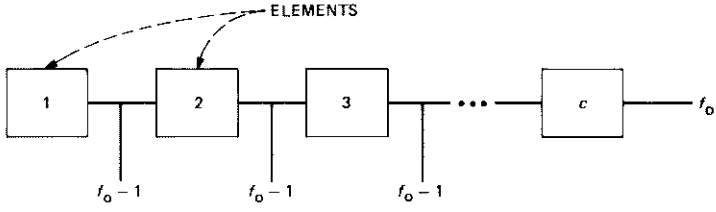

Fig. 3—An element string.

The two types of communication structures discussed in Ref. 5, namely the time-shared parallel bus and the cross-point matrix, will be considered here also. The partitioning algorithm discussed in the previous paper[5] partitions a circuit along its depth rather than its breadth. Since the signals in a circuit propagate in parallel, this places concurrent activities in different blocks. The same partitioning algorithm will be assumed here, since during fault simulation the signals still propagate in the same manner. The logic circuit to be simulated is partitioned into elements strings (see Fig. 3). The average number of communication events generated by one active element during a simulation cycle that have to be sent over the communication structure is:

$$e = \frac{[f_o + (c - 1)(f_o - 1)]}{c},$$

where $f_o$ is the average fanout and $c$ is the average number of elements in one element string. The typical value of $f_o$ can be taken as 2, and for large circuits $c$ is expected to be greater than 10. For $f_o = 2$ and $c = 10$, $e$ will be equal to 1.1.

#### *5.2.1 Time-shared parallel bus*

The total communication time during a simulation cycle for true-value simulation is given by[5]:

$$t_{c(bus)} = (n + 200)Ne \text{ ns}$$

This expression assumes one word of data to be transferred per active element. For fault simulation with $w$ words of data to be transferred per active element the expression becomes:

$$t_{c(bus)} = (n + 200)N_f ew \text{ ns.}$$

The number of words to be transferred is given by:

$$w = 1 + 2L_p,$$

where $L_p$ is the number of word pairs per value vector used in simulation. One word is required to carry the element number and the $2L_p$ words carry the value vector. Taking the value of $e = 1.1$:

$$t_{c(bus)} = (1.1n + 220)(1 + 2L_p)N_f \text{ ns.} \quad (2)$$

#### *5.2.2 Cross-point matrix*

In a cross-point matrix-based communication structure several processors can be simultaneously sending data to other processors. The total communication time during a simulation cycle for true value simulation is given by[5]:

$$t_{c(matrix)} = \frac{200Nke}{n} + 50j \text{ ns,}$$

where $j$ is the number of events for which the destination processor is found busy, i.e., the destination processor is communicating with some other processor. Once again this expression assumes one word of data transferred per active element. For $w$ words of data to be transferred, the expression for fault simulation becomes:

$$t_{c(matrix)} = \frac{200(N_f)kew}{n} + 50jw \text{ ns.}$$

For $k = 1.1$, $e = 1.1$, $w = 1 + 2L_p$, and $j = 0.1N_f/n$ (the channel is found busy for 10 percent of the transfer requests), the above expression can be rewritten as:

$$t_{c(matrix)} = (247 + 494L_p)\frac{N_f}{n} \text{ ns.} \quad (3)$$

### *5.3 Choice of communication structure*

The expressions for the processing time per simulation cycle per active element and the communication times per simulation cycle per active element for the bus and matrix structures are plotted in Fig. 4. The expressions are plotted for value vector length of one word (16 bits/word), i.e., $L_p = 1$.

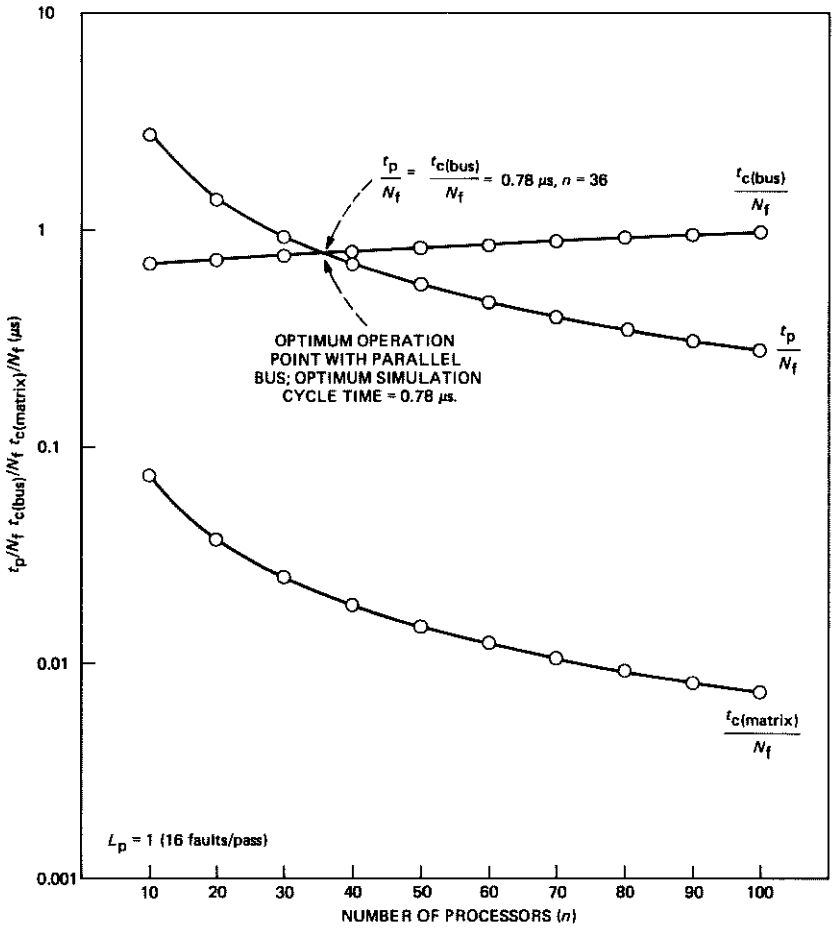

Fig. 4—Variation in processing and communication time.

The curves for the processing time and bus communication time for the parallel bus intersect at $n = 36$. The processing time is greater than the bus communication time for $n < 36$. Thus the processing time is the bottleneck. The processing time decreases as the value of $n$ increases. For $n > 36$ the bus communication time becomes larger than the processing time and the bus communication time becomes the bottleneck. Therefore, using more processors than $n = 36$ will not speed up the simulation. For optimum performance $n = 36$, and the length of the simulation cycle per active element becomes $t_m = 0.78$ μs. Based on the parallel simulation algorithm given in Appendix C, the actual simulation cycle length per active element for a single processor can be estimated as $t_1 = 24$ μs. The multiprocessor fault

simulator with a bus-based communication structure provides a speedup of 31 over the traditional single-processor logic fault simulator.

For further speedup a faster communication structure must be used. Figure 4 also shows the curve for the matrix communication time. This curve does not intersect with the curve for the processing time, and the communication time is always less than the processing time. The communication time will therefore never be a bottleneck. More processors can be added to speed up the simulator. For example, for $n = 100$ the speedup compared to the traditional single-processor logic fault simulator is 86 and for $n = 256$ the speedup is 220. The speedup of simulation is expected to be greater than two orders of magnitude for $n > 120$.

### *5.4 Multiple-bus communication structure*

The results of the previous section show that for a given number of faults per pass, the time-shared parallel bus is useful only for up to a fixed value of $n$. For further speedup the cross-point matrix has to be used. However, the cross-point is not used up to its maximum capability. For example, at 16 faults per pass and $n = 100$, the simulation cycle length is $280N_f$ ns while the communication cycle length is $7.4N_f$ ns, i.e., the communication structure is used less than 3 percent of the time. A communication structure that is slower and cheaper than the cross-point matrix might prove more cost-effective. This will be true especially since the control for the cross-point is very complex and thus expensive.

A communication structure that provides a capacity in between that of the time-shared parallel bus and the cross-point matrix is the multiple-bus structure. It consists of a bus arbitrator and several parallel buses. The configuration of the multiple-bus structure and its interface to the Output Data Sequencers (ODSs) and Input Data Sequencers (IDSs) of the slave units are given in Fig. 5. When the ODS needs to send data, it sets the Request To Send (RTS) line high and puts the destination address on the address lines. The requesting ODS keeps the RTS line high until granted a bus. The bus arbitrator grants it the use of the communication medium when it finds an unused bus and determines that the requested destination is not busy. The bus arbitrator grants the bus by setting the Bus Grant line high. The data are switched through the bus selector switch to the available bus. At the other end of the bus there is a line selector from which the data are sent to the destination processor. The ODS sends out all the data present in its Output FIFO Buffer (OFB). The data received by the IDS of the destination unit are put in its Input FIFO Buffer (IFB). The ODS then sets the RTS line low. This releases the bus, which is

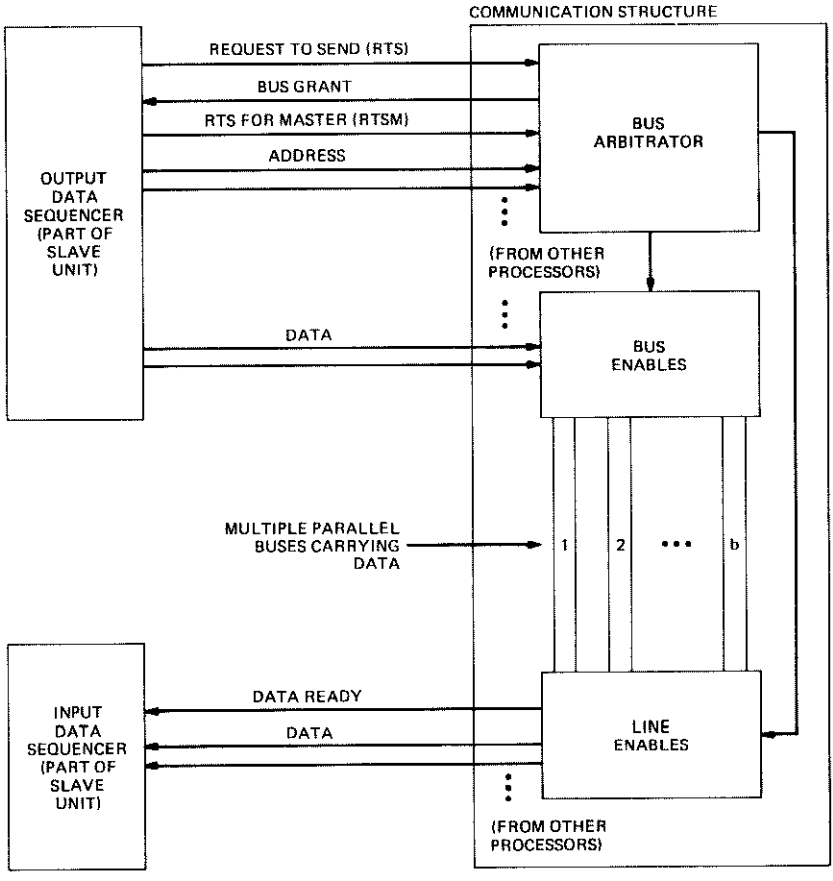

Fig. 5—Configuration of multiple-bus structure.

then granted by the bus control to another requesting slave or the master. All units have equal priority. The ODS will set the Request To Send line high again if it gets more data to transfer in the OFB.

The data sent out to a slave unit from another slave unit or the master consist of element information and changed value vectors. The data sent to a master consist of the address of the sending slave, element number (primary output or monitored point), and value vector. A separate line Request to Send to Master (RTSM) is used to address the master. When the destination is the master, the address lines from the ODS contain the sending slave unit address. This address together with the element number and value vector is stored in the master IFB by the master IDS.

To obtain an expression for the communication time for the multiple-bus structure, consider first of all the bus structure with only a

single bus. For this case, the communication time will consist of the same components as that for time-shared parallel bus[5]:

$$t_{c(mbus)} = (t_{brg} + t_{ds} + t_{da} + t_{br})(1 + 2L_p)(N_f)e,$$

where $t_{brg}$ is the bus request and grant time, $t_{ds}$ is the address and data setup time, $t_{da}$ is the data acknowledge, and $t_{br}$ is the bus release time. For the multiple-bus structure the bus request and grant time, $t_{brg}$, will be greater than in the parallel bus since extra checking has to be done before a bus is granted. The bus arbitrator will have to determine if a bus is available and if available then it has to further determine if the requested destination is busy. Assuming these extra actions double the time required for the bus request and grant time and the other times remain the same: $t_{brg} = 200$ ns, $t_{ds} = n$ ns, $t_{da} = 50$ ns, $t_{br} = 50$ ns, and $e = 1.1$. Each transaction across the multiple-bus has to wait for a bus to be granted. As more buses are added, the transactions can occur in parallel. Assuming the number of parallel buses is much smaller than the number of processors, the probability of the destination processor being busy will be small. The decrease in the total communication time will then be proportional to the number of buses. The expression for the total communication time for the multiple-bus communication structure becomes:

$$t_{c(mbus)} = \frac{(1.1n + 330)(1 + 2L_p)N_f}{b}, \tag{4}$$

where $b$ is the number of parallel buses.

Let $n_o$ be the number of processors at the optimum operation point, where $t_p = t_{c(mbus)}$. If the simulator operates with the number of processors not equal to $n_o$, then the speed of simulation will be lower. An expression for $n_o$ can be derived by equating eqs. (1) and (4):

$$n_o = -150 + 150\left(1 + b\left(\frac{0.49L_p + 0.64}{2L_p + 1}\right)\right)^{0.5}.$$

This expression is plotted for various values of $b$ with $L_p = 1$ in Fig. 6. It can be seen that higher performance is available with the multiple-bus structure compared to the single time-shared parallel bus for $b \geq 2$.

The implementation of the multiple-bus structure is expected to be less expensive than that of the cross-point matrix. The complexity of the communication structures and thus their cost is proportional to the number of switch points. For the cross-point matrix, the number of cross-points is proportional to the square of the inputs, i.e., $n^2$. For the multiple-bus structure two points have to be connected to establish a connection and thus the number of switch points is $2bn$. The cost of the multiple-bus structure will be less than that of the cross-point

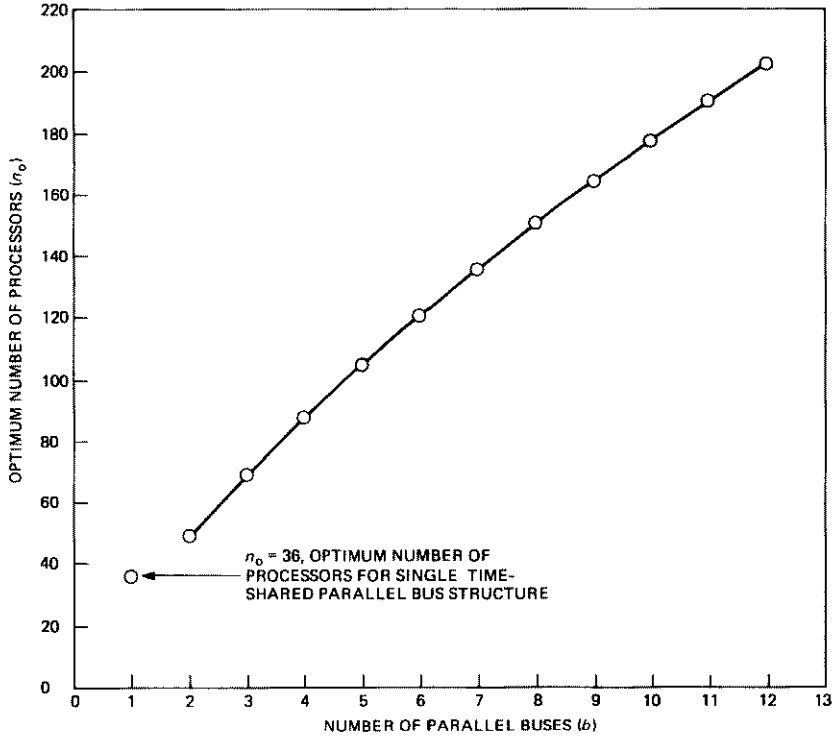

Fig. 6—Variation in the optimum number of processors with the number of parallel buses.

matrix as long as $2b < n$. As we saw in the analysis done earlier this will always be the case. For $b = 5$ and $n_o = 105$, the cost of the multiple-bus structure will be an order of magnitude lower than that of the cross-point matrix. Furthermore, it must also be noted that physical switching is not necessary in the case of the multiple-bus structure; it is cheaper to use logic enables for connecting an ODS and an IDS to a bus. This will result in even lower cost when compared with the cross-point matrix.

## VI. EFFECT OF NUMBER OF FAULTS PER PASS

When simulating a large number of faults per pass in parallel simulation, several pairs of words carrying the true and faulty values ($L_p$) must be manipulated per active element. All the faulty values in the words can be considered together as a vector. All the faulty values are evaluated even if only one faulty value is active.

The behavior of the multiprocessor fault simulator, using the parallel fault simulation algorithm, will be investigated for variations in the number of faults simulated per pass. Comparisons will be made

between 16, 32, 64, 256, and 1024 faults per pass, assuming a processor word length of 16 in all the cases.

Only the time-shared parallel bus and the cross-point matrix are discussed. The communication structure with multiple buses is not considered since the results for the time-shared parallel bus will apply, except for a scaling factor.

### *6.1 Simulator with time-shared parallel bus*

The expressions for processing time per simulation cycle, $t_p$, and the parallel bus communication time per simulation cycle, $t_{c(bus)}$, derived earlier in eqs. (1) and (2) are used to analyze the effects of variations in the number of faults per pass. It was seen earlier that the optimum operation point for the simulator occurs when the processing time and communication time are equal, i.e., $t_p = t_{c(bus)}$. An expression for the number of processors required to meet this condition for a given length of value vector ($L_p$) can be derived by equating the expressions for $t_p$ and $t_{c(bus)}$. Let $n_o$ be the number of processors at the optimum operation point and $t_o$ be the length of the processing and communication cycles at the optimum operation point. Values of $n$ smaller than the optimum $n_o$ cause the processing to be a bottleneck, while larger values of $n$ cause communication to be a bottleneck. Equating eqs. (1) and (2) yields the following expression for $n_o$, the number of processors required for optimum operation:

$$n_o = -100 + 100\left(\frac{3.11L_p + 2.44}{2L_p + 1}\right)^{0.5}.$$

Let $\alpha$ be the number of faults per pass. Then $\alpha = 16L_p$ assuming 16 bits per word. The above expression for $n_o$ can be rewritten as a function of the number of the faults $\alpha$, as:

$$n_o(\alpha) = -100 + 100\left(\frac{0.19\alpha + 2.44}{0.125\alpha + 1}\right)^{0.5}. \tag{5}$$

For $n = n_o(\alpha)$, the processing time per simulation cycle and the bus communication time per simulation cycle both reduce to:

$$t_o(\alpha) = (15.8 + 0.76\alpha)\frac{N_f(\alpha)}{n_o(\alpha)}. \tag{6}$$

For a simulator with optimum number of processors, $n_o(\alpha)$, the total time required to simulate a fixed number of faults is obtained by multiplying the time required for processing one active element ($t_o(\alpha)/N_f(\alpha)$) by the total number of active elements during the simulation ($N_T(\alpha)$):

$$T(\alpha) = \frac{t_o(\alpha)}{N_f(\alpha)} N_T(\alpha).$$

The total number of active elements during simulation is given by:

$N_T(\alpha) = N_f(\alpha) \times$ (number of simulation cycles per pass)

$\times$ (number of passes).

Substituting the expression for $t_o(\alpha)$ given in eq. (6):

$$T(\alpha) = (15.8 + 0.76\alpha)\frac{N_T(\alpha)}{n_o(\alpha)}. \tag{7}$$

Define the *simulation time ratio* as the ratio of the total time required to simulate a set of faults with $\alpha$ faults per pass to the total time required to simulate the given set of faults with 16 faults per pass, i.e., $T(\alpha)/T(16)$. Using a value of $n_o(16) = 36$ (eq. 5), the expression for the simulation time ratio is given by:

$$\frac{T(\alpha)}{T(16)} = \frac{(20.3 + 0.98\alpha)}{n_o(\alpha)} \frac{N_T(\alpha)}{N_T(16)}. \tag{8}$$

The values of the simulation ratio are first calculated theoretically and then compared with the experimental results.

#### *6.1.1 Theoretical simulation time ratio*

Let *simulation activity*, $N_T(\alpha)$, refer to the number of active elements during all passes of a simulation. The simulation activity can be expected to be inversely proportional to the number of faults per pass:

$$\frac{N_T(\alpha)}{N_T(16)} = \frac{16}{\alpha}.$$

For example, the expected simulation activity at 32 faults per pass will be half the simulation activity of 16 faults per pass since the number of passes needed will be halved. The theoretical expression for the simulation time ratio becomes:

$$\frac{T(\alpha)}{T(16)} = \frac{(20.3 + 0.98\alpha)}{n_o(\alpha)} \frac{16}{\alpha}. \tag{9}$$

Note that the theoretical simulation time ratio is independent of the simulation activity. Table II gives the variation of the optimum number of processors, $n_o$, and the variation of the simulation time ratio as a function of the number of faults per pass, $\alpha$. The theoretical results show that the simulation time ratio, and thus the total simulation time, decreases as the number of faults per pass increases.

Also, it is interesting to note that for 16 faults per pass the operation

Table II—Theoretical simulation time ratio

| Faults per Pass, $\alpha$ | Optimum Number of Processors, $n_o$ | Simulation Time Ratio, $\frac{T(\alpha)}{T(16)}$ |
|---|---|---|
| 16 | 36 | 1.0 |
| 32 | 32 | 0.81 |
| 64 | 29 | 0.72 |
| 256 | 26 | 0.65 |
| 1024 | 25 | 0.64 |

Table III—Experimental simulation time ratio

| Faults per Pass, $\alpha$ | Simulation Activity, $N_T(\alpha)$ | Optimum Number of Processors, $n_o$ | Simulation Time Ratio, $\frac{T(\alpha)}{T(16)}$ |
|---|---|---|---|
| 16 | 17586 | 36 | 1.0 |
| 32 | 9374 | 32 | 0.86 |
| 64 | 5204 | 29 | 0.84 |
| 256 | 1787 | 26 | 1.06 |
| 1024 | 689 | 25 | 1.6 |

peaks at 36 processors, while for 1024 faults per pass the operation peaks at 25 processors. As the number faults per pass increases, the point of optimum operation occurs for a slightly smaller number of processors. This is because the time required to transfer the increased data is more than the time required to process the increased data.

#### *6.1.2 Experimental simulation time ratio*

The values of $N_T(\alpha)$ averaged over several experimental runs made on the LAMP simulator[13] (with a mapping algorithm from deductive simulation to parallel simulation as discussed in Section 5.1) are given in Table III. Also shown in Table III are values for the simulation time ratio derived from eq. (8).

The experimental simulation time ratio, $T(\alpha)/T(16)$, is plotted together with the theoretical simulation time ratio in Fig. 7.

It is interesting to note that as the number of faults per pass increases, the experimental simulation time ratio falls below 1.0 initially, i.e., the simulation speeds up. After a certain point, the simulation time ratio then starts increasing and goes above 1.0. The fastest simulator is a 64 faults per pass simulator with 29 processors. On the other hand, the theoretical simulation time ratio always stays below 1.0 and keeps decreasing as the number of faults per pass increases. The difference in the experimental and theoretical results can be

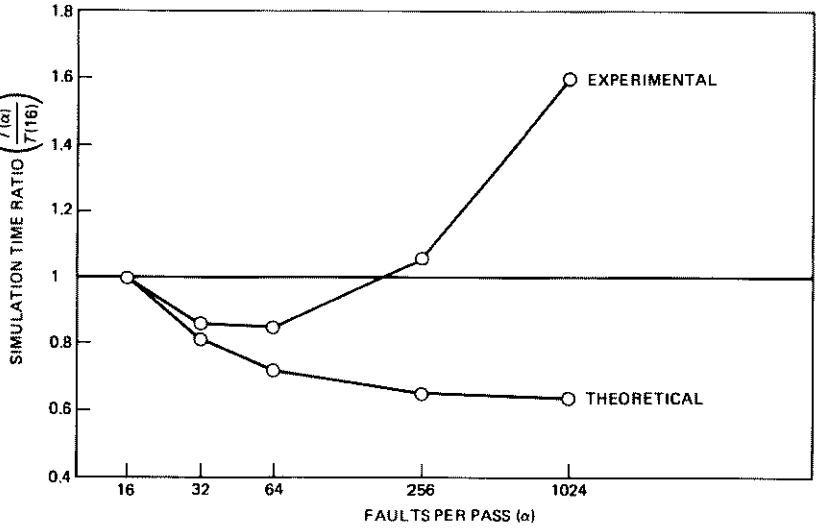

Fig. 7—Experimental and theoretical simulation time ratio for variation in number of faults per pass—a time-shared parallel bus.

explained by examining the variation in simulation activity as the number of faults per pass changes.

The curve for the theoretical simulation time ratio in Fig. 7 shows that the simulation speed increases as the number of faults per pass increases. This is as expected, since increasing the number of faults per pass decreases the number of passes and thus the fanout search and related processing time. In practice, however, there is extra simulation activity due to longer value vectors and this tends to increase the processing time. As more faults are simulated per vector, i.e., as the value of $\alpha$ gets larger, the simulation activity during the simulation will be higher than the theoretical. For example, as shown earlier, the theoretical activity at 32 faults per pass will be half the simulation activity at 16 faults per pass. However, the experimental simulation activity at 32 faults per pass will be more than the expected half. This is because the active faults in two value vectors at 16 faults per pass will not always directly map into one value vector at 32 faults per pass. Any active fault in the value vector will cause simulation activity even if the good value does not change. The effect of this is to cause extra schedulings. This increase in schedulings can be represented by an effective increase in the length of the simulation cycle and the number of simulation cycles. The runs made on the LAMP simulator show that most of the increase is in the length of the simulation cycle (i.e., more computation during the simulation cycle). The expected simulation activity and the actual simulation activity

obtained from runs made using the LAMP simulator are given in Table IV.

For 32 faults per pass, the simulation activity is only 1.07 times that theoretically expected. Thus the increase in processing time due to this extra activity is not substantial and the overall speed of simulation is higher due to the greater savings in the fanout search processing. For 1024 faults per pass, the simulation activity is 2.51 times that theoretically expected. In this case, the increase in processing time due to the extra activity is substantial compared to the savings obtained in the fanout search processing. This results in lowering the overall speed of simulation when compared with 16 faults per pass.

In summary, for the multiprocessor fault simulator with a parallel-bus-based communication structure, the fastest simulation speed occurs for 64 faults per pass and 29 processors. Note, however, that the number of processors required for 64 faults per pass is greater than the number of processors for 1024 faults per pass. Decreasing the number of processors for 64 faults per pass to 25 yields the total simulation time of 13,413 $\mu$s. This still favors the 64 fault per pass simulator over the 1024 fault per pass simulator.

### *6.2 Simulator with cross-point matrix*

The expressions for the processing time per simulation cycle, $t_p$, and the cross-point matrix communication time per simulation cycle, $t_{c(\text{matrix})}$, derived earlier in eqs. (1) and (3) are applicable to variations in the number of faults per pass. The increase in simulation activity caused by simulating more faults per pass will increase both the processing time and the communication time for the cross-point matrix. However, adding one word pair to the value vector will cause an increase in the communication time that is only 4 percent of the increase in the processing time. Thus, the communication time will always be less than the processing time. The cross-point matrix provides sufficient communication capacity for the parallel fault sim-

Table IV—Effect of multiple passes on simulation activity

| Faults per Pass, $\alpha$ | Experimental Simulation Activity, $N_T(\alpha)$ | Theoretical Simulation Activity, $N_T(\alpha)$ |
|---|---|---|
| 16 | 17,586 | 17,586 |
| 32 | 9374 | 8793 |
| 64 | 5204 | 4396 |
| 256 | 1787 | 1099 |
| 1024 | 689 | 275 |

ulator and does not cause a communication bottleneck. For faster fault simulation, more processors can be added.

The variation of the simulation time ratio as a function of the number of faults per pass will be investigated to obtain the optimum number of faults per pass. Since the processing time dominates, the total time required to simulate a set of faults with $\alpha$ faults will be equal to the total processing time. Using eq. (1):

$$T(\alpha) = (15.8 + 0.76\alpha)\frac{N_T(\alpha)}{n}.$$

The simulation time ratio is given by:

$$\frac{T(\alpha)}{T(16)} = (0.56 + 0.027\alpha)\,\frac{N_T(\alpha)}{N_T(16)}. \tag{10}$$

The experimental and theoretical simulation time ratios are plotted in Fig. 8. As was the case for the time-shared parallel bus, the experimental simulation time ratio increases after 64 faults per pass. This is because the time required to process the increased simulation activity is greater than the time saved in the fanout search overhead associated with each pass. For the multiprocessor fault simulator with a cross-point-matrix-based communication structure, the optimum number of faults per pass is 64. Using a different value for the number of faults per pass will decrease the speed of simulation. Note that the

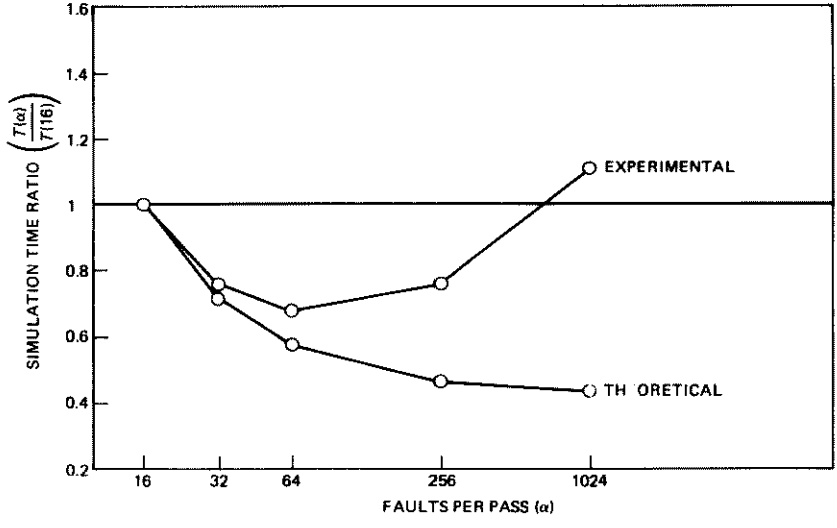

Fig. 8—Experimental and theoretical simulation time ratio for variation in number of faults per pass—cross-point matrix.

number of processors, $n$, does not affect the simulation time ratio. More processors can be added to obtain greater speed.

When compared with the parallel bus the cross-point matrix provides greater speed for any value of $n$ greater than the optimum $n$ for the parallel bus. For example, for 64 faults per pass, the cross-point matrix can be made faster than the parallel bus by selecting $n > 29$.

## VII. SUMMARY

In this paper we presented a special-purpose logic fault simulator based on the parallel simulation method. The simulator is expected to be two orders of magnitude faster than traditional logic fault simulators implemented on general-purpose computers. For both the time-shared parallel bus and the cross-point matrix, the simulator performs the best at 64 faults per pass. Decreasing the number of faults per pass slows down the simulation due to fanout search and other overhead required for every pass. Increasing the number of faults per pass also slows down the simulation due to the increase of simulation activity.

When the parallel bus is used, the power of the simulator can be increased over a certain range by increasing the number of slaves. The power of the simulator can be further increased by using the cross-point matrix.

The application of the special-purpose simulator to other fault simulation methods is being investigated currently.

## APPENDIX A

### *Architecture Description*

#### *A.1 Introduction*

The simulator consists of one master and a multiplicity of slaves (processors) interconnected by a communication structure (see Fig. 2). The communication structure can be either shared or dedicated. The circuit to be simulated is partitioned into subcircuits and each subcircuit is simulated in a separate processor. The partitioning is such that the number of simultaneously active subcircuits (processors) is maximum and the number of simultaneously active elements in each subcircuit (processor) is minimum while keeping the communication from being a bottleneck.

The circuit to be simulated is initially modeled in the general-purpose computer, partitioned and loaded into the slave memories. The general-purpose computer performs all functions of input, output, and user interactions. The simulation is carried out in the multiprocessor simulator.

The simulator can be programmed to output intermediate results to the general-purpose computer. It also can be interrupted by the general-purpose computer for intermediate results. The user can ask for information about a simulation run while it is in progress (e.g., the status of a variable) and make certain run-time decisions like continuing simulation, applying extra input vectors, or stopping. After simulating each vector input, the simulation results and any other user requested information are sent to the general-purpose computer. User-requested information typically includes output values of elements (monitored points) at specific simulated times or under some other specified conditions. The general-purpose computer formats this information for suitable presentation to the user.

#### *A.2 Multiprocessor operation*

At the beginning of each simulation cycle the master sends primary input values (if any) to the appropriate slaves using the communication structure. The master then issues a start signal to the slaves. This

signal informs the slaves to start processing for the next simulation cycle. During the processing of a simulation cycle a slave unit may generate data for the other slaves or the master. The data are sent to the destination slave or the master using the communication structure. Only data for the subsequent time interval are transferred between the slaves to reduce the amount of information sent over the communication structure, thus minimizing the communication overhead. Therefore, the scheduled time is not sent.

Each slave informs the master when it has finished processing and transferring data for the current simulation cycle. When all slaves have informed the master about their completion of processing for the current simulated time interval, and also the master has finished transferring any primary input values scheduled for the next simulated time interval to the slaves, the master issues a start signal to the slaves for the next simulation cycle.

There are two signal lines between each slave unit and the master. The master signals the slaves using a START signal and the slaves signal the master using the DONE line. The START line from the master initiates processing for the next simulation cycle. The DONE line will become one when all the slaves have finished processing for the current simulation cycle.

### *A.3 Slave unit*

Each slave unit consists of a processing unit (PU), an input FIFO buffer (IFB), an output FIFO buffer (OFB), an input data sequencer (IDS), and an output data sequencer (ODS).

The slave unit PUs perform the actual fault simulation. The PU stores any data it has for other PUs or the master in the OFB. The ODS makes a request for the communication structure if there are any data to be transferred from the OFB. The ODS of the slave, if granted the use of the communication structure, takes data from the OFB and sends it over the communication structure to other slaves or the master. The data are received by the IDS of the destination slave or the master. Any data received by an IDS are put in its IFB. End of Data (EOD) flags are used to separate data streams since a PU can be writing new data to the OFB before its ODS has finished transferring current data, and similarly, an IDS can be receiving new data in the IFB before its PU has finished reading current data.

The slave unit PU operation can be described in terms of two essentially concurrent processes, namely the simulation cycle (execution of simulation algorithm) and the communication cycle (communication of events). Data generated during a simulation cycle are transferred as they are generated in a corresponding communication cycle (see Fig. 5). The algorithm executed by the Slave Unit PU is

similar to the traditional parallel simulation algorithm used on general-purpose computers except that it is modified to operate on a data structure distributed over several processors (see Appendix C).

A communication cycle is the period in between two START commands issued from the master. This cycle is phased with respect to the simulation cycle as shown in Fig. 9.

### *A.4 Master processor*

The master processor is the interface between the general-purpose computer and the simulator. Its main functions are to keep track of simulated time, keep the slaves in synchronism, supply the slaves with primary input values, and gather the primary output values from the slaves. The configuration of the master is similar to that of a slave unit and is shown in Fig. 10. It consists of a central processing unit (CPU) with some local memory, an IFB, an OFB, an IDS, and an ODS.

### *A.5 Communication structure*

The communication structure is used as a medium for transferring data between the slaves and between the slaves and the master. Either a shared or a dedicated structure can be used for the multiprocessor

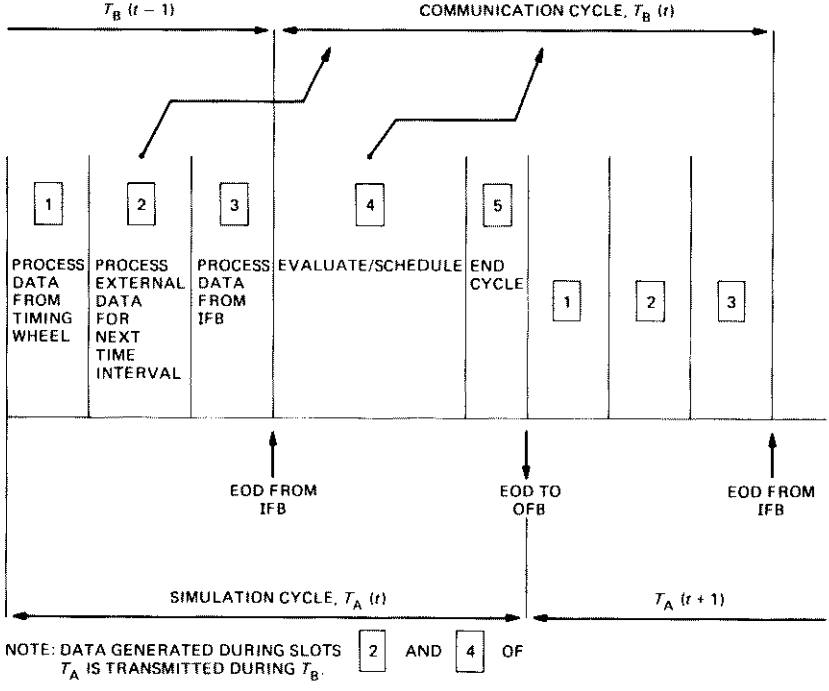

Fig. 9—Relationship between a simulation cycle and communication cycle.

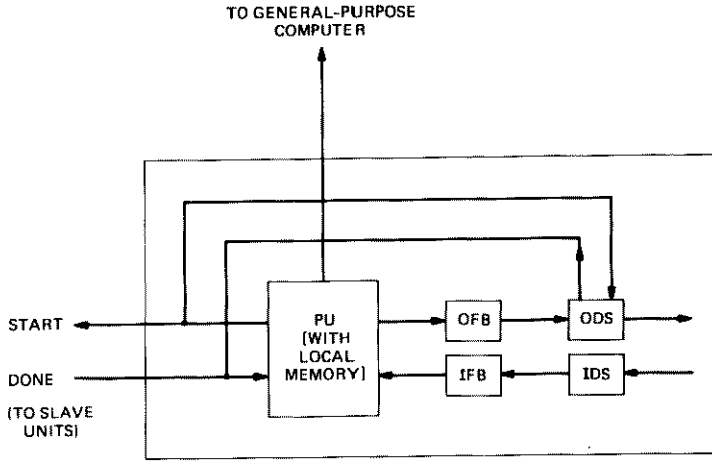

Fig. 10—Master configuration.

simulator. The details of a communication structure based on time-shared parallel bus and the cross-point matrix are discussed in detail in Ref. 5.

## APPENDIX B

### *Data Structure for Parallel Method*

The following data tables are used by each PU for its operation (see also Fig. 11):

1. Element table—This table contains the interconnection data and signal values for the circuit. For each element it contains the value vector, type, delay, fan-in list pointer and corresponding fan-in list, internal fanout list pointer and fanout list, external fanout list pointer and external fanout list. The value vector consists of a word pair. The first bit of each word of the word pair represents the good machine, while the remaining bits represent faulty machines. Three values can be represented: 0, 1, and X. If multiword parallel simulation is required, then additional word pairs are used to represent more faulty machines. The internal fanout list pointer and corresponding fanout lists give the fanout that remains in the subcircuit. The external fanout list pointer and corresponding fanout lists give fanout that goes to subcircuits located in other slaves. An element may have only internal fanout, only external fanout, or both internal and external fanout. Note that storing the external fanout takes up more space than storing an internal fanout, since both the destination processor address and element index have to be stored for the external fanout.

2. Activity list—This list is used to keep track of active elements during a simulation time interval. These elements are to be evaluated.

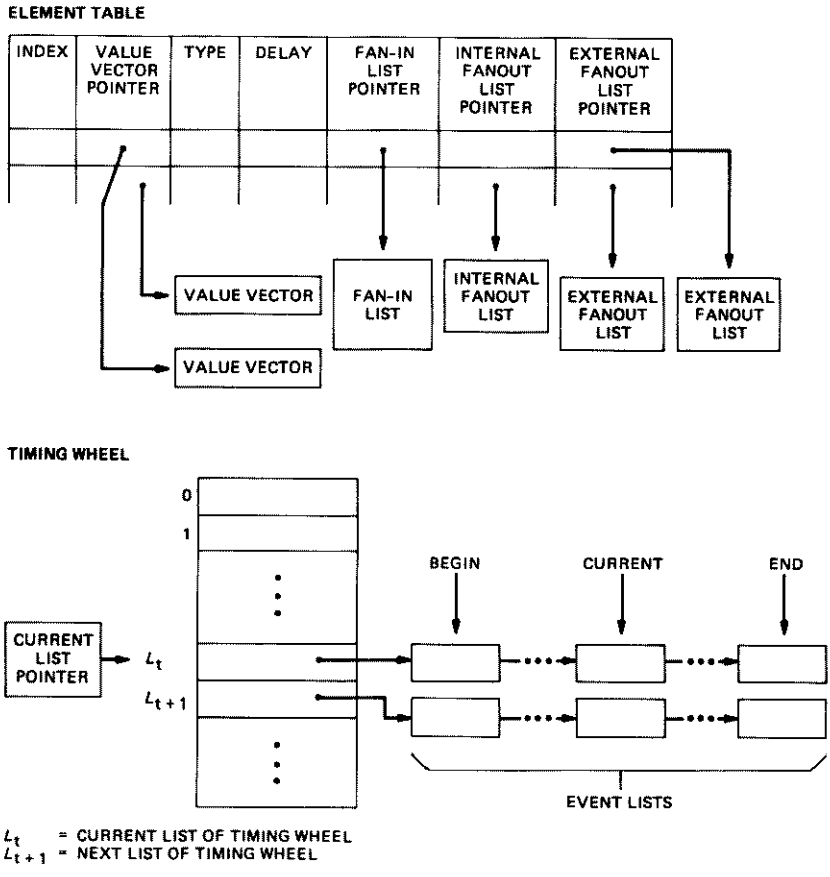

Fig. 11—Data tables for PU operation (parallel simulation).

3. Timing wheel—This data area contains the events that are scheduled in the future. A large amount of work has been done in this area.[15,16]

## APPENDIX C

### *Parallel Simulation Algorithm*

1. Update data from timing wheel

```
for each event in list L_t of timing wheel
  begin
    update value vector pointer in Element Table;
    for each fanout f of updated element
      if activity flag of f not set {
        set activity flag;
```

```
        put f on activity list;
      }
    end
  deallocate space on Timing Wheel;
```

2. Prepare external events for next time interval

```
  for each event in list L(t+1) of Timing Wheel
  begin
      if element has external fanout {
        for each external fanout {
          move destination processor address to OFB;
          move element number to OFB;
          for each word of value vector associated with event
            move word to OFB;
        }
        if element does not have internal fanout also
          deallocate space on Timing Wheel;
      }
    end
```

3. Update data from IFB

```
  enable interrupts from IFB;
  for each interrupt received from IFB
    begin
      if event is not EOD flag {
        for each word of value vector associated with event
          move word to Element Table;
        for each fanout f of updated element
          if activity flag of f not set {
            set activity flag;
            put f on activity list;
          }
      }
      else {
        disable interrupts from IFB;
        reset activity flags in Element Table;
        go to step 4 (Evaluate/Schedule);
      }
    end
```

(The EOD flag signifies end of data present in the IFB for the current simulation cycle. The EOD flag is loaded by the IDS when it receives a START signal from the master.)

4. Evaluate/schedule

```
  for each entry in activity list
    begin
```

```
            inject faults, if any, on inputs;
            for each set of words associated with input value vectors
            of element
              begin
                calculate corresponding output word;
                if output word changed from previous value
                  set change flag;
              end
            inject faults, if any, on outputs;
            if change flag set or faults injected {
              schedule event on Timing wheel;
              if (element delay is 1 && element has external fanout)
                for each external fanout {
                      move destination processor address to OFB;
                  move element number to OFB;
                  for each word of value vector associated with event
                    move word to OFB;
            }
        }
      end
```

5. End cycle

   store EOD flag in OFB;
   increment $t$;
   go to *STEP 1.*

## APPENDIX D

### Glossary

BIU—bus interface unit
CPU—central processing unit (part of a master unit)
EOD—end of data (flag)
IDS—input data sequencer
IFB—input first in first out (FIFO) buffer
$L_p$—number of word pairs used in parallel simulation
LAMP—logic analyzer for maintenance planning
LSI—large-scale integration
$L_t$—current list of timing wheel
$N$—average number of active elements per simulation cycle in true value simulation
$N_T$—total number of active elements during all passes of a simulation
$N_f$—average number of active elements per simulation cycle in fault simulation with 16 faults per pass
ODS—output data sequencer

OFB—output FIFO buffer
PU—processing unit (part of a slave unit)
T—time required to simulate a given set of faults
$c$—average number of elements in an element string
$f_i$—average fan-in of an element
$f_o$—average fanout of an element
$j$—number of events for which the channel is found busy in cross-point matrix
$k$—imbalance factor due to nonideal partitioning
$n$—number of processors in the multiprocessor simulator
$n_o$—number of processors required for optimum operation of multiprocessor simulator
$t_l$—length of simulation cycle for a single processor simulator
$t_a$—time required to process one active element
$t_{br}$—bus release time for a parallel bus structure
$t_{brg}$—bus request and grant time for a parallel bus structure
$t_c$—total communication time during one simulation cycle
$t_{c(bus)}$—total communication time during one simulation cycle for a single parallel bus structure
$t_{c(matrix)}$—total communication time during one simulation cycle for a matrix structure
$t_{c(mbus)}$—total communication time during one simulation cycle for a multiple parallel bus structure
$t_{da}$—data acknowledge time for a parallel bus structure
$t_{ds}$—address and data setup time for a parallel bus structure
$t_m$—length of simulation cycle for a multiprocessor simulator
$t_o$—average processing time, $t_p$, for number of processors $n = n_o$
$t_p$—average processing time per processor during one simulation cycle, where average processing time consists of the time required to process all active elements and schedule resulting events
VLSI—very large-scale integration
$w$—number of words to be transferred across the communication structure for one active event

# Two New Kinds of Biased Search Trees

By J. FEIGENBAUM* and R. E. TARJAN†

(Manuscript received May 20, 1983)

In this paper, we introduce two new kinds of biased search trees: biased, $a$, $b$ trees and pseudo-weight-balanced trees. A biased search tree is a data structure for storing a sorted set in which the access time for an item depends on its estimated access frequency in such a way that the average access time is small. Bent, Sleator, and Tarjan were the first to describe classes of biased search trees that are easy to update; such trees have applications not only in efficient table storage but also in various network optimization algorithms. Our biased $a$, $b$ trees generalize the biased 2, $b$ trees of Bent, Sleator, and Tarjan. They provide a biased generalization of $B$-trees and are suitable for use in paged external memory, whereas previous kinds of biased trees are suitable for internal memory. Our pseudo-weight-balanced trees are a biased version of weight-balanced trees much simpler than Bent's version. Weight balance is the natural kind of balance to use in designing biased trees; pseudo-weight-balanced trees are especially easy to implement and analyze.

## I. INTRODUCTION

The following problem, which we shall call the *dictionary problem*, occurs frequently in computer science. Given a totally ordered universe $U$, we wish to maintain one or more subsets of $U$ under the following operations, where $R$ and $S$ denote any subsets of $U$ and $i$ denotes any item in $U$:

access $(i, S)$—If item $i$ is in $S$, return a pointer to its location. Otherwise, return a special **null** pointer.

* Research done partly while a summer employee of Bell Laboratories and partly while a graduate student supported by Air Force grant AFOSR-80-042.

Permission to reproduce or republish any other portion of this paper must be obtained from the Editor.

insert $(i, S)$—Insert $i$ in $S$, assuming it is not previously there.

delete $(i, S)$—Delete $i$ from $S$.

join $(R, S)$ (two-way join)—Return the set consisting of the union of $R$ and $S$, assuming that every item in $R$ precedes every item in $S$. This operation destroys $R$ and $S$, and can be regarded as a concatenation of $R$ and $S$.

split $(i, S)$—Split $S$ into three sets $L$, $I$, and $R$, where $L$ and $R$ are the sets of items strictly smaller and strictly larger than $i$, respectively, and $I = \{i\}$ if $i$ is in $S$ (three-way split), $I = \emptyset$ if $i$ is not in $S$ (two-way split).

One way to solve the dictionary problem is to store the items of each set in the external nodes of a search tree in left-to-right order, one item per external node. To guide the operations, the search tree also contains auxiliary items, called *keys*, in the internal nodes. The worst-case access time in a search tree is proportional to the depth of the tree. By imposing any one of a number of well-known *balance conditions* on the tree, we can guarantee that its depth is $O(\log n)$, where $n$ is the number of items it contains. Such a balance condition can be maintained during update operations by performing appropriate local rearrangements of the tree. With balanced search trees, each of the dictionary operations has an $O(\log n)$ time bound. Examples of balanced trees include height-balanced (AVL) trees,[1] 2, 3 trees,[2] $B$-trees,[3] and trees of bounded balance.[4]

In many applications of search trees the access frequencies of different items are different, and we would like our data structure to take this into account. To deal with this problem formally we assume that each item $i$ has a known weight $w_i$ providing an estimate of the access frequency. The *biased dictionary problem* is that of implementing the dictionary operations so that operations on heavier items are faster than those on lighter items. In particular, when representing a set $S$ as a search tree, we wish to bias the tree so as to approximately minimize its total weighted depth $\sum_{i \in S} w_i d_i$, where $d_i$ is the depth of the external node containing item $i$, while preserving the ability to update the tree rapidly. In addition to the five dictionary operations, we allow the following operation for changing the weight of an item:

*reweight* $(i, w, S)$—Redefine the weight of item $i$ in set $S$ to be $w$.

The following theorem, due to Shannon, gives a lower bound on the total weighted depth of a search tree:

*Theorem 1:*[5] *If $T$ is a search tree for a set $S$ and every node of $T$ has no more than $b$ children, then*

$$\sum_{i \in S} w_i d_i \geq \sum_{i \in S} \frac{w_i}{W} \log_b \frac{W}{w_i},$$

*where $W = \sum_{i \in S} w_i$ is the total weight of the items in $S$.*

In light of Theorem 1, our goal is to devise classes of search trees that are easy to update and have $d_i = O(\log_b W/w_i)$ for every item $i$. We call $O(\log_b W/w_i)$ the ideal access time of item $i$.

Bent, Sleator, and Tarjan[6–8] have devised several kinds of such biased search trees. Our work is an extension of theirs. A thorough discussion of previous work by others on the biased dictionary problem may be found in Ref. 8.

In their running time analyses, Bent, Sleator, and Tarjan used a technique called *amortization*, which we shall also use. The idea of amortization is to average the running time of individual operations over a (worst-case) sequence of operations. As a tool in deriving amortized time bounds we use *credits*. A credit will pay for one unit of computing time. To each operation we allocate a certain number of credits, called the *credit time* or *amortized time* of the operation. If a given operation does not need all its credits, we can save them for use in later operations; if an operation needs more than its share of credits we can use those previously saved. In any analysis using credits, the objective is to prove that an arbitrary sequence of operations can be performed without running out of credits.

Three points about amortization using credits are worth making. First, credits are a way of charging earlier operations for later ones. If a credit analysis is successful, we can assert that any sequence of operations requires an amount of actual time that is at most a constant multiplied by the sum of the credit times of the individual operations; slow operations are only possible if there are corresponding earlier fast ones. Second, although the word "average" appears in the description of the technique, it is not the usual kind of average-case analysis, and in particular we make no probabilistic assumptions; we obtain worst-case bounds holding for *any* sequence of operations. Third, credits serve as a kind of "potential energy": we place them in regions of search trees that may cause abnormally long update operations. This idea may illuminate the credit invariants we define below.

The remainder of the paper consists of three sections. In Sections II and III, we define and analyze biased $a$, $b$ trees, which generalize the biased 2, $b$ trees of Ref. 8 and provide a biased version of $B$-trees. Biased $a$, $b$ trees are a form of biased tree appropriate for paged external memory; earlier forms of biased trees are more appropriate for internal memory. In Section IV we introduce pseudo-weight-balanced trees, which give a biased version of weight-balanced trees much simpler than Bent's earlier version.[6] Weight balance is the natural kind of balance to use in designing a biased search tree; pseudo-weight-balanced trees are especially easy to implement and analyze.

We shall assume that the reader is familiar with search trees. In particular we shall not discuss the use and updating of keys, and we

shall draw freely on the results and techniques of Ref. 8. We shall use the terminology of Ref. 8 except that we use "external node" in place of "leaf". When appropriate we shall regard a node $x$ of a search tree as denoting the entire subtree rooted at $x$, with the context resolving whether a node or a tree is meant. The **null** node denotes the empty search tree. We denote the parent of a node $x$ by $p(x)$; $p(x) =$ **null** if $x$ is a tree root.

## II. LOCALLY BIASED *a, b* TREES

Our first class of biased trees uses height balance to guarantee fast access and variable node size to allow easy updating. The class is parameterized by two positive integer constants $a$ and $b$ such that $2 \leq a \leq \lceil b/2 \rceil$. The integer $b$ specifies the maximum allowed number of children of an internal node. If an internal node has at least $a$ children, we say it is *filled*; otherwise it is *underfilled*. (An external node is always filled.) Ideally, we would like every node to have at least $a$ children; since in our scheme this is impossible to achieve, we allow underfilled nodes but treat them specially.

If $x$ is a node in a search tree, we define its *weight* $w(x)$ to be the sum of the weights of all items in descendants of $x$. (We use the convention that every node is a descendant of itself.) We define the *rank* $s(x)$ of $x$ recursively by $s(x) = \lfloor \log_a w(x) \rfloor$ if $x$ is an external node, $s(x) = 1 + \max\{s(y) | p(y) = x\}$ if $x$ is an internal node. A node $x$ is *minor* if $x$ is not a root and either $s(x) < s(p(x)) - 1$ or $x$ is underfilled. All other nodes are *major*. A *locally biased a, b tree* is a search tree with the following properties (see Fig. 1):

1. Every internal node has at least two and at most $b$ children;

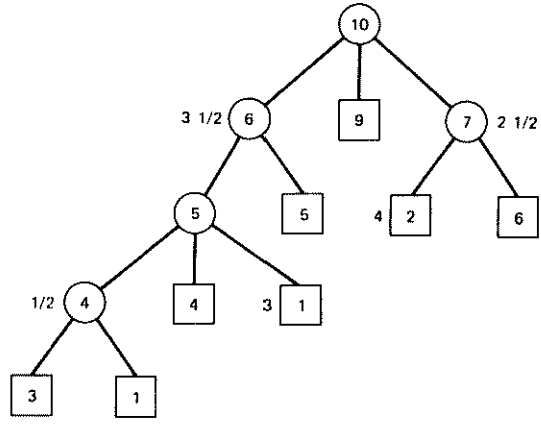

Fig. 1—A biased 3, $b$ tree. The numbers in nodes are ranks, and the numbers beside nodes are credits for the credit invariant.

2. If $x$ is a minor node, any adjacent sibling of $x$ is both major and external. When a node $x$ has this property, we say the tree is *locally biased* at $x$.

We call two nodes $r$-compatible if they can be adjacent children of a node of rank $r$ in a biased $a$, $b$ tree. That is, two nodes are $r$-compatible if both have rank at most $r-1$ and either at least one has rank $r-1$ and is external or both have rank $r-1$ and at least $a$ children each.

If $a = 2$ we obtain exactly the biased 2, $b$ trees of Bent, Sleator, and Tarjan. Our main new idea is in the definition and handling of underfilled nodes. Our first theorem guarantees that $a$, $b$ trees have ideal access time if $b$ is chosen appropriately.

*Lemma 1*: *Consider any biased $a$, $b$ tree. If $x$ is an external node, $a^{s(x)} \le w(x) < a^{s(x)+1}$. If $x$ is an internal node with at least one minor child, $a^{s(x)-1} \le w(x)$. If $x$ is an internal node with $k$ children, $k'a^{s(x)-2} \le w(x)$, where $k' = m\{k, a\}$.*

*Proof*: The first part of the lemma is immediate from the definition of rank. The second part follows from the first part and property 2: if $x$ has a minor child, it must have another child that is major and external. We prove the third part by induction on the height of $x$. If $x$ has a minor child, then $k'a^{s(x)-2} \le a^{s(x)-1} \le w(x)$ by the second part of the lemma. Otherwise, all children of $x$ are major. Let $y$ be a child of $x$. If $y$ is external, or internal with a minor child, then $a^{s(x)-2} = a^{s(y)-1} \le w(y)$. Otherwise, $y$ has at least $a$ major children, and by the induction hypothesis $a^{s(x)-2} = a \cdot a^{s(y)-2} \le w(y)$. Summing over the $k$ children of $x$ gives $ka^{s(x)-2} \le w(x)$. □

*Lemma 2*: *If $x$ is an external node in a biased $a$, $b$ tree of total weight $W$, the depth of $x$ is at most* $\log_a W/(w(x)) + 3$.

*Proof*: Let $r$ be the root of the tree and $d$ the depth of $x$. Since the rank increases by at least one from child to parent, $d \le s(r) - s(x)$. Lemma 1 implies $\log_a w(x) \le s(x) + 1$ and $\log_a W = \log_a w(r) \ge s(r) - 2$. Combining inequalities gives the lemma. □

*Theorem 2*: *A biased $a$, $b$ tree has ideal access time, with a constant factor proportional to* $\log_a b$.

*Proof*: Immediate from Lemma 2. □

According to Theorem 2, to minimize the access time in $a$, $b$ trees, we should choose $b$ as small as possible. The requirement $b \ge 2a - 1$ is necessary to allow efficient updating. The best choice of $b$ seems to be $2a - 1$ or $2a$. The choice $b = 2a$ allows purely up-down updates (see the end of Section III). The choice $b = 2a - 1$ gives a biased version of ordinary $B$-trees.[3] Any other choice gives a biased version of "hysterical" or "weak" $B$-trees.[9-11] Note also that Theorem 2 gives a worst-case example, not an amortized bound on the access time.

As Ref. 8 shows, all the update operations on search trees can be carried out using one or more joins. Our next task is thus to define a join algorithm for biased $a$, $b$ trees.

*Algorithm 1*: *local join* $(x, y)$. Join two locally biased $a$, $b$ trees with roots $x$ and $y$, assuming that all items in tree $x$ precede all items in tree $y$.

Case 0—$x =$ **null** or $y =$ **null.** If $x =$ **null,** return $y$; if $y =$ **null,** return $x$.

Case 1—$s(x) \geq s(y)$ and $x$ and $y$ are $(s(x) + 1)$-compatible, or $s(x) \leq s(y)$ and $x$ and $y$ are $(s(y) + 1)$-compatible. Create a new node with $x$ and $y$ as its children and return the new node.

Case 2—$s(x) = s(y)$ and $x$ and $y$ are not $(s(x) + 1)$ compatible. Let $u$ be the rightmost child of $x$ and $v$ the leftmost child of $y$ (see Fig. 2a). Perform *join*$(u, v)$, letting $w$ be the root of the resulting tree. If $s(w) < s(x)$, construct a node $z$ whose children are those of $x$ not including $u$, the node $w$, and the children of $y$ not including $v$. If $s(w) = s(x)$, construct a node $z$ whose children are those of $x$ not including $u$, those of $w$, and those of $y$ not including $v$ (see Fig. 2b). In either case, if $z$ has more than $b$ children, split it into two nodes $z'$ and $z''$ with $z$ as parent, dividing the old children of $z$ as evenly as possible between $z'$ and $z''$ (see Fig. 2c). Return $z$.

Case 3—$s(x) > s(y)$ and $x$ and $y$ are not $(s(x) + 1)$-compatible. Let $u$ be the rightmost child of $x$ (see Fig. 2d). Perform *join* $(u, y)$, letting $v$ be the root of the resulting tree. If $s(v) < s(x)$, replace $u$ as a child of $x$ by $v$. If $s(v) = s(x)$, replace $u$ as a child of $x$ by the set of children of $v$. If $x$ now has more than $b$ children, split it into two nodes $x'$ and $x''$ with $x$ as parent, dividing the old children of $x$ as evenly as possible between $x'$ and $x''$. Return $x$.

Case 4—$s(x) < s(y)$ and $x$ and $y$ are $(s(y) + 1)$-compatible. Symmetric to Case 3.

*Theorem 3*: *Given two biased a, b trees with roots x and y, the join algorithm produces a biased a, b tree whose root has rank* $\max\{s(x), s(y)\}$ *or* $\max\{s(x), s(y)\} + 1$. *In the latter case, the root of the new tree has exactly two children.*

*Proof*: An easy induction on rank shows that the root of the tree produced by the join has rank $\max\{s(x), s(y)\}$ or $\max\{s(x), s(y)\} + 1$ and that in the latter case the root has exactly two children. Furthermore, it is clear that every internal node in the new tree has at least two and at most $b$ children. All that remains is to show that any two adjacent siblings in the new tree are allowed to be adjacent by property 2. We prove this by induction on rank, using the same cases as in the algorithm.

Case 1—Assume without loss of generality that $s(x) \geq s(y)$. Since

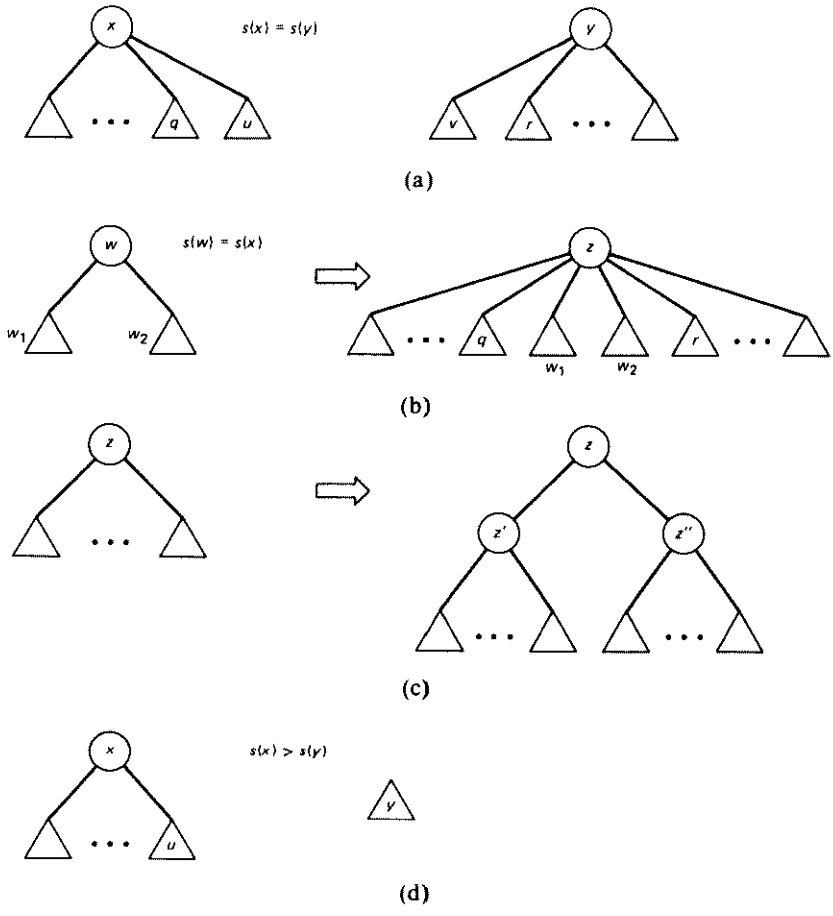

Fig. 2—Cases of the join algorithm. (a) Situation at the beginning of Case 2. (b) Recursive call *join* $(u, v)$ produces a tree of rank $s(x)$ with root $w$. (c) Division of an overfilled root. (d) Case 3.

$x$ and $y$ are $(s(x) + 1)$-compatible, the new tree is locally biased at $x$ and $y$.

Case 2—For the moment, ignore the split of $z$ if it takes place. Since $x$ and $y$ are not $(s(x) + 1)$-compatible, neither $x$ nor $y$ is external, and $u$ and $v$ exist. Suppose the left sibling of $u$, say $q$, is minor. Then $u$ is major and external, which means that the join of $u$ and $v$ will immediately terminate in Case 1, and the new right sibling of $q$ will be $u$. The symmetric statement holds for the right sibling of $v$. Finally, suppose $w$ is minor, i.e., $s(w) < s(x) - 1$ or $w$ has fewer than $a$ children. Then both $u$ and $v$ must be minor as children of $x$ and $y$, respectively, and both adjacent siblings of $w$ in the new tree will be major and external. Thus the tree before the split has property 2.

Splitting $z$ preserves property 2 since both new children of $z$ will have at least $a$ children of their own (this is where we use $b > 2a - 1$) and each will have rank $s(x)$. (Property 2 implies that before the split, of any two adjacent children of $z$, at least one has rank $s(z) - 1$).

Case 3—Similar to but simpler than Case 2. Case 4 is symmetric. □

To make our timing analysis as similar as possible to the one in Ref. 8 for biased 2, $b$ trees, we shall assume that credits can be divided in half, and that half a credit will pay for the work in one call of *join*, not counting the work in the recursive call. We use the following credit invariant: A nonroot node $x$ holds $s(p(x)) - s(x) - 1$ credits, plus an additional half credit if $x$ is underfilled.

*Theorem 4: The join algorithm runs in $O(|s(x) - s(y)|)$ amortized time. Specifically, carrying out the join while preserving the invariant takes $|s(x) - s(y)| + 1$ credits in Case 1 or 2, $|s(x) - s(y)| + 1/2$ credits in Case 3 or 4.*

*Proof*: We use induction on rank and a surprisingly complicated case analysis.

Case 1—Assume without loss of generality that $s(x) \geq s(y)$ and that if $s(x) = s(y)$, then $x$ is external or filled. We need half a credit for the work in the join and at most $s(x) - s(y) + 1/2$ credits to place on $y$, for a total of $s(x) - s(y) + 1$.

Case 2—The split of $z$, if it occurs, does not affect the credit invariant; therefore we ignore it. Assume without loss of generality that $s(u) \geq s(v)$. There are three subcases:

Subcase 2a—$s(w) = s(x)$ and *join* $(u, v)$ is a Case 1 join. The credits originally on $u$ and $v$ suffice to maintain the credit invariant on $u$ and $v$ after the join of $x$ and $y$ is completed. We have one credit on hand to join $x$ and $y$; we spend half for the work in the outer call and half for the work in the inner call.

Subcase 2b—$s(w) = s(x)$ and *join* $(u, v)$ is not a Case 1 join. To perform the join of $x$ and $y$ we are given one credit and can obtain at least $2s(x) - s(u) - s(v) - 2$ from $u$ and $v$, for a total of $2s(x) - s(u) - s(v) - 1$. We need half a credit for the work in the outermost call and at most $s(u) - s(v) + 1$ for the recursive call, for a total of at most $s(u) - s(v) + 3/2$. The difference between what we have and what we need is $2(s(x) - s(u)) - 5/2$. Since $s(x) - s(u) \geq 1$, we must find at most an additional half credit to spend.

If *join* $(u, v)$ is a Case 2 join, and $s(x) - s(u) = 1$, then either $u$ or $v$ is underfilled and yields an extra half credit. If *join* $(u, v)$ is a Case 3 join, we save half a credit on the join. Thus, in any case we can obtain the needed half credit.

Subcase 2c—$s(w) < s(x)$. As in Subcase 2b we have at least $2s(x) - s(u) - s(v) - 1$ credits to perform the join of $x$ and $y$. We need

one half for the work in the outermost call, at most $s(u) - s(v) + 1$ for the recursive call, and at most $s(x) - s(w) - 1/2$ to place on $w$, for a total of at most $s(x) + s(u) - s(v) - s(w) + 1$. The difference between what we have and what we need is $s(x) - s(u) + s(w) - s(u) - 2$. Since $s(x) - s(u) \geq 1$ and $s(w) \geq s(u)$, we have enough credits unless $s(x) - s(u) = 1$ and $s(w) = s(u)$, in which case we must find an extra credit.

Suppose $s(x) - s(u) = 1$ and $s(w) = s(u)$. Since $s(w) = s(u)$, *join* $(u, v)$ is not a Case 1 join, and $u$ is internal. If *join* $(u, v)$ is a Case 2 join, then both $u$ and $v$ are internal. Either both $u$ and $v$ are underfilled, giving us two additional half credits, or one of $u$ and $v$ is underfilled and $w$ is filled, giving us an extra half credit from $u$ or $v$ and saving a half credit that does not need to go on $w$. The only other possibility is that *join* $(u, v)$ is a Case 3 join, which saves us half a credit.

Furthermore in this case either $u$ is underfilled or $w$ is filled, either giving us an extra half credit from $u$ or saving us a half credit on $w$. Thus in all cases we obtain the necessary extra credit.

Case 3—We ignore the possible split of $x$, which does not affect the credit invariant. There are two subcases:

Subcase 3a—$s(v) = s(x)$. To perform the join we are given $s(x) - s(y) + 1/2$ credits and can obtain at least $s(x) - s(u) - 1$ more from $u$, for a total of $2s(x) - s(u) - s(y) - 1/2$. We need one half for the outermost call and at most $|s(u) - s(y)| + 1$ for the recursive call, for a total of $|s(u) - s(y)| + 3/2$. The difference between what we need and what we have is $2(s(x) - \max\{s(u), s(y)\}) - 2 \geq 0$.

Subcase 3b—$s(v) < s(x)$. To perform the join we have at least $2s(x) - s(u) - s(y) - 1/2$ credits. We need $|s(u) - s(y)| + 3/2$ for the outermost and recursive calls, plus at most $s(x) - s(v) - 1/2$ to place on $v$, for a total of $s(x) + |s(u) - s(y)| - s(v) + 1$. The difference between what we have and what we need is $s(x) - \max\{s(u), s(y)\} + s(v) - \max\{s(u), s(y)\} - 3/2$. We have enough credits unless $s(x) - \max\{s(u), s(y)\} = 1$ and $s(v) = \max\{s(u), s(y)\}$, in which case we need an extra half credit.

Suppose $s(x) - \max\{s(u), s(y)\} = 1$ and $s(v) = \max\{s(u), s(y)\}$. Then *join* $(u, y)$ is not a Case 1 join. If it is a Case 2 join, then either $u$ is underfilled, giving us an extra half credit, or $v$ is filled, saving us a half credit on $v$. If it is a Case 3 join, we save half a credit on the join. Thus in all cases we obtain the necessary half credit.

Case 4—Symmetric to Case 3. □

It is useful to restate Theorem 4 as follows. We say a biased $a, b$ tree with root $x$ is *cast to rank* $k$ if it satisfies the credit invariant and has $k - s(x)$ credits on its root. Theorem 4 implies that if $x$ and $y$ are

the roots of two biased $a, b$ trees cast to a rank $k > \max\{s(x), s(y)\}$, then they can be joined, without using additional credits, to produce a tree cast to rank $k$.

We can implement a split as a sequence of joins, exactly as described in Ref. 8. The following algorithm splits at an item $i$ in the tree:

*Algorithm 2*: *split* $(i, r)$. Split the biased $a, b$ tree with root $r$ at item $i$, assumed to be in the tree.

Locate the node $x$ containing item $i$. Initialize the current node to be $p(x)$ and the previous node to be $x$. Initialize the left and right trees to empty; they will contain the items smaller than and larger than $i$, respectively. Repeat the following step until the current node is **null** (the previous node is the root of the tree):

Split Step—Delete every child of the current node to the left of the previous node. If there is one such child, join it to the left tree; if there are two or more such children, give them a common parent and join the resulting tree to the left tree. Repeat this process with the children to the right of the previous node, joining the resulting tree to the right tree. Remove the previous node as a child of the current node and destroy it if it is not $x$. Make the current node the new previous node and its parent the new current node.

*Theorem 5*: *The split algorithm is correct and takes* $O(s(r) - s(x))$ *credit time, where* $x$ *is the node containing item* $i$.

*Proof*: Correctness follows immediately from the correctness of the join algorithm. The time bound follows as in Ref. 8; we shall sketch the idea. Let *cur*, *prev*, *left*, and *right* be the current node, the previous node, and the roots of the left and right trees, respectively. An induction shows that $s(prev) \geq \max\{s(left), s(right)\}$ just before each split step. Another induction shows that by allocating $O(s(cur) - s(prev))$ credits to a split step, we can carry out the step while preserving the invariant that the left and right trees are cast to a rank of $s(prev) + 1$. That is, the amortized time associated with a single step of the split is proportional to the rank difference of two consecutive nodes along the split path. If we sum over all split steps, then the sum telescopes, and we obtain the time bound in the statement of the theorem. □

Splitting at an item not in the tree is just like splitting at an item in the tree, except that the initialization is different. Let $r$ be the root of the tree, $i$ the item at which the split is to take place, $i^-$ and $i^+$ the largest item in the tree less than $i$ and the smallest item in the tree greater than $i$, respectively, and $x$ the *handle* of $i$, defined to be the nearest common ancestor of the external nodes containing $i^-$ and $i^+$. We can locate $x$ by searching down the path from $r$ to $x$ if appropriate keys are stored in the tree (see Ref. 8). To carry out the split, we combine all children of $x$ whose descendants contain items less than $i$

to form the initial left tree and all other children of $i$ to form the initial right tree. Then we initialize the previous and current nodes to be $x$ and $p(x)$, respectively, and repeat the split step until the current node is **null**. Such a split also runs in $O(s(r) - s(x))$ credit time.

We can implement insert, delete, and reweight as combinations of splits and joins: an insertion is a two-way split followed by two joins, a deletion is a three-way split followed by one join, and a weight change is a three-way split followed by two joins. Using the same kind of analysis as in Ref. 8, we obtain the following credit times for these three operations (we have stated the bounds in terms of weights rather than ranks):

$$\text{insert } (i, x)\text{: } O\left(\log_a\left(\frac{w(x) + w_i}{\min\{w_{i^-} + w_{i^+}, w_i\}}\right)\right),$$

where $i^-$ and $i^+$ are as defined above.

$$\text{delete } (i, x)\text{: } O\left(\log_a\left(\frac{w(x)}{w_i}\right)\right).$$

$$\text{reweight } (i, w, x)\text{: } O\left(\log_a\left(\frac{\max\{w(x), w\}}{\min\{w_i, w\}}\right)\right),$$

where $w(x)$ and $w_i$ are as defined before the weight change.

*Remark*: In all the time bounds derived in this section and the next the constant factor is proportional to $b$. □

## III. GLOBALLY BIASED *a, b* TREES

Local bias is sufficient to guarantee good amortized but not good worst-case running times for the dictionary operations. If it is important that every single operation be fast, we need a stronger balance condition. Figure 3 shows how a split can take more actual time than

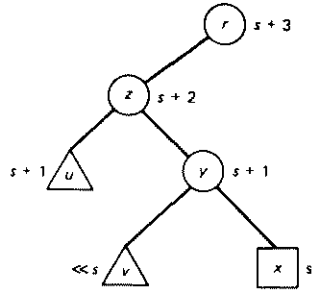

Fig. 3—Locally biased $a$, $b$ tree that cannot be split at $x$ in actual time $O(s(r) - s(x))$. Not all children of $y$, $z$, and $v$ are shown. Join of $u$ and $v$ can take an unbounded amount of time.

its credit time, and illustrates why local bias is not enough: a minor node that is the leftmost child of its parent has a constraint on its right but not on its left side, and symmetrically for a minor node that is the rightmost child of its parent. To overcome this problem we introduce globally biased $a$, $b$ trees.

If $x$ is a node in a search tree, we define $x^+$ to be the external node containing the smallest item greater than the largest item in a descendant of $x$. Symmetrically, $x^-$ is the external node containing the largest item less than the smallest item in a descendant of $x$. If $x$ is on the rightmost path of the tree, $x^+$ is undefined; if $x$ is on the leftmost path, $x^-$ is undefined. A *globally biased a, b tree* is a search tree with two properties (see Fig. 4):

1. Every internal node has at least two and at most $b$ children.

2. If $x$ is a minor nonroot node and $x^+$ is defined, $s(x^+) \geq s(p(x)) - 1$; if $x^-$ is defined, $s(x^-) \geq s(p(x)) - 1$. When a node $x$ has this property, we say the tree is *globally biased* at $x$.

Global bias implies local bias. Thus globally biased $a$, $b$ trees have ideal access time. We can join two globally biased $a$, $b$ trees using almost the same join algorithm as in Section II; the only difference is that the conditions determininng the cases are different. We shall call the algorithm in Section II *local join* to distinguish it from the following *global join* algorithm:

*Algorithm 3: global join* $(x, y)$. Join two globally biased $a$, $b$ trees with roots $x$ and $y$, assuming that all items in tree $x$ precede all items in tree $y$.

In each case, proceed as in the corresponding case of the local join algorithm:

Case 0—$x =$ **null** or $y =$ **null.**

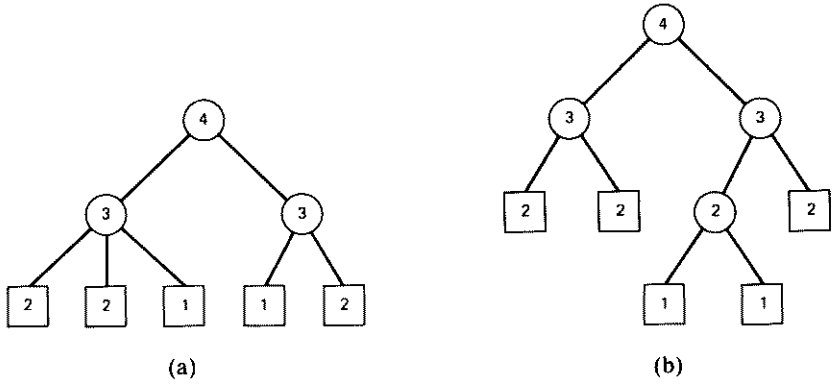

Fig. 4—Two biased 2, 3 trees with the same external nodes. Numbers in nodes are ranks. (a) Locally biased tree. (b) Globally biased tree.

Case 1—$s(x) \geq s(y)$ and $x$ is external, or $s(x) \leq s(y)$ and $y$ is external.

Case 2—$s(x) = s(y)$ and both $x$ and $y$ are internal.

Case 3—$s(x) > s(y)$ and $x$ is internal.

Case 4—$s(x) < s(y)$ and $y$ is internal.

The only difference between this and the local join algorithm is that if $x$ and $y$ have the same rank and both are internal with at least $a$ children, we apply Case 2 instead of Case 1. The algorithm is identical to the join algorithm for globally biased 2, $b$ trees given in Ref. 8.

*Theorem 6: The global join algorithm is correct.*

*Proof*: As in the proof of Theorem 3, we use induction on rank and a case analysis.

Case 1—Immediate.

Case 2—Ignore the split of $z$ if it takes place. Let $q$ be the left sibling of $u$ (recall that $u$ is the rightmost child of $x$). Suppose $q$ or one of the nodes on the rightmost path descending from $q$ is minor. Let this minor node be $r$. The join changes neither $p(r)$ nor $r^+$ and thus preserves global bias at $r$. The symmetric statement holds for the right sibling of $v$ (recall that $v$ is the leftmost child of $y$). Suppose $w$ (the join of $u$ and $v$) or one of the nodes on the leftmost path descending from $w$ is minor. Let this minor node be $r$. There must be a corresponding minor node $r'$ on the leftmost path descending from $u$, such that $s(p(r)) \leq s(p(r'))$. Since the original tree is globally regular at $r'$, the new tree must be globally regular at $r$. The symmetric statement holds for the rightmost path descending from $w$. Thus the new tree is globally biased before the split. The split preserves global bias.

Case 3—Similar to but simpler than Case 2. Case 4 is symmetric. □

*Theorem 7: The worst-case running time of the global join algorithm is* $O(\max\{s(x), s(y)\} - \max\{s(u), s(v)\})$, *where $u$ is the rightmost external descendant of $x$ and $v$ is the leftmost external descendant of $y$.*

*Proof*: The global join algorithm descends rank by rank concurrently along the rightmost path descending from $x$ and the leftmost path descending from $y$, until reaching a leaf; then it ascends. The theorem follows. □

We split a globally biased $a$, $b$ tree in exactly the same way as a locally biased $a$, $b$ tree, *using local rather than global joins.* This method not only produces globally biased trees, it has a worst-case time bound equal to the amortized bound given in Theorem 5.

*Theorem 8: Algorithm 2 (or its variant for an item not in the tree) correctly splits a globally biased $a$, $b$ tree with root $r$ at a node $x$ in* $O(s(r) - s(x))$ *worst-case time.*

*Proof*: The proof is the same as the corresponding proof for globally

biased 2, $b$ trees given in Ref. 8. For completeness, we sketch it here. Let $x_1, x_2, \cdots, x_k$ be the roots of the trees joined to form the final left tree. Let $y_1 = x_1$ and for $i = 2, \cdots, k$ let $y_i$ be the root of the tree formed by executing join $(x_i, y_{i-1})$. With this definition $y_k$ is the final left tree. Each node $x_i$ is either a child of an ancestor of $x$, say $a_i$, in the original tree, or the newly constructed parent of a set of children of such a node $a_i$; furthermore $a_{i+1}$ is a proper ancestor of $a_i$ for $i = 1, \cdots, k-1$. Consider a node $x_i$ for $i \geq 2$. If $x_i$ is a child of $a_i$, global bias implies $x_i$ is a major child, for otherwise its right sibling is external, which is impossible since this right sibling has $x_1$ or its children as ancestors. Thus $s(x_i) = s(a_i) - 1$. If $x_i$ is the new parent of children of $a_i$, then $s(x_i) = s(a_i)$. It follows that $s(x_i) \leq s(x_{i+1})$ for $i = 1, \cdots, k-1$. As noted in the proof of Theorem 5, an induction shows that $s(y_i) \leq s(a_i)$ for $i = 1, \cdots, k$; if $i \geq 2$ and $s(x_i) = s(a_i)$, $x_i$ has at most $b-1$ children, and the join of $x_i$ and $y_{i-1}$ cannot split $x_i$. Thus if $i \geq 2$, $s(a_i) - 1 \leq s(x_i) \leq s(y_i) \leq s(a_i)$.

Consider the join of $x_{i+1}$ and $y_i$. The join will descend rank by rank along the rightmost path from $x_{i+1}$ and the leftmost path from $y_i$. Global bias in the original tree implies that if the descent from $x_{i+1}$ encounters a minor node $z$ (other than the root of $x_{i+1}$), the leftmost external node of $y_i$ will have rank at least $s(p(z)) - 1$ and the join will immediately terminate. Thus the join either terminates by reaching an external descendant of $x_{i+1}$ of rank at least $s(y_i)$, in which case the global bias of the joined tree is immediate, or it reaches an internal descendant, say $z$, of $x_{i+1}$ of rank exactly $s(y_i)$. Now we need a similar but more complicated statement about the leftmost path from $y_i$. There are several cases.

Case 1—$s(x_i) < s(a_i)$ and $x_i$ is minor in the original tree. This can only happen if $i = 1$, i.e., $x_i = y_i$. Global bias implies that the rightmost external descendant of $x_{i+1}$ has rank at least $s(a_i) - 1$. The join descends along the path from $x_{i+1}$ to this external node and then ascends.

Case 2—$s(x_i) < s(a_i)$, $x_i$ is major, and $s(x_i) < s(y_i)$. In this case $y_i$ is also major and the leftmost paths descending from $x_i$ and $y_i$, not including $x_i$ and $y_i$ themselves, are identical. If $z$ is underfilled, $y_i$ is external, and the join terminates in Case 1. If $z$ is filled, $y_i$ is either external or filled, and the join also terminates in Case 1.

Case 3—$s(x_i) < s(a_i)$, $x_i$ is major, and $s(x_i) < s(y_i)$. In this case the left child of $y_i$ is major and the join stops descending either at rank $s(y_i)$ (if $y_i$ is external or filled) or at rank $s(y_i) - 1$ (if $y$ is internal).

Case 4—$s(x_i) = s(a_i)$. In this case the leftmost paths descending from $x_i$ and $y_i$, not including $x_i$ and $y_i$ themselves, are identical. If $y_i$ is external or filled, the join will stop descending at rank $s(y_i)$. If $y_i$ is underfilled, the join will stop at rank $s(y_{i-1})$; either the rightmost child

of $z$ or the leftmost child of $y_i$ is external of rank $s(y_{i-1})$, or both are filled and of rank $s(y_{i-1})$.

In all cases the global bias of the original tree implies that the joined tree is globally biased. This means that the final left tree is globally biased. Furthermore, the time required for joining $x_{i+1}$ and $y_i$ is $O(s(a_{i+1}) - s(a_i))$ in all cases. Summing over all joins gives a time bound of $O(s(r) - s(x))$ to form the final left tree. A symmetric argument applies to the right tree. □

If we implement insertion, deletion, and weight change as described in Section II, we obtain the following worst-case time bounds for the various operations on globally biased $a$, $b$ trees (see Ref. 8):

$$\text{split } (i, r)\text{: } O\left(\log_a \left(\frac{w(r)}{w_i}\right)\right)$$

if $i$ is in the tree, or

$$O\left(\log_a \left(\frac{w(r)}{w_{i^-} + w_{i^+}}\right)\right)$$

if $i$ is not in the tree, where $i^-$ and $i^+$ are the items before and after $i$ in the tree, respectively.

$$\text{insert } (i, x)\text{: } O\left(\log_a \frac{w(x)}{w_{i^-} + w_{i^+}} + \log_a \frac{w(x) + w_i}{w_i}\right).$$

$$\text{delete } (i, x)\text{: } O\left(\log_a \frac{w(x)}{w_i} + \log_a \frac{W'}{w_{i^-} + w_{i^+}}\right),$$

where $W'$ is the weight of the tree root after the deletion.

$$\text{reweight } (i, w, x)\text{: } O\left(\log_a \frac{w(x)}{w_i} + \log_a \frac{W'}{w}\right),$$

where $w(x)$ and $w_i$ are as defined before the weight change, and $W'$ is the weight of the tree root after the change.

As compared with the amortized time bounds for locally biased $a$, $b$ trees, the worst-case bounds for globally biased $a$, $b$ trees are larger for *join* and *delete* and the same for the other operations.

We conclude our discussion of biased $a$, $b$ trees with two remarks. First, if $b \geq 2a$ we can implement either local or global join in an iterative, purely top-down fashion by preemptively splitting nodes with $b$ children as they are encountered. By extending this idea we can implement all the operations top-down. This is a reason to choose $b = 2a$ over $b = 2a - 1$.

Second, for appropriate large values of $a$ and $b$, biased $a$, $b$ trees offer a biased alternative to $B$-trees. One of the advantages of $B$-trees is that there are no underfilled nodes except tree roots; thus if nodes

are stored one node per page in fixed-size pages, the storage efficiency is at least 50 percent, not counting root pages. Biased $a, b$ trees do not share this property. We leave open the problem of devising a space-efficient version of biased $a, b$ trees.

## IV. PSEUDO-WEIGHT-BALANCED TREES

In biased $a, b$ trees, we maintain balance through a height constraint. However, there are other possible balance constraints, such as weight balance. Nievergelt and Reingold[4] defined trees of bounded balance by imposing upper and lower bounds on the ratio *leftweight/rightweight* at each internal node, where the left and right weights count the number of items in the left and right subtrees, respectively. Bent developed a biased version of weight-balanced trees.[6] However, his data structure suffers from a complicated seven-case join algorithm that needs up to three recursive calls and also uses rebalancing rotations more complicated than standard single and double rotations. In this section we introduce a form of biased weight-balanced trees much simpler than Bent's. Our simplification comes from two new ideas: we discretize the weights and allow arbitrarily bad imbalance in some situations where balancing is possible. We call our trees pseudo-weight-balanced.

We consider binary trees, in which each internal node $x$ has exactly two children, a left child $l(x)$ and a right child $r(x)$. As in Section II we define the *weight* $w(x)$ of a node $x$ by $w(x) = w_i$ if $x$ is an external node containing item $i$, $w(x) = w(l(x)) + w(r(x))$ if $x$ is an internal node. We define the *rank* $s(x)$ of a node $x$ differently: $s(x) = \lfloor \lg w(x) \rfloor$. We call a binary search tree *pseudo-weight-balanced* (pwb) if it has two properties:

1. If three nodes in a row, say $x$, $p(x)$, and $p(p(x))$, have the same rank, then $x$ is external and either $x$ is a left child and $p(x)$ a right child or vice-versa (see Fig. 5a).

2. If $x$ and $l(x)$ (symmetrically $x$ and $r(x)$) are internal nodes of the same rank, then $w(r(l(x))) + w(r(x))$ (symmetrically $w(l(r(x))) + w(l(x))$) is at least $2^{s(x)}$ (see Figure 5b). (This property allows us to do single rotations when necessary to maintain property 1.)

The following result bounds the access time in pwb trees.

*Theorem 9: A pwb tree has ideal access time for all items. Specifically, if $x$ is an external node containing item $i$ in a tree of total weight $W$, then the depth of $x$ is at most* $2 \lg(W/w_i) + 3$.

*Proof:* Let $r$ be the root of the tree and $d$ the depth of $x$. According to property 1, after the first step up from $x$, every two steps taken along the path from $x$ to $r$ must cause a rank increase. Thus $\lfloor (d-1)/2 \rfloor \leq s(r) - s(x) = \lfloor \lg W \rfloor - \lfloor \lg w(x) \rfloor$, which implies $d \leq 2\lfloor (d-1)/2 \rfloor + 1 \leq 2(\lg W - \lg w(x) + 1) + 1 \leq 2 \lg (W/w(x)) + 3$. □

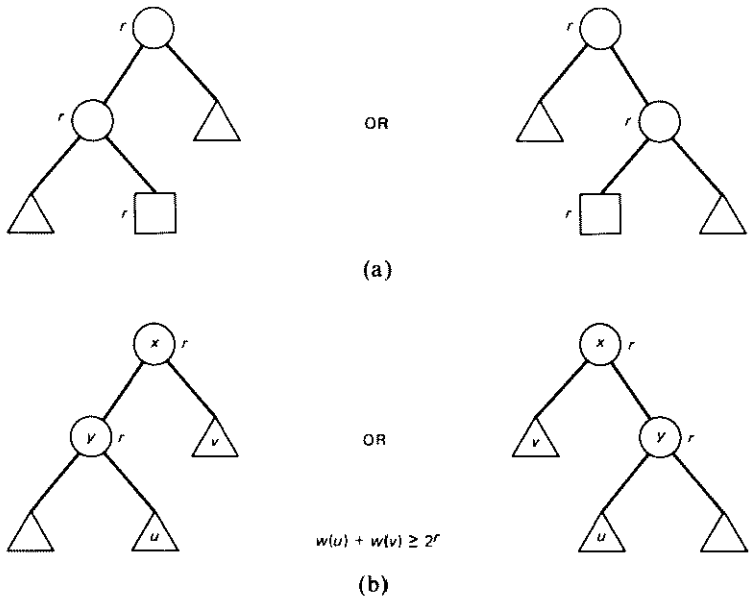

Fig. 5—Legal configurations in a pseudo-weight-balanced tree. (a) Three nodes of the same rank in a row. (b) Two internal nodes of the same rank in a row.

We join two pwb trees using the following algorithm:

*Algorithm 4: join* $(x, y)$. Join two pwb trees with roots $x$ and $y$, assuming that all items in tree $x$ precede all items in tree $y$.

Case 0—$x =$ **null** or $y =$ **null.** Return $y$ if $x =$ **null** or $x$ if $y =$ **null.**

Case 1—$\lg(w(x) + w(y)) \geq 1 + \max\{s(x), s(y)\}$ or the heavier of $x$ and $y$ is an external node. Return a new root with left child $x$ and right child $y$.

Case 2—$s(x) > s(y)$ and $\lg(w(x) + w(y)) < 1 + s(x)$ and $x$ is not external. If $r(x)$ is external, or internal of rank at most $s(x) - 1$, replace $r(x)$ by *join* $(r(x), y)$. Otherwise, perform a single left rotation at $x$ and replace the right child $r(u)$ of the new root $u$ by *join* $(r(u), y)$ (see Fig. 6).

Case 3—$s(x) < s(y)$ and $\lg(w(x) + w(y)) < 1 + s(y)$. Symmetric to Case 2.

*Remark*: Although the join algorithm is stated recursively, it is easy to implement it in an iterative, purely top-down fashion, since the rank of a node depends only on the total weight of its descendants and not on their arrangement.

*Theorem 10*: *Algorithm 4 produces a pwb tree of rank* $\max\{s(x), s(y)\}$ *or* $1 + \max\{s(x), s(y)\}$.

*Proof*: By induction on the depth of the recursion. The definition of rank implies that the rank of the new tree is $\max\{s(x), s(y)\}$ or $1 +$

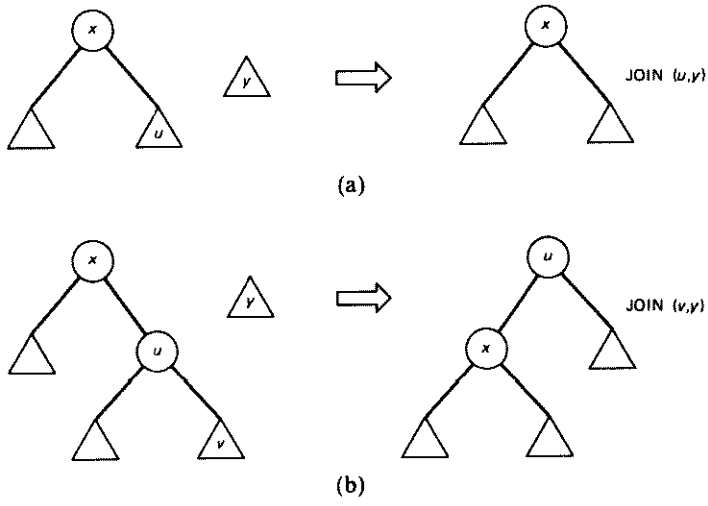

Fig. 6—Case 2 of the join algorithm for pwb trees. (a) Node $u = r(x)$ external or $s(u) < s(x)$: no rotation. (b) Node $u$ internal and $s(u) = s(x)$: rotation.

$\max\{s(x), s(y)\}$. In the latter case, the join must have executed Case 1 and both children of the new root must have rank smaller than the root's rank. Case 1 obviously constructs a tree with properties 1 and 2. In Case 2, property 2 guarantees that the single rotation, if it occurs, creates a pwb tree. If the tree produced by the recursive join has rank less than $s(x)$, the overall joined tree clearly has properties 1 and 2. This is also true if the tree produced by the recursive join has rank $s(x)$, by the observation above. □

In analyzing the running time of Algorithm 4, we use the following credit invariant: Any node $x$ contains $\max\{0, s(p(x)) - s(x) - 1\}$ credits.

*Theorem 11*: *Algorithm 4 runs in* $O(|s(x) - s(y)|) = O(\lg (w(x) + w(y))/\min\{w(x), w(y)\})$ *amortized time. Specifically, if we assume without loss of generality that* $s(x) \geq s(y)$, *performing the join while maintaining the credit invariant takes at most* $s(x) - s(y) + 1$ *credits.*

*Proof*: We consider the same cases as in the algorithm.

Case 1—We need one credit to build the new tree and either $s(x) - s(y)$ or $s(x) - s(y) - 1$ to establish the invariant on $y$, for a total of at most $s(x) - s(y) + 1$.

Case 2—Suppose the single rotation does not take place. We have on hand $s(x) - s(y) + 1$ tokens for performing the join plus $s(x) - s(r(x)) - 1$ from $r(x)$, for a total of $2s(x) - s(y) - s(r(x))$. We need one token for performing the outermost call of *join* plus $\max\{s(r(x)), s(y)\} - \min\{s(r(x)), s(y)\} + 1$ for the recursive call plus $s(x) - \max\{s(r(x)), s(y)\} - 1$ to establish the invariant on the root of the

tree returned by the recursive call, for a total of $s(x) - \min\{s(r(x)), s(y)\} + 1 \leq 2s(x) - s(y) - s(r(x))$, since $s(x) > \max(s(r(x)), s(y))$. Exactly the same argument applies if the rotation does take place, since the rotation preserves the credit invariant. □

The algorithm for splitting a pwb tree is almost identical to but simpler than the algorithm for splitting a biased $a, b$ tree.

*Algorithm 5*: *split* $(x, r)$. Split a pwb tree with root $r$ at a node $x$.

Initialize the current node *cur*, the previous node *prev*, and the left and right nodes *left* and *right* to be $p(x)$, $x$, $l(x)$, and $r(x)$, respectively. Repeat the following step until *cur* = **null:**

Split step—If *prev* = $l(cur)$, replace *right* by *join* (*right*, $r(cur)$); otherwise, replace *left* by *join* ($l(cur)$, *left*). Remove *prev* as a child of *cur* and destroy it if it is not $x$. Replace *prev* and *cur* by *cur* and $p(cur)$, respectively.

This algorithm is the same as that described by Bent, Sleator, and Tarjan[8] for splitting biased binary trees, and indeed will work for any class of binary search trees for which a join algorithm is known.

*Theorem 12*: The amortized time of *split* $(x, r)$ is

$$O\left(\lg\left(\frac{w(r)}{w(x)}\right)\right).$$

More precisely, performing the split while maintaining the credit invariant takes $O(s(r) - s(x))$ credits, where $x$ is the node containing item $i$.

*Proof*: The definition of ranks implies that $s(prev) \geq \max\{s(left), s(right)\}$ before each split step. An easy induction shows that if we allocate $O(s(cur) - s(prev) + 1)$ credits to each split step, we can carry out the step while maintaining the credit invariant on the trees *left* and *right* and in addition maintaining $2s(prev) - s(left) - s(right)$ credits on hand. Summing over all split steps and using property 2 gives the theorem. □

Using the appropriate combinations of *join* and *split*, we obtain the same amortized time bounds as in Section II (with binary logarithms) for insertion, deletion, and weight change in pwb trees. Pseudo-weight-balanced trees are a very simple version of locally biased trees, competitive with the biased binary trees presented in Ref. 8. We have been unable to devise a globally biased version of pwb trees and leave this as an open problem.

# An Algebraic Theory of Relational Databases

By T. T. LEE*

(Manuscript received December 10, 1982)

In this paper we present a theory of relational database systems based on the partition lattice, which represents a new mathematical approach to the structure of relational database systems. A partition lattice can be defined for any given relation. This partition lattice is shown to be a meet-morphic image of the Boolean algebra of subsets of the attribute set. The partial ordering in the lattice is proved to be equivalent to the concept of functional dependency, and thus Armstrong's axioms for functional dependencies are proved. We solve the problem of finding the list of all keys by seeking the prime implicants of the Boolean function associated with the principal ideals generated by the attributes. We demonstrate the properties of the Boyce-Codd Normal Form (BCNF), and give a modified algorithm for synthesizing an information-lossless BCNF based on the principal filter. The necessary and sufficient conditions for multivalued dependency (MVD) are given in terms of a lattice equation, and the inference rules of MVD are proved. The necessary and sufficient conditions for join dependency (JD) are given; consequently, we can prove the known result that acyclic join dependency (AJD) is equivalent to a set of MVDs. The concept of data independence is introduced, and is extended to conditional independence and mutual independence. We established this algebraic theory of relational databases in the same spirit that the theory of probability was constructed. We present a comparison that demonstrates the similarities.

## I. INTRODUCTION

The existing theory of relational databases is based on Codd's relational model of data.[1,2] This relational database theory can be considered to be the study of data dependencies (or independencies).

The theory was initiated by Codd with the introduction of the concept of functional dependency; Codd observed that this concept can be used to design better, normalized, database schemes. The advantage of normalized database schemes is that they remove the possibility of updating anomalies caused by undesirable data dependencies.[2-5]

In the existing theory of logical database design, functional dependencies are input constraints that must always hold in the relation.[6] In the present paper, however, we take a different approach. We assume that for a particular database designer, there exists a (finite) universal relation $R[\Omega]$ for a given set of attributes $\Omega$, such that any relation $T$ on $\Omega$ is a subset of $R[\Omega]$. Furthermore, each subset $X$ of $\Omega$ corresponds to an equivalence relation (partition) on the set of tuples of $R[\Omega]$. That is, if two tuples in $R[\Omega]$ have the same $X$ value, then they are in the same equivalence class. With this approach, the concept of functional dependency becomes equivalent to the refinement partial ordering of the partition lattice. The partitions on the (finite) set of tuples of the universal relation $R[\Omega]$ can then be considered as the fundamental constraints, from which the functional dependencies (partial ordering) can be derived. Consequently, with our approach, the functional dependencies are inherent properties of the universal relation $R[\Omega]$. The input constraints of course must be consistent with the inherent properties within the database.

Another kind of data dependency, proposed by Fagin[7] and Zaniolo,[8] is the multivalued dependency, which includes functional dependency as a special case. Multivalued dependency is the necessary and sufficient condition for the lossless-join decomposition of a relation into two subrelations, such that the original relation can be regenerated by the (natural) join operation.[7-11] Using the partition lattice we propose, we can formulate multivalued dependency as a lattice equation (see Section VI). We show that the axioms for functional dependencies[12] and the inference rules of multivalued dependencies[13] can all be proved as theorems within the framework of partition lattice theory. We show how the concept of join dependency[10,11,14] is connected to multivalued dependency. We give the necessary and sufficient condition for join dependency and, consequently, we can prove the known result that the acyclic join dependency is equivalent to a set of MVDs.[15,16] We also introduce the concept of data independence, and the extension to conditional independence and mutual independence of sets of attributes.

The problem of listing all the keys of a relation is solved by using the concept of principal ideals in lattice theory. One form of a relation having desirable properties is the Boyce-Codd Normal Form (BCNF); we show that the concept of the principal filter (dual ideal) can be used to produce information-lossless Boyce-Codd Normal Forms.

Both the theoretical foundation and the practical application of the existing theory of relational databases appear to be fragmented. This paper shows that all the diverse kinds of data dependencies can be formulated within the lattice theory, which has the important advantage of unifying the theory of relational databases into a coordinated whole. Because of this, it would appear that future work in relational databases should be conducted using lattice theory as the basic framework.

The establishment of this algebraic theory of relational databases is done in the same spirit as the construction of the theory of probability, although probability theory is of course unrelated to database theory. We are convinced that the lattice theory could play a role in the theory of relational databases similar to the role that measure theory plays in the theory of probability.[17]

The basic notion of relational databases is defined in Section II, and the partition lattice of the relation is introduced in Section III. The problem of listing all keys is solved in Section IV, where the Boolean functions associated with the principal ideals are defined. The properties of the Boyce-Codd Normal Form are studied in Section V, where we present a modified algorithm for synthesizing information-lossless BCNFs based on the principal filters. Section VI is devoted to the proof of equivalence between multivalued dependency and a lattice equation. Section VII discusses join dependency and acyclic join dependency. Finally, in Section VIII we outline a possible direction for future research, as well as a comparison that shows the similarities between probability theory and the algebraic theory of relational databases. In Appendix A we list the laws of lattice theory for reference. The proofs of the axioms for functional and multivalued dependencies are listed in Appendix B.

Unless otherwise stated, we refer to the universal relation as simply "the relation" in the remainder of this paper.

## II. RELATIONS

An *attribute* is a symbol taken from a finite set $\Omega = \{A_1, A_2, \cdots, A_n\}$. For each attribute $A$ there is a set of possible values called its *domain*, denoted DOM($A$). We will use capital letters from the beginning of the alphabet ($A, B, \cdots$) for single attributes, and capital letters from the end of the alphabet ($X, Y, \cdots$) for sets of attributes. For a set of attributes $X \subseteq \Omega$, an $X$-value $x$ is an assignment of values to the attributes of $X = \{A_{i_1}, A_{2_2}, \cdots, a_{i_k}\}$ from their respective domains. The notation $XY$ will be used to represent the union of two arbitrary sets of attributes $X, Y \subseteq \Omega$.

A *relation* $R$ on the set of attributes $\Omega = \{A_1, \cdots, A_n\}$ is a subset of the Cartesian product DOM($A_1$) $\times \cdots \times$ DOM($A_n$). The elements

(rows) of $R$ are called *tuples*. A relation $R$ on $\{A_1, \cdots, A_n\}$ will be denoted by $R[A_1 \cdots A_n]$. Similarly, if $R$ is defined on the union of sets $(X_1, X_2, \cdots, X_m)$, then the notation $R[X_1 \cdots X_m]$ will be used. A relation can be visualized as a table whose columns are labeled with attributes and whose rows depict tuples. The ordering of the rows and columns is immaterial. The *cardinal* of $R$ is the total number of tuples in $R$ and is denoted by $|R|$.

Let $t$ be a tuple in $R[\Omega]$. For $X \subseteq \Omega$, $t[X]$ denotes the tuple that contains the components of $t$ corresponding to the attributes of $X$. The *projection* of $R$ on $X$, denoted by $R[X]$, is defined as follows:

$$R[X] = \{t[X] \mid t \in R\}.$$

Similarly, the *conditional projection* of $R$ on $X$ by a $Y$-value $y$, where $Y \subseteq \Omega$, is defined as follows:

$$R_y[X] = \{t[X] \mid t \in R \quad \text{and} \quad t[Y] = y\}.$$

Let $R[XZ]$ and $S[XZ]$ be relations where $X$, $Y$, and $Z$, are disjoint sets of attributes. The *join* (natural join) of $R$ and $S$, denoted by $R \mid \times \mid S$, is the relation $T[XYZ]$ whose attributes are $XYZ$, and is defined as follows:

$$\begin{aligned} T[XYZ] &= R[XZ] \mid \times \mid S[YZ] \\ &= \{(x, y, z) \mid (x, z) \in R \quad \text{and} \quad (y, z) \in S\}. \end{aligned}$$

The join can also be defined as the union of a collection of Cartesian products:

$$\begin{aligned} T[XYZ] &= R[XZ] \mid \times \mid S[YZ] \\ &= \{R_z[X] \times S_z[Y] \times (z) \mid (z) \in R[Z] \cap S[Z]\}. \end{aligned}$$

Let $R$ be a relation on the set of attributes $\Omega$. We may have two sets of attributes $X$, $Y$, $\subseteq \Omega$, such that for any two tuples $t_1$, $t_2 \in R$, $t_1[X] = t_2[X]$ implies $t_1[Y] = t_2[Y]$. We say then that $X$ *functionally determines* $Y$ in $R$, and denote this fact by $X \rightarrow Y$. A functional dependency (FD) $X \rightarrow Y$ is *trivial*, meaning it holds in all relations, if $Y \subseteq X$. Note that FDs enjoy the projectivity and inverse projectivity properties.[3,4] For sets $X$, $Y \subseteq \Omega' \subseteq \Omega$, the FD: $X \rightarrow Y$ is valid in $R[\Omega]$ iff it is valid in $R[\Omega']$.

We say that a set of relations $\{R[\Omega_1], \cdots, R[\Omega_n]\}$ has the *information-lossless join* property if $\Omega = \Omega_1 \cdots \Omega_n$ and

$$R[\Omega] = R[\Omega_1] \mid \times \mid \cdots \mid \times \mid R[\Omega_n].$$

If the set $\{R[\Omega_1], \cdots, R[\Omega_n]\}$ does not have this property, we say that it has a *lossy join*.[14] An important property of functional dependency[10] is that if FD: $X \rightarrow Y$ is valid in $R[\Omega]$ then

$$R[\Omega] = R[(\Omega - Y)X] \mid\times\mid R[XY].$$

This property will be discussed in more detail in Section VI.

## III. THE RELATION LATTICE

If $S$ is a nonempty set, then a subset $\rho$ of $S \times S$ is called a *binary relation* on $S$. The *product* of two binary relations $\rho$, $\rho' \subseteq S \times S$ is defined as:

$$\rho \circ \rho' = \{(a, b\} \in S \times S \mid \exists c \in S \text{ such that } (a, c) \in \rho, (c, b) \in \rho'\}.$$

We say that a relation $\rho$ on $S$ is *reflexive* if $(a, a) \in \rho$ for every $a$ in $S$; that $\rho$ is *symmetric* if $\rho^{-1} = \rho$, i.e., if

$$(\forall a, b \in S), \qquad (a, b) \in \rho \quad \text{implies} \quad (b, a) \in \rho;$$

and that $\rho$ is *transitive* if $\rho \circ \rho \subseteq \rho$, *i.e.*, if

$$(\forall a, b, c \in S), \qquad (a, b) \in \rho \quad \text{and} \quad (b, c) \in \rho \quad \text{imply} \quad (a, c) \in \rho.$$

A binary relation is called an *equivalence relation* if it is reflexive, symmetric, and transitive.

A family $\pi = \{B_i \mid i \in I\}$ of subsets, called *blocks* of $S$, is said to form a *partition* of $S$ if the following conditions hold:

1. Each $B_i$ is nonempty
2. For all $i \neq j$ in $I$, $B_i \cap B_j = \varnothing$
3. $\cup\{B_i \mid i \in I\} = S$.

The two apparently different notions of "equivalence relation" and "partition" are interchangeable: Let $\rho$ be an equivalence relation on a set $S$. Then the family $a_\rho = \{b \mid (a, b) \in \rho\}$ of subsets of $S$ is a partition of $S$. Conversely, if $\pi = \{B_i \mid i \in I\}$ is a partition of $S$, then the relation $\{(a, b) \mid (\exists i \in I), (a, b) \in B_i\}$ is an equivalence relation on $S$.

If $\rho$ is an equivalence relation (partition) on $S$, we shall sometimes write $a\rho b$ as an alternative to $(a, b) \in \rho$. The sets $a_\rho$ that form the associated partition of the equivalence relation are called *$\rho$-classes.* The set of $\rho$-classes is called the *quotient set* of $S$ by $\rho$ and is denoted by $S/\rho$.

A binary relation $\leqq$ on the set $S$ is a *partial ordering* of $S$ if and only if $\leqq$ is reflexive; antisymmetric, i.e., if

$$(\forall a, b \in S), \qquad a \leqq b \quad \text{and} \quad b \leqq a \quad \text{imply} \quad a = b;$$

and transitive. A set $S$ with a partial ordering $\leqq$ is called a *partially ordered set* (poset) and it is denoted by the pair $(S, \leqq)$.

Let $(S, \leqq)$ be a poset and let $T$ be a subset of $S$. Then, $a \in S$ is the *greatest lower bound* (g.l.b.) of $T$ iff

1. $(\forall t \in T)$, $a \leqq t$.

2. $(\forall t \in T)$, $a' \leqq t$ implies $a' \leqq a$.

Similarly, $a \in S$ is the *least upper bound* (l.u.b.) of $T$ iff

1. $(\forall t \in T)$, $t \leqq a$.
2. $(\forall t \in T)$, $t \leqq a'$ implies $a \leqq a'$.

A *lattice* is a poset in which any two elements $a$ and $b$ have a g.l.b., called a *meet* and denoted by $a \cdot b$, and a l.u.b., called a *join* and denoted by $a + b$. We sometimes write the meet $a \cdot b$ as $ab$ if no confusion is created. The properties of the meet and join operations of a lattice[18] are listed in Appendix A.

Let the set of all partitions $\pi_i$ on $S$ be denoted by $\prod(S)$, and define the partial ordering on $\prod(S)$ as follows:

$$\text{If } (\forall a, b \in S), \quad a\pi_1 b \text{ implies } a\pi_2 b, \quad \text{then } \pi_1 \leqq \pi_2.$$

The poset $(\prod(S), \leqq)$ is seen to be a lattice $(\prod(S), \cdot, +)$ with a universal lower bound $\mathbf{0} = \{B_i | i \in I\}$ such that every block $B_i$ is a singleton, and an universal upper bound $\mathbf{1} = \{S\}$. To specify a particular partition, we list the elements, and distinguish blocks with bars and semicolons. For example, if $S = \{1, 2, 3, 4, 5\}$ and partition $\pi$ on $S$ has blocks $\{1, 3, 4\}$, $\{2, 5\}$, then we write $\pi = \{1, 3, 4; 2, 5\}$. The meet and join of any two partitions $\pi_1, \pi_2 \in \prod(S)$ can be determined as follows:

1. $(\forall a, b \in S)$, $a\pi_1 \cdot \pi_2 b$ iff $a\pi_1 b$ and $a\pi_2 b$.
2. $(\forall a, b \in S)$, $a\pi_1 + \pi_2 b$ iff $\exists n \in N$ and $c_0, \cdots, c_n \in S$ such that $a = c_0$, $b = c_n$ and $c_i \pi_1 c_{i+1}$ or $c_i \pi_2 c_{i+1}$ for each $i$, $0 \leqq i \leqq n - 1$.

A complemented distributive lattice is called a *Boolean algebra* (see Appendix A). The set of all subsets of $S$, called the *power set* of $S$, and denoted by $\mathbf{2}^S$, with the partial ordering $(\forall S_1, S_2 \in \mathbf{2}^S)$, $S_1 \leqq S_2$ iff $S_1 \supseteq S_2$, is a Boolean algebra $(\mathbf{2}^S, \cdot, +, ^-)$ with the universal bounds $\mathbf{0} = S$ and $\mathbf{1} = \varnothing$. The *dual* of a poset is the poset with the converse partial ordering on the same elements. The Boolean algebra defined above is the dual of the conventional Boolean algebra of the power set. The operations of meet and join are defined by

1. Meet (g.l.b.) $S_1 \cdot S_2 = S_1 \cup S_2$,
2. Join (l.u.b.) $S_1 + S_2 = S_1 \cap S_2$,

and the complement of $S_1 \in \mathbf{2}^S$ is $\bar{S}_1 = S - S_1$.

Let $\psi$: $L \to M$ be a function from a lattice $L$ into a lattice $M$. We say $\psi$ is a *meet-morphism* if

$$(\forall a, b \in L), \qquad \psi(a \cdot b) = \psi(a) \cdot \psi(b),$$

and $\psi$ is a *join-morphism* if

$$(\forall a, b \in L), \qquad \psi(a + b) = \psi(a) + \psi(b).$$

Meet-morphisms and join-morphisms are both *isotone* (order-preserving); i.e.,

$$(\forall a, b \in L), \qquad a \leqq b \quad \text{implies} \quad \psi(a) \leqq \psi(b),$$

and any order-preserving one-to-one mapping with an inverse is an *isomorphism.*[18]

Let $R$ be a relation on the set of attributes $\Omega$. The set of all subsets of $\Omega$, denoted $\mathbf{2}^{\Omega}$, with the partial ordering defined by set-containment, is a Boolean algebra $(\mathbf{2}^{\Omega}, \cdot, +, ^{-})$,[18] where the meet, join, and complement operations are defined as above. For every $X \in \mathbf{2}^{\Omega}$, there is an equivalence relation (partition) on the set of tuples in $R[\Omega]$ defined as follows:

Definition 1: Let $R$ be a relation on the set of attributes $\Omega$. Each subset of $\Omega$ is associated with a partition of the set of tuples of $R$. We define the function $\theta$: $\mathbf{2}^{\Omega} \rightarrow \prod(R[\Omega])$, which we call the *partition function* (associated with $R[\Omega]$), by

$$\theta{:}X \rightarrow \theta(X) = \{(t_1, t_2) \in R[\Omega] \times R[\Omega] \mid t_1[X] = t_2[X]\}. \quad \blacksquare$$

In general, the image set $Im(\theta)$ of $\theta$ is not a sublattice of $\prod(R[\Omega])$. Since $\pi_1, \pi_2 \in Im(\theta)$ implies $\pi_1 \cdot \pi_2 \in Im(\theta)$, $Im(\theta)$ is a complete lattice in its own right,[20] and it will be called the *relation lattice* of $R[\Omega]$, and denoted by $L(R[\Omega])$. Note that there are no duplicated tuples in $R[\Omega]$, so that $\theta(\Omega) = \mathbf{0}$. Since the tuples cannot be "differentiated" by the empty set of attributes, we define $\theta(\varnothing) = \mathbf{1}$. The universal bounds of $L(R[\Omega])$ are the same as those in $\prod[R)\Omega])$. We immediately recognize the concept of functional dependency to be equivalent to the refinement partial ordering of the partitions.

*Lemma 1: Let $R[\Omega]$ be a relation on the set of attributes $\Omega$, and let $\theta$: $\mathbf{2}^{\Omega} \rightarrow \prod(R[\Omega])$ be the partition function associated with $R[\Omega]$, defined above. Then*

$$X \rightarrow Y \quad \text{iff} \quad \theta(X) \leqq \theta(Y). \quad \blacksquare$$

An immediate consequence of the above lemma is that the projection $R[X]$ of $R[\Omega]$ on $X$ is simply the quotient of $R[\Omega]$ by $\theta(X)$, i.e., $R[X] = R[\Omega]/\theta(X)$. Thus each tuple in $R[X]$ corresponds to a $\theta(x)$-class in $R[\Omega]/\theta(X)$ and it takes the $X$-value only. Note that $\theta(X) = \theta(Y)$ does not imply $R[X] = R[Y]$ because the attributes $X$ and $Y$ may have different sets of values.

*Theorem 1: Let $R$ be a relation on the set of attributes $\Omega$, and let $L(R[\Omega])$ be the relation lattice of $R$. Then the partition function $\theta{:}\mathbf{2}^{\Omega} \rightarrow L(R[\Omega])$ is a meet-morphism.*

*Proof:* We want to show that

$$\theta(XY) = \theta(X)\theta(Y), \qquad \forall X, Y \in \mathbf{2}^{\Omega}.$$

Suppose $t_1\theta(XY)t_2$. Then, $t_1[XY] = t_2[XY]$, which implies

$$t_1[X] = t_2[X] \quad \text{and} \quad t_1[Y] = t_2[Y].$$

Hence,

$$t_1\theta(X)t_2 \quad \text{and} \quad t_1\theta(Y)t_2.$$

By the definition of the meet operation, we have

$$t_1\theta(X)\theta(Y)t_2,$$

so that

$$\theta(XY) \leqq \theta(X)\theta(Y).$$

Suppose $t_1\theta(X)\theta(Y)t_2$. Then,

$$t_1\theta(X)t_2 \quad \text{and} \quad t_1\theta(Y)t_2,$$

so that

$$t_1[X] = t_2[X] \quad \text{and} \quad t_1[Y] = t_2[Y],$$

and thus

$$t_1[XY] = t_2[XY].$$

Consequently,

$$t_1\theta(XY)t_2,$$

so that

$$\theta(X)\theta(Y) \leqq \theta(XY).$$

Hence

$$\theta(XY) = \theta(X)\theta(Y). \quad \blacksquare$$

Note that the partition function $\theta$ is order-preserving, but it is in general not a join-morphism.* However, if $\theta(X + Y) = \theta(X) + \theta(Y)$ holds in $L[R]$, the pair $(X, Y)$ has a special property in the relation. This is discussed further in Section VI.

It is clear now that Armstrong's axioms for functional dependencies become theorems within the framework of lattice theory. The proofs of the axioms for functional dependencies are given in Appendix B.

Let $R$ be a relation on the set of attributes $\Omega$, and let $\theta$: $\mathbf{2}^{\Omega} \rightarrow L[R(\Omega)]$ be the partition function associated with $R[\Omega]$. Then the relation $\theta \circ \theta^{-1}$ on $\mathbf{2}^{\Omega}$ defined by

$$\theta \circ \theta^{-1} = \{(X, Y) \in \mathbf{2}^{\Omega} \times \mathbf{2}^{\Omega} \mid \theta(X) = \theta(Y)\}$$

is obviously an equivalence relation. Sets in the quotient set $\mathbf{2}^{\Omega}/\theta \circ \theta^{-1}$ will be called $\theta$ *classes.*

* The join of $\pi_1$ and $\pi_2$ in $L(R[\Omega])$ may be different from their join in $\prod(R[\Omega])$. We will use the notation $\pi_1 \oplus \pi_2$ to denote the join of $\pi_1$ and $\pi_2$ in $\prod(R[\Omega])$, while $\pi_1 + \pi_2$ will denote the join of $\pi_1$ and $\pi_2$ in $L(R[\Omega])$; e.g., in Example 1 below, $\theta(E) \oplus \theta(S) = \{1, 2, 3, 4, 5, 6; 7, 8\}$, and $\theta(E) + \theta(S) = \{1, 2, 3, 4, 5, 6, 7, 8\}$.

Table I—Relation $R[ECSY]$

| | Employee | Child | Salary | Year |
|---|---|---|---|---|
| 1 | Hilbert | Hubert | \$35K | 1975 |
| 2 | Hilbert | Hubert | \$40K | 1976 |
| 3 | Gauss | Gwendolyn | \$40K | 1975 |
| 4 | Gauss | Gwendolyn | \$50K | 1976 |
| 5 | Gauss | Greta | \$40K | 1975 |
| 6 | Gauss | Greta | \$50K | 1976 |
| 7 | Pythagoras | Peter | \$15K | 1975 |
| 8 | Pythagoras | Peter | \$20K | 1976 |

Example 1: Consider the relation $R$ in Table I (see Ref. 7). Let $\Omega = \{E, C, S, Y\}$ be the set of attributes, where $E$ = employee, $C$ = child, $S$ = salary, $Y$ = year. Then

$$\mathbf{2}^{\Omega} = \{\varnothing, E, C, S, Y, EC, ES, EY, CS, CY, SY, ECS, ECY, ESY, CYS, CESY\},$$

and

$$\theta(\varnothing) = \{\overline{1, 2, 3, 4, 5, 6, 7, 8}\} = \mathbf{1},$$

$$\theta(E) = \{\overline{1, 2}; \overline{3, 4, 5, 6}; \overline{7, 8}\} = \pi_1,$$

$$\theta(C) = \theta(EC) = \{\overline{1, 2}; \overline{3, 4}; \overline{5, 6}; \overline{7, 8}\} = \pi_2,$$

$$\theta(S) = \{\overline{1}; \overline{2, 3, 5}; \overline{4, 6}; \overline{7}; \overline{8}\} = \pi_3,$$

$$\theta(Y) = \{\overline{1, 3, 5, 7}; \overline{2, 4, 6, 8}\} = \pi_4,$$

$$\theta(ES) = \theta(EY) = \theta(SY) = \theta(ESY) = \{\overline{1}; \overline{2}; \overline{3, 5}; \overline{4, 6}; \overline{7}; \overline{8}\} = \pi_5,$$

$$\theta(CS) = \theta(CY) = \theta(ECY) = \theta(ECS) = \theta(CSY) = \theta(ECSY) = \{\overline{1}; \overline{2}; \overline{3}; \overline{4}; \overline{5}; \overline{6}; \overline{7}; \overline{8}\} = \mathbf{0}.$$

The Hasse diagram[18,21] of the relation lattice is illustrated in Fig. 1. ■

## IV. LIST OF KEYS

Let $R$ be a relation on the set of attributes $\Omega$. We say that $X \subseteq \Omega$ is a *superkey* of $R$ if $X \rightarrow A$, $\forall A \in \Omega$. If $X$ is a superkey and no proper subset of $X$ is a superkey, $X$ is said to be a *key* of $R$.[1,2,5]

*Lemma 2:* $X \subseteq \Omega$ *is a superkey of* $R$ *iff* $\theta(X) = \mathbf{0}$.

*Proof:* (Necessity) Let $\Omega = \{A_1, \cdots, A_n\}$, and $X \rightarrow A_i$, $\forall A_i \in \Omega$. Then,

$$\theta(X) \leqq \theta(A_i), \qquad \forall A_i \in \Omega.$$

By the definition of the meet operation, we have

$$\theta(X) \leqq \theta(A_1)\theta(A_2) \cdots \theta(A_n).$$

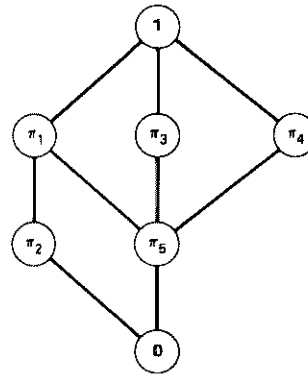

Fig. 1—Relation lattice $L(R[\Omega])$.

It follows from Theorem 1 that

$$\theta(X) \leqq \theta(A_1A_2 \cdots A_n) = \theta(\Omega) = \mathbf{0}.$$

Hence,

$$\theta(X) = \mathbf{0}.$$

(Sufficiency) Suppose $\theta(X) = \mathbf{0}$. Then

$$\theta(X) \leqq \theta(A_i), \qquad \forall A_i \in \Omega.$$

Hence,

$$X \rightarrow A_i, \qquad \forall A_i \in \Omega. \quad \blacksquare$$

An *ideal* is a subset $J$ of a lattice $L$ with the properties[18]

1. $a \in J$, $x \in L$, and $x \leqq a$, imply $x \in J$,
2. $a, b \in J$ implies $a + b \in J$.

For every $a \in L$, the subset of all elements "less than or equal to" $a$ is evidently an ideal; it is called the *principal ideal* of $L$ generated by $a$, and is denoted by $(a]$, i.e.,

$$(a] = \{x \in L \mid x \leqq a\}.$$

Definition 2: Let $R$ be a relation on the set of attributes $\Omega = \{A_1, \cdots, A_n\}$. For each $A_i \in \Omega$, $J_i = (\theta(A_i)]$ is the principal ideal of the relation lattice $L(R[\Omega])$ generated by $\theta(A_i)$. A Boolean function

$$f_i(A_1, \cdots, A_n) = \sum_{\theta(X) \in J_i} X$$

defined on $\mathbf{2}^\Omega$ is the Boolean sum of all $X \in \mathbf{2}^\Omega$ such that $\theta(X) \leqq \theta(A_i)$. We will call $f_i$ the *principal ideal function* (generated by $A_i$). ■

This function plays a role similar to the Boolean function used in Ref. 16.

*Theorem 2: Let $R$ be a relation on $\Omega = \{A_1, \cdots, A_n\}$. $X \subseteq \Omega$ is a superkey of $R$ iff $X$ is a product term in the expansion of the Boolean function*

$$F(A_1, \cdots, A_n) = \prod_{i=1}^{n} f_i(A_1, \cdots, A_n),$$

*where $f_i$ is the principal ideal function generated by $A_i$.*

*Proof:* The Boolean function $F(A_1, \cdots, A_n)$ has the expansion

$$F(A_1, \cdots, A_n) = \prod_{i=1}^{n} f_i = \sum_{\theta(X_i) \in J_i} X_1 \cdots X_n.$$

We want to show that every term $K = X_1 \cdots X_n$ is a superkey. Since $\theta(X_i) \in J_i = (\theta(A_i)]$, it follows that

$$\theta(X_i) \leqq \theta(A_i), \qquad 1 \leqslant i \leqslant n.$$

From L6 in Appendix A, we have

$$\theta(X_1)\theta(X_2) \cdots \theta(X_n) \leqq \theta(A_1)\theta(A_2) \cdots \theta(A_n).$$

It follows from Theorem 1 that

$$\theta(X_1X_2 \cdots X_n) \leqq \theta(A_1 \cdots A_n) = \theta(\Omega) = \mathbf{0},$$

and thus

$$\theta(X_1X_2 \cdots X_n) = \mathbf{0}.$$

Hence, $K = X_1X_2 \cdots X_n$ is a superkey of $R$.

Conversely, suppose $X$ is a superkey of $R$. Then

$$X \rightarrow A_i, \qquad \forall A_i \in \Omega.$$

Thus,

$$\theta(X) \leqq \theta(A_i), \qquad 1 \leqslant i \leqslant n.$$

By the definition of the principal ideal $J_i$, we must have

$$\theta(X) \in J_i = (\theta(A_i)], \qquad 1 \leqslant i \leqslant n.$$

It follows that $X = X \cdots X$ ($n$ times) is a product term in the expansion of $F(A_1, \cdots, A_n)$. ■

It is natural to call $F(A_1, \cdots, A_n)$ the *key Boolean function* of the relation $R[A_1 \cdots A_n]$. Since any key $X$ is a superkey of $R$, $X$ must be a product term of the key Boolean function $F(A_1, \cdots, A_n)$. Since no proper subset of $X$ is a superkey, then by the definition of the *prime implicant* of a Boolean function,[22] we have

*Corollary 1: Let $R$ be a relation on the set of attributes $\Omega = \{A_1, \cdots, A_n\}$. $X \subseteq \Omega$ is a key of $R$ iff $X$ is a prime implicant of the key Boolean function $F(A_1, \cdots, A_n)$.* ■

An attribute $A \in \Omega$ is *prime* in $R[\Omega]$ if $A$ is in any key of $R$; otherwise $A$ is *nonprime*. $A \subseteq \Omega$ is a nonprime attribute if and only if the key Boolean function is independent of $A$.

*Theorem 3: Let $R$ be a relation on $\Omega$. $A \in \Omega$ is a nonprime attribute iff there exists $X \subseteq \Omega$ such that*

1. $A \notin X$, $X \rightarrow A$,
2. $AZ \rightarrow X$ implies $Z \rightarrow X$.

*Proof:* (Necessity) Let $A \in \Omega$ be a nonprime attribute, and let $X$ be any key of $R$. Then

$$A \notin X, \quad \text{and} \quad X \rightarrow A.$$

Suppose $AZ \rightarrow X$. Then $\theta(AZ) \leqq \theta(X) = \mathbf{0}$. It follows that $\theta(AZ) = \mathbf{0}$ and thus $AZ$ is a superkey; it contains a key $K \subseteq AZ$ and $A \notin K$. We have $K \subseteq Z$, so that

$$\theta(Z) \leqq \theta(K) = \mathbf{0} = \theta(X).$$

Hence,

$$Z \rightarrow X.$$

(Sufficiency) Let $\Omega = \{A_1, \cdots, A_n\}$, $n \geqslant 2$. Assume there is an $X = A_2, \cdots, A_m$, such that (1) $X \rightarrow A_1$, and (2) $A_1Z \rightarrow X$, implies $Z \rightarrow X$. We want to show that $A_1$ must be a nonprime attribute. The key Boolean function $F(A_1, \cdots, A_n)$ of $R[\Omega]$ can be written in the form

$$F(A_1, \cdots, A_n) = \prod_{i=1}^{n} f_i = f_1 f_2 \cdots f_m f_{m+1} \cdots f_n$$

$$= (f_1 f_X f_{m+1}) \cdots (f_1 f_X f_n),$$

where $f_X = f_2 \cdots f_m$. For any product term $Y$ in $f_X$ we have

$$\theta(Y) \leqq \theta(X) \leqq \theta(A_1).$$

Therefore, $Y$ must be a term in $f_1$. It follows that $f_1$ has the form

$$f_1 = f_X + g$$

for some Boolean function $g$. Since $\theta(A_1Z) \leqq \theta(X)$ implies $\theta(Z) \leqq \theta(X)$, $f_X$ can be written in the form

$$f_X = A_1 h + h + p = h + p$$

for some Boolean functions $h$ and $p$ which are independent of $A_1$. Also, every $f_j$, $j = m + 1, \cdots, n$, can be written in the form

$$f_j = f_1 e + f_X e + q$$

for some Boolean functions $e$ and $q$, which are independent of $A_1$. It follows that

$$
\begin{aligned}
f_1 f_X f_j &= f_1 f_X (f_1 e + f_X e + q) \\
&= f_X (f_1 e + f_1 f_X e + f_1 q) \\
&= f_X (f_1 e + f_1 q) \\
&= f_1 f_X (e + q) = (f_X + g) f_X (e + q) \\
&= f_X (e + q) = (h + p)(e + q).
\end{aligned}
$$

Since $h$, $p$, $e$, and $q$ are all independent of $A_1$, we know that $f_1 f_X f_j$ is independent of $A_1$ for all $j = m + 1, \cdots, n$. Clearly, no prime implicant of $F(A_1, \cdots, A_n)$ contains $A_1$, and therefore $A_1$ is a nonprime attribute. ■

Example 2: Consider the relation $R$ in Example 1. To obtain the prime implicants of the key Boolean function $F$, we can first simplify each principal ideal function. The principal ideal functions of the relation $R[ECSY]$ are

$$
\begin{aligned}
f_E &= E + C + SY, \\
f_C &= C, \\
f_S &= S + EY + CY, \\
f_Y &= Y + ES + CE,
\end{aligned}
$$

and the key Boolean function is

$$
\begin{aligned}
F(E, C, S, Y) &= (E + C + SY) \cdot C \cdot (S + EY + CY) \\
&\qquad \cdot (Y + ES + CE) \\
&= CS + CY.
\end{aligned}
$$

The sets $CS$ and $CY$ are the keys, and $E$ is the only nonprime attribute. ■

## V. BOYCE-CODD NORMAL FORM

Normalization is a logical database design process that can be viewed as the decomposition of a relation into a set of subrelations, such that the original relation can be regenerated by the joins of the subrelations. The purpose of decomposition is to separate the independent components into distinct relations, to avoid updating anomalies.[2] It is claimed in Ref. 4 that the Boyce-Codd Normal Form is one that is free of insertion and deletion anomalies. This section is devoted to the BCNF and its relation lattice. A modified algorithm for synthesizing an information-lossless BCNF[6] is included, based on the concept of the principal filter of the relation lattice.

Recall that a functional dependency $X \rightarrow Y$ is trivial if $Y \subseteq X$. A

relation $R[\Omega]$ is said to be in Boyce-Codd Normal Form if, for all nontrivial FDs $X \rightarrow Y$, $X$ is a superkey.[2,4]

Definition 3: Relation $R[\Omega]$ is in BCNF if $X \rightarrow Y$ implies either

1. $X$ is a superkey, i.e., $\theta(X) = \mathbf{0}$,

or

2. $Y \subseteq X$. ■

If a relation is in BCNF, we will show that its relation lattice has some special properties. To analyze these properties we need the concept of the principal filter.[18]

An ideal of the dual of the lattice $L$ is called a *filter* of $L$. A subset $M$ of $L$ is a filter of $L$ if

1. $a \in M$, $x \in L$, and $x \geqq a$, imply $x \in M$,
2. $a, b, \in M$ implies $a \cdot b \in M$.

For every $a \in L$, the subset of all elements "greater than or equal to" $a$ is a filter; it is called the *principal filter* of $L$ generated by $a$, and is denoted by $[a)$, i.e.,

$$[a) = \{x \in L \mid x \geqq a\}.$$

If $a$ and $b$ are elements of a lattice $L$, where $a < b$, and there is no $c \in L$ such that $a < c < b$, then we say that $a$ is *covered* by $b$ (or $b$ covers $a$).[18] An element that covers the universal lower bound $\mathbf{0}$ of $L$ is referred to as an *atom* of $L$.[18]

Definition 4: Let $R$ be a relation on the set of attributes $\Omega$, and let $\pi$ be an atom of the relation lattice $L(R[\Omega])$. Let $\Omega_\pi = \{A \mid A \in \Omega, \theta(A) \geqq \pi\} \subseteq \Omega$. Then the projection $R[\Omega_\pi]$ of $R$ and $\Omega_\pi$ is called an *atomic projection*, and $[\pi)$ is called an *atomic filter*. ■

It is easy to verify that the relation lattice of the atomic projection $R[\Omega_\pi]$ is isomorphic to the principal filter $[\pi)$ of $L(R[\Omega])$ generated by $\pi$.

Definition 5: Let $R$ be a relation on the set of attributes $\Omega$, and let $\pi \in L(R[\Omega])$ be an atom. The principal filter $[\pi)$ of $L(R[\Omega])$ is called *normal* iff whenever $X \rightarrow Y$ is valid in the atomic projection $R[\Omega_\pi]$ then $Y \subseteq X$; otherwise, it is called *abnormal*. ■

*Lemma 3: A relation $R[\Omega]$ is in BCNF iff every atomic filter of $L(R[\Omega])$ is normal.*

*Proof*: (Necessity) Trivial.

(Sufficiency) Suppose $X \rightarrow Y$ and $X$ is not a superkey, i.e., $\theta(X) \neq \mathbf{0}$. Then there must exist an atom $\pi$, such that

$$\mathbf{0} < \pi \leqq \theta(X) \leqq \theta(Y).$$

It follows that $X$, $Y \subseteq \Omega_\pi$ and that $X \rightarrow Y$ is valid in the atomic projection $R[\Omega_\pi]$, which is assumed normal. Therefore $Y \subseteq X$. ■

The join operation in the Boolean algebra $(\mathbf{2}^{\Omega}, \cdot, +, ^{-})$ is not always preserved by the $\theta$ mapping. But for a relation $R[\Omega]$ in BCNF, if $X, Y \subseteq \Omega$ and neither $X$ nor $Y$ is a superkey of $R[\Omega]$, then the join $X + Y$ is preserved by $\theta$. We have

*Corollary 2: If $R[\Omega]$ is in BCNF, $X, Y \subseteq \Omega$, $\theta(X) \neq \mathbf{0}$, and $\theta(Y) \neq \mathbf{0}$, then*

$$\theta(X + Y) = \theta(X) + \theta(Y).$$

*Proof*: Since $X + Y \subseteq X$ and $X + Y \subseteq Y$, we have

$$\theta(X) \leqq \theta(X + Y) \quad \text{and} \quad \theta(Y) \leqq \theta(X + Y).$$

By definition of the join operation, we have

$$\theta(X) + \theta(Y) \leqq \theta(X + Y).$$

Suppose there is a $Z \subseteq \Omega$ such that

$$\theta(X) \leqq \theta(Z) \quad \text{and} \quad \theta(Y) \leqq \theta(Z).$$

Given $\theta(X) \neq \mathbf{0}$ and $\theta(Y) \neq \mathbf{0}$, we have

$$Z \subseteq X \quad \text{and} \quad Z \subseteq Y.$$

Thus,

$$Z \subseteq X + Y,$$

so that

$$\theta(X + Y) \leqq \theta(Z).$$

By the definition of least upper bound, we have

$$\theta(X + Y) = \theta(X) + \theta(Y). \quad \blacksquare$$

The most important characteristic of the BCNF is given in the following theorem.

*Theorem 4: The relation $R[\Omega]$ is in BCNF iff every atomic filter $[\pi)$ of $L(R[\Omega])$ is isomorphic to the Boolean algebra $(\mathbf{2}^{\Omega_\pi}, \cdot, +, ^{-})$.*

*Proof*: (Necessity) Since $[\pi)$ is a meet-morphic image of $\theta$ restricted to $\mathbf{2}^{\Omega_\pi}$, it is sufficient to show that $\theta$ is a one-to-one mapping on $\mathbf{2}^{\Omega_\pi}$. Let $X, Y \in \mathbf{2}^{\Omega_\pi}$, and $\theta(X) = \theta(Y)$. It follows that

$$\theta(X) = \theta(Y - X)\theta(Y + X) \leqq \theta(Y - X),$$

which implies

$$X \rightarrow Y - X.$$

Since $\mathbf{0} < \pi \leqq \theta(X)$ and $[\pi)$ is normal, we have

$$Y - X \subseteq X.$$

Hence,

$$Y \subseteq X.$$

Similarly,

$$X \subseteq Y.$$

Therefore, $X = Y$, and $\theta$ is a one-to-one mapping on $\mathbf{2}^{\Omega_\pi}$.

(Sufficiency) Suppose $X \rightarrow Y$ is valid in $R[\Omega_\pi]$. Then $\theta(X) \leqq \theta(Y)$. Since the inverse of an isomorphism is also order-preserving, it follows that $X \supseteq Y$. Therefore, $[\pi)$ is normal and $R[\Omega]$ is in BCNF. ■

The above theorem implies that if $[\pi)$ is normal, the only key of $R[\Omega_\pi]$ is $\theta^{-1}(\pi) = \Omega_\pi$.

It is known that any relation has a lossless-join decomposition into Boyce-Codd Normal Form, and an algorithm for determining the decomposition is given in Ref. 6. We will show how the concept of the principal filter can be used to modify this algorithm. In the algorithm for synthesizing the Third Normal Form,[5] a concept similar to the principal filter is used implicitly by Bernstein when he partitions the functional dependencies (Step 2). Before describing the improved algorithm, we need the following:

*Lemma 4: Let $R$ be a relation on $\Omega$. Let $\pi \in L(R[\Omega])$ be an atom of the relation lattice, and let $K$ be a key of the atomic projection $R[\Omega_\pi]$. Then,*

$$R[\Omega] = R[(\Omega - \Omega_\pi)K] \,|\times|\, R[\Omega_\pi].$$

*Proof*: $K \subseteq \Omega_\pi$ and $K \rightarrow \Omega_\pi$. ■

The algorithm for determining the lossless-join decomposition into BCNF is simply to construct a sequence of decompositions $D_i = (R_1, \cdots, R_m)$ of $R$, each with lossless join: Initially, let $D_0$ consist of $R$ alone. If $T[\Omega]$ is a relation in $D_i$, and $T[\Omega]$ is not in BCNF, let $\pi$ be an atom of $L(T[\Omega])$ for which the principal filter $[\pi)$ is abnormal. Let $K$

Table II—Relation $R[MSPCNY]$

| | Model Number | Serial Number | Price | Color | Name | Year |
|---|---|---|---|---|---|---|
| 1 | 1234 | 342 | 13.25 | blue | pot | 1974 |
| 2 | 1234 | 347 | 13.25 | red | pot | 1974 |
| 3 | 1234 | 410 | 14.23 | red | pot | 1975 |

| 14 | 1654 | 435 | 28.55 | red | kettle | 1975 |

be a key of the atomic projection $T[\Omega_\pi]$. Now replace $T[\Omega]$ in $D_i$ by $T[\Omega - \Omega_\pi)K]$ and $T[\Omega_\pi]$ to obtain $D_{i+1}$. Continue the process until all the relations in the decomposition $D_k$ are in BCNF.

Example 3: Let us consider the relation $R[MSPCNY]$ from Ref. 23, where $M$ = model number, $S$ = serial number, $P$ = price, $C$ = color, $N$ = name, and $Y$ = year. The tuples of the relation $R[MSPCNY]$ are shown in Table II.

The Hasse diagram of the relation lattice $L(R[\Omega])$ is illustrated in Fig. 2, where

$$\pi_1 = \{\overline{1, 8, 9, 10, 13}; \overline{2, 3, 6, 7, 14}; \overline{4, 5, 11, 12}\},$$

$$\pi_2 = \{\overline{1, 2, 3}; \overline{4, 5, 6, 7, 8}; \overline{9, 10, 11, 12, 13, 14}\},$$

$$\pi_3 = \{\overline{1, 2, 4}; \overline{3, 11, 12, 13, 14}; \overline{5, 6, 7, 8, 10}; \overline{9}\},$$

$$\pi_4 = \{\overline{1, 2, 3}; \overline{4, 5, 6, 7, 8}; \overline{9, 10, 11, 12, 13}; \overline{14}\},$$

$$\pi_5 = \{\overline{1, 2}; \overline{3}; \overline{4}; \overline{5, 6, 7, 8}; \overline{9}; \overline{10}; \overline{11, 12, 13, 14}\},$$

$$\pi_6 = \{\overline{1}; \overline{2, 3}; \overline{4, 5}; \overline{6, 7}; \overline{8}; \overline{9, 10, 13}; \overline{11, 12}; \overline{14}\},$$

$$\pi_7 = \{\overline{1, 2}; \overline{3}; \overline{4}; \overline{5, 6, 7, 8}; \overline{9}; \overline{10}; \overline{11, 12, 13}; \overline{14}\},$$

$$\pi_8 = \{\overline{1}; \overline{2, 4}; \overline{3, 11}; \overline{5, 10}; \overline{6}; \overline{7}; \overline{8}; \overline{9}; \overline{12}; \overline{13}; \overline{14}\},$$

$$\pi_9 = \{\overline{1}; \overline{2}; \overline{3}; \overline{4}; \overline{5}; \overline{6, 7}; \overline{8}; \overline{9}; \overline{10}; \overline{11, 12}; \overline{13}; \overline{14}\},$$

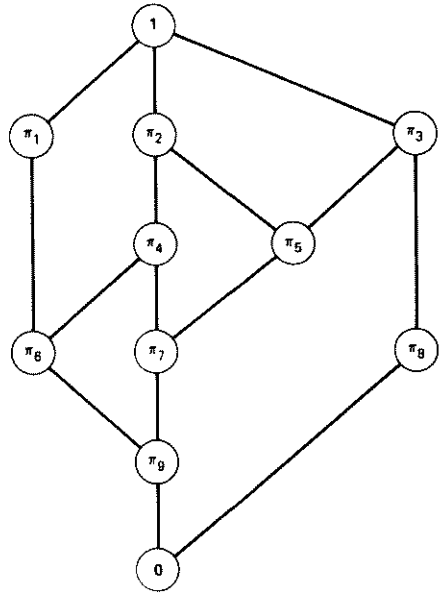

Fig. 2—Relation lattice $L(R[MSPCNY])$.

and $\theta(C) = \pi_1$, $\theta(N) = \pi_2$, $\theta(Y) = \pi_3$, $\theta(M) = \pi_4$, $\theta(P) = \pi_5$, $\theta(S) = \pi_8$. For $X \subseteq \Omega$, $\theta(X)$ can be obtained easily by carrying out the meet operations on the attributes in $X$.

The principal ideal functions of $R[MSPCNY]$ are

$$f_C(M, S, P, C, N, Y) = C + MS + NS + PS,$$

$$f_N(M, S, P, C, N, Y) = N + M + P + CY + CS,$$

$$f_P(M, S, P, C, N, Y) = P + MY + CS + MS + NS,$$

$$f_M(M, S, P, C, N, Y) = M + CN + CP + CY + NS + PS + CS,$$

$$f_Y(M, S, P, C, N, Y) = Y + P + S,$$

$$f_S(M, S, P, C, N, Y) = S,$$

and the key Boolean function is

$$\begin{aligned} F(M, S, P, C, N, Y) &= (C + MS + NS + PS)\cdot(N + M + P + CY \\ &\quad + CS) \\ &\quad \cdot(P + MY + CS + MS + NS) \\ &\quad \cdot(M + CN + CD + CY + NS + PS + CS) \\ &\quad \cdot(Y + P + S)\cdot S \\ &= CS + MS + NS + PS. \end{aligned}$$

The keys of $R[MSPCNY]$ are $\{CS, MS, NS, PS\}$, and $Y$ is the only nonprime attribute.

Initially, let $D_0 = \{R(MSPCNY)\}$. Since both atomic filters $[\pi_8)$ and $[\pi_9)$ are abnormal, we arbitrarily choose $\pi_9$, and let $\Sigma = \Omega_{\pi_9} = MPCNY$. The relation lattice of $R[\Sigma]$ is isomorphic to $[\pi_9)$. The principal ideal functions of $R[\Sigma]$ are

$$g_C(M, P, C, N, Y) = f_C(M, \mathbf{0}, P, C, N, Y) = C,$$

$$g_N(M, P, C, N, Y) = f_N(M, \mathbf{0}, P, C, N, Y) = N + M + P + CY,$$

$$g_P(M, P, C, N, Y) = f_P(M, \mathbf{0}, P, C, N, Y) = P + MY,$$

$$g_M(M, P, C, N, Y) = f_M(M, \mathbf{0}, P, C, N, Y) = M + CN + CP + CY,$$

$$g_Y(M, P, C, N, Y) = f_Y(M, \mathbf{0}, P, C, N, Y) = Y + P,$$

and the key Boolean function is

$$\begin{aligned} G(M, P, C, N, Y) &= C\cdot(N + M + P + CY)\cdot(P + MY) \\ &\quad \cdot(M + CN + CP + CY)\cdot(Y + P) \\ &= CP + CMY. \end{aligned}$$

We choose the key $CP$ and replace $R[MSPCNY]$ in $D_0$ by $R[(\Omega - \Sigma)K] = R[SPC]$ and $R[\Sigma] = R[MPCNY]$ to obtain $D_1 = \{R[SPC], R[MPCNY]\}$. The relation $R[SPC]$ and its lattice are shown in Table III and Fig. 3, respectively.

The relation $R[SPC]$ is in BCNF, but the relation $R[MPCNY]$ is not. The relation lattice of $R[MPCNY]$ is isomorphic to the filter $[\pi_9)$. We will not duplicate the figure. Both "atoms" $\pi_6$ and $\pi_7$ of $[\pi_9)$ are abnormal. We choose the filter $[\pi_7)$. The principal ideal functions of $R[\Sigma_{\pi_7}] = R[MPNY]$ are

$$h_M(M, P, N, Y) = g_M(M, P, \mathbf{0}, N, Y) = M,$$
$$h_N(M, P, N, Y) = g_N(M, P, \mathbf{0}, N, Y) = N + M + P,$$
$$h_P(M, P, N, Y) = g_P(M, P, \mathbf{0}, N, Y) = P + NY,$$
$$h_Y(M, P, N, Y) = g_Y(M, P, \mathbf{0}, N, Y) = Y + P,$$

and the key Boolean function of $R[MPNY]$ is given by

$$H(M, P, N, Y) = M \cdot (N + M + P) \cdot (P + MY) \cdot (Y + P)$$
$$= MP + MY.$$

We choose the key $K' = MP$ and replace $R[MPCNY]$ in $D_1$ by $R[(\Sigma - \Sigma_{\pi_7})K'] = R[MPC]$ and $R[MPNY]$ to obtain $D_2 = \{R[SPC], R[MPC], R[MPNY]\}$. The relation $R[MPC]$ and its relation lattice are illustrated in Table IV and Fig. 4, respectively.

Now we have to decompose the relation $R[MPNY]$ in $D_2$. The relation lattice of $R[MPNY]$ is isomorphic to $[\pi_7)$ of $L(R[MSPCNY])$. We choose the abnormal filter that is isomorphic to $[\pi_5)$. Since $\Sigma_{\pi_5} = PNY$ and the only key is $P$, we can replace $R[MPNY]$ in $D_2$ by $R[MP]$ and $R[PNY]$ to obtain $D_3 = \{R[SPC], R[MPC], R[MP], R[PNY]\}$. All the relations in $D_3$ are in BCNF. The relations $R[MP]$, $R[PNY]$ and

their respective lattices are shown in Tables V and VI, and Figs. 5 and 6. ■

## VI. MULTIVALUED DEPENDENCIES

Multivalued dependency (MVD) proposed by Fagin[7] and Zaniolo[8] is the necessary and sufficient condition for a (binary) lossless-join decomposition. A similar concept, called hierarchical dependency, was defined by Delobel.[24] A bit later, the concept of multivalued dependency was generalized to join dependency by Rissanen.[10,11] A set of "axioms" or inference rules for multivalued dependencies was given by Beeri, Fagin, and Howard.[25] We know from our previous discussion that functional dependency is equivalent to partial ordering in the partition lattice. In this section we show that multivalued dependency

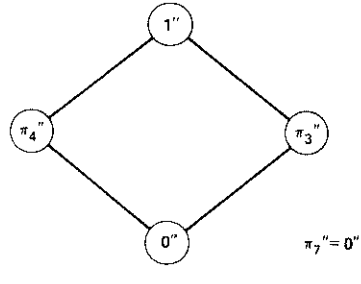

Fig. 5—Relation lattice $L(R[MP])$.

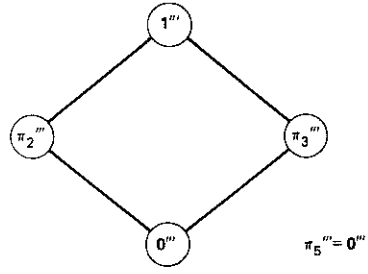

Fig. 6—Relation lattice $L(R[PNY])$.

is equivalent to a lattice equation. First, however, we state the definition of MVD and show that MVD guarantees information-lossless join decomposition.

Definition 5: Let $R$ be a relation on the set of attributes $\Omega = XYZ$, where $X$, $Y$, and $Z$ are disjoint subsets of $\Omega$. We say there is a multivalued dependency $X \longrightarrow\!\!\!\!\!\rightarrow Y$ if

$$R_{xz}[Y] = R_x[Y], \qquad \forall (x) \in R[X], \qquad (z) \in R[Z]. \quad \blacksquare$$

*Lemma 5: Let $R$ be a relation on $\Omega = XYZ$, where $X$, $Y$, and $Z$ are disjoint subsets. Then,*

$$R[XYZ] = R[XY] \mid \times \mid R[XZ]$$

*iff*

$$R_x[YZ] = |R_x[Y]| \cdot |R_x[Z]|, \qquad \forall (x) \in R[X].$$

*Proof*: (Necessity) $R[XYZ] = R[YX] \mid \times \mid R[XZ]$ implies

$$R_x[YZ] = R_x[Y] \times R_x[Z], \qquad \forall (x) \in R[X].$$

Hence,

$$|R_x[YZ]| = |R_x[Y]| \cdot |R_x[Z]|.$$

(Sufficiency) It is easy to verify that

$$R_x[YZ] \subseteq R_x[Y] \times R_x[Z], \qquad \forall (x) \in R[X].$$

The given cardinal identity assures that

$$R_x[YZ] = R_x[Y] \times R_x[Z], \qquad \forall (x) \in R[X]. \quad \blacksquare$$

*Theorem 5: Let $R$ be a relation on the set of attributes $\Omega = XYZ$, where $X$, $Y$, and $Z$ are disjoint subsets.* Then,*

$$R[XYZ] = R[XY] \mid \times \mid R[XZ] \textit{ iff } X \longrightarrow\!\!\!\!\!\rightarrow Y.$$

---

* For convenience, we assume $X$, $Y$, and $Z$ to be disjoint. It will later become clear that this assumption is not necessary.

*Proof*: (Necessity) From Lemma 5, it is sufficient to show that

$$|R_x[YZ]| = |R_x[Y]| \cdot |R_x[Z]|, \qquad \forall (x) \in R(X)$$

iff

$$R_{xx}[Y] = R_x[Y], \qquad \forall (x) \in R(X), \qquad (z) \in R(Z).$$

Since

$$R[XYZ] = R[XY] \mid \times \mid R[XZ]$$

implies

$$R_{xz}[Y] \times (x, z) = R_x[Y] \times (x, z), \qquad \forall (x) \in R[X], \qquad (z) \in R[Z].$$

Hence,

$$R_{xz}[Y] = R_x[Y].$$

(Sufficiency) For every $(x) \in R[X]$, we have

$$\begin{aligned}(x) \times R_x[ZY] &= \{(x, z_i) \times R_{xz_i}[Y] \mid (x, z_i) \in R[XZ]\} \\ &= \{(x, z_i) \times R_x[Y] \mid (x, z_i) \in R[XZ]\} \\ &= (x) \times R_x[Z] \times R_x[Y].\end{aligned}$$

Since $|x| = 1$, it follows that

$$|R_x[YZ]| = |R_x[Y]| \cdot |R_x[Z]|, \qquad \forall (x) \in R[X]. \quad \blacksquare$$

We need the commutative property of the product of two equivalence relations (partitions) to establish the lattice equation of multivalued dependency. The product of two equivalence relations may not be an equivalence relation; if it is an equivalence relation then the product must be commutative and vice versa.

Definition 6: Two binary relations $\rho$ and $\rho'$ and $S$ are *permutable* (commute) if and only if $\rho \circ \rho' = \rho' \circ \rho$. This means that if $a \; \rho \; x \; \rho' \; b$ for some $x \in S$, then $a \; \rho' \; y \; \rho \; b$ for some $y \in S$, and conversely.[18] ■

*Lemma 6*: *Let $\rho$ and $\rho'$ be equivalence relations (partitions) on $S$. Then the following are equivalent*:

1. $\rho \circ \rho' = \rho \circ \rho$
2. $\rho \circ \rho' = \rho \oplus \rho'$
3. $\rho \circ \rho'$ is an equivalence relation
4. $\rho \circ \rho'$ is symmetric.

*Proof*: The proof of Lemma 6 is given in Ref. 21. ■

*Lemma 7*: *Let $R$ be a relation on the set of attributes $\Omega$ and let $X, Y, Z \subseteq \Omega$. Then,*

$$\theta(X) = \theta(XY) + \theta(XZ) = \theta(XY) \circ \theta(XZ) = \theta(XZ) \circ \theta(XY)$$

*iff*

$$\theta(X) \subseteq \theta(XY) \circ \theta(XZ).$$

*Proof*: (Necessity) Trivial.

(Sufficiency) Suppose $t_1\theta(XY) \circ \theta(XZ)t_2$. Then there exists $t_3 \in R[\Omega]$ such that

$$t_1\theta(XT)t_3\theta(XZ)t_2,$$

which implies

$$t_1\theta(X)t_3\theta(X)t_2.$$

Therefore,

$$t_1\theta(X)t_2.$$

Hence,

$$\theta(XY) \circ \theta(XZ) \subseteq \theta(X).$$

It follows that

$$\theta(X) = \theta(XY) \circ \theta(XZ).$$

From Lemma 6, we have

$$\theta(X) = \theta(XY) \oplus \theta(XZ) = \theta(XY) \circ \theta(XZ) = \theta(XZ) \circ \theta(XY).$$

Since

$$\theta(XY) \leqq \theta(XY) + \theta(XZ) \quad \text{and} \quad \theta(XZ) \leqq \theta(XY) + \theta(XZ),$$

by the definition of the join operation $\oplus$ in $\prod(R[\Omega])$, we must have

$$\theta(X) = \theta(XY) \oplus \theta(XZ) \leqq \theta(XY) + \theta(XZ).$$

But,

$$\theta(XY) + \theta(XZ) \leqq \theta(X) + \theta(X) = \theta(X),$$

so it follows that

$$\theta(X) = \theta(XY) + \theta(XZ) = \theta(XY) \circ \theta(XZ) = \theta(XZ) \circ \theta(XY). \quad \blacksquare$$

The following theorem shows that the multivalued dependency can be formulated as a lattice equation.

*Theorem 6*: *Let $R$ be a relation on the set of attributes $\Omega = XYZ$, where $X$, $Y$, and $Z$ are disjoint subsets. Then, $R[XYZ] = R[XY] \mid\times\mid R[XZ]$ iff*

$$\theta(X) = \theta(XY) + \theta(XZ) = \theta(XY) \circ \theta(XZ) = \theta(XZ) \circ \theta(XY).$$

*Proof*: (Necessity) Since $R[XYZ] = R[XY] \mid\times\mid R[XZ]$ implies

$$R_x[YZ] = R_x[Y] \times R_x[Z], \qquad \forall (x) \in R[X],$$

there is a one-to-one and onto mapping $\phi_x$: $R_x[YZ] \rightarrow R_x[Y] \times R_x[Z]$, which takes every tuple $(y, z) \in R_x[YZ]$ into $\phi_x((y, z)) = ((y), (z)) \in R_x[Y] \times R_x[Z]$, $\forall(x) \in R[X]$. Suppose $t_1, t_2 \in R[XYZ]$ and $t_1\theta[X]t_2$, and assume $t_1 = (x, y_1, z_1)$ and $t_2 = (x, y_2, z_2)$. As

$$(y_1, z_1), (y_2, z_2) \in R_x[YZ] = R_x[Y] \times R_x[Z],$$

we have

$$(y_1), (y_2) \in R_x[Y] \quad \text{and} \quad (z_1), (z_2) \in R_x[Z].$$

Since $\phi_x$ is an onto mapping, there must exist two tuples $t_3 = (x, y_1, z_2)$, and $t_4 = (x, y_2, z_1) \in R[XYZ]$. Hence,

$$t_1\theta(XY)t_3\theta(XZ)t_2,$$

which means

$$t_1\theta(XY) \circ \theta(XZ)t_2.$$

It follows that

$$\theta(X) \subseteq \theta(XY) \circ (XZ).$$

From Lemma 7, we have

$$\theta(X) = \theta(XY) + \theta(XZ) = \theta(XY) \circ \theta(XZ) = \theta(XZ) \circ \theta(XY).$$

(Sufficiency) We know $R[XYZ] \subseteq R[XY] \mid \times \mid R[XZ]$. Suppose $t = (x, y, z) \in R\,[XY] \mid \times \mid R[XZ]$. Then there exist $t_1 = (x, y, z')$, $t_2 = (x, y', z) \in R[XYZ]$. Thus,

$$t_1\theta(X)t_2,$$

which implies

$$t_1\theta(XY) \circ \theta(XZ)t_2.$$

There must exist $t_3 \in R[XYZ]$ such that

$$t_1\theta(XY)t_3\theta(XZ)t_2.$$

Therefore,

$$t_3 = (x, y, z) = t \in R[XYZ],$$

and thus

$$R[XY] \mid \times \mid R[XZ] \subseteq R[XYZ].$$

Hence,

$$R[XYZ] = R[XY] \mid \times \mid R[XZ]. \quad \blacksquare$$

It should be noted that in the above proof we use the fact that $\Omega = XYZ$ and $\theta(\Omega) = \theta(XYZ) = \mathbf{0}$, i.e., there are no duplicated tuples in

$R[\Omega]$. The inference rules of MVD are given and proved in Appendix B.

Example 4: Consider the relation $R[ECSY]$ of Example 1. We have the MVD: $E \twoheadrightarrow SY$, where $\theta(E) = \pi_1 = \{1, 2; 3, 4, 5, 6; 7, 8\}$, $\theta(EC) = \pi_2 = \{1, 2; 3, 4; 5, 6; 7, 8\}$, $\theta(ESY) = \pi_5 = \{1; 2; 3, 5; 4, 6; 7; 8\}$. It is easy to verify that

$$\pi_1 = \pi_2 + \pi_5 = \pi_2 \circ \pi_5 = \pi_5 \circ \pi_2. \quad \blacksquare$$

It is known that if $R$ is a relation on $\Omega = XYZ$, and $X \twoheadrightarrow Y$ then $X \twoheadrightarrow Z$. The symmetricity of the MVD can easily be seen in the lattice equation of Lemma 7.

If $XYZ \subset \Omega$ and $\theta(X) = \theta(XY) + \theta(XZ) = \theta(XY) \circ \theta(XZ) = \theta(XZ) \circ \theta(XY)$ holds, then $X \twoheadrightarrow Y|Z$ is called an embedded multivalued dependency (EMVD)[7]; this is simply a multivalued dependency in the projection $R[XYZ]$ of $R[\Omega]$.

Theorem 6 clearly indicates that the MVD is actually a condition pertaining to data *independency* rather than data dependency. For this reason, we introduce the notion of decomposition of two sets of attributes in a relation as follows.

Definition 7: Let $R$ be a relation on the set of attributes $\Omega$. The two sets of attributes $\Omega_1, \Omega_2 \subseteq \Omega$ are decomposable in $R$ if

$$\theta(\Omega_1 + \Omega_2) = \theta(\Omega_1) + \theta(\Omega_2) = \theta(\Omega_1) \circ \theta(\Omega_2) = \theta(\Omega_2) \circ \theta(\Omega_1). \quad \blacksquare$$

It is easy to see that $\Omega_1$ and $\Omega_2$ are decomposable in $\Omega$ iff $\Omega_1 + \Omega_2 \rightarrow \rightarrow \Omega_1 - \Omega_2 | \Omega_2 - \Omega_1$ is an EMVD in $R$. Furthermore, if $\Omega_1\Omega_2 = \Omega$ then $\Omega_1 + \Omega_2 \twoheadrightarrow \Omega_1 - \Omega_2$ (or $\Omega_1 + \Omega_2 \twoheadrightarrow \Omega_2 - \Omega_1$) is an MVD in $R$. In the latter case, $(\Omega_1, \Omega_2)$ is called a *decomposition pair* by Armstrong and Delobel.[26]

We feel that decomposition is a basic concept in the study of the structure of databases. It can be naturally generalized to the concepts of projective decomposition and mutual decomposition. Projective composition concerns the data independence of two sets of attributes on the projection of a relation. Mutual decomposition extends the concept of decomposition to more than two sets of attributes.

Let $\rho$ be a partition on the set $S$, the function $\rho^* = S \rightarrow S/\rho$ maps $a \in S$ into $(a)\rho^* = a_\rho$ is called the *canonical function* of $\rho$. For $S = \{a, b, \ldots, e\}$, we will use the notation

$$\rho^* = \begin{pmatrix} a & b & \cdots & e \\ a_\rho & b_\rho & \cdots & e_\rho \end{pmatrix}$$

to illustrate the canonical function $\rho^*$. The equivalence relation

$$\ker \rho^* = \rho^* \circ \rho^{*-1} = \{(a, b) \in S \times S | \rho^*(a) = \rho^*(b)\}.$$

is called the *kernel* of $\rho^*$. Notice that $\ker \rho^* = \rho$.

Let $\rho$ and $\sigma$ be partitions on $S = \rho \leqq \sigma$; then there is a unique function $f$ from $S/\rho$ onto $S/\sigma$ such that $(a_\rho)f = a_\sigma$. The kernal of $f$,

$$\ker f = f \circ f^{-1} = \{(a_\rho, b_\rho) \in S/\rho \times S/\rho \mid a \; \sigma \; b\},$$

is an equivalence on $S/\rho$. It is usual to write ker $f$ as $\sigma/\rho$, the quotient of $\sigma$ and $\rho$. Note that $a_\rho(\sigma/\rho)b_\rho$ if and only if $a \; \sigma \; b$ and the mapping $g$: $(S/\rho)/(\sigma/\rho) \rightarrow S/\sigma$ defined by $((a_\rho)_{\sigma/\rho})g = a_\sigma$ is one-to-one and onto. Thus the function $f$ defined above is in fact the canonical function of $\sigma/\rho$, i.e., $f = (\sigma/\rho)^*$. It is easy to see the diagram in Fig. 7 commutes, that is $\rho^* \circ (\sigma/\rho)^* = \sigma^*$.

Example 5: Let $\rho$, $\sigma$ be partitions on the set $S = \{1, 2, 3, 4, 5, 6, 7, 8\}$, such that $\rho = \{1, 2; 3, 4; 5, 6; 7, 8\}$ and $\sigma = \{1, 2, 3, 4; 5, 6, 7, 8\}$ with $\rho \leqq \sigma$. Then $S/\rho = \{I, II, III, IV\}$, where $I = 1, 2$, $II = 3, 4$, $III = 5, 6$, $IV = 7, 8$, and $S/\sigma = \{\alpha, \beta\}$, where $\alpha = 1, 2, 3, 4$, $\beta = 5, 6, 7, 8$. The canonical functions of $\rho$ and $\sigma$ are

$$\rho^* = \begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 \\ I & I & II & II & III & III & IV & IV \end{pmatrix}$$

and

$$\sigma^* = \begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 \\ \alpha & \alpha & \alpha & \alpha & \beta & \beta & \beta & \beta \end{pmatrix}.$$

It follows that

$$\sigma/\rho = \{\overline{I, II}; \overline{III, IV}\}$$

and

$$(\sigma/\rho)^* = \begin{pmatrix} I & II & III & IV \\ \alpha & \alpha & \beta & \beta \end{pmatrix}. \quad \blacksquare$$

*Lemma 8: Let $\rho$, $\sigma_1$, $\sigma_2$ be partitions on $S$ such that $\rho \leqq \sigma_1$, $\rho \leqq \sigma_2$, and $\sigma_1 \circ \sigma_2 = \sigma_2 \circ \sigma_1$. Then*

$$(\sigma_1 \circ \sigma_2)/\rho = (\sigma_1/\rho) \circ (\sigma_2/\rho).$$

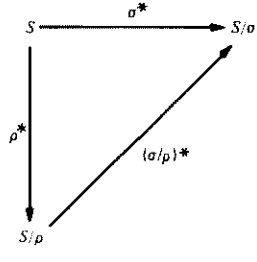

Fig. 7—Canonical function of quotient partition.

*Proof:* It is clear that $\sigma_1 \circ \sigma_2$ is a partition on $S$ and $\rho \leqq \sigma_1 \circ \sigma_2 = \sigma_2 \circ \sigma_1$. It follows from the definition of quotient partition that the lemma is true. ■

*Lemma 9: Let $\rho$, $\sigma_1$, $\sigma_2$ be partitions on $S$, such that $\rho \leqq \sigma_1$, $\rho \leqq \sigma_2$. Then*

$$\sigma_1 \circ \sigma_2 = \sigma_2 \circ \sigma_1$$

*iff*

$$(\sigma_1/\rho) \circ (_2/\rho) = (\sigma_2/\rho) \circ (\sigma_1/\rho).$$

*Proof:* (Necessity)

$$(\sigma_1/\rho) \circ (\sigma_2/\rho) = (\sigma_1 \circ \sigma_2)/\rho = (\sigma_2 \circ \sigma_1)/\rho = (\sigma_2/\rho) \circ (\sigma_1/\rho).$$

(Sufficiency) Suppose $a\sigma_1 \circ \sigma_2 b$. Then there is a $c \in S$ such that $a\sigma_1 c\sigma_2 b$. It follows that

$$a_\rho(\sigma_1/\rho)c_\rho(\sigma_2/\rho)b_\rho.$$

There must be a $d \in S$ such that

$$a_\rho(\sigma_2/\rho)d_\rho(\sigma_1/\rho)b_\rho.$$

Thus

$$a\sigma_2 d\sigma_1 b,$$

and

$$a\sigma_2 \circ \sigma_1 b.$$

Hence

$$\sigma_1 \circ \sigma_2 \subseteq \sigma_2 \circ \sigma_1.$$

Similarly, we have $\sigma_2 \circ \sigma_1 \subseteq \sigma_1 \circ \sigma_2$. Then $\sigma_1 \circ \sigma_2 = \sigma_2 \circ \sigma_1$. ■

Definition 8: Let $R$ be a relation on the set of attributes $\Omega$. For $\Omega_1$, $\Omega_2 \subseteq \Omega$, the *projective partition* defined by

$$\theta(\Omega_1|\,\Omega_2) = \theta(\Omega_1 + \Omega_2)/\theta(\Omega_2)$$

is a partition on the set of tuples of $R[\Omega]/\theta(\Omega_2) = R[\Omega_2]$. The canonical function of $\theta(\Omega_1|\,\Omega_2)$ is denoted by $\theta^*(\Omega_1|\,\Omega_2) = (\theta(\Omega_1 + \Omega_2)/\theta(\Omega_2))^*$, which satisfies $\theta^*(\Omega_2) \circ \theta^*(\Omega_1|\,\Omega_2) = \theta^*(\Omega_1 + \Omega_2)$. ■

Certain properties of the projective partition are demonstrated in the following theorems and their proof directly follows from the definition of projective partition.

*Theorem 7: Let $R$ be a relation on the set of attributes $\Omega$ and $\Omega_1, \cdots, \Omega_n \subseteq \Omega$. Then*

$$\theta^*\left(\bigcap_{k=1}^{n} \Omega_k\right) = \theta^*(\Omega_1) \circ \theta^*(\Omega_2|\,\Omega_1) \circ \cdots \circ \theta^*(\Omega_n|\bigcap_{k=1}^{n-1} \Omega_k). \quad ■$$

*Theorem 8: Let $R$ be a relation on the set of attributes $\Omega$ and $X$, $\Omega_1$, $\cdots$, $\Omega_n \subseteq \Omega$, such that*

$$\bigcup_{k=1}^{n} \Omega_k = \Omega.$$

*Then*

1. $\theta(X) = \prod_{k=1}^{n} \ker(\theta^*(\Omega_k) \circ \theta^*(X|\Omega_k))$
2. $\theta(\Omega_m|X) = \ker(\theta^*(\Omega_m) \circ \theta^*(X|\Omega_m))/\prod_{k=1}^{n} \ker(\theta^*(\Omega_k) \circ \theta^*(X|\Omega_k))$. ■

Definition 9: Let $R$ be a relation on the set of attributes $\Omega$ and $\Omega_1$, $\Omega_2$, $\Sigma \subseteq \Omega$. We say $\Omega_1$ and $\Omega_2$ are projectively decomposable on $\Sigma$ if

$$\begin{aligned}\theta(\Omega_1 + \Omega_2|\Sigma) &= \theta(\Omega_1|\Sigma) + \theta(\Omega_2|\Sigma) \\ &= \theta(\Omega_1|\Sigma) \circ \theta(\Omega_2|\Sigma) \\ &= \theta(\Omega_2|\Sigma) \circ \theta(\Omega_1|\Sigma). \quad ■\end{aligned}$$

The EMVD is a special case of projective decomposition, which can be seen from the following theorem.

*Theorem 9: Let $R$ be a relation on $\Omega$, and let $\Omega_1$, $\Omega_2$, $\Sigma \subseteq \Omega$. Then $\Omega_1$ and $\Omega_2$ are projectively decomposable on $\Sigma$ iff*

$$\begin{aligned}\theta(\Omega_1 + \Omega_2 + \Sigma) &= \theta(\Omega_1 + \Sigma) + \theta(\Omega_2 + \Sigma) \\ &= \theta(\Omega_1 + \Sigma) \circ \theta(\Omega_2 + \Sigma) = \theta(\Omega_2 + \Sigma) \circ \theta(\Omega_1 + \Sigma).\end{aligned}$$

*Proof:* The proof follows from Lemma 8 and 9. ■

Example 6: Consider the relation $R$ on $\Omega = ABCDE$ in Table VII. The Hasse diagram of the relation lattice $L(R[\Omega])$ is shown in Fig. 8, where

$$\begin{aligned}\pi_1 &= \{\overline{1, 2, 3, 5, 6, 7};\ \overline{4}\} = \theta(A), \\ \pi_2 &= \{\overline{1, 3, 4};\ \overline{2, 5, 6, 7}\} = \theta(B), \\ \pi_3 &= \{\overline{1, 6, 7};\ \overline{2, 3, 4, 5}\} = \theta(C), \\ \pi_4 &= \{\overline{1, 3};\ \overline{2, 5, 6, 7};\ \overline{4}\} = \theta(AB), \\ \pi_5 &= \{\overline{1, 6, 7};\ \overline{2, 3, 5};\ \overline{4}\} = \theta(AC), \\ \pi_6 &= \{\overline{1};\ \overline{2, 5};\ \overline{3, 4};\ \overline{6, 7}\} = \theta(BC), \\ \pi_7 &= \{\overline{1, 6, 7};\ \overline{2, 5};\ \overline{3};\ \overline{4}\} = \theta(D), \\ \pi_8 &= \{\overline{1, 3};\ \overline{2, 6};\ \overline{4};\ \overline{5, 7}\} = \theta(E), \\ \pi_9 &= \{\overline{1};\ \overline{2, 5};\ \overline{3};\ \overline{4};\ \overline{6, 7}\} = \theta(ABC) = \theta(ABD).\end{aligned}$$

Let $\Omega_1 = ABD$, $\Omega_2 = ACE$, $\Sigma = ABC$. We find that

Table VII—Relation lattice $L(R[\Omega])$

| | $A$ | $B$ | $C$ | $D$ | $E$ |
|---|---|---|---|---|---|
| 1 | $a_1$ | $b_1$ | $c_1$ | $d_1$ | $e_1$ |
| 2 | $a_1$ | $b_2$ | $c_2$ | $d_2$ | $e_2$ |
| 3 | $a_1$ | $b_1$ | $c_2$ | $d_3$ | $e_1$ |
| 4 | $a_2$ | $b_1$ | $c_2$ | $d_4$ | $e_3$ |
| 5 | $a_1$ | $b_2$ | $c_2$ | $d_2$ | $e_4$ |
| 6 | $a_1$ | $b_2$ | $c_1$ | $d_1$ | $e_2$ |
| 7 | $a_1$ | $b_2$ | $c_1$ | $d_1$ | $e_4$ |

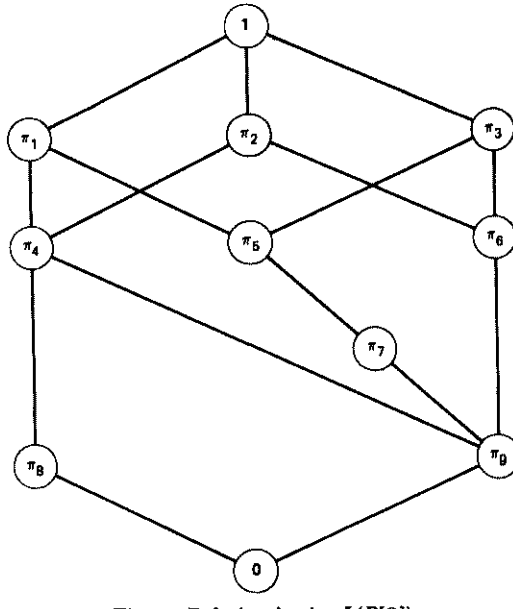

Fig. 8—Relation lattice $L(R[\Omega])$.

$$\theta(\Omega_1 + \Omega_2 | \Sigma) = \theta(A | ABC) = \theta(A)/\theta(ABC) = \{\overline{I, II, III, V}; \overline{IV}\},$$

$$\theta(\Omega_1 | \Sigma) = \theta(ABD | ABC) = \theta(AB)/\theta(ABC) = \{\overline{I, III}; \overline{II, V}; \overline{IV}\},$$

$$\theta(\Omega_2 | \Sigma) = \theta(ACE | ABC) = \theta(AC)/\theta(ABC) = \{\overline{I, V}; \overline{II, III}; \overline{IV}\},$$

and

$$\theta(ABC) = \{I, II, III, IV, V\},$$

where $I = \overline{1}$, $II = \overline{2, 5}$, $III = \overline{3}$, $IV = \overline{4}$, $V = \overline{6, 7}$.

It is easy to see that $ABD$ and $ACE$ are projectively decomposable on $ABC$, i.e.,

$$\begin{aligned}\theta(A | ABC) &= \theta(ABD | ABC) + \theta(ACE | ABC) \\ &= \theta(ABD | ABC) \circ \theta(ACE | ABC) \\ &= \theta(ACE | ABC) \circ \theta(ABD | ABC).\end{aligned}$$

But the MVD: $A \twoheadrightarrow BD$ (or $A \twoheadrightarrow CE$) does not hold in $R[\Omega]$. Nevertheless, the EMVD: $A \rightarrow B \mid C$ does hold in $R[\Omega]$. ■

So far we have discussed the properties of decomposition of two sets of attributes. The concept of decomposition certainly can be extended to any $n > 2$ sets of attributes. We define the notion of mutual decomposition as follows:

Definition 10: Let $R$ be a relation on the set of attributes $\Omega$. The sets of attributes $\Omega_1, \Omega_2, \cdots, \Omega_n \subseteq \Omega$ are mutually decomposable, if for any $I \subseteq N = \{1, \cdots, n\}$ and $J \subseteq N - I$, the two sets of attributes $\Omega_I = \cup_{i \in I} \Omega_i$ and $\Omega_J = \cup_{j \in J} \Omega_j$ are decomposable. ■

*Theorem 10: Let $R$ be a relation on the set of attributes $\Omega$ and $\Omega_1 \cdots \Omega_n = \Omega$. Suppose $\Omega_1, \cdots, \Omega_n$ are mutually decomposable. Then*

$$R[\Omega] = R[\Omega_1 \cdots \Omega_n] = R[\Omega_1] \mid \times \mid \cdots \mid \times \mid R[\Omega_n].$$

*Proof:* It follows from the definition of mutual decomposition that

$$R[\Omega_1 \cdots \Omega_m] = R[\Omega_1 \cdots \Omega_{m-1}] \mid \times \mid R[\Omega_m], \qquad m = 2, \cdots n.$$

Therefore the assertion is true by induction. ■

The above theorem states that mutual decomposition implies an information-lossless join. The converse is not true in general. The necessary and sufficient condition of an information-lossless join is called join dependency, which will be discussed in the next section.

## VII. JOIN DEPENDENCIES

*Join dependency* (JD)[10,11,14] is a generalization of MVD. It refers to a collection $\{\Omega_1, \cdots, \Omega_n\}$ of subsets of $\Omega$ such that

$$\Omega = \Omega_1 \cdots \Omega_n$$

and

$$R[\Omega] = R[\Omega_1] \mid \times \mid \cdots \mid \times \mid R[\Omega_n].$$

Join dependency can be considered as a "set of coordinates" of the relation. The connection between join dependencies and multivalued dependencies is given by the following lemma:

*Lemma 10: Let $R[\Omega] = R[\Omega_1] \mid \times \mid \cdots \mid \times \mid R[\Omega_n]$, let $N_0$ be a subset of $\{1, \cdots, n\}$, and let $N_1 = \{1, \cdots, n\} - N_0$. Then $(\Omega_{N_0}, \Omega_{N_1})$ is a decomposition pair, where*

$$\Omega = \Omega_1 \cdots \Omega_n, \qquad \Omega_{N_0} = \bigcup_{i \in N_0} \Omega_i, \qquad \text{and} \qquad \Omega_{N_1} = \bigcup_{i \in N_1} \Omega_i.$$

*Proof:* Since

$$R\left[\bigcup_{i \in N_0} \Omega_i\right] \subseteq \underset{i \in N_0}{|\times|} R[\Omega_i],$$

and

$$R\left[\bigcup_{i\in N_1}\Omega_i\right] \subseteq \bigl|\times\bigr|_{i\in N_1} R[\Omega_i],$$

it follows that

$$R[\Omega_{N_0}] \,|\times|\, R[\Omega_{N_1}] \subseteq \left(\bigl|\times\bigr|_{i\in N_0} R[\Omega_i]\right) |\times| \left(\bigl|\times\bigr|_{i\in N_1} R[\Omega_i]\right).$$

Since the natural join operation is commutative and associative,[6] we have

$$R[\Omega_{N_0}] \,|\times|\, R[\Omega_{N_1}] \subseteq R[\Omega_1] \,|\times|\, \cdots \,|\times|\, R[\Omega_n] = R(\Omega).$$

But we know

$$R[\Omega] \subseteq R[\Omega_{N_0}] \,|\times|\, R[\Omega_{N_1}].$$

Hence,

$$R[\Omega] = R[\Omega_{N_0}] \,|\times|\, R[\Omega_{N_1}]. \quad \blacksquare$$

Let $x$ be an $X$-value, and assume $Y \subseteq X$. We shall denote the $Y$-value in $x$ as $x[Y]$. Let $t \in R[\Omega]$ be a tuple and let $\Omega = \Omega_1 \cdots \Omega_n$. The notation $t \triangleq (w_1, \cdots, w_n)$ will be used to indicate that $t[\Omega_i] = w_i$, $\forall i \in N$, where $N = \{1, \cdots, n\}$ denotes the index set.

Before we state the necessary and sufficient conditions for join dependency, we first introduce the concepts of *a set of consistent values* and an *indexed family of tuples.*

Definition 11: Let $R$ be a relation on the set of attributes $\Omega$, and let $\{X_i \mid i \in N\}$ be a collection of subsets of $\Omega$. The set of values $\{x_i \mid x_i$ is an $X_i$-value, $i \in N\}$ is called *a set of consistent values* of $\{X_i \mid i \in N\}$ if the values of $X_i \cap X_j$ in $x_i$ and $x_j$ agree, i.e., if

$$x_i[X_i \cap X_j] = x_j[X_i \cap X_j], \qquad \forall i, j \in N.$$

The set of tuples $\{t_i \mid i \in N\}$ of $R[\Omega]$ is called an *indexed family of tuples* with respect to $\{X_i \mid i \in N\}$ if $\{x_i \mid t_i[X_i] = x_i, i \in N\}$ is a set of consistent values. $\blacksquare$

*Theorem 11: Let $R$ be a relation on the set of attributes $\Omega$, and let $\Omega = \Omega_1 \cdots \Omega_n$. Then*

$$R[\Omega] = R[\Omega_1] \,|\times|\, \cdots \,|\times|\, R[\Omega_n]$$

*iff for every indexed family of tuples $\{t_i \mid i \in N\}$ with respect to $\{X_i \mid i \in N\}$ there is a tuple $t \in R[\Omega]$ such that $t[\Omega_i] = t_i[\Omega_i]$, $\forall i \in N$, where $X_i = \Omega_i \cap \hat{\Omega}_i$, and $\hat{\Omega}_i = \cup_{j\neq i}\Omega_j$.*

*Proof:* (Necessity) Let $\{t_i \mid i \in N\}$ be an indexed family of tuples of $R[\Omega]$ with respect to $\{X_i \mid i \in N\}$. Thus, $\{x_i \mid t_i[X_i] = x_i, i \in N\}$ is a set of consistent values. Suppose $t_i[\Omega_i] = w_i$, $i \in N$. We want to show that

there exists a tuple $t \triangleq (w_1, \cdots, w_n) \in R[\Omega]$. We will prove this by mathematical induction. We know that $s_1 = (w_1) \in R[\Omega_1]$ and $(w_2) \in R[\Omega_2]$. Thus,

$$w_1[X_1] = x_1 \quad \text{and} \quad w_2[X_2] = x_2.$$

Since $\{x_i \mid i \in N\}$ is consistent, it follows that

$$w_1[X_1 \cap X_2] = x_1[X_1 \cap X_2] = x_2[X_1 \cap X_2] = w_2[X_1 \cap X_2].$$

It is known that

$$X_i \cap X_j = (\Omega_i \cap \hat{\Omega}_i) \cap (\Omega_j \cap \hat{\Omega}_j) = \Omega_i \cap \Omega_j, \qquad i \neq j.$$

Therefore,

$$w_1[\Omega_1 \cap \Omega_2] = w_2[\Omega_1 \cap \Omega_2].$$

By the definition of natural join, we know that there exists a tuple $s_2 \triangleq (w_1, w_2) \in R[\Omega_1] \mid\times\mid R[\Omega_2]$.

Suppose there is a tuple $s_{n-1} \triangleq (w_1, \cdots, w_{n-1}) \in R[\Omega_1] \mid\times\mid \cdots \mid\times\mid R[\Omega_{n-1}]$. Then

$$\begin{aligned} s_{n-1}[X_i \cap X_n] &= w_i[X_i \cap X_n] = x_i[X_i \cap X_n] \\ &= x_n[X_i \cap X_n] = w_n[X_i \cap X_n], \qquad i = 1, \cdots, n-1. \end{aligned}$$

Hence,

$$\begin{aligned} s_{n-1}[\Omega_n \cap \hat{\Omega}_n] &= s_{n-1}[\Omega_n \cap (\Omega_1 \cup \cdots \cup \Omega_{n-1})] \\ &= s_{n-1}[(\Omega_1 \cap \Omega_n) \cup \cdots \cup (\Omega_{n-1} \cap \Omega_n)] \\ &= s_{n-1}[(X_1 \cap X_n) \cup \cdots \cup (X_{n-1} \cap X_n)] \\ &= w_n[(X_1 \cap X_n) \cup \cdots \cup (X_{n-1} \cap X_n)] \\ &= w_n[\Omega_n \cap \hat{\Omega}_n]. \end{aligned}$$

It follows that there exists a tuple $t$ such that

$$t = s_n \triangleq (w_1, \cdots, w_n) \in R[\Omega_1] \mid\times\mid \cdots \mid\times\mid R[\Omega_n] = R[\Omega].$$

(Sufficiency) We know that

$$R[\Omega] \subseteq R[\Omega_1] \mid\times\mid \cdots \mid\times\mid R[\Omega_n].$$

For any $t \triangleq (w_1, \cdots, w_n) \in R[\Omega_1] \mid\times\mid \cdots \mid\times\mid R[\Omega_n]$, there exists an indexed family of tuples $\{t_i \mid t_i[\Omega_i] = w_i, i \in N\}$ of $R[\Omega]$ with respect to $\{X_i \mid i \in N\}$ that has a set of consistent values $\{x_i \mid w_i[X_i] = x_i, i \in N\}$. It follows that $t \triangleq (w_1, \cdots, w_n) \in R[\Omega]$. Hence,

$$R[\Omega] = R[\Omega_1] \mid\times\mid \cdots \mid\times\mid R[\Omega_n]. \quad \blacksquare$$

The necessary and sufficient conditions for JD given in the above

theorem are similar to the notion of template dependency introduced by Sadri and Ullman.[27] The following condition can be considered as an extension of the binary natural join operation.

*Corollary 3: Let $R$ be a relation on the set of attributes $\Omega$, and $\Omega = \Omega_1 \cdots \Omega_n$. Then,*

$$R[\Omega] = R[\Omega_1] \mid \times \mid \cdots \mid \times \mid R[\Omega_n]$$

*iff*

$$R_{x_1,\ldots,x_n}[\Omega] = R_{x_1}[\Omega_1] \mid \times \mid \cdots \mid \times \mid R_{x_n}[X_n]$$

*for every set of consistent values $\{x_i \mid i \in N\}$ of $\{X_i \mid i \in N\}$, where $X_i = \Omega_i \cup \hat{\Omega}_i$, $\forall i \in N$, and $R_{x_1,\ldots,x_n}[\Omega] = \{t \mid t \in R[\Omega], t[X_i] = x_i, \forall i \in N\}$.*

*Proof:* The proof follows from Theorem 11. ■

Clearly, for any $t \in R[\Omega] = R[\Omega_1 \cdots \Omega_n]$, the set of values $\{x_i \mid t[X_i] = x_i, X_i = \Omega_i \cap \hat{\Omega}_i, i \in N\}$ is always consistent. The converse is not necessarily true. Suppose for any set of consistent values $\{x_i \mid x_i$ is an $X_i$-value, $i \in N\}$ there is a tuple $t \in R[\Omega]$ such that $t[X_i] = x_i$, $\forall i \in N$; in this case we say $\{\Omega_i \mid i \in N\}$ is *complete*.

*Corollary 4: Let $R$ be a relation on the set of attributes $\Omega$, and $\Omega = \Omega_1 \cdots \Omega_n$. Then $\{\Omega_i \mid i \in N\}$ is complete iff*

$$R[X_1 \cdots X_n] = R[X_1] \mid \times \mid \cdots \mid \times \mid R[X_n],$$

*where $X_i = \Omega_i \cap \hat{\Omega}_i$, $i \in N$.*

*Proof:* The proof follows directly from Theorem 11. ■

The necessary and sufficient conditions for JD may be stated in a different form, as follows:

*Theorem 12: Let $R$ be a relation on the set of attributes $\Omega$, and $\Omega = \Omega_1 \cdots \Omega_n$. Then*

$$R[\Omega] = R[\Omega_1] \mid \times \mid \cdots \mid \times \mid R[\Omega_n]$$

*iff*

1. *$\{\Omega_i, \hat{\Omega}_i\}$ is a decomposition pair, $i \in N$,*
2. *$\{\Omega_i \mid i \in N\}$ is complete, i.e.,*

$$R[X_1 \cdots X_n] = R[X_1] \mid \times \mid \cdots \mid \times \mid R[X_n], \quad X_i = \Omega_i \cap \hat{\Omega}_i, \quad i \in N.$$

*Proof:* (Necessity) Condition 1 follows from Lemma 10. Condition 2 is a consequence of Theorem 11.

(Sufficiency) We know that

$$R[\Omega] \subseteq R[\Omega_1] \mid \times \mid \cdots \mid \times \mid R[\Omega_n].$$

Suppose $t \triangleq (w_1, \cdots, w_n) \in R[\Omega_1] \mid \times \mid \cdots \mid \times \mid R[\Omega_n]$. Then there is an indexed family of tuples $\{t_i \mid t_i[\Omega_i] = w_i, i \in N\}$ of $R[\Omega]$ with respect

to $\{X_i \mid i \in N\}$ and the set of consistent values $\{x_i \mid w_i[X_i] = x_i, X_i = \Omega_i \cap \hat{\Omega}_i, i \in N\}$. We will prove by mathematical induction that $t \triangleq (w_1, \cdots, w_n) \in R[\Omega]$.

Since $\{\Omega_i \mid i \in N\}$ is complete, there exists a tuple $s \triangleq (y_1, \cdots, y_n) \in R[\Omega]$ such that

$$s[X_i] = x_i, \qquad \forall i \in N.$$

We know that

$$t_1[\Omega_1 \cap \hat{\Omega}_1] = t_1[X_1] = w_1[X_1] = x_1 = s[X_1] = s[\Omega_1 \cap \hat{\Omega}_1],$$

which means

$$t_1 \theta(\Omega_1 \cap \hat{\Omega}_1) s.$$

Since $(\Omega_1, \hat{\Omega}_1)$ is a decomposition pair, there exists a tuple $s_1 \in R[\Omega]$ such that

$$t_1 \theta(\Omega_1) s_1 \theta(\hat{\Omega}_1) s.$$

Hence,

$$s_1 \triangleq (w_1, y_2, \cdots, y_n) \in R[\Omega].$$

Suppose there is a tuple $s_{n-1} \triangleq (w_1, \cdots, w_{n-1}, y_n) \in R[\Omega]$. It follows that

$$t_n[\Omega_n \cap \hat{\Omega}_n] = t_n[X_n] = w_n[X_n] = x_n = s_{n-1}[X_n] = s_{n-1}[\Omega_n \cap \hat{\Omega}_n].$$

Thus there is a tuple $s_n \in R[\Omega]$ such that

$$t_n \theta(\Omega_n) s_n \theta(\hat{\Omega}_n) s_{n-1}.$$

Hence

$$t = s_n \triangleq (w_1, \cdots, w_n) \in R[\Omega]. \quad \blacksquare$$

It is known that a special class of JD, called *acyclic join dependency*, has many desirable properties; this class makes operations like updates and joins especially easy.[15, 28] A collection of subsets $\{\Omega_i \mid i \in N\}$ of the set of attributes $\Omega$ is called *acyclic* if all the attributes can be deleted by repeatedly applying the following two operations:[15,28]

1. Delete from some $\Omega_i$ an attribute $A$ that appears in no other $\Omega_j$
2. Delete one $\Omega_i$ if there is an $\Omega_j$, $i \neq j$, such that $\Omega_i \subseteq \Omega_j$.

A reduction $\{Y_j \mid j \in J \subseteq N$, and $\forall i \in N - J \exists j \in J$ such that $Y_i \subseteq Y_j\}$ is obtained by removing from $\{Y_i \mid i \in N\}$ each $Y_i$ that is contained in another $Y_j$.

Definition 12: Let $\mathbf{S} = \{\Omega_i \mid i \in N\}$ be a collection of subsets of $\Omega$. The *core* of $\mathbf{S}$, denoted by $\dot{\mathbf{S}}$, is defined as follows:

1. $\dot{\mathbf{S}} = \varnothing$, for $|\mathbf{S}| = N = 1$
2. $\dot{\mathbf{S}}$ is the reduction of $\{\Omega_i \cap \hat{\Omega}_i \mid i \in N\}$, for $|\mathbf{S}| = N > 1$. $\blacksquare$

There are many different but equivalent conditions that characterize a collection of subsets as acyclic.[15] We will use the following one:

*Lemma 11: A collection* $\mathbf{S} = \{\Omega_i \mid i \in N\}$ *of subsets of* $\Omega$ *is acyclic iff its core* $\dot{\mathbf{S}}$ *is acyclic.*

*Proof:* $\dot{\mathbf{S}}$ can be obtained from $\mathbf{S}$ by performing the operations 1 and 2 defined above. It follows that if $\mathbf{S}$ is acyclic then $\dot{\mathbf{S}}$ is acyclic and vice versa. ■

*Corollary 5: Let* $\mathbf{S} = \{\Omega_i \mid i \in N\}$ *be an acyclic collection of subsets of* $\Omega$. *Then* $|\mathbf{S}| > |\dot{\mathbf{S}}|$.

*Proof:* For $|\mathbf{S}| = 1$, $|\dot{\mathbf{S}}| = |\varnothing| = 0$. For $|\mathbf{S}| \geqslant 2$, we know that $|\mathbf{S}| \geqslant |\dot{\mathbf{S}}|$. Suppose $|\mathbf{S}| = |\dot{\mathbf{S}}|$. Then any attribute $A$ in $\dot{\mathbf{S}}$ must be contained in at least two distinct subsets of $\dot{\mathbf{S}}$. Let $A \in \Omega_i \cap \hat{\Omega}_i$. Then $A \in \Omega_i$ and $A \in \hat{\Omega}_i$. There is a $j \neq i$ such that $A \in \Omega_j$. Since $\Omega_i \subseteq \hat{\Omega}_j = \cup_{k \neq j} \Omega_k$ it follows that

$$A \in \Omega_j \cap \hat{\Omega}_j \in \dot{\mathbf{S}}.$$

Since $|\dot{\mathbf{S}}| = |\mathbf{S}| \geqslant 2$, $\dot{\mathbf{S}}$ is not empty. Now, neither operation 1 nor 2 can be applied to reduce $\dot{\mathbf{S}}$. From Lemma 11 we know this contradicts the assumption that $\mathbf{S}$ is acyclic. Thus, $|\mathbf{S}| > |\dot{\mathbf{S}}|$. ■

A JD $R[\Omega] = R[\Omega_1] |\times| \cdots |\times| R[\Omega_n]$, $\Omega = \Omega_1 \cdots \Omega_n$, is an acyclic join dependency if $\{\Omega_i \mid i \in N\}$ is acyclic. A recursive condition for acyclic join dependency is as follows:

*Corollary 6: Let R be a relation on the set of attributes* $\Omega = \Omega_1 \cdots \Omega_n$. *Then*

$$R[\Omega] = R[\Omega_1] |\times| \cdots |\times| R[\Omega_n]$$

*is an acyclic join dependency iff*

1. $(\Omega_i, \hat{\Omega}_i)$ *is a decomposition pair of* $R[\Omega]$, $i = 1, \cdots, n$,
2. $R[X_1 \cdots X_m] = R[X_1] |\times| \cdots |\times| R[X_m]$ *is an acyclic join dependency over the set* $X_1 \cdots X_m \subseteq \Omega$, *where* $\{X_i \mid i = 1, \cdots, m\}$ *is the core of* $\{\Omega_i \mid i \in N\}$.

*Proof:* The join dependency of a collection of sets and the join dependency of its reduction are equivalent.[25] The proof easily follows from Theorem 12 and Lemma 11. ■

The above corollary simply states that acyclic join dependency is equivalent to a set of MVDs and EMVDs, i.e., a set of simultaneous lattice equations that can be derived recursively. It has been shown by hypergraph theory that an acyclic join dependency is equivalent to a set of MVDs.[15,16] That is, the converse of Lemma 10 is true for acyclic join dependency; we will prove that the converse of Lemma 10 is a consequence of Corollary 6.

*Theorem 10: Let R be a relation on the set of attributes* $\Omega = \Omega_1 \cdots \Omega_n$ *such that* $\{\Omega_i \mid i \in N\}$ *is acyclic. Suppose for any* $N_0 \subseteq N = \{1, \cdots, n\}$, $N_1 = N - N_0$, *and*

$$R[\Omega] = R[\Omega_{N_0}] \mid \times \mid R[\Omega_{N_1}].$$

*Then*

$$R[\Omega] = R[\Omega_1] \mid \times \mid \cdots \mid \times \mid R[\Omega_n]$$

*is an acyclic join dependency.*

*Proof:* This theorem will be proved by mathematical induction on $n$. For the smallest nontrivial case $n = 3$, let the core set $\{X_i \mid i = 1, \cdots, m\}$ of $\{\Omega_i \mid i = 1, 2, 3\}$ be the reduction of $\{Y_i = \Omega_i \cap \hat{\Omega}_i \mid i = 1, 2, 3\}$. First we want to show that

$$R[X_1 \cdots X_m] = R[X_1] \mid \times \mid \cdots \mid \times \mid R[X_m].$$

We know $m < 3$ from Corollary 5. There is nothing to be proved if $m < 2$. For $m = 2$, without loss of generality, let $X_1 = Y_1$, $X_2 = Y_2$, and $Y_3 \subseteq Y_2 = X_2$. Then

$$X_1 \cap X_2 = Y_1 \cap Y_2 = Y_1 \cap Y_2Y_3 = (Y_1 \cap Y_2) \cup (Y_1 \cap Y_3)$$

$$= (\Omega_1 \cap \Omega_2) \cup (\Omega_1 \cap \Omega_3) = \Omega_1 \cap \Omega_2\Omega_3.$$

Since $(\Omega_1, \Omega_2\Omega_3)$ is a decomposition pair,

$$\theta(X_1 \cap X_2) = \theta(\Omega_1 \cap \Omega_2\Omega_3) \subseteq \theta(\Omega_1) \circ \theta(\Omega_2\Omega_3).$$

Also we have

$$\Omega_1 \supseteq Y_1 = X_1,$$

and

$$\Omega_2\Omega_3 \supseteq Y_2Y_3 = Y_2 = X_2.$$

Thus

$$\theta(\Omega_1) \leqq \theta(X_1),$$

$$\theta(\Omega_2\Omega_3) \leqq \theta(X_2),$$

and

$$\theta(\Omega_1) \circ \theta(\Omega_2\Omega_3) \subseteq \theta(X_1) \circ \theta(X_2).$$

It follows that

$$\theta(X_1 \cap X_2) \subseteq \theta(X_1) \circ \theta(X_2).$$

Hence

$$R[X_1X_2] = R[X_1] \mid \times \mid R[X_2].$$

It follows from Corollary 6 that

$$R[\Omega] = R[\Omega_1] \mid \times \mid R[\Omega_2] \mid \times \mid R[\Omega_3].$$

Suppose the theorem is true for all $k < n$. Let the core set $\{X_i \mid i = 1,$

$\cdots, m\}$ of $\{\Omega_i \mid i \in N\}$ be the reduction of $\{Y_i = \Omega_i \cap \hat{\Omega}_i \mid i \in N\}$. We know $m < n$ and for any $M_0 \subseteq M = \{1, \cdots, m\}$ and $M_1 = M - M_0$ there is an $N_0 \subseteq N$ and $N_1 = N - N_0$ such that

$$M_0 \subseteq N_0, \qquad M_1 \subseteq N_1,$$

and

$$X_{M_0} = Y_{N_0}, \qquad X_{M_1} = Y_{N_1}.$$

Then,

$$X_{M_0} \cap X_{M_1} = Y_{N_0} \cap Y_{N_1} = \bigcup_{i \in N_0, j \in N_1} (Y_i \cap Y_j)$$

$$= \bigcup_{i \in N_0, j \in N_1} (\Omega_i \cap \Omega_j) = \Omega_{N_0} \cap \Omega_{N_1}.$$

Since $(\Omega_{N_0}, \Omega_{N_1})$ is a decomposition pair, we have

$$\theta(X_{M_0} \cap X_{M_1}) = \theta(\Omega_{N_0} \cap \Omega_{N_1}) \subseteq \theta(\Omega_{N_0}) \circ \theta(\Omega_{N_1}).$$

Also, we know

$$\Omega_{N_0} \supseteq Y_{N_0} = X_{M_0},$$

and

$$\Omega_{N_1} \supseteq Y_{N_1} = X_{M_1}.$$

Thus

$$\theta(\Omega_{N_0}) \leqq \theta(X_{M_0}),$$

$$\theta(\Omega_{N_1}) \leqq \theta(X_{M_1}),$$

and

$$\theta(\Omega_{N_0}) \circ \theta(\Omega_{N_1}) \subseteq \theta(X_{M_0}) \circ \theta(X_{M_1}).$$

It follows that

$$\theta(X_{M_0} \cap X_{M_1}) \subseteq \theta(X_{M_0}) \circ \theta(X_{M_1}).$$

Hence

$$R[X_1 \cdots X_m] = R[X_{M_0}] \mid \times \mid R[X_{M_1}]$$

for any $M_0 \subseteq M$, $M_1 = M - M_0$.

Since the theorem is true for $m < n$, we have

$$R[X_1 \cdots X_m] = R[X_1] \mid \times \mid \cdots \mid \times \mid R[X_m].$$

It follows from Corollary 6 that

$$R[\Omega_1 \cdots \Omega_n] = R[\Omega_1] \mid \times \mid \cdots \mid \times \mid R[\Omega_n]. \quad \blacksquare$$

Further discussion of the properties of acyclic join dependencies can be found in Refs. 15 and 16. A linear-time algorithm for testing acyclicity is given in Ref. 28.

## VIII. CONCLUSIONS

We have shown that lattice theory is a powerful tool in the analysis of the structure of relational database systems. Using this tool, we have established a unified theory of relations. As we have seen, almost every concept in the existing relational database theory has a counterpart in the lattice theory. This suggests that further study of relations should be carried out within the framework of lattice theory. The independency theory of lattices, which is a generalization of the familiar notion of independency in the geometries,[18,21] is especially important and relevant to the structure of relational database systems if its relation lattice is modular. This approach may lead to a geometric interpretation of data dependencies and independencies, which would make the theory more intuitive and also more useful for practical application.

The establishment of this algebraic theory of relational databases is done in the same spirit as the construction of probability theory. A probability space is a triple $(\Omega, \Sigma, P)$, where $\Omega$ is the sample space, $\Sigma$ is a $\sigma$-algebra of the subsets of $\Omega$, and $P$ is a real-valued function, called a *probability measure*, defined on the $\sigma$-algebra $\Sigma$.[17,29] The notion

Table VIII—Comparison of probability theory and the theory of relational databases

| Probability Theory | Theory of Relational Databases |
|---|---|
| Sample space $\Omega$ | Set of attributes $\Omega$ |
| $\Sigma$, the $\sigma$-Algebra of subsets of $\Omega$ | $\mathbf{2}^{\Omega}$, the Boolean algebra of subsets of $\Omega$ |
| Probability measure<br>$P\colon \Sigma \to R[0, 1]$ | Partition function<br>$\theta\colon \mathbf{2}^{\Omega} \to \Pi[R(\Omega)]$ |
| $\sigma$-additivity:<br>$\{X_k\}$ is an denumerable union of disjoint events<br>$P\left(\bigcup_{k=1}^{\infty} X_k\right) = \sum_{k=1}^{\infty} P(X_k)$ | Meet-morphism:<br>$\{X_k\}$ is a finite collection of sets of attributes<br>$\theta\left(\bigcup_{k=1}^{n} X_k\right) = \theta(X_1) \cdots \theta(X_n)$ |
| $P(\Omega) = 1$<br>$P(\varnothing) = 0$ | $\theta(\Omega) = \mathbf{0}$<br>$\theta(\varnothing) = \mathbf{1}$ |
| $0 \leqslant P(X) \leqslant 1, \forall X \in \Sigma$ | $\mathbf{0} \leqq \theta(X) \leqq \mathbf{1}, \forall X \in \mathbf{2}^{\Omega}$ |
| If $X \subseteq Y$,<br>$P(X) \leqslant P(Y)$ | If $X \supseteq Y$,<br>$\theta(X) \leqq \theta(Y)$ |
| If $\Omega_1$ and $\Omega_2$ are independent,<br>$P(\Omega_1 \cap \Omega_2) = P(\Omega_1)P(\Omega_2)$ | If $\Omega_1$ and $\Omega_2$ are decomposable,<br>$\theta(\Omega_1 \cap \Omega_2) = \theta(\Omega_1) + \theta(\Omega_2)$<br>$= \theta(\Omega_1) \cdot \theta(\Omega_2) = \theta(\Omega_2) \cdot \theta(\Omega_1)$ |

of a $\sigma$-algebra of sets also has an abstract generalizaton, namely it is a particular case of a Boolean $\sigma$-algebra.[30] A comparison of the algebraic theory of relational databases and probability theory is shown in Table VIII.

We feel that this theory of relational databases can be used to analyze the nonquantitative aspects of data dependencies (or independencies), whereas probability theory is the basis of quantitative data analysis, namely statistics. This comparison is not meant to imply that there is a one-to-one correspondence between the theory of relational databases and the theory of probability. Nevertheless, we are convinced that the lattice theory could play a role in the theory of relational databases similar to the role measure theory plays in the theory of probability.[17]

The computational algorithms for meet and join operations of partitions are given in Ref. 31, which provides the basic tools for future development of algorithms for relations.

## IX. ACKNOWLEDGMENT

I am grateful to Dr. M. Eisenberg for his careful review of the manuscript and his helpful comments and suggestions.

## APPENDIX A

### *Properties of Meet and Join Operations*

In any lattice $(L, \cdot, +)$, the operations of meet and join satisfy the following laws:

L1—$a \cdot a = a$, $a + a = a$; (*Idempotent*)

L2—$a \cdot b = b \cdot a$, $a + b = b + a$; (*Commutative*)

L3—$a \cdot (b \cdot c) = (a \cdot b) \cdot c$,
$a + (b + c) = (a + b) + c$; (*Associative*)

L4—$a \cdot (a + b) = a + (a \cdot b) = a$; (*Absorption*)

L5—$a \leqq b$ iff $a \cdot b = a$,
$a \leqq b$ iff $a + b = b$; (*Consistency*)

L6—$b \leqq c$ implies $a \cdot b \leqq a \cdot c$
$b \leqq c$ implies $a + b \leqq a + c$; (*Isotone*)

L7—$a \cdot (b + c) \geqq (a \cdot b) + (a \cdot c)$
$a + (b \cdot c) \leqq (a + b) \cdot (a + c)$; (*Distributive Inequalities*)

L8—$a \leqq c$ implies $a + (b \cdot c) \leqq (a + b) \cdot c$. (*Modular Inequality*)

A lattice is called *distributive* if equality holds in L7 and is called

*modular* if equality holds in L8. A Boolean algebra is a lattice $(L, \cdot, +, \bar{\ })$ with the following additional properties:[30]

L9—$a\cdot(b+c) = (a\cdot b) + (a\cdot c)$,
$a + (b\cdot c) = (a + b)\cdot(a + c)$; (*Distributive Identities*)

L10—$a \leqq c$ implies $a + (b\cdot c) = (a + b)\cdot c$; (*Modular Identity*)

L11—$L$ contains universal bounds $\mathbf{0}$, $\mathbf{1}$, which satisfy
$\mathbf{0}\cdot a = \mathbf{0}$, $\mathbf{0} + a = a$,
$\mathbf{1}\cdot a = a$, $\mathbf{1} + a = \mathbf{1}$;

L12—$\forall a \in L$, $\exists \bar{a} \in L$ such that
$a\cdot\bar{a} = \mathbf{0}$, $a + \bar{a} = \mathbf{1}$, $\bar{\bar{a}} = a$,
$\overline{(a\cdot b)} = \bar{a} + \bar{b}$, $\overline{(a + b)} = \bar{a}\cdot\bar{b}$.

## APPENDIX B

### *The Proofs of Axioms for Functional and Multivalued Dependencies*

The first three of the following are Armstrong's axioms for functional dependencies:[12]

B1. (Reflexivity for functional dependencies)
If $Y \subseteq X \subseteq \Omega$, then $X \rightarrow Y$.

*Proof:* $\theta(X) = \theta(Y(X - Y)) = \theta(Y)\theta(X - Y) \leqq \theta(Y)$. ■

B2. (Augmentation for functional dependencies)
If $X \rightarrow Y$ and $Z \subseteq \Omega$, then $XZ \rightarrow YZ$.

*Proof:* $\theta(XZ) = \theta(X)\theta(Z) \leqq \theta(Y)\theta(Z) = \theta(YZ)$. ■

B3. (Transitivity for functional dependencies)
If $X \rightarrow Y$ and $Y \rightarrow Z$, then $X \rightarrow Z$.

*Proof:* $\theta(X) \leqq \theta(Y)$ and $\theta(Y) \leqq \theta(Z)$ imply $\theta(X) \leqq \theta(Z)$. ■

The next three axioms apply to multivalued dependencies:[13]

B4. (Complementation for multivalued dependencies)
If $X \twoheadrightarrow Y$ then $X \twoheadrightarrow \Omega - X - Y$.

*Proof:* $\theta(X) = \theta(XY) + \theta(XZ) = \theta(XY) \circ \theta(XZ) = \theta(XZ) \circ \theta(XY)$, where $Z = \Omega - X - Y$. ■

B5. (Augmentation for multivalued dependencies)
If $X \twoheadrightarrow Y$, and $V \subseteq W$, then $WX \twoheadrightarrow VY$.

*Proof:* Without loss of generality,* we can let $\Omega = ABCDEFGHIJKL$, $X = ABCDEF$, $Y = BCGHFI$, $W = CDEFHIJK$, $V = EFIJ$ (see Fig. 9). Then $\Omega - X - Y = JKL$ and $\Omega - WX - VY = L$.

We want to show that

$$\theta(ABCDEF) \subseteq \theta(ABCDEFGHI) \circ \theta(ABCDEFJKL)$$

* This proof is carried out in terms of equivalence relations (partitions). It is irrelevant here whether an equivalence relation is the image of a single attribute or the image of a set of attributes.

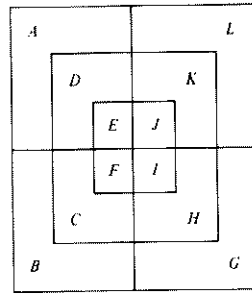

Fig. 9—Set of attributes Ω for B5.

implies

$$\theta(ABCDEFHIJK) \subseteq \theta(ABCDEFGHIJK) \circ \theta(ABCDEFHIJKL).$$

Suppose

$$t_1\theta(ABCDEFHIJK)t_2. \tag{1}$$

Then

$$t_1\theta(ABCDEF)t_2.$$

There exists $t_3$, such that

$$t_1\theta(ABCDEFGHI)t_3\theta(ABCDEFJKL)t_2. \tag{2}$$

From (1) and (2), we have

$$t_3\theta(JK)t_2\theta(JK)t_1.$$

It follows from (2) that

$$t_1\theta(JKG)t_3. \tag{3}$$

Combining (2) and (3), we have

$$t_1\theta(ABCDEFGHIJK)t_3. \tag{4}$$

Relation (2) also implies that

$$t_1\theta(HI)t_3.$$

From (1), we know

$$t_1\theta(HI)t_2,$$

and therefore

$$t_3\theta(HI)t_2. \tag{5}$$

It follows from (2) and (5) that

$$t_3\theta(ABCDEFHIJKL)t_2. \tag{6}$$

Combining (4) and (6), we have

$$t_1\theta(ABCDEFGHIJK)t_3\theta(ABCDEFHIJKL)t_2.$$

It follows that

$$\theta(ABCDEFHIJK) \subseteq \theta(ABCDEFGHIJK) \circ \theta(ABCDEFHIJKL). \quad \blacksquare$$

B6. (Transitivity for multivalued dependencies)

If $X \twoheadrightarrow Y$ and $Y \twoheadrightarrow Z$, then $X \twoheadrightarrow Z - Y$.

*Proof:* Again, without loss of generality, we can let $\Omega = ABCDEFGH$, $X = AFGH$, $Y = BCFG$, $Z = CDGH$ (see Fig. 10). Then $Z - Y = DH$, $\Omega - XY = DE$, $\Omega - YZ = AE$, $\Omega - X(Z - Y) = BCE$.
We want to show that

$$\theta(AFGH) \subseteq \theta(ADEFGH) \circ \theta(ABCFGH)$$

and

$$\theta(BCFG) \subseteq \theta(ABCEFG) \circ \theta(BCDFGH)$$

imply

$$\theta(AFGH) \subseteq \theta(ADFGH) \circ \theta(ABCEFGH).$$

Suppose $t_1\theta(AFGH)t_2$. Then there exists $t_3$ such that

$$t_1\theta(ADEFGH)t_3\theta(ABCFGH)t_2. \tag{7}$$

Since $t_2\theta(BCFG)t_3$, there exists $t_4$ such that

$$t_2\theta(ABCEFG)t_4\theta(BCDFGH)t_3. \tag{8}$$

It follows that

$$t_1\theta(AFG)t_3\theta(AFG)t_2\theta(AFG)t_4. \tag{9}$$

From (7) and (8), we have

$$t_1\theta(DH)t_3\theta(DH)t_4. \tag{10}$$

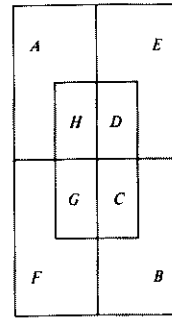

Fig. 10—Set of attributes Ω for B6.

Combining (9) and (10) yields

$$t_1\theta(ADFGH)t_4. \tag{11}$$

From (7) and (8), we have

$$t_4\theta(H)t_3\theta(H)t_2.$$

It follows from (8) that

$$t_4\theta(ABCEFGH)t_2. \tag{12}$$

Relations (11) and (12) yield

$$t_1\theta(ADFGH)t_4\theta(ABCEFGH)t_2.$$

Hence

$$\theta(AFGH) \subseteq \theta(ADFGH) \circ \theta(ABCEFGH). \quad \blacksquare$$

The last two axioms relate functional and multivalued dependencies.

B7. If $X \rightarrow Y$ then $X \twoheadrightarrow Y$.

*Proof:* Let $Z = \Omega - XY$. We want to show that

$$\theta(X) \leqq \theta(Y) \quad \text{implies} \quad \theta(X) \subseteq \theta(XY) \circ (XZ).$$

Suppose $t_1\theta(X)t_2$. Since $\theta(X) \leqq \theta(Y)$ implies $\theta(XY) = \theta(X)$, then $t_1\theta(XY)t_2$. It follows that

$$t_1\theta(XY)t_2\theta(XZ)t_2.$$

Hence

$$\theta(X) \subseteq \theta(XY) \circ \theta(XZ). \quad \blacksquare$$

B8. If $X \twoheadrightarrow Y$, $Z \subseteq Y$, and for some $W$ disjoint from $Y$, we have $W \rightarrow Z$, then $X \rightarrow Z$.

*Proof:* Again, without loss of generality, we can let $\Omega = ABCDEFGH$,

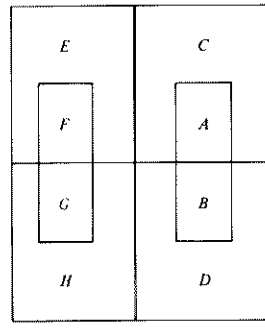

Fig. 11—Set of attributes $\Omega$ for B8.

$X = ACEF$, $Y = EFGH$, $Z = FG$, and $W = AB$ (see Fig. 11). Then $\Omega - XY = BD$.

We want to show that

$$\theta(ACEF) \subseteq \theta(ACEFGH) \circ \theta(ABCDEF)$$

and

$$\theta(AB) \leqq \theta(FG)$$

imply

$$\theta(ACEF) \leqq \theta(FG).$$

Suppose $t_1\theta(ACEF)T_2$. Then there exists $t_3$ such that

$$t_1\theta(ACEFGH)t_3\theta(ABCDEF)t_2.$$

Since

$$t_1\theta(FG)t_3 \quad \text{and} \quad t_3\theta(AB)t_2,$$

we have

$$t_1\theta(FG)t_3 \quad \text{and} \quad t_3\theta(FG)t_2,$$

and thus

$$t_1\theta(FG)t_2.$$

Hence

$$\theta(ACEF) \leqq \theta(FG). \quad \blacksquare$$

# Generation of Syntax-Directed Editors With Text-Oriented Features

By B. A. BOTTOS* and C. M. R. KINTALA†

(Manuscript received March 16, 1983)

Often, syntax-directed editors rely solely on menu selection for program construction. We describe here the generation of *hybrid editors* that give a programmer the option of either (1) using menu selection and tree navigation as in a syntax-directed editor, or (2) entering text for parsing and navigating through the text as in a conventional editor at *any* stage during the expansion of a program. A prototype system, HEG (Hybrid Editor Generator), has been built to automatically generate such a hybrid editor from a high-level specification of a grammar for an application language. Each such generated hybrid editor is called an AGE (Automatically Generated Editor). We describe the HEG meta-language and briefly summarize the editing process in AGEs. We also describe possible extensions to the meta-language to describe program semantics, and the generation of the procedures to check those semantics during program construction.

## I. INTRODUCTION

In the past, there has been a dichotomy between the way a development tool such as a text editor would manipulate the text of a computer program and the way another development tool such as a parser would manipulate the same text. The advent of syntax-directed editing has removed this difference by introducing the use of editors that store and manipulate programs entirely as (partially) instantiated syntax trees.[1-8] The question, though, of whether a program should be manipulated *only* in terms of its syntax tree, or also in terms of its

textual representation, is yet to be resolved.[8,9] Some editing systems purport to allow the programmer both points of view, but provide only one, predetermined, choice for the manipulation of each construct in the language.[7] We introduce here the concept of a *hybrid editor*, which integrates the tree-navigation and menu-selection capabilities of a syntax-directed editor with the text-navigation and the string-entry capabilities of a conventional editor. Either of these views of a program can be taken at *any* stage during the expansion of the program in a hybrid editor.

One of the features of the hybrid editors discussed herein is the fact that a complete editing system is automatically generated from a high-level description of a language. The concrete and abstract syntaxes of the language are both described by one context-free grammar; and both the syntax-directed editor, and the incremental parser for use with the editor, are generated from this grammar.

In this paper, we outline the overall design of a hybrid editor generator and describe briefly the interface presented to a programmer by the hybrid editor. We define the meta-language in which the application language is specified for the generator, and describe the operations performed on the language specification in the process of generating the editor. Based on this design, a prototype hybrid editor generator, called HEG, has been built and is being tested. We describe possible extensions to the meta-language to describe program semantics, and the generation of the procedures to check those semantics during program construction.

## II. BACKGROUND

Although syntax-directed editing can be very helpful to a programmer who is unfamiliar with the language he is using, one who knows the syntax of the language may easily become frustrated with the plethora of menu choices that must be made to "write" a program substructure as simple as an assignment statement. For this reason, allowing the programmer the option of giving the editor a string to parse and insert into the partially expanded program is a desirable feature to have in such a menu-driven editor. We define a hybrid editor to be a syntax-directed editor with the ability to parse and to integrate into the program tree a string given at any time during the expansion of a program.

There have been attempts to generate syntax-directed editors automatically for several programming languages from specifications of the syntactic (given by a context-free grammar)[5] and the semantic (given using attributes for the symbols in the grammar) aspects of a language.[10] There is also a system in use that requires only the addition of a context-free grammar for any new language for which it is to

operate.[4] (In this latter system, detailed knowledge of the structure of the grammar seems to be required in order to use the editor with any grace.) Usually, however, such editors are built individually for each programming language. This is because (1) high-level programming languages have many context-sensitive semantic constraints that cannot be expressed by a context-free grammar, (2) programmers using high-level languages usually need more local context-sensitive aid than syntactic help, and (3) the external interface that such an editor is expected to provide depends heavily upon the language it supports.

Little attention, however, has been paid to syntax-directed editors for special-purpose languages such as the input specification languages for Yet Another Compiler-Compiler (YACC)[11] and database interface languages such as HISEL.[12] Yet it is for these seldom used, but numerous, languages that a hybrid editor would be most useful. Users of such application programs often write their input in a file using a regular text editor and manually check conformity with the syntactic constraints imposed by the particular application program. Some of these application programs have parsers in their front ends to check the syntactic correctness of their input. (Sometimes these parsers are automatically generated from utilities such as YACC.[11]) Others just assume that their input is syntactically correct and abort when it is not. If, in place of the parser, a hybrid editor is available within the application program, the user can be guided by the program's editor during input construction.

A tool to automatically generate such editors for application languages can be quite useful for several reasons: (1) A special-purpose application language, unlike a programming language, is likely to change more rapidly with an evolving application program. (2) Many application programs are not frequently used and hence their idiosyncratic syntactic constraints are likely to be forgotten. (3) The amount of syntactic help from a hybrid editor can be determined by the programmer. (4) The derivation tree built by the hybrid editor may be used by the application program to process its input in a more structured manner than is often possible when only a textual view of the input is available to the program. It is for these types of languages that HEG-generated hybrid editors, called AGEs (Automatically Generated Editors), are most valuable.

## III. THE EDITING PROCESS

In a HEG-generated hybrid editor for a given language, a program is internally represented by a derivation tree of the program in that language, along with a symbol table containing the programmer-defined character strings. (See Appendix A for an example of a short session with an AGE.) When the programmer wishes to expand a

particular nonterminal in the tree by syntax-directed menu selection, and if there are two or more production rules for that nonterminal, then the AGE creates a one-item-at-a-time wraparound menu, on the bottom line of the screen, displaying the menu strings associated with those production rules. After a production rule is chosen for expansion, the internal node for the nonterminal is grown in such a way that the frontier of the subtree rooted at that internal node corresponds to the right-hand side of the production rule selected. If, however, the programmer wishes to forego menu selection, he/she may expand a nonterminal by entering a string that is derivable from the nonterminal. The editor will parse the string, build a subtree representing the string, and graft the subtree into the program tree at the node corresponding to the nonterminal. The string given by the programmer may be any combination of terminal strings and nonterminal names.

Even though the internal representation of a program is a tree, both tree and text interfaces are provided to the programmer for navigation through the program. At any moment, a tree cursor navigating around the internal nodes of the tree is available. The programmer sees the cursor spanning the entire frontier of the subtree rooted at the tree-cursor node. He can move the tree cursor along the internal nodes of the tree (using the commands up [^], down [V], left-sibling under the same parent [<], right-sibling under the same parent [>], next internal node of the same type under the same parent [N], etc). Or, he can navigate textually (using the commands n for next word, b for back word, CR for next line, - for previous line) through the program. The commands 'e' and 'u' provide syntax-driven expansion and unexpansion facilities. Commands 'p' and 'r' allow parser-driven nonterminal expansion and file-reading facilities.

When the programmer quits editing, both the text and the tree versions of the program are saved. The tree is saved by storing the leftmost derivation sequence of the production rules in the derivation tree and the symbol table. This sequence is used to reconstruct the tree for a later editing session on that program. The test is saved for possible use by other tools.

## IV. ARCHITECTURE OF HEG

HEG produces a generalized table-driven syntax-directed editor, linked with a parser, for a given application language. The application language is specified by an AGE grammar in the meta-language described in the next section. A parser generator front end, named 'GENPAR', generates a YACC file and a LEX file[13] from this specification of a language. The parser generated from these two files is capable of parsing strings, which may contain nonterminal names,

starting from any nonterminal of the grammar. The grammar tables used by the editor, the parser, and the generic editing routines are then linked together to generate an AGE for the given language.

Figure 1 shows the interactions between the different components of an AGE.

## V. THE META-LANGUAGE

The "meta-language" for HEG is the grammar specification language in which the production rules of any context-free grammar are specified, along with the pretty-printing information required by the display utilities of the editor (e.g., indentation and color codes, if available) and the strings for the menu lists. As an example of the use of the language,

```
query       : ⟨QUERY⟩
              | "select" list "where" conds
              ;
```

is a normal production rule. Here, ⟨QUERY⟩ is a "user-friendly" name for the nonterminal symbol 'query'. The sequence of strings following the character '|' specifies a production for the nonterminal 'query'. Strings within double quotes in the production specification are terminal characters and others are nonterminals. The terminal character strings may also contain the following special characters denoting pretty-printing information: '\n' for a new-line, '~' for a blank character, '\t' for tabbing one position to the right and increasing the tab count by one for the starting positions of the subsequent lines, and '\T' for decreasing the tab count by one for the current and the subsequent lines.

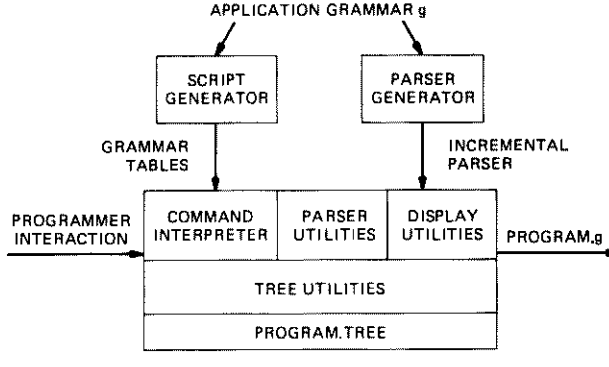

Fig. 1—Interactions between the components of an AGE.

Another example is

```
list        : ITEM_LIST
            | +item ","
            ;
```

This is an iterative production rule. It specifies that the nonterminal, 'list', can be expanded into one or more occurrences of the nonterminal, 'item', separated by the terminal character string ','. A '*', in place of the '+' above, would denote zero or more occurrences of the nonterminal.

There may be more than one production rule for a nonterminal; if so, all of the rules for the nonterminal must be specified in one rule set, each preceded by a '|'. For example, the following two sets of rules show several possible expansions for the corresponding nonterminals:

```
clause      : CLAUSE
            | field_name "~" op "~" constant
            | constant "~" op "~" field_name
            | field_name "~" op "~" field_name
            ;
op          : OPERATOR
            | "="
            | "!="
            | ">="
            | "<="
            | ">"
            | "<"
            ;
```

For each production rule, the grammar specification must include an associated "expansion character". This expansion character must be unique within the set of rules for that nonterminal. If there are two or more rules for the expansion of a nonterminal and if an instance of that nonterminal in the program is to be expanded, the programmer must indicate his choice by typing the expansion character associated with the desired rule. However, if the programmer wishes to examine all the choices for that nonterminal, the AGE creates a one-item-at-a-time wraparound menu on the bottom line of the screen, from which the programmer may choose a production. Therefore, the implementor (the person defining the grammar) must provide a "menu-item-string", which is displayed in the menu for each production rule. These menu items should be suggestive of the associated production rule for better communication with the programmer. When a particular rule is chosen for the expansion, the right-hand side of that rule replaces the left-hand side nonterminal node in the program's syntax tree.

To illustrate the provision of menu information in a grammar for HEG as above and to clarify the grammar specifications further, a complete set of rules for a database query language HISEL[12] is given below. Sentences (queries) in this language have the form:

select x1.fld1,x2.fld2, ··· where ⟨CLAUSES⟩ or ⟨CLAUSES⟩ ···

where 'x' is a cursor name, 'fld' is a field name, and ⟨CLAUSES⟩ is a conjunctive sequence of field conditions. The single characters following the menu items in the rules are the expansion characters. For the rule sets having just one production rule, meaningless menu-item strings (e.g., 'xxx') and expansion characters (e.g., 'x') are used for uniformity in the meta-syntax. Observe that there is no white space in the menu-item strings.

```
query      : ⟨QUERY⟩
           | xxx x "select" list "\nwhere~" conds
           ;
list       : ⟨ITEM_LIST⟩
           | xxx x + item ","
           ;
item       : ITEM
           | xxx x cursor "." field_name
           ;
conds      : ⟨CONDITIONS⟩
           | xxx x *disjunct "\n~~~or~"
           ;
disjunct   : ⟨CLAUSES⟩
           | xxx x +clause "~,~"
           ;
clause     : CLAUSE
           | field_op_const 1 field_name "~" op "~" constant
           | const_op_field 2 constant "~" op "~" field_name
           | field_op_field 3 field_name "~" op "~" field_name
           ;
op         : OPERATOR
           | equal = "="
           | not_equal ! "!="
           | greater_equal 1 ">="
           | less_equal 2 "<="
           | greater > ">"
           | less < "<"
           ;
```

The left-hand side nonterminal of the first rule in the grammar specification (i.e., 'query', above) is the starting nonterminal. If no

production rule is available for a nonterminal (e.g., 'field_name'), and that nonterminal appears during the derivation of a program, then it is assumed to expand into a character string to be provided by the programmer at the time of expansion. Such nonterminals are said to derive "identifiers". A regular expression specification for any such nonterminal can be used to restrict the format of the identifier strings that a programmer may supply at the time of expansion. HEG provides a default specification for all nonterminals deriving identifiers and having no regular expression specification.

As another example, the following is a grammar in the meta-language (meta-grammar) for the meta-language described in this section. In fact, one can invoke an AGE for this meta-language to enter a grammar specification for any user-defined language.

```
gram        : ⟨AN_AGE_GRAMMAR⟩
            | xxx x cfrules "\n%%\n" rerules
            ;
cfrules     : ⟨CONTEXT_FREE_RULES⟩
            | xxx x +ruleset "\n"
            ;
ruleset     : ⟨A_RULE_SET⟩
            | xxx x nonterm-name "\t:~" user_name "\n" rules
              "\n;\n\T"
            ;
rules       : ⟨RHS_OF_A_RULE_SET⟩
            | xxx x +rule "\n"
            ;
rule        : ⟨A_RULE⟩
            | normal-rule n "|~" menu_string "~" exp_char "~"
              tklist
            | nonempty-rec-rule + "|~xxx~x~+" nonterm_name
            "~\"" separator "\""
            | empty-rec-rule * "|~xxx~x~*" nonterm_name "~\""
              separator "\""
            ;
tklist      : ⟨A_SEQ_OF_TOKENS⟩
            | xxx x +token "~"
            ;
token       : TOKEN
            | nonterminal-token n nonterm_name
            | terminal-token t "\"" terminal_str "\""
            ;
rerules     : ⟨REGULAR_EXP_RULES⟩
            | xxx x *rerule "\n"
            ;
```

```
rerule      : ⟨REG_EXP_RULE⟩
            | xxx x nonterm-name "~~\~##!" reg_expr
            ;
%%
exp_char    ~##![a-zA-Z0-9+* ^<>&]
```

## VI. THE PARSER GENERATOR FOR HEG

The tools YACC and LEX are used to produce a parser and a scanner for an AGE system. The parser generator front end, GENPAR, takes, as input, the AGE grammar specification for the desired language and produces YACC and LEX specification files. (Note that the use of YACC implies that the input grammar must be LALR(1) in order to generate a parser for an AGE system.)

The generated parser can be invoked to parse an input string representing the expansion of any nonterminal node in the program derivation tree. The string to be parsed can be any combination of terminal strings and nonterminal names that is derivable from the nonterminal at the "current" position of the editing cursor.

### *6.1 The parsing of an input string*

When the programmer provides a string to be parsed, rather than making a menu selection, the AGE system opens a temporary file, writes the prefix *$$NONTERMINAL_NAME$$* to the file (where *NONTERMINAL_NAME* represents the nonterminal from which the programmer's input string is to be derived), and appends the input string. The parser is called to process the entire string contained in the file. The prefix is considered to be an integral part of the input string. If the portion of the string entered by the programmer cannot be derived from the nonterminal indicated by the prefix, the input will be considered syntactically incorrect. If a syntax error is found, the temporary file is saved in case the programmer should wish to edit the string and resubmit it to the parser.

The parser will parse its input in a "backtracking bottom-up" fashion, constructing a syntax tree to represent the derivation of the input string. After the tree is constructed, a preorder traversal of the tree is performed, producing a list of production numbers representing the leftmost derivation of the input string. This list is then passed back to the controlling program in AGE.

In an AGE, the YACC-generated parser is run subordinate to a "parser monitor" to provide a certain amount of parser backtracking, made necessary by the conflict resolution scheme of the LEX-generated scanner. For such a scanner, the lexical tokens desired are specified by regular expressions. When two or more of the given regular expressions match equal-length segments of the input (starting at the

"current input position" of the scanner), and these are the longest matches possible, the scanner will select the regular expression that had been listed first (textually) in the input specification file as the "correct" match, and return the corresponding token number. If the parser is expecting one of the other possible matches at the current input position, the parser will find a "syntax error" where no error may, in fact, exist.

The parsers produced by the YACC program are standard shift/reduce ("bottom-up") parsers. The required backtracking is accomplished through the interaction of code at two levels of the parsing scheme. At the lowest level, the handling of multiple matches in the scanner is slightly modified by forcing the scanner to "reject" an "identifier" match, after linking the token number associated with the match into a "token map." In this manner, all possible matches for an "identifier" are linked into the token map for the parse. At the highest level, the parser monitor runs the shift/reduce parser, handing the parser token numbers from either the scanner or the token map, depending upon the current state of the parse. Then, if the YACC-generated portion of the parser discovers a syntax error in the input, the monitor can rotate the last set of entries in the token map to (temporarily) "forget" the "preferred" token number for the last "choice position" in the input stream, allowing the use of another possible token number for that position.* In this manner, no syntactically correct input will be declared to contain a syntax error, and an incorrect input will only be rejected after trying the allowable combinations of token numbers for the "identifier" positions.

### *6.2 What the parser generator does*

Several transformations must be applied to the AGE grammar to produce a grammar specification that is acceptable to YACC, and that will specify a parser offering the features and enforcing the constraints desired. All the transformations are performed and the YACC grammar specification is produced in a single pass over the input grammar.

#### *6.2.1 Starting the derivations from arbitrary nonterminals*

For every nonterminal in the AGE grammar, two additional productions are generated. One such set of productions makes it possible to

---

*Due to the relative simplicity of most application languages (in terms of permissible "identifier" combinations and possible token map complexity), the erroneous "identifier" token number will usually be in the last set of entries in the token map. So, in most cases, only the last one or two "identifiers" need to be retried (if the input really is syntactically correct). In all cases, the LALR(1) property of the grammar should aid in the isolation of groups of points in the "identifier" cross-product space that could not possibly be characteristic of a correct parse. The points in these groups, then, need not be considered individually during parsing.

start a derivation from any nonterminal in the original grammar, even though YACC will allow the specification of only one start symbol for a grammar. Each such added production is of the form:

ppstart : AGE_TERM_20 clause

where "ppstart" is a newly defined start symbol for the grammar, "clause" is a nonterminal in the original grammar, and "AGE_TERM_20" is the token returned by the scanner when it reads the prefix (e.g., "$$clause$$") encoding the nonterminal from which the remainder of the input is to be derived. This type of production also allows the enforcement of the rule that the input string must be derivable from the nonterminal at the "current" node in the program tree.

#### *6.2.2 Use of nonterminal names*

The second set of productions generated for each nonterminal allows the acceptance of a "user-name" for a nonterminal, in place of a string that could be derived from that nonterminal, wherever the nonterminal may appear in an input sentence. Each of these productions is of the form:

clause : AGE_TERM_22

where "AGE_TERM_22" is the token returned by the scanner when it reads the user-name for the nonterminal on the left-hand side of the production (e.g., "clause").

#### *6.2.3 Iteration in the grammars*

The iterative specifications in the AGE grammar must be transformed into explicit left recursions, with the separators appropriately treated. Since the most general form of iteration in AGE grammars is that of a list item repeated zero or more times, with a nonwhite-space separator, that case is considered here. The AGE grammar specification for such a list might be:

clauses : *clause ","

where "clause" is the nonterminal to be repeated in the list structure and "," is the terminal separator to appear between list elements.

The YACC specification corresponding to the above production would be:

clauses : Xclause_2_0X

where Xclause_2_0X is a new nonterminal encoding the nonterminal to be repeated as the list elements (e.g. "clause"), the number of the terminal string to be used as the list element separator (e.g., "2"), and

the minimum number of times the nonterminal must appear in the list (e.g., "0"). Such encoding permits the use of the list item nonterminal, "clause," as the repeated element in other lists with different separators and/or different minimal numbers of occurrences.

To derive the required number of occurrences of "clause," sets of productions of the following form must be added to the YACC grammar:

```
Xclause_2_0X  : e
              | Xclause_2_1X
```

where "e" represents the empty string. The second new nonterminal, Xclause_2_1X, denotes one or more occurrences of "clause" separated by occurrences of terminal number 2. For this second new nonterminal, sets of productions of the following form are added to the YACC grammar:

```
Xclause_2_1X  : clause
              | Xclause_2_1X AGE_TERM_2 clause
```

where "AGE_TERM_2" denotes the required separator ("terminal number 2") between elements of the list.

Note that other iterative specifications are specializations of the above case. If the list must be nonempty, only the second new nonterminal, with its associated productions, is generated. If the list element separator is not significant (i.e., if it is any form of white space), then no terminal is encoded in the new nonterminal(s) or included in any of the new productions.

#### *6.2.4 Treatment of identifiers*

In an AGE input grammar, there are no explicit productions for the derivation of character strings representing identifiers. Any nonterminal that does not appear on the left-hand side of any production, in an AGE grammar specification, may produce an identifier. Since there are no such implied rules in a YACC grammar specification, GENPAR must add explicit productions to the grammar to allow the reduction of terminal identifier strings to appropriate nonterminals. These productions are of the form:

```
cursr : AGE_IDENTIFIER_5
```

where an identifier number (e.g., "5") is specified only if the default lexical specification is overridden for the nonterminal on the left-hand side of the production (see below).

To handle the lexical specification for each terminal identifier, the grammar designer has two choices. The designer may use GENPAR's default specification, which allows identifiers to be any combination

of letters, digits, and the characters "-", "_", and ".", which begins with a letter, and is not a reserved terminal string in the language. He may, instead, associate an arbitrary LEX specification with any nonterminal that may derive an identifier. The given specification would then be used to override the default identifier specification for that particular nonterminal.

#### *6.2.5 Treatment of white space*

In the generation process, all types of white space in the AGE grammar specifications of terminal strings are treated identically, and are considered insignificant to the specification of the generated grammar. For example, if a "PROGRAM" is specified as a "list of statements separated by new-lines", the YACC-generated parser will accept any "list of statements separated by any white space (e.g., blanks, tabs, or new-lines)" as a "PROGRAM".

### *6.3 Generation of YACC actions*

If the input string to the parser is valid, AGE requires the output of the parser to be a list of rule numbers, symbol table indices, and list item occurrence counts representing the leftmost derivation of the input string. Since the YACC-generated parser is a shift/reduce parser, the order in which that parser uses the grammar productions will not represent a leftmost derivation of the input. To produce the proper input for the AGE monitor, the parser builds a tree to represent the derivation of its input string as it parses the input string, and, as part of the last production applied (reduction to the start symbol), performs the preorder traversal of the tree, generating the required list of numbers.

The building of this tree is the main activity of the "actions" generated for each production in the YACC specification. To generate code to appropriately link nonterminal sub-trees, the positions of all the nonterminals in a given production rule must be saved as the production is processed by the generator. This is accomplished by counting the tokens on the right-hand side of the given production rule and stacking the position numbers that correspond to nonterminals. Actions are then generated that call precoded subroutines that link the tree nodes together. These subroutines, and their associated data and type declarations, are constant across all grammars, and are included in the appropriate sections of each generated YACC grammar.

### *6.4 The size of the processed grammar*

The growth of the grammar in the generation process is actually not as large as may be imagined. If $n$ = the total number of nonterminals and $r$ = the number of iterative nonterminals in the original

AGE grammar, at most $3n + 3r < 6n$ productions, $2n - 1$ nonterminals, and betweeen $2n + 1$ and $3n - r$ terminals are added to the grammar before YACC generates the parser.

## VII. ATTRIBUTES AND SEMANTIC PROCESSING

One possible extension to this work would involve the addition of attributes to the grammars described above. These attributes could allow a certain amount of semantic checking of user programs, in addition to allowing interpretation and/or code generation (for simple application languages) during program construction. The basic principles behind attribute grammars are described elsewhere;[14] we shall only discuss the required extensions to our meta-language and the generation of evaluation functions for the attributes.

### *7.1 Extensions to the meta-language*

The meta-language described in Section V can be enhanced to include attributes and their evaluation routines in each production. An example of the use of the enhanced meta-language is shown below.

```
clause      : CLAUSE
              inherited: int temp_loc;;
              synthesized: int next_temp;
            | field_op_const 1 field_name "~" op "~" constant
              {
              $0.next_temp = $0.temp_loc;
              }
            | const_op_field 2 constant "~" op "~" field_name
              {
              $0.next_temp = $0.temp_loc;
              }
            | field_op_field 3 field_name "~" op "~" field_name
              {
              $0.next_temp = $0.temp_loc + 2;
              }
            ;
```

In general, the attributes and their evaluation rules are specified in a pseudo-C language notation. We provide data typing facilities for the attribute variables.* The inherited attributes of a nonterminal and their data types are listed after the key word "inherited", which appears after the user-name of that nonterminal. The synthesized attributes

*As with the attributed grammars for programming languages, our experience in using attributed grammars for application languages suggests that facilities that include standard libraries of functions, user-defined types, and global attributes are needed.

of that nonterminal are then listed in a similar fashion. The attribute evaluation rules are listed after each production specification, within braces. "$0.attribute_name" in these rules refers to the correspondingly named attribute of the nonterminal in the left-hand side of the production. "$i.attribute_name" refers to the correspondingly named attribute of the $i$th nonterminal in the right-hand side of the production.

For each inherited attribute of each nonterminal appearing in the right-hand side of a production rule, there must be an evaluation rule (a function call or an arithmetic expression) assigning a value to that attribute associated with that production rule. Similarly, for each synthesized attribute of the left-hand side nonterminal of a production rule, there must be a rule (a function call or an arithmetic expression) assigning a value to that attribute. These rules may take as arguments the inherited attributes of the left-side nonterminal and/or synthesized attributes of the nonterminals in the right-hand side. These rules must not, however, violate the properties defining $L$-attributedness[14] of the grammar in order for the proposed evaluation scheme to work.

For iterative production rules, the semantic specifications appear as:

```
disjunct      : ⟨CLAUSES⟩
                inherited:;
                synthesized:;
                |xxx x +clause "~,~"
                 {
                 int current_temp;
                 init: {
                    current_temp = 0;
                 }
                 repeat: {
                    $1.temp_loc = current_temp;
                    current_temp = $1.next_temp;
                 }
                 }
                ;
```

The routine following the key word "init:" is executed when this production rule is initially chosen. Then, for each instance of the nonterminal "clause" under the parent "disjunct", the specification following the key word "repeat:" is used. The "$1" in the latter specification refers to the instance of the nonterminal "clause" whose attributes are being evaluated. These evaluation specifications must follow the same guidelines as those of the regular productions. Nonterminals deriving "identifiers" (i.e., those having no production rules)

are assumed to have only one synthesized attribute, "value", whose value is the string entered by the programmer at the time of expansion.

### *7.2 Generation of the attribute evaluators*

In any specification of an application language as above, each implementor-defined attribute evaluation function is associated with a specific production. For each distinct attribute in the grammar, the calls to these functions are collected into one generated evaluation function, which determines the appropriate implementor-defined function to call, based on the rule that produced the associated nonterminal. To make the required environment information accessible during the attribute evaluation, a pointer to the tree node at which the generated function is to be evaluated is passed as a parameter to the generated function. The evaluation functions for inherited attributes must be passed a pointer to the parent node of the nonterminal node with which the attribute is associated (i.e., inherited attributes are evaluated when the associated nonterminal appears on the right-hand side of a production). Synthesized attribute evaluation functions must be passed a pointer to the nonterminal node with which the attribute is associated (i.e., synthesized attributes are evaluated when the associated nonterminal is expanded).

Each generated evaluation function for an inherited attribute contains a section of code for each production in which the associated nonterminal can appear on the right-hand side. Similarly, each generated evaluation function for a synthesized attribute contains a section of code for each production in which the associated nonterminal appears on the left-hand side. Within each of these sections of code is the code for the appropriate implementor-defined function, along with the function calls required to evaluate the actual parameters of the implementor's function. The attributes are evaluated only as required, and the evaluation nesting is managed automatically by the C (target programming language) procedure calling mechanism.

## VIII. REMARKS

The editor generator HEG, as described here (excluding the semantic analysis), currently exists and has been used for a variety of application languages. The novel aspects of this system include: (1) the ability to give a programmer the option to use menu selection or to enter strings containing terminal characters and nonterminal names at *any* stage during the expansion of a program in the user-language, and (2) the ability to generate a hybrid editor from a high-level specification of a user grammar. This system was an experiment to investigate only these aspects of editing. Various other related issues such as building a robust syntax-sensitive editor for higher-level

languages (e.g., C language), experimenting with different ways of exhibiting the menus, and human-factors issues are being addressed separately.[5]

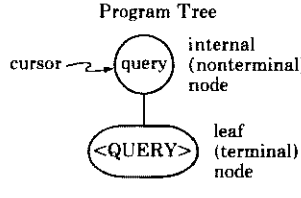
## APPENDIX A

### *An Editing Session With 'Hisel.age'*

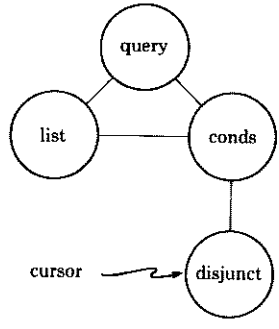
\$hisel.age
program? test
Initializing the tree/text for test..
Terminal Screen
1) ⟨QUERY⟩



:r <- user command - invisible
file name? temp

Assume that there is a file named 'temp' in the working directory and that it has the string "select ⟨ITEM_ LIST⟩ where ⟨CLAUSES⟩". AGE will read it, recognize the two nonterminal names, parse the string, create the subtree, and graft it to the root as shown below.

2) select ⟨ITEM_ LIST⟩
   where ⟨CLAUSES⟩

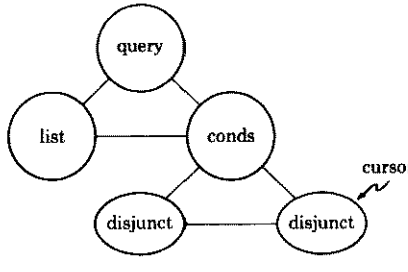


(Leaves are not shown)

:a

This will add one more instance of CLAUSES. The screen after this command will be:

3) select ⟨ITEM_ LIST⟩
   where ⟨CLAUSES⟩
      or ⟨CLAUSES⟩



:e
:e

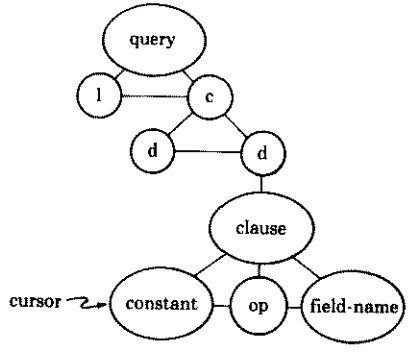
AGE will install a CLAUSE in place of ⟨CLAUSES⟩ after the first e command. Since there is a choice for the expansion corresponding to the next e command, the following menu items will appear one after

another if the user asks for a menu:

expansion character (type ? for menu): ? <- user types this
field_op-const 1 y(es), n(ext), q(uit)? n <- user types this
const-op-field 2 y(es), n(ext), q(uit)? y

The screen after this will be:

4) select ⟨ITEM_LIST⟩
   where ⟨CLAUSES⟩
     or constant OPERATOR field_name



:w
This command will write the above text into test.hisel file and the tree representation in test.lmd file.
:q
AGE will then print:
BYE! test hasn't been fully expanded; call me back later.

## APPENDIX B

### *AGE Command Summary*

***Text-navigation commands:***

cr - a carriage return : go to the next line
- - the character minus: go back one line
space-bar or n : go to the next word
b : go back one word

***Tree-navigation commands:***

^ : go to the parent of the current nonterminal
V : go to the first son of the current nonterminal
> : go to the right neighboring nonterminal under the same parent
< : go to the left neighboring nonterminal under the same parent
N : go the next unexpanded nonterminal
B : go backwards for the next unexpanded nonterminal

*Nonterminal expansion commands:*

p : parse text for the current nonterminal
r : read text from a file and parse it for the current nonterminal
e : expand the current nonterminal by menu selection
a : append an instance of a 'listy' (i.e., iterative) nonterminal
i : insert an instance of a 'listy' nonterminal
d : delete the current instance of the 'listy' nonterminal

*Other commands:*

U : unexpand nonterminal
w : write program
q : quit editing with AGE

# Performance Analysis of a Preemptive Priority Queue with Applications to Packet Communication Systems

By M. G. HLUCHYJ,* C. D. TSAO,* and R. R. BOORSTYN†

(Manuscript received May 6, 1983)

In this paper we analyze the performance of a preemptive priority queue. We give the model description in the context of a packet communication system where message sources, having different priorities, share a common communication channel. Each source generates, as an independent Poisson process, messages consisting of an arbitrarily distributed, random number of fixed-length packets. The channel server can only begin service at integer multiples of the packet transmission time (i.e., a time-slotted channel is assumed), and the server will preempt an ongoing message transmission at the next packet boundary whenever there is a message arrival from a higher-priority source. The average in-queue waiting time for each packet in any given source message and the average message delay are derived along with the corresponding moment-generating functions. Also, comparisons are made with the first-come first-served queueing discipline.

## I. INTRODUCTION

We analyze the performance of a preemptive priority queueing system. To make clear at the outset the importance of the particular queueing system studied, we describe the system model in a packet communication context. Specifically, as Fig. 1 illustrates, a number of data sources share a single communication channel. Each source generates, according to a Poisson process, messages consisting of a

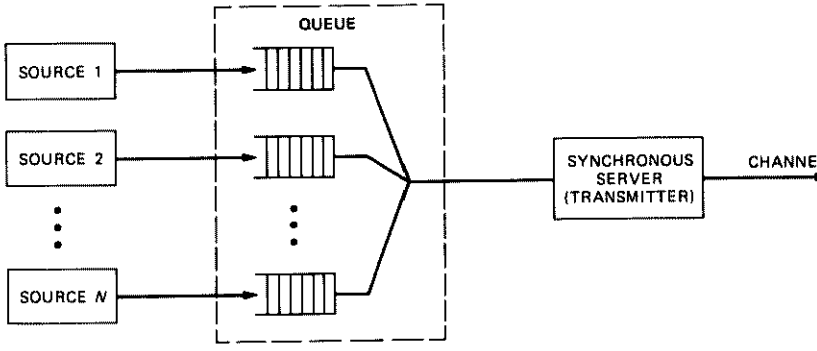

Fig. 1—Queueing model for a packet communication system.

random number of fixed-length data packets. The packets comprising a message arrive in bulk to be transmitted on the communication channel. For clarity, we view each source as having its own separate buffer to queue packets. Here, packets generated by the source wait for access to the channel.

Packet transmissions on the channel are synchronized. More precisely, time is divided into a sequence of fixed-length intervals or time slots. Each time slot is just large enough to allow the transmission of one packet, and packet transmissions must occur within time-slot boundaries. Hence, a packet arriving at the queue, at the very least, must wait until the start of the next time slot before its transmission can begin.

Packets from any given source are served (i.e., transmitted) on a first-come first-serve basis. The sources, however, are assigned fixed priorities: the first source has the highest priority, the last has the lowest. At the start of each time slot, the first packet queued from the highest-priority source is served. That is, a packet at the head of the source $k$ buffer is transmitted if and only if the buffers associated with sources 1 to $k-1$ are empty. Hence, an ongoing packet transmission cannot be preempted; however, an ongoing message transmission will be preempted (at the next slot boundary) whenever there is a message arrival from a higher-priority source.

Such a priority queueing discipline arises naturally in many packet communication systems. The channel might be a link in a data communication network, or may simply be a shared data bus. The use of priority may be required to give more urgent messages lower delay. For example, one might choose to give network control messages higher priority than interactive data messages, which in turn are given higher priority than long file transfers. In some situations, the priority structure is inherent in the mechanism for sharing the channel among the independent messages sources. This is the case with Datakit,[1]

where the module (i.e., the interface between the source and the channel) with the highest address always wins the channel contention. It is also true of some slotted ring systems, where the physical order of sources along the ring imposes a priority ordering for access to the channel.[2]

The first results on queues with preemptive priority appear to be due to White and Christie.[3] Shortly thereafter, others studied the problem using different assumptions about the service time distribution. A comprehensive treatment of some of the early work is given in Jaiswal,[4] and a more up-to-date, but less comprehensive, discussion may be found in Kleinrock.[5] The models examined, however, all assume an "asynchronous" server where service starting times and preemption times are not constrained to certain periodically recurring points. The use of a synchronous service facility in queueing models arises in the context of computer and data communication systems where there is a natural elementary unit of time such as the machine cycle of a processor, or the bit, byte, or packet transmission time on a channel. Many such models are reviewed, and references given, in Kobayashi and Konheim.[6] As we indicated, the model we have selected for study has applications to slotted ring systems, and it is here that one finds analysis of other models similar to ours. The model that seems to come closest is by Konheim and Meister,[2] where the main differences have to do with the arrival process. Konheim and Meister assume discrete arrivals (between slots) of packets, whereas we assume continuous arrivals of messages with each message containing an arbitrarily distributed number of packets. In this way, we are better able to examine message delays in the system.

In this paper we analyze the performance of the above preemptive priority queueing system. We begin in Section II by summarizing the queueing model and introducing performance measures that are of interest. In Section III we derive the average in-queue waiting time for each packet in any given source message. From this result we easily obtain the average delay in transporting a message. The corresponding moment-generating functions are derived in the appendix. Finally, in Section IV, we compare performance with the First-Come First-Served (FCFS) queueing discipline.

## II. QUEUEING MODEL

In this section we briefly summarize the important points of the queueing model, and indicate the steady-state statistics that are of interest. Notation established here is used in the performance analysis that follows.

The queueing system under study has the following properties:

1. $N$ sources of messages.

2. Priorities are assigned to sources in decreasing order (i.e., source $k$ has higher priority than source $k+1$, $k = 1, 2, \cdots, N-1$).

3. Source $k$ generates messages as an independent Poisson process with rate $\lambda_k$ messages per time slot. Each such message has its length (in packets) selected independently from the distribution $P_{m_k}(\cdot)$ with first and second moments, $\overline{m}_k$ and $\overline{m_k^2}$, respectively.

4. During busy periods, one packet is transmitted in each time slot and is always selected at the beginning of the time slot from the head of the highest-priority, nonempty source buffer.

5. Each source buffer is assumed infinite, and packets enter and are removed from the buffer on a first-in first-out basis.

We define $W_{kj}$ as the steady-state in-queue waiting time for the $j$th packet in a message from source $k$, $k = 1, 2, \cdots, N$. In addition, we define

$$\rho_k = \lambda_k \overline{m}_k,$$

where $\rho_k$ is interpreted as the fraction of time the server is busy with source $k$ packets. We also find it convenient to define

$$\sigma_k = \sum_{i=1}^{k} \rho_i.$$

Other notation is introduced as needed in the analysis.

## III. PERFORMANCE ANALYSIS

We begin this section by deriving $\overline{W}_{kj}$, the average in-queue waiting time for the $j$th packet in a message from source $k$. Using this result we then obtain the average delay in transporting a message from source $k$. Included in the discussion are specific numerical examples to illustrate the derived results.

### *3.1 Average waiting time analysis*

In Fig. 2, observe that we may express the waiting time for the $j$th packet in a source $k$ message as

$$W_{kj} = W_{k1} + \sum_{\ell=1}^{j-1} w_{k\ell}, \tag{1}$$

where the incremental waiting time $w_{k\ell}$ is defined by

$$w_{k\ell} = W_{k,\ell+1} - W_{k\ell}.$$

For a given message length, $m_k$, the random variables $\{w_{k1}, w_{k2}, \cdots, w_{k,m_k-1}\}$ are independent and identically distributed. We observe that at the beginning of a slot during which a packet from source $k$ is in service, there are no packets from sources 1 to $k-1$ in the system.

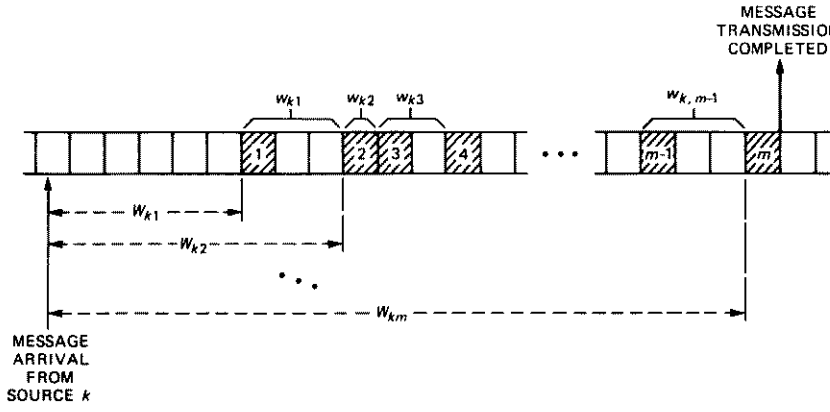

Fig. 2—Waiting times for packet transmissions.

Any messages that arrive from sources 1 to $k-1$ while this source $k$ packet is in service spawn a busy period of service, starting in the next slot, for sources 1 to $k-1$. All such busy periods are independent and identically distributed, and hence so are the random variables $\{w_{k1}, w_{k2}, \ldots, w_{k,m_k-1}\}$.

Note that the incremental waiting time $w_{k\ell}$ consists of one slot time to transmit the $\ell$th packet in the source $k$ message plus the time to serve all messages from sources 1 to $k-1$ that arrive in the interval $w_{k\ell}$. Hence, the average incremental waiting time $\overline{w}_{k\ell}$ satisfies

$$\overline{w}_{k\ell} = 1 + \sigma_{k-1}\overline{w}_{k\ell},$$

from which we obtain

$$\overline{w}_{k\ell} = \frac{1}{1-\sigma_{k-1}}.$$

It then follows from (1) that the average in-queue waiting time for the $j$th packet in a source $k$ message is given by

$$\overline{W}_{kj} = \overline{W}_{k1} + \frac{j-1}{1-\sigma_{k-1}}. \tag{2}$$

Hence we are left with having to determine $\overline{W}_{k1}$, the average waiting time for the first packet in the message.

By applying standard queueing arguments, we have

$$\overline{W}_{k1} = \frac{1}{2} + \sum_{i=1}^{k}\sum_{j=1}^{\infty}\rho_{ij}\overline{W}_{ij} + \sum_{i=1}^{k-1}\rho_i\overline{W}_{k1}, \tag{3}$$

where

$$\rho_{ij} \triangleq \lambda_i \Pr[m_i \geq j]. \tag{4}$$

The first term on the right-hand side of (3) is simply the average time between the arrival of a message and the start of the next slot. The second term is, by Little's result, the average number of packets of equal or higher priority awaiting transmission at the moment the message arrives. Finally, the last term corresponds to the average number of packets of higher priority that arrive while the first packet in the source $k$ message waits on queue.

Now substituting (2) into (3) yields

$$\overline{W}_{k1} = \frac{1}{2} + \sum_{i=1}^{k} \sum_{j=1}^{\infty} \rho_{ij} \left( \overline{W}_{i1} + \frac{j-1}{1-\sigma_{i-1}} \right) + \sum_{i=1}^{k-1} \rho_i \overline{W}_{k1}. \tag{5}$$

Note from the definition of $\rho_{ij}$ in (4) that

$$\begin{aligned} \sum_{j=1}^{\infty} \rho_{ij} &= \lambda_i \sum_{j=1}^{\infty} \Pr[m_i \geq j] = \lambda_i \sum_{j=1}^{\infty} \sum_{\ell=j}^{\infty} \Pr[m_i = \ell] \\ &= \lambda_i \sum_{\ell=1}^{\infty} \sum_{j=1}^{\ell} \Pr[m_i = \ell] = \lambda_i \sum_{\ell=1}^{\infty} \ell \Pr[m_i = \ell] \\ &= \lambda_i \overline{m}_i = \rho_i. \end{aligned} \tag{6}$$

Similarly, we have that

$$\sum_{j=1}^{\infty} (j-1)\rho_{ij} = \frac{\lambda_i}{2} (\overline{m_i^2} - \overline{m}_i). \tag{7}$$

Hence, using (6) and (7), we may rewrite (5) as

$$\overline{W}_{k1} = \frac{\frac{1}{2} + \sum_{i=1}^{k-1} \rho_i \overline{W}_{i1} + \sum_{i=1}^{k} \lambda_i (\overline{m_i^2} - \overline{m}_i)/2(1-\sigma_{i-1})}{(1-\sigma_k)}.$$

Solving recursively, we obtain

$$\overline{W}_{k1} = \frac{1 + \sum_{i=1}^{k} \lambda_i (\overline{m_i^2} - \overline{m}_i)}{2(1-\sigma_k)(1-\sigma_{k-1})}. \tag{8}$$

Finally, substituting (8) into (2) yields

$$\overline{W}_{kj} = \frac{1 + \sum_{i=1}^{k} \lambda_i (\overline{m_i^2} - \overline{m}_i)}{2(1-\sigma_k)(1-\sigma_{k-1})} + \frac{j-1}{1-\sigma_{k-1}}. \tag{9}$$

This concludes the derivation of the average in-queue waiting time $\overline{W}_{kj}$. The derivation of the moment-generating function for $W_{kj}$ (from which $\overline{W}_{kj}$ can be obtained directly) is given in the appendix.

To illustrate the performance, we begin by considering a homoge-

neous system where $\lambda_k = \lambda$, $\overline{m}_k = \overline{m}$, and $\overline{m_k^2} = \overline{m^2}$ for $k = 1, 2, \cdots, N$. For this case, (8) becomes

$$\overline{W}_{k1} = \frac{1 + \frac{k}{N}\rho\,(\overline{m^2}/\overline{m} - 1)}{2\left(1 - \frac{k}{N}\rho\right)\left(1 - \frac{(k-1)}{N}\rho\right)}, \tag{10}$$

where $\rho$ is the total system utilization (or load) defined by

$$\rho = \sum_{i=1}^{N} \rho_i$$

$$= N\lambda\overline{m} \qquad \text{(for a homogeneous system).}$$

If we take $N = 10$ and assume a constant message length of 10 packets (i.e., $\overline{m} = 10$, $\overline{m^2} = 100$), Fig. 3 is a plot of $\overline{W}_{k1}$ vs. $\rho$ for $k$ varying from

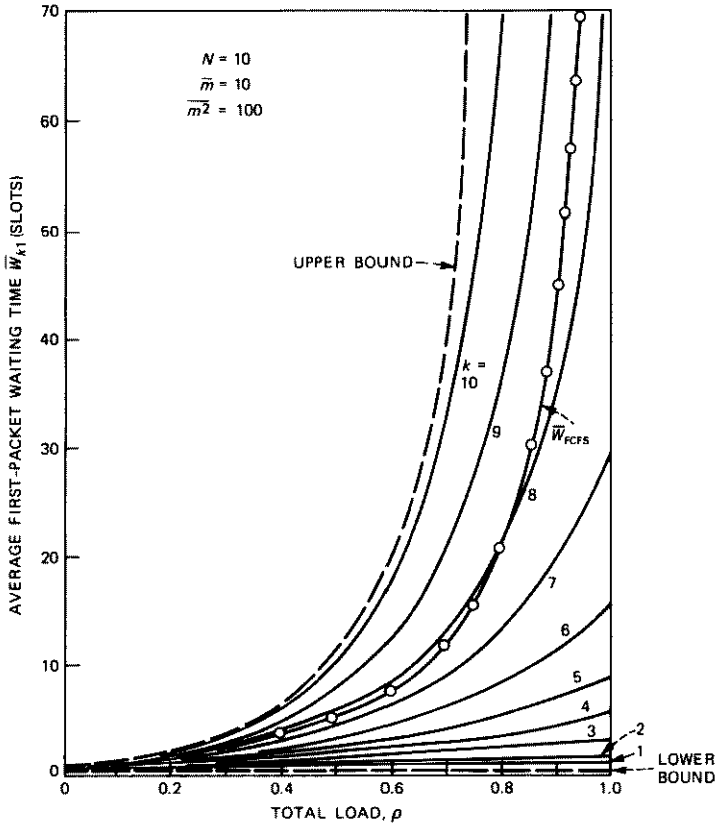

Fig. 3—Average first packet waiting time $\overline{W}_{k1}$ vs. total load $\rho$.

1 to 10. Also shown in Fig. 3 is the average waiting time for the first-come first-served (FCFS) queueing discipline, which is derived in Section IV. Note from (10) that if we allow $N \to \infty$, then

$$\overline{W}_{11} \to \frac{1}{2}$$

$$\overline{W}_{N1} \to \frac{1 + \rho(\overline{m^2}/\overline{m} - 1)}{2(1 - \rho)^2}.$$

These two expressions represent, respectively, lower and upper bounds on the average first packet waiting time for all sources and arbitrary $N$. These bounds are plotted as dashed lines in Fig. 3. Finally, if we assume the same values for $N$, $\overline{m}$, and $\overline{m^2}$ as in Fig. 3, Fig. 4 is a plot of the average incremental waiting time $\overline{w}_{k\prime}$ vs. $\rho$ for $k$ varying from 1 to 10. Also shown in Fig. 4 is the upper bound $1/(1 - \rho)$ on $\overline{w}_{k\prime}$, valid for all parameter values.

### *3.2 Average message delay analysis*

We now consider the average message delay. Defining $\overline{D}_k(m)$ as the average delay (in slots) from the arrival to the queue of an $m$-packet

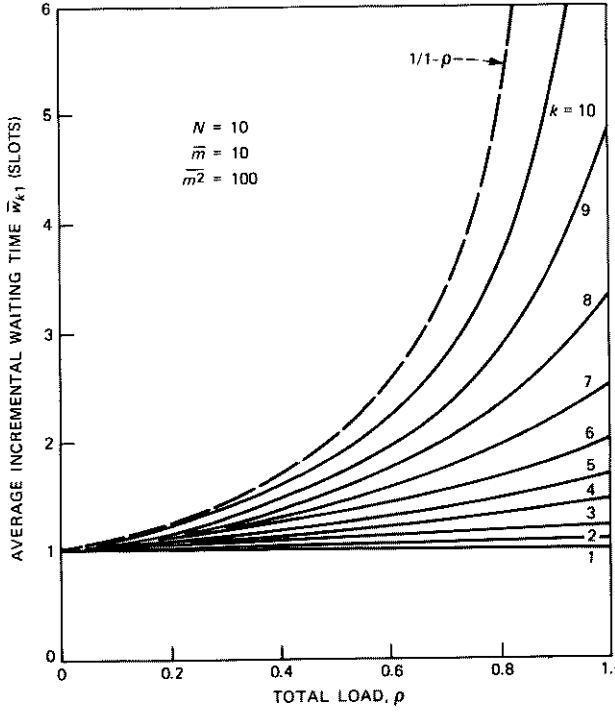

Fig. 4—Average incremental waiting time $\overline{w}_{k1}$ vs. total load $\rho$.

message from source $k$ until the end of its transmission, we have

$$\overline{D}_k(m) = \overline{W}_{km} + 1.$$

Letting $\overline{D}_k$ denote the average delay over all messages from source $k$, it follows, since $\overline{W}_{km}$ is linear in $m$, that

$$\begin{aligned}\overline{D}_k &= \sum_m \overline{D}_k(m) P_{m_k}(m) \\ &= \overline{W}_{k,\overline{m}_k} + 1. \end{aligned} \tag{11}$$

If we assume the same homogeneous system as represented in Figs. 3 and 4, Fig. 5 is a plot of $\overline{D}_k$ vs. $\rho$ for $k$ varying from 1 to 10. Also shown in Fig. 5 is an upper bound on $\overline{D}_k$, obtained from the upper bounds on $\overline{W}_{k1}$ and $\overline{w}_{k\ell}$. Specifically, we have

$$\overline{D}_k \leq \frac{1 + \rho[\overline{m^2}/\overline{m} - 1]}{2(1-\rho)^2} + \frac{\overline{m} - 1}{(1-\rho)} + 1,$$

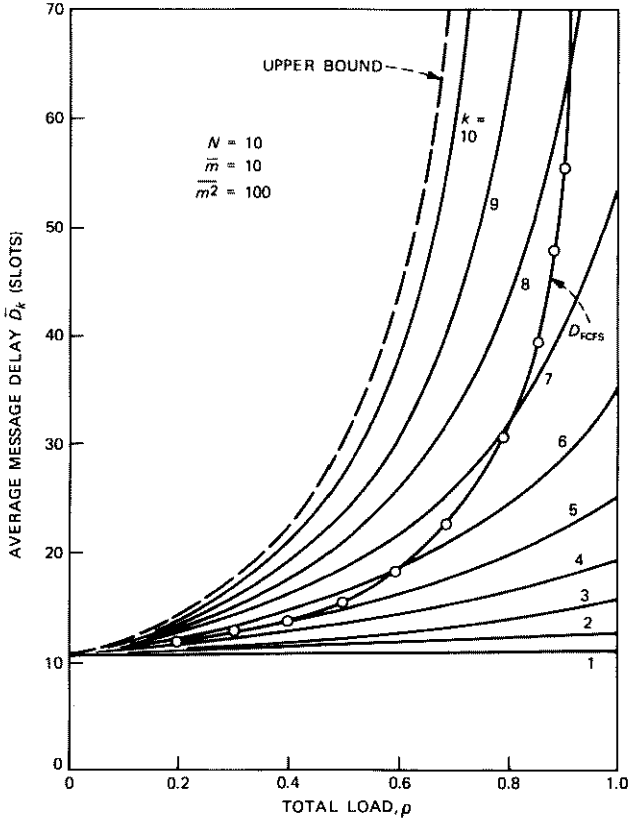

Fig. 5—Average message delay $\overline{D}_k$ vs. total load $\rho$.

which depends on $\overline{m}$ and $\overline{m^2}$, but is valid for all sources and arbitrary $N$.

To complete this section, we consider a nonhomogeneous system consisting of 10 host computers and 300 terminals. The terminals and hosts correspond to the message sources and may be viewed as sharing a common time-slotted bus. There is a priority ordering of the terminals and hosts, with terminals having priority over hosts (i.e., the terminals correspond to sources 1 to 300 and the hosts correspond to sources 301 to 310). Each host is assumed to generate two types of traffic: host-to-host file transfers consisting of fixed-length 32-packet messages, and host-to-terminal messages with an average message length of 2 packets and a standard deviation of 1. Each terminal, on the other hand, only generates messages that are one packet in length and destined to a host. The message generation rates for each of the two types of host traffic are the same for all hosts. Similarly, all terminals generate messages at the same rate. The specific generation rate of each traffic type is such that the total load on the channel is divided as follows: 30 percent host-to-host, 60 percent host-to-terminal, and 10 percent terminal-to-host. The average delay performance for this system is plotted in Fig. 6. Observe that the results obtained allow us to distinguish between different types of traffic generated by the same source. In particular, in Fig. 6, the average message delay performance for the host-to-host and host-to-terminal traffic are shown separately.

From the moment-generating function for $D_k$ derived in the appendix, one can obtain the second moment of the message delay. This, in turn, may be used to compute the message delay standard deviation. For hosts 1 and 10 (i.e., the two extremes), shown in Fig. 7 for the host-to-host messages and in Fig. 8 for the host-to-terminal messages, we see the mean delay and mean delay plus one, two, and three standard deviations (denoted by $1\sigma$, $2\sigma$, and $3\sigma$). The second-moment-of-message delay depends on the first three moments of message length, and in Fig. 8 we set $\overline{m^3} = 15$.

## IV. COMPARISONS WITH FCFS

In this section we compare the average delay performance of the priority queueing discipline studied in the previous section with that of the First-Come First-Served (FCFS) discipline. With the FCFS discipline, messages are served in the order in which they are generated, independent of the source from which they originate. In this way, the FCFS discipline allocates the communication channel more fairly than does the priority discipline. For simplicity, we assume in the analysis a homogeneous system where $\lambda_k = \lambda$, $\overline{m}_k = \overline{m}$, and $\overline{m_k^2} = \overline{m^2}$ for $k = 1, 2, \cdots, N$.

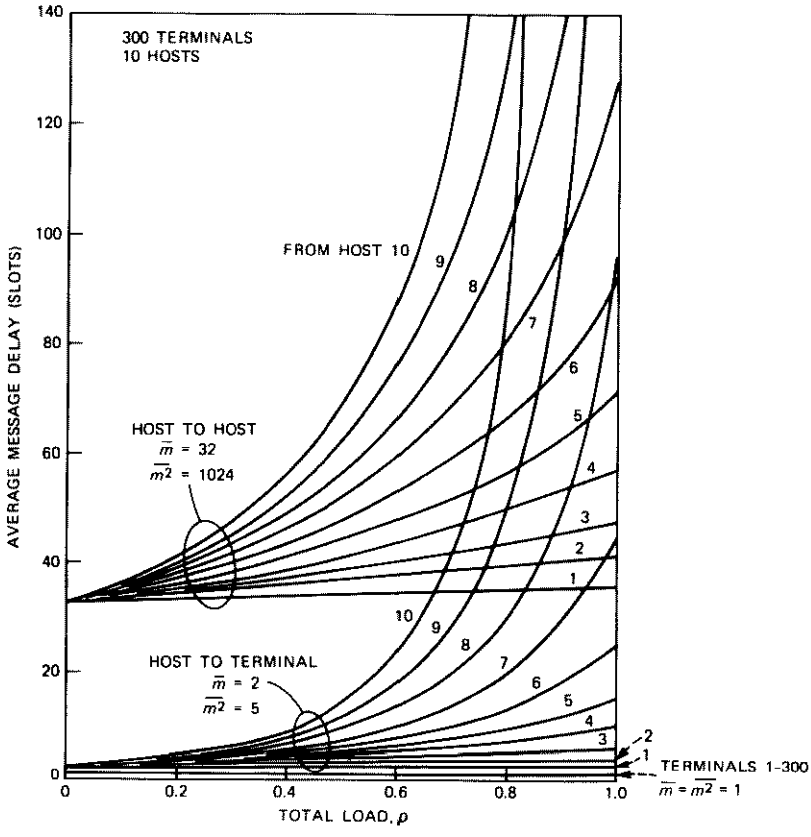

Fig. 6—Average message delay vs. total load $\rho$.

The performance analysis of the FCFS queueing discipline is a special case of the results obtained for the priority discipline. Specifically, we combine the $N$ independent Poisson streams into a single Poisson stream (using the well-known result that the sum of independent Poisson processes is a Poisson process) with rate $N\lambda$. From (10) we have that the average in-queue waiting time for a message generated by this combined (single) source is given by

$$\overline{W}_{\text{FCFS}} = \frac{\rho(\overline{m^2}/\overline{m})}{2(1-\rho)} + \frac{1}{2}, \tag{12}$$

where again $\rho = N\lambda\overline{m}$ is the total system utilization. The average message delay for the FCFS system is given by

$$\begin{aligned}\overline{D}_{\text{FCFS}} &= \overline{W}_{\text{FCFS}} + \overline{m} \\ &= \frac{\rho(\overline{m^2}/\overline{m})}{2(1-\rho)} + \frac{1}{2} + \overline{m}.\end{aligned} \tag{13}$$

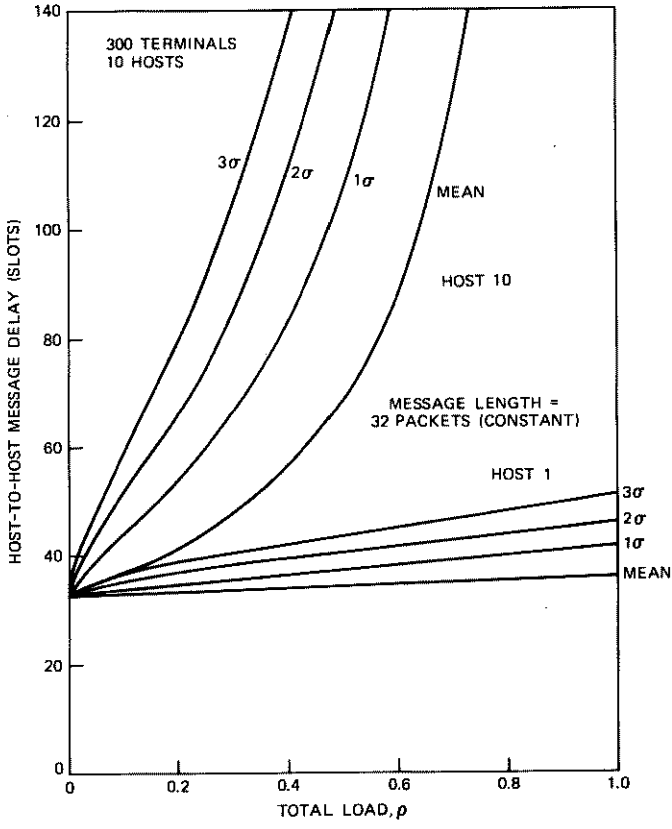

Fig. 7—Host-to-host message delay vs. total load $\rho$.

$\overline{W}_{\text{FCFS}}$ is plotted in Fig. 3 and $\overline{D}_{\text{FCFS}}$ is plotted in Fig. 5 for the assumed system parameter values.

It is worth noting that the waiting time and delay results given by (12) and (13), respectively, differ from those corresponding to the standard M/G/1 queueing system by the additional term 1/2. This added term results from the synchronous nature of the server and represents the average time an arriving message must wait before the start of the next time slot.

We continue the priority and FCFS comparison by focusing on the unfairness issue. Specifically, we consider the ratio of the average message delay for source $N$ to that of source 1, $\overline{D}_N/\overline{D}_1$. Since all sources encounter the same average delay in the FCFS discipline, $\overline{D}_N/\overline{D}_1 = 1$. With the priority discipline, source $N$ has the lowest priority and source 1 the highest; hence $\overline{D}_N/\overline{D}_1 > 1$ for $\rho > 0$. In particular, we have from (9) and (11) that

$$\overline{D}_k = \frac{1 + \frac{k}{N}\rho[(1 + c_m^2)\overline{m} - 1]}{2\left(1 - \frac{k}{N}\rho\right)\left(1 - \frac{(k-1)}{N}\rho\right)} + \frac{\overline{m} - 1}{\left(1 - \frac{(k-1)}{N}\rho\right)} + 1, \quad (14)$$

where $c_m^2$ is the squared coefficient of variation for the message-length distribution defined by

$$c_m^2 = \frac{\text{variance}(m)}{(\overline{m})^2}.$$

Hence, for large $N$ we have from (14) that

$$\overline{D}_1 = \frac{\frac{\rho}{N}(1 + c_m^2)\overline{m}}{2\left(1 - \frac{\rho}{N}\right)} + \frac{1}{2} + \overline{m}$$

$$\approx \frac{\overline{m}}{2}\left[\frac{1}{\overline{m}} + \frac{\rho}{N}(1 + c_m^2) + 2\right]$$

and

$$\overline{D}_N = \frac{1 + \rho[(1 + c_m^2)\overline{m} - 1]}{2(1 - \rho)\left(1 - \frac{(N-1)}{N}\rho\right)} + \frac{\overline{m} - 1}{\left(1 - \frac{(N-1)}{N}\rho\right)} + 1$$

$$\approx \frac{\overline{m}\left[(1 + c_m^2)\rho + \left(2 - \frac{1}{\overline{m}}\right)(1 - \rho) + \frac{2}{\overline{m}}(1 - \rho)^2\right]}{2(1 - \rho)^2}.$$

It follows then that

$$\frac{\overline{D}_N}{\overline{D}_1} \approx \begin{cases} \dfrac{1 + c_m^2\rho + 2(1 - \rho)^2}{3(1 - \rho)^2} & \text{for } \overline{m} = 1 \\ \dfrac{2 + (c_m^2 - 1)\rho}{2(1 - \rho)^2} & \text{for } \overline{m} \gg 1. \end{cases}$$

Observe that for large $N$ and fixed $\rho$, the increase in $\overline{D}_N/\overline{D}_1$ is approximately linear with the squared coefficient of variation $c_m^2$. In Fig. 9, the ratio $\overline{D}_N/\overline{D}_1$ is plotted against total utilization $\rho$ for the FCFS and priority disciplines with $c_m^2 = 0$ and 1.

To complete this section, we compare the average delay performance of the FCFS discipline with the overall average delay of the priority discipline. That is, we compare $\overline{D}_{\text{FCFS}}$ as given by (13) to the quantity

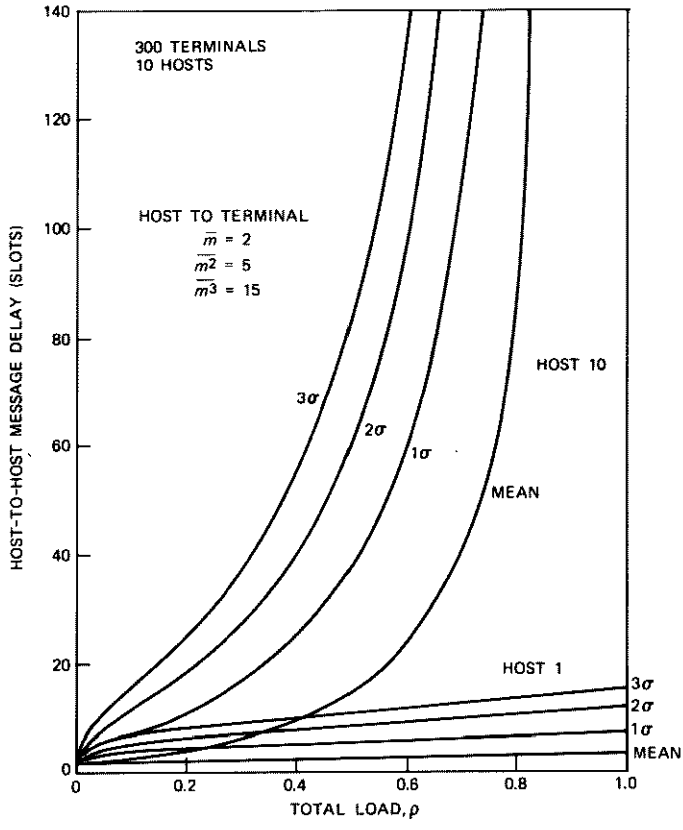

Fig. 8—Host-to-terminal message delay vs. total load $\rho$.

$$\overline{D} \triangleq \frac{1}{N} \sum_{k=1}^{N} \overline{D}_k.$$

Using the expression for $\overline{D}_k$ given in (14), we obtain after some manipulation

$$\overline{D} = \frac{(1 + c_m^2)\overline{m}}{2(1 - \rho)} + \frac{1}{2N} [2\overline{m} - 1 - (1 + c_m^2)\overline{m}]\gamma + 1,$$

where

$$\gamma = \sum_{k=1}^{N} \left[1 - \frac{(k-1)}{N} \rho\right]^{-1}.$$

From this, one may show that

$$\overline{D}_{\text{FCFS}} \leq \overline{D} \quad \text{for} \quad 0 \leq c_m^2 \leq \frac{\overline{m} - 1}{\overline{m}}$$

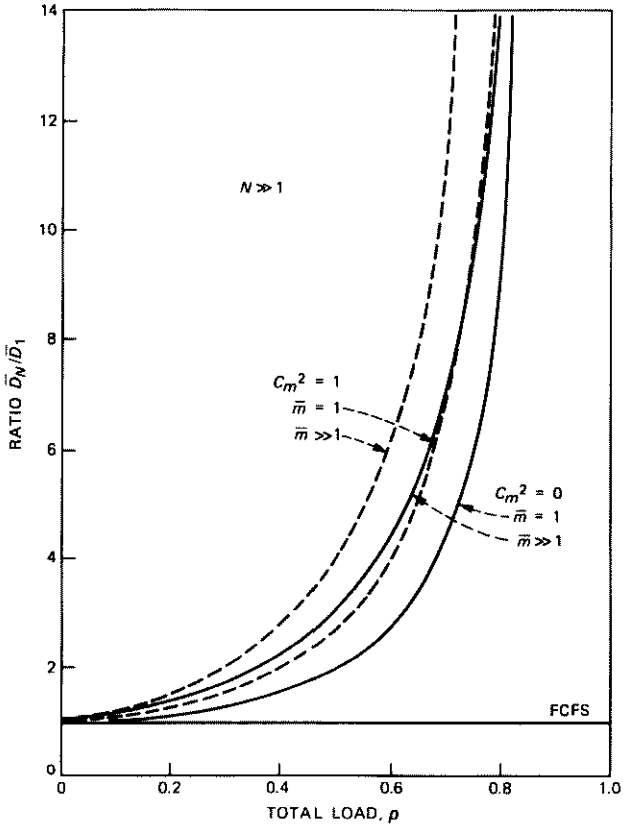

Fig. 9—Ratio $\overline{D}_N/\overline{D}_1$ vs. total load $\rho$.

and

$$\overline{D}_{\text{FCFS}} \geq \overline{D} \quad \text{for} \quad c_m^2 \geq \frac{\overline{m} - 1}{\overline{m}}.$$

Hence, for sufficiently large message-length coefficient of variation $c_m^2$, the overall average delay for the priority discipline is less than the average delay for the first-come first-served discipline. Of course, as we saw earlier, as $c_m^2$ increases so does the relative unfairness of the priority discipline over the FCFS discipline.

## V. CONCLUSIONS

We analyzed the performance of a preemptive priority queue, which has direct applications to packet communication systems. The main distinguishing feature of the system studied compared to the standard M/G/1 preemptive resume priority queue[5] is that the server can only

begin serving a "customer" (and preemptions take place) at integer multiples of time corresponding to packet slot boundaries in the communication context. Mean value formulas for in-queueing waiting time and average message delay were derived and comparisons made to the FCFS queueing discipline. A derivation of the waiting time and delay moment-generating functions is given in the appendix.

## APPENDIX

### *Derivation of the Waiting Time and Message Delay Moment-Generating Functions*

As we introduced in Section II, $W_{kj}$ is the steady-state in-queue waiting time for the $j$th packet in a message from source $k$, $k = 1, 2, \cdots, N$. Its Moment-Generating Function (MGF), defined as

$$G_{W_{kj}}(v) = E[e^{vW_{kj}}]$$

is derived in this appendix. From this result, the message delay MGF is easily obtained. The approach taken parallels in many respects the analysis given in Section III.

We begin the derivation by examining the duration of a busy period for sources 1 to $k-1$, denoted by $Y_k$. Such a busy period starting in a slot is initialized by one or more message arrivals from sources 1 to $k-1$ in the previous slot (which contains no packet from sources 1 to $k-1$). Let $A_k$ denote the total number of packets that arrive from sources 1 to $k-1$ in this previous slot. For the $i$th packet in this set, we define the "sub-busy" period $X_k(i)$ to consist of the duration of the "virtual" busy period (i.e., as if $i = A_k = 1$) initiated by the messages (if any) that arrive from sources 1 to $k-1$ while this $i$th packet is in service. In other words, we conceptually reorder the priorities so that each of the $A_k$ packets, and the sub-busy period it spawns, is served in turn. This does not change $Y_k$ and is a standard approach to busy-period analysis.

Due to the memoryless property of the arrival process, the sub-busy period random variables $X_k(i)$, $i = 1, 2, \cdots, A_k$, are independent and

identically distributed (*iid*). In addition, note that $Y_k$ has the same distribution as the generic random variable $X_k$, and satisifies the relation

$$Y_k = A_k + \sum_{i=1}^{A_k} X_k(i). \tag{15}$$

The Probability-Generating Function (PGF) for the discrete random variable $X_k$ is defined as

$$\Phi_{X_k}(z) = E[z^{X_k}] = \sum_{i=0}^{\infty} z^i \Pr[X_k = i].$$

Using (15) and the result that $X_k$ is distributed as $Y_k$, we obtain

$$\begin{aligned}\Phi_{X_k}(z) &= E[z^{Y_k}] \\ &= E\left[z^{A_k + \sum_{i=1}^{A_k} X_k(i)}\right] \\ &= E[(z\Phi_{X_k}(z))^{A_k}] \\ &= \Phi_{A_k}(z\Phi_{X_k}(z)),\end{aligned} \tag{16}$$

where $\Phi_{A_k}(z)$ is the PGF for the random variable $A_k$.

Now, $A_k$ is equal to the total number of packets arriving from sources 1 to $k-1$ in one time slot. Recall that each source $i$ generates messages as an independent Poisson process with rate $\lambda_i$; and each such message has its length selected independently from the distribution $P_{m_i}(\cdot)$, whose PGF we denote by $\Phi_{m_i}(z)$. It follows then that

$$\begin{aligned}\Phi_{A_k}(z) &= \prod_{i=1}^{k-1} \left\{ \sum_{r=0}^{\infty} \frac{\lambda_i^r e^{-\lambda_i}}{r!} \cdot [\Phi_{m_i}(z)]^r \right\} \\ &= \prod_{i=1}^{k-1} e^{\lambda_i[\Phi_{m_i}(z)-1]}.\end{aligned} \tag{17}$$

Hence, substituting (17) into (16), we obtain

$$\Phi_{X_k}(z) = \prod_{i=1}^{k-1} e^{\lambda_i[\Phi_{m_i}(z\Phi_{X_k}(z))-1]}. \tag{18}$$

As we shall see, $\Phi_{X_k}(z)$, the PGF for the duration of a busy period for sources 1 to $k-1$, plays an important role in the derivation of $G_{W_{kj}}(v)$, the waiting time MGF.

Returning to eq. (1) in Section III, we note that $W_{kj}$ is the sum of $W_{k1}$ and the $j-1$ *iid* random variables $w_{k1}, w_{k2}, \cdots, w_{k,j-1}$. Observe, however, that $w_{k\ell}$, $\ell = 1, 2, \cdots, j-1$, is distributed as $X_k + 1$. That is, $w_{k\ell}$ is composed of the service time for the $\ell$th packet plus the busy

period for sources 1 to $k-1$ initiated during this service time. In addition, it follows that the waiting time for the first packet in a source $k$ message, $W_{k1}$, is statistically independent of $w_{k\ell}$, $\ell = 1, 2, \cdots, j-1$. Hence we may write

$$G_{W_{kj}}(\nu) = G_{W_{k1}}(\nu) \cdot [e^{\nu} \Phi_{X_k}(e^{\nu})]^{j-1}. \tag{19}$$

This leaves us with having to determine the MGF for $W_{k1}$.

Let us for the moment consider the time-dependent behavior for the number of packets queued from sources 1 to $k$. For time slot $n$, we let $Q_k(n)$ denote the number of such packets queued just after the beginning of the slot and, to be consistent with our previous notation, we let $A_{k+1}(n)$ denote the number of packets that arrive from sources 1 to $k$ during the $n$th slot. It follows that

$$Q_k(n+1) = [Q_k(n) + A_{k+1}(n) - 1]^+, \tag{20}$$

where

$$[\epsilon]^+ = \begin{cases} \epsilon & \text{if } \epsilon \geq 0 \\ 0 & \text{if } \epsilon < 0. \end{cases}$$

From (20) we obtain the relation

$$E[z^{Q_k(n+1)}] = E[z^{[Q_k(n)+A_{k+1}(n)-1]^+}], \tag{21}$$

which may be rewritten as

$$\begin{aligned}
\Phi_{Q_k(n+1)}(z) &= E[z^{[Q_k(n)+A_{k+1}-1]^+}] \\
&= \Pr[Q_k(n) + A_{k+1} = 0] + \Pr[Q_k(n) + A_{k+1} > 0] \\
&\quad \cdot z^{-1} E[z^{Q_k(n)+A_{k+1}} \mid Q_k(n) + A_{k+1} > 0] \\
&= \Pr[Q_k(n) = 0]\Pr[A_{k+1} = 0] \\
&\quad + z^{-1} \sum_{i=1}^{\infty} z^i \Pr[Q_k(n) + A_{k+1} = i] \\
&= \Pr[Q_k(n) = 0]\Pr[A_{k+1} = 0] \\
&\quad + z^{-1}\{E[z^{Q_k(n)+A_{k+1}}] - \Pr[Q_k(n) = 0]\Pr[A_{k+1} = 0]\} \\
&= \Pr[Q_k(n) = 0]\Pr[A_{k+1} = 0](1 - z^{-1}) \\
&\quad + z^{-1} \Phi_{Q_k(n)}(z) \Phi_{A_{k+1}}(z),
\end{aligned} \tag{22}$$

where we have used the fact that $Q_k(n)$ and $A_{k+1}$ are statistically independent. Taking the limit as $n \to \infty$ on both sides of (22) (the limits exist for $\sigma_k < 1$) yields

$$\Phi_{Q_k}(z) = \Pr[Q_k = 0]\Pr[A_{k+1} = 0](1 - z^{-1}) + z^{-1} \Phi_{Q_k}(z) \Phi_{A_{k+1}}(z), \tag{23}$$

where $Q_k$ represents the steady-state number of packets queued from sources 1 to $k$ at the beginning of a slot. Rearranging the terms in (23), we obtain

$$\Phi_{Q_k}(z) = \frac{\Pr[Q_k = 0]\Pr[A_{k+1} = 0](z - 1)}{z - \Phi_{A_{k+1}}(z)}. \tag{24}$$

Taking the limit as $z \to 1$ on both sides of (24) yields

$$\Pr[Q_k = 0]\Pr[A_{k+1} = 0] = 1 - \frac{\partial}{\partial z}\Phi_{A_{k+1}}(z)\bigg|_{z=1}$$

$$= 1 - \sigma_k.$$

Hence, using this result and (17), (24) may be rewritten as

$$\Phi_{Q_k}(z) = \frac{(1 - \sigma_k)(z - 1)}{z - \prod_{i=1}^{k} e^{\lambda_i[\Phi_{m_i}(z) - 1]}}. \tag{25}$$

Now consider the end of the time slot during which a source $k$ message is generated. The number of packets of higher or equal priority that are queued and must be transmitted before the first packet in this source $k$ message is given by

$$Q_k + A_k + B_k,$$

where $Q_k$ is the number of queued packets from sources 1 to $k$ just after the beginning of the slot, $A_k$ is the number of packets from sources 1 to $k - 1$ that arrive during the slot, and the new random variable, $B_k$, represents the number of packets from source $k$ that arrive during the slot prior to the generation of the source $k$ message in question. The $i$th packet in this set of $(Q_k + A_k + B_k)$ packets initiates a sub-busy period of duration $X_k(i)$. Hence we may write

$$W_{k1} = U + \sum_{i=0}^{(Q_k+A_k+B_k)} [1 + X_k(i)], \tag{26}$$

where $U$ is a random variable, uniformly distributed over one slot time, that represents the time from when the source $k$ message is generated until the start of the next slot.

From (26) we may write

$$E[e^{\nu W_{k1}} \mid U = u,\ Q_k = q_k,\ A_k = a_k,\ B_k = b_k] = e^{\nu u}[e^{\nu}\Phi_{X_k}(e^{\nu})]^{(q_k+a_k+b_k)}.$$

Removing the conditioning on the independent random varaibles $Q_k$ and $A_k$ yields

$$E[\alpha^{W_{k1}} \mid U = u,\ B_k = b_k]$$

$$= \alpha^{u}[\alpha\Phi_{X_k}(\alpha)]^{b_k}\Phi_{Q_k}(\alpha\Phi_{X_k}(\alpha))\Phi_{A_k}(\alpha\Phi_{X_k}(\alpha)), \tag{27}$$

where, for simplicity, we have substituted $\alpha$ for $e^{\nu}$. Now, using the same approach as we did with $A_k$, we obtain

$$E[z^{B_k} \mid U = u] = e^{\lambda_k(1-u)[\Phi_{m_k}(z)-1]}.$$

Thus, removing the conditioning on $B_k$ in (27) yields

$$E[\alpha^{W_{k1}} \mid U = u] = \alpha^u e^{\lambda_k(1-u)[\Phi_{m_k}(\alpha\Phi_{X_k}(\alpha))-1]} \cdot \Phi_{Q_k}(\alpha\Phi_{X_k}(\alpha))\Phi_{A_k}(\alpha\Phi_{X_k}(\alpha))$$

$$= [e^{\nu-\lambda_k[\Phi_{m_k}(\alpha\Phi_{X_k}(\alpha))-1]}]^u \Phi_{Q_k}(\alpha\Phi_{X_k}(\alpha))\Phi_{A_{k+1}}(\alpha\Phi_{X_k}(\alpha)).$$

Now, removing the conditioning on $U$, we obtain

$$G_{W_{k1}}(\nu) = G_U\{\nu - \lambda_k[\Phi_{m_k}(\alpha\Phi_{X_k}(\alpha)) - 1]\}\Phi_{Q_k}(\alpha\Phi_{X_k}(\alpha))\Phi_{A_{k+1}}(\alpha\Phi_{X_k}(\alpha)),$$

where

$$G_U(\nu) = \int_0^1 e^{\nu u} du = \frac{1}{\nu}[e^{\nu} - 1]. \tag{28}$$

Finally using (19), we obtain

$$G_{W_{kj}}(\nu) = G_U\{\nu - \lambda_k[\Phi_{m_k}(\alpha\Phi_{X_k}(\alpha)) - 1]\}$$
$$\cdot \Phi_{Q_k}(\alpha\Phi_{X_k}(\alpha))\Phi_{A_{k+1}}(\alpha\Phi_{X_k}(\alpha)) \cdot [\alpha\Phi_{X_k}(\alpha)]^{j-1},$$

where $\alpha = e^{\nu}$, $G_U(\nu)$ is given by (28), $\Phi_{Q_k}(z)$ is given by (25), $\Phi_{A_{k+1}}(z)$ is given by (17), and $\Phi_{X_k}(z)$ is given by (18).

The delay in transmitting a source $k$ message of length $m$, $D_k(m)$, is given by

$$D_k(m) = W_{km} + 1.$$

Hence, the MGF for $D_k(m)$ is given by

$$G_{D_k(m)}(\nu) = e^{\nu} G_{W_{km}}(\nu).$$

It follows that the MGF for $D_k$, the delay in transmitting a randomly selected source $k$ message, is given by

$$G_{D_k}(\nu) = G_{W_{k1}}(\nu)\Phi_{m_k}(e^{\nu}\Phi_{X_k}(e^{\nu}))/\Phi_{X_k}(e^{\nu}).$$

## *The AR6A Single-Sideband Microwave Radio System:*

# Prologue

By R. E. MARKLE*

(Manuscript received January 27, 1983)

The AR6A Single-Sideband Amplitude Modulation (SSBAM) Transmission System makes very efficient use of the radio spectrum by transmitting 6000 message circuits in a 29.65-MHz radio channel. This capability is achieved by maintaining a tighter frequency spacing of the multiplexed mastergroup signals and by discarding redundant sideband signals before transmission over the radio path. The AR6A System can provide a maximum capacity of 42,000 message circuits for the 6-GHz portion of the radio network when all eight channels are utilized. This capability, combined with the alternate use of the 4-GHz spectrum for message or digital circuits, provides the proper mix of network capability choices. This introduction gives an overview of the AR6A System and a brief history of single-sideband evolvement in the Bell System. It also is a prologue to the papers in this volume, which describe some of the specifics of the system design.

## I. INTRODUCTION

On January 12, 1981, the first AR6A† Microwave Radio System was placed in service between Hillsboro, Missouri, and La Cygne, Kansas. This event marked the first application of single-sideband transmis-

sion to the Bell System long-haul microwave radio network. The AR6A System is designed for use in the 6-GHz common carrier band and can provide a route capacity of 42,000 high-quality, 4-kHz, two-way message circuits when all radio channels in the 6-GHz band have been equipped (i.e., one protection and seven service channels). If TD radio operating in the 4-GHz band is used on the same route at 1800 message circuits per radio channel, the combined route capacity is an impressive 61,800 message circuits.

## II. EVOLUTION OF LONG-HAUL RADIO

The evolution of the Bell System long-haul radio network is outlined in Table I; in 31 years the radio channel capacity has been increased by a factor of 12.5 and the route capacity by a factor of 25.75. The ubiquitous TD-2 System was placed in service in 1950 and had a channel capacity of 480 message circuits with a maximum capability of five service channels in the 4-GHz band. In 1954 the circuit loading was increased to 600 message circuits per radio channel, and in 1959 the route capacity was further extended through the use of interstitial radio channels to provide a total of ten service channels. The deployment of TH-1 in the 6-GHz band in 1961 expanded the route capacity by 10,800 circuits to a total of 16,800 message circuits; the advent of

Table I—Evolution of long-haul radio capacities

| System/Channel Capacity | Initial Availability | Protection Configuration (Protection × Service) | Route Capacity in Message Circuits |
|---|---|---|---|
| TD/480 | 1950 | 1 × 5* | 2400 |
| TD/600 | 1953 | 1 × 5 | 3000 |
| TD/600 | 1959 | 2 × 10 | 6000 |
| TD/600 + TH/1800 | 1961 | 2 × 10<br>2 × 6 | 16,800 |
| TD/1200 + TH/1800 | 1968 | 2 × 10<br>2 × 6 | 22,800 |
| TD/1500† + TH/1800† | 1973 | 2 × 18 | 28,800 |
| TD/1800†,‡ + TH/2400† | 1979 | 2 × 18 | 36,000 |
| TD/1800†,‡ + AR 6/6000 | 1981 | 1 × 11<br>1 × 7 | 61,800 |

* Automatic protection on the basis of one protection channel for five service channels (1 × 5) was not available until 1953; five service channels are used here for consistency in comparing route capacities.
† Each channel also can be equipped with a 1.544-Mb/s system.
‡ The channel alternately can be used to provide 20-Mb/s capability or (beginning in 1983) 45-Mb/s capability.

TD-3 in 1968, with a capacity of 1200 circuits per radio channel, increased the route capacity by an additional 6000 circuits. By 1973, the use of crossband protection switching systems and 1500-circuit loading on TD provided a radio route capacity of 28,800 circuits. Six years later, the circuit loadings of both TD and TH had been increased to 1800 and 2400 circuits, respectively, to give a capability of 36,000 circuits for a fully loaded radio route.

In parallel, the radio systems have grown in digital transmission capability to match network needs. In 1974 data-under-voice capability of 1.544 Mb/s was added to each FM radio channel. The alternate use of a TD-2 radio channel to provide 20-Mb/s capacity was first available in 1979, and an upgrade to 45-Mb/s capacity was provided in 1983.

Even with this capacity some radio routes were expected to be filled by the mid-1980s, and meeting additional growth needs would have required building parallel radio routes or providing some other new facility for relief. It was expected that some of the new radio routes would be difficult to engineer because of radio frequency interference encountered at radio station junctions in the existing radio network. The availability of AR6A in 1981 increased the long-haul radio route capacity to 61,800 circuits and postponed the time when new radio routes would need to be constructed, which in turn postponed the initial capital investment required for land, buildings, towers, and associated station equipment.

### III. AR6A SYSTEM FEATURES

The AR6A System allows for orderly growth in the existing radio network, since it uses the same frequency plan as TH-3 and can be used for conversion of TH routes as well as for additions to existing TD routes. The radio equipment is designed to be installed in existing radio stations and shares the use of the radio towers, antennas, common waveguide runs, power plant, and alarm telemetry systems. Additional space-diversity antennas are required over those used on existing FM routes because the single-sideband signal is more susceptible to the effects of multipath fading.

The AR6A System is designed to meet a two-way outage objective of 0.02 percent and a radio channel dynamic-amplitude-misalignment objective of 2 dB or less for 99.9 percent of the time. For a 4000-mile route length, the noise objective is 40 dBrnc0. The system meets these objectives by the appropriate use of space-diversity reception and dynamic equalization in conjunction with a single-channel frequency-diversity protection system.

In meeting intermodulation noise objectives the multiplex, protection, and radio equipment were designed to linearity requirements far more stringent than those of previous radio systems. Of particular

note is the AR6A transmitter-receiver (TR)* unit that has a linearity that is more than 30 dB better than the comparable TH-3 TR unit. This is achieved by the use of ultralinear semiconductor devices in the intermediate frequency circuits and predistortion in the transmitter to improve the linearity of the frequency converter and traveling-wave-tube amplifier combination.

The frequency stability required for AR6A is much tighter than that for FM systems (typically by a factor of about 25). This stability allows equalizer pilots to be selected by narrowband crystal filters and reduces the frequency range over which the receiving multiplex terminal must operate.

The AR6A System uses microprocessor-controlled maintenance and surveillance methods to monitor system performance and to isolate troubles to a specific station on a radio route. Automated testing is performed under the control of a central minicomputer at access points provided in both the multiplex and the protection switching equipment. Both in-service and out-of-service testing capabilities are provided with special stress-testing features implemented at radio repeater locations for use in trouble isolation and diagnosis. The computer-controlled measurement system is designated "Transmission Surveillance System—Radio" and is described in detail in this issue of the *Journal.*

## IV. SINGLE-SIDEBAND HISTORY

In the late 1960s, detailed system studies were performed by A. J. Giger to define linearity requirements for radio repeaters (TR units) for long-haul single-sideband transmission. Several methods were recommended for achieving the necessary transmitter performance. Subsequently, experiments were performed in the early 1970s with feedforward microwave techniques to improve the linearity of traveling-wave-tube amplifiers, the most difficult challenge in achieving the radio transmitter intermodulation noise requirement. The success of these experiments led to addressing the problems of overall repeater linearity, equalization for multipath fading effects, and the effects of interference when used in the existing FM radio network.

Studies were performed to obtain a better understanding of traveling-wave-tube distortion, and this resulted in the use of predistortion to meet transmitter linearity requirements. Additional field data were gathered on multipath fading, and these data were a key ingredient in achieving a simplified dynamic equalization design. Supporting studies of a subjective nature also were conducted to provide more detailed

* Acronyms and abbreviations used in the text are defined at the back of this *Journal.*

definitions of tone and crosstalk annoyance objectives when Single-Sideband Amplitude Modulation (SSBAM) was used in the radio network; the frequency control plan and the intermediate frequency (IF) filter design were chosen to meet these objectives. The adequacy of the methods for linearization, equalization, and interference control were established by a field test performed in the 4-GHz network in 1974 and early 1975.

Detailed system design of AR6A for the 6-GHz network started in 1975, and in 1979 a complete system was installed on a 6-hop radio route from Hillsboro, Missouri, to Windsor, Missouri. All subsystems of AR6A were tested and evaluated on this 177-mile route, and system verification testing was completed on June 14, 1980. This route then was extended by three radio hops (71 miles) to La Cygne, Kansas, and became the first single-sideband amplitude modulation route to be placed in commercial service on January 12, 1981.

## V. ACKNOWLEDGMENTS

The feasibility demonstration of SSBAM transmission on the long-haul 4-GHz radio network in 1974–1975 was the culmination of the efforts of many people in different organizations throughout Bell Laboratories. The realization of AR6A for the 6-GHz network was the result of the dedicated efforts of many organizations at Bell Laboratories working with Western Electric and in close concert with AT&T Communications. Technology foundations were provided by the TD, TH, and L5 Systems and these were augmented by advances in filter, network, and device designs, as well as the effective use of the many computational and measurement facilities available at Bell Laboratories. The authors of this volume express their appreciation to all those who have contributed to the ultimate attainment of SSBAM transmission on the long-haul radio network.

## *The AR6A Single-Sideband Microwave Radio System:*

# System Design and Performance

by J. GAMMIE,* J. P. MOFFATT,* R. H. MOSELEY,* and W. A. ROBINSON*

(Manuscript received February 14, 1983)

This paper describes the overall architecture of the first long-distance microwave telephone transmission system to use Single-Sideband Amplitude Modulation in the microwave transmission path. Compared with commonly used frequency modulation systems, the AR6A Single-Sideband Microwave Radio System more than doubles the number of telephone circuits that can be carried per unit of microwave bandwidth. Included in the description are the system design model, performance objectives, and the allocation of performance impairments. Also discussed are the computer-controlled automated maintenance features and the results of laboratory and field tests.

## I. GENERAL DESCRIPTION

### *1.1 Introduction*

The AR6A† System is the first long-haul microwave transmission facility to employ Single-Sideband Amplitude Modulation (SSBAM)‡ in the microwave transmission path. To fully exploit this alternative to the widely used frequency-modulation (FM) system, it has been necessary to develop for SSBAM new subsystems to accomplish the

functions commonly associated with an integrated microwave transmission facility. In this sense, the use of SSBAM affects not only the design of the transmitter-receiver (TR) equipment but all ancillary equipment as well.

Broadly speaking, the main functional elements of the system are fairly conventional, but a number of SSBAM's basic requirements have had a major impact on the AR6A System design. The first and most obvious of these is the high level of linearity needed in many of the transmission elements to control intermodulation distortion. Although the most taxing task was making the transmitting traveling-wave-tube amplifier meet overall system linearity objectives, the intermodulation performance of many other elements required careful scrutiny and improvement. Frequently, the more stringent linearity requirements have been associated with higher quiescent current for transistors and, in general, with increased power requirements relative to comparable elements in an FM system. Nevertheless, when power requirements are normalized to a per-circuit or a per-mastergroup basis, power utilization efficiencies are very competitive.

In addition, the direct dependence of signal amplitude response on the response of the transmission medium is particularly stressing during multipath fading. This requires adding a capability for dynamic amplitude equalization. Design of the necessary adaptive equalizers required an extensive experimental effort aimed at quantitatively describing the statistics for and understanding the effects of multipath fading on channel amplitude shape. The dynamic dispersive channel resulting from multipath fading required not only adaptive equalizers but also the use of space diversity.

Unlike FM, in which demodulation is performed relative to a transmitted FM carrier, accumulated frequency shifts due to multiple modulation and remodulation at repeaters must be removed. This adds to the complexity of the terminal multiplex equipment that performs the frequency-correction function.

Finally, successful transmission of SSBAM requires new maintenance and equalization considerations. In FM systems, minor amounts of transmission slope and absolute amplitude changes do not greatly affect the quality of the recovered baseband signal. The greater sensitivity of SSBAM to these effects, particularly their potentially cumulative nature, requires much closer control of equalization and absolute amplitude levels. These considerations, combined with the trend towards centralized operational support systems, resulted in the integrated development of a minicomputer-based Transmission Surveillance System—Radio (TSS-R) with associated trouble isolation and stress test features.

During development, effort was initially focused on applications

employing frequency-diversity protection, the most commonly used system arrangement. This work was later supplemented by the development of hot-standby and space-diversity arrangements for applications where lower cross-sectional growth rates preclude the use of frequency-diversity protection.

Because of the many new system features, AR6A underwent an early but limited field trial between Ashburnham and Wendell, Massachusetts, in the period October 1977 to July 1978. This two-hop installation provided valuable initial field experience prior to a more comprehensive field evaluation between Hillsboro and Windsor, Missouri. The Missouri evaluation involving a six-hop radio section with frequency- and space-diversity protection switching encompassed the period from April 1979 to June 1980. The evaluation of hot-standby arrangements was performed later on a two-hop section between Colorado Springs and Cedarwood, Colorado. The shipment of standard AR6A equipment began in June 1980; first commercial service was placed on the AR6A route between Hillsboro, Missouri, and La Cygne, Kansas, in January 1981.

The following paragraphs are devoted to an overview of the AR6A System using the block diagram of Fig. 1. The figure and discussion relate to a system configuration using frequency-diversity protection switching which, besides being the most common application, will provide a satisfactory medium for describing the main features of the system.

### *1.2 Multiplex*

#### *1.2.1 Mastergroup translators*

The AR6A System interfaces with the standard Bell System analog multiplex hierarchy at the basic U600 mastergroup level. This is also the highest level in the multiplex hierarchy at which AR6A can be interconnected to other broadband transmission facilities. The U600 mastergroup contains 600 4-kHz circuits in the frequency band 564 to 3084 kHz. Figure 1 illustrates how the basic mastergroup is delivered from the Mastergroup Distributing Frame (MGDF) to the first frequency translation step provided by the Mastergroup Translator, Type B (MGTB). Five MGTBs translate and frequency multiplex five separate mastergroup signals into adjacent positions in a multimastergroup band extending from 8.628 to 21.900 MHz. With a fixed intermastergroup spacing of 168 kHz, the tight packing provided by the MGTB is an important factor in being able to place two multimastergroups (ten mastergroups) in each 30-MHz broadband radio channel.

In addition to modulation and demodulation, the MGTB modems supply the 2840-kHz mastergroup pilot which is used in the receiving

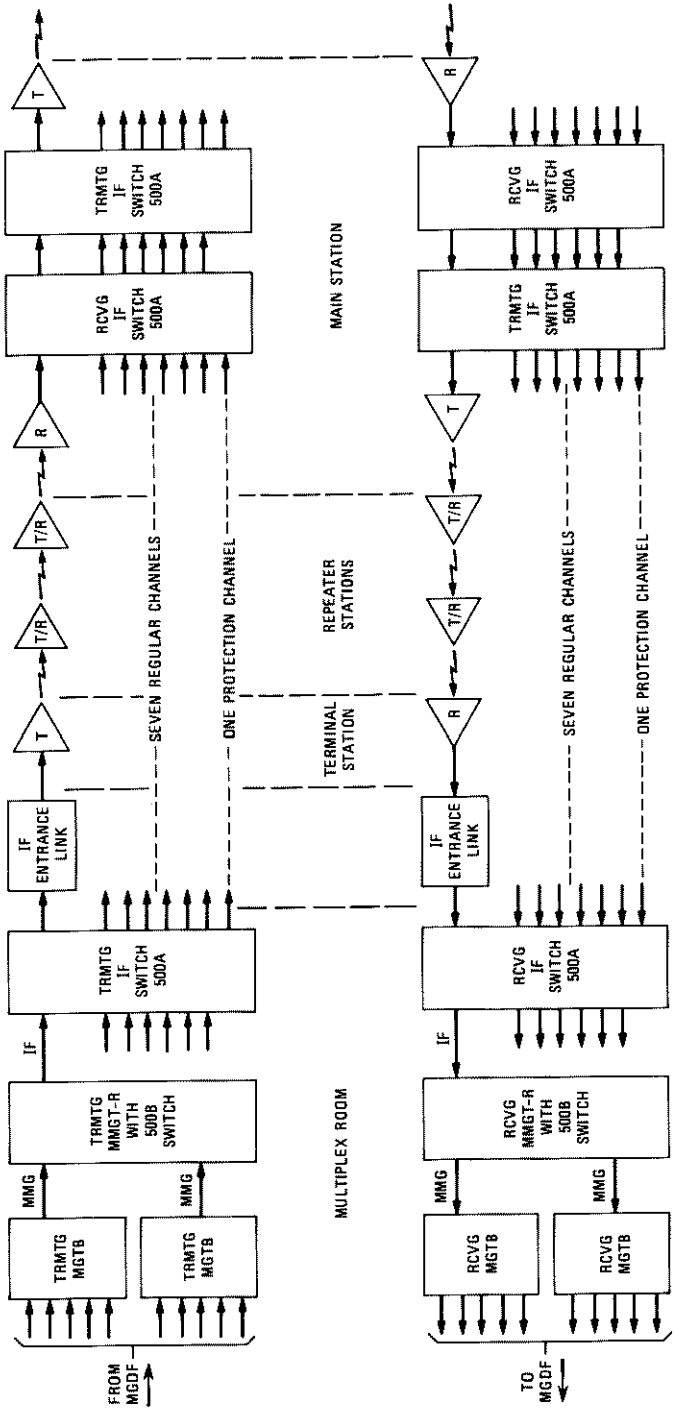

Fig. 1—Block diagram of AR6A System.

portion of the modem for gain regulation purposes. Other functions associated with the MGTB combining circuits are (1) means for inserting a 13.920-MHz multimastergroup continuity pilot for sectionalizing troubles, (2) a comb filter with narrowband band-stop sections which remove signals and noise from intermastergroup slots prior to the insertion of line pilots, and (3) test access points for TSS-R and other automated measuring facilities.

#### *1.2.2 Multimastergroup translators*

The Multimastergroup Translator—Radio (MMGT-R) performs the next modulation step by translating two multimastergroups into the intermediate frequency (IF) band centered at 74.13 MHz. The disposition of the multimastergroups and the previously described translation steps from basic mastergroup are illustrated in Fig. 2.

In the MMGT-R, the two multimastergroups are translated to IF by separate modulators with independent, unsynchronized, crystal-controlled local oscillators. On the receiving side, the demodulating carriers are supplied by Voltage-Controlled Oscillators (VCOs). Each VCO tracks the accumulated line frequency errors with a Phase-Locked Loop (PLL) to deliver a frequency-corrected multimastergroup signal at the receiving end of the terminal section. Essential to the frequency-correcting process is the addition of an intermastergroup recovery pilot to each multimastergroup signal before it is translated to IF. This pilot at 16.608 MHz is frequency locked to a 512-kHz synchronizing signal derived from the Bell System Reference Frequency (BSRF). In view of the recovery pilot's importance, the synchronizing source supplied to the MMGT-R is duplicated and automatically protected. At the output of the receiving MMGT-R, the demodulated recovery pilot is compared with a locally generated reference frequency to provide the PLL error signal for frequency correction. An important additional function of the receiving PLL is to reduce accumulated phase jitter on the radio line.

In addition to recovery pilots, the transmitting portion of the MMGT-R supplies three radio-line pilots from free-running crystal oscillators. When translated to IF these pilots are located near the center and band edges of the radio channel, as illustrated in Fig. 2. At radio receivers, the pilots provide a reference signal for Automatic Gain Control (AGC) and, in addition, provide information on channel amplitude shape for dynamic amplitude equalization. The radio pilots, recovery pilots, and multimastergroup pilots are each transmitted at a level of −10 dBm0.

#### *1.2.3 Office master frequency supply*

Carrier supplies for the Bell System analog multiplex hierarchy are

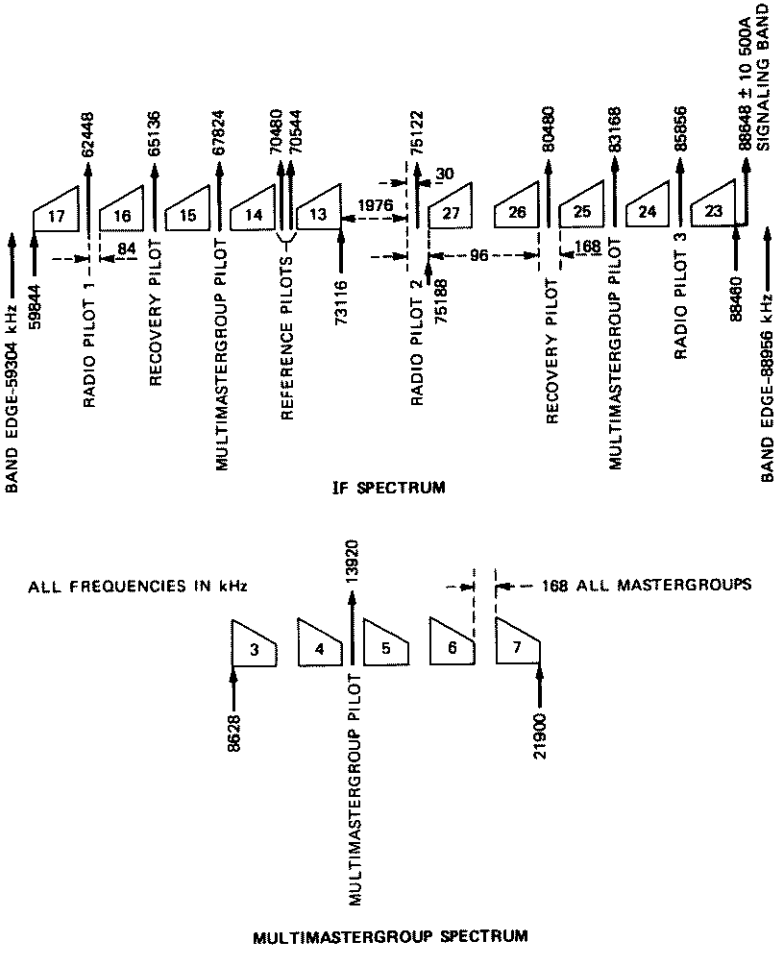

Fig. 2—Multimastergroup and IF spectrum.

locked to a 64- or 512-kHz synchronizing source derived from an office Primary Frequency Supply (PFS). The PFS is in turn synchronized to a signal with a frequency accuracy that is traceable within very narrow limits to that of the BSRF source at Hillsboro, Missouri. If the PFS temporarily loses its input synchronizing signal, the output frequency will suddenly change to the unit's natural or rest frequency. This frequency transient, although tolerable at lower levels in the multiplex hierarchy, was considered excessive in a synchronizing source for the AR6A recovery pilots. For this reason, a new Office Master Frequency Supply (OMFS) was developed which provides 64- and 512-kHz synchronizing signals that are quasi-frequency locked to the 2.048-MHz BSRF. With quasi-frequency lock, instead of being

synchronized to the incoming reference signal, the highly stable OMFS oscillators are free-running. Their frequency is compared with the reference frequency at intervals and smoothly updated if the error exceeds the prescribed threshold. If the reference frequency is temporarily lost, updating is inhibited and the oscillators continue to run at their most recently updated frequency. In this way the OMFS shields dependent multiplex equipment from transient effects on the synchronizing network.

#### *1.2.4 Reference frequency transmission*

The 2.048-MHz Bell System Reference Frequency must be available at all AR6A terminal stations for the purposes described in Section 1.2.3. The reference signal can be made available over a variety of transmission facilities, but there are instances where the only available transmission medium will be the AR6A System. To provide this capability, an optional reference frequency sending unit is available that inserts two pilots between MG13 and MG14 (Fig. 2) at a level of −15 dBm0. The pilot frequencies differ by 64 kHz with an accuracy determined by the sending end BSRF. At the receiving end of the terminal section, a reference frequency receiving unit recreates a BSRF at 2.048 MHz from the accurately defined 64-kHz difference frequency. In this way, reference frequency transmission accuracy is unaffected by inaccuracies in the multiple frequency translations experienced on the radio line. Sixty-four-kHz rather than a wider frequency separation was chosen to minimize transmission dispersion effects and to optimize pilot positions from the standpoint of noise and freedom from interaction with other system pilots. The sending and receiving frequency units are physically associated with the MMGT-R equipment.

### *1.3 The radio line*

#### *1.3.1 Entrance links*

Figure 1 shows that the IF signal from the MMGT-R is fed to the radio transmitting equipment via the 500A Protection Switching System, which will be discussed in Section 1.4. Since the radio transmitters may be at some physical distance from the preceding multiplex equipment, provision must be made for handling trunk losses and associated transmission shapes. In some instances, the trunks may be so long that they require amplification, necessitating automatic protection of the active circuits. In the AR6A System, the 500A protection switching equipment is located near the MGTB and MMGT-R multiplex equipment. In this way, the trunks or entrance links become extensions of the radio line and may, therefore, share the 500A protection facilities.

For distances up to 600 feet, the entrance link trunks are passive

and are equalized to within 25 feet. Greater distances require amplification by amplifiers located in the TR bays for both the transmitting and receiving trunks. This provides for entrance link distances of up to 1200 feet using 728-type office coaxial cable. Entrance link distances up to 3600 feet can be accommodated with 0.375-inch coaxial cable.

#### *1.3.2 Transmitter-receiver equipment*

The heterodyne-type transmitter-receiver (TR) bays are designed for overbuilding on existing 4-GHz radio routes with an average repeater spacing of 25.6 miles. The nominal repeater gain is 61.7 dB with up-fade and down-fade ranges of 15 and 46 dB, respectively. The full-load transmitter output power is +24.6 dBm, reflecting an average power per 4-kHz message circuit of −19.6 dBm0.

The TR bay equipment is designed to permit field installation by technicians into existing bay frameworks. This modular installation allows the bay frameworks to be installed and the station wiring to be done for all radio channels at one time. The TR modules are installed as required by the route traffic.

The transmitter uses IF predistortion to compensate for the nonlinearities of the up converter and the output traveling-wave-tube amplifier. Automatic gain control (AGC) at each receiver is based on maintaining the voltage average of the three pilots constant at the receiver output. In addition to AGC, the last receiver in each switch section is equipped with a dynamic amplitude equalizer.

A microwave preamplifier with a noise figure of approximately 3 dB is provided in the common receiving waveguide run on each polarization. If the hop length is less than 63 percent of nominal, the preamplifier is omitted.

To meet long-haul reliability objectives within the FCC-prescribed limit of only one frequency-diversity protection channel to serve up to seven service channels, it is estimated that approximately half the radio hops will require space diversity. The TR bay is, therefore, equipped with an optional space-diversity switch that is actuated by a 36-dB fade in any one of the three radio-line pilots.

In the event of a loss of received signal due to equipment trouble or other reasons, a pilot resupply signal is automatically inserted at the receiver output. In addition to supplying the three radio-line pilots, the resupply source provides a fourth pilot that is located in the center noise-monitoring slot of the 500A Protection Switching System. The channel with resupply is thereby marked noisy and unavailable for service. The pilot resupply signal at each station is provided from a common source and distribution network located in a radio support bay.

Networks in the IF shelf provide repeater bandpass shaping and

basic equalization for the nominal repeater transmission shape. Also, positions are provided for limited amounts of mop-up equalization for nonsystematic amplitude response variations.

Carrier supplies for up and down frequency conversion are provided by the TR bay microwave generator and its associated 252-MHz shift oscillator. To maintain pilot frequencies within the passband of the narrowband pilot pick-off filters at each repeater, the carrier frequencies must be accurate to better than one part in $10^7$. This is achieved by locking the microwave generators and shift oscillators to a common submultiple frequency, 308.87354 kHz. This synchronizing frequency is distributed to each TR bay from a common synchronizing source located in the radio support bay. If the synchronizing signal fails, both the microwave generator and shift oscillator have memory circuits that maintain their frequencies at the most recently updated values. Subsequent drifting is at a rate that allows a one- to two-day window for repairing the failed synchronizing source.

#### *1.3.3 Support bay*

The support bay contains the Microwave Carrier Synchronization Supply (MCSS) and the pilot resupply source, along with associated distributing circuits. In addition, it provides power distribution, fusing, and alarm arrangements for up to eight microwave preamplifiers. The support bay is designed to supply up to 16 TR bays corresponding to one fully loaded route passing through a repeater station. In hot-standby applications, the radio support bay also contains the hot-standby control unit.

#### *1.3.4 Antenna system*

Since a common application of AR6A will involve overbuilding on existing 4-GHz radio routes, the system is designed around the currently used horn antenna system with associated system combining and separation networks. The space-diversity path should essentially duplicate the main path for a number of reasons, including the anticipated later application of space-diversity combining. With nominal tower heights and hop lengths, the combined section loss, waveguide losses, network losses, and antenna gains give a net overall nominal section loss of 61.7 dB.

### *1.4 Protection switching*

#### *1.4.1 500B Switching System*

Since each MMGT-R carries 6000 message circuits, automatic transfer of the message load to a hot-standby protection unit is necessary for reliability and maintenance. The function is handled by the 500B System. One microprocessor-based controller oversees a 1 ×

14 protection arrangement for transmitting MMGT-Rs and a corresponding 1 × 14 protection arrangement for receiving MMGT-Rs. Since the protection function is local, multimastergroup translators from more than one route may be associated within the same 1 × 14 switching system.

In its automatic mode, a switch is initiated by a number of conditions including loss of the multimastergroup continuity pilot and loss of synchronization.

### *1.4.2 500A Protection Switching System*

The 500A System provides frequency-diversity protection switching on the radio line. Switching sections may be up to ten hops in length and the microprocessor-based control functions are located at the receiving end. The protection switching systems in the two directions of transmission are electrically independent.

Each protection channel can serve up to seven working channels. A frequency shift-keyed (FSK) tone transmitted over the oppositely directed radio channels signals between the receiving and head end of the switch section. The FSK tone is inserted at IF near the upper channel edge and is blocked at the receiving end of each switch section.

Switch initiators monitor each of the three radio-line pilots as well as the noise in three narrowband slots adjacent to the pilots. This multiple monitoring causes more switching activity than the single-point monitoring on FM systems and is partly responsible for the approximately 50-percent space-diversity requirement for AR6A. In addition to protecting against frequency-selective fading, particularly on hops without space diversity, 500A protects against equipment failure and provides out-of-service access to the radio channels for maintenance purposes.

Maintenance access to a radio channel via a maintenance switch command to the 500A System is an essential element in the implementation of the centralized Transmission Surveillance System—Radio (TSS-R). Besides providing switched access to a channel at the transmit and receive ends of the switch section, the 500A control logic is responsible for ensuring that accessing the channel is subordinate to maintaining service continuity. Even after out-of-service access to a channel is permitted, a preemption feature in the 500A logic will restore the channel to service automatically if this is necessary to prevent a service outage. When a channel is opened at the head end of the switch section to allow maintenance access, a fresh set of locally generated radio pilots must be inserted to provide proper control at subsequent radio receivers. These pilots are provided by the 500A System in the same way as resupply pilots are provided at repeaters.

### *1.5 Hot standby*

On routes where the cross-sectional growth rate is low, current FCC rules do not permit the use of frequency-diversity protection channels. In these circumstances, protection against outage due to multipath fading is generally provided by using space diversity. To protect against radio equipment outage, space diversity must be supplemented with hot-standby radio equipment that is automatically switched into service when the need arises. This hot-standby configuration is available on AR6A although the number of applications is expected to be small compared to the frequency-diversity configuration.

Since radio repeaters are frequency-dependent, each working TR bay generally has a separate hot-standby bay. In this sense, hot-standby configurations are equipment-intensive. To ease this situation in AR6A, the east-west and west-east repeaters on a given radio channel are identical, including the frequency-dependent components. By providing appropriate switching and control arrangements, a common TR bay can be used to protect equipment for both directions of transmission. Main stations do not lend themselves to this reduced configuration and are, therefore, arranged with conventional one-for-one hot standby.

Hot-standby manual and automatic control functions at repeaters are provided by a microprocessor-based control unit. The same unit with a subset of features is used at main stations to control hot-standby switching of transmitters. Main station receivers are protected by the 501A Protection Switching System, which also has a double feed to the regular and hot-standby transmitters. In addition to providing noise and pilot-level monitoring with 500A-type initiators, the 501A System also enables the TSS-R System to monitor in service.

On a hot-standby route, each repeater has its own protection against equipment outage and multipath fading. There is, therefore, no natural equivalent to the multihop switch section of the frequency-diversity configuration. However, since hot-standby routes will often be converted to frequency diversity when growth permits, main station TR bay and waveguide configurations are recommended at those stations which at a later time may become switching or main stations. Since the main station configuration implies the use of the 501A switch with surveillance access, this sectionalizing of hot-standby routes into surveillance sections subdivides the route naturally for purposes of dynamic equalization, transmission monitoring, and trouble isolation. The interface transmission levels on the 501A System are identical to those on the 500A switch to further simplify the transition from hot standby to frequency diversity.

### *1.6 Maintenance*

Compared with FM systems, the somewhat less rugged modulation

technique and the higher capacity of the AR6A System have emphasized the need for careful maintenance planning in the overall system design. Supplementing these considerations is the ongoing trend towards a demand maintenance scenario, improved trouble isolation procedures, and centralized transmission surveillance capabilities.

On AR6A, status reporting and command functions are handled conventionally utilizing the C1 or E2 systems in conjunction with the Surveillance and Control of Transmission Systems (SCOTS) or Telecommunication Alarm Surveillance and Control (TASC) central processors. However, in the 500A-to-E2 interface, which can involve a sizeable number of wire pairs, optional arrangements have been developed to provide a serial interface with only two wired pairs. This feature capitalizes on the 500A microprocessor that can communicate serially to microprocessor-based alarm remotes such as E2A.

For trouble-isolation purposes, a significant new feature is the ability to break the transmission path and insert resupply pilots at any selected station by remote command. This is supplemented by the capability to remotely modify the resupply signal to perform a variety of stress tests. With this feature, in conjunction with a measuring capability at the receiving end of a switch section, a variety of transmission troubles can be localized by making out-of-service measurements on successively shortened portions of the switch section. Of course, these capabilities must be circumscribed with protections against service interruption and loss of the 500A preemption feature. These matters are discussed more fully in Section 4.9.

Another important new maintenance feature is the Transmission Surveillance System—Radio (TSS-R). This system uses programmable measuring, signal source, and access equipment at radio main stations that are under the control of a local microprocessor. This microprocessor is, in turn, accessible and controlled via the Direct Distance Dialing (DDD) network from a central minicomputer. Data link dial-up and communication protocol, measuring, evaluation, and reporting routines residing in the central software provide for a variety of switch section transmission measurements that can be made either on an in-service or out-of-service basis. Furthermore, by allowing the TSS-R central minicomputer to talk to a SCOTS or TASC central, the trouble-isolation and stress test features described in the preceding paragraph can be integrated into automated programmable procedures. It should again be noted that access to a radio channel for in-service or out-of-service measurements is subject to approval by the 500A System control logic. It is anticipated that five TSS-R centrals will be able to cover all AR6A routes in the continental United States.

With respect to equipment maintenance, test equipment is, in general, conventional. However, transmitter linearization and precise

frequency adjustment of the MCSS require some special test equipment, which is described in a companion paper.[1]

## II. PERFORMANCE OBJECTIVES

### *2.1 Noise*

The 4000-mile, voice-circuit noise objective is 40 dBrnc0 under standard (free-space) propagation conditions. Attaining this level of performance requires state-of-the-art designs for many devices in the system and the recognition that the current per-circuit average power in the telephone network is lower than previous designs had assumed. The per-circuit average power used in the system design is −19.6 dBm0. This level has been found to be representative of both radio trunks[2] and the telephone network as a whole.[3] With the current increase in the use of common channel interoffice signaling, it is expected that this average power will decrease slightly.

### *2.2 Amplitude equalization*

#### *2.2.1 Static equalization*

The static amplitude equalization objective requires the amplitude shape developed across a mastergroup to be not greater than ±3 dB in 4000 miles. This limit is established to be within the available correction range of regulators in the receiving multiplex equipment. Typical regulators have a ±6 dB range and ±3 dB is chosen as the allocation for the radio system. A supplementary objective of ±0.5 dB is established for the total misalignment within a radio channel in any given switch section. This limit prevents excessive errors in voiceband data systems during frequency-diversity switching between the regular and protection radio channels.

#### *2.2.2 Dynamic equalization*

As a result of the time-variant nature of propagation over typical microwave radio paths, an objective for time-variant signal amplitude is established. The objective is that for a 4000-mile circuit, the amplitude error should be less than ±2 dB for 99.9 percent of the time. The ±2 dB limit is chosen since variations exceeding this level can cause errors in some voiceband data systems. Ordinary telephone service is more tolerant of this impairment.

### *2.3 Tone interference*

The tone interference objective uses the ratio of spurious tone power to background (masking) noise power in a voice circuit as the measure of impairment. This measure is directly related to the annoying effect perceived by the customer. It also has the desirable feature of being

straightforward to administer in a large system, since each subsystem produces its own background noise and the tone requirements for the individual subsystems follow directly. The objective is stated on a percent of time basis as follows. The tone-to-noise power ratio should be less than: (1) −10 dB for 99 percent of the time, (2) 0 dB for 99.9 percent of the time, and (3) 2 dB 100 percent of the time.

In applying the tone objective to the radio line, it is found that on long routes the radio-line noise is dominated by the noise of a faded hop for more than 1 percent of the time. For tone mechanisms that increase with fading, the receiver thermal noise is then used as the background noise for the per-repeater tone objective. For tones that do not increase in level, the total radio repeater noise is used.

### *2.4 Crosstalk*

Separate objectives have been established for intelligible and unintelligible crosstalk. The objective for the former is that the crosstalk index should be less than 0.5 percent. This corresponds approximately to a probability of 0.005 of hearing one or more syllables of intelligible crosstalk during an average duration call. The unintelligible crosstalk or babble objective is stated in terms of a babble-to-noise power ratio that must be met during certain percentages of the time. The babble-to-noise ratio must be less than −10 dB 99 percent of the time and less than 7 dB 100 percent of the time.

### *2.5 Phase jitter*

The objective for phase jitter (unwanted phase modulation) in 4000-mile circuits is 8 degrees peak to peak. The objective applies to jitter with either discrete or continuous frequency components. The jitter is measured by a standard jitter indicator[4] that is sensitive to spectral components in the range of 20 through 300 Hz.

### *2.6 Reliability*

The reliability objective for a 4000-mile circuit is that it should be available for two-way service with noise less than 55 dBrnc0 for 99.98 percent of the time. This objective is apportioned among three sources of outage as follows: (1) equipment outage, 0.005 percent; (2) flat fading, 0.005 percent; and (3) selective fading, 0.010 percent. To meet the equipment reliability objective, the system design requires either frequency-diversity or hot-standby protection switching. The application of space-diversity antennas to meet the selective fading objective is discussed in Section 4.7.

## III. SYSTEM MODEL AND PERFORMANCE ALLOCATIONS

### *3.1 The 4000-mile system model*

As a basis for calculating the expected performance of the radio

system, a 4000-mile system model is used. The model is derived from the characteristics of the existing Bell System microwave radio network. The network has a mean hop length of approximately 25.6 miles, resulting in 156 hops in 4000 miles. The network root-mean-square (rms) hop length is 27.1 miles and this latter value is used for thermal noise and received signal-level calculations. The section loss corresponding to the rms hop is assumed to be 61.7 dB with typical antenna systems. This value includes all losses and gains from the output monitor-shutter in the transmitter to the input of either the receiving bay lineup or the microwave preamplifier if it is installed. The 4000-mile route is assumed to have 52 switch sections averaging three hops in length. Multiplex and terminal equipment is assumed to be located at nine intermediate points on the route. A 4000-mile circuit is thus assumed to pass through ten sets of MMGT-R and MGTB equipment. In addition, the circuit is assumed to pass through a total of nine sets of supergroup multiplex, six sets of group multiplex, and three sets of channel banks. The mastergroups within the spectrum of a radio channel are assumed to be interchanged or frogged every 400 miles for six of the terminal sections and 800 miles for two of the terminal sections.

### *3.2 Performance allocations*

#### *3.2.1 Noise*

Figure 3 shows the noise allocation for the system. The terminal equipment allocation results from assuming two-thirds of the multiplex equipment below mastergroup level is LMX-2 and one-third is LMX-3. This mix is representative of the network during the initial introduction of the system. Thermal and intermodulation noise are the primary contributors to the terminal equipment and protection switching allocations.

Four major interference mechanisms contribute to the RF interference allocation. Cochannel same-route exposures occur at the nine intermediate multiplex stations in the system model. At other stations, the same-route mechanism produces talker echo as a result of the system frequency stability and Radio Frequency (RF) channel plan. At stations with intersecting routes, cochannel junction interference occurs. The allocation assumes a mixture of AR6A and FM intersecting routes that will exist during the initial introduction of AR6A into the radio network. The third mechanism is cochannel interference from other terrestrial radio systems. All stations in the system model are subject to this interference. The final mechanism is cochannel interference from geostationary satellite earth stations. An allocation of 30 dBrnc0 has been set for this source.

The major contributors to the radio repeater allocation are thermal

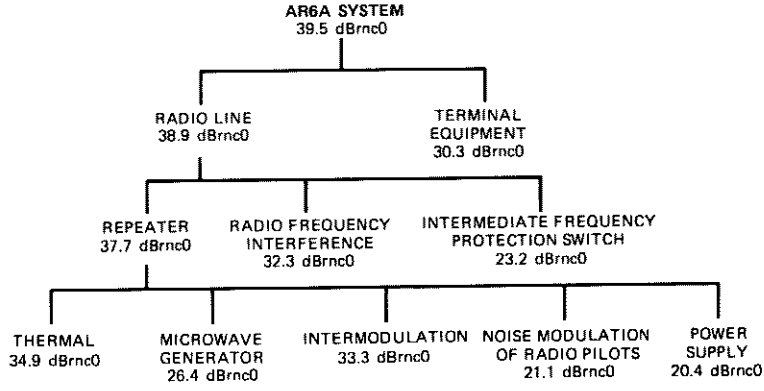

Fig. 3—AR6A noise allocation.

and intermodulation noise. The relative levels of these contributors result from an optimization of the overall system noise with respect to transmitter output power. During the development process, the allocations for these sources were lowered as a result of the use of the microwave preamplifier and the lower per-circuit average power of −19.6 dBm0.

The microwave generator allocation results from phase noise sidebands produced by the generator. In the modulation processes that use the generator output, these sidebands are convolved with the signal and produce an unwanted additive noise. In the system design, this noise is minimized at repeater stations by using one microwave generator to down-convert and up-convert each channel. The noise introduced in the two conversions nearly cancels. The predominant contributors to the allocation are the separate microwave generators used at main stations.

Since the system gain is controlled by the detected level of the three radio pilots, any spurious energy entering the passbands of the detection circuitry causes unwanted amplitude modulation of the signal. The modulation results in additive noise. The allocation for noise modulation of the radio pilots results from accumulation within a multiplex section of radio-line thermal and other noise near the radio pilots. At multiplex locations, the noise from previous paths, within the detection circuitry bandwidth, is removed and new pilots are inserted.

The power supply allocation results from a similar process. Ripple or other nonuniformity of the power supply voltages results in unwanted modulation of the signal. That portion of the modulation energy that is outside of the radio pilot detection circuitry bandwidth remains on the signal and produces noise. The predominant contributor to this allocation is the traveling-wave-tube (TWT) power supply.

#### *3.2.2 Amplitude equalization*

The static equalization objective for mastergroup shape is allocated among: (1) the residual shape of IF and MMG trunks, (2) the residual shape of an equalized radio bay, (3) echoes in the antenna and waveguide systems, (4) signal leakage through the space-diversity switch, and (5) tertiary interference. The predominant shape component is slope. The slopes introduced by all of the above sources are random and contribute to an estimated rms slope of 1.21 dB in 4000 miles. The slope distribution is approximately normal and the probability of exceeding a slope of 3 dB is then 1.3 percent. This probability is sufficiently small to satisfy the intent of the objective.

#### *3.2.3 Crosstalk*

The main sources of crosstalk in AR6A are interference exposures at junction stations and multiplex locations. The type of crosstalk produced by these exposures depends on the relative frequency stability of the interfering and desired signals. The calculated probabilities for the interference exposures producing intelligible crosstalk and babble are 0.45 and 0.55, respectively. Calculations using interference coupling levels typical of the radio network result in a crosstalk index of 0.12 percent for 4000-mile routes. The calculated probability of exceeding a −10 dB babble-to-noise ratio is 0.32 percent for 4000-mile routes. The remainder of the crosstalk and babble objectives are allocated to mechanisms producing discrete-frequency incidental modulation in the radio line.

## IV. DESIGN ASPECTS

### *4.1 Frequency plan*

#### *4.1.1 Channel assignments*

The AR6A System uses the standard 6-GHz frequency plan, which is shown in Fig. 4. This plan permits eight channels in each direction of transmission, which are designated the same as in the TH System: 11 through 18 in the lower portion of the frequency band and 21 through 28 in the upper portion of the frequency band. This plan places the receivers in one-half of the band and the transmitters in the other half. A station using the frequency plan shown in Fig. 4 is called a "low-high" station, because the receive channels are in the low-frequency portion of the band and the transmit channels are in the high-frequency portion of the band. Adjacent stations will be "high-low" stations. The microwave carrier frequencies, which are used in the receiver and transmitter modulators, are also shown in the figure, along with the channels served.

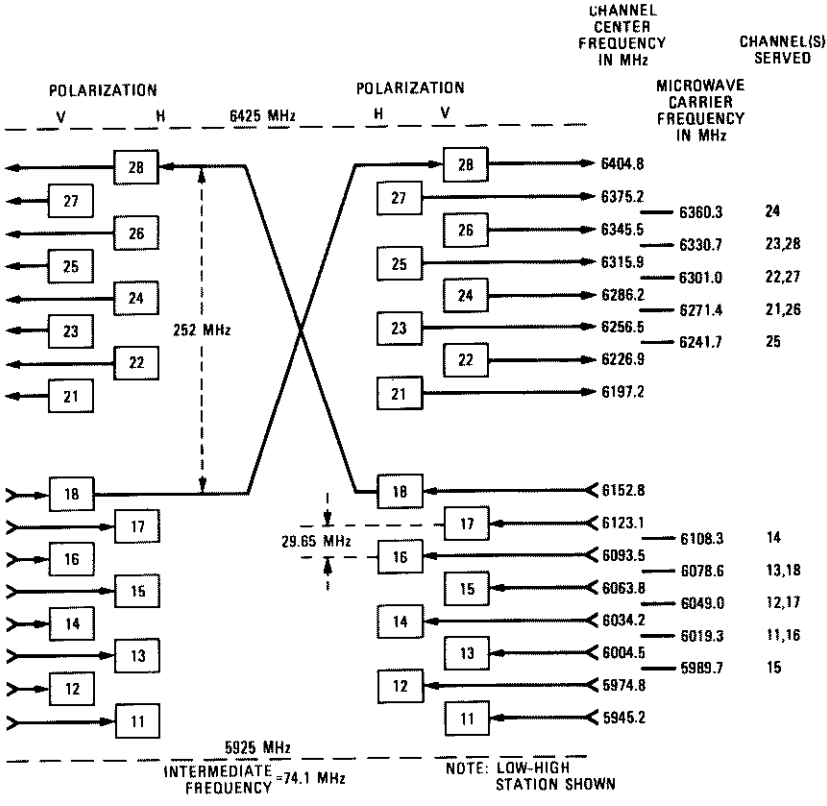

Fig. 4—AR6A frequency plan.

### *4.1.2 Choice of IF*

An IF band centered at a frequency that is an odd multiple of half the channel separation is the best choice for minimizing the effects of microwave carrier leakages. With this choice of IF center frequency, these leakages appear at the edge between two channels and do not need as much suppression as they would if they fell inside a channel. On this basis the best IF center frequency for the 6-GHz frequency plan is 74.12965 MHz (usually referred to as 74.1 MHz). In addition to the advantage of controlling the effect of the microwave carrier leakages, a 74.1-MHz center frequency permits a reduction from 16 to 10 of the microwave carrier and filter codes needed, since some microwave carrier frequencies can be used for two channels by using upper and lower sideband modulators. These design factors favor the choice of 74.1 MHz. Consideration was given to using a center frequency of 70.0 MHz, which is used in the TH-3 and TD Radio Systems. This choice would permit the direct IF interconnection of FM systems

onto an AR6A radio channel. The ability to handle both AM and FM signals would have excessively complicated the AR6A design; therefore, an IF center frequency of 74.1 MHz was used.

#### *4.1.3 IF band utilization*

At both IF and microwave frequencies, the SSBAM signal with suppressed carrier occupies no additional bandwidth over the original baseband signal. Thus, mastergroups can be translated into the channel bandwidth with a spacing determined by the filtering requirements needed for separation when shifted back to baseband. Carrier systems previously used a frequency spacing between mastergroups of approximately 4 percent of the frequency, where the mastergroup was to be located based on the desire to separate mastergroups (block and branch) at the multimastergroup level. The use of mastergroup translators makes it more convenient and economical to make these rearrangements at the basic mastergroup level, which permits the use of a fixed frequency separation at the multimastergroup level. Improvements in filter performance have made it possible to form the MMG spectrum with only 168-kHz spacing between mastergroups. The number of mastergroups that can be placed in the radio channel bandwidth is constrained by cochannel interference from FM systems. Clearly, the center of the channel, which may contain interfering FM carriers, cannot be used, and further allowance must be made for the close-in sidebands of the FM signal since these are strong enough to cause serious interference into AR6A voice circuits. The situation for TH-3 is shown in Fig. 5. Consequently, a center gap of 2.072 MHz has been provided which, with frogging of the mastergroups, keeps interference at an acceptable level, and achieves a loading of ten mastergroups in the 29.65-MHz channel bandwidth. The addition of pilot tones in the gaps between mastergroups for regulation and control purposes completes the IF spectrum as shown in Fig. 2.

### *4.2 Frequency stabilization*

#### *4.2.1 Need for stabilization*

An important aspect of the system design is the required frequency stability along a radio route. The radio pilots, which are transmitted as part of the IF spectrum, must be centered in their respective pick-off filters in each receiver. For best operation, the pilots should be within ±2 kHz of their nominal frequencies. The necessary frequency accuracy is achieved by locking the microwave generators and shift oscillators at each station to a high-stability synchronization oscillator located in each station. This will stabilize both the microwave and the IF frequencies of the system.

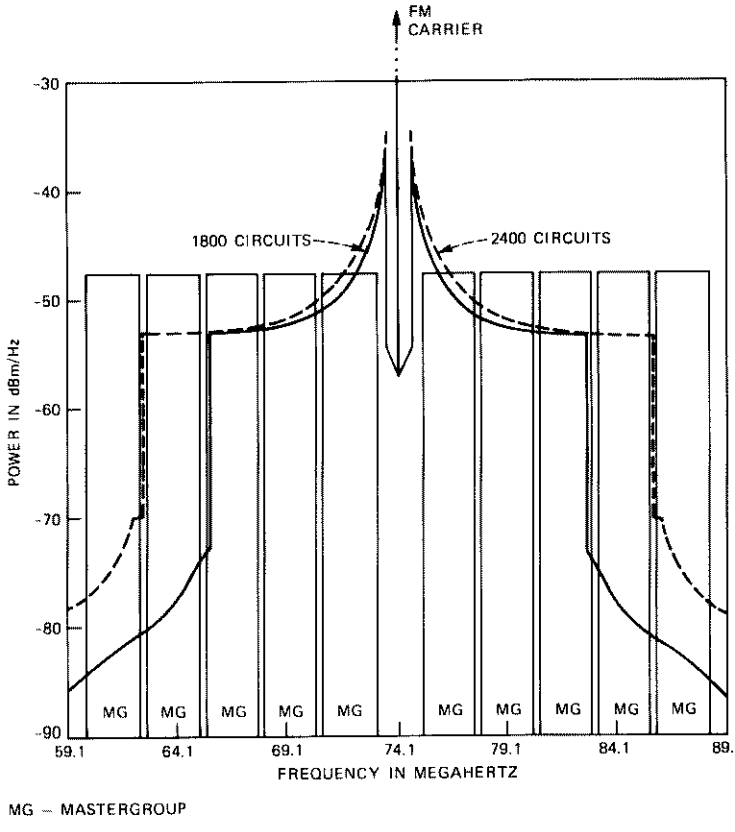

Fig. 5—AR6A and TH spectra.

### *4.2.2 Method of stabilization*

As a result of choosing the IF center frequency of 74.12965 MHz, all the microwave generator frequencies and the shift oscillator frequency are multiples of 14.825930 MHz. Because the best crystal frequency stability is obtained around 5 MHz, the AR6A synchronization supply oscillator was chosen to have a frequency of 4.94197666 MHz, which is one-third of 14.825930 MHz. This oscillator is oven controlled and has a stability of two parts in $10^8$ over the required temperature range and an aging rate of less than five parts in $10^{10}$ per day. In order to get all the harmonics needed for locking the microwave generators and for circuit convenience, the AR6A synchronization oscillator frequency is divided by 16 to obtain 0.30887354 MHz. This latter frequency is distributed to the phase-locked loops associated with microwave generators and the shift oscillators. The phase-locked loops contain circuitry that will hold the frequency at its last value

and prevent a frequency jump if the synchronization signal is lost. The AR6A synchronization oscillator supplies the synchronization for all 16 bays of a fully equipped repeater station and is protected by automatic switching to a second unit.

### *4.3 Signal recovery*

The customer-to-customer frequency offset objective of the Bell System is ±2 Hz. This means that carriers used in translating baseband signals up and down in frequency must be very accurate in frequency. This is accomplished by locking these carriers to a primary frequency supply (PFS) which itself is locked to the Bell System master oscillator in Hillsboro, Missouri. Frequency-division multiplex systems such as LMX, MMX, and JMX all operate in this manner. A newly developed OMFS is provided in AR6A terminal stations to meet the frequency offset objective.

In the AR6A System no carrier is transmitted along with the AM sidebands, so one must be accurately generated in the receiving MMGT-R. The IF signal into the receiving MMGT-R can be a few hundred hertz from nominal because of accumulated frequency errors from intermediate repeaters. The receiving carrier generated in the MMGT-R receiver is controlled in frequency to compensate for the accumulated frequency errors by using recovery pilots (one in each half of the IF spectrum). These recovery pilots at the input to the receiving MMGT-R have the same accumulated frequency offset as the rest of the IF signal. The receiving MMGT-R translates each half of the IF spectrum down to the MMG spectrum independently. In each case, the received recovery pilot is selected from the MMG spectrum and is compared in a phase-locked loop with an oscillator locked to the local OMFS. The output error signal from the comparator is used to adjust the frequency of the carrier used in the receiving demodulator. In this way, the receiving carrier "tracks" the frequency offset of the incoming signal and the MMG signal is recovered with no frequency offset.

### *4.4 Equalization*

#### *4.4.1 Static*

The objective for amplitude deviation from flatness over the 30-MHz channel for each switch section is ±0.5 dB. To help achieve this objective on a radio hop, each TR bay receiver includes a basic bay equalizer, which compensates for known systematic amplitude misalignments of the microwave and IF components. Mop-up equalizers are available in ±0.5 dB slope and parabolic shapes to enable each switch section to meet its ±0.5 dB objective. The amount of mop-up equalization required is specified automatically from switch section

amplitude response measurements made by the TSS-R System. Places are available in the 500A protection switch and in each radio receiver to mount the needed mop-up equalizers.

#### *4.4.2 Dynamic*

The objective for time-variant amplitude variations is that they be less than ±2 dB for 99.9 percent of the time. The primary source of transient amplitude variations is selective fading of the microwave signal due to unusual atmospheric conditions. An extensive measurement and analysis program was started in 1970 to determine the effects of selective fading on a 6-GHz microwave radio channel.[5] As a result of computer simulation studies made with the collected fading data, the following three strategies were recommended to minimize selective fading effects:[6]

1. Use space-diversity reception for each hop that has significant selective fading.
2. Use a simple automatic gain control (AGC) amplifier in each receiver.
3. Use a dynamic equalizer that will provide slope and parabolic shape correction at the end of each switch section.

The use of space diversity is recommended to reduce the amount of time the microwave signal is in a deep fade where the largest amplitude variations occur. This is discussed further in Section 4.7. The use of an AGC amplifier in each receiver to compensate for the flat gain portion of microwave signal variations is standard in radio systems. In the AR6A System, the AGC amplifier gain is controlled by the voltage average of the three received radio pilots. To compensate for the shape portion of the amplitude variations, a dynamic equalizer has been designed[7] and is used in each main station receiver. The dynamic equalizer contains one bump network located at each end of the IF band. The gains of these networks are continuously controlled by the voltage difference between the edge radio pilots and the center radio pilot of the received channel. Figure 6 shows a typical fade shape across the IF band before and after equalization.

### *4.5 Interference*

#### *4.5.1 Impairments*

An important aspect of any new radio system design is the consideration of the interference environment. The AR6A System has to coexist with the existing FM radio systems, other AR6A routes, and self-interference. One effect of interference is to add to the background noise of the channel; this is compensated for by the inclusion of 32.3 dBrnc0 for interference in the system noise allocation.

Other effects are crosstalk, babble, and tone interference, which can

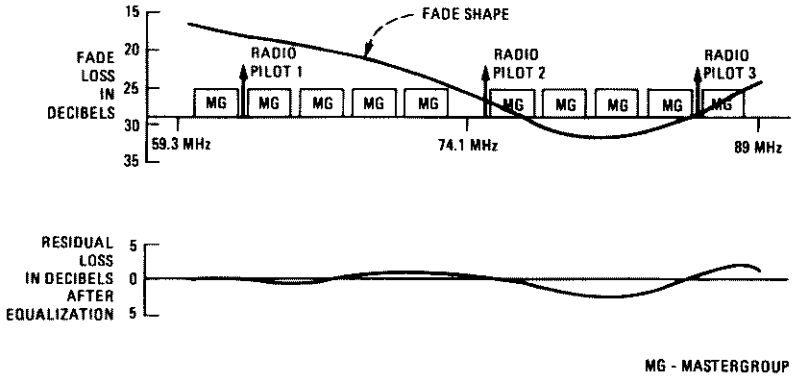

Fig. 6—Dynamic equalization of a fade.

occur when two AR6A channels carrying different traffic interfere with each other.

If both the interfering signal and the desired signal are voice signals and are exactly aligned in frequency, the effect is crosstalk. If the two signals are increasingly offset in frequency, the interference becomes less intelligible until, at ±500 Hz, the interference is judged to be unintelligible crosstalk and referred to as babble. Should the interfering signal be an idle circuit tone or a data signal, the effect will be tone interference regardless of any frequency offset. This type of coupling between two AR6A channels can occur at junction stations or between two routes not sharing a station but in the same geographical area. These effects must be evaluated in terms of the crosstalk, babble, and tone interference objectives. In FM systems, the poorer RF frequency stability and the effects of carrier spreading render these impairments negligible.

Another interference effect is talker echo that results from coupling—primarily antenna coupling—between the east- and westbound channels of the same route. For administrative purposes, the east- and westbound halves of the 4-kHz voice circuits are in corresponding locations in their respective channels. Thus, if these two channels are within 500 Hz of each other, the result is talker echo. Beyond 500 Hz, the effect will be a babbled talker echo, which is judged to be almost as annoying. The magnitude of the talker echo may be described in terms of the effective return loss of the system.

#### *4.5.2 Cochannel interference*

To avoid interference from cochannel FM carriers, the center of the AR6A channel is left vacant. The noise effect of the FM sidebands is controlled by properly selecting the channel center gap and frogging

Table I—Impairment calculation summary

| Impairment | Objective | Estimated Performance (Percent) |
|---|---|---|
| Crosstalk | ≤ 1 percent | 0.12 |
| Babble/Noise | ≥ −10 dB no more than 1 percent of time | 0.32 |
| Tone/Noise | ≥ −10 dB no more than 1 percent of time | 0.55 |

the mastergroups. The noise effect of another cochannel AR6A System is controlled by requiring at least a 64-dB signal-to-interference ratio.

Studies were conducted to evaluate the ability of the AR6A System to meet the crosstalk, babble, and tone objectives. These impairments are largely controlled by the antenna system discrimination against interfering signals and route layout. Most of AR6A installation would be on existing routes, which means antennas and routes are already fixed. A design choice that was open was the frequency stability of the radio line. As noted in Section 4.2, the microwave carrier supplies required stabilization to keep the radio pilots within the passband of their pick-off filters. Several stabilization plans with different degrees of stabilization were analyzed to determine their effect on crosstalk, babble, and tone interference. These included a plan that introduced a series of fixed frequency offsets on different radio channels to reduce crosstalk. The results showed that a highly stabilized plan was the best for balancing the impairments. A summary of these impairments for the 4000-mile system model is shown in Table I.

One remaining cochannel interference that required analysis was the same route interference that gives rise to talker echo. The requirement for a 4000-mile system is an effective return loss of at least 30 dB. Calculations estimate that the return loss of the radio line is 41 dB.

#### *4.5.3 Adjacent-channel and tertiary inference*

The AR6A System has no significant signal-related energy outside of its channel bandwidth. Thus, adjacent-channel noise effects are negligible for adjacent AR6A channels. However, mutual problems occur when an AR6A and an FM channel are adjacent. If the FM channel is an RF squelch-equipped TH-3 System, this feature must be removed because the initiator noise slot is located inside the AR6A channel in a mastergroup position. Without removal the initiator would be continuously operated. Another problem is generated due to the wide bandpass of the IF filters needed in the FM systems to reduce their own channel noise. These filters couple into the FM receiver a portion of the adjacent AR6A signal, which is limited primarily by the cross-polarization discrimination of the antenna system. The noise

caused by this interference restricts the number of exposures to 10 or 15. In addition, the tertiary interference effect of a portion of the AR6A signal coupled into the adjacent FM channel is also undesirable. This AR6A signal when coupled back into the AR6A channel will produce modulation on the edge radio pilot and an amplitude shape deviation, depending upon the phase relationship between the signal and the interference. Estimates of these effects indicate they should be avoided if possible, but if they cannot be avoided during route conversion from FM to AR6A, then the AR6A channel adjacent to an FM channel must be either the protection channel or a working channel with the five adjacent mastergroups vacant.

### *4.6 Linearity*

#### *4.6.1 General*

Low intermodulation distortion (IM) properly optimized relative to other noise contributors is a basic consideration in the design of a transmission system. It is of particular interest in the AR6A System since the achievement of satisfactory linearity in the transmitting microwave amplifier is a key factor in making the SSBAM Microwave System possible. Transmitting amplifiers with power-handling capacities comparable to those commonly used on current FM systems fall short of meeting SSBAM linearity requirements by some 20 to 30 dB. Achieving stable distortion reductions of this magnitude was thus a crucial design task. Furthermore, although transmitter nonlinearity is dominant, care must be exercised in the design of all other in-line elements to ensure that their cumulative distortion contribution is not excessive.

Since at microwave frequencies and even at intermediate frequencies we are dealing with narrowband channels, the only significant distortion contributors are the odd-order, nonlinear terms. In AR6A, third-order distortion is dominant, fifth order is on the fringes of importance, while seventh and higher odd-order terms are negligible.

A related and crucial design consideration is the question of how the distortions from tandem nonlinear networks combine within and between repeaters. This is referred to as the Law-Of-Addition (LOA) question. Differences between the extreme assumptions of coherent and noncoherent addition strongly influence a variety of design choices. For example, the LOA influences the optimum system drive level, it affects how frequently mastergroups must be relocated or frequency frogged, and it affects equalization strategies. For these reasons, studies and estimates of the LOA received early attention, while subsequent verification of the assumptions was an important element in the field evaluation.

#### 4.6.2 Distortion estimates

To make system distortion estimates, first the distortion contribution must be estimated from individual system elements. This, in turn, must be based on some suitable measured parameter(s) indicative of the unit's nonlinearity. For AR6A computations, a practical approach starts from a power series description of the unit's input/output relationship. Functional ratios of the power series coefficients can then be related to measurable modulation coefficients and vice versa.

To estimate distortion, the broadband message load can be simulated by zero-mean Gaussian noise with appropriate spectral shaping. Multiple convolutions weighted according to power series coefficients may then be used to determine expected IM distortion. In AR6A, since the signal spectrum is flat, the IM noise computation can be greatly simplified by using the work of Y. L. Kuo.[8] Distortion-to-signal ratios are evaluated in terms of power series coefficients, which are then related to measurable modulation coefficients. The final result is expressed in the following relationships, which assume that the odd-order power series has no significant terms beyond the fifth

$$N_3 = 4.23 + 2P_{\text{out}} + M_{\alpha+\beta-\gamma}$$

$$N_{35} = 4.77 + 3P_{\text{out}} + \frac{1}{2}\,(M_{\alpha+\beta-\gamma} + M_{2\alpha-2\beta+\gamma})$$

$$N_5 = 8.32 + 4P_{\text{out}} + M_{2\alpha-2\beta+\gamma}, \tag{1}$$

where

$N_3$ = ratio of third-order distortion power in a narrowband $\Delta W$ to signal power in the same bandwidth. The ratio is expressed in decibels and the band $\Delta W$ is located at the center of the simulated, spectrally flat, message load,

$N_5$ = the corresponding fifth-order power ratio,

$N_{35}$ = the corresponding fourth-order power ratio being an interaction term between the third- and fifth-order distortion mechanisms,

$M_{\alpha+\beta-\gamma}$ = a third-order modulation coefficient expressed in decibels,

$M_{2\alpha-2\beta+\gamma}$ = a fifth-order modulation coefficient expressed in decibels, and

$P_{\text{out}}$ = total simulated message-load power in dBm at the device output.

The noise-to-signal power ratios can be converted to dBrnc0s as follows:

$$\textit{noise}\ (\text{dBrnc0}) = N + P_1 + 86.8, \tag{2}$$

where $N$ is the noise-to-signal power ratio in dB and $P_1$ is the average signal power per 4-kHz message circuit at 0 transmission level (TL). These relationships involve a number of simplifying assumptions and should be used with caution. For example, the $M$ values are assumed to be constants independent of drive level and frequency; addition of $M_{\alpha+\beta-\gamma}$ and $M_{2\alpha-2\beta+\gamma}$ in the expression for $N_{35}$ is subject to some uncertainty because of the absence of product phase information in the definition of $M$; and, finally, the expressions apply at the band center of an idealized simulation of the message load. In AR6A applications, cross-checks have been made against pseudorandom noise load measurements[9] with satisfactory agreement if nominal drive levels are not exceeded by more than a few decibels.

With typical values for an output traveling-wave-tube amplifier of $M_{\alpha+\beta-\gamma} = -90$ dB, $P_{\text{out}} = +25$ dBm, and $P_1 = -19.6$ dBm0, the estimated IM noise is 23 dBrnc0 per repeater. Taking account of product addition laws, thermal noise contributions, etc., led to the earlier assertion that distortion reductions of at least 20 dB are needed to make the SSBAM System viable.

#### *4.6.3 Law of addition*

For a string of $n$ identical nonlinear devices, the law of addition ($K$) for intermodulation noise (IM) is defined by

$$W_n = K \log n + W \text{ dBrnc0}, \tag{3}$$

where

$W_n$ = intermodulation noise of the string,

$W$ = intermodulation noise of one device.

Odd-order distortion from some elements of a repeater are going to add systematically corresponding to $K \approx 20$. Other sources of repeater IM are going to accumulate in a random fashion corresponding to $K \approx 10$. The overall law of addition is going to be somewhere between those extremes and will depend on the relative magnitude of the two types of contributors. Clearly, the net value of $K$ is going to be an extremely important factor in estimating total system noise on a long route.

In the case of IM contributed by repeater elements subject to predistortion correction, the residual distortion can be expected to have a random phase orientation. However, some departures from randomness will be experienced if there are systematic degradations in predistorter improvement due to frequency response or aging effects.

Nonlinear elements not subject to predistorter compensation, such as IF amplifiers, will generate IM that adds systematically. Again,

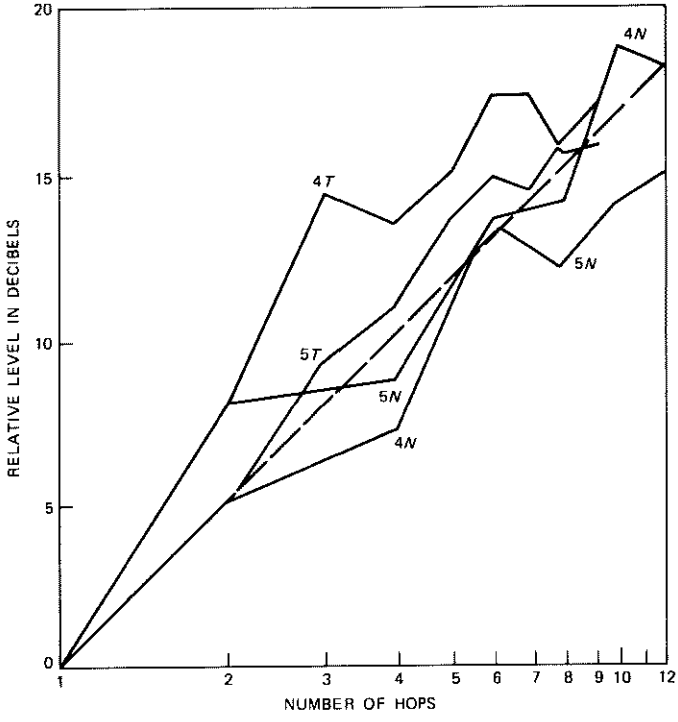

Fig. 7—Intermodulation noise law of addition.

however, there are modifying circumstances such as repeater delay distortion that in this case can reduce the rate of accumulation. Computations involving multiple convolutions of the signal indicate that on AR6A, delay distortion reduces the law of addition from 20 to approximately 19 near band center with larger reductions near the band edges.

For design purposes, law-of-addition estimates were based in broad terms on the power addition of transmitter IM, the voltage addition of receiver IM, and power addition of the combination. Depending on detailed assumptions, this led to estimates for $K$ in the range 16 to 18.

Measurements using pseudorandom noise loading[9] for 12 pairs of repeaters in the initial field installation yielded an average value $K = 16.9$. These same repeaters were then connected in loops of 2 through 12 hops, and the pseudorandom noise load results for radio channels 4 and 5 ($4N$, $5N$) shown in Fig. 7 were obtained. The dotted line in the figure refers to the expected law of addition ($K = 16.9$). Measurements using a three-tone test ($4T$, $5T$) are also shown in the figure. Reasonable agreement with the expected law of addition is observed.

### 4.7 Application of frequency- and space-diversity protection

#### 4.7.1 Microwave propagation of the AR6A signal

In the early development of AR6A, it was recognized that it would be necessary to characterize the effects of selective fading on the broadband SSBAM signal. Propagation studies were conducted in 1971 on a 26.4-mile path from Palmetto to Atlanta, Georgia. The studies quantified the fading effects on a statistical basis and determined many of the basic system design features, including the choice of the three radio pilots to control system gain, the type and amount of dynamic equalization, and the algorithms for space- and frequency-diversity switching.[10]

In microwave radio system design, multipath (Rayleigh) fading is usually characterized by the equation[11]

$$T(L) = rT_0L^2,\ L < 0.1, \tag{4}$$

where

$L$ = the ratio of received carrier amplitude to nominal or free-space received carrier amplitude,
$T_0$ = time base or total time of the study,
$r$ = fade occurrence factor representing the fraction of time that selective fading occurs, and
$T(L)$ = time in seconds during the period $T_0$ that the received carrier amplitude ratio is below the level $L$.

This relation is descriptive of any single frequency in the AR6A spectrum. The propagation studies expanded this signal characterization to four frequencies. Statistics representative of the fading of any independent frequency in the spectrum were generated with conditioning on the state of the three radio pilots. The equation modeling the fading becomes

$$T(L) = rT_0L^2(U(L) + P(L)), \tag{5}$$

where

$U(L)$ = the conditional probability that the radio pilots are less faded than the ratio $L$ given that the frequency of interest is faded at least to the ratio $L$, and
$P(L) = 1 - U(L)$.

The probability $U(L)$, shown as the curve $L_F = L$ in Fig. 8, is less than 0.1 for fades less than about 36 dB ($L = 0.016$) and increases monotonically with fade depth to about 0.5 for fades greater than 48 dB ($L = 0.004$). Since the radio pilots are used to control the system gain and switching functions, this characterization allows various equalization and switching plans to be evaluated.

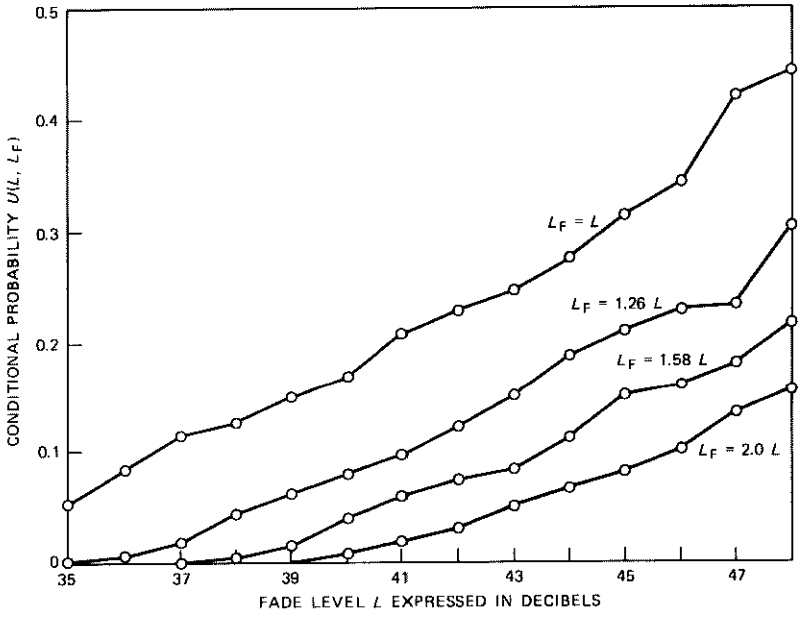

Fig. 8—The conditional probability $U(L, L_F)$.

In addition to the four frequency fading characterization, the 1971 propagation data were also used to characterize the amplitude response of the signal during fading. The data were used as the input to a computer program that simulated the response of the dynamic equalizer. The results of this study are shown in Fig. 9. This plot indicates the expected average severity of gain deviations during fading. The averaging process includes an average over all voice-circuit locations in the signal spectrum. The plot is similar to a cumulative distribution with the maximum fade level of the radio pilots as the independent variable. The 2-dB gain deviation limit corresponds to the dynamic equalization objective. As indicated in the figure, fades with radio pilot attenuation less than 30 dB contribute essentially no gain deviation time. For fades with radio pilot attenuation exceeding 40 dB, comparison of Fig. 9 with the Rayleigh model of eq. (4) shows that almost all of the fade time has gain deviations exceeding ±2 dB. These results led to the recognition that in order to meet the system 2-dB gain deviation objective, space-diversity switching at radio pilot fade levels in the range of 30 to 40 dB would be required.

#### *4.7.2 Frequency- and space-diversity switching during multipath fading*

With the recognition that both frequency- and space-diversity switching would be required for AR6A, a fading model including the

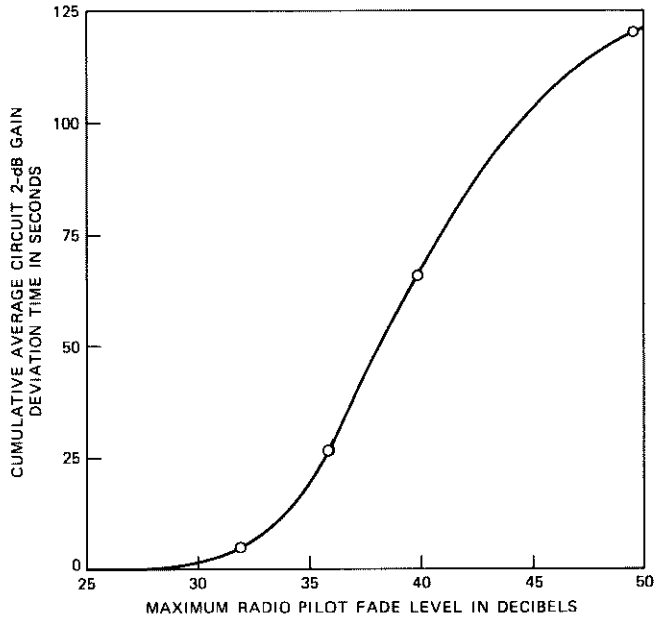

Fig. 9—Average gain deviation time of an AR6A circuit for 600 seconds of multipath fading at the 30-dB level.

effects of both switching systems was developed.[6] The resulting equation representing the fading performance of a hop equipped with both types of switching is

$$T_p(L) = \frac{rT_0L^2}{I_s(L_s)}\left[U(L, L_F) + \frac{P(L, L_F)}{I_F(L_F)}\right], \; L \leqslant L_F < L_S < 0.1, \quad (6)$$

where

$L_F$ = the pilot fade level corresponding to the frequency-diversity switch threshold,
$L_S$ = the pilot fade level corresponding to the space-diversity switch threshold,
$I_F(L_F)$ = the improvement factor resulting from frequency-diversity switching, typically $I_F > 1$,
$I_S(L_S)$ = the improvement factor resulting from space-diversity switching, typically $I_S \gg 1$,
$U(L, L_F)$ = the conditional probability that the three radio pilots are less faded than $L_F$ given that the frequency of interest is faded to level $L$,
$P(L, L_F)$ = $1 - U(L, L_F)$, and
$T_p(L)$ = time that the protected signal is faded below level $L$.

The quantities $I_F$ and $I_S$ vary as $L^2$ but differ from the conventional,[10] single-frequency improvement factors. Typical values in the current system design are $I_F = 15$ and $I_S = 100$. The conditional probability function $U(L, L_F)$ is shown in Fig. 8 with the relationship between $L$ and $L_F$ as a parameter. The results in the figure are calculated from the 1971 data without smoothing. Since $I_F(L_F) > 1$, eq. (6) shows that higher values of $P(L, L_F)$ are desirable. The increase in $P(L, L_F)$ corresponds to an increase in the fade time that is protected by frequency-diversity switching and a decrease in outage time.

The 2-dB gain deviation time for a path protected by frequency- and space-diversity switching is modeled by the equation[6]

$$T_2(L) = \frac{rT_0}{0.6}\left[D(L_s) + \frac{D(L_F) - D(L_s)}{I_s(L_s)} + \frac{D(L) - D(L_F)}{I_s(L_s)I_F(L_F)}\right], \quad L < L_F < L_s, \tag{7}$$

where the function $D$ is the 2-dB gain deviation time given in Fig. 9. Equations (6) and (7) formed the basis for evaluating various space- and frequency-diversity switching algorithms.

#### *4.7.3 Reliability and dynamic equalization requirements*

During the development process, the performance of the radio system with respect to the reliability and dynamic equalization objectives was evaluated for several space- and frequency-diversity switching algorithms. In particular, various combinations of the switching levels $L_S$ and $L_F$ were studied. System performance for both voice and voiceband data was included. It was found that lower values of $L_S$ and $L_F$ improved the reliability performance but degraded the dynamic equalization. The current system design represents an approximate optimum in the trade-off between these requirements.

The space-diversity switching level was chosen to correspond to a 36-dB fade on a 27.1-mile path. For longer or shorter paths, the switching level varies inversely with the received signal level. The frequency-diversity switching level was chosen to be 53 dBrnc0 corresponding to a 44-dB fade on a 27.1-mile path. With this switching arrangement, approximately one-half of the hops in an average fading area are expected to require space diversity.

#### *4.7.4 Computerized implementation*

An interactive computer program was developed to facilitate the application of frequency- and space-diversity protection to new AR6A switch sections.[6] The evaluation of a proposed section's performance with respect to the outage and dynamic equalization objectives is

accomplished by the program after input data are supplied by the program user. The data are used to characterize the expected fading on the various hops in the section. For each hop, the input data include a climatic factor; the mean annual temperature; the hop length, roughness, and fade margin; and a description of any proposed space-diversity antenna.[10] The program first evaluates the performance of the section without space diversity. The estimated performance is compared to the objectives after prorating them to the length in miles of the section. If the objectives are met, the program stops and the route can be installed without space diversity. If they are not met, the program reevaluates the performance with space diversity applied initially on the worst fading hop. The program continues in this manner until the objectives are met. The route would then be installed with space diversity on the specified hops.

### *4.8 Mastergroup frogging*

Noise, reliability, and dynamic equalization in AR6A are functions of voice-circuit location in the IF passband. Circuits located near the IF band center receive relatively high levels of interference noise from FM-FDM and FM-TV systems. Reliability and dynamic equalization are best for circuits located near one of the radio pilots. Because of these variations, more uniform performance is attained on long trunks by varying their location within the IF spectrum. The variation is accomplished by interchanging or frogging mastergroups at specified distances. The maximum allowable frogging distance chosen for field applications is 800 miles. This value provides acceptable system performance and reduces the amount of multiplex equipment required solely for frogging. The effects of frogging distance on system performance are described in the following sections.

#### *4.8.1 Noise performance*

The system noise components that are influenced by frogging include: intermodulation noise, radio pilot modulation noise, and worst-circuit FM RF interference noise. The levels of these components all increase with frogging distance and are listed in Table II for distances of 400, 800, and 1600 miles. The intermodulation noise increase with

Table II—Noise performance with various frogging rules

| | Noise in dBrnc0 | | |
|---|---|---|---|
| Noise Type | 400-Mile Rule | 800-Mile Rule | 1600-Mile Rule |
| Intermodulation | 31.7 | 33.3 | 34.0 |
| Radio pilot modulation | 16.1 | 21.1 | 26.1 |
| Worst-circuit FM RF interference | 27.4 | 30.4 | 31.9 |

frogging distance is due to the radio receiver. The receiver intermodulation products produced on hops within a frogging section are nearly coherent. A small reduction, estimated to be 2.6 dB for an 800-mile frogging section, results from the phase characteristic of the IF filter. The receivers' products in different frogging sections are incoherent because of the changed signal. The radio pilot modulation noise also increases with frogging distance as a result of hop-to-hop coherence.

Although the average noise resulting from the FM RF intereference does not change with frogging distance, the distribution of the noise does. Circuits located near the center radio pilot experience maximum interference. When the frogging distance is increased beyond 400 miles, some circuits receive significantly more noise than the average. The resulting worst-circuit noise is shown in Table II.

#### *4.8.2 Reliability and dynamic equalization performance*

Since the noise initiator slots for the 500A Protection Switching System are located near the radio pilots, voice circuits located near the pilots receive relatively good selective fading protection. For these circuits unprotected fade time is small. For circuits located between the radio pilots, some selective fades can cause outage without producing enough noise in the slots to initiate a switch. As a result, the outage performance of the system varies with IF frequency. With a 400-mile frogging rule, all mastergroups transmitted 4000 miles occupy each mastergroup location in the signal spectrum for approximately 400 miles. When the frogging distance is extended beyond this interval, the performance is no longer uniform. With the 800-mile rule, calculations indicate that the outage of the worst circuits will exceed the average circuit by 44 percent. To ensure that these circuits meet the overall multipath fading objective, an algorithm was added to the computer program for the application of space diversity. For switch sections located in frogging sections between 400 and 800 miles in length, worst-circuit performance is calculated and compared to the objective. Additional space-diversity protection is then required for the switch section to meet the system requirement. This procedure allows the engineers responsible for a route to trade off the cost of additional multiplex required for a shorter frogging section with the cost of additional space diversity required for a longer one.

For frogging distances greater than 400 miles, the dynamic equalization performance of the system parallels the reliability performance. Worst-circuit gain deviation time with the 800-mile frogging rule is approximately 48 percent greater than the average circuit time. This factor is also included in the computer program for the application of space diversity, and the worst circuits are required to meet the system objective.

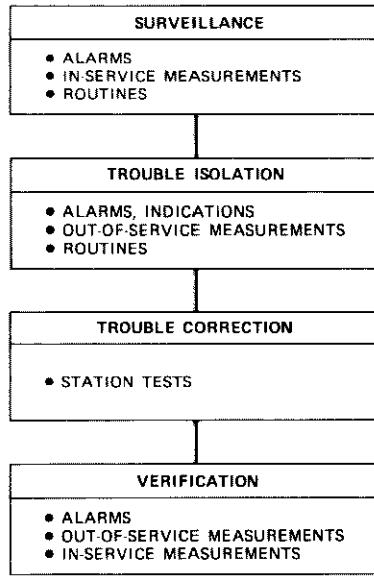

Fig. 10—AR6A generalized maintenance plan.

### *4.9 Maintenance*

#### *4.9.1 General*

Maintenance was discussed in general terms in Section 1.6 with particular mention of the importance of adequate transmission surveillance capability. In AR6A, the new surveillance functions are combined with traditional remote alarm and reporting features to form an overall maintenance plan that is summarized in very general terms in Fig. 10.

The alarm reporting system is a full-time monitoring facility using either C1 or E-type alarm remotes under the centralized jurisdiction of a SCOTS or TASC central minicomputer. In general, remote alarm reporting is limited to isolating trouble to a particular station and direction of transmission, not the particular unit in trouble. Locally, however, more detailed visual indications and test points simplify the trouble isolation process. This approach is based on the premise that prior knowledge of the detailed trouble condition is unnecessary if it is assumed that, on a station visit, the technician is equipped to deal with any on-site problem or any additional problems that become known enroute.

Except for a few legally required routine tests, maintenance is performed on an as-needed basis. When a trouble has been identified and isolated, a technician is dispatched to the trouble site with a defined set of spare parts and station test equipment. The principal station test sets are:

1. Transmitter-receiver transmission test set
2. Scanning intermodulation test set
3. Portable rubidium frequency standard
4. Pilot selection test set
5. TWT power supply test load.

#### *4.9.2 Transmission Surveillance System*

The AR6A Transmission Surveillance System—Radio (TSS-R) consists of programmable equipment for access and testing located at radio switching stations. It can perform a variety of transmission measurements under the direction of a central minicomputer. Communication between the central computer and remote measuring sites is via *DATAPHONE** data communications service with its attendant flexibility and expandability. Unlike the alarm reporting system, TSS-R measures system performance on a scheduled or as-needed basis, providing snapshot rather than continuous information.

Figure 11 is a block diagram of TSS-R. The central minicomputer has a peripheral disk storage capacity of approximately 20 Mb allocated to program, database, and data storage functions. Automatic call-out units provide DDD access to the measuring remotes as well as to maintenance and other centers programmed to receive reports. It is expected that five central computers will be capable of covering all AR6A deployment within the continental United States.

At switching stations, test access, measuring equipment, and data interchange with the central computer are under the control of a microprocessor with its associated firmware. Physically, these functions are grouped in the TSS-R distribution bay as indicated in Fig. 11. All measurements are performed by a Selective Transmission Measuring Set (STMS) with a frequency range of 10 kHz to 160 MHz. The set is controlled by the distribution bay microprocessor via an IEEE control bus. Programmable functions include level and frequency measurements, bandwidth selection, and the selection of a phase-jitter measuring mode.

Switched access for measurement purposes is provided at transmitting and receiving mastergroup combiners and at transmitting and receiving 500A switches. Measurements at mastergroup combiners can be made on a bridged, in-service basis only; measurements at the 500A switches can be made either on an in-service or out-of-service basis.

In-service measurements can be made conventionally using bridging hybrid transformers in conjunction with director switches to route the selected test point to the STMS. Signals available for measurements

* Registered service mark of AT&T.

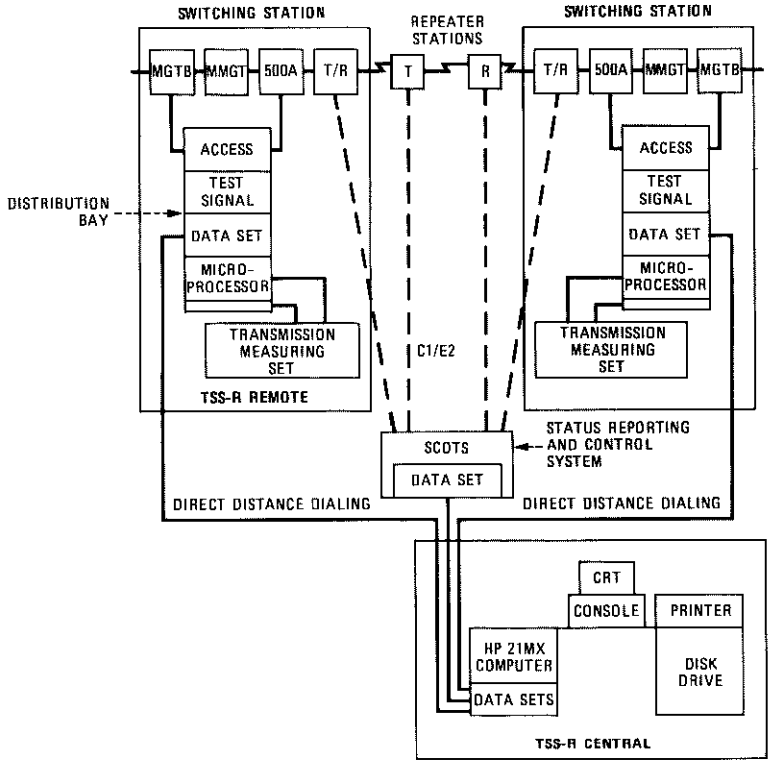

Fig. 11—Transmission Surveillance System.

are elements of the normal system load such as mastergroup pilots, system pilots, and intermastergroup noise. Since in-service measurements are made without affecting the main transmission path, they are made frequently and routinely at intervals of approximately one week.

On the other hand, out-of-service measurements require that service be temporarily transferred to the protection channel. This frees the selected working channel for end-to-end switch section measurements. To measure the channel, access at the head end of the switch section is provided by the 500A maintenance switch as indicated in Fig. 12. Since operation of a maintenance switch opens the channel and removes normal pilots, a substitute set of pilots must be supplied via the maintenance measuring path (see Fig. 12). At the receiving end of the switch section, the channel under test is routed to the STMS for making the selected out-of-service measurements.

Since the operation of a maintenance switch can be done under program control, safeguards must be provided against untimely oper-

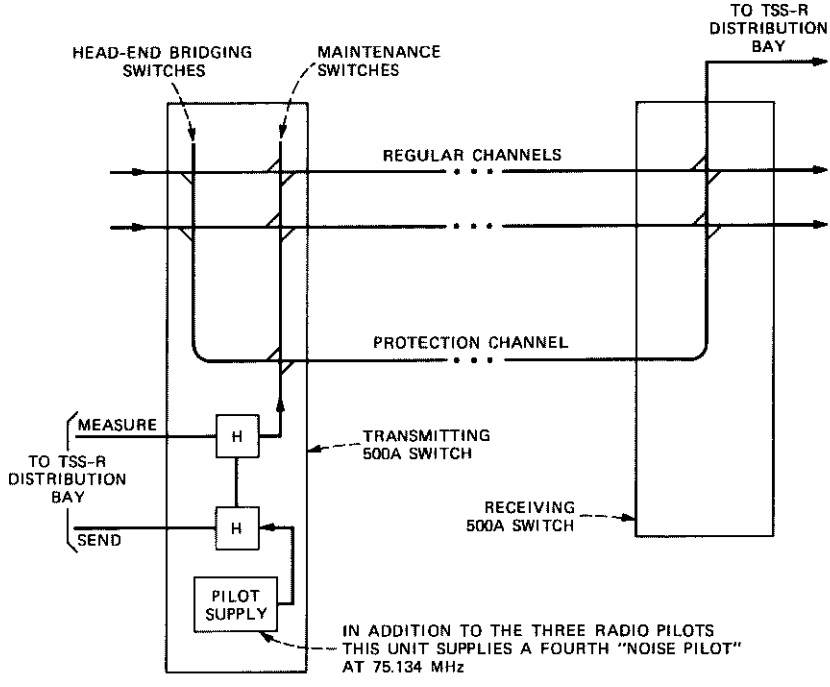

Fig. 12—Simplified diagram of switch section out-of-service test access arrangements.

ation of the switch by TSS-R. This is achieved by making the 500A control circuits the ultimate arbiter of all switching decisions.

Some out-of-service measurements require only that the head-end of the channel under test be terminated. Other tests require the insertion and measurement of a test signal at the head end of the channel as well as its measurement at the receive end. Provisions for inserting test signals, combining them with pilots, and providing head-end measuring access are shown in Fig. 12. For example, to measure out-of-service amplitude response, a comb signal with a tone spacing of 130 kHz that encompasses the entire IF band is available from the distribution bay. This signal, when needed, is sent to the test signal input port (Fig. 12) and measured at each end of the channel under test. The measured data are returned to the TSS-R central minicomputer where a comparison of transmitting and receiving levels provides the desired amplitude response characteristic for the channel.

Special mention is made of the following out-of-service switch-section measuring capabilities:

1. Spurious modulation—This involves the insertion of a +5 dBm0 test tone (83.168 MHz) at the head end of the switch section. At the receiving end, TSS-R looks for spurious modulation sidebands on the

test tone. These might be due to modulation of the test tone by spurious switching tones from a bad power supply, spurious modulation by a faulty microwave local oscillator, or spurious modulation by some other unwanted mechanism.

2. Linearity—This measurement is of special interest for verifying continued satisfactory adjustment of transmitter predistorters. Two high-level (+17 dBm0) test tones located ±44 kHz on either side of the 74.13-MHz channel center frequency are inserted at the head end of the switch section. Third-order nonlinearities produce IM products located 88 kHz on either side of the radio-line pilots. These products are measured at the receiving end of the switch section as an indication of switch section linearity. Positioning the +17 dBm0 full-load test tones close to band center minimizes the impact of cochannel interference on other systems. In other words, the tones are no worse from an interference standpoint than cochannel FM carriers.

3. Transmitter gain check—The +17 dBm0 test tones mentioned in (2) can also be used as a coarse check on transmitter gain. When turned on at the head end of a switch section, power monitors on the output of each succeeding transmitter provide a remote indication if the power is within a ±3 dB window of nominal.

A complete listing of all in-service and out-of-service tests is given below.

1. In-service tests—switch section
   (a) Pilots—level and frequency
   (b) Intermastergroup noise
   (c) Pilot slot noise—before pilot insertion
2. Out-of-service tests—switch section and hop by hop
   (a) Idle noise
   (b) Noise and tone scan
   (c) Linearity
   (d) Amplitude response
   (e) Interference
   (f) Cross-polarization discrimination
   (g) Transmitter gain
   (h) Space-diversity switch point
3. Other tests
   (a) Head-end pilot supply on 500A
   (b) Phase jitter—in-service and out-of-service
   (c) Diagnostic tests

#### *4.9.3 Stress-test and trouble-isolation features*

Distinct from, but enhanced by, TSS-R are a number of supplementary features for stress testing and trouble isolation. Central to implementing these features is the capability to remotely operate any

selected resupply switch at intermediate repeaters via the alarm reporting and command system. When a resupply switch is operated, a locally generated set of pilots is inserted into the channel under test. By measuring the channel with TSS-R at the receiving end of the switch section, it is possible to characterize systematically shortened portions of the switch section to isolate trouble.

To ensure that a resupply switch can only be operated remotely on an out-of-service channel, the switch command is enabled by the presence of the noise pilot on the out-of-service channel (see Fig. 12). Since the noise pilot can only be present subsequent to the operation of a head-end maintenance switch and the prior transfer of service to a protection channel, the requisite protection is provided.

An important additional function of the noise pilot is associated with the switching system preemption feature. If TSS-R is measuring a foreshortened portion of a channel in a switch section, rapid restoral of the intermediate resupply switch is essential if the channel under test has to be preempted for service. Since a first step in the preemption process is to pull down the head-end maintenance switch and thereby remove the noise pilot provided by the head-end resupply, all downstream resupply switches are automatically disabled and returned to normal. This avoids the slow restoral procedure that would result if resupply switches had to be reset via the alarm reporting and command system.

Trouble isolation capabilities associated with the remote control of resupply switches are further enhanced by providing means to remotely modify the resupply signal. For example, the two high-level test tones used for switch section linearity measurements can also be turned on at intermediate resupply points. This provides the capability to isolate hops with high nonlinearity by looking at systematically foreshortened portions of the switch section. The isolation of linearity problems to a particular hop is further enhanced by turning on the aforementioned linearity test signal at a selected intermediate station; but instead of applying the radio pilots at their normal −10 dBm0 level, they are applied at 0 dBm0. This enhances the third-order nonlinearity product contributed by the first hop of the foreshortened switch section by 10 dB. At succeeding receivers on the switch section, AGC restores the radio pilots to −10 dBm0 and correspondingly reduces the high-level test tones by 10 dB to +7 dBm0. Thus, the third-order products contributed by succeeding hops are reduced by 20 dB, thereby making the first hop contribution dominant.

Another stress test feature is provided by remotely commanding the resupply pilots to be inserted 32 dB below their normal level of −10 dBm0. When this is done, AGC on the first receiver beyond the resupply point increases its gain by 32 dB to restore the pilots to their

normal −10 dBm0 level at the receiver output. This enhances the front-end idle noise contribution of that particular receiver by a corresponding amount and will, therefore, be dominant when TSS-R measures noise at the end of the switch section. In effect, therefore, this measurement gives an indication of the receiver noise figure on the artificially faded hop. There is a corresponding 32-dB enhancement of incident interference on the faded hop providing a means for identifying the interference level and point of entry. This same technique may also be used to measure the level of the nearest radio pilot in the adjacent AR6A channel to obtain a measure of cross-polarization discrimination on a hop-by-hop basis.

## V. TESTING

### *5.1 Laboratory testing*

A test facility was established at Merrimack Valley to perform initial testing of AR6A bays. This test facility served the needs of developing shop and field testing information, initial testing for radio bay components, and pursuing problems observed in the later planned field trial program. Two sets of frequency-compatible bays were installed along with a support bay. The bays were configured so that each set had a main-station-configured bay and a repeater-station-configured bay. This arrangement allowed for the greatest flexibility for an ongoing testing program.

Figure 13 depicts the laboratory bay arrangement. Bays 1 and 2 were configured as main station bays. The waveguide runs connecting repeater bays 3 and 4 contain RF preamplifiers and the loss of each run was built out to simulate a nominal hop length of 27.1 miles (61.7 dB of section loss). Two MCSS supplies were available in the support

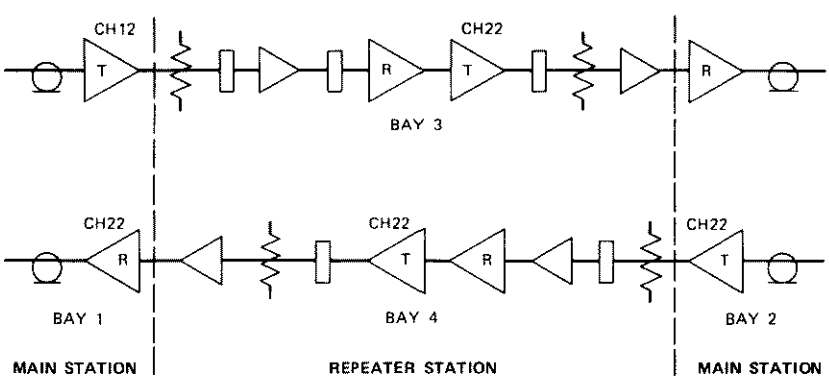

Fig. 13—Laboratory bay arrangement.

bay to allow for all bays to be locked to the same unit or for separate MCSS signals for bays 1 and 2 as testing required.

Initial testing concentrated on tests and measurements to ensure that an assembled bay met system requirements. Extensive tests were performed to isolate and reduce noise pickup and cross-coupling of signals in the bay wiring. These and results from the later field trial showed that a frame filter was necessary to filter the power from the −24 volt plant if noise objectives were to be met.

Modular design of the radio bay implied that a set of pretested modules could be inserted into a basic framework and a working bay obtained with a minimum of alignment. Initial testing was directed toward this goal. It was necessary to specify a series of tests for each module to ensure that when a set of modules was assembled into a bay, the bay performed satisfactorily. Test procedures for the overall bay were then developed for bay alignment. Once these procedures were deemed sufficient, they were incorporated into Bell System Practices (BSPs), which were then debugged using the laboratory bay facility.

### *5.2 String tests*

Since all components of the AR6A System were designed and available at Merrimack Valley, a tandem test arrangement was achieved by utilizing trunking between laboratories to construct a complete system comprised of MGTBs, MMGT-R multiplexing equipment, 500A Switching System, and the radio bays. This permitted injecting a signal into the system at basic mastergroup level and testing for switching transients with tandem units. A fade could be introduced producing a space-diversity switch, and as the fade was increased, correct switching activity for the 500A switch and the pilot resupply function in a radio bay could be observed and tested.

Noise load tests were performed on the tandem system, first on the MMGT-R connected back to back, then with the loopback at the 500A switch, and finally with a radio bay. This allowed testing of up to a four-hop switch section.

Phase jitter was also investigated on the system. Figure 14 depicts the test setup for a typical measurement. Pictures A and B in the figure show examples of the demodulated phase-jitter voltage display on an oscilloscope and a spectrum analyzer, respectively. Peak-to-peak switch-section jitter, measured in this fashion, is typically 1.2 degrees.

This laboratory facility was used constantly over the next two years as the minitrial was conducted in western Massachusetts and the field trial was conducted in Missouri. Problems seen in the field were

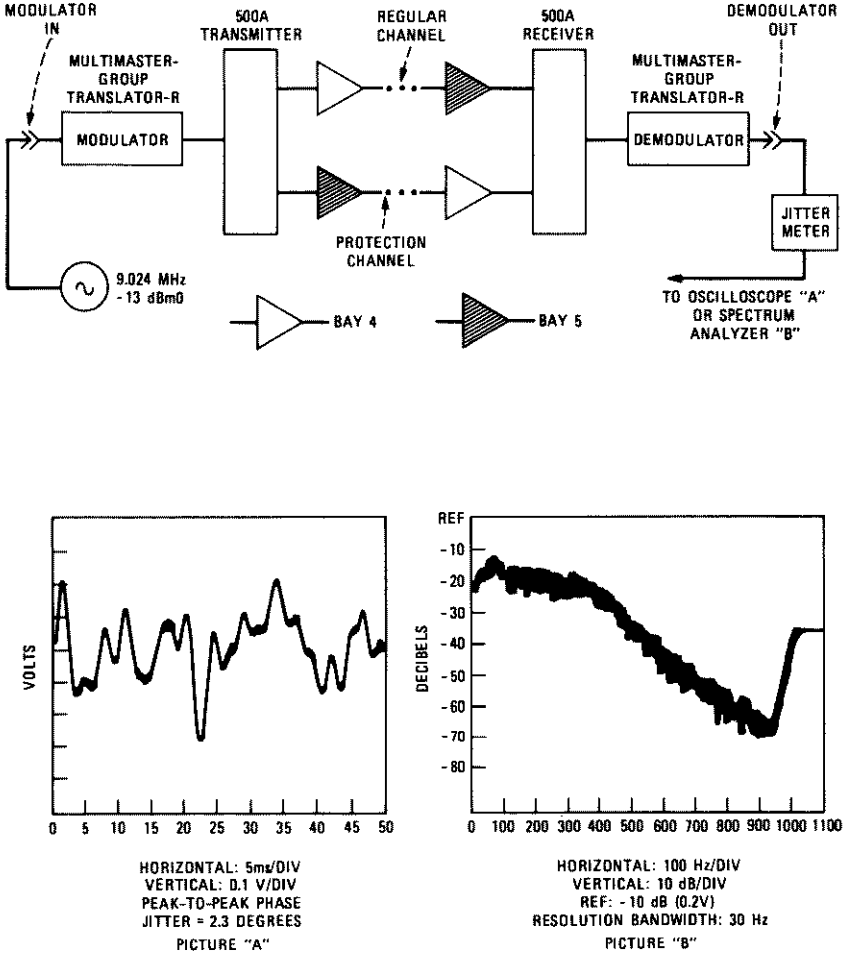

Fig. 14—Phase-jitter measurements.

pursued on the laboratory setup, thus eliminating a great deal of travel time and allowing testing, which led to a rapid resolution of problems.

For example, during the minitrial in western Massachusetts, a fade deep enough to produce either a space-diversity switch or pilot resupply switch caused multiple switching activity. The laboratory setup showed that although the average signal level was insufficient to call for the switch, switching was being initiated by noise spikes due to a peak detector with minimum filtering. Modifications were made to the detector circuitry such that switching was done on an average value over a few milliseconds rather than on an instantaneous peak value, thus eliminating the great number of switches that were occurring.

### 5.3 Ashburnham-Wendell field trial

#### 5.3.1 Configuration

A field trial consisting of a one-hop loopback of AR6A prototype radio bays was conducted during the period of October 1977 to July 1978 between Northeastern Area Long Lines radio stations in Ashburnham and Wendell, Massachusetts. The Ashburnham station was equipped as a main station and the Wendell station as a repeater site. The hop length was 29.3 miles, and BTL model 656A microwave preamplifiers were used at both receivers. The Ashburnham radio bay transmitted on radio channel 22 (6226.89 MHz) with vertical polarization and the Wendell bay transmitted on channel 12 (5974.85 MHz) with horizontal polarization, which made both bays standard in their channel arrangements. Both stations had prototype support bays that contained the pilot resupply and microwave carrier synchronization supply (MCSS) equipment. In addition to the radio equipment, each station was equipped with a PDP-8 computer which served as a Data Acquisition System (DAS) for complete monitoring and recording of all bay alarm and indication activity. A simplified diagram of the trial equipment is shown in Fig. 15.

#### 5.3.2 Installation and alignment

As a test of the modular design concept Western Electric installers installed the basic bay framework and wiring. The actual assembly of the TR modules in the bay framework was performed by AT&T Long Lines personnel. The installation process was photographed and these photographs along with the documentation from Bell Laboratories were used to generate the installation Bell System Practices.

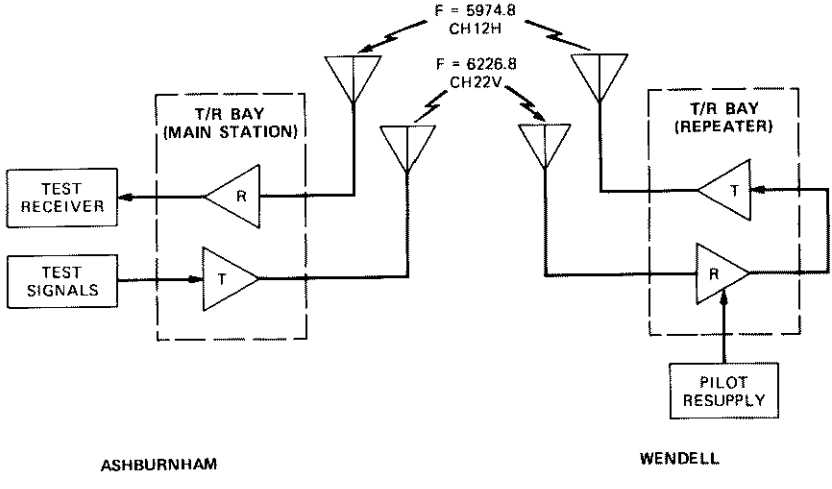

Fig. 15—Ashburnham-Wendell field trial equipment configuration.

#### *5.3.3 System performance*

Prior to shipping, the AR6A radio equipment underwent extensive laboratory measurements to fully characterize it. The measurements included thermal and intermodulation (IM) noise, and amplitude response. Initial system measurements made on the Ashburnham-Wendell installation showed good agreement with the laboratory results. Received signal levels agreed with calculated values indicating nominal section loss in the two directions of transmission. These results were further confirmed by thermal noise measurements. Long-term measurements were conducted on received signal strength, IM performance, and thermal noise. The results of these measurements indicated performance adequate or better than that required to meet system requirements. In particular, the long-term behavior of the IM noise was encouraging, indicating that the predistorter realignment intervals would be acceptably long. Examination of the received signal strength and noise slot data during fading activity indicated that the AGC amplifier and dynamic equalizer responded adequately and that space-diversity switch requests were generated at the planned level of 36 dB of fading.

### *5.4 Factory testing*

Historically, radio bays have been installed and tested on site by Western Electric installers. Fully tested and operating bays are then turned over to the operating company. The AR6A modularity concept changed this procedure to one where the customer receives factory tested modules and assembles them to produce a working bay. To ensure that the customer could bring his equipment on line in a timely manner, two procedures were initiated. First, a level of spares was specified that should ensure inhand replacement units to offset initial failures and units damaged in shipment. Secondly, a factory testing program was initiated requiring that all modules be assembled in a test bay and functionally tested before shipment. Both of these procedures are now standard practice.

#### *5.4.1 Bay alignment*

The set of modules comprising a radio bay are installed into test bays and then the bay is aligned. Any units not functioning correctly are replaced and trouble sheets on the failed units are filed. The data collected in this procedure are then used to identify problem units and the type of problem often helped identify the solution.

#### *5.4.2 Back-to-back testing*

To ensure that a quality product was shipped from the factory, the eight performance tests listed below were performed on each aligned bay:

1. Amplitude response
2. Phase jitter—TR pair
3. Phase jitter—microwave generator
4. Spurious tones
5. Spurious modulation
6. Thermal noise
7. Intermodulation noise
8. Pilot resupply operation.

When factory production was first begun, the bays were produced in frequency-compatible pairs. After bay alignment was completed, the pair was connected back to back (at RF) and the performance tests conducted. As production increased, test bays containing a frequency shifter were constructed so that the performance test could be performed on individual bays. After 126 bays had been tested it was determined that other bay tests were sufficient, so that back-to-back tests were discontinued.

### *5.5 Missouri trial*

During the period from July 1979 through June 1980, an initial evaluation of AR6A was conducted on a six-hop trial switch section between Hillsboro and Windsor, Missouri. This was part of a new 6-GHz route being established between Hillsboro, Missouri, and La Cygne, Kansas, for the first service route of AR6A (see Fig. 16). To allow field evaluation of upper and lower sideband transmitter modulators, radio channel 4 employing the lower sideband and channel 5 employing the upper sideband were installed. This arrangement also allowed for the measurement of adjacent-channel interference, an important factor in overall noise performance.

#### *5.5.1 Installation*

The 6-hop trial route was equipped as a two-way, 1 × 1 frequency-diversity protection system. Hillsboro and Windsor were equipped as terminal main stations and the five stations, Richwood, Rosati, Brinktown, Barnett, and Cole Camp were the connecting repeater stations. Installed at each of the repeater stations were four repeater bays and a support bay. Hillsboro, which is a terminal main station, was equipped with standard radio bays configured for main station application. In addition to the radio bays, a 500A protection switch, MMGT-R, 500B protection switch, and MGTB multiplex were also installed.

Windsor is a repeater station on the final expansion of the route to La Cygne, but for this trial was to serve as a terminal main station for AR6A. This required that two transmitter-only bays and two receiver-only bays (standard options) be installed at Windsor for normal

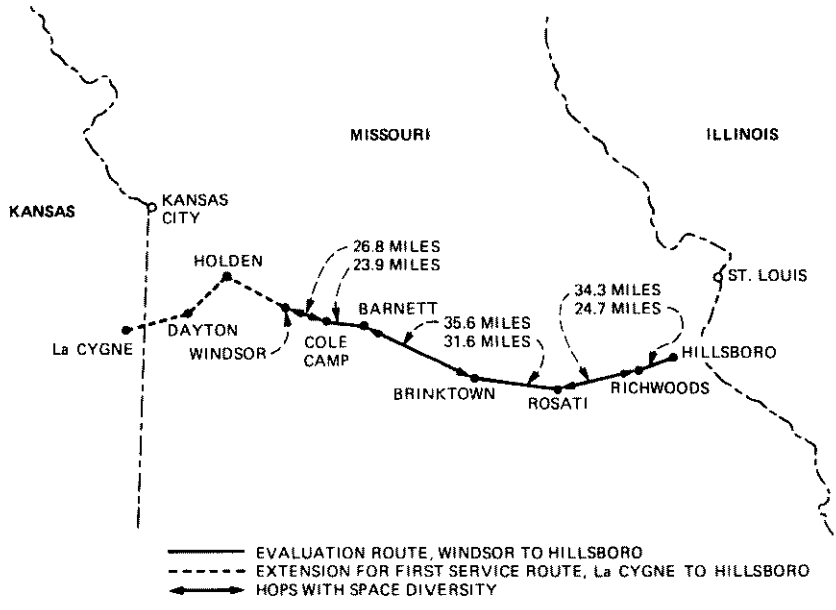

Fig. 16—First service route of the AR6A System.

connection to the indoor waveguide. And, of course, a 500A protection switch, MMGT-R, 500B protection switch, and MGTB multiplex were also installed. To allow signals transmitted from Hillsboro to be looped back to Hillsboro, a set of mastergroup connectors also were installed at Windsor.

Alternate hops on this route were equipped with the space-diversity option. This required that a space-diversity antenna be installed at all stations but Hillsboro.

A Bell Laboratories prototype TSS-R remote distribution bay was installed at both Hillsboro and Windsor. This allowed field evaluation of the distribution bays and their interaction with the TSS-R central minicomputers located at Bell Laboratories.

In addition to the radio equipment, each station was supplied with a PDP-8 computer that served as a Data Acquisition System for complete monitoring and recording of all bay alarm and indication activity. This system was connected to a PDP-8 computer at Bell Laboratories, Merrimack Valley, to allow for continual monitoring of the trial.

### *5.5.2 Antenna tests*

The trial route, being part of a new 6-GHz route, had newly installed antennas between Hillsboro and Richwood and newly installed space-diversity antennas. A series of antenna measurements were made to

characterize the transmission environment for AR6A radio. The measured parameters included section loss (SL), amplitude response, cross-polarization discrimination (XPD), and front-to-back (FB) ratio. In addition, checks for RF interference were made at each receiving antenna. The test results indicated generally good antenna performance; however, one antenna at Cole Camp did have to be reoriented slightly to meet AR6A System requirements. Junction interference from a TH-3 crossing route at Rosati was severe and had the potential to cause an improper sequence of operation of the space-diversity and 500A switching systems. This situation was corrected before the AR6A hop and switch section tests began.

#### *5.5.3 Hop tests*

The installation and alignment of the TR bays were performed by AT&T Long Lines technicians and served as a field trial for the initial issue of the BSPs. Radio bay hop tests were then performed jointly by AT&T Long Lines communication technicians and Bell Laboratories personnel. These tests afforded an opportunity to update and refine the hop turn-up BSP. These tests check such parameters as path loss space-diversity switch point, and pilot resupply initiate switch point.

#### *5.5.4 Switch section tests*

Switch section tests were performed in three parts. First, those tests necessary to condition a switch section for service were performed. Second, a series of tests were performed to measure the channel performance, and, third, testing was done with TSS-R to verify its performance. Initial switch section testing normally is performed by TSS-R, as discussed in Section 4.9.2. However, at the start of this field trial, TSS-R was not in operation. The same measurements were performed manually as would have been performed by an operational TSS-R System to condition the switch section for service. Performance of the test in this manner served two purposes. First, a database was generated for comparison with initial TSS-R measurements and, second, the latter measured performance of the switch section would determine if the set of TSS-R tests was adequate to condition a channel for service.

The amplitude response of each of the four channels of the switch section from 500A transmitting switch to 500A receiving switch were measured. The results of these tests were then used to compute the number and type of 989-type mop-up equalizers required to equalize the channel to a 0.5 dB flatness. Figure 17 shows a typical radio channel response after amplitude equalization. These tests showed that ordering information for mop-up equalizers did not supply a proper selection of equalizers. New ordering information for the mop-

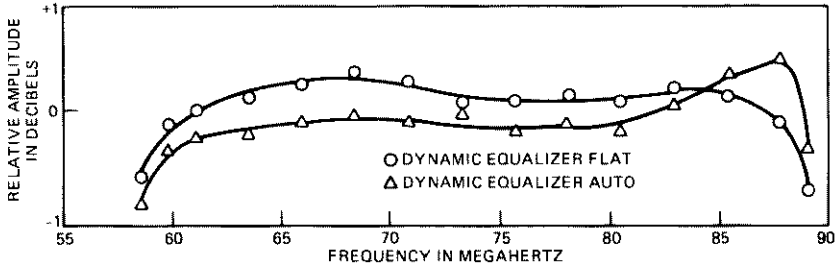

Fig. 17—Typical radio channel response after amplitude equalization.

up equalizers was generated based upon the results of these tests and analysis of factory test data from the initial bays.

The rest of the out-of-service switch section tests listed in Section 4.9.2 were performed on the four channels. The measured thermal noise was slightly higher than desired. This result was not totally unexpected since some of the initial TWTs had a higher noise figure plus gain sum than specified. This sum (noise figure plus gain) is now used as one of the screening tests for tubes used in systems now operating.

A test of system linearity was of significant importance. Hop and switch section linearity were specified based upon the system model. During the trial, it was found that even though every transmitter met its linearity requirement, some hop and switch section limits were difficult to meet. It was determined that these limits were too stringent because of such variables as hop length, systematic level error, and intermodulation noise contribution from the end hop containing a 500A switch. As a result, new limits for hop and switch section linearity were developed that were more realistic, yet ensured system integrity.

The noise and tone scan performed on each channel showed a few undesired tones in the band, which were identified as originating in the multiplex. These tones are harmonics of carriers and, with production-type filters, are eliminated. With the out-of-service tests completed, noise loading tests began. During this second phase of testing, three types of noise load tests were made. The first type was performed using a test signal generated at basic mastergroup level. Ten basic mastergroups of noise were generated and loaded onto the system at the MGTB. The second type of noise loading was performed by bridging on a live signal obtained at the mastergroup distribution frame. This allowed a comparison of random noise load results with a live signal result. The third type of noise loading used a pseudorandom noise source.[9] These tests were performed to determine (1) the level and type of nonlinearities in the system, and (2) the law of addition, i.e., how these nonlinearities add on a hop-to-hop basis.

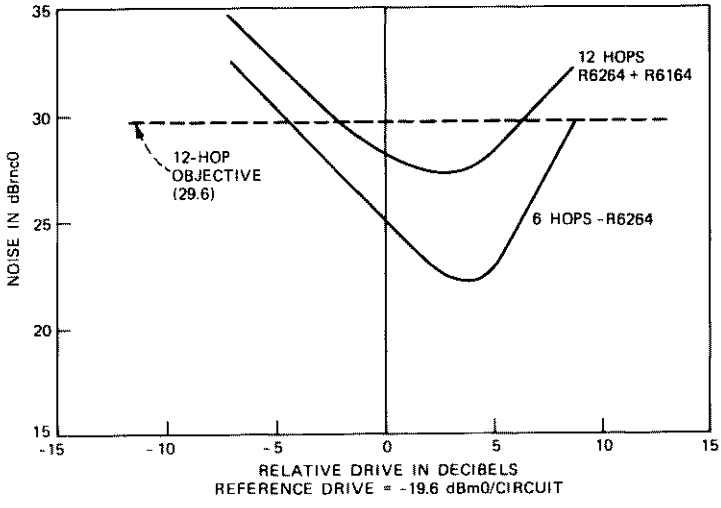

Fig. 18—Noise load tests made during the AR6A field evaluation.

Random noise load measurements were made first on each of the six-hop channels using a random noise load. This measurement was made by looking in a noise slot in each of the ten mastergroups. Figure 18 depicts the results of one such measurement. Measurements were then repeated for a 12-hop switch section by looping back at Windsor first at the 500A, and then at the MGTB employing mastergroup connectors between the transmit and receive MGTB. The results of 6- and 12-hop switch section measurements are shown in Fig. 18. These types of measurements were made early during the field trial, again after several months of operation in which no particular effort was made to keep the channel in peak operating condition. They were then repeated near the end of the trial after all transmitters were realigned to ensure their best linearity performance. A hands-off period of two months was then allowed, and the noise loading tests were repeated to obtain aging information.

Noise loading was also performed using live signal load before and after the hands-off period. The tests employing a live load used nine mastergroups bridged from the mastergroup distributing frame and one mastergroup of random noise containing the measurement slot. This mastergroup could be placed on any of the ten mastergroup positions in the channel. The results showed slightly better performance than the random signal, since the average load with a live signal is less than a noise load due to varying talker activity and volume.

Pseudorandom noise loading allowed measurement of IM distortion produced in the channel. These measurements were performed on the radio portion of the switch section only, that is, from transmitter "in"

to receiver "out" of the switch section. The test signal was applied at the transmitter "in" on the radio bay at Hillsboro and recovered from the receiving "out" port of the same bay. To complete the circuit, a patch was made at Windsor to loop back the signals between receiver and transmitter. The receiver of the test set measures the total IM signal (generated by the 12 radio bays) that falls into a narrow (3-kHz) band. These measurements were made for the expected range of system signal powers to ensure that the IM products were within limits for all operating conditions.

As we discussed in Section 4.6.2, the IM products and their law of addition when a large number of repeaters are connected in tandem is of critical importance. A scheme was derived whereby the law of addition could be determined from a series of pseudorandom noise measurements. To perform these measurements, it was necessary to have personnel present at three stations to perform the patching so that each repeater could be measured individually and then in combination. The results of the measurements were discussed in Section 4.6.2 with the results shown in Fig. 7.

A period of the trial was devoted to TSS-R testing. During this phase of testing, each of the TSS-R measurements was performed remotely from the Merrimack Valley central computer and then repeated manually on site. This was to ensure that both the proper measurement was being made, that it was being made on the intended unit and, finally, that the results were correct. Maintenance of the AR6A System relies upon a combination of SCOTS alarm and radio indications and TSS-R in-service and out-of-service measurements. When a problem occurred on a channel, the indications from SCOTS in conjunction with TSS-R measurements were used to identify the problem and its location, so that maintenance personnel could be dispatched to that location with the necessary equipment and spare parts to effect a repair. As a result of this brief evaluation period, the maintenance scheme was judged viable, but further documentation was necessary for the users to take full advantage of the powerful tools put at their disposal.

During the course of the field trial, several minor problems were uncovered in the functional operation of both radio bays and associated 500A Switching System and the multiplex. Identification of these problems allowed for the necessary circuit changes to be implemented into the product prior to full production.

## VI. HOT STANDBY

### *6.1 System configuration*

#### *6.1.1 Repeaters*

As we mentioned in Section 1.5, the AR6A hot-standby configura-

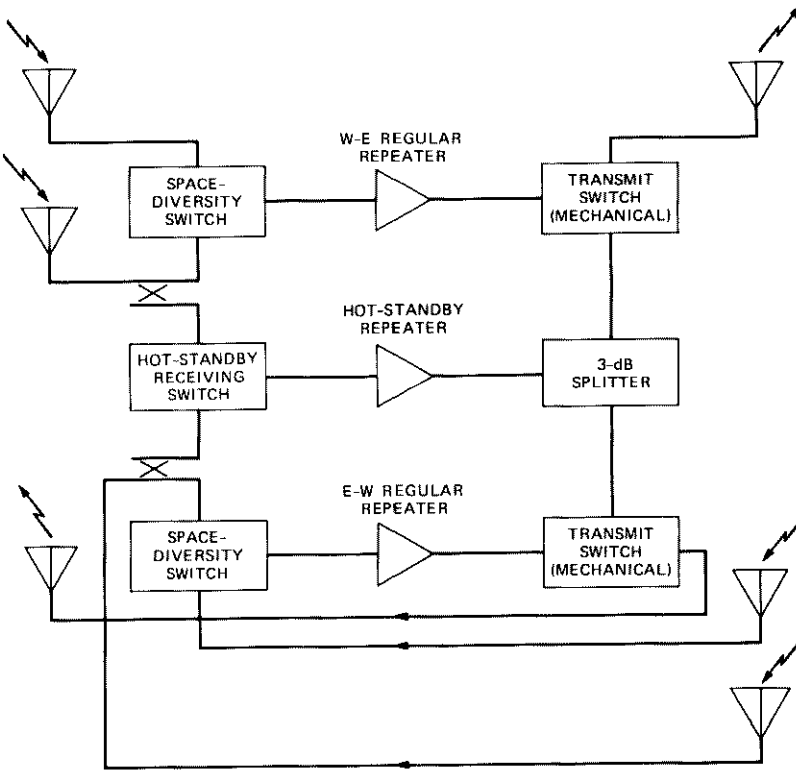

Fig. 19—Hot-standby repeater configuration with space diversity.

tion uses a single hot-standby repeater to protect both directions of transmission. This is illustrated in Fig. 19, which shows a repeater configuration using space diversity.

The primary monitoring function determining whether a TR bay is in satisfactory condition is provided by a broadband power monitor at the transmitter output. Under some trouble conditions associated with high receiver gain, it would be possible for broadband receiver noise to look like a message load, thereby deceiving the power monitor. To avoid this difficulty, high receiver gain operates the pilot resupply switch at the receiver output in the same way as it does in frequency-diversity applications. However, since resupply pilots are not needed for hot standby, the normal pilot input port can be terminated. Thus, when the resupply switch is operated, the transmitter input is automatically terminated, providing the equivalent of a squelch.

Figure 19 shows that in the hot-standby mode the hot-standby receiver does not have space diversity. This eliminates the necessity and complication of transferring the space-diversity control function

between regular and hot-standby bays. The simplification is justified on the grounds that the estimated simultaneity of equipment failure and fading is small enough to be neglected.

The microprocessor-based control unit, in addition to monitoring transmitter power output and other status indicators, arranges the sequence of switch operations during the transfer to or from hot standby. In addition, it provides local and remote status information and supervises local and remote commands with predetermined override priorities. Important considerations relating to the reliability of the 1 × 2 hot-standby configuration are discussed in Section 6.2.

### *6.1.2 Main stations*

Main stations do not lend themselves to a 1 × 2 hot-standby protection arrangement since in general there is only one TR unit per channel at these locations. As a result, main station protection is provided on a one-for-one basis for both transmitters and receivers. A block diagram of the protection arrangement that is integrated with the 501A Protection Switching System is shown in Fig. 20. In essence, the transmitting portion of the 501A System double feeds two transmitters whose outputs are selected by a transmitting switch supervised by a control unit similar to the one used at hot-standby repeaters. On the receive side, receiver selection is performed by the 501A switch on

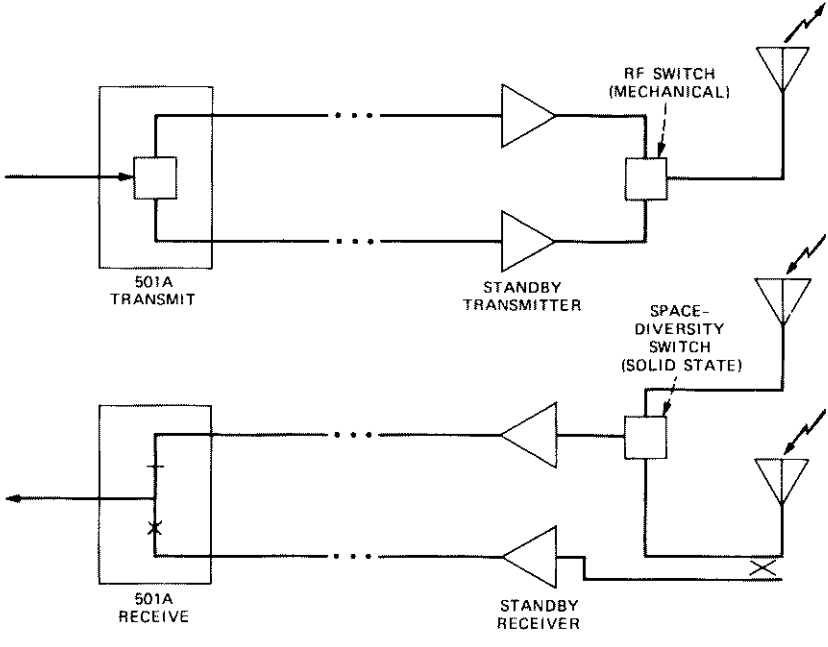

Fig. 20—Hot-standby main station configuration with space diversity.

the basis of noise and pilot monitor information identical to that employed on the 500A System.

Interface levels between the 501A System, TR equipment, and multiplex equipment are identical to those employed in the frequency-diversity 500A configuration. This simplifies the conversion from hot standby to frequency diversity when justified by growth in the route cross section.

### *6.2 Reliability considerations*

The main station 1 × 1 hot-standby configuration follows conventional design practice and will not be discussed in detail. For these systems, the use of high-reliability components and subsystems provide adequate overall equipment reliability.

The outage probability of the repeater station configuration shown in Fig. 19 can be expressed as

$$P_0 = P_B^3 + 3P_B^2(1 - P_B) + 2P_S P_B(1 - P_B)^2 + 3P_S' S_B(1 - P_B)^2 + P_S'(1 - P_B)^3, \quad (8)$$

where

$P_0$ = two-way equipment outage probability,
$P_B$ = outage probability of a radio bay,
$P_S$ = probability of switching system failures that do not cause immediate service outage, and
$P_S'$ = probability of switching system failures that cause immediate service outage.

An example of a failure included in $P_S$ is a loss of power to the switching system when it is in the normal state with both regular radio bays operable. The system equipment outage objective results in the requirement that $P_0 \leq 3.21 \times 10^{-7}$. Preliminary calculations showed that, for expected equipment failure rates and a 2.25-hour mean repair time,[12] the sum of the first four terms of eq. (8) would be less than the required $P_0$ with reasonable margin. Preliminary calculations for $P'$s, however, showed that the last term would be roughly equal to the requirement and special design features would be needed. The probability $P'$s was reduced by requiring two independent circuits to simultaneously cause the electromechanical switch shown in Fig. 21 to connect the hot-standby bay to the antenna. Failures in either circuit then cannot cause a loss of service if the opposite direction of transmission is connected to the hot-standby bay input. With this design feature, the equipment outage objective is met for the calculated equipment failure rates.

For hops having space diversity, it was found that in order to meet equipment reliability objectives the space-diversity switch would have

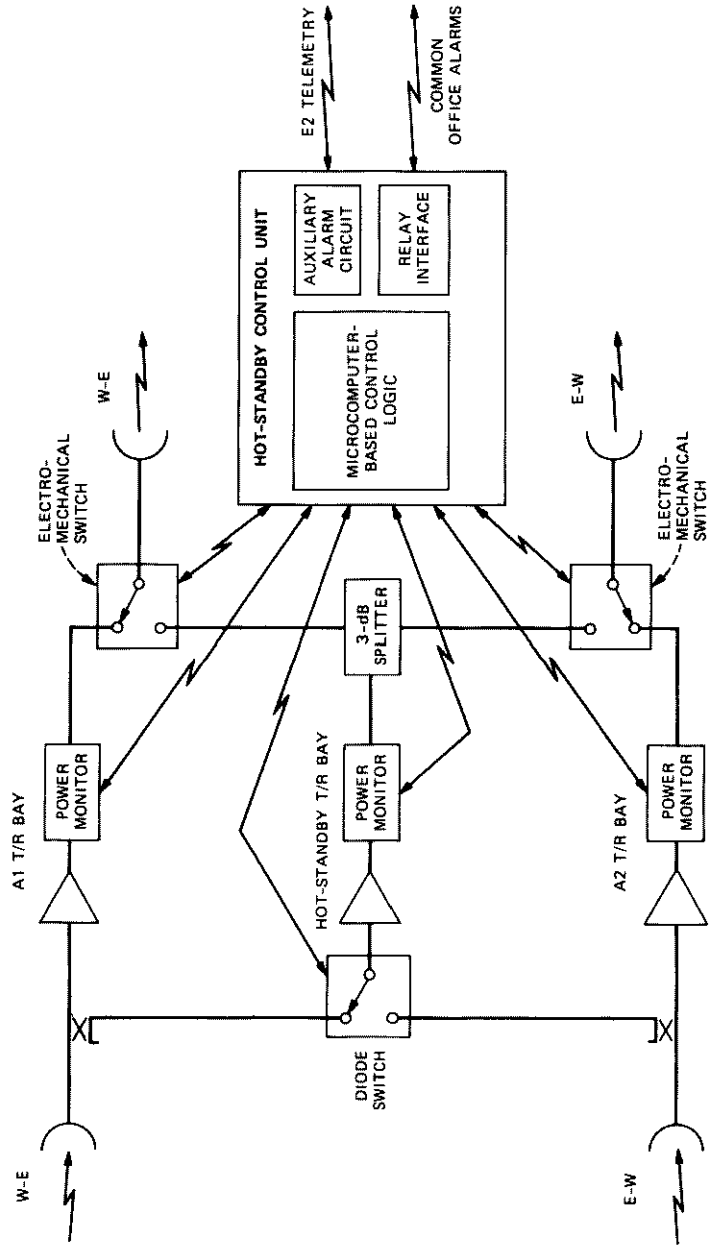

Fig. 21—Block diagram of the 1 × 2 Hot-Standby Protection System.

to be included within the transmission path protected by the standby bay. This leaves the hop without space-diversity protection when the regular radio bay fails but the calculated increase in fading outage is less than 5 percent. The overall reliability of this configuration is better than a design that leaves the switch outside the protected path.

### *6.3 Switching and control features*

A block diagram of the hot-standby switching and control system configuration for repeater stations is shown in Fig. 21. A microcomputer-based control unit is used to control all switching activity and provide equipment checking for alarm purposes. The auxiliary alarm circuit monitors dc power and provides information to the common office alarms. The relay interface conditions the alarm signals for the C1 or E2 telemetry and common office alarm systems.

The hot-standby control unit has three modes of operation: automatic, local, and remote manual. Under normal conditions in the automatic mode, the transmitter electromechanical switches connect the regular (A1 and A2) TR bays to the transmitting antennas. Radio bay failures are detected by the power monitors. A failure of either bay A1 or A2 will cause the system to replace it with the hot-standby bay. For transmitter failures, the loss of signal during switching will normally be less than 15 ms. For receiver failures, the loss will be approximately 50 ms. The standby bay will remain in service until either the regular bay returns to normal or a switch command in the local mode is issued. To revert automatically from the standby bay, the regular bay must be operating correctly for 2 seconds. If another bay should fail when the standby bay is in service, then the appropriate service failure alarm will be set. To prevent unnecessary switching due to failures at a previous repeater, a simultaneous failure of a regular bay and the hot-standby bay is interpreted as an input signal failure and no switching action is taken.

The local mode of operation is provided for maintenance and trouble isolation. The local actions include manual switching of the hot-standby bay to replace either regular bay and a lockout of the standby bay. When the local mode is entered, the pushbutton actions take precedence over switch requests indicated by the power monitors.

If the system is in the automatic mode and the standby bay is idle, the remote manual mode can be enabled by the C1 or E2 telemetry. The remote switching and lockout commands are identical to the local ones. If a service-affecting failure occurs while the system is in the remote mode, a reversion to the automatic mode takes place and the service is protected.

## VII. CONCLUSION

The economic attractiveness and efficient spectrum use of the AR6A

System has led to its rapid deployment throughout the United States. The relatively trouble-free introductory experience with this new technology system is a tribute to the many people who contributed to its development. As the authors of this overview article reporting on the work of many colleagues, we wish to acknowledge the contributions of all who participated in the project.

## *The AR6A Single-Sideband Microwave Radio System:*

# Radio-Line Physical Design

By S. A. HARVEY* and P. D. PATEL*

(Manuscript received February 7, 1983)

The physical design of the AR6A radio-line equipment is the product of combining the system operating requirements with the technology available to meet those requirements economically. As part of the description of the radio-line equipment, we discuss the practical considerations for partitioning the circuit block diagrams into realizable units. Modularity is a new feature incorporated into the design of the transmitter and receiver radio bay. We also describe a novel thermal design detail used with discrete transistors in the IF circuits to ensure their reliable operation.

## I. INTRODUCTION

AR6A† radio is a new high-capacity, long-haul microwave radio relay system operating in the 6-GHz common carrier band. The use of single-sideband modulation for this high-capacity system was made possible only through the achievement of a high degree of system linearity, which was obtained by designing each circuit within the AR6A System to meet a linearity performance objective. Closely coupled with the system and circuits development of AR6A was the physical design of the radio-line equipment. The Transmitter-Receiver

(TR)* bay, the TR support bay, and their constituent modules are the principal elements of the AR6A radio-line equipment.

The configuration of this equipment is the culmination of the physical design effort applied to the AR6A System requirements. Physical design is a product creation process that takes a design concept through an iterative development stage and then into manufacture. The driving force behind any new product development, such as AR6A, is the potential market for that product. The AR6A market was identified as the need for a high-capacity, long-haul 6-GHz microwave radio system to overbuild the existing operating companies' long-haul 4-GHz TD-2 and TD-3 radio routes. The principal operating environment for the AR6A radio-line equipment would be within the existing radio station buildings of the TD radio network.

The physical design process began when the AR6A transmitter-receiver was transformed from a systems concept into a functional block diagram. Partitioning the system block diagram into realizable circuit modules was the first step toward the physical design concept. Consideration for the existing buildings and the goals of the operation and maintenance plans was used to determine several fundamental physical design objectives. These objectives were: (1) to assemble a single AR6A transmitter and receiver unit into one radio bay framework, (2) to assemble the common radio-line equipment into one support bay unit, (3) to design for modular field assembly of the TR bay, and (4) to design the radio-line equipment for a nonair-conditioned building environment.

The physical design effort can be divided into two categories: (1) an overall equipment design level, and (2) an individual module design level. The overall equipment design effort is concerned with putting together the many individual circuit modules into one functioning unit, while at the individual design level we concentrated on providing the required circuit functions within the physical bounds determined by the overall equipment design concept. These two categories of design must go on together during development as neither can proceed very far without some knowledge of the other.

The overall radio-line equipment concept was the outcome of an iterative process of configuring each circuit module and then arranging the modules spatially within the framework so that all the physical design objectives were met simultaneously. The particular configuration of each circuit module was influenced by three principal factors: (1) the technology available to implement the required circuit function, (2) the thermal design requirements of the module, and (3) the spatial

* Acronyms and abbreviations used in the text and figures of this paper are defined at the back of this *Journal*.

relationship of the circuit module with respect to the overall equipment concept. The final physical form of each module emerged from the integration of its individual design objectives into the overall equipment concept.

The challenge of this physical design process was to produce AR6A radio-line equipment designs which met both the system performance requirements, and were economically attractive to purchase, to operate, and to maintain.

## II. RADIO-LINE EQUIPMENT DESCRIPTION

Figure 1 is a simplified block diagram showing the AR6A transmitter, receiver, and the common radio-line functions. The physical design realizations of this functional diagram are the AR6A TR bay and the AR6A TR support bay.

### *2.1 Transmitter-receiver bay*

The AR6A TR bay, as shown in Fig. 2, is assembled onto a 19-inch panel framework with overall dimensions of 22-3/8 inches wide by 15-1/2 inches deep by 9 feet tall. All the TR bay components are mounted below the 7-foot level in accordance with human factors design considerations. The TR bay is composed of three sections: (1) an upper section consisting of an Intermediate Frequency (IF) shelf assembly and plug-in units, (2) a middle Radio-Frequency (RF) section made up of waveguide-type components, and (3) a lower housing for power supplies and the microwave generator. The predominant color is light gray, which is in harmony with existing radio station equipment. The rest of the color scheme is black, red, and dark blue-gray blended with natural and applied finishes on aluminum, brass, copper, and steel.

The six common alarm and control interface circuits are on printed wiring boards complete with faceplates and are located on the top left level of the IF shelf assembly. A dc-to-dc power converter, which is the common low-voltage power supply for the IF shelf, is located at the upper right-hand side. The majority of the transmitter and receiver IF circuit functions are housed in 12-inch by 12-inch by 2-inch plug-in modules. These IF modules are arranged together for ease of interconnection and operational access into the IF shelf. The transmission path connections are made coaxially across the front of the plug-in modules. A display panel, located immediately below the IF shelf, provides a surface for visual information and dresses the interface between the IF and RF sections.

The receive RF signal path from the indoor waveguide run or from an adjacent AR6A TR bay comes into the channel-separating filter at the 5-1/4 foot level and then down the center of the RF section. With the space-diversity option there are two receive signal paths and two

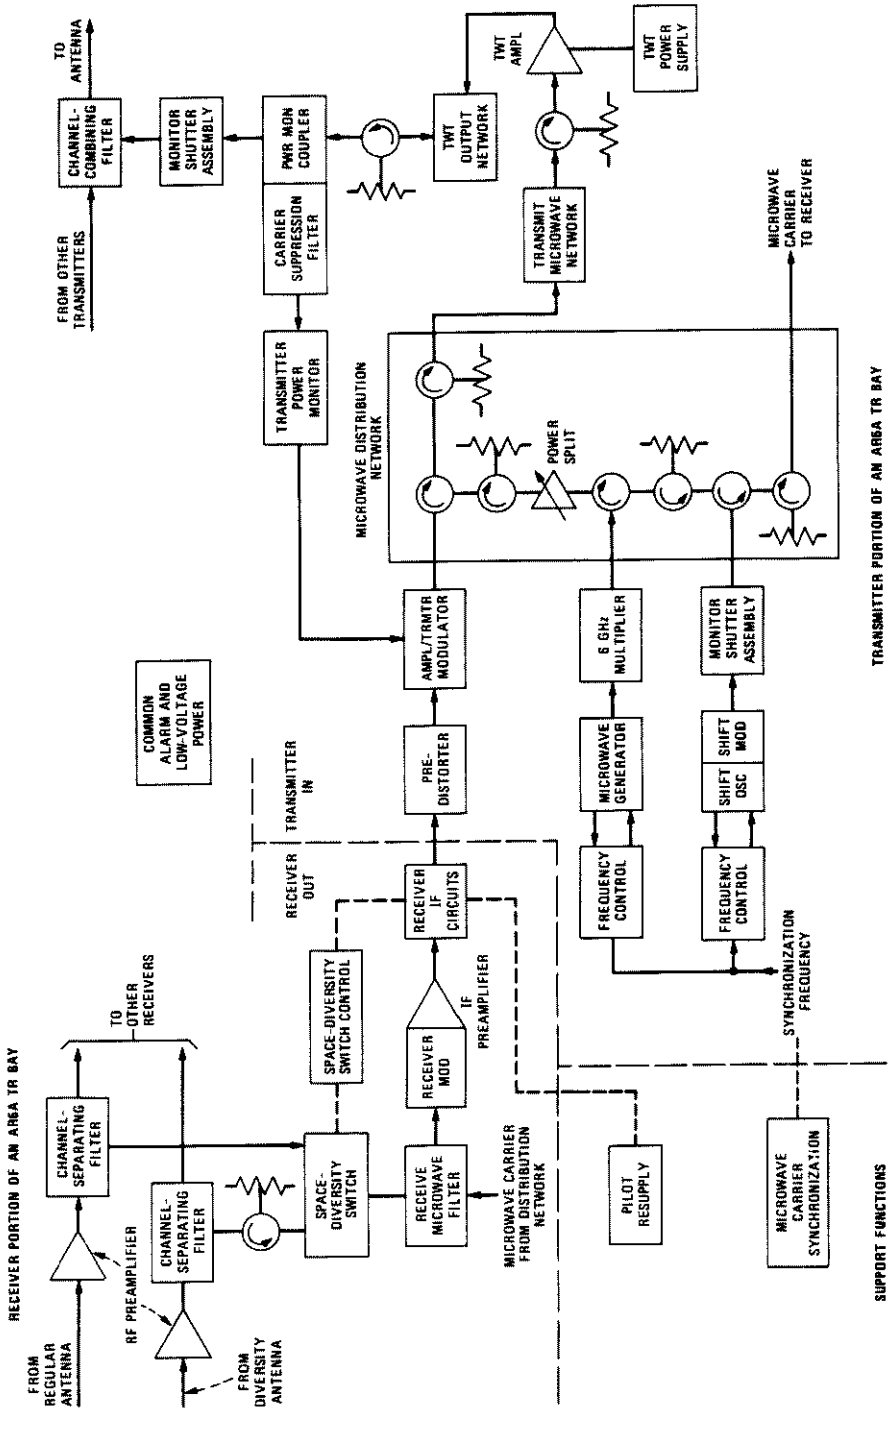

Fig. 1—Block diagram of the AR6A radio line.

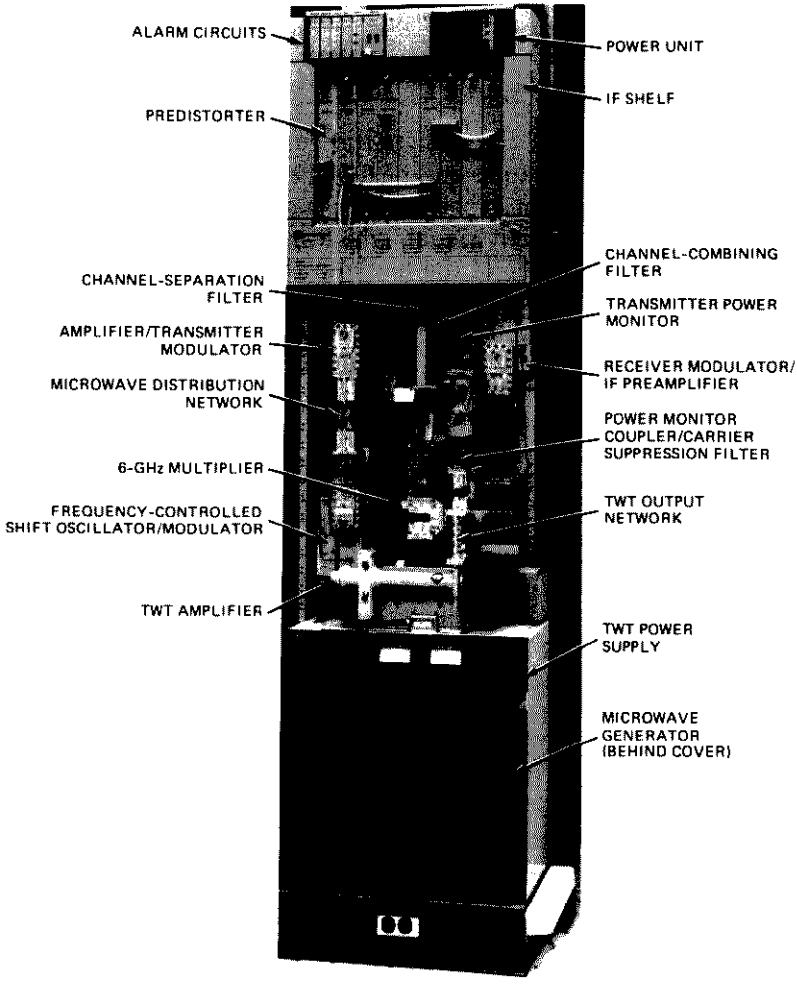

Fig. 2—AR6A transmitter-receiver bay.

channel-separating filters. The upper portions of the RF channel filters are hidden from view behind the removable display panel. The space-diversity switch allows either the RF signal from the main or the diversity antenna to be connected into the receiver. Control of the switch is provided through the switch control unit under the direction of the receiver IF section. The receive signal output from the space-diversity switch is fed through flexible waveguide up to the right, through a waveguide RF filter, and into the receiver modulator. Here the RF signal is down converted to a 59- to 89-MHz IF signal and

then amplified in the IF preamplifier unit. This IF signal is cabled up the right to the IF shelf modules where it is passed through each IF module from right to left. The IF modules include filters, amplifiers, and equalizers.

The first element of the transmitter function is the predistorter, which is the leftmost unit on the IF shelf. In a repeater TR bay configuration the output of the receiver is connected directly into the transmitter. The transmit signal, which is still in the IF format, is cabled down the left side of the bay into the IF driver amplifier and transmitter modulator. After the up-conversion process, the resulting signal is transmitted through an RF waveguide filter to the Traveling-Wave-Tube (TWT) amplifier. A transition-to-coaxial cable is used to provide the input to the TWT. The amplified RF signal continues up through a reduced-height waveguide filter and into a waveguide directional coupler. A small sample of the output RF signal is passed through a waveguide filter and then coaxially fed into a power monitor. The RF signal path continues up through a monitor port and into a fixed waveguide-to-coaxial-to-waveguide network. This network makes a compact RF connection to the channel-combining filter. The transmit RF signal path continues out from the combining filter into an adjacent AR6A TR bay or into the indoor waveguide run.

The TWT high-voltage power supply is located in the lower housing directly below the traveling-wave-tube amplifier. The outer shell of the TWT power supply fills the available space for safety and operational considerations. The distinctive shape and color forms a visual transition between the RF section and the lower third of the TR bay. The microwave generator and a −19V dc power regulator unit are mounted behind the cover in the lower housing. The microwave generator is an oven-controlled crystal oscillator with multiplier stages to achieve a 1-GHz output. An external reference frequency is used to stabilize the output frequency. The 1-GHz output from the microwave generator is fed coaxially up to the RF section where a microstrip RF multiplier unit provides the local oscillator signal. This local oscillator signal is supplied via coaxial cable to a distribution network where it is split into two signal paths. One signal path goes directly to the transmitter modulator and the other signal goes to a frequency shifter. The shift oscillator/modulator shifts the transmitter local oscillator signal frequency by 252 MHz to provide the receiver with its local oscillator signal. The shift oscillator is also stabilized by an external reference through a frequency control unit.

### *2.2 TR support bay*

The common functions that are required to operate and maintain the AR6A radio-line transmission path have been configured into a

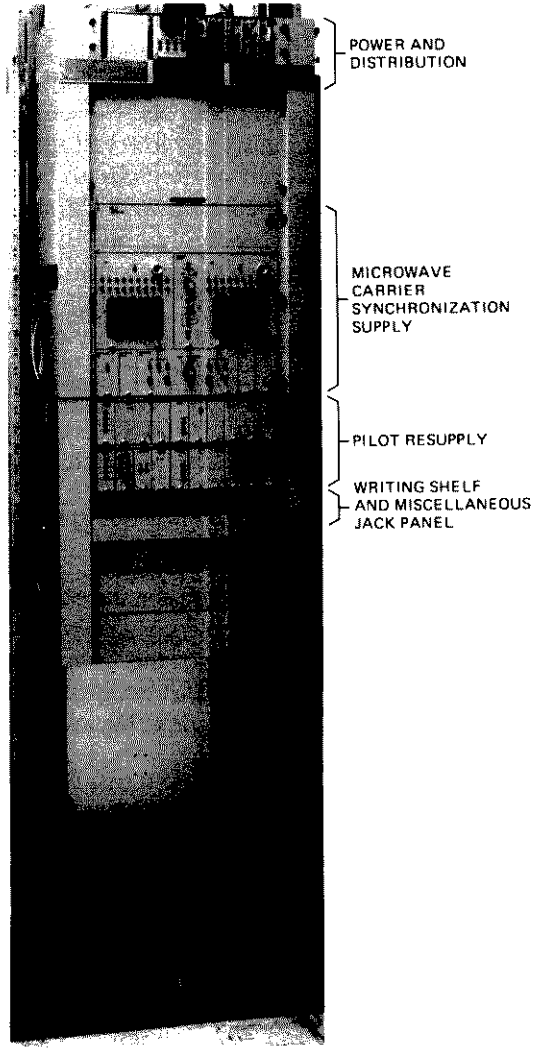

Fig. 3—AR6A transmitter-receiver support bay.

TR support bay unit, which is shown in Fig. 3. These common functions are: (1) the station reference oscillator and its control circuits for synchronization of the local oscillator frequencies within the TR bays, (2) the radio-line pilot resupply oscillators, (3) the additional oscillators and control circuits for out-of-service testing of the TR bays, and (4) the fusing and alarm circuits for the common waveguide RF preamplifiers.

The TR support bay uses the same size framework as does the TR

bay so that it can be placed compatibly in the same equipment lineup as the TR bay. Its color scheme is light gray and black in keeping with the TR bay. As with TR bay, all the TR support bay components are mounted below the 7-foot level. The upper shelf assembly provides the mounting for the common TR support bay low-voltage power converters and for the fuse and alarm circuit printed circuit boards associated with the RF preamplifiers. Both the Microwave Carrier Synchronization Supply (MCSS) and the pilot resupply units, configured as shelf assemblies with plug-in modules, are positioned in the upper half of the bay framework for easy access during operation. The panel above the MCSS is reserved for the optional hot standby control unit, while the panels below the jack and access panel provide storage space for the pilot resupply distribution cables.

Additional descriptive information for the TR bay and TR support bay modules is detailed in companion articles in this issue.

## III. THE MODULAR APPROACH

An important consideration in any equipment design concept is how the individual parts are put together to form the whole. This section reviews the development of the AR6A radio-line equipment design concept as a modular approach. The AR6A radio-line equipment just described is the result of physical design planning and decision making. The planning and decision process began with the conversion of the system blocks into realizable circuits. Further refinement of the system block diagram produced the evolutional equipment partitioning into the circuit modules.

### *3.1 Modular design concept*

Recall that the physical design objectives included the design of the TR bay for modular field assembly. Station engineering and installation costs may be reduced by initially installing a complete lineup of unequipped, factory-tested, wired bay frameworks in a station, as opposed to engineering each radio-channel addition separately. Channel growth can then be accomplished by installing factory-tested TR modules, as needed, to fill out the radio route. This capability for TR bay modular field assembly provided an added challenge in the development of the radio-line equipment concept.

The initial equipment-concept decision was the selection of the 19-inch panel, duct-type framework for the radio-line equipment. We determined that the floor space available in existing radio station buildings would be sufficient for a full array of frameworks of this size. A smaller framework size would not, therefore, "save" floor space. On the contrary, a more compact framework size might create addi-

tional difficulties in engineering for the thermal design, for maintenance access, and for future changes.

A decision on the framework size could not be made without some confidence that its volume would be appropriate for the transmitter and receiver circuit modules. The size and shape of each circuit module was initially approximated based on the proposed technology for each circuit module. Alternate design options were evaluated within the criterion of meeting the overall AR6A System objectives economically. Basic decisions such as these were part of an iterative decision-making process where the impact of a decision on the adjacent levels of the physical design process was fed back to the decision makers.

Various equipment configurations of the TR bay were evaluated as possible design alternatives. The significant factors that influenced the spatial organization of the circuit modules into the final radio-line equipment concept were: (1) the modular assembly objective, (2) the human factors considerations for operation and maintenance, (3) the integration of the overall thermal design concept into the overall equipment concept, (4) the inherent size and shape of some of the circuit modules, and (5) the performance-related objective of minimizing the lengths of the transmission path circuit interconnections.

Modular field assembly was successfully accomplished by structuring the TR bay as the combination of (1) a wired basic bay, (2) a wired IF shelf assembly, and (3) an assemblage of modular RF components. The basic bay is the 19-inch panel, duct-type framework with a minimal amount of factory-installed wiring and a few mechanical piece parts to accept the mounting of the TR bay modules. The installed wiring provides an interface to the radio station dc power and alarm systems and provides the nontransmission path interconnections between the TR bay modules. Some of the mechanical piece parts are factory located with fixtures to assure the proper alignment of the RF components when they are assembled into the basic bay. This bare-bones design approach allows the basic bay to be installed in a radio station with a minimum of additional capital investment.

In the modular design concept, the IF shelf is a wired framework for plug-in modules that has a connectorized interface to the basic bay. Installation of the IF shelf and its plug-ins into the basic bay is a straightforward procedure. In contrast, the RF components did not lend themselves to a traditional modular assembly concept. However, by using the modularity guideline of ease of assembly and by carefully engineering the interface with the basic bay, an innovative modular design was achieved. Each of the RF circuit modules was connectorized, and their mounting arrangements were made easily accessible from the front of the TR bay. The frequency-sensitive waveguide components were assembled together on a supporting framework to

minimize the number of waveguide connections that would need to be made in the field. This main RF module is positioned into the basic bay on locating pins for accurate alignment of the channel filters. As an additional dividend from the modular design approach, both the factory assembly of complete TR bays and the field replacement of TR units have been made uncomplicated. The TR support bay has followed the modular design example by using wired shelf assemblies and plug-in modules. There is no advantage in field assembly, however, as the support bay must be installed completely for use with the initial group of TR bays in a station.

### *3.2 IF circuits subsystem*

The IF shelf assembly is a subsystem module within the TR bay as a whole, and, as such, it was treated as a separate entity. A close-up view of the IF shelf assembly is shown in Fig. 4. The subsystem consists of the receiver IF circuits (represented as a single block in Fig. 1) and the closely associated predistortion, alarm and interface, and low-voltage power circuits. These modules are mounted in a two-level shelf assembly that interconnects the modules via backplane wiring. The mechanical design of the shelf assembly is a combination

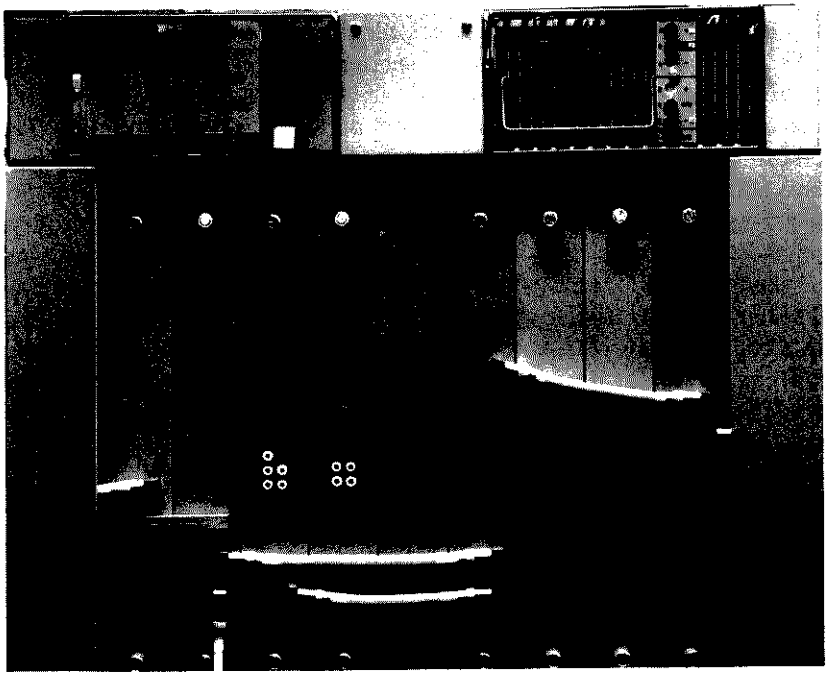

Fig. 4— IF shelf assembly.

of sheet metal fabrication and assembly techniques. Access to the bay framework mounting and the bay cabling is provided by hinged side panels.

A manufacturability cost study showed that for the IF circuits a few large integrated units would be more economical to produce than many smaller units. An electrical and physical partitioning of the receiver IF circuits was achieved based on this study. The block diagram of the receiver IF circuits is shown in Fig. 5. Each of the dashed blocks represents an identifiable circuit function. These circuit functions have been packaged as individual modules: filter/equalizer, dynamic equalizer, Automatic Gain Control (AGC) amplifier, receiver control, pilot detector, and resupply switch. A spare plug-in space is available for future needs. Further description of these modules is found in Ref. 1.

## IV. TECHNOLOGY SELECTION

The single most important physical design requirement is that the manufactured product be capable of meeting the AR6A System performance requirements. Therefore, a suitable design technology must be selected for each circuit module that will allow us to meet the individual performance requirements. The choice of design technologies affects the basic partitioning of the circuit functions into physical modules and the total volume needed to realize an equipment design concept. The evaluation of the design technology to implement any circuit function was based on an engineering estimate of: (1) the technical risk factor to achieve the performance requirements, (2) the anticipated cost to manufacture, and (3) the expected reliability.

### *4.1 Circuit implementation*

Circuit linearity is one of the most important of the AR6A performance requirements. The traveling-wave tube was selected for the critical RF amplifier function with the assurance that its inherent nonlinear, third-order characteristic could be controlled and then compensated by predistortion. The performance requirements for the three modulators (receive, shift, and transmit) could be met using modified versions of waveguide structure designs previously used in TH-3 radio.[2] Existing waveguide-based designs were selected as the technology for most of the remaining RF circuit functions. These selections were based on the technical risk confidence factor, performance, and on economic compatibility with the RF section equipment concept. For example, waveguide filters have less loss than dielectric resonator-type filters.

Key elements in the IF circuitry were developed in printed circuit board technology using discrete components. Computer-aided design

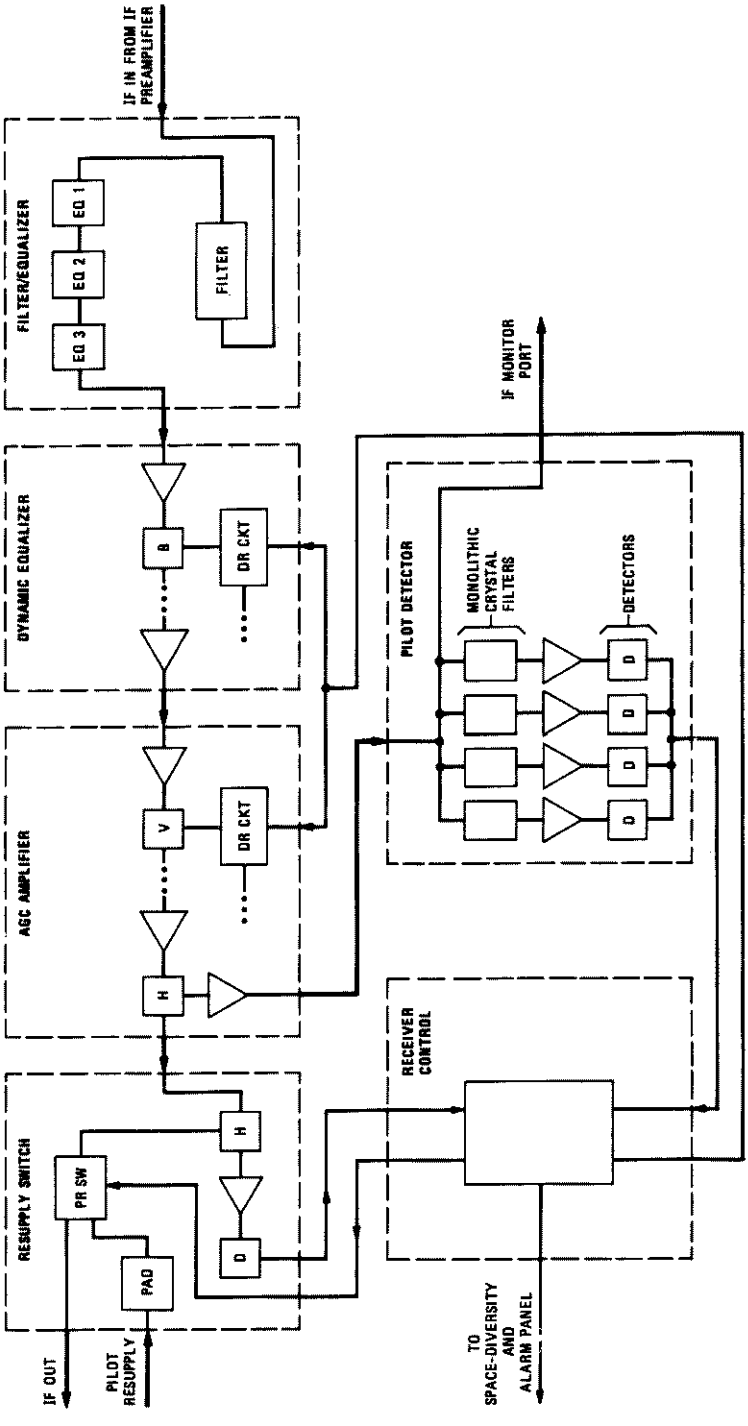

Fig. 5—Receiver IF circuits.

facilities were used to document the critical layout geometries which are characteristic of IF circuits. The performance requirements in the IF circuits were met with amplifier designs based on a hybrid-transformer feedback-transistor stage biased for linear operation. Magnetic components and crystals needed in the IF frequency range were most compatible with the use of printed circuit board technology.

### *4.2 Mechanical implementation*

A technology selection of a different kind was applied to the design of the mechanical piece parts that make up the housings and structures of the AR6A radio-line equipment. The cost of these parts and the labor to assemble them together make up a significant fraction of the total equipment cost. The economics of providing and assembling the mechanical parts is a function of the number of units to be produced. Typically for the radio-line product lines the number of units is not very large, and we use existing manufacturing facilities and tooling wherever possible. Aluminum die castings are used for the microwave assemblies to achieve the required close tolerance forms at relatively low cost due to the reduced need for secondary machining. Aluminum extrusions were utilized as linearly shaped raw material for fabrication into the IF circuit housings. These extrusions can be combined to form electrically isolated compartments within the same plug-in housing. Dip brazing techniques were used to seal those compartment sections that were particularly sensitive to Electromagnetic Interference/Radio Frequency Interference (EMI/RFI) leakage. Close tolerance stamping and forming of sheet metal provides an economical method of creating structural members and parts for the shelf assemblies.

## V. THERMAL DESIGN

The critical importance of thermal design to the operation of electronic circuits should not be underestimated. The operating temperature of the components in a circuit affects the performance of the circuit as well as its reliability. The primary objective of thermal design is to maintain the individual circuit components within the temperature limits necessary to achieve circuit performance and reliability objectives. The component temperatures will be determined by: (1) the amount of heat generated by the components, (2) the thermal impedance (°C/watt) between the components and the local ambient, and (3) the local ambient temperature. The thermal environment for the AR6A radio-line equipment is the moderately controlled interior of the radio station. The ambient temperature in a typical, nonair-conditioned, but heated, radio station may range from +4°C (40°F) to +49°C (120°F), depending on the region of the country and the season of the year. It is the upper end of this temperature range that concerns

us the most, although some unusual problems may occur at low temperatures.

### *5.1 Thermal management*

Thermal management is a design coordination method that economically achieves the thermal design objectives of the individual circuit modules within the design intent of the overall equipment concept. The thermal aspects of the AR6A radio-line equipment concept were a result of design considerations taken from two perspectives. A total assembly view arranges the circuit modules within the equipment framework to minimize the surface temperature rise of the modules above the station ambient. As part of the initial allocation of physical space within the AR6A TR bay and TR support bay, the thermal design requirements of the individual modules were important decision parameters. The individual module view considers the circuit components as heat sources and devises low thermal impedance paths to the local ambient surrounding each module. In both views physical separation of major heat sources was used to reduce the effects of localized heating on adjacent parts. Potential hot spots were identified by estimating the heat load per volume from the circuit and component information. Natural convection techniques dominate the AR6A radio-line thermal management plan in the total assembly view. In the individual module view, conduction and radiation are combined with natural convection to meet the thermal design objectives. These passive techniques are preferred over aided thermal techniques, such as fans, because of their inherent reliability and no additional energy requirement. Another aspect of the thermal management plan was the design influence directed toward energy efficiency. By reducing the power requirements for the individual circuit designs, we reduced the thermal design heat load as well.

### *5.2 Thermal design concept*

Due in large measure to the thermal management influence, the volume of the AR6A radio-line equipment framework is large enough to rely on natural convection for cooling the component modules. The thermal management plan for the TR bay is to induce air from the station to enter and flow around or through the modules. Conduction paths between the modules and the mounting bracketry aid in effectively increasing the surface area for the ultimate convection heat transfer to the station ambient. The open expanse of the middle RF section allows air from the station to circulate around the waveguide components. Some of this air is drawn up and through the IF shelf, while the rest of the air mixes back into the station ambient. The purposeful up-front position of the TWT provides for an almost direct

free-convection transfer of heat to the station ambient. Equipment mounted in the lower housing is cooled by the air that enters through openings in the lower cover, circulates, and then exits up into the rear of the RF section. For the relatively lightly loaded TR support bay, the plan was to design for natural convection from the module faceplates as the principal heat transfer mechanism. Some airflow is induced into and through the shelf assemblies for added heat dissipation.

### *5.3 Thermal design of modules*

The thermal design of each circuit module must be compatible with its other functional requirements. An ideal application of natural convection cooling would be to have the individual circuit components located within unimpeded natural airflow paths. However, because of EMI/RFI requirements, many of the AR6A circuit modules are constructed with completely closed housings. In these modules the power densities are low enough that we can use passive internal heat transfer mechanisms to provide adequate thermal paths. Special attention was paid to the localized hot spots to assure low thermal impedance paths to the outer housing. With a large surface area relative to the thermal load, the heat from these modules can be transferred to the local ambient with a small temperature gradient.

### *5.4 Special thermal considerations*

The largest single heat source in the TR bay is the traveling-wave tube used as the transmitter RF amplifier. Most of the energy in the electron beam is converted into heat at the collector end of the TWT. A critical operating requirement for the TWT is to maintain the temperature of the glass-to-metal seal at the collector below 150°C. This requirement was successfully met by a carefully designed conduction path from the collector to an external-finned heat sink. The thermal impedance between the TWT heat sink and the local ambient was minimized by choosing the optimum fin spacing permitted within the physical space allocated to the TWT.

When a thermal design requirement specifies that a component is to be operated within a narrow temperature range, it may be necessary to control the component's temperature above the ambient temperature by the addition of heat. Several of the frequency-controlling crystal oscillators in the AR6A radio-line equipment are temperature stabilized with thermally insulated oven units. The insulation provides a relatively high thermal impedance path to reduce the heating energy requirements. The control circuit of the oven is set to add no heat at the maximum expected ambient temperature and the full output at the minimum expected ambient temperature.

Two of the closed housing IF modules, the dynamic equalizer and the AGC amplifier, required additional thermal design treatment. Both these modules were provided with perforations on the top and bottom of their frames to allow air to circulate through them. The size of these perforations was selected to use the cutoff waveguide effect to minimize the EMI/RFI leakage. The AGC amplifier dissipates approximately 30 watts of power, mostly from 15 discrete transistors. A vertically finned heat sink has been integrated into the design of the frame for this module. A low thermal impedance path between the discrete transitors and this heat sink is described in the next section.

### *5.5 Heat-dissipating device*

One of the most important circuit designs used in the AR6A System is an IF amplifier stage with very stringent amplitude linearity requirements. To achieve the required linearity, each transistor is biased with a relatively large collector current. Two watts of transister bias power that is converted to heat must be dissipated while the junction temperature is maintained below 125°C. The internal thermal impedance between the junction and the external package of the transistor is 30°C/watt. A patented conduction path package[3] has been devised for this application. Figure 6 shows a cross-section of the heat-dissipating assembly. The purpose of this assembly is not only to provide a low thermal impedance between transistor header and external heat sink but also to provide a means to connect several devices mounted on a printed circuit board to a common heat sink.

The assembly consists of a cylindrical tellurium-copper body, a phenol fiber insulator, a curved stainless steel washer, and a brass ferrule. The body consists of two annular seating surfaces, or "shelves," on the inside surface. The lower shelf provides contact with the transistor, while the upper one provides a stop for the ferrule. Two diametrically opposite pins on the bottom surface of the body engage holes in the printed circuit board to provide rotational locking. The ferrule compresses the spring washer, which exerts a controlled axial force through the insulator to the transistor and, thus, provides a uniform contact pressure between the transistor header and the copper body. A selective indium plating on the inner surface of the body forms a soft interface to improve thermal contact resistance. The insulator provides electrical insulation between the transistor cover and the copper body. The ferrule has a tapped hole for assembly to the common heat sink. It seats on the upper shelf of the body when assembled. An annular groove in the top of the ferrule provides a cylindrical surface for grasping the ferrule during assembly. The outer perimeter of the top of the ferrule is chamfered so that the body may be crimped over for locking. An internal groove in the body simplifies crimping. The

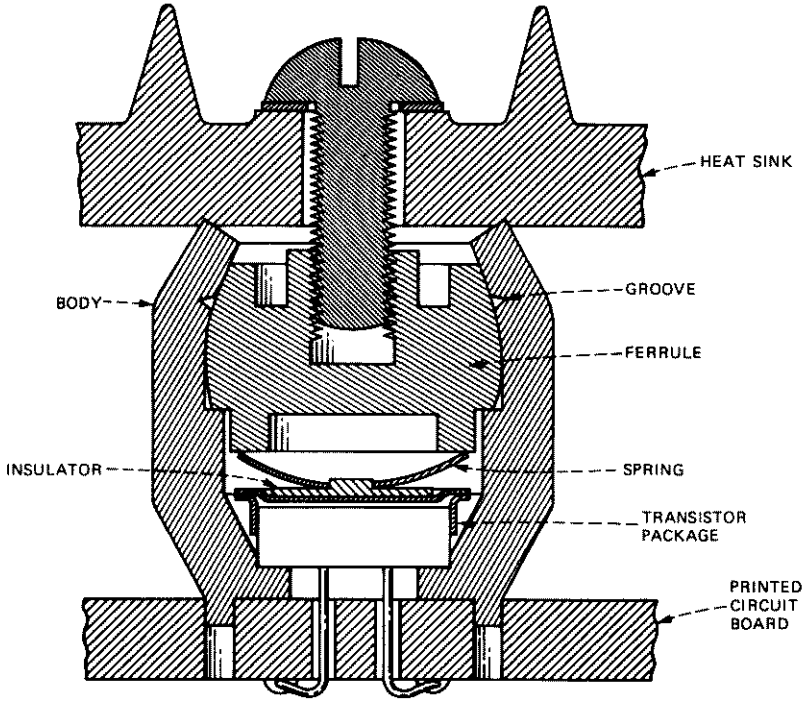

Fig. 6—Heat-dissipating assembly.

tapped hole in the ferrule is "blind" to ensure that the inadvertent use of a long screw does not damage the transistor and to keep metallic debris out of the assembly. When assembled, the ferrule is recessed slightly below the top of the body to provide consistent annular thermal contact between the body and the heat sink.

The material chosen for the body is copper alloy 145. It has high thermal conductivity and good machinability. The free-machining brass of the ferrule is excellent for screw-machine production. Most of the components are designed for screw machining for low-cost production. An assembly fixture presses the ferrule into the body and crimps the body over in a single operation. It also aligns the three transistor leads and two antirotation pins during assembly.

## VI. ADDITIONAL DESIGN CONSIDERATIONS

Every product line has a set of standard physical design criteria that all products are expected to meet. Included among these criteria, which have also been applied to the design of the radio-line equipment, are minimum requirements for structural integrity, shock and vibration, and materials selection for nonflammability and corrosion protection.

Beyond these criteria are the special physical design considerations for electromagnetic interference, human factors, and appearance.

### *6.1 Electromagnetic interference/radio frequency interference*

A continued awareness of the potential electromagnetic and radio frequency interference (EMI/RFI) problems was maintained throughout the physical design process. To prevent unwanted signals from propagating into the radio-line circuits, careful attention was placed on the application of interference suppression techniques. Closed conductive housings were used for the sensitive modules and low-pass filters were applied to their dc power and control leads. Grounding locations, and the integrity of those grounds, were particularly reviewed. Wiring and cabling paths were planned to minimize the possible radiated pickup of other signals. These requirements were purposefully blended into the physical fabrication objectives of the modules.

### *6.2 Human factors*

Human factors is a physical design consideration that includes all the interfaces a product may have with people. Of these interfaces, the most important one is safety and personnel protection. Both defined objective safety criteria and subjective value judgments were applied to design details ranging from interlocked high-voltage compartments to the removal of sharp edges and corners from exposed surfaces. Another human factors concern was the operation and maintenance aspect of the radio-line equipment. Panel and faceplate displays should be easily seen and understood by operating personnel, and normal access to the equipment should be unobstructed. On the TR and TR support bays all the important display features have been assigned to favorable eye-zone regions. The AR6A radio-line equipment has been designed for access completely from the front of the bays. Test equipment access points have been brought to front-facing surfaces, and the circuit modules are easily replaced as a part of the modular assembly concept.

### *6.3 Equipment appearance*

Appearance or visual appeal was an important design consideration in the development of the AR6A radio-line equipment. While appearance may not be the final factor in judging any equipment design, first impressions are often lasting impressions. A harmonious design is easier to work with and is given more care by operating personnel. Good design appearance in the radio-line equipment was achieved by incorporating balance into the size, the shape, and the placement of the circuit modules. The same planned attention to detail was applied

to the design of the circuit modules to provide functional visual appeal. Color has been used with the radio-line equipment where appropriate to enhance the visual effect. Aesthetically pleasing designs need not be at odds with any other design requirements. Rather, the ultimate objective in physical design is to create simple, but truly elegant, designs.

## VII. STATION ARRANGEMENTS

The most economical application of AR6A is to overbuild established TD microwave radio routes. Existing building floor space and facilities, as well as the microwave antennas and towers, can be further utilized at minimal incremental cost. The physical size of the AR6A TR bays was determined with this specific overbuild objective in mind.

### *7.1 Repeater station—frequency diversity*

AR6A uses the same channelization plan as does the TH-3 Microwave Radio System.[4] At a repeater station the two RF signal polarizations in each direction of transmission result in four lineups of four TR bays each. In addition, one TR support bay is required at each station with up to a maximum of 16 TR bays per route. The TR support bay is constrained to be located within 40 cabling feet of any TR bay so that the pilot resupply tone signals may be provided to each TR bay at the same power level.

A typical AR6A repeater station floor plan layout is shown in Fig. 7. Since the radio-line equipment has been designed for front access, the radio bay lineups may be placed against a wall or back to back with another radio bay lineup. The empty bay position opposite the

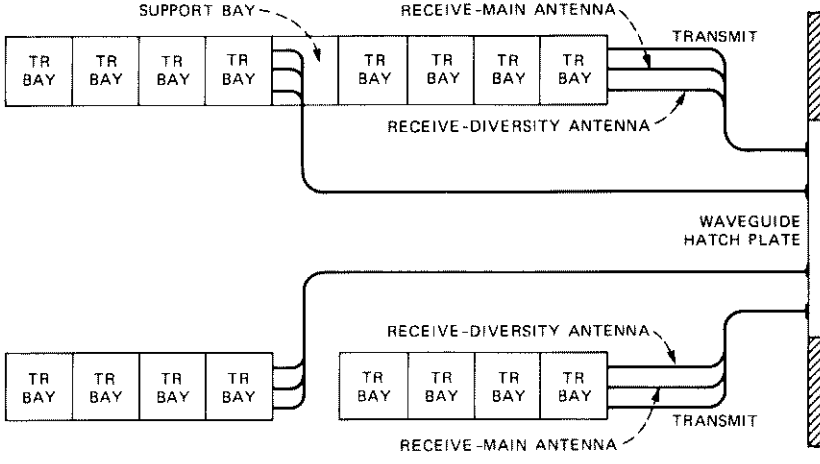

Fig. 7—Floor plan layout for a typical AR6A repeater station.

TR support bay is maintained to provide E-W and W-E channel symmetry across the aisle for operating clarity.

The indoor waveguide arrangements are similar to those used in TH-3. When space diversity is applied there will be three indoor waveguide runs (transmit, main receive, and diversity receive) connected to each bay lineup. To minimize the frequency shift of waveguide filter cavities, dry air is supplied from the station dehydrator using the indoor waveguide for distribution to the TR bays. The indoor waveguide is routed above the bay frameworks and brought down to the 5-1/4 foot level of the channel filters at the end of each TR bay lineup. The common channel RF preamplifiers are mounted in the receive waveguide runs at the top of the first bay in the lineup. Either right-hand or left-hand feed direction is permitted due to the mounting of the channel filters on the TR bay center line. Space has been allocated in the upper section of the TR support bay to allow the indoor waveguide to pass behind the upper side covers. RF connections between the channel filters of adjacent radio bays are made using 4-inch sections of flexible waveguide. Alignment of these connections is made possible by having the radio bay frameworks bolted together through factory-fixtured brackets on the basic bays. Low-pass power filters, which reduce any 60-Hz and harmonic tones from the -24 volts dc power feeds, are located in each bay at the 8-foot level. A photograph showing the AR6A radio-line equipment installed in the Hillsboro, Missouri station is shown in Fig. 8.

### *7.2 Repeater station—hot standby*

When the forecasted channel growth does not permit a frequency-diversity route plan, a hot-standby arrangement is required. Figure 9 shows a hot-standby floor plan for a typical repeater station with one working channel in each direction of transmission. A single standby TR bay protects the two opposite direction regular channels from equipment outage. The receive RF signal paths from the main antenna are split in couplers to provide the inputs from two transmission directions to the standby bay. The microprocessor-based hot-standby control unit, mounted in the TR support bay, controls the selection to an RF switch in the standby bay. The transmit output from the standby bay is split in a coupler above the standby bay and the same transmit signal is sent to another RF switch in each of the regular TR bays. This switch, also under control of the microprocessor controller, determines whether transmit signal from the regular or the standby bay goes out to the antenna. Space diversity may be applied to a hot-standby arrangement but only on the regular TR bays. An additional working channel would share the common receive RF paths but would require a duplication of the other equipment required for the first

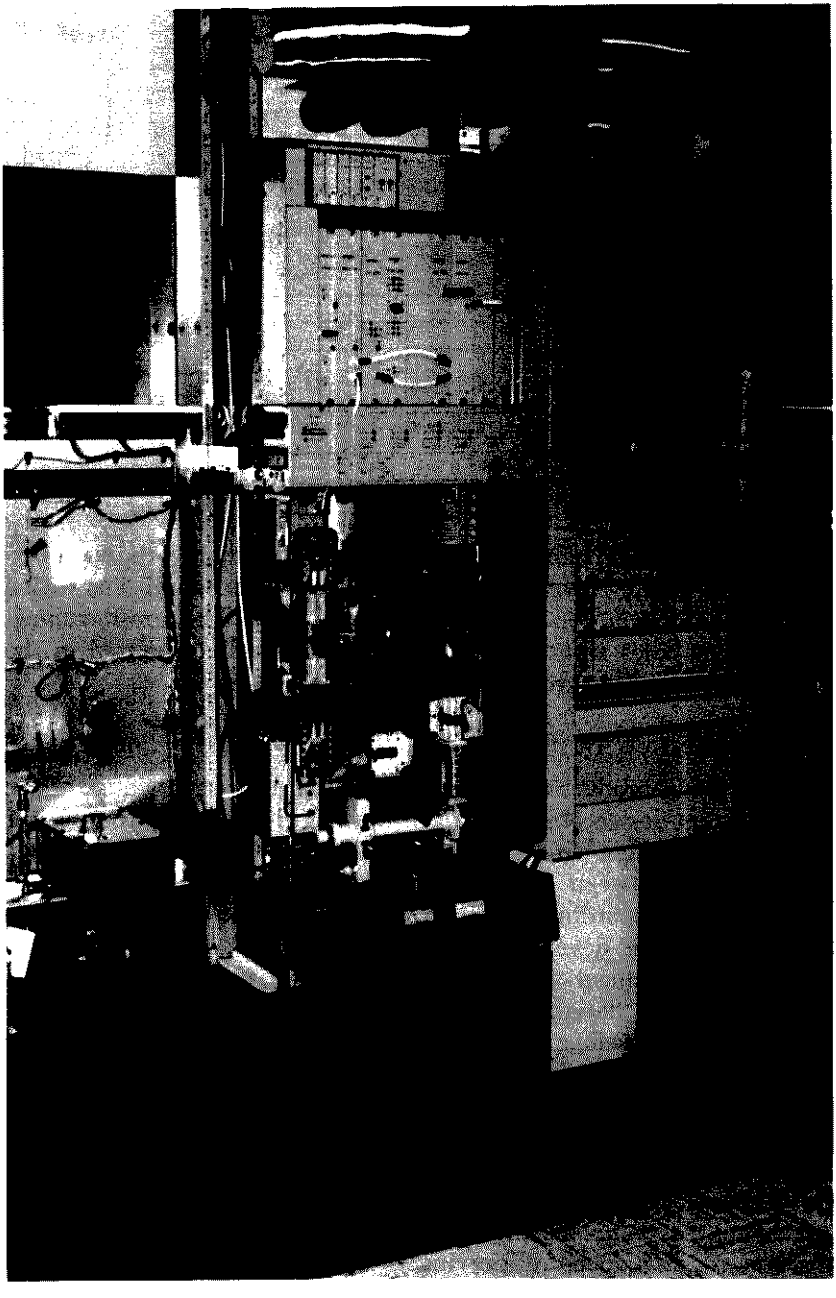

Fig. 8—AR6A radio-line equipment installed at Hillsboro, MO.

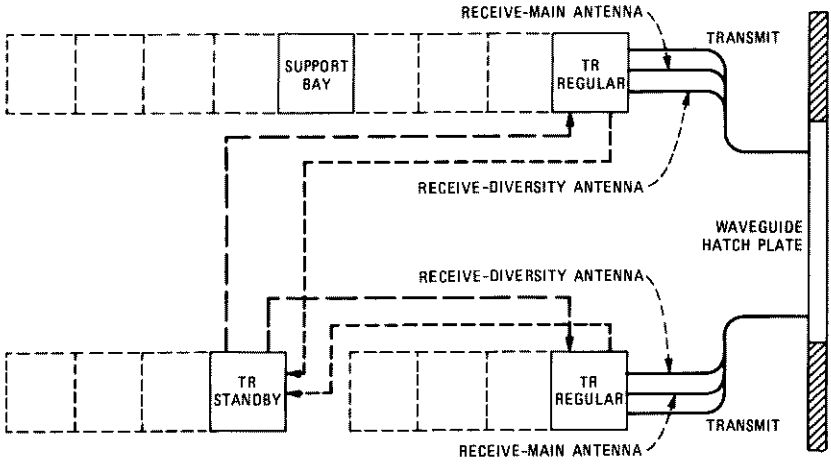

Fig. 9—Hot-standby floor plan layout for a typical AR6A repeater station.

working channel. When there is sufficient channel growth, a conversion to a frequency-diversity arrangement can be accomplished with a minimum of disruption to the working channels. The nonfrequency-sensitive modules from the standby TR bays may be reused in the field assembly of the growth channel TR bays.

## VIII. FINISHING TOUCHES

A successful product design is the result of a careful balance of the many system design objectives. Maintaining that balance throughout the physical design process called for increased emphasis on design coordination between the many engineers involved in this major project. Design coordination has become an area of increasing importance in product developments to evaluate design alternatives, to reduce the technical risks, and to keep the project on schedule. Throughout the design cycle of AR6A many formal and informal design review sessions were held to monitor design status and to maintain continuity with the overall design concept. For convenience in keeping all the design engineers informed, the documentation of the equipment design concept was maintained in the format of size-and-feature outline control drawings.

The physical design of the AR6A radio-line equipment will continue to change as technologies improve and new system concepts and circuits are introduced. Improving the product has always been part of the physical design process. In the design of this equipment we have tried to anticipate these future changes so that the physical design modifications may be accomplished gracefully.

It would be unusual in our modern world of design if a complex

product, such as AR6A, were created by a few individuals. In addition to the many individuals who were involved in the project, we would like to acknowledge in particular the contributions made by R. E. Caron, G. B. Gregoire, T. Kuliopulos, and L. F. Travis.

## *The AR6A Single-Sideband Microwave Radio System:*

# Radio Transmitter-Receiver Units

By R. C. HEIDT,* E. F. COOK,* R. P. HECKEN,* R. W. JUDKINS,* J. M. KIKER, Jr.,* F. J. PROVENZANO, Jr.,* and H. C. WANG*

(Manuscript received February 7, 1983)

This paper describes the essential features and the performance of the AR6A microwave transmitter and receiver. Subsystems that are major contributors to repeater noise are explained in detail. Design objectives for each of these units are given and compared to typical results obtained from measurements. Transmitter linearity was improved substantially through the use of predistortion. The thermal noise contribution of the receiver was reduced by use of a new low-noise microwave preamplifier.

## I. INTRODUCTION

The two basic portions of the AR6A† radio bay are the transmitter and receiver units. These units have a natural interface at the Intermediate Frequency (IF)‡ and are described in the next two sections.

In general, the receiver establishes the required noise figure, and provides the required frequency selectivity, automatic gain control,

and both dynamic and static equalization. The transmitter supplies microwave gain with low intermodulation distortion at the required output power.

The alarm and control system spans the entire bay. This system monitors the operation of the radio bay and provides remote switching capability to exercise important repeater functions to facilitate maintenance testing.

## II. THE AR6A RECEIVER

### *2.1 General*

Figure 1 is a block diagram of the AR6A receiver equipped for the space-diversity application. The multichannel Radio Frequency (RF) signals from both the main antenna and diversity antenna (when implemented) are amplified by the optional waveguide microwave preamplifier in each waveguide run. The desired channel is then selected by channel-separation filters. The outputs of the separation filters are input to the space-diversity switch at a nominal full-load power level of −28.6 dBm. The output of the diversity switch is combined with the receive microwave carrier (local oscillator) signal in the receive microwave filter and applied to the Schottky diode single-ended down converter. Integral to the down converter is an IF preamplifier that boosts the signal level to about −4 dBm. In the case when the receiver is not equipped for space diversity, the waveguide from the diversity antenna and the associated channel-separation filter are omitted and the space-diversity switch is replaced by an isolator and a shutter monitor assembly.

The remaining elements of the receiver are located in the IF shelf. The filter portion of the filter/equalizer[1] provides the basic selectivity for the repeater, while the equalizer is used to compensate for static residual amplitude shape due to the various repeater components. At a repeater station the output of the filter/equalizer is applied to the Automatic Gain Control (AGC) amplifier, which provides flat gain with a dynamic range of 61 dB to compensate for fading. Correction is made for both up fades and down fades. The AGC is controlled by the receiver control unit, which maintains the average of the three detected radio pilot voltages constant. The radio pilots are fed to the pilot detector unit through an auxiliary output port of the AGC amplifier. The pilot detector unit filters and detects each of the radio pilots. The output level of each of the detectors is provided as the inputs to the receiver control unit. An IF monitoring point for the radio channel is accessible at the front panel of the pilot detector unit.

At main stations, a dynamic equalizer is used in conjunction with the AGC amplifier to provide up to 16 dB of linear slope or 8-dB

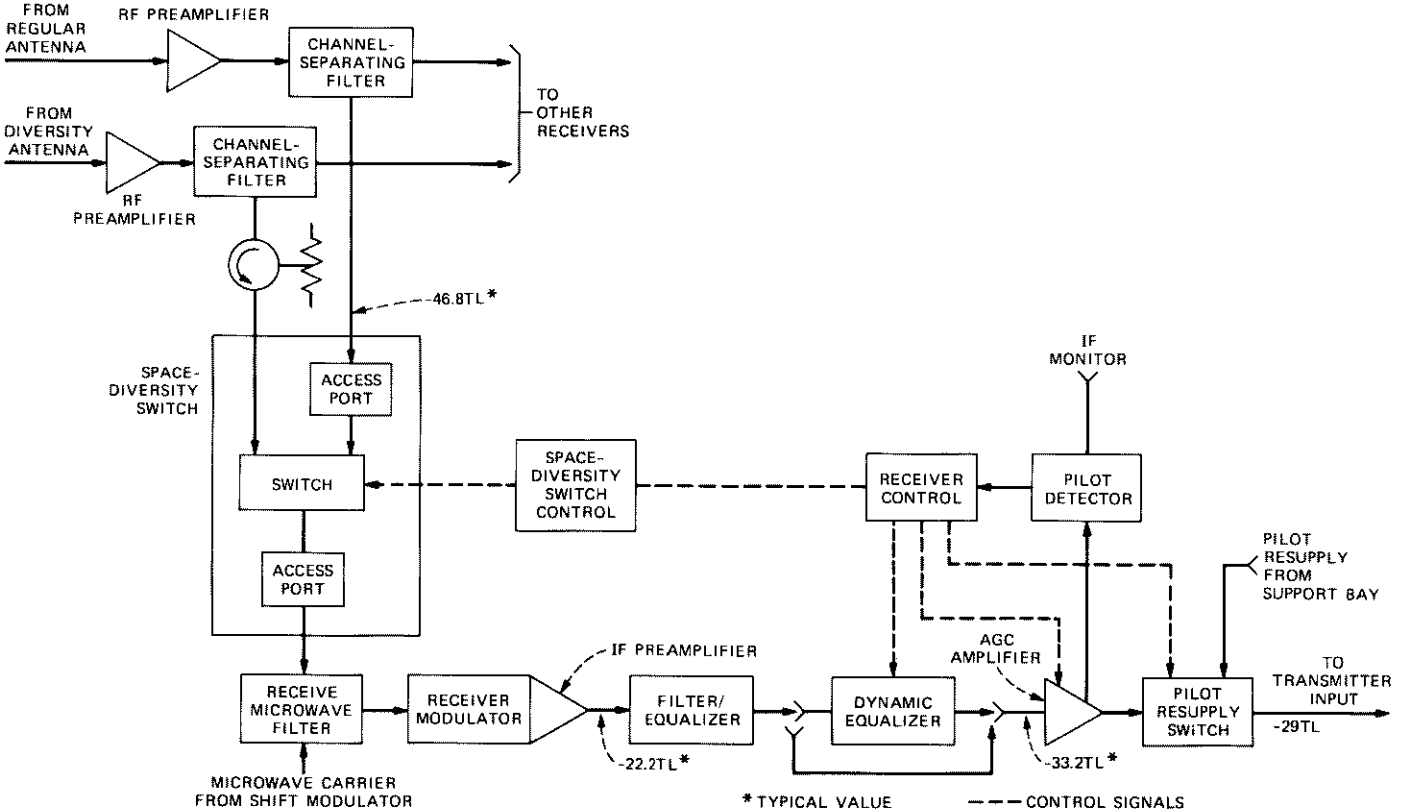

Fig. 1—Receiver portion of an AR6A TR bay.

parabolic amplitude shape to compensate for dispersive fades. The operation of the dynamic equalizer is also governed by the receiver control unit by monitoring the relative differences in level of the three radio pilots.

The output of the AGC amplifier is passed through the pilot resupply switch to the receiver output. Signal loss or signal overpower will cause the receiver control unit to actuate the pilot resupply switch. This action terminates the AGC amplifier output and connects another set of radio pilots from the AR6A support bay to the receiver output. The resupply pilots prevent following repeaters from going to full gain on loss of the channel load.

The receiver control unit also signals the switch request to the space-diversity switch control unit. This request is given when any radio has faded 36 dB or more below the normal received level on a nominal 27.1-mile hop length. This information is derived from the pilot detector signals and the control voltage outputs.

The equalization strategy and operation of the AGC amplifier, dynamic equalizer, receiver control unit, and pilot detector unit are described elsewhere.[2] Further details of the space-diversity switch and control circuit, the receiver modulator/IF preamplifier, pilot resupply switch, and the microwave preamplifier are presented in the following sections.

### *2.2 Circuit description*

#### *2.2.1 Low-noise microwave preamplifier*

An optional low-noise microwave preamplifier (656A) is used in the common waveguide run feeding TH-3, as well as AR6A, receivers on a given polarization. The signal on a TH-3 channel is 16 dB higher in power than the full-load AR6A signal; therefore, the amplifier must exhibit excellent linearity to prevent intermodulation "crosstalk" between radio channels. The 656A amplifier intermodulation distortion performance is good enough to allow this common waveguide amplifier to be used with a mix of TH-3 and AR6A on a given route.

The single-stage amplifier using a gallium arsenide (GaAs) field effect transistor (FET) (103B) was designed to operate over the band of 5.925 to 6.425 GHz. The average gain ranges from 8 to 10 dB, with a ±0.5 dB gain shape allowed over the frequency band. A maximum loss requirement of 10 dB is imposed on the amplifier when the transistor is unpowered. The maximum noise figure is 3 dB with typical values measured around 2.7 dB. Typically, the third-order intermodulation coefficient, $M_{A+B-C} = -45$ dB.

Mechanical construction of this amplifier is very similar to the 4-GHz amplifier previously designed for use in the TD Radio System.[3] The GaAs FET is mounted in a microstrip circuit module. Three

circulators in air strip-line (Fig. 2) provide good return loss at the input and output waveguide ports as well as an effective passive bypass circuit in case the amplifier module fails. The amplifier has a return loss requirement of 30 dB minimum at both waveguide ports.

The dc operating point for the GaAs FET is a compromise between noise figure and linearity. A built-in regulator sets the gate voltage so that $I_D = 15$ mA at $V_{DS} = 4.8$ volts. The amplifier operates from a −24 volt supply drawing 60 mA. In case of transistor or power supply failure, a contact closure is provided for an alarm indication. At the same time, a visible green Light-Emitting Diode (LED) will be turned off.

#### *2.2.2 Receiver modulator/IF preamplifier*

The modulator mixes the received RF signal with the locally generated microwave carrier (LO), which is at a frequency 74.1 MHz above or below the center frequency of the received signal. The modulator, a direct use of an existing TH-3 FM radio design,[4] consists of a stepped waveguide transformer, a waffle-iron low-pass filter, and a diode-mount waveguide section. The basic arrangement of the circuit is shown in Fig. 3. The IF signal is fed through a coaxial low-pass filter to the IF preamplifier input. To obtain improved third-order intermodulation performance for AR6A applications, an LO level of +10 dBm is used instead of +6 dBm as for TH-3. An $M_{A+B-C}$ of about −21 dB is obtained for this LO drive level and optimized diode dc biasing.

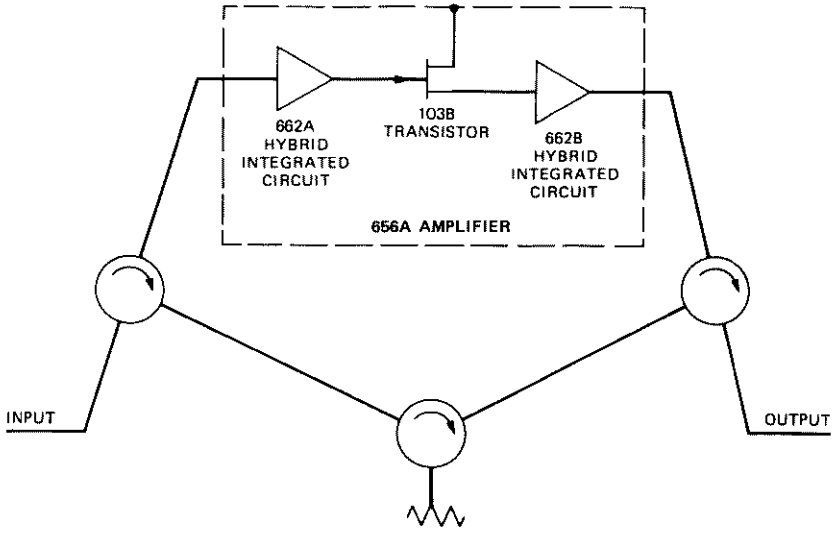

Fig. 2—RF preamplifier.

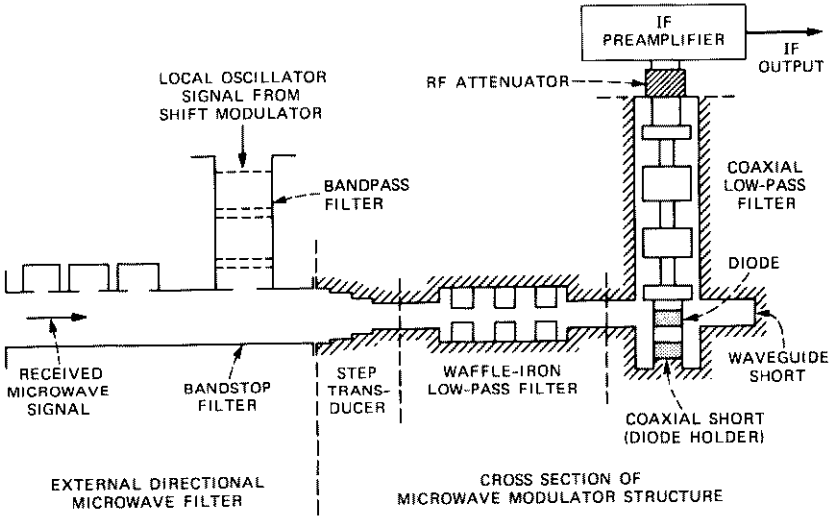

Fig. 3—Basic arrangement of receiver modulator and IF preamplifier assembly.

The 3-stage IF preamplifier has an overall gain of approximately 32 dB. A gain control allows a gain variation of ±3 dB. A slope control is used to achieve flat gain across the band, and two return loss controls are used to provide 30 dB or greater output return loss. The first stage is a low-noise common emitter configuration followed by two hybrid-feedback stages in the output. This configuration provides low-distortion and high-output return loss. The first-stage transistor is designed for low thermal noise performance, but a trade-off was made between best thermal noise and low intermodulation noise. With a dc bias current of about 25 mA and $V_{CE}$ of 3 volts, a gain of 17 dB is realized in this stage with a noise figure of 2.7 dB and an intermodulation coefficient $M_{A+B-C}$ of −45 dB. The following two stages are biased for high-linearity performance. With both transistors biased at an $I_c$ of 120 mA and $V_{CE}$ of 13 volts, the noise figure of the two stages combined is 8 dB with $M_{A+B-C}$ of −80 dB. The complete receiver modulator/preamplifier provides a nominal 28 dB of RF-to-IF gain at a full-load output level of −4 dBm with a noise figure of 8 dB and an overall $M_{A+B-C}$ of −75 dB.

### *2.2.3 Pilot resupply switch*

Figure 4 is a simplified block diagram of the pilot resupply switch circuit. The unit contains a 10-dB directional coupler, a wideband power detector, and an IF switch. The −10 dB port of the coupler is connected through an IF isolation amplifier and power detector. The signal path through the coupler is connected to the receiver-out port

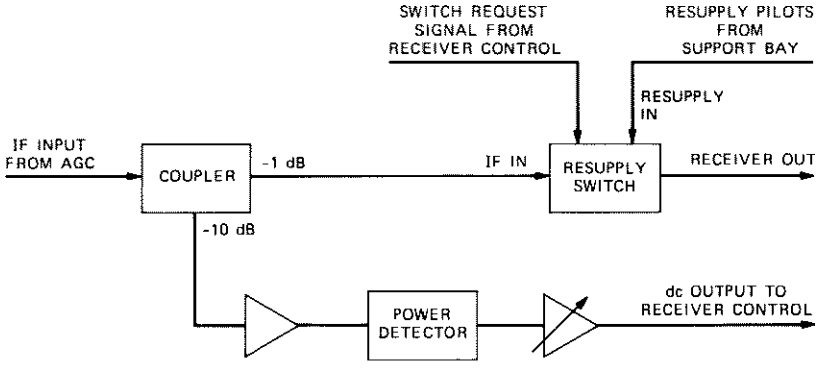

Fig. 4—AR6A resupply switch circuit.

through the normally closed contacts of the switch. The insertion loss through the pilot resupply switch unit is 1 dB. The local set of resupply pilots from the AR6A support bay is applied to the normally open contacts. In this condition, there is 90 dB or greater isolation between the resupply input port and the receiver output port.

The dc output from the power detector is buffered by a variable gain operational amplifier and connected to the receiver control unit. The gain of the amplifier is adjusted to achieve a prescribed output level for a corresponding reference IF power input. This circuit also provides an overpower monitoring feature. If the output exceeds a given threshold for a period of about 80 ms, the receiver control unit will initiate a pilot resupply switch request. The threshold corresponds to an overpower condition of about 12 dB. The receiver control will also initiate a switch request for an underpower condition and in response to a local or remote switch request.

Operation of the resupply switch is controlled by the receiver control unit. When the switch request is made, the IF input from the AGC amplifier is disconnected from the receiver output port and terminated internally in 75 ohms. At the same time the internal termination is disconnected from the local set of resupply pilots, which are then connected through to the receiver output port.

#### *2.2.4 Space-diversity switch and control*

The 436A switch, shown in Fig. 5, provides switching between two input ports and a single waveguide output port. One input is WR159 waveguide and is connected to the channel-separation filter that is part of the common waveguide lineup connecting to the main (or preferred) antenna. The other input, an SMA-coaxial port, is connected to the channel-separation filter that connects to the diversity

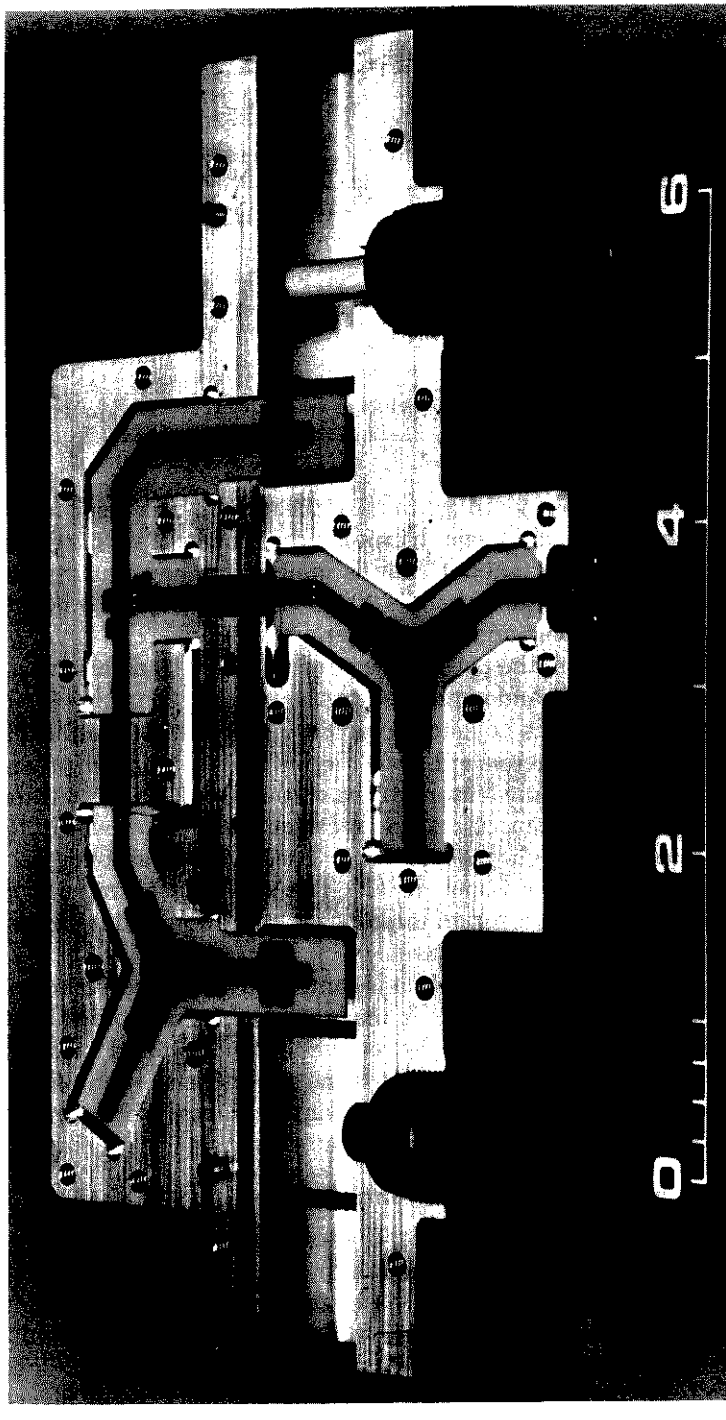

Fig. 5—Space-diversity switch.

antenna. Isolators are built into each port. They provide a load to the channel-separation filters when either path of th is in its open state. The return loss of the input waveguide required to exceed 30 dB; the output waveguide port, 20 dB; i input coaxial port 25 dB. The insertion loss is required to be les ...an 1.75 dB. An air leakage path is provided between input and output waveguide ports to provide a path for air when used in a pressurized waveguide system. The switch is designed to fit into the space normally occupied by the 16B shutter monitor and 23A isolator in nonspace-diversity applications. Therefore, the switch is equipped with test access ports and shorting plates to perform the functions of a shutter monitor.

Diode modules in each of the input paths of the switch incorporate three p-i-n diodes. In the preferred signal path the diode module is zero biased to its low-loss (closed) state. In the nonpreferred signal path the diode module is forward biased to its high-loss (open) state. Isolation between input and output ports in the open state exceeds 70 dB.

The space-diversity switch control unit contains the control circuitry for the 436A switch. The circuit can be separated into an analog portion that delivers the driving current function for each p-i-n diode module and a digital portion that includes the fault and alarm circuitry, the reversion circuitry, the main switching circuitry, and the test circuitry.

The switch control panel contains three red LEDs for indicating fault conditions, two green LEDs for indicating which antenna is connected to the receiver, a momentary pushbutton switch for resetting fault conditions or manual antenna selection, and a mode select switch that allows manual or automatic operation.

Although there are no field adjustments, it is necessary to position two miniplugs for selecting various options. One of these user-selectable options allows either antenna to be designated as the preferred antenna and the other enables the automatic reversion option. Other miniplugs are for factory test purposes only.

In operation the main switching circuitry responds to a digital switch request signal generated in the receiver control unit. This switch request will be honored only if the control unit is in the automatic mode and has not switched in the previous 10 seconds. Two driving functions are employed to control the separate diode modules in the space-diversity switch. These driving functions are identical but 180 degrees out of phase and are overlapped to provide a make-before-break type of transition. The maximum rate of switching is limited to one transition every 10 seconds.

If the automatic reversion option was chosen and the receiver has

been connected to the nonpreferred antenna for 30 minutes, the reversion circuitry will cause a switch back to the preferred antenna. If a switch request is received during the next 3 minutes, indicating that signal fading is still excessive on the preferred antenna, the control circuit will switch the receiver input back to the nonpreferred antenna and reinitiate the 30-minute timer. If a switch request had not been received during the 3-minute interval, the receiver would remain connected to the preferred antenna.

Any one of six fault conditions will result in a space-diversity switch alarm. Seizure faults are generated whenever either antenna is selected manually or whenever either test function is selected. A reversion fault occurs after 14 consecutive reversion attempts fail. The 15th attempt will cause a 7.5-hour timer to time out thereby inhibiting the operation of the reversion circuitry while allowing the rest of the control circuitry to function normally. A reversion fault is reset by depressing the EXCHANGE ANTENNA/RESET switch. A switch request fault is produced whenever a continual switch request is present for more than 85 minutes. The antenna in use is then seized and further operation of the control is blocked to prevent indefinite switching at a 10-second rate. This fault is reset when a low-to-high logic-level transition is received on the switch request input or the EXCHANGE ANTENNA/RESET switch is depressed.

All control unit input and output levels are Transistor-Transistor Logic (TTL) except the two analog signals driving the space-diversity switch. The ALARM output provides a signal to the alarm and control interface circuit. The output labeled SDS ACTIVITY provides a means of monitoring the space-diversity switch performance.

## III. THE AR6A TRANSMITTER

### *3.1 General*

Figure 6 shows the signal-carrying components of the transmitter, together with other ancillary units. The input signal to the transmitter is the 10-mastergroup IF spectrum and includes all pilot tones. This spectrum at a full-load power level of −10.8 dBm comes from either the 500A switch or the output of the preceding receiver and is first applied to the predistorter.[5] The predistorter adds a specific amount of third-order intermodulation distortion with the proper phase relative to the main signal to reduce the intermodulation distortion generated by the remainder of the transmitter. After the signal is predistorted, it enters the amplifier/transmitter modulator, which consists of an IF buffer amplifier, slope equalizer, and a single-ended up converter. The double-sideband RF signal out of the modulator, at a nominal full-load level of −16.7 dBm per sideband, is directed

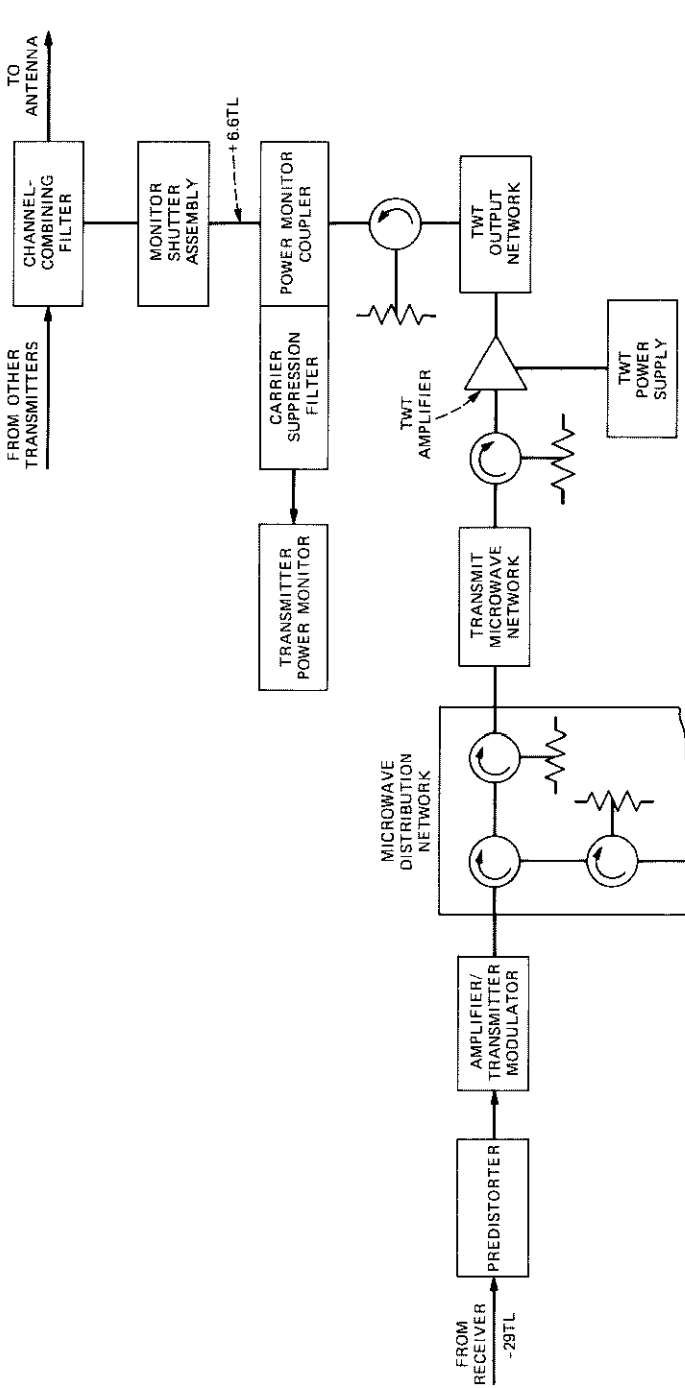

Fig. 6—Transmitter portion of an AR6A TR bay.

through the microwave distribution network to the transmit microwave network (1450 type), which is a bandpass filter with a 1-section delay equalizer. The bandpass filter selects the appropriate sideband and attenuates the carrier and unwanted sideband. More details are given in the next section of this chapter. From the transmit microwave network the signal passes through an isolator to the input of the TWT amplifier.[6] The traveling-wave tube has a typical gain of 44 dB, with gain plus noise figure ≤69.5 dB, and a third-order intermodulation coefficient $M_{A+B-C} \leq -90.5$ dB. A coaxial-to-waveguide transducer is integrated with the tube mount at the input. At the output of the TWT the signal is stripped of its second harmonic content in the TWT output network, which is the combination of a waffle-iron filter, stepped waveguide transformer, and an isolator. The signal is directed through the power monitor/coupler and shutter monitor assembly where the full-load RF power is approximately +25 dBm. The channel-combining filter combines the signal with the spectra of other radio channels.

### *3.2 Circuit descriptions*

#### *3.2.1 The IF predistorter*

Figure 7 is a block diagram of the predistorter used in AR6A. After amplification to a level of approximately +1 dBm, the spectrum enters the phase resolver circuit.[1] The phase resolver splits the input signal into two parts with the phase angle between the two output ports being adjustable. The signal passing through the delay line is the main signal and constitutes the reference. The phase-shifted signal is applied to the other path, which is referred to as the cuber path. The delay line in the main signal path is used to match the delay of the other path to within ±0.1 ns.

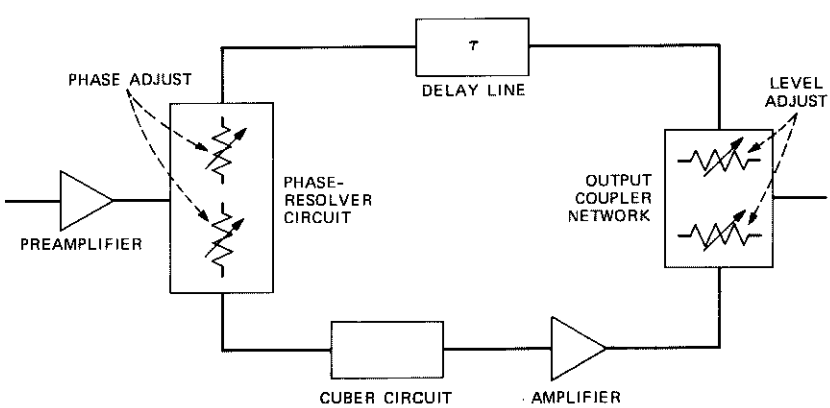

Fig. 7—Block diagram of a predistorter.

The cuber circuit[7] generates the desired complementary distortion products. The cuber circuit consists primarily of two pairs of back diodes connected antiparallel and in opposite branches of a bridge circuit. In this bridge arrangement fundamental frequency signals are canceled by at least 60 dB. The antiparallel pair of diodes generates predominantly odd-order intermodulation products. They are carefully selected for best conversion efficiency and performance that is not level-dependent. Other design considerations and requirements are described in a companion article in this issue.[5] The distortion amplifier brings these complementary distortion products to the desired level and feeds them directly into the output coupler, where the complementary distortions products are combined with the main signal.

The output coupler circuit contains two variable attenuators allowing the independent level adjustment of the main signal and distortion signal prior to combining them. At the output of the predistorter the main path nominal signal level is approximately −14 dBm and the complementary distortion products are at a level of about −71 dBm.

#### *3.2.2 Amplifier/transmitter modulator*

The amplifier/transmitter modulator, shown in Fig. 8, is used to translate a 59- to 89-MHz IF signal to the 6-GHz communications band with minimum distortion. The amplifier serves as a buffer between the IF input port and the Schottky diode of the transmitter modulator to minimize variations in the input return loss. Slope and gain compensation of the overall transmission characteristic is accomplished by adjustments located on the amplifier. The amplifier is also equipped with a p-i-n diode attenuator that protects the transmitter output networks by limiting the maximum input power to the transmitter.

The transmitter modulator combines the IF input signal from the amplifier with the microwave carrier. This combining or mixing action results in the creation of a lower sideband (LSB) and a upper sideband (USB) referenced to the microwave carrier.

The amplifier consists of two transistor stages. Ahead of these stages is a transmitter gain adjustment, which sets the transmitter output power by attenuating the IF input signal level. This adjustment is capable of varying the IF signal level over a 20-dB range although, typically, an adjustment less than ±3.9 dB is required.

The first amplifier stage is a common base configuration designed to exhibit very low third-order intermodulation distortion. A slope equalizer network follows the first amplifier stage. When the slope adjustment is rotated clockwise, the network forms a low-pass filter with a negative slope transmission characteristic. When rotated counterclockwise the network becomes a high-pass filter with a positive

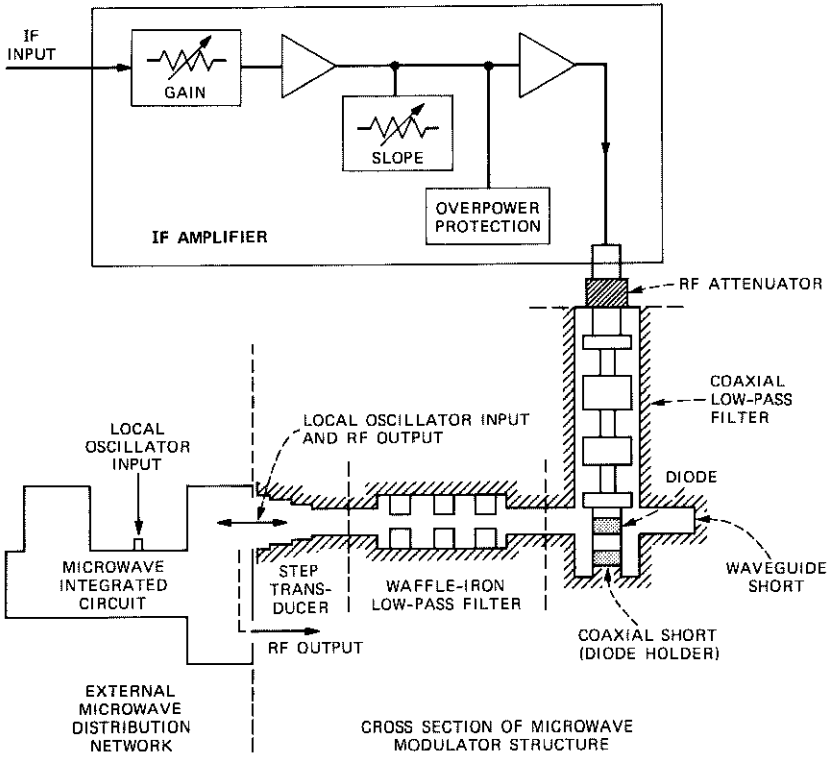

Fig. 8—Basic arrangement of an amplifier/transmitter modulator.

slope transmission characteristic. The slope equalizer network adjustment is capable of varying the IF channel slope over a range greater than ±1 dB although, typically, an adjustment less than ±0.2 dB is required.

The second amplifier stage is a common emitter configuration. It provides approximately 5 dB of additional gain and buffers the transmitter modulator Schottky diode from the slope equalizer network.

The p-i-n diode attenuator network is controlled by a third transistor. Under normal operating conditions, no dc current flows through the p-i-n diode and, therefore, its ac impedance is extremely high. However, should the transmitter output power increase to the point where limiting is required, the transistor will drive dc current through the p-i-n diode and cause its ac impedance to become very low. This loads down the collector of the first-stage transistor thereby attenuating the IF signal by a nominal 10 dB.

The 59- to 89-MHz IF signal from the amplifier and the dc bias for the Schottky diode are fed through an RF attenuator and low-pass

coaxial filter to the diode in the transmitter modulator. The coaxial filter suppresses 6-GHz fundamental frequencies and their second and third harmonics while the attenuator provides additional loss at frequencies above 1 GHz to prevent this energy from feeding back to the amplifier. The combined insertion loss of the coaxial filter and attenuator is approximately 3 dB at 800 MHz and 50 dB at 6 GHz.

The microwave carrier frequency is applied to the Schottky diode through a waveguide input port, a stepped waveguide transformer and a waffle-iron filter. The Schottky diode is physically mounted between a coaxial short, which is also the diode holder, and one end of the coaxial low-pass filter. The distance that the coaxial short extends into the diode cavity and the position of the waveguide short are designed to achieve the desired conversion efficiency and eliminate second-harmonic waveguide resonances, which could adversely affect the linearity of the transmitter modulator circuit.

The stepped waveguide transformer provides a smooth transition of the RF transmission characteristic from the reduced height waveguide, used in the design of the waffle-iron filter and diode mount, to full-height WR159 waveguide. The waffle-iron filter prevents the second-harmonic frequencies, which are generated in the transmitter modulator, from appearing at the waveguide port. The waffle-iron filter has an insertion loss of approximately 3 dB at 8.2 GHz and 40 dB at 12 GHz.

The IF signal and the microwave carrier are mixed in the Schottky diode to obtain the RF sideband frequencies. The sideband frequencies appear at the waveguide port and are then filtered to select the desired sideband. The single-tone output power level of the transmitter modulator is nominally −16.7 dBm when a single-tone IF input power level of −13.8 dBm is applied to the amplifier and a microwave carrier power of +16 dBm is applied to the transmitter modulator. A supply voltage of −15 volts dc at approximately 155 mA is required to operate the amplifier/transmitter modulator.

#### *3.2.3 Traveling-wave-tube amplifier*

The traveling-wave-tube amplifier supplies the necessary microwave gain. The amplifier has unique linearity requirements: it must provide low third-order intermodulation levels ($M_{A+B-C} < -90.5$ dB) and must have a constant gain and third-order intermodulation coefficient over a wide range of output power (from 23 to 35 dBm).

The amplifier, which is convection cooled, consists of a TWT envelope, focusing mount, and power supply. The input to the amplifier is through an SMA-coaxial connector. The output is reduced height (0.1-inch) WR159 waveguide. Focusing adjustments on the mount minimize helix current.

The power supply provides all voltages required by the TWT. The -24 volt battery, fed through a frame filter to reduce low-frequency (60-Hz harmonics) ripple, is used to operate the high-voltage TWT power supply. Front-panel meters measure helix and collector (or beam) currents. A helix voltage adjustment on the front panel is used to set the TWT to its proper operating point.

## IV. MICROWAVE NETWORKS

Various microwave components used in the TR bays were designed some time ago for applications in previous 6-GHz microwave radio systems. Therefore, we are limiting our discussion to new components designed for AR6A.

The 1379-type filter is used as both a channel-separating and channel-combining filter. This filter is mechanically identical to the 1340-type channel-combining filter of the TH-3 System.[8] It is a six-cavity, pseudodirectional filter in WR159 waveguide with a 3-dB bandwidth of 54.15 MHz. To reduce the passband insertion loss slope due to the inductive nature of discontinuities used in the design, the filter is tuned 1 MHz lower than the channel frequency. The insertion loss at the channel frequency should be less than 0.75 dB. In the stopband the loss follows well with the calculated loss of a six-cavity, maximally flat, waveguide bandpass filter.

The receiver modulator filter (1374 type) is a three-cavity directional filter in WR159 waveguide that couples the microwave carrier (LO) and the signal into the receiver modulator. The insertion loss at the LO frequency is no more than 1 dB and the 3-dB bandwidth is 17 MHz. Selectivity at frequencies ±25 MHz away from the center of the bandpass is more than 30 dB. The return loss for both signal and LO ports is required to be at least 30 dB.

The transmitter microwave network (1450 type) is used to block the unwanted sideband at the output of the transmitter modulator. It consists of a seven-cavity, maximally flat, bandpass filter (1373 type) in WR159 waveguide and a microwave delay equalizer.[9] The 1373 filter has a 3-dB bandwidth of 70 MHz. The return loss over the 34-MHz passband is required to be better than 30 dB. The insertion loss at midband is less than 0.65 dB. The delay equalizer adds no more than 0.35 dB to the filter passband loss. The residual delay distortion of the network should be less than ±0.2 ns over a 30-MHz passband.

The TWT output network (1451 type) serves the two functions of transducing the reduced height waveguide at the TWT output port to the full-height WR159 waveguide and of rejecting harmonics from the TWT. It consists of a three-section waffle-iron low-pass filter and a three-section quarter-wavelength step impedance transducer. The net-

work has a 30-dB return loss requirement over the 6-GHz band. The insertion loss at the second-harmonic frequency is about 40 dB.

The 1452 network is a power-monitoring coupler in the transmitter. The main signal path consists of a 26.5-dB cross-guide coupler and a 90-degree step twist. The coupled arm has a two-cavity, band-reject filter to block the LO frequency and a waveguide-to-SMA coaxial transducer in the output port. A 30-dB return loss requirement over the entire frequency band is imposed on the main signal path. The coupled arm requires a 20-dB return loss over a 30-MHz band centered at the channel frequency. About 55-dB rejection is provided at the LO frequency by the band-reject filter.

To reduce multiple reflections in the RF signal path of the radio bay, a long section of bent semirigid coaxial cable in the transmitter was tuned and tested together with its two transducers to WR159 waveguide, as a network (1453 type). It requires 30-dB return loss over the entire frequency band. This network is particularly sensitive because of its connection directly to the 1379-type filter. If a mismatch occurs in the 1453 network, severe ripple may occur in the channel.

Three shutter monitors are also required in the bay: the 16A, used in the transmitter, consists of three sliding shorts and two probes; the 17A shutter-monitor, used in the shift modulator circuit, consists of one sliding short and one probe; the 16B, used in the receiver when the space-diversity switch is not used, is similar to the 16A. The shutter-monitor is a waveguide component that has an access port in the broad wall in which a coaxial probe can be inserted. Slides may be inserted into slots cut into the narrow wall, thus providing a short across the waveguide. The resulting assembly is similar to a coaxial-to-waveguide transducer. With the probe and slides removed, the assembly becomes a simple waveguide section. A minimum return loss of 23 dB can be expected from the coaxial probe, and about 35-dB insertion loss per inserted sliding short can be achieved.

## V. ALARM AND CONTROL INTERFACE CIRCUITS

The alarm and control interface circuits consist of six units that provide the alarms, indications, and commands needed for one TR bay. These circuits provide a means for external identification of the particular failure, visual indications of trouble conditions on the TR bay display panel, remote indications of trouble conditions, maintaining visual alarms when audible alarms are silenced or disabled, and converting a command from C- or E-type telemetry equipment to a TTL level for interfacing with the TR bay.

The command unit translates command pulses (generated by a contact closure) from a C- or E-type telemetry system to a latched

logic-level change for the remote operation of a function in the TR bay. The command circuits in the bays use a multiplex scheme requiring two command pulses from the telemetry system for the operation of any one function. One command pulse from the telemetry equipment for each bay is used for addressing that bay. This is followed by a second command associated with a particular function. This second command is fed to all other radio bays in both directions of transmission but is accepted only by the addressed bay. It is necessary to readdress the bay for each subsequent operation of a function. The five operations that can be remotely performed by command are as follows: RESUPPLY INITIATE, FLAT EQUALIZER SHAPE, NOMINAL RECEIVER GAIN, GAIN MEASUREMENT REQUEST, and BAY RESET.

Conditions causing alarms and indications are listed in Table I. Inputs to the receiver alarm unit are from the receiver or common equipment only; inputs to the transmitter alarm unit are from the transmitter or common equipment only; and inputs to the common alarm unit are from the equipment shared by both the transmitter and the receiver.

The alarm fuse unit provides two fused sources of -24 volts. One source is used for powering all of the alarm and control interface circuit relays. The other is an additional source of power for the power alarm relays.

The alarm relay unit translates TR bay alarms into contact closures for the operation of external audible, visual, and remote alarms. The

Table I—Conditions causing alarms and indications

| Condition | Receiver Alarm | Transmitter Alarm | Remote Indication | Display Panel Indication |
|---|---|---|---|---|
| Space-diversity switch alarm | X | | | X |
| Receiver control alarm | X | | | |
| Resupply initiate alarm (delayed) | X | | | |
| Equalizer at maximum range (delayed) | X | | | |
| Shift oscillator loss of lock | X | | | X |
| Radio bay enabled | | | | X |
| Predistorter off | | X | | |
| Low or high transmitter power | | X | | X |
| Low dc power | X | X | | |
| Microwave generator low power | X | X | | X |
| Microwave generator loss of lock | X | X | | X |
| Transmitter gain normal | | | X | X |
| TWT beam fault | | | X | |
| Space diversity initiated | | | X | |
| Shift oscillator or microwave generator memory fault | | | X | X |
| Resupply initiated by command | X | | X | X |
| Receiver gain nominal by command | X | | X | |
| Equalizer flat shape by command | X | | X | |

unit also has an alarm cutoff function for silencing the audible alarms. LEDs on the faceplate provide a visual indication for a bay alarm or a power alarm.

## *The AR6A Single-Sideband Microwave Radio System:*

# Terminal Multiplex Equipment

By A. DUBOIS,* D. N. RITCHIE,* and F. M. SMITH*

(Manuscript received February 2, 1983)

A combination of new multiplex facilities provides the 6000-message-circuit loading for AR6A radio. It includes a Mastergroup Translator Type-B (MGTB) arrangement that accepts five U600 mastergroups to translate and combine them into a Multimastergroup (MMG) spectrum. A new multimastergroup translator for radio accepts two such MMG spectra from MGTB to produce the intermediate frequency signal and pilots for the AR6A line. A pair of pilots from the Bell System reference frequency transmission unit may be added to the MMG spectrum to be recovered at the receiving end for office synchronization. An office master frequency supply sends synchronization frequencies accurate to within one part in $10^9$ for the MGTB and Multimastergroup Translator-Radio translating equipment. Description, design features, and performance characteristics are described in detail below.

## I. INTRODUCTION

This section describes the frequency-division multiplex facilities that form and recover the 6000-message-circuit load for the AR6A† Radio System. Starting with the U600 mastergroup (MG)‡ spectrum formed by existing multiplex facilities, terminal equipment recently

developed to form the multimastergroup (MMG) spectrum for the L5E Coaxial Cable System is also used to form the MMG spectrum for AR6A. This equipment is the Mastergroup Translator Type B (MGTB).

An assembly of five MGTB mastergroup translators translates for five U600 input signals (0.564 to 3.084 MHz), each having a 2.840-MHz mastergroup pilot. The combined outputs of the five translators form an MMG spectrum to which a 13.920-MHz continuity pilot is added. This MMG spectrum occupies the frequency band of 8.628 to 21.900 MHz.

Two such MMG spectra are used as inputs to the Multimastergroup Translator for Radio (MMGT-R). The transmitting MMGT-R terminal combines each MMG with specific recovery and radio-line pilots and modulates each MMG separately to form the IF spectrum of 59.844 to 88.460 MHz. Figure 1 shows the basic mastergroup, MMG, and IF spectra.

Figure 2 shows the process used in MGTB and MMGT-R terminals to translate and recover the ten U600 basic mastergroups.

An accuracy of one part in $10^9$ is required for some carrier and pilot frequencies to generate, administer, and recover the mastergroup, MMG, and IF spectra. This accuracy is achieved by synchronizing the carrier and pilot generators to the 2.048-MHz Bell System frequency standard. For locations where this signal is not available, two reference pilots generated by the Bell System Reference Transmitting Unit (BSRTU) are added to the first MMG of an AR6A channel. The precise 64-kHz frequency difference between these pilot tones of 11.200 and 11.264 MHz is derived from the nationwide Bell System Reference Frequency Distribution System. The Bell System Reference Tone (BSRT) receiver unit retrieves the 64 kHz from these pilots for synchronization of the Office Master Frequency Supply (OMFS), which serves the MMGT-R and MGTB facilities.

## II. MGTB TRANSLATOR

### *2.1 Introduction*

The block diagram of the mastergroup translator is shown in Fig. 3. Each translator provides modulation and demodulation, serving both directions of transmission. The same basic design is used for all five translators for AR6A. Only the carrier generator frequency and the bandpass filters in the modulator and demodulator are changed to achieve the desired translated spectrum.

### *2.2 Improved spectrum utilization*

Earlier designs of mastergroup multiplex equipment translate and combine up to six mastergroups to form an MMG spectrum with

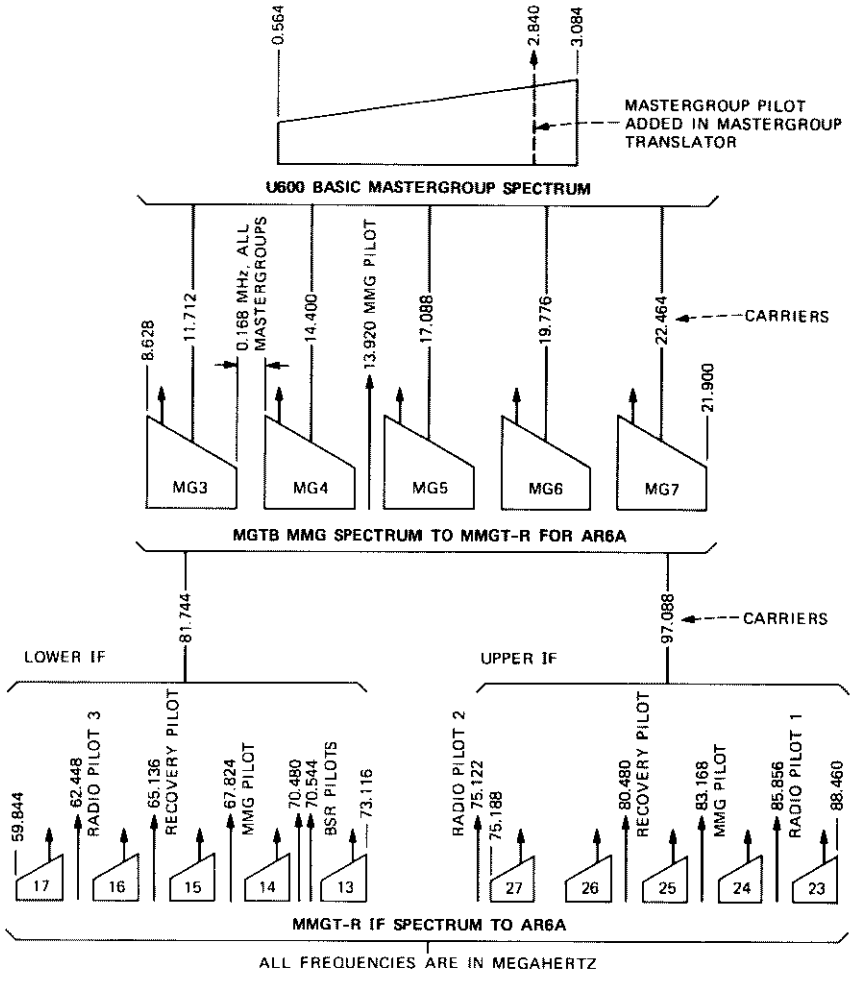

Fig. 1—AR6A terminal equipment spectra.

unequal spacing between the mastergroups. Use of that equipment permitted transmission of 18 mastergroups (10,800 voice circuits) per single coaxial cable or four mastergroups (2400 voice circuits) per FM radio channel.

For the L5E System[1] MGTB equipment translates and combines up to eight mastergroups with a fixed spacing of 168 kHz between mastergroups in the MMG spectrum. By applying three of the MGTB MMG spectra to associated equipment, a total of 22 mastergroups (13,200 voice circuits) are transmitted over a single coaxial cable.

This concept of improved spectrum utilization was carried over into the AR6A development by using five MGTB mastergroups (3 through

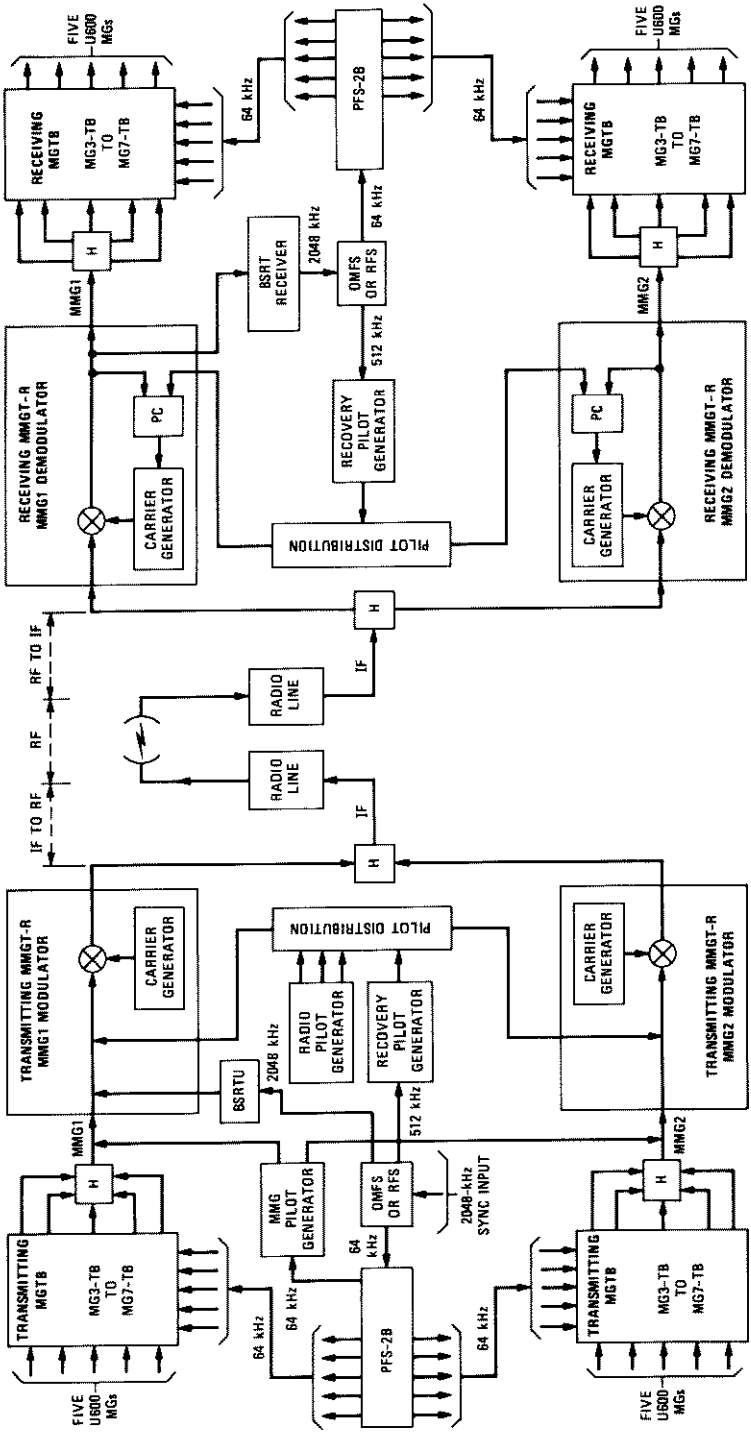

Fig. 2—Block diagram of AR6A terminal equipment.

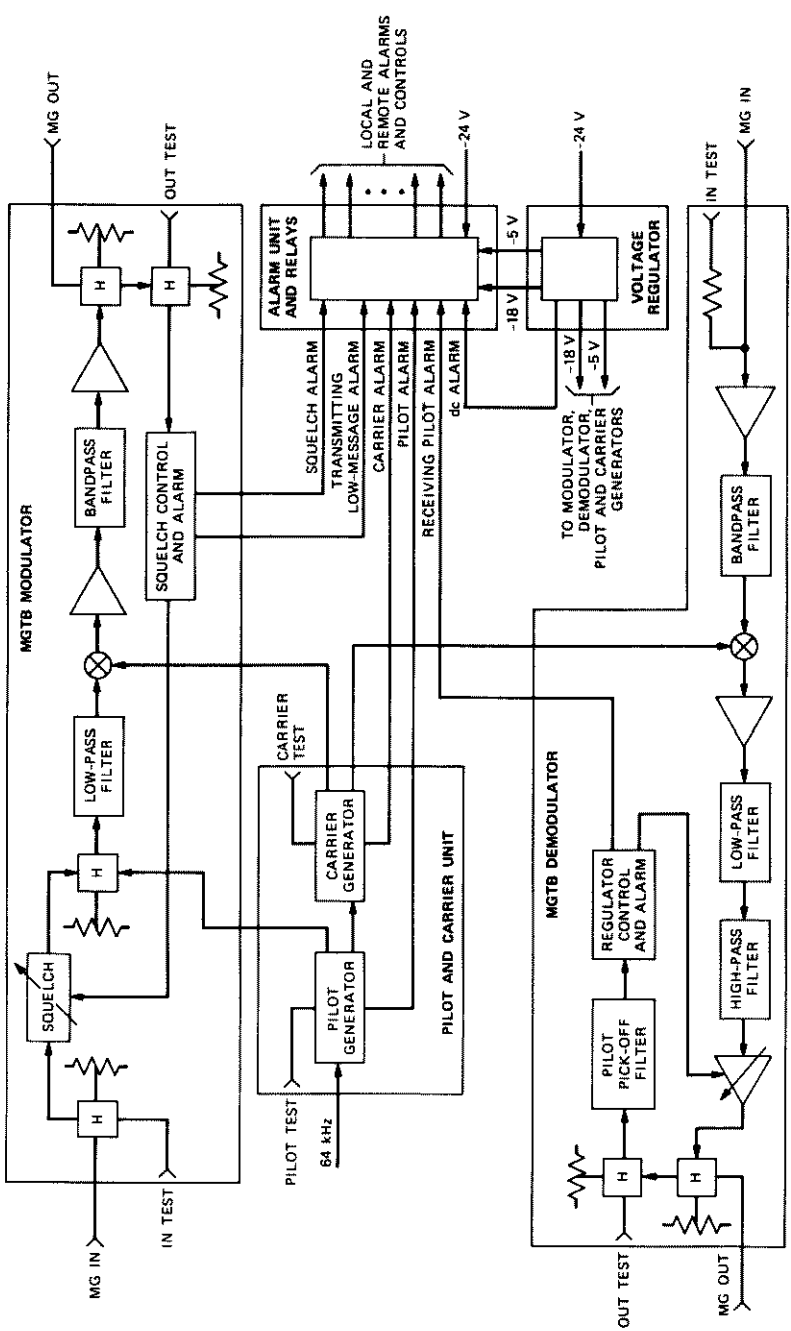

Fig. 3—Block diagram of mastergroup translator shelf.

7) to form the MMG spectrum for input to the MMGT-R. These particular mastergroups were selected to facilitate the realization of filters within the MMGT-R equipment.

### *2.3 Small size and low initial cost*

With MGT designs, the only common equipment in a bay is its battery, fuse, and synchronization distribution panel. Cost of this common equipment is a small portion of the cost of a fully equipped bay. Hence, the incremental growth cost per mastergroup is essentially the cost of the MGT shelf itself. An MGTB bay occupies only half the space needed for earlier equipment designs providing equivalent capability. All circuits for an MGT mastergroup are contained in five small plug-in units per shelf, permitting simplified maintenance or replacement.

### *2.4 Overall design features*

The five plug-in units of an MGTB mastergroup translator are a voltage regulator, alarm unit, pilot and carrier generator, and modulator and demodulator units. These five units contain the circuitry required to translate the U600 mastergroup signal to and from its line spectrum. Test jacks on the plug-in units permit signal monitoring at the inputs and outputs of the modulator and demodulator and at the outputs of the mastergroup pilot and carrier generators.

Transmission and circuit function alarms are displayed locally by indicators on the alarm plug-in and atop the bay. They are also made available to remote surveillance systems. These alarms may be operated in a latched mode, which causes retention of alarm indications until a memory release function is performed.

During a persisting alarm state, the audible alarms are silenced by depressing an Alarm Cutoff (ACO) switch on the alarm unit.

### *2.5 Circuit design features*

#### *2.5.1 Voltage regulator circuit*

A −24 volt office battery input drives two series voltage regulators to provide −18 and −5 volt outputs to power the mastergroup translator shelf circuits. The dc drain on the office battery is 1.3 amperes per MGTB shelf.

#### *2.5.2 Pilot and carrier generator circuit*

A −20 dBm0, 2.840-MHz mastergroup pilot is used to indicate the relative signal level of the mastergroup. This pilot is added in between supergroups of the mastergroup signal in the transmitting circuit before modulation. Thus, it appears in the line spectrum translated by the carrier frequency. This pilot is used for automatic regulation

and alarming. The pilot generator oscillator is phase locked to a stable Primary Frequency Supply (PFS) synchronization source which is locked to an OMFS. Hence, the stability and frequency accuracy of the mastergroup pilot are essentially the same as those of the OMFS supply.

The 64-kHz synchronization signal from the primary frequency supply is divided down to 32 kHz. This 32 kHz is used as a reference signal at one input of a phase comparator. The output of a voltage-controlled crystal oscillator, also divided down to 32 kHz, is fed to the second input of the phase comparator. Phase comparison of these two signals results in a dc control voltage to the oscillator to alter its frequency until the phases of both 32-kHz signals at the comparator inputs are identical. This constitutes the phase-locked loop concept of signal generation wherein the generated signal is stated as being phase locked to a reference signal. A filter at the generator output suppresses harmonics of the pilot frequency.

The MGTB carrier generation is similar to that of the mastergroup pilot generation previously described. The same 64-kHz synchronization signal used for pilot generation is used directly to phase lock the carrier generator to the Bell System reference signal. Two outputs at +10 dBm serve the modulator and demodulator in each MGT shelf. (See Table I for characteristics and performance of MGTB.)

Table I—Characteristics and performance of MGTB

| Characteristic | Performance |
|---|---|
| Type of modulation | SSB-SC-AM |
| Number of VF channels | 600 |
| Basic MG spectrum (U600) | 0.564 to 3.084 MHz |
| MG3B spectrum | 8.628 to 11.148 MHz |
| MG4B spectrum | 11.316 to 13.836 MHz |
| MG5B spectrum | 14.004 to 16.524 MHz |
| MG6B spectrum | 16.692 to 19.212 MHz |
| MG7B spectrum | 19.380 to 21.900 MHz |
| Return loss, all ports across their spectrum | >20 dB |
| Back-to-back frequency response | flat within ±0.4 dB |
| Receive pilot regulation range | ±5 dB |
| Loss of pilot regulation | Receiver reverts to normal manual gain setting when input pilot level deviates >−10 dB from nominal. |
| Noise performance (fully loaded and back to back) | <10 dBrnc0 |
| Phase-jitter performance (back to back) with two independent carrier supplies | <1° peak to peak, Bell weighted |
| MG carrier phase jitter | <0.7° peak to peak, Bell weighted |
| MG carrier supply frequency stability | $1 \times 10^{-9}$ with PFS-2B supply and OMFS |
| dc current drain per MGT shelf | 1.3 ampere, maximum at −24 volts dc |
| dc supply voltage | −20 to −28 volts dc |

## III. MMGT-R TRANSLATOR

### *3.1 Introduction*

The MMGT-R provides frequency translation between MMG spectra at the MGTB translators and the IF spectrum for AR6A radio. Two MMG signals (MMG1 and MMG2) are individually translated and combined to form the lower and upper portions of the AR6A IF spectrum centered at 74.1 MHz. Three radio-line pilots, required for regulation in the AR6A System, are generated in the MMGT-R transmitter.

Because the signal output of the MMGT-R transmitter is single sideband, suppressed carrier, and amplitude modulated (SSB-SC-AM), minimal carrier energy is transmitted with the sideband information. To enable the receiving translator to track and reconstruct the transmitted message accurately, a substitute form of carrier is added to the message in the transmitting translator. This is a highly stable, 16.608-MHz recovery pilot that serves as an input to a phase-locked loop in the receiving translator to control its demodulator carrier frequency. This corrects frequency offset on message due to repeatered transmission.

MMGT-R terminals are protected on a basis of one protection T and R translator pair for up to 14 regular T and R translator pairs.

### *3.2 Overall description*

#### *3.2.1 Regular terminal*

The block diagrams for the regular transmitting and receiving translator portions of the MMGT-R terminal are shown in Figs. 4 and 5, respectively.

In the transmitting direction, MMG1 and MMG2 with 13.920-MHz continuity pilots from MGTB are each translated independently up to adjacent frequency bands of the radio IF spectrum. Their combining produces a composite IF signal of two uncorrelated spectra of 3000 circuits each in the band from 59.8 to 88.5 MHz, centered at 74.1 MHz.

A number of pilots for functions required by MMGT-R and AR6A are generated within the MMGT-R transmitter and are added to the MMG signal at a −10 dBm0 level prior to translation. These include three radio-line pilots at 11.232 and 21.966 MHz in MMG2, and 19.296 MHz in MMG1. Their translated positions in the IF spectrum are shown in Fig. 1. They control automatic gain and dynamic amplitude equalizers in the radio receivers. They also serve as continuity pilots for the 500A Protection Switching System.

A 16.608-MHz recovery pilot is added to both MMG1 and MMG2 spectra prior to translation in the MMGT-R transmitters. This pilot is used in place of the suppressed carrier for demodulator carrier

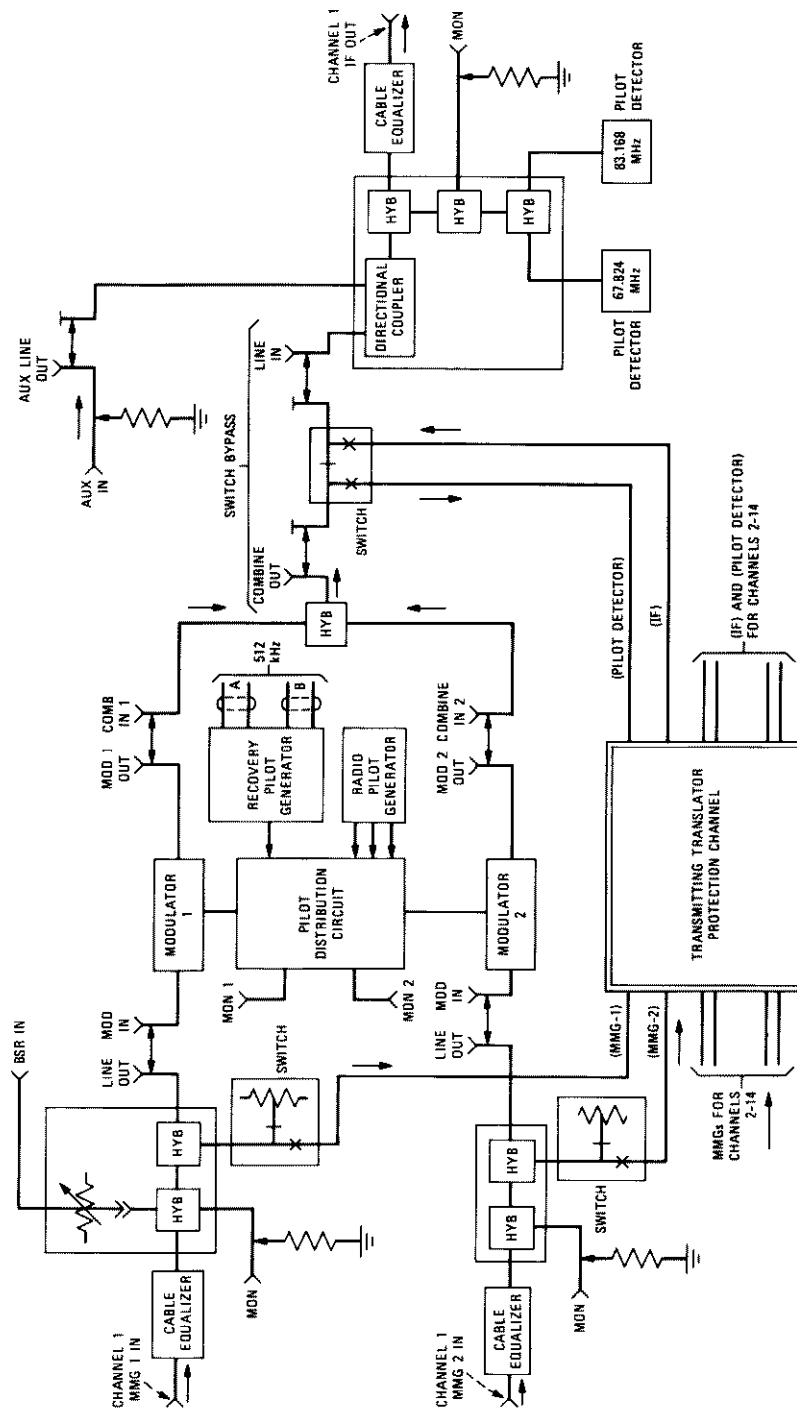

Fig. 4—Simplified block diagram of transmitting MMGT-R translator.

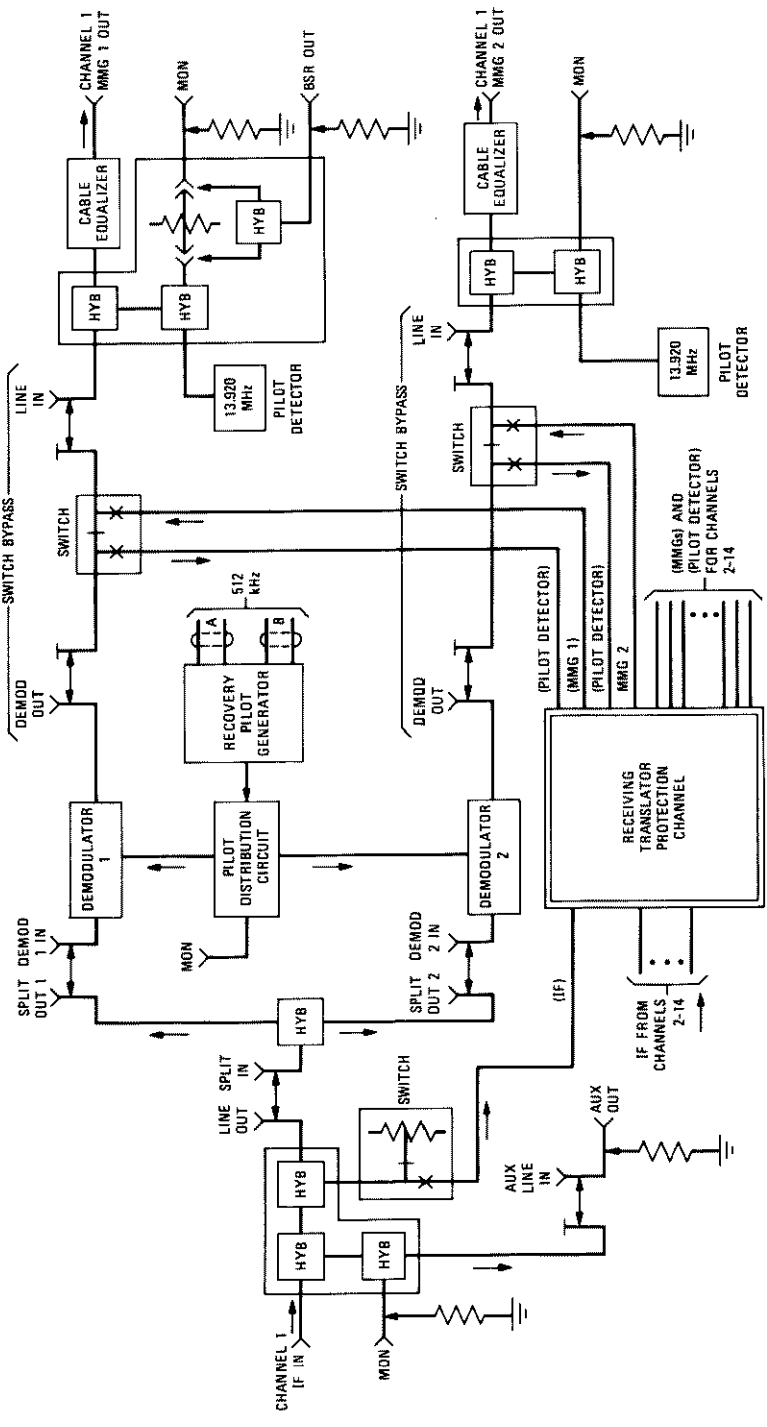

Fig. 5—Simplified block diagram of receiving MMGT-R translator.

frequency control at the receiving station. This function is discussed in greater detail later.

On occasion, it is necessary to use AR6A to transmit the Bell System reference frequency generated at Hillsboro, Missouri, to points not served by other carrier facilities. A BSRTU generator converts a 2.048-MHz reference frequency to two pilot tones separated by 64 kHz. These 11.200- and 11.264-MHz tones are added to MMG1 prior to translation in the MMGT-R transmitter. They are recovered at the receiving MMGT-R where a BSRT receiver converts their difference frequency to the original 2.048-MHz reference frequency. Although the absolute frequencies of the two tones may have shifted because of frequency error attributed to radio repeaters, their precise 64-kHz difference is preserved. Thus, the Bell System reference frequency integrity is preserved.

In the receiving direction, the IF signal from AR6A radio is passed through a splitting hybrid. A pair of upper and lower IF sideband filters separates the signal into its two original sideband components. Each sideband is then translated downward to the multimastergroup spectrum for further demodulation to the basic mastergroup spectrum in MGTB equipment.

### *3.2.2 Protection terminals*

As shown in Figs. 4 and 5, protection transmitting and receiving translators are provided for equipment protection, maintenance, and restoration. The equipment required for this includes switches, pilot detectors, pilot oscillators, and a microprocessor control circuit. The switches, pilot detectors, and oscillators are located in the MMGT-R shelves. The 500B protection switch microprocessor control unit is located in an adjacent bay. Thus, only dc control leads are required between the 500B and MMGT-R bays, and transmission cable lengths are minimized.

Service is routed through the protection translator when a fault is detected in a regular translator or when a manual switch is requested. One protection translator provides protection for up to 14 regular translators. Receiving and transmitting translators are protected independently of each other. This results in two separate 1 × 14 switching arrangements under the common control of a single 500B controller at each MMGT-R location.

Loss of the 13.920-MHz continuity pilot in an MMG is detected by the MMGT-R equipment. When a failure occurs, the 500B controller transfers both MMG1 and MMG2 to protection even though a failure may have been associated with only one MMG. Local and remote alarms and indications are provided by the 500B.

### 3.3 Detailed description

#### 3.3.1 Transmitting translator

Each transmitting translator includes all of the networks and circuits required to translate a pair of MMG signals to the lower and upper IF frequencies (see Fig. 1). The protection transmitting translator differs from the regular one only in the peripheral circuits associated with the input and output functions. Plug-ins MODULATOR 1 and MODULATOR 2 (see Fig. 6) each contain a balanced diode ring modulator, amplifiers, and a free-running, crystal-controlled carrier oscillator. IF bandpass filters select the lower sideband of each modulator.

A 16.608-MHz recovery pilot generator (RCVRY PLT GEN) is phase locked to a local 512-kHz signal derived from the OMFS which is locked to the Bell System reference. A hybrid transformer network distributes the recovery pilots to the MMGT-R modulators.

The radio-line pilots are generated by three free-running crystal oscillators at frequencies of 11.232, 19.296, and 21.966 MHz and are added to the MMG signals by the hybrid transformer network above.

The distribution network maintains at least 85 dB of isolation between the two MMG signal paths of an MMGT-R.

MMG1 and MMG2 input networks provide terminated monitoring access and split the signal to provide inputs to the protection translator. The Bell System Reference (BSR) input option is required only for MMG1.

An output port is available to make terminated measurements of the IF output signal. An auxiliary input port may be used for restoration. Pilot detectors monitor the translated 13.920-MHz continuity pilots to initiate a switch of both MMGs to protection when the level of either or both drops 6 dB or more.

#### 3.3.2 Receiving translator

The receiving translator accepts an IF signal from AR6A via the 500A protection switch. This IF signal is split into two paths by a hybrid, following which the upper and lower IF bands are selected with IF bandpass filters. Each is then demodulated to the MMG

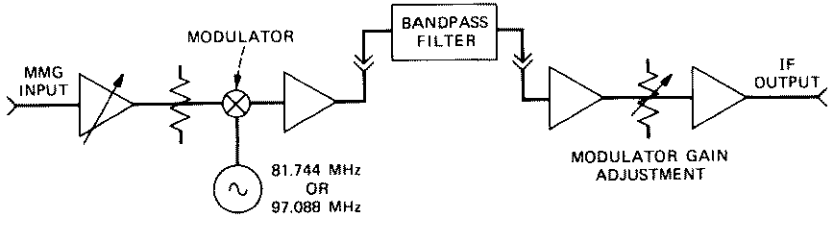

Fig. 6—MMG1 or MMG2 modulator.

spectrum for connection to receiving MGTB equipment. Plug-ins DEMODULATOR 1 and DEMODULATOR 2 (see Fig. 7) use ring-type modulators as in the transmitting direction. The demodulator carriers are generated by voltage-controlled crystal oscillators. Their frequency is controlled by a phase-locked technique to correct the frequency error that accumulates along the radio line. This technique is described below.

A 16.608-MHz recovery pilot is generated in the receiving office translator in a manner identical to that used in the transmitting office translator. It is phase locked to the Bell System reference via the local 512-kHz reference frequency at the receiving site. This 16.608-MHz signal serves as the reference input to the phase-locked loop of each demodulator carrier generator.

From each demodulated MMG in the receiving MMGT-R, the recovered 16.608-MHz pilot, with any frequency offset acquired over the radio line, is selected by a narrowband crystal filter. The phase of this received pilot is compared to that of the locally generated 16.608-MHz signal. Any phase difference between them is converted to a dc control voltage change. This voltage change alters the frequency of the carrier oscillator in a direction to correct frequency offsets of at least ±2500 Hz in the received signal. This technique ensures that the recovered MMG signal is a faithful reproduction of the original transmitted signal.

To enhance the pull-in range of the phase-locked loop, a low-frequency (≈2 Hz) oscillator has been added to the loop filter feedback circuit. This oscillator is activated upon interruption of one or both phase comparator input signals, and when activated, it modulates the

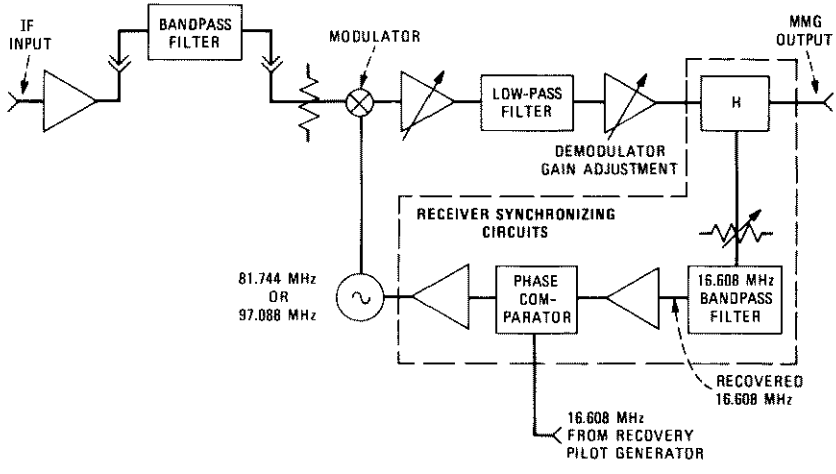

Fig. 7—MMG1 or MMG2 demodulator.

oscillator dc control voltage with sufficient amplitude to sweep the carrier frequency over a range of ±2500 Hz from nominal. This facilitates recapture of a restored signal. In addition, the low-frequency signal is peak detected to generate an out-of-lock alarm and a protection-switch request. Once the loop reacquires lock, the low-frequency oscillator is immediately disabled and has no effect on normal operation.

To accommodate space-diversity applications, the receiver phase-locked loop has been designed such that large phase hits coupled with sudden signal up fades will result in less than 2 ms of loop-phase instability.

The receiving IF network provides terminated monitoring access and splits the signal for protection switching. It also provides an auxiliary output for restoration. Signal monitoring access is provided at both translated MMG outputs. Pilot detectors monitor the recovered 13.290-MHz continuity pilots to initiate protection switching. On a 6 dB or more drop in level of either or both MMG pilots, both MMGT-R translators will switch to protection.

#### *3.3.3 Recovery pilot generator*

The 16.608-MHz recovery pilot generator is shown functionally in Fig. 8. Reproducing the transmitted signal accurately is highly dependent upon synchronizing the pilot generator to accurate 512-kHz reference frequency signals. These are derived from the OMFS, which, in turn, is locked to the Bell System frequency source at Hillsboro, Missouri.

To enhance overall reliability, redundant 512-kHz inputs, designated A and B, are supplied to each recovery pilot generator. This is done over separate 135-ohm balanced cable buses and, where possible, via different cable ducts.

The recovery pilot generator accepts two 512-kHz signals, filters them in narrowband crystal filters, amplifies them, and via a divider, converts each to a 32-kHz square wave. A logic switch, preferential to the A signal, provides the selected 32-kHz square wave to one input of a digital phase comparator. The second input to the phase comparator is derived from a portion of the 16.608-MHz crystal oscillator output, which is converted to a 32-kHz square wave. Phase comparison of these two signals results in a dc control voltage that locks the oscillator precisely at 16,608,000 Hz.

Manual test operation of the 32-kHz logic switch is provided. However, phase hits could occur due to reference frequency signal switching. To prevent this, manual switching in the regular channel recovery pilot generator is inhibited unless service is being carried on the protection channel. Conversely, a manual switch in the protection

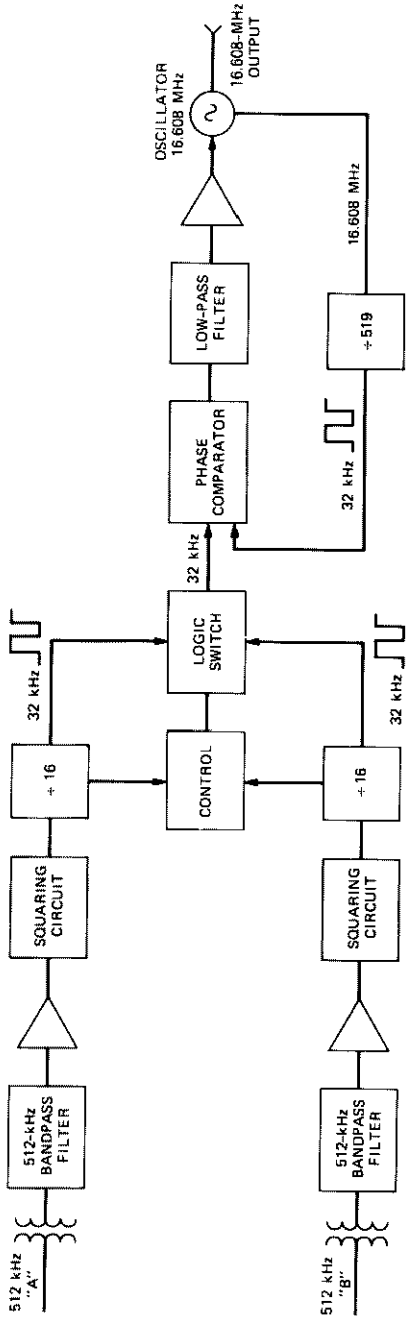

Fig. 8—Functional diagram of a recovery pilot generator.

channel recovery pilot generator can only be made when the protection channel is idle. (See Tables II and III for characteristics and performance of MMGT-R.)

### *3.4 Realization of objectives*

The performance objectives listed represent acceptable levels of performance. Measured data reflect a level of performance better than the values shown. Examples may be seen in Figs. 9 and 10. Figure 9 shows a plot of amplitude versus frequency for a production transmitting and receiving translator pair connected back to back. Figure 10 shows representative noise load data for the same equipment in the same configuration. As the figure indicates, noise performance is thermally limited.

The overall amplitude versus frequency curve in Fig. 9 is a nonadjustable parameter. It is influenced by the response of the individual components (amplifiers, filters, etc.). The only equalization used with

Table II—Characteristics and performance of MMGT-R

| Characteristics | Performance |
|---|---|
| Type of modulation | SSB-SC-AM |
| Number of MMGs | 2 per AR6A channel |
| Number of MGs | 5 per MMG (10 total) |
| MMG spectrum (MG 3-7) | 8.628 through 21.900 MHz |
| IF output spectrum | 59.844 through 88.460 MHz |
| MMG transmit input level | −41.6 dBTL |
| IF transmit output level | −23.9 dBTL |
| IF receive input level | −32.1 dBTL |
| MMG receive output level | −22.4 dBTL |
| Return loss (all ports) | >25 dB |
| dc power—input voltage | −20 to −28 volts dc |
| dc current drain (per shelf) | 2.8 amperes maximum at −24 volts dc |
| Normal power dissipation per 7-foot bay (3T/R pairs) | 400 watts |
| Protection | 500 B − 1 × 14 maximum |

Table III—Performance of MMGT-R

| Performance Objectives | Worst-Case Deviation |
|---|---|
| Gain frequency response (1 − TR pair) | <±0.3 dB peak to peak across any MG |
| Noise performance (equivalent 6000-circuit load, 1 − TR pair) | <15 dBrnc0 |
| Crosstalk | <−100 dB |
| Carrier leak | ≤−70 dBm0 |
| Spurious tones | ≤−70 dBm0 |
| Phase-jitter performance for ten terminal pairs in tandem | ≤1° peak to peak, Bell weighted |
| Frequency stabilities (over 80° ±20°F temperature range and permissible power supply variation) | |
| Transmitter carrier oscillator frequency | ±200 Hz |
| Radio-line pilot oscillator frequency | ±4 parts per million |

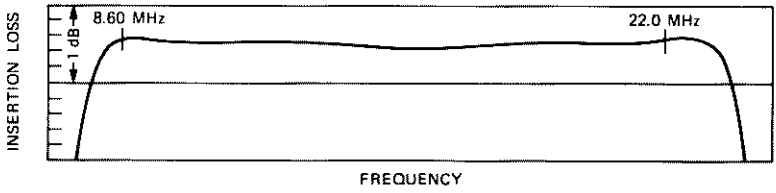

Fig. 9—Typical amplitude vs. frequency response of transmitting/receiving translator.

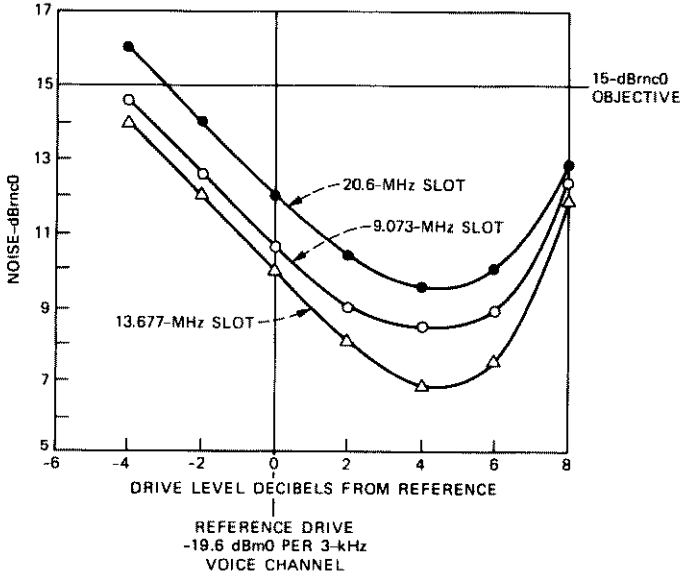

Fig. 10—Typical noise load performance of transmitting/receiving translator.

MMGT-R compensates for amplitude slope due to cable lengths in trunks between the MMGT-R, the MGTB, and the 500A equipment.

Mastergroups assigned to AR6A contain a mixture of analog-voice and voiceband data circuits subject to impairment due to excessive phase jitter. Strict phase-jitter requirements are placed on the transmit and receive carrier generators and on the recovery pilot generator to minimize phase-jitter transfer to data signals.

### *3.5 Physical design considerations*

#### *3.5.1 Goals*

The physical arrangement of the MMGT-R equipment is oriented to achieve three major goals: (1) high reliability; (2) ease of installation, maintenance, and growth; and (3) cost-effectiveness. The first two items influence the third.

### 3.5.2 Reliability

When considering that an MMGT-R shelf carries up to 6000 two-way voice circuits and that a 7-foot bay carries up to 18,000 such circuits, reliability is of utmost concern. With this in mind, an early decision was made to minimize the amount of common equipment and to have each transmitting and receiving translator function independently.

This simplified the protection aspects of the system and minimized the risks to remaining operational parts of the system when equipment failures require repair or maintenance.

Carriers and recovery and radio-line pilots are all generated on a per-shelf basis with plug-in modules that may be replaced easily.

Converters of the dc-to-dc type are provided on a per-shelf basis with separate power for switching and transmission functions. A switching power failure does not impair transmission, and active transmission circuits are fully protected.

By locating switches and detectors in the same shelf as the equipment they protect, transmission cable lengths and interbay wiring and cabling are minimized.

The shelf and plug-in layouts promote rapid and natural heat dissipation. A combination of baffles and perforated cover assemblies permit the free flow of air vertically and from front to rear of each shelf. Each shelf has its own airflow pattern, avoiding high concentration of heat in the upper region of the bay.

### 3.5.3 Ease of installation, maintenance, and growth

The combination of the factors described previously led to a completely self-contained, totally connectorized shelf design. Thus, it requires no installer wiring for initial or subsequent growth installation. An alarm and fuse panel at the top of each bay constitutes the only MMGT-R common equipment. The protection MMGT-R and switch controller are naturally required with the initial installation to permit subsequent growth.

Redundant diode-firmed −24 volt power leads and 512-kHz reference frequency leads are connectorized and provided from the fuse panel to each shelf position in the bay. All active circuitry is of the plug-in type and all passive circuitry uses connectors for ease of removal or replacement. Access ports are provided for components outside protection switching boundaries to readily permit their bypassing for removal or replacement without delaying service restoration. These design concepts achieve a highly reliable and easily maintained circuit and equipment arrangement capable of "graceful growth."

### *3.5.4 Cost-effectiveness*

As we stated earlier, achievement of the first two goals contributes significantly to providing a cost-effective system. By minimizing the amount of common equipment, the costs for new installations or for low cross-section systems with limited growth potential are reduced. Thus, the costs per circuit mile tend to be distributed more evenly. The reduced time required for installation and maintenance also contributes to lower overall operating expenses as well.

## *The AR6A Single-Sideband Microwave Radio System:*

# Frequency Control

By J. M. KIKER, Jr.* and S. B. PIRKAU*

(Manuscript received February 14, 1983)

The AR6A Radio System requires precise control of the local oscillator frequency at repeaters and main stations, so that the IF equalizer pilots will be accurately located with respect to the narrowband crystal pick-off filters. In addition, the accumulated frequency error from each repeater and main station must be limited to a value that can be corrected by the tracking receiver of the multimastergroup terminal. Precise frequency control is maintained along the route by locking local oscillators to a stable and accurate frequency reference provided at each repeater station by the Microwave Carrier Synchronization Supply (MCSS). The MCSS provides a source and a backup for this signal. Extensive monitoring circuitry in the MCSS detects failed conditions. The accuracy of the two oscillators is continuously monitored by making frequency comparisons of their output. These frequency-monitoring circuits are also used to make yearly adjustments to the oscillators using a rubidium frequency standard as reference. This paper describes the MCSS System that has been developed for the AR6A Radio System.

## I. INTRODUCTION

Compared with current 6-GHz FM Radio Systems like TH-1 or TH-3, the new AR6A† Radio System requires much tighter radio-frequency tolerances to keep radio-line pilots within narrowband pick-

off filters. These pilots should remain within ±2 kHz of the center frequency of their pick-off filters, which translates to a frequency tolerance of about three parts in $10^7$ compared to the TH-3 tolerance of two parts of $10^5$. This tighter tolerance is beyond the capability of currently available microwave generators used as carrier sources for up conversion and down conversion in the radio Transmit-Receive (TR)* units. The required stability is obtained by synchronizing the microwave generators and shift oscillators to a highly stable frequency synchronization supply located in each radio station. This AR6A Microwave Carrier Synchronization Supply (MCSS) is described in the following sections. The paper then presents an overall block diagram description of the MCSS and discusses in more detail the various subsystem components.

## II. FUNCTIONAL DESCRIPTION OF THE MCSS

The MCSS distributes a highly accurate sine-wave frequency of 308.8735416 kHz (abbreviated as 308.9 kHz) to each TR-bay microwave generator and shift oscillator as illustrated in Fig. 1. All microwave-generator frequencies and the shift-oscillator frequency are harmonics of this reference signal and are locked to it by phase-locked loop circuitry located in the frequency control units. The distribution bus provides 32 isolated outputs that can supply reference signals to a fully loaded route of eight two-way AR6A radio channels (eight channels by two directions by two oscillators per bay).

Figure 2, a block diagram of the MCSS, shows two symmetrical sections (frequency supplies), one of which is used for on-line operation and the other for standby. The major component in each of the two sections is a crystal-controlled, 4.94197666-MHz (hereafter abbreviated to 4.94 MHz) oscillator that has a long-term frequency stability of 1.8 parts in $10^7$ per year. Each oscillator is associated with a divider/switch unit, which performs both a frequency division of 16 and power monitoring functions. Although only one of the two oscillators is used at a time, a continuous frequency comparison between them checks for an excessive frequency difference and generates appropriate alarm signals if the difference exceeds certain values. The interconnection between the two sections is accomplished through the control unit, which offers automatic switching between output signals under trouble conditions or manual switching for maintenance purposes.

Figure 3 is a picture of the MCSS that shows the major component parts described above.

## III. DETAILED CIRCUIT DESCRIPTION

### *3.1 4.94-MHz oscillator**

The 4.94-MHz oscillator, shown in block diagram form in Fig. 4, consists of a crystal-controlled oscillator, RF amplifier, frequency-controlling network, and temperature-control network in a thermally stable environment. Because of repeater-station temperature variations, use of a stable oven is necessary to obtain the required frequency stability. Other peripheral circuitry such as the heater power amplifier, the binary frequency-controlling switches, and their display Light Emitting Diodes (LEDs) are exposed to ambient temperature.

#### *3.1.1 Radio Frequency (RF) oscillator and amplifier*

The RF oscillator is a modified Pierce-type crystal oscillator using a precision quartz crystal unit. A capacitance and varactor-diode network is in series with the crystal for frequency adjustment of ±3 ppm from the nominal frequency of 4.94197666 MHz. This stage has automatic gain control to ensure stable frequency operation. The crystal unit is a third-overtone AT-cut resonator having a turnover temperature between 76 degrees and 86 degrees Celsius. The output

* The MCSS oscillator was designed by M. W. Zuidervliet, Jr. of Bell Laboratories in Allentown, PA.

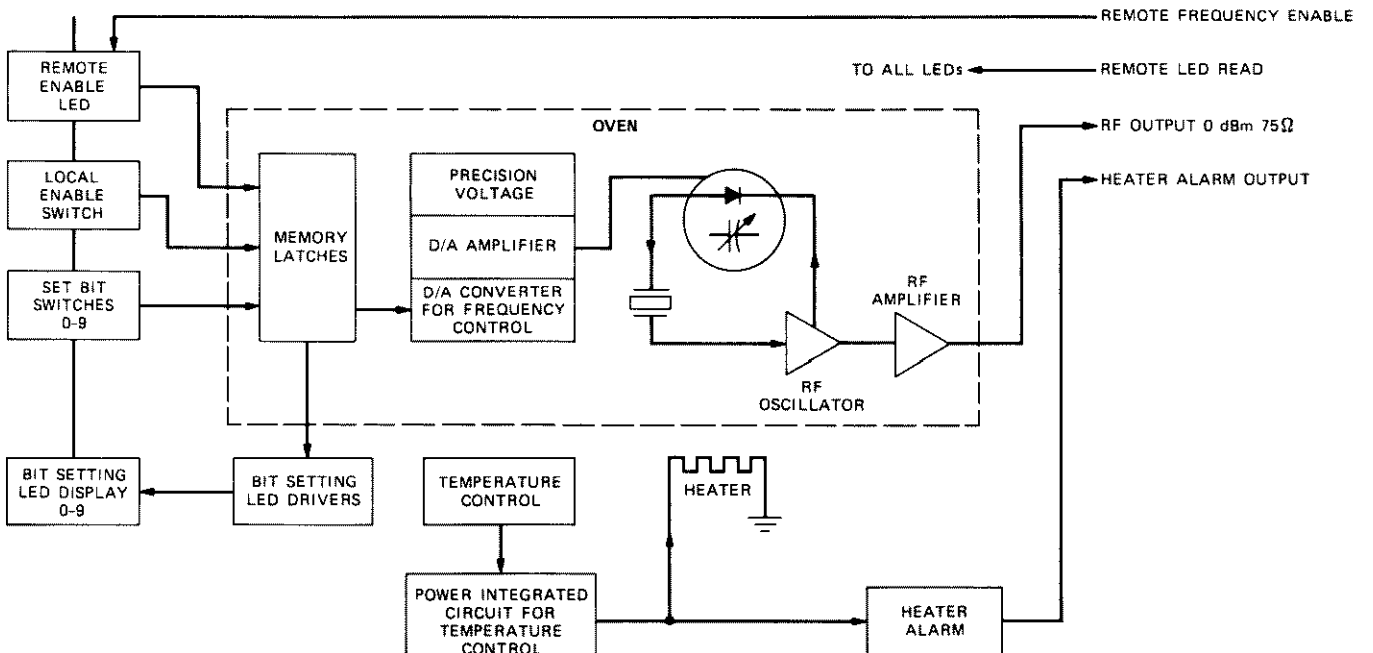

Fig. 4—Block diagram of MCSS oscillator.

of the oscillator is at the base of a low-noise transistor that uses the crystal unit to filter out any noise generated in the transistor that is more than a few hertz from the operating frequency. The output impedance of the oscillator is 50 ohms.

The RF amplifier consists of four transistor stages that buffer the oscillator from the output and boosts the output signal level of 0 dBm at an output impedance of 75 ohms.

### *3.1.2 Frequency tuning circuitry*

The varactor diode, in series with the crystal, is biased from the frequency adjust circuitry made up of a precision voltage reference source, Digital-to-Analog (D/A) converter, and current-to-voltage operational amplifier. Front-panel toggle switches control memory-latch circuits that, when enabled, supply digital input to the D/A converter. The D/A converts this input to a precision current value utilizing the precision voltage reference. A voltage proportional to this current is applied as bias to the varactor diode. The ten toggle switches are arranged for binary weighting with the least-significant bit giving a frequency change of one part in $10^8$. A new switch setting is input to the memory latches only when a remote enable signal is present and a load button on the oscillator is depressed. At other times the position of the toggle switches has no effect. This feature is present to prevent accidental detuning of the oscillator. Since the switch settings do not necessarily agree with the status of the memory latches, display LEDs are provided on the front panel that, when enabled, indicate the value of the digital input to the D/A.

### *3.1.3 Temperature control and heater alarm*

The temperature of the oven is maintained by a proportional temperature control using a Wien Bridge oscillator where the sensing elements are two thermistors in series. These thermistors are imbedded in the wall of the oven and are tightly coupled to the heater winding. The output of the Wien Bridge oscillator is buffered by an amplifier that has variable gain for adjustment of the sensitivity of the temperature-control circuit. This amplifier drives a power integrated circuit that provides the dc power to the heater winding. The power stage limits the current into the 15-ohm heater winding to approximately 1-1/3 amps.

There is an alarm circuit that senses the heater-winding control voltage and emits an alarm if this voltage moves beyond the window for normal operation. This is an indication that the oscillator already has or is about to lose temperature control and therefore change frequency.

### *3.2 Divide-by-16 circuit*

The main purpose of this circuit is to convert the 4.94-MHz input to 308.9 kHz and gate this signal to the distribution bus when the supply is on-line. There are two identical circuits corresponding to sides A and B.

Figure 5 shows a block diagram of the divide-by-16 circuit. Following the main signal path, the 4.94-MHz sinusoidal input signal is converted to a Transistor-Transistor Logic (TTL)-compatible square wave and divided by 16. The signal from the divider is input to one side of an AND gate. If this supply is to be selected as on-line, a select signal from the control unit enables the other gate input and the 308.9-kHz signal is output to the distribution bus.

Various monitors in the circuit detect improper operation. At the input, a detector monitors the level of the incoming 4.94-MHz signal and, if that level drops 2 dB, outputs an alarm to the control unit. A gradual 2-dB drop in level is not sufficient to cause the sine-wave-to-square-wave comparator to fail; thus, the alarm to switch to the other supply can be given before actual loss of 308.9 kHz occurs.

A coarse frequency monitor of the 308.9-kHz signal guards against a failure of the divider. This will detect a gross error that would occur if the divider malfunctioned to produce the wrong division ratio. A detected error of this type is output as an alarm to the control unit.

The level of the 308.9-kHz signal output to the distribution bus is monitored. The output gate for this signal is the last active circuit component of the reference signal path to the TR-bay frequency control units. The alarm indication for loss of level is output to the control unit but is meaningful only if the gate output is on-line.

The circuit buffers and provides a TTL line driver output of the 4.94-MHz signal to the frequency comparator unit where precise frequency comparisons between the two oscillators occur.

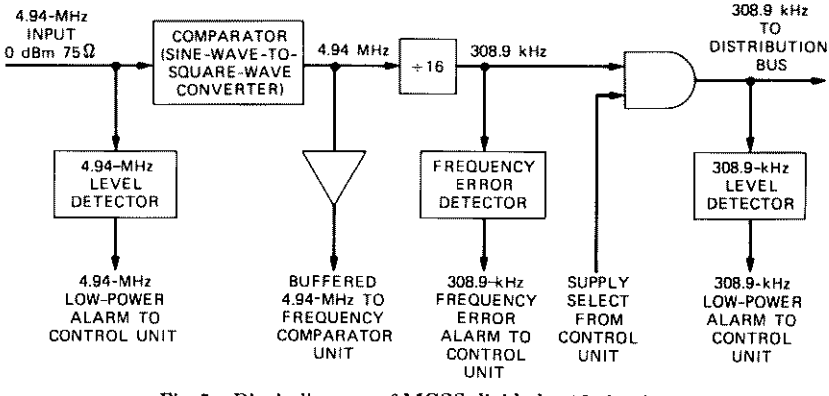

Fig. 5—Block diagram of MCSS divide-by-16 circuit.

### *3.3 308.9-kHz distribution*

The outputs of the two divider switch circuits are gated to the distribution circuit. Either circuit, but only one at a time, provides a 308.9-kHz TTL signal for the distribution bus. The two signal inputs are combined in a resistive power combiner followed by a 308.9-kHz bandpass filter that provides at least 40 dB of loss to frequencies of 618 kHz and higher with a passband loss of less than 1 dB.

The 308.9-kHz sine-wave output from the filter, at an impedance level of 135 ohms, is fed to a balanced transformer with a 135- to 8.06-ohm impedance transformation. This output drives a passive resistive distribution bus that provides 33 outputs balanced at an impedance of 135 ohms. Thirty-two of the outputs are for distribution to the TR bays and are terminated if not used. The remaining tap provides a monitor port for measurement of signal level at the bus output. There is 18 dB of signal loss from the filter output to any tap output, and the tap-to-tap isolation is 36 dB.

### *3.4 MCSS control unit*

The interconnection between the two 308.9-kHz sources of the MCSS is accomplished through the control unit. The control unit handles all MCSS alarms, as well as power and frequency sensor functions, and performs four separate major functions:

1. Selects (puts on-line) one of the two MCSS oscillators as the 308.9-kHz source.
2. Offers automatic switching to the other MCSS oscillator should the on-line unit develop any trouble.
3. Originates the general MCSS alarm together with visual indications pinpointing the specific alarm condition.
4. Furnishes the interface for the two oscillators, two divider and switch units, the frequency comparator unit, and the alarm unit.

All of the above-listed functions can be performed in either the auto or manual operating modes. The auto mode of operation is the normal operating condition of the control unit. In this mode, all sensors are monitored and an automatic switch will occur if there is a failure in the on-line supply. The sensors monitor the following items:

1. Power output of the 4.94-MHz oscillators
2. Operation of the oven within the oscillator unit
3. 308.9-kHz coarse output frerquency and power
4. Frequency difference between the two oscillators.

The sensors for items 1 and 3 are located on the divider and switch units and for item 4 on the frequency comparator unit.

The most severe alarm condition is the cut-reference alarm. When this alarm is generated the MCSS outputs to the TR bays are removed

and the microwave generators and shift oscillators become free running. This alarm can be generated for two reasons:

1. The frequency offset between the two oscillators is greater than 39.3 parts in $10^8$ (measured by the frequency comparator unit).

2. A failure has occurred first in the on-line section, causing an auto switch, and then in the former standby section, which was put on-line by the auto switch mentioned above. If the failure is in the standby supply, an oscillator fail alarm is generated and all switching between supplies is inhibited. Subsequent failure of the on-line supply will cause a cut-reference alarm.

The manual mode of operation is primarily for maintenance and repair of the MCSS. It permits a manual switch resulting in an interchange of the on-line and the standby section of the MCSS. However, consideration had to be given to the fact that whenever a manual switch to the standby supply is executed, a check has to be performed to determine if the newly selected supply does have a signal output of correct amplitude. Therefore, once a new supply is selected and on-line, enough time has to be allowed to permit a switchback to the previous on-line supply should the new one fail to produce a suitable output signal. Delay circuits permit this.

Since an auto switch will only occur as a result of a failure in the on-line section of the MCSS, a switchback is not possible and the check for a good output signal of the standby section is not necessary.

### *3.5 MCSS comparator unit*

#### *3.5.1 Functional description of the MCSS comparator unit*

The comparator unit performs two major functions in the MCSS.

1. For normal operation, there is continuous monitoring of the frequency difference between the two 4.94-MHz oscillators. An alarm signal is generated if the frequency difference exceeds 16.6 parts in $10^8$. A second alarm and cut-reference signal is generated when this difference increases to, or exceeds, 39.3 parts in $10^8$. The cut-reference signal removes the synchronization tone from the microwave generators and shift oscillators, and these units become free running.

2. Replacement or yearly routine maintenance requires frequency adjustment of the 4.94-MHz oscillator. In the frequency check mode of operation, the comparator aids in oscillator adjustment by indicating the frequency difference between the oscillator being adjusted and an external frequency calibration standard. In this mode, the comparator has a resolution of $\pm 1$ part in $10^8$, which is based on the settability of the 4.94-MHz oscillators whose smallest frequency adjustment increment is one part in $10^8$.

The position of the front-panel mounted function select switch, which can be in either the check A or check B position, determines

which 4.94-MHz oscillator is being checked against the external frequency standard. In the check B position, the external frequency standard takes the place of oscillator A and in the check A position the external frequency standard takes the place of oscillator B.

When in the check A or check B position, all frequency alarms are inhibited. The four light-emitting diodes on the front panel of the unit are enabled. These LEDs are labeled and arranged in the following manner:

$10^{-7}$
HIGH
$10^{-8}$
$10^{-8}$
LO
$10^{-7}$

The HIGH or LO indicates the direction of frequency deviation of the checked 4.94-MHz oscillator in comparison with the frequency standard. By observing the LEDs, the oscillator can be adjusted to within one part in $10^8$ of the 4.94-MHz signal.

Adjusting the oscillator is accomplished through ten toggle switches, labeled zero through 9, arranged in a binary weight fashion with the least significant bit being switch zero.

### *3.5.2 Method of detecting frequency offset*

The conventional method of detecting a frequency difference between two oscillators, in which one oscillator will generate a gate pulse during which the other oscillator is counted, results in large time intervals to detect small offsets. For example, to detect one part in $10^8$ for the MCSS 4.94-MHz oscillators would require a minimum time of $1/\Delta f = 20$ seconds, which is an unreasonable time interval.

The method chosen for measuring frequency differences in the MCSS is the same as that used on the Jumbogroup Frequency Supply (JFS) of the L5 System, which Fig. 6 shows utilizing the block diagram of the MCSS comparator. In this method, one of the two frequencies being compared is divided by D and then mixed with itself, with the sum signal A + A/D chosen by a bandpass filter. This signal is mixed with oscillator B and passed through a low-pass filter with the resulting signal difference of frequency

$$A + \frac{A}{D} - B = \frac{A}{D} + \Delta f.$$

This signal is used as a clock signal for an N divider that generates a gate pulse. During the gate-pulse interval, counts are accumulated by the C counter. This has the effect of multiplying the real fractional

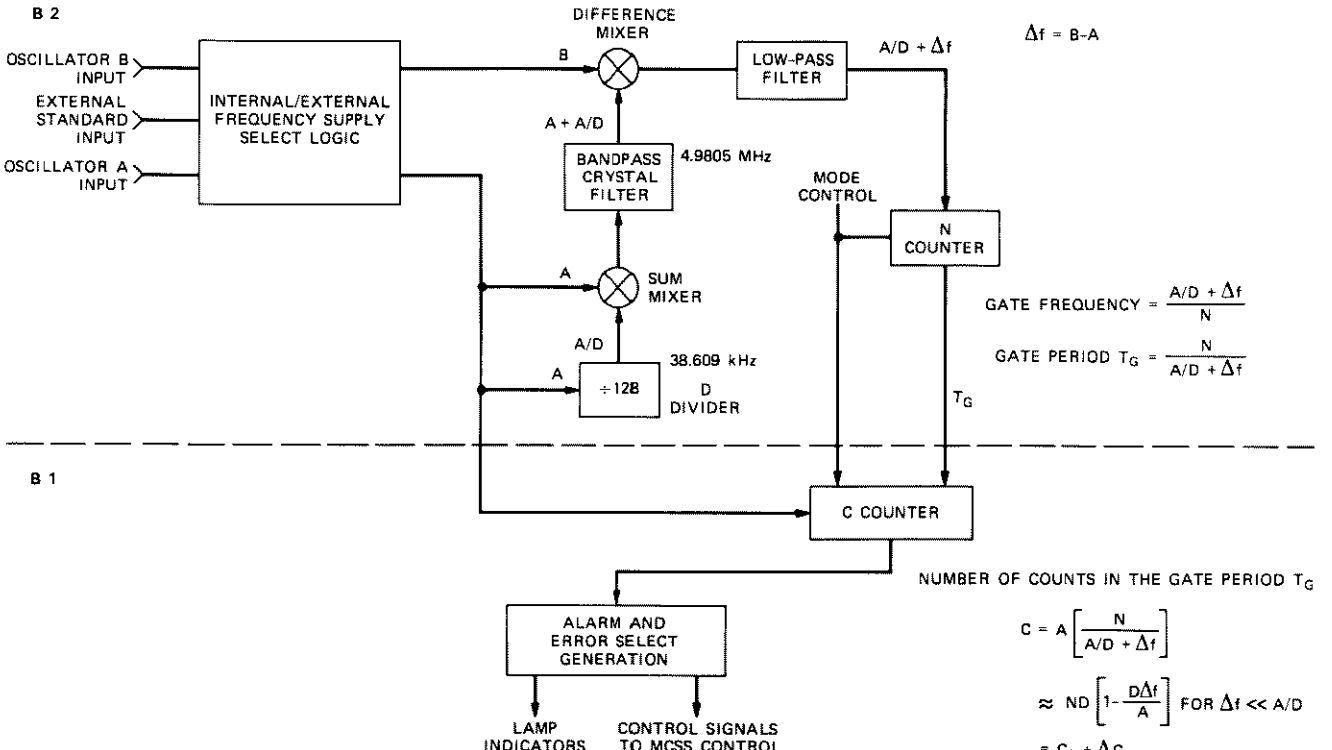

Fig. 6—Block diagram of MCSS comparator unit.

frequency error by a factor D. For the MCSS a value of D = 128 was chosen as realistic when considering the need for the bandpass filter that must pass A + A/D and reject A − A/D. Now the minimum time to detect an error of one part in $10^8$ is the time for $ND^2\Delta f/A$ to equal one, i.e., one extra or one less count than normal for no frequency error. Solving for N, one obtains

$$N = \frac{A}{D^2\Delta f}$$

The gate interval for the minimum count to occur is $T_G \approx ND/A = 1/D\Delta f$. This time interval is shorter than that for the conventional methods by a factor of 128.

#### *3.5.3 Block diagram and description*

Figure 6 shows the block diagram representation of the comparator unit. Two printed circuit boards (B1 and B2) are used to accommodate the large number of integrated circuits and the relatively large inductors comprising the low-pass filter. The inputs to the comparator unit, during normal operation, are two 4.94-MHz TTL signals derived from oscillators A and B. For routine maintenance and oscillator calibration, a third input signal, also TTL compatible, from an external frequency standard is also connected to the comparator unit.

The input signal frequency to the 14-stage N counter is A/D + Δf. The output of this counter is the gate pulse ($T_G$) for the C counter. The 22-stage C counter is preset to a value $C_0$ dependent on the operating mode. The clock input signal is from oscillator A, which counts down the C counter during the gate period $T_G$. If oscillators A and B are identical in frequency, the C counter will count down from $C_0$ to zero. The value of the C counter is determined by monitoring the Q signals of each counter stage. The Q signals are gated together to detect values of ΔC which correspond to frequency differences. The count can be either positive or negative, depending on whether the counter went through zero or not. For normal operation, only the magnitude of the ΔC count is significant. However, during frequency adjustment of the two oscillators, the sign of the count is also important because the frequency of the oscillator being adjusted is compared to an external frequency standard and the sign of the frequency error must be known for proper adjustment. In the frequency check modes, instead of generating alarms for excessive frequency differences, the comparison circuit uses the four LEDs on the front panel to indicate the magnitude and direction of frequency deviation of the oscillator.

#### *3.5.4 Other design considerations*

Except during oscillator adjustment and routine maintenance, the comparator unit operates in the normal mode. In this mode, only a

frequency alarm and cut-reference signal and alarm are generated when the frequency difference between MCSS oscillators is 16.6 parts in $10^8$ or 39.3 parts in $10^8$, respectively. The frequency comparison period in this mode of operation is only 78 milliseconds. It is possible for erroneous counts to occur because of plant battery hits or other office transients. To guard against false alarms occurring due to these erroneous counts, four-stage shift registers are used to output the frequency alarm and the cut-reference signal. To obtain an output from these shift registers, four consecutive readings exceeding the appropriate $\Delta C$ limit must occur. This, of course, delays the alarm signals by 312 milliseconds, but is quite acceptable in this application and does eliminate false alarms or, more seriously, loss of sync to an entire station because of an erroneous cut-reference signal.

### *3.6 MCSS dc power*

The MCSS dc power is provided by regulated dc-to-dc converters (−24 to +5 volts dc), which are current limited, over-voltage protected, and low-voltage alarmed. The two 4.94-MHz oscillators are powered by separate 5-volt dc converters. These same converters also individually power the divider/switch circuits. The comparator and control unit are dual fed from the two converters using diodes. These procedures are used in the MCSS to guard against reference signal loss due to failure of any single power unit.

### *3.7 Alarm unit*

The alarm unit in the MCSS provides visual and audible alarms of low power and other trouble conditions in the MCSS. It generates remote indications via telemetry systems to the alarm center, as well as local station alarms. Standard ACO features are available that can be activated at any miscellaneous key, jack, and lamp panel in the support bay or at any TR-bay display panel.

## IV. SUMMARY

The paper has described the important features of the AR6A MCSS. The MCSS provides a precise reference signal at 308.9 kHz to which the microwave generator and shift oscillator in a repeater bay are locked. The MCSS is settable to one part in $10^8$ and is stable to within five parts in $10^{10}$ per day. Extensive monitoring of performance and the provision of a standby reference signal ensure a high degree of reliability to the system.

## *The AR6A Single-Sideband Microwave Radio System:*

# Microwave Carrier Supply

By J. GONDA* and J. M. KIKER, Jr.*

(Manuscript received February 14, 1983)

In the AR6A repeater bay, microwave carrier power for both the receiver and the transmitter is derived from a single voltage-controlled crystal oscillator. For long-term stability, this oscillator is phase locked to an external-reference frequency, available at each radio station. From the output signal of this oscillator, an active frequency-multiplier chain generates about +21 dBm power in the 6-GHz band. Part of this power serves as the local oscillator signal for the transmitter directly. The other part is shifted in frequency, to produce the local oscillator signal for the receiver.

## I. INTRODUCTION

Two microwave carriers are needed in an AR6A† repeater bay for up and down conversion. These carriers have to be spaced 252 MHz apart and must have low noise, low jitter, and exceptional frequency stability.

In the microwave carrier supply, both carriers are derived from a single Voltage-Controlled Crystal Oscillator (VCXO)‡. An active frequency-multiplier chain generates the 6-GHz carrier for the up con-

verter directly. Part of this 6-GHz power is split off and shifted 252 MHz in frequency, to be used in the receiver down converter.

For frequency stability, the VCXO is phase locked to an external reference, available at each radio station. Steps are taken to ensure adequate frequency stability even during temporary loss of the external-reference signal.

Along with the detailed performance objectives, a general circuit description of the microwave generator is given in this paper, with the key circuits described in somewhat more detail. Typical test results and a brief description of the method used to measure FM noise close to the carrier concludes the paper.

## II. PERFORMANCE OBJECTIVES

Some of the performance objectives for the microwave carrier source designed for AR6A are similar to those required in FM radio systems; others are unique. The performance objectives for this new carrier source are enumerated below with discussion of those items dictated by application in the AR6A Radio System.

### *2.1 Frequencies*

The TR-bay microwave carrier supply has to provide two carriers separated by 252 MHz, in the 6-GHz band at any of the 10 Local Oscillator (LO) frequencies given in the AR6A frequency plan.[1]

### *2.2 Power output*

The available microwave carrier power requirement is +17 dBm for the transmitter and +11 dBm for the receiver at the shifted LO frequency.

### *2.3 Frequency stability*

The microwave carriers must be stable in frequency to about two parts in $10^7$ per year so that the equalizer pilots at IF will be located accurately with respect to the narrowband (12 kHz) crystal pick-off filters in each AR6A receiver. In addition, the accumulated frequency error from each repeater in a terminal section must be limited to a value that can be corrected by the multimastergroup terminal receiver. This stability objective of two parts in $10^7$ is about two orders of magnitude more accurate than for carriers for FM radio application. To meet the strict frequency-stability requirement, the microwave carriers are phase locked to an external-reference frequency,[2] having the required frequency accuracy and stability.

With conventional phase-lock control, if lock is lost the error-correction signal to the oscillator will go to zero and the frequency of

oscillation will shift to a free-running condition that will depend on temperature and oscillator aging since last tuning. In many cases this shift would be sufficient to render the radio channel unusable. To prevent this almost certain channel loss, an additional objective is specified for the phase-locked circuitry that on loss of lock the oscillator control voltage be maintained to keep the 6-GHz output frequency within ±200 Hz of the value when loss of lock occurred. Under these conditions the microwave generator free runs and drifts with temperature and time from this frequency.

Large temperature changes in a nonair-conditioned repeater station during a time that the microwave generator is free running could cause excessive frequency drift. Such large changes may occur from day-to-night temperature variations. To minimize these effects, a final objective on frequency stability is that the free-running frequency shall not change by more than 0.5 ppm over any 30-degrees F ambient temperature change within the limits of 40 to 140 degrees F. This objective is intended to provide acceptable frequency stability during the time the source is free running over a period of days if technicians cannot be immediately dispatched to clear the loss-of-lock condition.

The free-running frequency stability, together with the phase-locked error voltage memory, ensures continuous service on the AR6A route even in the unlikely event of the loss of the reference signal from the Microwave Carrier Synchronization Supply (MCSS), when every microwave source in the station is unlocked.

### *2.4 Phase noise*

The phase noise requirements for a microwave source used on an AM radio system are more stringent than for use on FM systems. For an AM system the microwave source phase-noise spectrum close to the carrier is dominant in the contribution of voice-circuit noise.

To demonstrate this fact, consider a baseband signal $a(t)$ that is up converted in frequency by a local oscillator with frequency $\omega_c$ and phase noise $\theta(t)$. If transmitted single sideband, the signal $s(t)$ can be represented as

$$s(t) = a(t)\cos[\omega_c t + \theta(t)] \pm \hat{a}(t)\sin[\omega_c t + \theta(t)], \tag{1}$$

where $\hat{a}(t)$ is the Hilbert transform of $a(t)$. The sign of the second term is negative if the upper sideband is selected and positive if lower sideband is selected. To evaluate the noise contribution from one source, assume the demodulation is done by a noise-free source. The applicable output terms, $r(t)$, at baseband are given by

$$r(t) = a(t)\cos[\theta(t)] \pm \hat{a}(t)\sin[\theta(t)]. \tag{2}$$

For the LO source $|\theta(t)| \ll 1$, so that $\cos[\theta(t)] \approx 1$ and $\sin[\theta(t)] \approx$

$\theta(t)$. In this case eq. (2) becomes

$$r(t) \approx a(t) \pm \hat{a}(t)\theta(t). \tag{3}$$

The output consists of the desired signal $a(t)$ plus a noise term given by $\hat{a}(t)\theta(t)$. Let $A(f)$ denote the power spectral density of the desired signal and $S_a(f)$ the spectral density of the phase noise. The spectral density of the Hilbert transform of a signal is equal to the spectral density of the signal itself; therefore, the spectral density, $N(f)$, of the noise term in eq. (3) is

$$N(f) = A(f) * S_a(f), \tag{4}$$

where $*$ denotes convolution.

The spectral density of the 6000 voice-circuit channel is noiselike and essentially flat over the 30-MHz frequency band. Since the phase spectral density of crystal oscillators as used in the microwave source increases as $1/f^3$ close to the carrier, the close-in noise components contribute the most to the convolution.

Since the phase jitter is present on the carrier recovery pilot, the Multimastergroup Translator for Radio (MMGT-R)[3] tracking receiver at the end of a terminal section will remove some of this noise. The remaining phase noise will not be reduced further by the following section since new carrier recovery pilots are inserted at the beginning of the next span. The total phase noise will accumulate as each terminal section is traversed. Taking into account the phase-noise reduction that can be obtained from the terminal, the phase-noise spectral density objective of the microwave generator necessary to meet its 4000-mile noise allocation was determined. This objective is shown as the upper curve in Fig. 1.

Though not part of the dBrnc0 noise-tree allocation, the phase noise of the microwave sources will affect voice-circuit phase-jitter objectives, which are important when the channels are used for voiceband data transmission.

## III. MICROWAVE-GENERATOR CIRCUIT DESCRIPTION

Figure 2 shows the block diagram of the microwave carrier supply for an AR6A repeater. A 21.5-dBm, 6-GHz signal is generated using a 1-GHz microwave generator and a 6X frequency multiplier. The 6-GHz power is split in the carrier distribution network, with +17 dBm going directly to the transmitter modulator; the remainder drives the shift modulator to generate the carrier for the receiver modulator. The shift oscillator frequency is 252 MHz.

Both the 1-GHz generator and the shift oscillator are phase-locked to a central 308.9-kHz reference signal through their respective frequency control units. In case of a reference-signal failure, the frequency

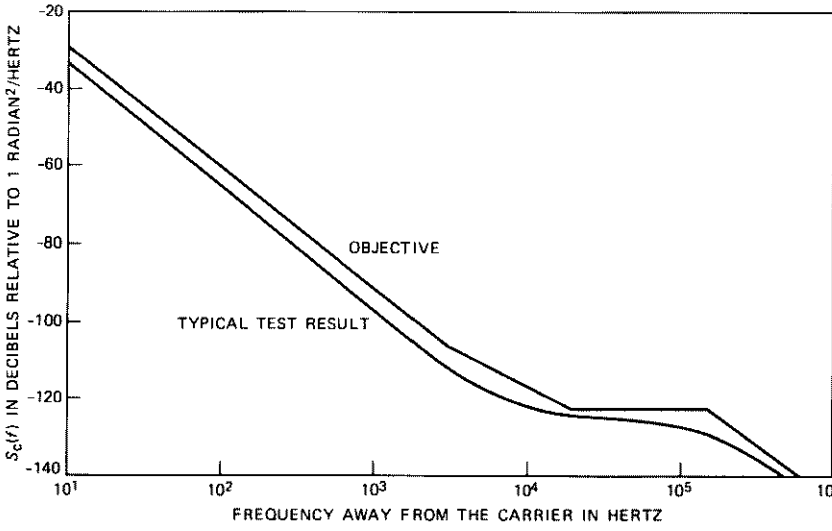

Fig. 1—Phase-noise objective and typical test result for the microwave generator.

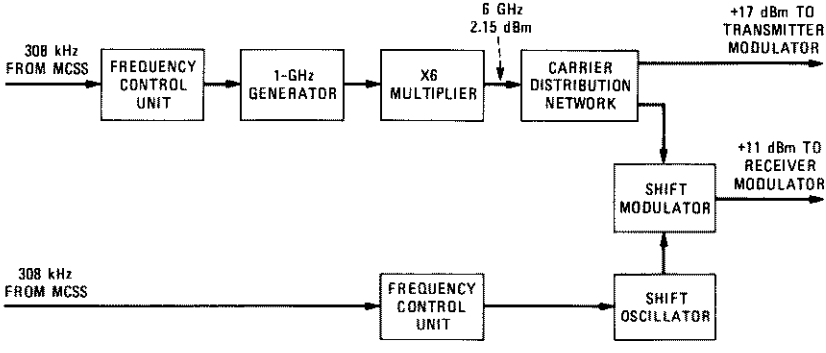

Fig. 2—Microwave carrier supply.

control units will put the oscillators on memory in order to continue to supply the microwave carrier and keep their frequencies within the required accuracy.

### *3.1 1-GHz generator*

At the beginning of the AR6A development, several candidates had been investigated for the 1-GHz generator, including general trade products. For stability, performance, and cost effectiveness the 1-GHz generator developed earlier for the TH-3 Radio System[4] was adopted and improved for AR6A radio use. Figure 3 shows the block diagram of the 1-GHz generator.

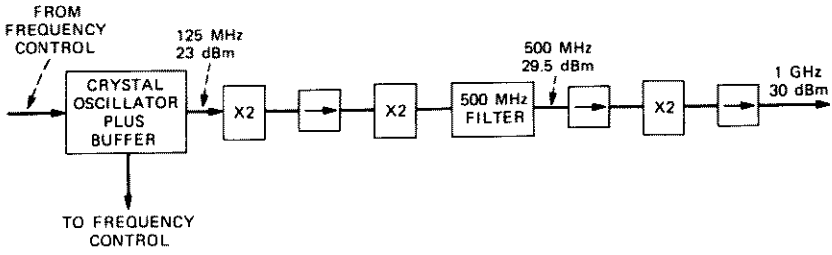

Fig. 3—1-GHz generator.

The generator is a straight multiplier chain of three active frequency doublers, driven by a crystal oscillator in the 125-MHz frequency band. Three isolators are used between successive stages to stabilize the doublers and facilitate tuning. A high Q INVAR cavity is used at 500 MHz to strip off multiplied white noise far from the carrier.

### *3.1.1 Oscillator and buffer amplifier*

The crystal oscillator is built with a Western Electric NPN transistor in the common base configuration. The third-overtone crystal operates in series resonance, and it is connected in the feedback loop between the emitter and collector of the transistor. A high Q varactor diode is connected in series with the crystal to provide voltage control of the oscillator frequency.

To meet the AR6A requirement for low noise close to the carrier, it was important to keep the $1/f$ noise of the transistor low by keeping the collector current low, to use a crystal with high unloaded Q, and to design the oscillator circuit (including the varactor) such that the Q of the total oscillator would approach the Q of the crystal itself. To keep intermodulation in the transistor at minimum, and to keep the conversion of $1/f$ noise into the 125-MHz frequency band low, limiter diodes are used to control the amplitude of oscillation, instead of relying on the nonlinearities of the transistor itself.

For long-term stability the crystal current is kept below 1 mA, which gives about +7 dBm power at the oscillator output.

Under normal operating conditions, the varactor voltage is regulated by the Phase-Locked Loop (PLL) in the frequency control unit to keep the crystal-oscillator frequency locked to a high-order harmonic (404th to 429th, depending on channel frequency) of the 308.9-kHz reference signal. In case of loss of lock (because of an MCSS failure, for example), the frequency control unit goes on memory, and the varactor voltage in the crystal oscillator is kept constant at the last (locked) value. In this free-running mode the crystal oscillator has to stay within 1 ppm of its nominal frequency until the unit is repaired (two days at most). To meet this requirement in stations without air

conditioning, the crystal is placed in an oven. The turnover temperature of the crystal is 65 degrees C.

A two-stage wideband buffer amplifier follows the crystal oscillator. A shunt-mounted PIN diode between the two stages of the buffer can be used to adjust levels for the entire microwave generator. The output level range of the buffer is 13 to 25 dBm.

A sample of about 12 dBm is decoupled from the buffer output to the frequency control unit for phase locking.

### *3.1.2 Frequency doublers*

The three active frequency doublers in the 1-GHz generator are built with Western Electric overlay transistors. Besides doubling their respective input frequencies, these stages have several decibels of gain each. Figure 4 shows a common simplified schematic of the doubler circuits.

Due to the ac short in the collector circuit at the input frequency, *f*, these stages have substantial current gain at that frequency. The increased collector current pumps the nonlinear capacitance of the collector-base junction, producing harmonic voltage components between collector and base. A second series resonant circuit between base and ground provides a current path for the generated second harmonic, bypassing both the input matching network and the base emitter junction of the transistor. The two matching networks transform the input and output impedance of the doubler circuit to 50 ohms.

Principally, all three doubler stages are as described. Only the impedance levels vary with frequency and the physical form of the circuit elements. In the first doubler from 125 to 250 MHz most elements are lumped; the third stage, however, from 500 MHz to 1 GHz is built entirely of distributed elements.

Nominal output power levels for the three doublers are: 27 dBm at 250 MHz, 30 dBm at 500 MHz, and 31 dBm at 1 GHz. With interstage losses taken into account, this corresponds to conversion gains of 4, 3, and 2 dB, respectively.

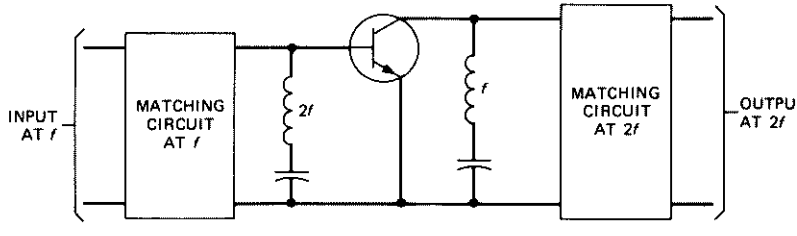

Fig. 4—Transistor doubler.

### 3.1.3 Isolators

All three isolators in the multiplier chain are of the lumped element design.[5] They have been developed at Bell Laboratories, Allentown, Pennsylvania. Their insertion loss is typically 0.5 dB forward, and greater than 20 dB in the reverse direction.

### 3.1.4 Noise-suppression filter

Although the excess noise of the frequency doublers is minimal, they increase the FM noise originating in the oscillator and buffer by a factor of 20 log $n$ along the multiplier chain. Far from the carrier, therefore, the multiplied noise could exceed system requirements.

To prevent this, a noise-suppression filter is inserted into the multiplier chain at 500 MHz.[6] The filter is a coaxial reentrant cavity with an unloaded Q of about 3000. Its 3-dB bandwidth is about 300 kHz, with about 2-dB insertion loss. For frequency stability the cavity is extruded from INVAR.

## 3.2 The 1- to 6-GHz multiplier

The 1- to 6-GHz multiplier is a broadband 6X frequency multiplier,[7] driven by the 1-GHz generator at a 29.5-dBm level. It delivers 21.5-dBm, 6-GHz power to the carrier distribution network. All unwanted harmonics are kept at least 80 dB below the carrier.

The multiplier circuit is built on alumina microstrip. The photograph in Fig. 5 shows the circuit details. Figure 6 gives the approximate lumped element equivalent circuit.

A self-biased commercial step recovery diode with zero bias capacitance of 3.3 pF is used for the nonlinear element. The diode is mounted into a hole in the microstrip circuit. One side is soldered to the ground plane on the back, the other side is thermocompression bonded to the microstrip pattern using a 20-mil wide gold ribbon.

Both the input and output filters are three-resonator bandpass, 0.1-dB Tchebyscheff type, designed to transform the diode impedance to 50 ohms in their respective passbands. The input filter is realized using quarter-wavelength resonators in an interdigital configuration. The output filter consists of side-coupled, half-wavelength resonators. The diode itself is part of the first resonator in the output filter. The radial lines at the input side of the diode are used to suppress unwanted harmonics; at the same time they act together as a capacitor for the pulse-forming circuit.

In order to meet the very strict spectral purity requirement for the AR6A System at the up and down converter inputs, as discussed earlier, all the unwanted harmonics had to be suppressed to at least 80 dB below the carrier at the 6X multiplier output. This requirement was met by adding a seven-resonator interdigital filter to the output

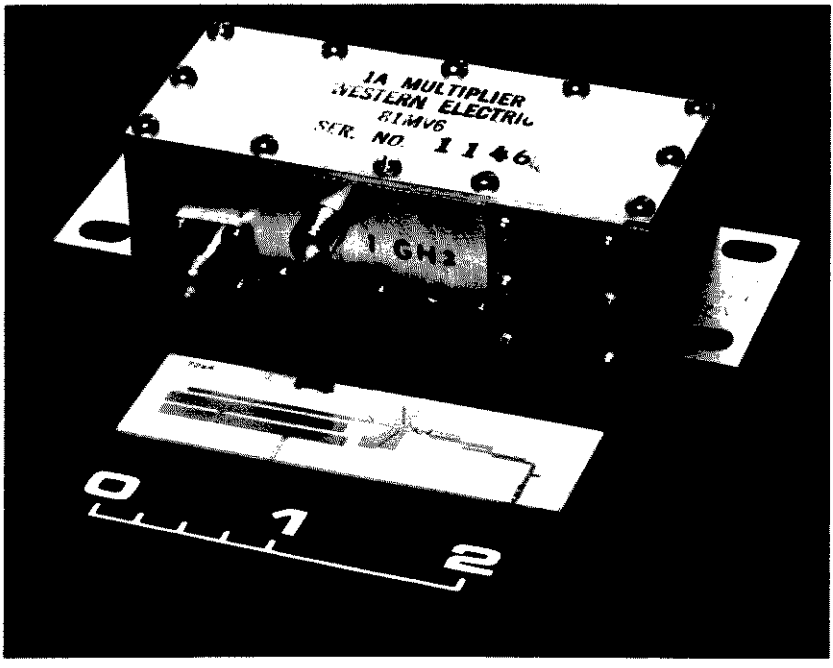

Fig. 5—Photograph of the 6X multiplier.

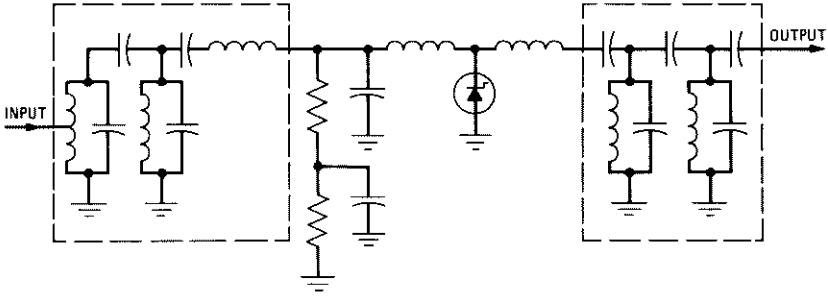

Fig. 6—Lumped element equivalent circuit of the 6X multiplier.

of the 6X multiplier. This filter is built into the back of the multiplier housing, and it has about 0.5-dB passband insertion loss. The overall size of the 6X multiplier, excluding the SMA connectors, is 3/4 by 1/4 by 3 inches. The typical swept response of the multiplier is shown in Fig. 7. One code covers the total AR6A bandwidth.

### *3.3 Carrier distribution network*

As indicated in Fig. 2, the carrier distribution network is used to split the output signal of the microwave generator between the trans-

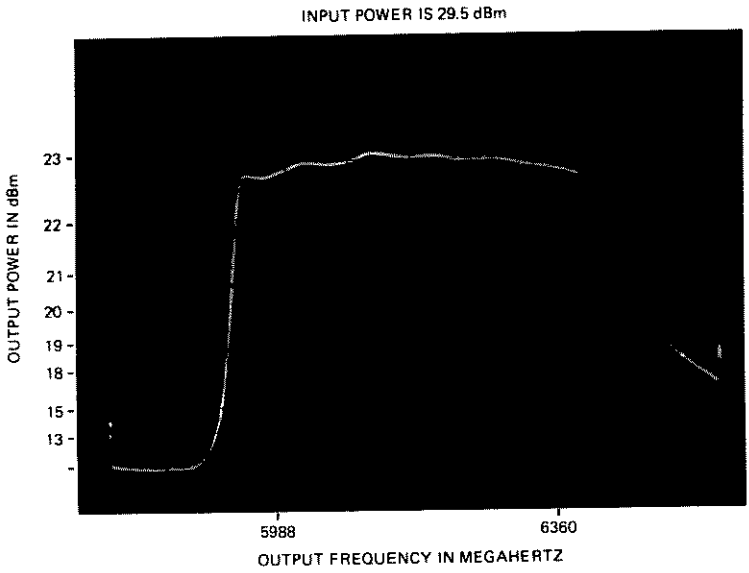

Fig. 7—Typical swept response of the 6X multiplier.

mitter and the shift modulator in a repeater station. The detailed description of this circuit can be found elsewhere.[8]

### *3.4 Shift modulator and shift oscillator*

The purpose of the shift modulator is to shift the frequency of the microwave generator by ±252 MHz and thus provide the local oscillator signal for the receiver modulator.

The shift oscillator generates the 252-MHz signal for the shift modulator using a 126-MHz crystal oscillator and a frequency-doubler circuit. As shown in Fig. 2, the shift oscillator is phase locked to the MCSS signal.

Reference 9 gives a more detailed description of both the shift modulator and the shift oscillator.

## IV. FREQUENCY CONTROL UNIT

The microwave generator and shift oscillator are phase locked to a harmonic of the microwave carrier synchronization supply frequency of 308.9 kHz[†] by means of two frequency control units. These units contain a comb generator to produce the desired harmonic of the 308.9-kHz signal; a phase-locked loop to synchronize the microwave generator or shift oscillator to the proper 308.9-kHz harmonic; a memory circuit that operates in conjunction with the phase-locked

[†] The actual frequency is 308.8735416 kHz.

loop to provide the control voltage to the oscillators; and alarm circuitry to provide bay alarms on loss of lock and memory end of range. The overall description of operation and some details of these individual circuits are given in the following sections.

### *4.1 Frequency control unit circuit description*

Figure 8 shows the block diagram of the frequency control unit. The 308.9-kHz reference signal from the MCSS is applied to the comb generator. The proper harmonic for locking the crystal oscillator is produced by the comb generator and applied to one input of the phase detector in the phase-locked circuit. A signal sample of the crystal oscillator to be controlled is applied to the other phase-detector input of the phase-locked loop. The output of the phase-locked loop is an analog error signal proportional to the phase difference between the reference and controlled oscillators. This error signal is applied as one input to the varactor of the controlled oscillator, with the other inputs from the memory circuit and a bias voltage source. The purpose of the fixed bias is to place operation of the varactor diode at the suitable point on its voltage-versus-capacitance characteristic and to offset the midrange digital error-correction voltage to zero. On initial alignment no digital error-voltage component (after offset) is applied to the varactor diode. In time, due to aging and temperature changes, the analog error voltage will change to maintain lock, and when the change reaches a certain value, the memory circuit will add a digital error-voltage component of a value equal to the change. In order to maintain the total error signal the same, the analog component will return back to its original value. As further changes occur, the memory circuit will continue to add or subtract steps as the analog signal either increases

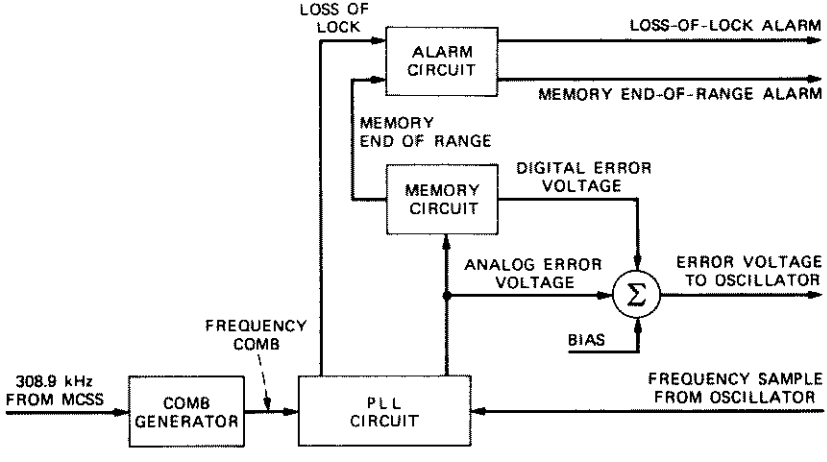

Fig. 8—Block diagram of frequency control unit.

or decreases. In this way the memory circuit provides the major part of the error signal with the phase-locked loop error signal varying an amount equal to the memory change threshold. If the reference signal from the MCSS is lost, the analog loop is opened and the analog error signal goes to zero. The memory continues to supply the digital error-signal component. In this way the generator is free running very near its last correct frequency. The maximum error is plus or minus the memory threshold value which is about 3.2 Hz at 125 MHz, which translates to a maximum error of about 155 Hz at 6 GHz.

There are 1024 steps of memory available with step 512 initially set when the oscillator is aligned. This provides for 512 steps in either direction to compensate for increase or decrease in frequency. This corresponds to ±1600 Hz at 125 MHz or about ±1.28 parts in $10^5$.

The alarm circuit monitors the memory step location and generates a bay alarm when 88 percent of the available range has been used. This is a warning to the operating personnel that manual retuning of the oscillator should be done. In addition, the alarm circuitry provides an alarm if phase lock between the reference signal and the controlled oscillator is lost.

### *4.2 Comb generator*

The comb generator[10] consists of three basic parts: (1) a sine-wave-to-square-wave converter, (2) a narrow pulse generator, and (3) a gated oscillator tunable in frequency and with output always beginning at the same phase.

The input 308.9-kHz sine-wave reference signal is converted into a TTL-level square wave using a high gain amplifier followed by a comparator. The comparator output is used to trigger a monostable multivibrator that generates 0.5-microsecond pulses at the reference-frequency rate. This narrow pulse is used to gate an oscillator that always starts at the same phase. The frequency of oscillation can be manually tuned. Let $f_r$ denote the frequency of the reference signal, A and $f_{osc}$ the amplitude and frequency of the gated oscillator, and $T_w$ the width of the gating pulse. A Fourier analysis shows that the output spectrum, $S_o(f)$, of the gated oscillator is given by

$$S_o(f) = Af_rT_w \sum_{n=-\infty}^{\infty} \frac{\sin \pi(f_{osc} - nf_r)T_w}{\pi(f_{osc} - nf_r)T_w} \delta(f - nf_r). \qquad (5)$$

The output is seen to consist of harmonics of the reference signal with amplitudes proportional to the sin x/x function. By tuning $f_{osc}$ at or near the desired harmonic, say $n_df_R$, the output of the comb generator will provide maximum output to the PLL at that frequency. Tuning of the oscillator is easily accomplished by observing the beat signal at the output of the PLL phase detector and tuning the oscillator

for maximum amplitude. The other harmonics that are present at the phase detector are not important since a given crystal oscillator can never be pulled far enough to lock to the wrong harmonic.

### *4.3 Phase-lock loop*

Figure 9 shows a block diagram of the phase-locked loop circuit. A sample from the controlled oscillator is buffered and amplified by a common base transistor amplifier and applied to one input of the phase detector. The frequency comb is the other input to this detector. The phase detector has a sinusoidal characteristic and is implemented using a double-balanced mixer. In normal operation, a small region around the zero crossing of this characteristic is used to approximate a linear phase detector. The output of the phase detector is amplified to provide the desired PLL loop gain and applied through a Complementary Metal-Oxide Semiconductor (CMOS) Single Pole Double Throw (SPDT) switch to the loop filter and the memory circuit. The output of this filter is the analog portion of the error voltage applied to the varactor.

The CMOS switch is under control of the loss-of-lock detector. As long as the loop is locked the control voltage holds the switch in the through-path position. A prolonged loss of lock will cause the switch to open, which reduces the analog portion of the error signal to zero. At this point only the memory circuit is providing error correction. The reset control forces the switch closed initially so that phase lock can be achieved.

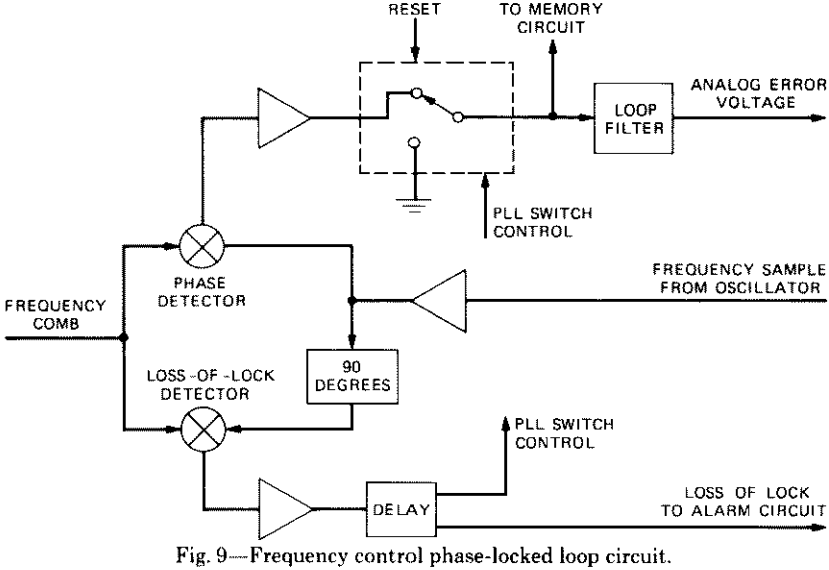

Fig. 9—Frequency control phase-locked loop circuit.

The loss-of-lock detector uses a second double-balanced mixer but with the frequency sample input shifted 90 degrees. When in phase lock, the loop phase detector is operating around the 0-degree point on the characteristic and the lock detector will be operating about the 90-degrees point providing a dc voltage output. This output is amplified and applied to a delay circuit. Loss of lock must occur for the entire period of this delay before the PLL switch is opened and a loss-of-lock alarm given. This delay is necessary to keep the loop closed long enough to reacquire lock lost because of a hit or by a switch in the MCSS from one reference source to another.

Dynamically, the PLL is a second-order type. Since its purpose is for long-term frequency stability, bandwidth is relatively narrow. The primary consideration for bandwidth is that it be adequate to reacquire lock when the MCSS reference switches and that the unit be fairly easy to lock initially when manual tuning of the controlled oscillator is required to bring the frequency within locking range. The pertinent frequency control parameters of the loop are as follows:

1. Natural frequency $\Omega_n$ is 51 rad/s.
2. Damping factor is 0.7.
3. Overall loop gain is $2.7 \times 10^3$ rad/s.

### *4.4 Memory circuit*

Figure 10 shows a block diagram of the memory circuit. The digital error voltage is derived from a 10-bit Digital-to-Analog (D/A) converter that is driven by a 10-stage up/down counter. On initial alignment the counter is preset to a count of 512, the midpoint of the counter. The output of the D/A converter for this count is offset by the bias source so that the effective digital error signal is zero.

The analog error-voltage sample from the PLL is heavily filtered and fed to two comparators. One comparator is set to switch when the

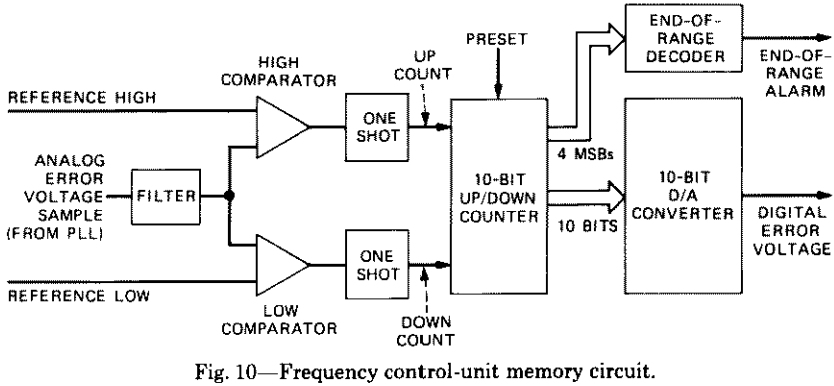

Fig. 10—Frequency control-unit memory circuit.

error voltage indicates a high-frequency correction, the other for a low-frequency correction. The references are set for thresholds corresponding to ±3.2 Hz at 125 MHz. The operation of the comparator activates a one shot, which generates one up-count or down-count pulse to the counter. The scaling of the D/A converter output is such that a 1-bit step will produce a change in output corresponding to a 3.2-Hz correction.

The four most significant bits of the counter are examined for an all 1's or all 0's condition. This indicates that 87.5 percent of the counter's range has been used in the upward or downward direction, respectively. This condition is decoded and output to the alarm circuit as an end-of-range alarm.

### *4.5 Alarm circuit*

The alarm circuit interfaces the frequency control unit to the TR-bay alarm circuits. The end-of-range indication from the memory circuit is latched before it is sent to the TR bay. The loss-of-lock signal is sent directly but buffered by TTL driver gates.

## V. PERFORMANCE

### *5.1 Power output variation with temperature*

Figure 11 shows the output power of the microwave generator, measured at the output of the sextupler, as a function of the ambient temperature. The total variation is about 1.6 dB. This is satisfactory for the AR6A System even in a nonair-conditioned environment.

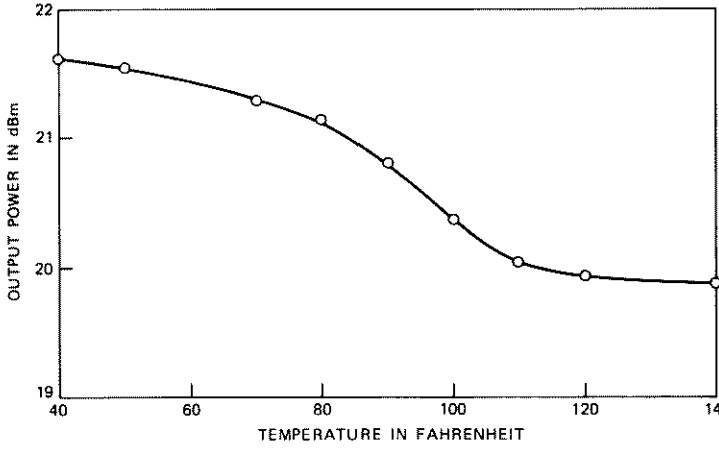

Fig. 11—Output power of the microwave generator as a function of ambient temperature.

### *5.2 Free-running frequency as a function of temperature*

Figure 12 plots the free-running frequency of the microwave generator as a function of the ambient temperature. This characteristic is important only when the oscillator is not locked to the MCSS (due to maintenance or MCSS failure). The variation is within the maximally allowed 0.5 ppm for any 30-degree F change in temperature.

### *5.3 Phase-noise performance*

#### *5.3.1 Measurement method*

There are several known methods (Refs. 11–13) to measure phase noise close to the carrier, each of them having its advantages and disadvantages. We have used all of the three methods referred to above during development. Figure 13 shows the block diagram of the phase-noise test set presently used in production. Two microwave generators are phase locked to each other by a narrowband phase-locked loop. The output signal of both are multiplied in frequency up into the 6-GHz band and then fed into a double-balanced mixer in phase quadrature. The output of the mixer goes into a spectrum analyzer after being amplified in a low noise amplifier. The output of the spectrum analyzer is plotted on an X-Y plotter directly as the noise spectral density, $S_\phi$(dB) versus frequency separation from the carrier.

#### *5.3.2 Measured phase noise*

Figure 1 shows the measured phase-noise spectral density of the microwave generator. The test results are typically 5 dB better than the requirement.

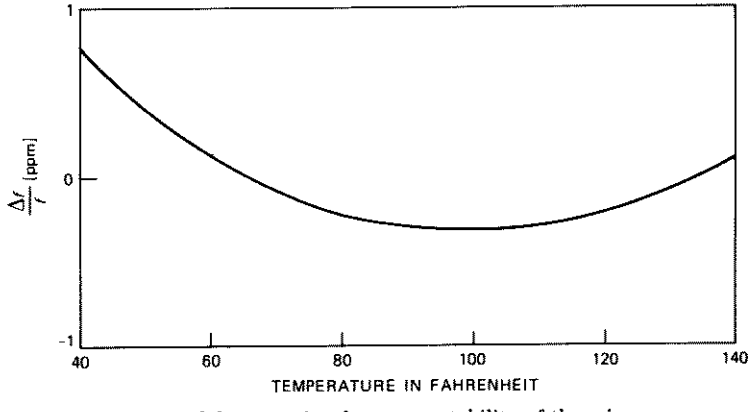

Fig. 12—The measured free-running frequency stability of the microwave generator as a function of the ambient temperature.

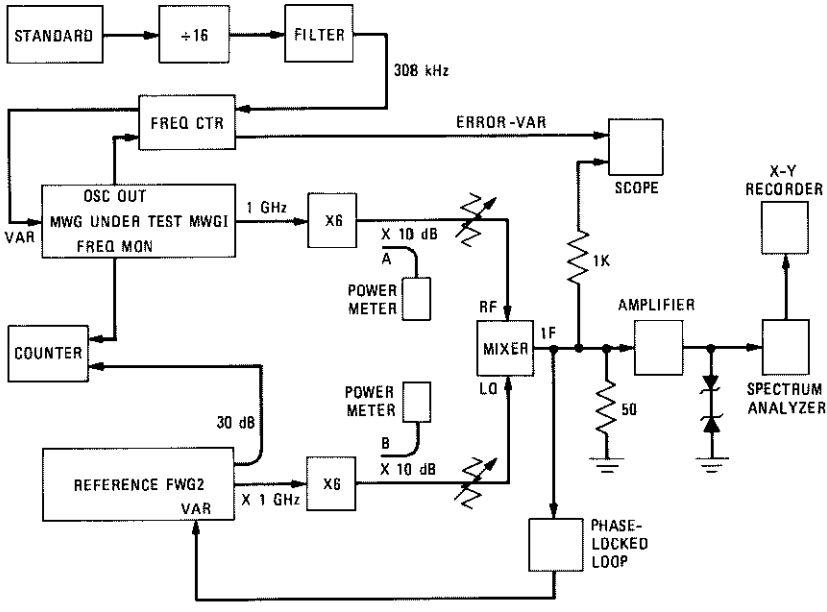

Fig. 13—Block diagram of the test set used to measure noise of the microwave generator.

### *5.4 Phase jitter*

The measured phase jitter of the microwave generator is 10 to 25 degrees peak to peak, using the filter recommended in Ref. 14, and about 0.5 to 0.7 degrees peak to peak with the jitter reduction provided by the MMGT-R and the weighting of the same filter.

### *5.5 Spurious tones*

There are low-level tones in the output spectrum of the microwave generator when the generator is operating in the bay. These tones are harmonics of 60 Hz, coming from the battery power plant, which is charged continuously, and 20- and 40-kHz tones generated by dc-to-dc converters in the power supplies in the bay. All of these tones are at least 40 dB below the carrier at the output of the microwave generator. Also present are 308.9-kHz sidebands from the phase-locked reference. These are better than 70 dB below the desired output.

## VI. SUMMARY

A low-noise, phase-locked microwave carrier supply has been developed for the AR6A Radio System with exceptional frequency stability. Steps were taken to ensure system survival even in the extreme case of reference-signal loss.

The architecture and key circuits of the carrier supply have been described, along with performance objectives and typical test results.

## VII. ACKNOWLEDGMENTS

The development of the microwave carrier supply was the combined accomplishment of many individuals. Among them the authors wish to acknowledge the contributions of T. J. Case, H. Goldstein, and J. R. Scoville.

## *The AR6A Single-Sideband Microwave Radio System:*

# Equalization for Multipath Fading

By N. O. BURGESS,* R. C. MacLEAN,* G. J. MANDEVILLE,* D. I. McLEAN,* M. E. SANDS,* and R. P. SNICER*

(Manuscript received February 25, 1983)

Multipath fading can introduce severe amplitude distortion and level changes in a radio channel. These must be dynamically equalized to meet the toll transmission requirements of AR6A. This article describes equalizer circuitry at intermediate frequencies, which continuously senses the level as a function of frequency in the transmission band and dynamically corrects the effects of multipath fading.

### I. FADING CHARACTERISTICS

In line-of-sight microwave radio transmission, the broadband radio channels (20 to 30 MHz) can exhibit the phenomena of both selective and nonselective fading. During nonselective fading, the signal power across the channel remains constant with frequency and simply decreases in level. This type of fade can be caused by attenuating effects of the atmosphere or it can be the precursor of selective fading. Some atmospheric conditions can cause propagation over two or more distinct paths, resulting in the reception of multipath components.[1] This event can cause the channel to experience selective fading. During selective fading, not only does the channel show a decrease in received signal power, but the signal level measured as a function of frequency (frequency response) also contains one or more minima.[2] Reference 2

contains graphs of measured field data showing typical time-varying frequency responses of a channel during selective fading.

A fade model consisting of four to six multipath components can match most observed channel characteristics.[3] However, a two-path fade model closely approximates a large number of observed channel characteristics.[4] The two-path model has the transfer function:

$$H(f) = 1 - re^{-j2\pi(f-f_0)\tau},$$

where $f_0$ is the frequency of maximum fade (i.e., minimum signal level) and $\tau$ is the delay difference in the two path lengths. The expression $-20 \log (1 - r)$ is the fade depth at frequency $f_0$.

Computer simulations were used to show that a two-path fade with a fade depth of 20 dB, a time-delay difference of 4 ns, and all possible frequencies of fade maximum ($f_0$) matches adequately the amplitude characteristics of the worst fades that would have to be equalized to meet system outage objectives for AR6A.*,† An equalizer that could compensate for such a fade to within ±2 dB of the nominal level for all values of the fade center frequency, $f_0$, will meet system specifications. Some examples of channel characteristics undergoing a two-path, 20-dB, 4-ns fade are shown in Fig. 1.

A good approximation of this selective fade characteristic can be obtained using a power series expansion truncated after the quadratic term: $H(f) = A_0 + A_1(f - f_m) + A_2(f - f_m)^2$, where $f_m$ is the midchannel frequency. The flat term, $A_0$, can be compensated using an Automatic Gain Control (AGC) amplifier leaving the shaped component alone to be equalized.

From the two-path model of the fading channel, the range of the linear term, $A_1$, must be ±18.5 dB and the range of the quadratic term, $A_2$, must be 17 dB. However, large values of the quadratic and linear shaping coefficients are not required simultaneously. This allowed the use of two Bode "bump" networks[5] with center frequencies at the channel ends to jointly realize the linear and quadratic correction terms.[6] It was further determined that a ±10 dB range on each of the Bode "bump" networks is sufficient to meet system requirements on shape equalization. Figures 2 and 3 depict the approximation of linear and quadratic correction functions by Bode "bump" networks. This technique has many advantages with respect to dynamic range and control circuitry, as well as noise figure and intermodulation distortion.

The remaining system equalization objective concerns the rate of change of the channel shape as a selective fade sweeps through the channel. Field data indicate that during deep selective fading, the rate

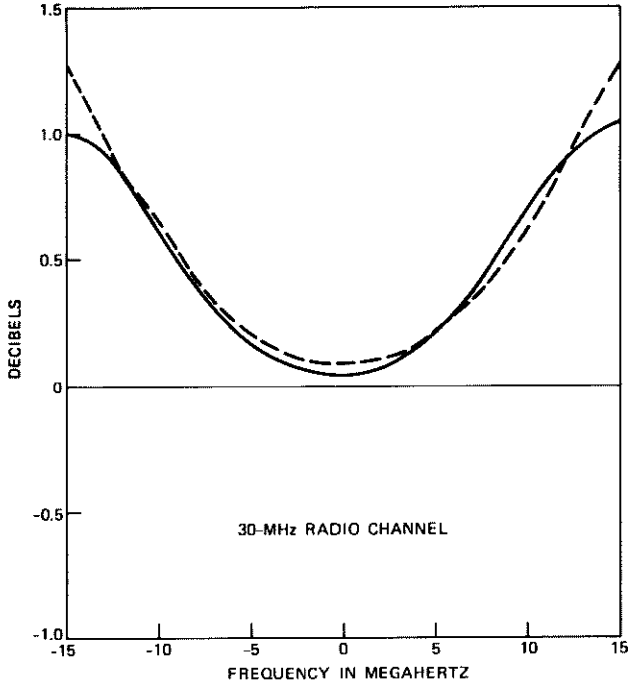

Fig. 3—Summation of two Bode "bump" networks to approximate a quadratic shape.

of change of signal level can be as high as 90 dB per second. Since the most severe fades will be eliminated by space-diversity switching, an objective of adapting to a rate of change of 50 dB per second was established.

## II. FUNCTIONAL DESCRIPTION

An error-detecting, zero-forcing technique was chosen to dynamically control the variation of the AGC and shape units. Three pilot tones are transmitted in the radio channel, one near each edge and one near the center. The pilot errors are determined by analog processing of the detected pilot levels. The errors thus determined are fed back to an analog circuit that varies the AGC and equalizer shape coefficients to force the detected errors to zero at the pilot frequencies. The control loop also detects when a space-diversity switch or pilot resupply should be initiated.

Figure 4 is a functional block diagram of the units comprising the dynamic equalizer.

### *2.1 Gain and equalization control*

Gain in the intermediate frequency (IF) channel is controlled by an AGC amplifier that is present at both repeater and main stations. The

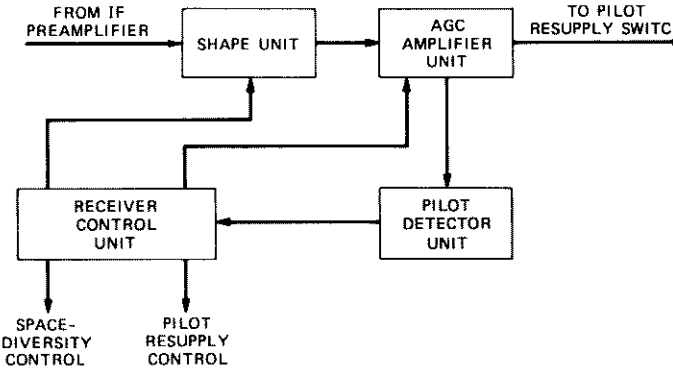

Fig. 4—Block diagram of the AR6A dynamic equalizer.

frequency characteristics of the IF channel are controlled by a shape unit that consists of electronically controlled Bode "bump" networks peaked at the high and low ends of the band. The shape unit is provided only at main stations.

The detector unit senses the levels of the three equalization control pilots and the pilot resupply enable pilot. Processing of the detected pilot levels is done within the receiver control unit. An error voltage for the low (high) bump is derived by subtracting a reference from the difference of the low (high) pilot level and the center pilot. An error voltage for the AGC is formed by subtracting a reference from the average of the three equalization pilot levels. These error voltages will all be zero when the three equalization pilots are at their nominal level. The error voltages are amplified, low-pass filtered, and used as the electronic control for the AGC amplifier and bump shapes.

Nonlinear shaping is provided in the control characteristics of the AGC gain and bump networks such that the gain (in dB) introduced is proportional to the drive voltages. A closed-loop gain of 100 is provided. A 1-Hz cutoff in the loop filter results in a closed loop response time of 10 ms.

The dynamic equalizer has been designed to regulate the pilot levels to within 0.5 dB of their nominal value under conditions of nominal input. For a 20-dB step change in input, the equalizer will settle to within 2 dB of its final value in under 10 ms. Also, a maximum dynamic tracking error of 2 percent of the fade depth in decibels is achieved for fade rates of less than 50 dB per second.

The dynamic equalizer has been designed to achieve a gain flatness of ±0.15 dB at nominal temperatures and ±0.5 dB over the temperature range of 40 to 120 degrees F.

The dynamic equalizer achieves a maximum noise figure of 20.7 dB and third-order intermodulation coefficient for $A + B - C$ products of −72.9 dB for main-station applications.

### 2.2 *Space-diversity and pilot resupply control*

The regulation accuracy requirements dictate that the pilot detector realize a precise measure of the nominal pilot level. A low-precision realization of the control loop would suffice were it not for a requirement to precisely determine the crossing of thresholds used to initiate a space-diversity switch.

A space-diversity switch will be initiated if any pilot at the *input* to the dynamic equalizer is more than 36 dB below its nominal level. To avoid the need for separate detectors to monitor this condition, the space-diversity control is derived within the dynamic equalizer circuitry. It turned out that this requirement limited the control circuitry design.

The detector output is an indication of the output pilot value relative to its nominal value. The control voltages to the AGC and bump networks are an indication of the amount of gain supplied between the equalizer input and output. Nonlinear shaping of the detector, AGC, and bump-network control characteristics yields a linear relationship in units of dB per volt; a weighted sum of the detector outputs and the control voltages yields a measure of the input pilot levels. These characteristics must be precisely controlled to provide accurate threshold comparisons.

In addition to the space-diversity control, the equalizer circuitry realizes the control signal that initiates a pilot resupply. This circuitry utilizes a fourth pilot detector, which senses the level of the resupply enable pilot.

## III. DETECTOR AND CONTROL CIRCUITS

### 3.1 *Detector*

The detector circuit contains four separate pilot detectors interconnected by a tree of hybrid transformers (see Fig. 5). Each pilot detector consists of a hybrid transformer, an IF bandpass filter, an IF amplifier detector, and an operational amplifier gain circuit.

The IF bandpass filter is a two-section, monolithic crystal filter with a 3-dB bandwidth of approximately ±6 kHz and a 60-dB bandwidth of approximately ±50 kHz. The midband loss is approximately 3 dB. Figure 6 shows a typical characteristic of these filters.

The IF amplifier (see Fig. 7) consists of two stages of a series-shunt feedback pair.[7]

The detector portion of the circuit consists of a Schottky diode. An R-C circuit serves as a filter for the detected signal. This circuit acts essentially as a peak detector that derives a dc voltage proportional to the peak of the input IF signal.

The operational amplifier circuit is used as a buffer between the

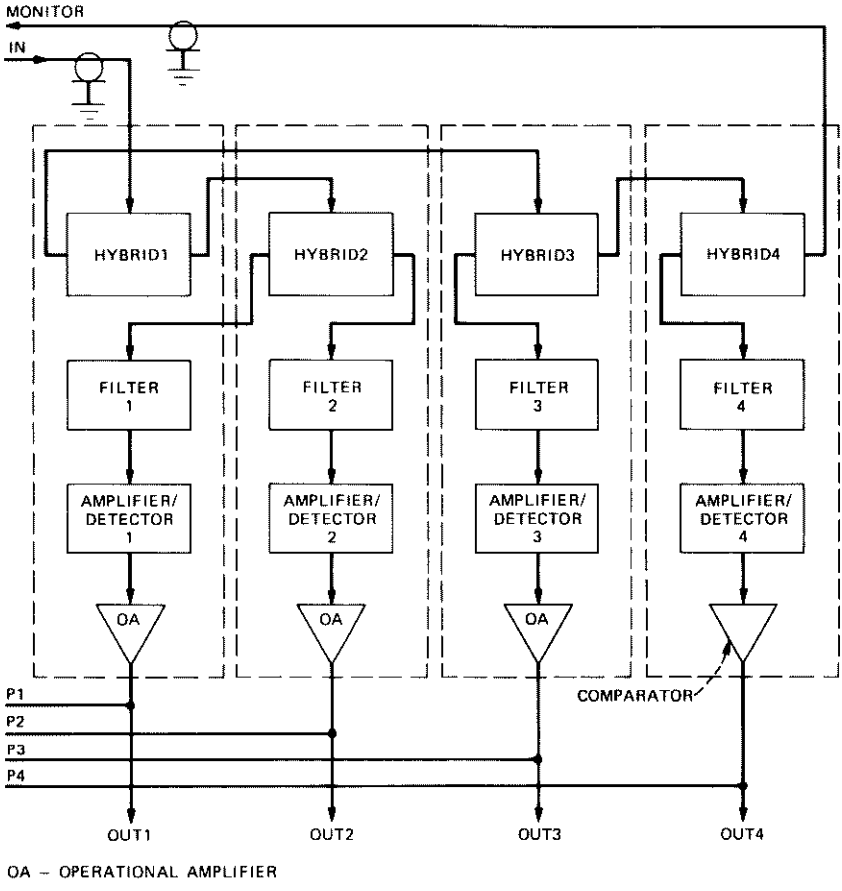

Fig. 5—Pilot detector circuit.

detector and the output of the circuit. This circuit has two adjustments. One is an offset adjustment used to adjust for zero output voltage with a nominal input signal level. The other is a gain adjustment that is set for a given dc output when the input level is 10 dB below nominal. This adjustment is required to compensate for variations in gain at the three pilot frequencies and also for variations in the Schottky diode.

The resupply-enable pilot detector is similar to the three other detectors except that the operational amplifier gain circuit is replaced by a comparator circuit, and the only adjustment is the comparator threshold voltage. A single adjustment is sufficient because only the detection of the presence of the resupply pilot above a certain level is required.

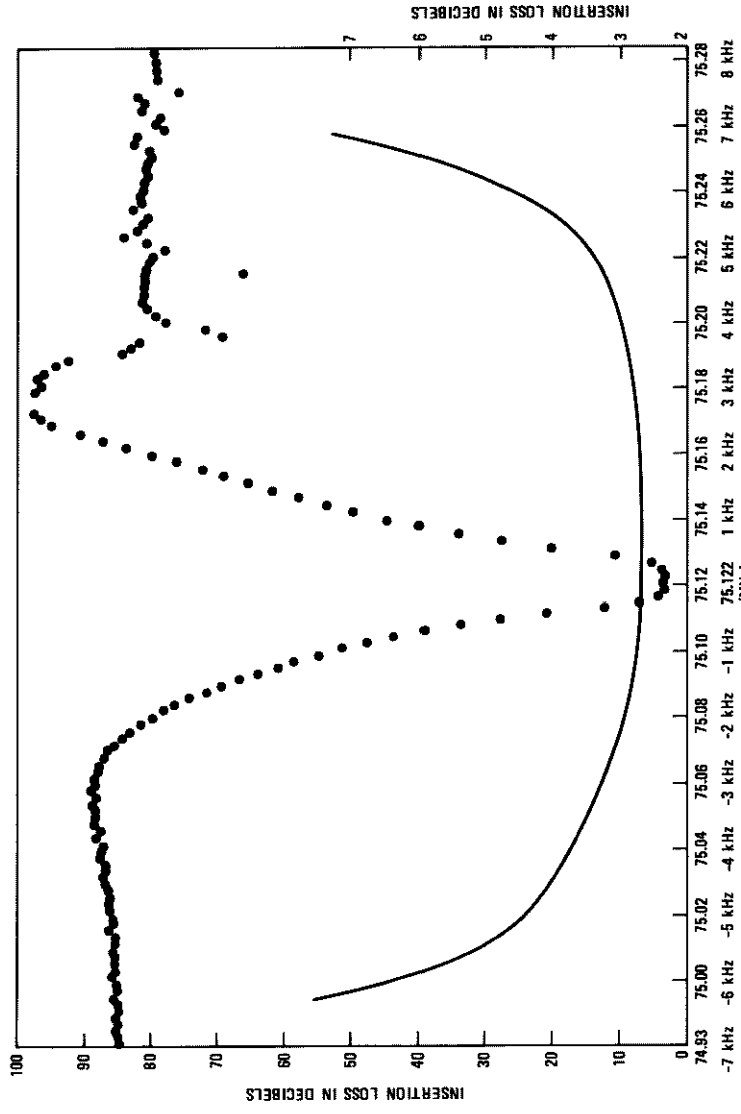

Fig. 6—Typical IF bandpass filter characteristic.

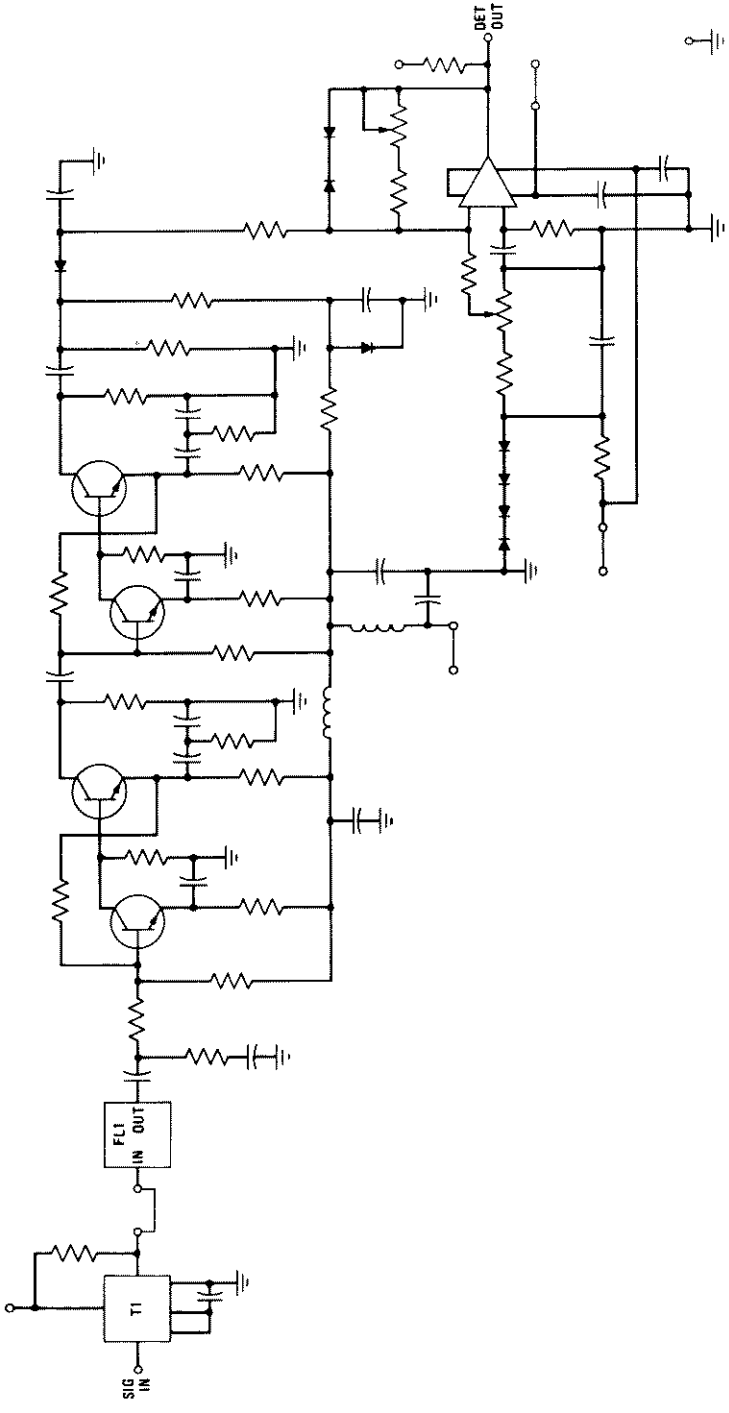

Fig. 7—Pilot detector circuit.

### *3.2 Receiver control circuit*

There are two types of receiver control units. The type that only controls the gain of the AGC amplifier is used at repeater stations. The type used only at main stations controls the gain of a shape unit as well as an AGC amplifier.

The receiver control circuit also generates the following initiation signals: (1) a signal to initiate a pilot resupply switch when the receiver is either underpowered or overpowered, and (2) a signal to initiate a space-diversity switch when the level of any one of the three line pilots drops below a certain threshold.

The circuit controls manual and remote receiver gain and remote pilot resupply, and also controls alarm initiating signals when the receiver is in other than its normal mode of operation.

Figure 8 is a block diagram of a main-station receiver control unit. The operation of the circuit is as follows.

To generate the space-diversity switch initiating signal, the inputs

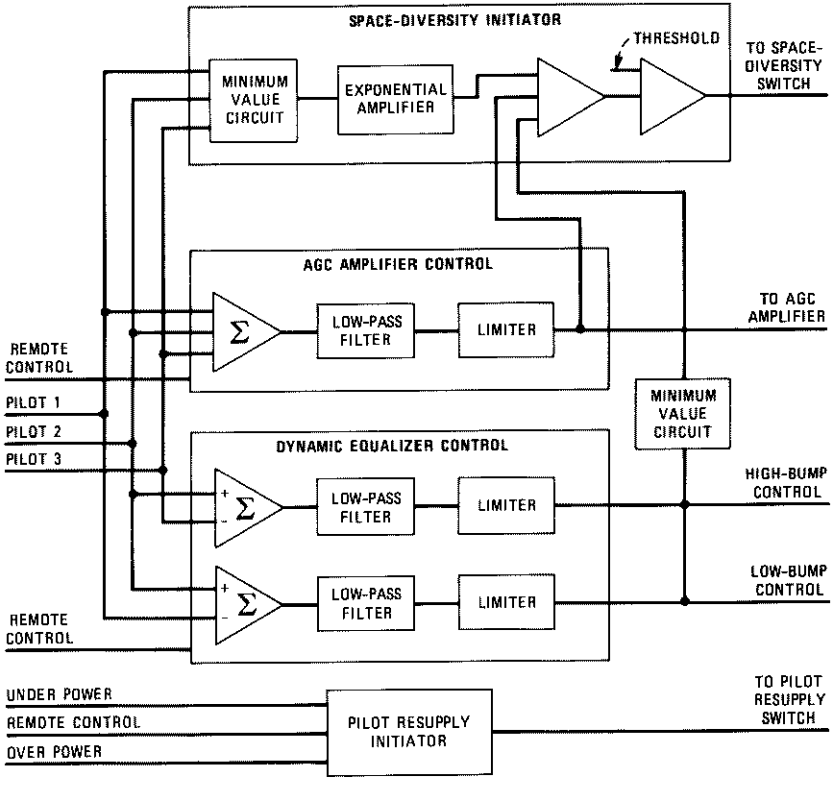

Fig. 8—Main-station receiver control circuit.

from the pilot detector circuits (PLT1–PLT3) are applied to a minimum value circuit. This circuit takes the level representing the lowest level pilot and applies it to an exponential amplifier. The output of this amplifier is a voltage that is linearly proportional to the decibel pilot level. The other input that determines the space-diversity threshold point is the AGC amplifier control voltage. The AGC amplifier is designed so that the gain in decibels is a linear function of the control voltage. The AGC control voltage is determined by the average of the three pilots. The comparator threshold is set to trip when the input voltages are such that the AGC control voltage and the voltage representing the level of the minimum-level pilot indicates that one of the pilots is 36 dB below nominal. The only difference between the repeater-station and the main-station receiver control circuits is that in the main-station circuit the control voltages for the shape unit are also used to determine the space-diversity initiation circuit trip point.

The pilot resupply is initiated in any one of three ways. It will be initiated when the power at the receiver output remains approximately 12 dB above nominal for 100 milliseconds. In this case, the functional input to the receiver control unit is from the resupply switch unit, which senses the total power and produces a control voltage proportional to the average power at the output of the AGC amplifier. The pilot resupply circuit will also be initiated if the average level of the three pilots drops 5 dB below nominal. It releases when the average level returns to less than 4 dB below nominal. This condition is derived from inputs from the detector unit. The pilot resupply can also be initiated remotely via the command and control system.

The AGC amplifier control section takes the voltage proportional to the level of the three pilots, averages them, and low-pass filters the resulting voltage to set the bandwidth of the loop. The output of the low-pass filter is applied to a limiter to limit the maximum gain of the AGC amplifier.

The shape unit control section of the receiver control unit takes the difference between the level of the center pilot and the upper or lower end pilots to control the appropriate bump equalizer in the shape unit. These voltages are also low-pass filtered and limited.

The repeater station receiver control unit does not contain a shape unit control section because a repeater station does not use a shape unit.

The receiver control unit also allows for the AGC amplifier to be set to nominal gain or manually adjusted over its entire gain range. Light-emitting diodes (LEDs) on the faceplate of the unit indicate when the dynamic equalizer is in other than its normal mode of operation.

## IV. THE SHAPE UNIT

The shape unit is composed of four Bode-type adjustable "bump" networks separated by amplifiers and controlled by four driver circuits as shown in Fig. 9. Two identical networks provide a bump-type characteristic at 59.8 MHz. The remaining two networks are also identical and peak at 88.5 MHz. Each network section is separated by amplifiers to provide both impedance buffering and gain to offset the flat loss introduced by the networks. High-frequency network sections are alternated with low-frequency sections to minimize interaction between like sections.

Each network section has an associated drive circuit. This provision allows for the independent operation of each network section so that varying p-i-n diode characteristics may be compensated in the driver element of the network section.

### *4.1 The bump equalizer sections*

Each "bump" network section is composed of a series-type, adjustable Bode network as shown in Fig. 10. The adjustable element is a p-i-n diode. The p-i-n diode acts as a resistor that varies in accordance with a bias voltage supplied by the drive circuit. As the resistance value of the p-i-n diode varies, the network shapes the amplitude of the transmission above and below the flat loss level. Measured amplitude shapes are shown in Fig. 11.

### *4.2 The buffer amplifiers*

As shown in Fig. 12, all of the amplifiers provide hybrid-type inputs and outputs. All amplifiers are designed to present 75-ohm input and output impedances. The amplifiers are, however, tuned to operate against the 301-ohm impedance presented by each "bump" network section. Each amplifier provides 7 dB of gain to compensate for the loss introduced by the bump sections.

### *4.3 The drive circuits*

The drive circuits receive the drive voltages from the receiver control unit. As shown in Fig. 9, two voltage follower circuits isolate the drive circuits from the receiver control unit. A schematic description of the drive circuits is shown in Fig. 13.

Each drive circuit is a unity gain dc amplifier. Potentiometer R26 allows for the adjustment of the offset voltage to the input of the amplifier. It is adjusted to provide flat transmission over the 59- to 89-MHz band with a drive voltage of 0V.

Elements R13 through R20, CR2, and CR3 function to make the insertion loss in decibels at the 62.448- and 85.856-MHz pilot frequencies proportional to the drive voltages. The circuit is adjusted so that

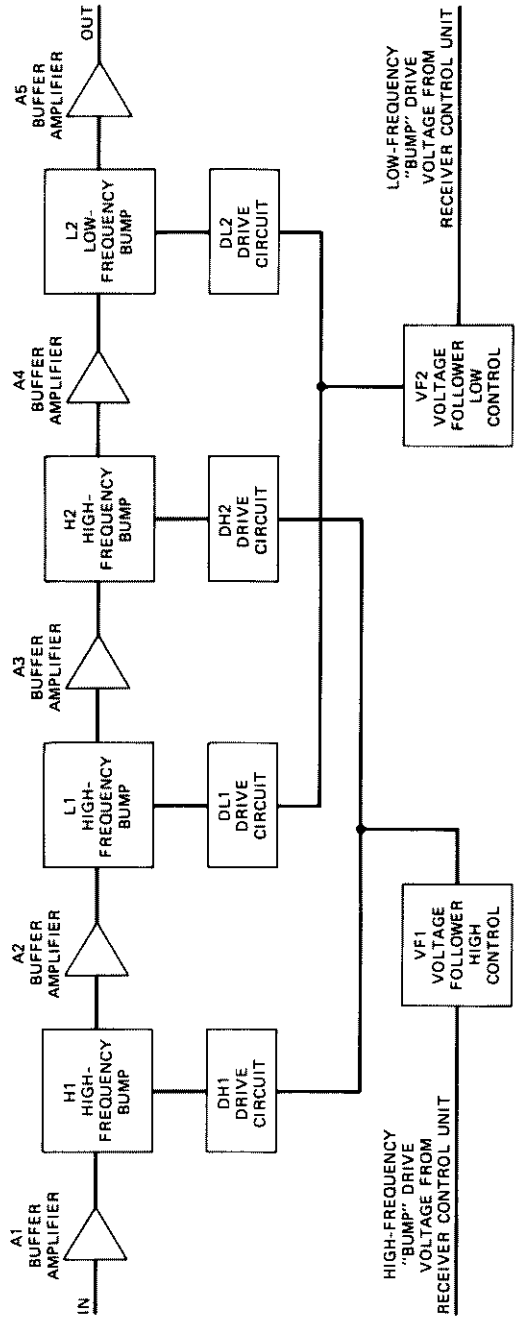

Fig. 9—Block diagram of the dynamic equalizer.

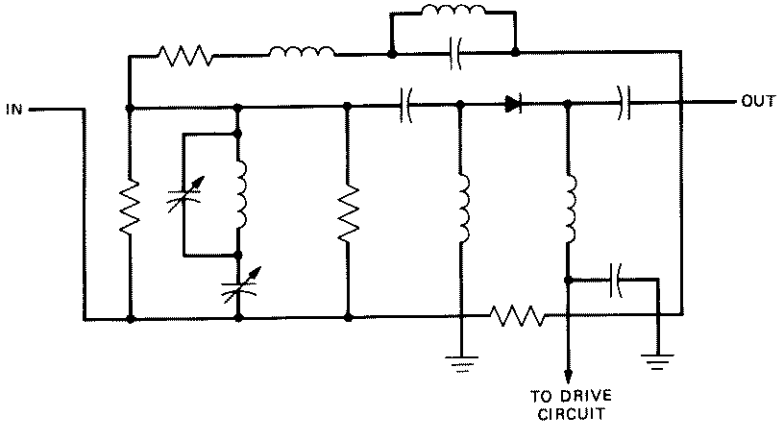

Fig. 10—Bode-type adjustable equalizer.

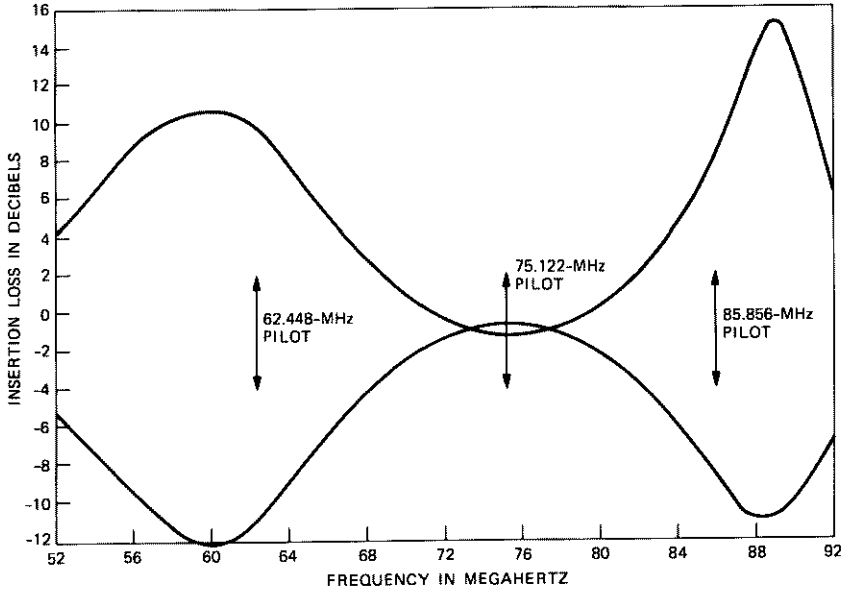

Fig. 11—Typical amplitude shapes generated by the dynamic equalizer for the AR6A System.

a change of 1V in drive voltage results in a 1-dB change in transmission for each network section. This linear relationship is the criterion upon which the space-diversity switching is based.

Diodes CR4 through CR6 act as temperature-sensing elements. Their purpose is to compensate for the temperature versus resistance characteristic of the p-i-n diode. Over the 40- to 140-degrees F temperature range, amplitude distortions in the transmission amount to

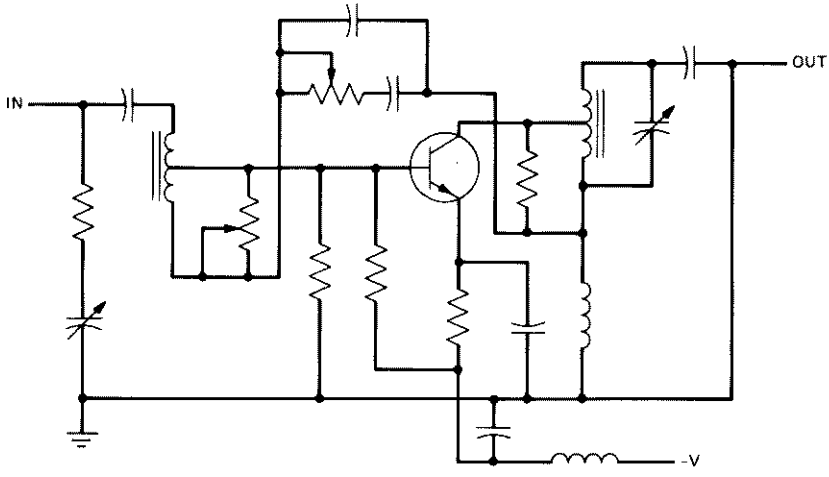

Fig. 12—Buffer amplifier.

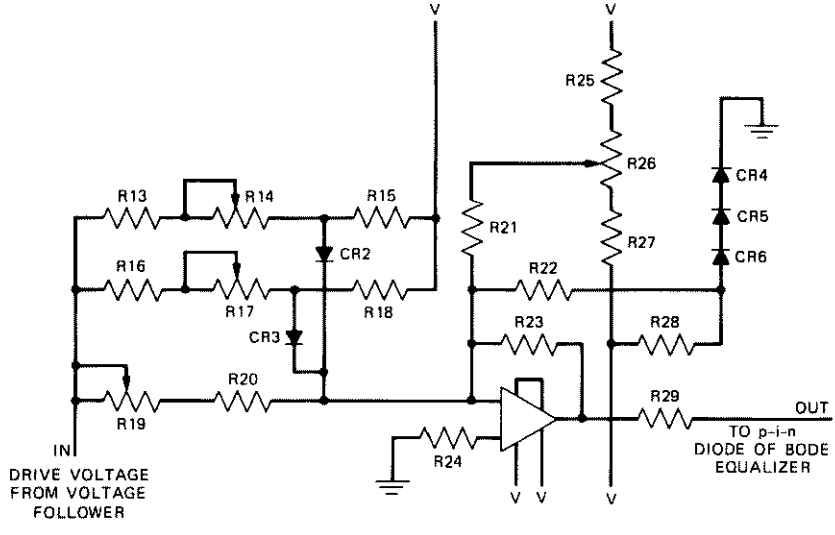

Fig. 13—Drive circuit.

as much as ±1.5 dB between pilot frequencies without compensation circuitry. With compensation these distortions are held to within ±0.25 dB.

## V. AUTOMATIC GAIN CONTROL AMPLIFIER

The AGC amplifier normally operates at a nominal gain of 15.7 dB and has a gain range of 61 dB. It is made up of a series of fixed-gain amplifier blocks alternating with variolossers (see Fig. 14). Each

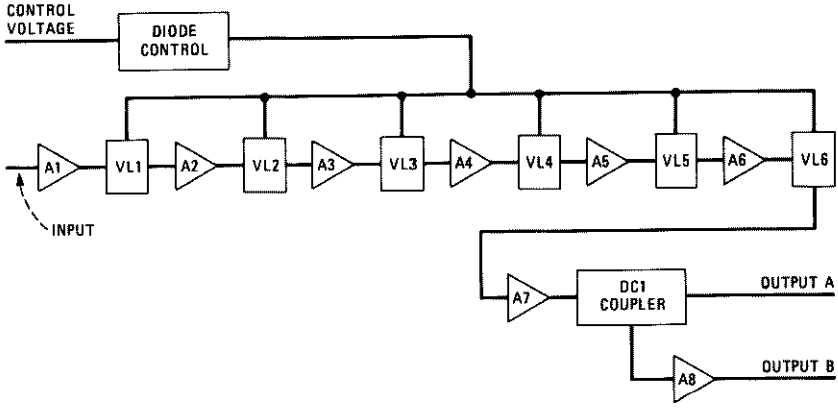

Fig. 14—Block diagram of an AGC amplifier.

variolosser has a dynamic range of approximately 10 dB, so six are necessary to provide the required 61-dB overall control range.

A control circuit is provided to convert the AGC input control voltage to a form that can be used to control the loss of the variolossers. This circuit is basically a voltage-controlled current source that linearizes the input control voltage versus overall AGC gain transfer curve. Another function of the control circuit is to stabilize the temperature of the AGC amplifier.

### *5.1 Amplifier blocks*

Eight fixed-gain amplifiers of the same basic design are required in the AGC amplifier.

Amplifiers A1 through A6 (see Fig. 14) are two-stage feedback amplifiers with a gain of 10.5 dB each. Amplifier A7 has a gain of 16 dB. This gain distribution was chosen to optimize the noise figure and intermodulation performance of the AGC amplifier. Very careful attention had to be paid to the physical design and layout since there is a total distributed gain of almost 80 dB.

The buffer amplifiers in the AGC saturate at a rather high power level due to the heavy biasing required to achieve low intermodulation distortion. Interstage clamping circuitry was added to the AGC to limit the output power to a safe level without affecting normal operation.

Directional coupler DC1 samples a portion of the main path signal and directs this signal to the amplifer A8. Amplifier A8 is a single-stage feedback amplifier with a gain of 8.5 dB. This output provides the signal to the pilot detector unit.

All eight of the amplifier blocks utilize a hybrid transformer impedance-matching configuration (see Fig. 15). This circuit can easily

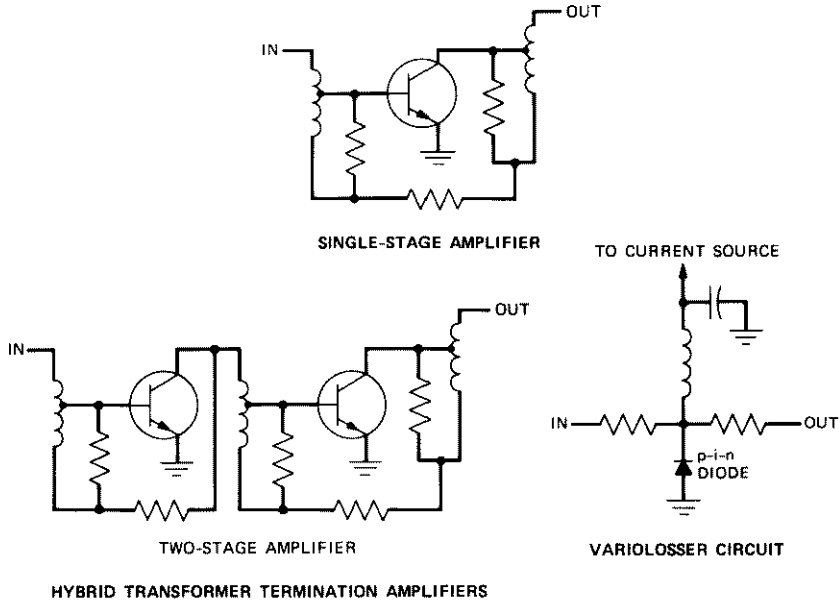

Fig. 15—Functional diagram of the AGC amplifier.

provide better than 30-dB return loss, which is important for the input and output ports of the AGC amplifier and for providing good buffering characteristics to mask the variolosser impedance variation.

The amplifiers in the AGC have been designed for optimum linearity performance to minimize intermodulation distortion. All eight amplifiers use a transistor that has been designed for optimum linearity. To utilize this transistor properly it must be operated at a collector voltage of 13V and an emitter current of 120 mA. Since 15 transistors are required for the AGC amplifier, the result is a relatively high total dc power consumption of 2 amps at −14.7V, or 30W. Consequently, a rather elaborate heat sink and ventilation scheme was required (see Fig. 16). The heat removal problem[8] was complicated by a very tight radio frequency interference requirement on the AGC amplifier.

### *5.2 Variolossers*

The variolosser is essentially a T-pad attenuator with a p-i-n diode as the shunt arm to ground (see Fig. 15). The impedance of the p-i-n diode is varied by changing the bias current through the diode. The p-i-n diode is a type that was developed specifically for this application.

The input AGC control voltage is common to all variolossers (see Fig. 14), but each p-i-n diode has its own voltage-controlled current source. The loss of each variolosser is variable from approximately 3 to 13 dB.

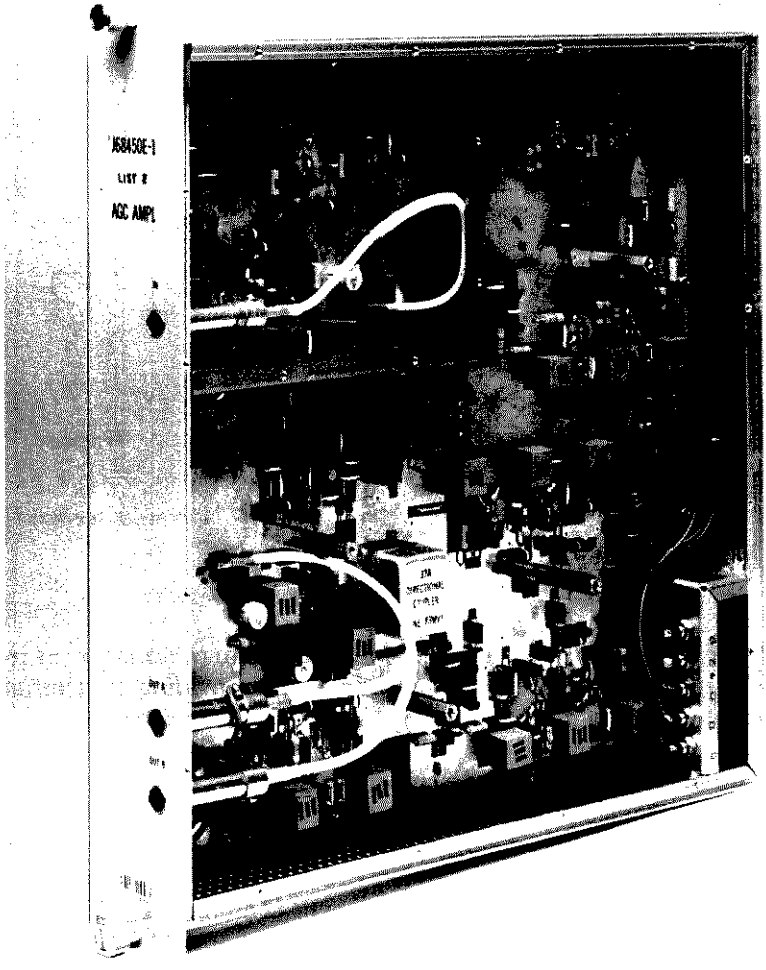

Fig. 16—AGC amplifier.

### *5.3 Control circuit*

The control circuit linearizes the control voltage versus decibel AGC gain curve and compensates for the temperature in the AGC amplifier.

It was necessary to linearize the control function since the p-i-n diode variolosser characteristics are very nonlinear. The AGC control section introduces a compensating distortion in the control function so that the overall transfer function is linear.

The p-i-n diodes in the variolossers are temperature sensitive so the ambient temperature variations must be compensated for. The ex-

pected ambient variation is from 40 to 140 degrees F. The voltage across a forward-biased silicon diode is used as a temperature-sensing element. This temperature-dependent voltage is used to modify the variolosser drive voltage in the proper way so that the AGC gain remains constant as the ambient temperature varies.

The decision was made to utilize a two-point "switched" temperature compensation concept rather than attempting the formidable task of tracking the constantly changing p-i-n diodes. With this method two points on the AGC gain curve are perfectly temperature compensated with an acceptable smooth transition in between.

## VI. CONCLUSION AND ACKNOWLEDGMENTS

A dynamic equalizer consisting of an AGC amplifier, a shape unit made up of Bode "bump" networks, and control circuitry has been designed to correct for the effects of selective fading in an AR6A channel. The use of Bode "bump" networks is key to the realization of a dynamic equalizer that is low in complexity and yet adequately meets system requirements.

Credit is due to many individuals associated with phases of this development. The authors specifically wish to acknowledge J. M. Kiker, Jr., for his guidance of the AGC amplifier development and P. D. Patel for the physical design of the dynamic equalizer units and IF shelf. The support and encouragement of F. J. Witt throughout the project is also gratefully acknowledged.

## *The AR6A Single-Sideband Microwave Radio System:*

# The Traveling-Wave-Tube Amplifier

By J. F. BALICKI,* E. F. COOK,* R. C. HEIDT,* and V. E. RUTTER*

(Manuscript received February 4, 1983)

This paper describes the amplifier for the AR6A radio transmitter, which consists of a Traveling-Wave Tube (TWT), its magnetic focus system, and driving power supply. The amplification of single-sideband modulated signals requires an unusually low intermodulation noise level and relatively low thermal noise power at the amplifier output. Further, owing to the use of predistortion to achieve the overall repeater intermodulation level objective, the amplifier must perform at high stability. These objectives have been met by choosing suitable TWT design parameters, operating the tube far below its saturated power capability, and devoting close attention to the details of tube construction. The power supply provides well-regulated heater, helix, and collector voltages to control the TWT gain. The supply also regulates the beam current. Current detection circuits protect the tube and power supply from tube internal arcs.

## I. GENERAL

The development of a traveling-wave-tube amplifier was undertaken to fulfill all proposed operating requirements for noise, signal intermodulation, gain, safety, and mechanical stability. Prior experience with Western Electric Traveling-Wave Tubes (TWTs)† indicated the

direction of design. Subsequent application in the AR6A* Radio System has shown that the device, designated the 473A TWT, when operated with the power supply described in this article, meets all detailed repeater requirements. The use of this TWT was discontinued following the decision to terminate the manufacture of all Western Electric traveling-wave tubes. An equivalent TWT obtained from a commercial source and meeting the same requirements is now used in production of the AR6A Radio System.

## II. THE TRAVELING-WAVE TUBE

### *2.1 Requirements on the TWT*

The 473A TWT includes the vacuum tube and the focusing magnetic circuit (Fig. 1). This combination must be united at the manufacturing location, so that optimum focus and Radio Frequency (RF) operating parameters are achieved.

The following list of major requirements specified for the TWT includes the operating conditions specified over the frequency band of 5.925 to 6.425 GHz (with full-load output power of 24.8 dBm and gain reduced 2 dB below the optimum value by increasing the helix voltage):

1. RF gain—40 to 48 dB.
2. Gain plus noise figure—69.5 dB maximum.
3. Third-order intermodulation (three-tone test method)[1]—$M_{A+B-C}$ = −90.5 dB maximum, and constant within ±0.4 dB with the power per tone varied from 18 to 30 dBm.
4. Fifth-order intermodulation ($M_{2A+2B-C}$)— from 22- to 30-dBm output power, −180-dB maximum at 18-dBm output power, −160-dB maximum.

The device developed to meet these requirements consists of a helix-type, single-collector, convergent-flow, electron-gun traveling-wave tube, focused by a Periodic Permanent Magnetic (PPM) field.

As observed from the requirements, noise figure, signal intermodulation, and gain were the major operating parameters to be satisfied. Also, implied by the application, long operating life requires low cathode current loading and minimum interception of current from the beam by the helical slow-wave structure. Further, a critical need for this application is mechanical stability; it was verified that minute movement of the helix results in significant shift in intermodulation (IM) performance.

## III. TWT COMPONENT DESIGN APPROACH

### *3.1 Focus circuit and tube envelope*

The PPM focus circuit was adapted from an existing Western Electric manufactured circuit used on the 461A TWT. The existing

*Amplitude Modulation Radio at 6 GHz for the initial (A) version of the system.

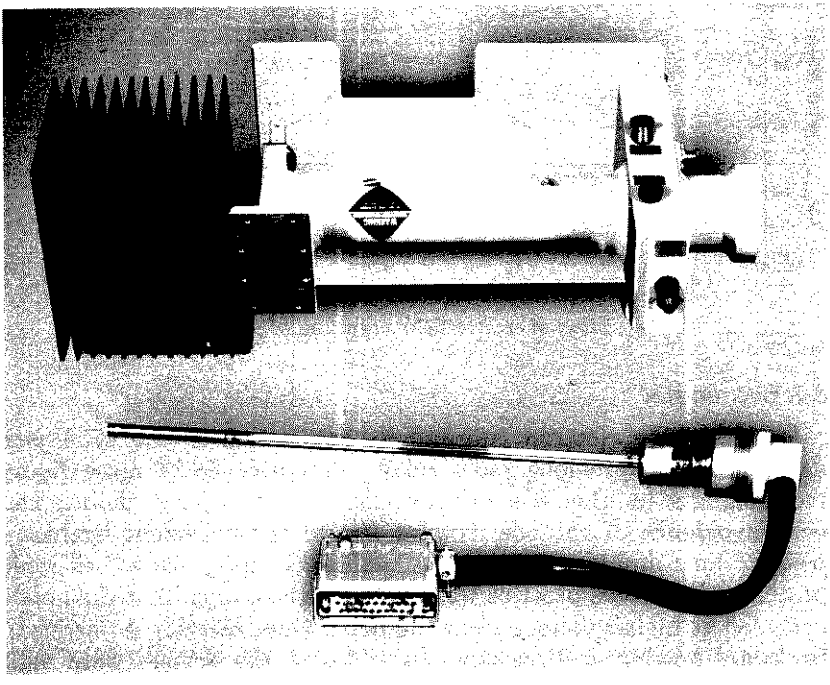

Fig. 1—Picture of AR6A 473A TWT.

glass envelope was also used so that it fit the magnet and pole piece parts. Since the TWT was required to be convection cooled by free air, a finned cooling structure was developed. An SMA coaxial RF input was specified and the coaxial-to-waveguide transition was made an integral part of the circuit.

Of major importance was the introduction of a cross-magnetic field in the collector region. The reason for this is that elastically reflected electrons or electrons emitted by secondary emission from the tube collector resulted in feedback to the input, which has a deleterious effect on intermodulation performance. The smoothing effect, with power variation, upon the third-order intermodulation, with and without the use of a cross field, is shown in Fig. 2.

The focus circuit is assembled from Alnico 8 magnets and soft iron pole pieces on precision mandrels so that no trimming of the magnetic field is necessary for tube focus. A movable pole piece near the input waveguide allows optimum focus to be reached. Cooling fins are coupled to the copper collector of the tube via a thin layer of conducting silicone grease. Adjustable tuning plungers in the waveguide optimize the RF impedance match between the input and output waveguides and helix.

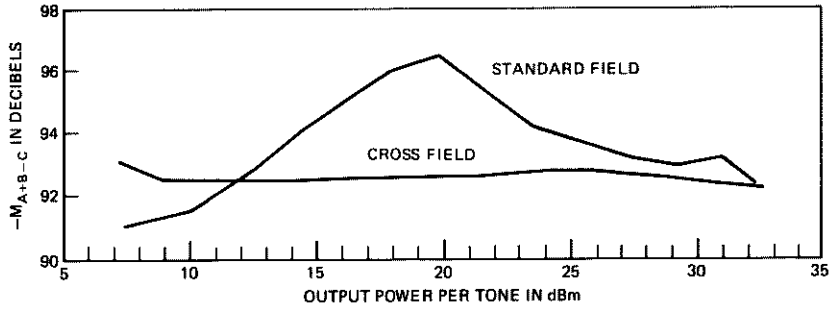

Fig. 2—Effect of crossed-field magnet on $M$ performance.

### *3.2 Electron gun*

Design of the electron gun and its application in the 473A is a departure from previous radio relay tubes because of noise figure requirements. In other Western Electric designs, major guidelines had been avoidance of cathode damage due to bombardment by heavy positive ions and use of moderate cathode loading. To afford ionic protection, previous practice was to design the gun so that the anode operated at higher voltage than the helix, thus, erecting a barrier to backward-flowing positive ions. In addition, the devices were built with highly convergent beam profiles, i.e., with the cathode diameter being much greater than the diameter of the beam projected through the helix. Typically, the emission density in such designs is $0.2\text{A/cm}^2$ of cathode area.

The effect on noise figure of both helix-voltage-to-anode-voltage ratio, $E_w/E_c$, and cathode current density, $J_C$, is shown in Fig. 3. The upper plot, evaluated at $J_C = 0.2$, shows the noise figures obtained with previous design rules. Clearly, lower noise figure can be obtained with $E_w/E_c > 1$ and with the cathode diameter smaller. A standard oxide cathode coating would be advantageous over other less proven, high-current types if the cathode loading could be reduced to allow its use. The anode voltage was set at 3150, nominal, so that $E_w/E_c = 1.3$. Diminishing benefit would be obtained from a higher ratio, and leakage problems on insulators would also increase. The resulting electron gun is a glass-rod supported triode that emits 70 mA dc from an oxide-coated cathode. The cathode-heater structure is designed to operate at 740 degrees Celsius (observed pyrometric temperature).

The life capability of the cathode has not been entirely confirmed. Based on calculation and extrapolation, greater than 30,000 hours is predicted. Limited facilities allowed five tubes to be run individually over times ranging from 3100 to 8500 hours. One of the five showed significant cathode degradation at 6000 hours; the other four were stable. No short-life problems have been encountered in application.

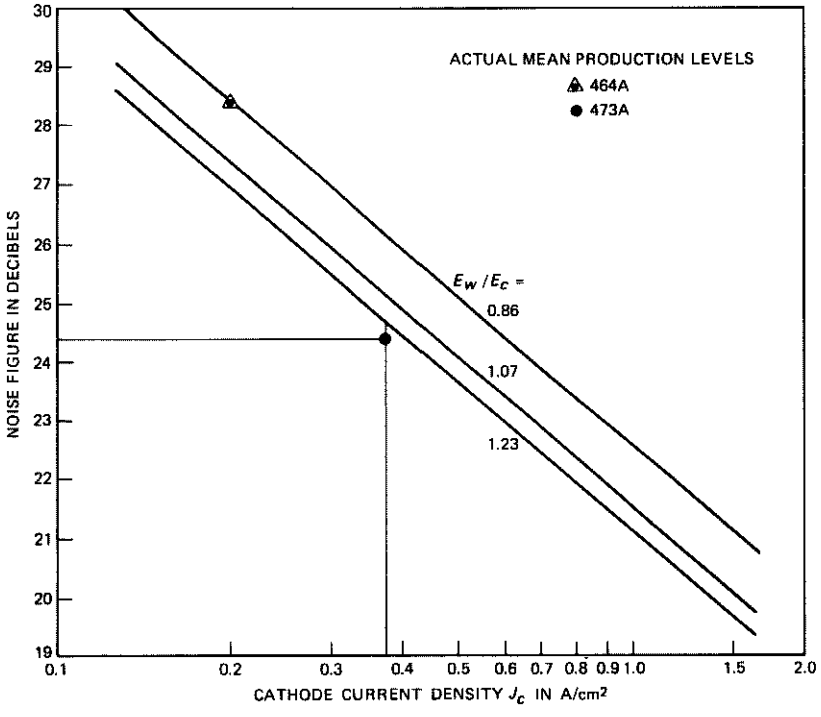

Fig. 3—Effect of cathode loading on noise figure for different voltage profiles.

### *3.3 Helical slow-wave circuit*

Initial tests confirmed the work of Curtice,[2] showing that for lowest intermodulation distortion the helix RF loss should be minimized and the gain parameter $C$ (which is proportional to the 1/3 power of beam-current-to-helix-voltage ratio) should be maximized.

Consideration of the effect of the gain parameter led to design of the helix to operate at 4100 volts. It is noted also that minimum helix loss is desirable for minimizing tube noise figure, although the effect is not as pronounced as it is on intermodulation. Low loss and mechanical rigidity tend to be opposed, because additional support material adds to RF losses.

The helix structure, therefore, utilized beryllium oxide rods. After refining the processing, rods with round cross section had nearly as low loss as those with modified T-shape cross section. The round cross-section rods were used and were bonded to the helix wire with glass frit (glaze). This arrangement was considered the best compromise from the standpoint of intermodulation and noise performance, mechanical rigidity, and heat dissipation.

The helix sever loss (i.e., the loss deliberately added to the midsec-

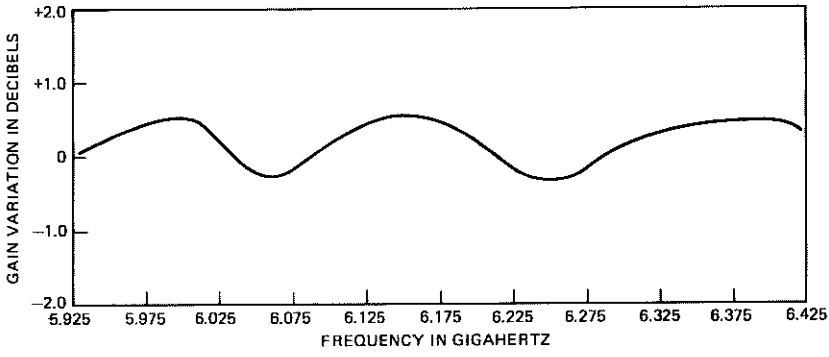

Fig. 4—Typical 473A traveling-wave-tube broadband gain variation.

tion of the helix to prevent self-oscillation and to provide good external RF matches) is a tantalum-aluminum sputtered film with Ta/Al ratio of 70/30 atomic percent.* This loss section is highly stable and not easily altered by bombardment with the 4000-volt electrons of the TWT beam.

The taper applied at the beginning and end of the sever loss is critical to achieving the desired broadband transmission shape. Figure 4 shows the typical broadband gain characteristic of the TWT. The required variation must be less than 1.2 dB peak to peak with no more than four cycles in the 500-MHz band.

### *3.4 Collector*

Construction similar to that employed in other Western Electric designs was used. The material is copper, of a length such that the modulated beam is well within the collector before significant beam spread occurs. This point is important from the standpoint of secondary emission. As noted previously, control of secondary electrons and reflected electrons is obtained by a cross-magnetic field over the collector.

### *3.5 Processing*

The design included careful attention to parts cleaning, degassing, and handling. Final exhaust was conducted with titanium gettering pumps and seal-off of each vacuum envelope was accomplished only after indicated internal pressure was in the region of $10^{-8}$ mm Hg.

## IV. TWT DEVELOPMENT PROBLEMS

Performance of the TWT was evaluated on a number of models. Problem areas that would likely result in low yield in manufacture were identified and changes were made.

*This film was originally developed for film resistors.[3]

### *4.1 Electron gun interelectrode leakage*

Initially, a gun structure using ceramic rod supports similar to that used in the Western Electric 461A[4] TWT was used. It was soon found that the higher voltages resulted in electrical breakdown across the support rods. A glass rod support structure was designed, leading to much improvement in the leakage problem. It was also necessary to maintain careful parts cleaning and processing. To keep electric fields low, adjacent parts, such as the gas getter and leads, were precisely placed and an initial voltage treatment of the gun was incorporated. The power supply was designed, as later described, to be insensitive to arcs that may occasionally occur. These actions resulted in attaining control over leakage and arcing problems.

### *4.2 Low-frequency noise*

The output of early tubes often showed noise at a few hertz and a few tenths of a decibel in amplitude. A rather elaborate computer-based study indicated that the noise was due to oscillation of ions trapped in potential depressions in the electron gun. The study also gave direction to gun design changes required. However, during the period of this study, the gas getter was changed from a nonevaporating type to an evaporating type; the change was actually made from the considerations of lowering cost and using less space within the envelope. It was found that the oscillation problem disappeared, presumably because the new getter reduced the pressure of the offending ion. Though attempts were made, the ion responsible for noise generation was never identified.

## V. TWT RESULTS

The gain and third-order intermodulation coefficient were characterized using a special three-tone intermodulation test set.[5] Several hundred tubes (including preproduction versions) were characterized. Typical results are shown in Figs. 5 and 6, which plot the gain and $M_{A+B-C}$ versus power and helix voltage, respectively. These measurements versus power were particularly important because of the requirement for constant third-order performance, which is necessary for the application of the predistorter to the AR6A transmitter.

Sample distributions of three major operating parameters from production—gain, third-order intermodulation, and noise figure plus gain sum—are shown in Figs. 7 through 9. Excellent control within the specification requirements is demonstrated. The remaining important parameter, fifth-order intermodulation, was measured only occasionally and was always well below the specification limits.

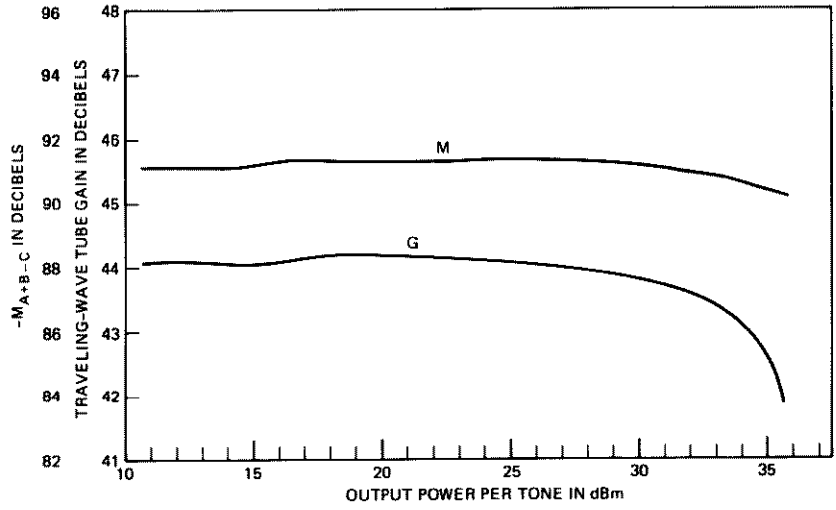

Fig. 5—Typical results of 472A TWT performance study showing third-order intermodulation coefficient and gain versus RF output.

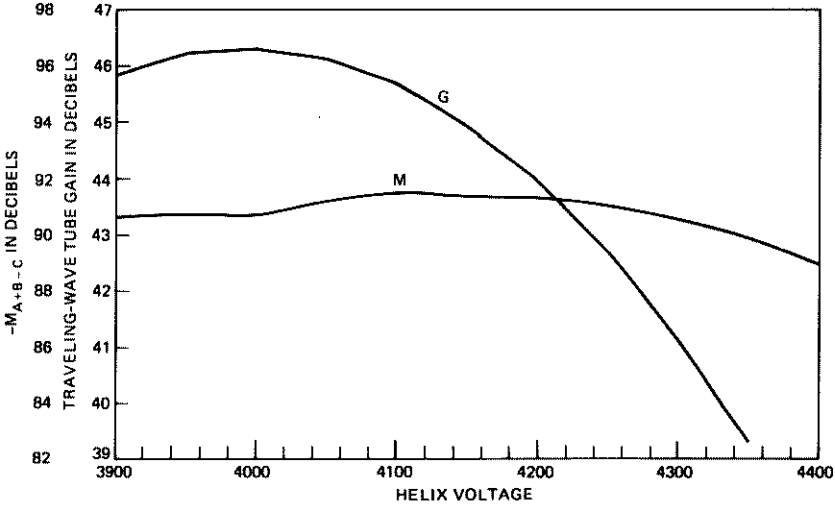

Fig. 6—Typical results of 472A TWT performance study showing third-order intermodulation coefficient and gain versus helix voltage.

## VI. REQUIREMENTS ON THE POWER SUPPLY

The requirements for the TWT power supply, with emphasis on those features that directly interact with the TWT, are summarized as follows:

1. Well-regulated heater and helix voltages and beam current are required to control the TWT gain and intermodulation noise.

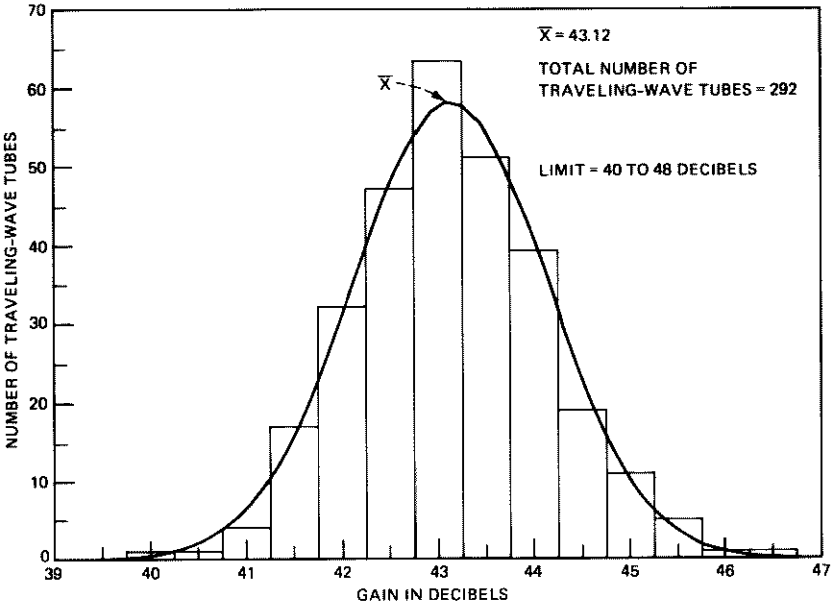

Fig. 7—473A TWT gain.

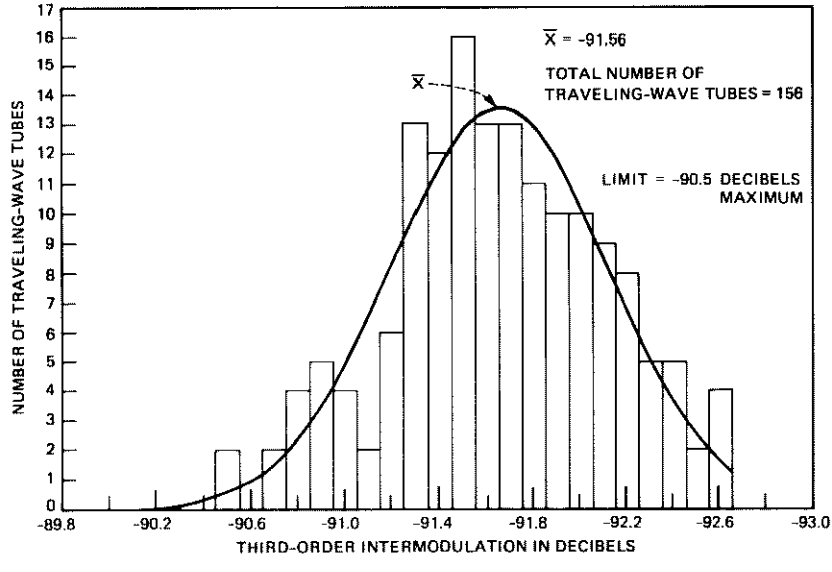

Fig. 8—473A TWT third-order intermodulation ($-M3$).

2. During turnon and turnoff, the electrode voltages must be sequenced so that damaging helix and anode currents do not occur.

3. Current detection circuits must protect the TWT and supply from tube internal arcs.

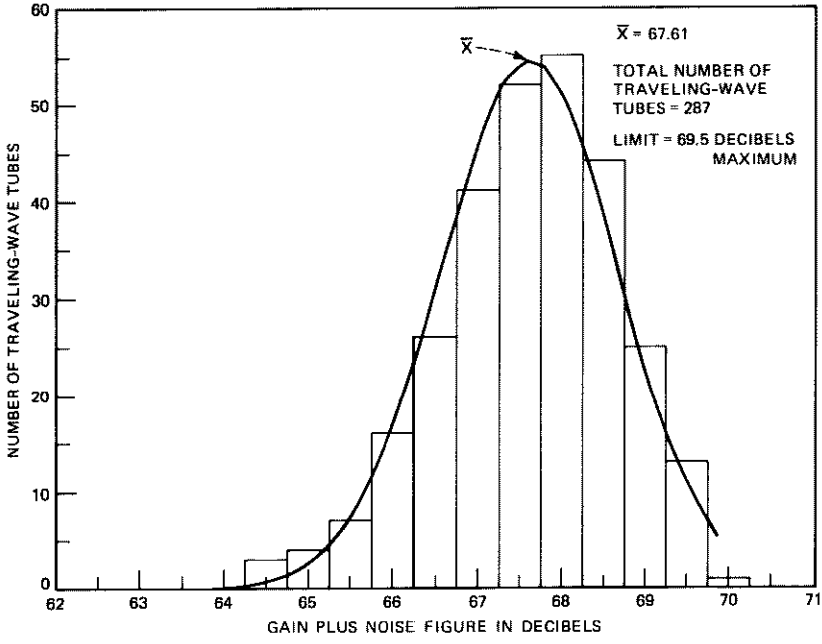

Fig. 9—473A TWT noise figure plus grain sum.

4. Side tones generated by the power supply and TWT combination must be more than 77 dB lower than a single-tone test signal.

## VII. POWER ARRANGEMENT AND REGULATION APPROACH

Figure 10 shows a block diagram of the power supply. The power supply and TWT parameters are summarized in Table I. The heater/Beam-Forming Electrode (BFE) dc-to-dc converter supplies 6.3 volts at 1.2 amperes to the TWT heater. The heater voltage is regulated to ±2 percent by controlling the duty cycle of the converter. During initial turnon, the current in the cold heater is limited to about 1.9 amperes by a limit circuit (not shown) within the converter.

The BFE supply is used to turn the TWT on and off electrically. When the TWT is running normally the BFE-to-cathode voltage is less than 1V (nominally 0V). During the time when turnon, turnoff, or internal TWT arcs occur, transistor Q1 is turned off. This causes the BFE potential to be approximately −450V, thus turning the TWT beam off. The BFE switching procedures are discussed in more detail in a later section.

Since the cathode is the common terminal of the TWT amplifier, electrode voltages are, therefore, normally specified with respect to the cathode (even though the collector is grounded). The collector

converter supplies +1800V. The 1800V output is controlled by the duty cycle of the converter to achieve ±2 percent regulation.

The anode converter and collector voltages are applied in series combination to provide from 2800 to 3500V to the anode. The beam current is monitored and the output voltage of the anode converter is regulated to control the beam current to 70 mA ±0.5 percent through control of the anode-to-collector voltage. The helix current ($I_w$) is also monitored. If $I_w$ is less than 1.75 mA, the anode converter regulates the beam current as discussed. Should $I_w$ reach 1.75 mA (corresponding to an unfocused TWT), the anode voltage ($E_c$) is controlled to hold $I_w$ at 1.75 mA. However, this causes the beam current to fall out of regulation, and when it is 2 percent lower than 70 mA, a trouble indication is generated. This indication occurs when a TWT cathode has become deactivated.

The helix converter and collector converter are applied in a series combination to provide from 4000 to 4550V to the helix. The helix voltage is adjustable using a resistive voltage divider. Since the TWT gain is extremely sensitive to changes in helix voltage, the helix converter includes a series regulator to control the helix voltage to ±0.5 percent. The converter being controlled supplies only the helix-to-ground voltage.

Both the helix converter and anode converter supply only a portion of their respective electrode voltages; the collector supply provides the remaining voltage. This arrangement is used for two reasons. First, the power transformer used in each converter is inexpensive since its secondary must withstand only the voltage it generates itself rather than approximately 1800V plus its self-generated voltage. Second, inexpensive monitoring circuitry may be used since it operates near ground (rather than cathode) potential.

## VIII. POWER SUPPLY OPERATION

### *8.1 Turnon and turnoff*

When −24V is connected to the input of the power supply through an external switch, the heater/BFE converter and the timer start immediately. The timer supplies a shutdown signal to the collector converter. Since the helix and anode converters depend on base-drive signals for their inverters from the collector converter, they are also shut down. The timer continues to supply a shutdown signal for a nominal 6 (minimum of 5) minutes to allow the TWT to warm up. During this preheat period the timer also supplies a signal that causes −450V to be applied to the BFE during warm-up to inhibit spurious emissions from the cathode.

At the end of the 6-minute warm-up period, the shutdown signal to

Table I—Parameters of TWT power supply requirements

| | |
|---|---|
| Heater current | 1.2 amps maximum |
| Heater voltage | 6.3 volts ±2 percent |
| BFE voltage | 0 |
| Anode current | 0.5 mA maximum |
| Anode voltage | As required for collector current |
| Helix current | 1.8 mA maximum |
| Helix voltage | Adjusted for 5 percent above synchronous operation; regulated to ±0.5 percent after adjustment |
| Collector current | 70 mA |
| Collector voltage | 1800 volts ±2 percent |

the collector converter is removed. The collector, helix, and anode converters then start. The time constants of each converter are designed so that these electrode voltages reach their respective final values in the order named above. The BFE voltage is not switched to zero until the collector converter has started, and the helix voltage has reached 4000V. This arrangement prevents excessive helix current while the TWT is turning on.

The external −24V switch is used for normal turnoff. On removal of −24V, the electrode voltages decay, the timer resets, and the BFE supply loses its continuous source of energy. As soon as the helix voltage reaches 4000V, the remaining BFE voltage is applied. There is still enough stored energy in the BFE supply's internal capacitor to inhibit the beam until the other electrode voltages fall safely below levels that would otherwise cause damaging values of helix and anode currents.

### *8.2 Arc detection*

On occasion a TWT arcs. Any combination of electrodes might be involved in the arc, but the direct or indirect result is almost always a large value of helix and/or anode current. When the helix plus anode current exceeds 10 mA, a shutdown signal is applied to the collector converter. Of course the helix and anode converters also shut down, since they depend on the collector converter for base drive signals. Decay of these voltages then causes the arch to extinguish. At this time the collector converter is again turned on and the tube voltages rise toward their respective normal values.

During the arc and subsequent shutdown, the RF output of the TWT is less than normal. When the TWT is turning back on, the process is controlled so that the AR6A protection switching system can operate properly. The RF output is held off by applying −450V to the BFE for at least 150 milliseconds, thus allowing AR6A Radio System transients, which may occur during the arcing process, to subside completely before reapplying RF signal to the system.

The arc detection arrangement described above not only protects

the TWT by turning it off for the prescribed time period, but also has proved to be successful in protecting the supply. One particularly arc-prone TWT was life tested for 14 days. A total of 110 arcs occurred, but no supply damage resulted. The TWT parameters gradually fell out of specified limits, but the TWT performance did not change significantly as the result of any one arc.

### *8.3 Tones*

The power-supply ripple requirements are not directly specified. Instead, they are implied by the requirement that the TWT sidetones must be more than 77 dB below the test tone.

Output filters are used in each converter. Additional Inductance Capacitance (LC) sections are mounted in a shielded steel box. A shielded cable connects the output of the filter box to the TWT.

The dominant sidetones occur at 20 kHz, the frequency of the helix and anode converters, and at 30 kHz, the switching frequency of the heater/BFE converter. These sidetones are caused by interwinding capacitance current that is generated in the power transformer in the helix, anode, and BFE converters. These currents are bypassed where appropriate, but they are still the dominant tone sources. In addition, special filtering is provided for transistor Q1 to prevent it from being turned off at a 30-kHz rate by interwinding capacitance current.

## IX. AMPLIFIER OPERATION

The TWT and power supply are electrically connected by a shielded cable. At the TWT end, the cable is potted into the end of the tube. The cable connector mates to the power supply connector, which is accessible through a slot cut into the top cover of the power supply. A safety arrangement prevents power-supply operation when the TWT connector is disconnected.

The RF signal connections to the TWT are via an SMA coaxial connector at the input and a reduced height WR159 waveguide at the output. Adjustable shorts are provided for RF matching at the input and output.

Meters on the front panel of the power supply are supplied to measure the helix and collector currents. On the front panel, a helix-voltage adjustment (labeled RF gain) is provided. This adjustment is made during alignment of the amplifier so that the TWT operates at a helix voltage higher than the synchronous value, thus providing gain that is approximately 2 dB lower than that achievable at the synchronous helix-voltage value.

All amplifiers were tested in a bay environment. The gain-versus-frequency characteristic (transmission characteristic) of the amplifier embedded in the AR6A transmitter was measured for each amplifier

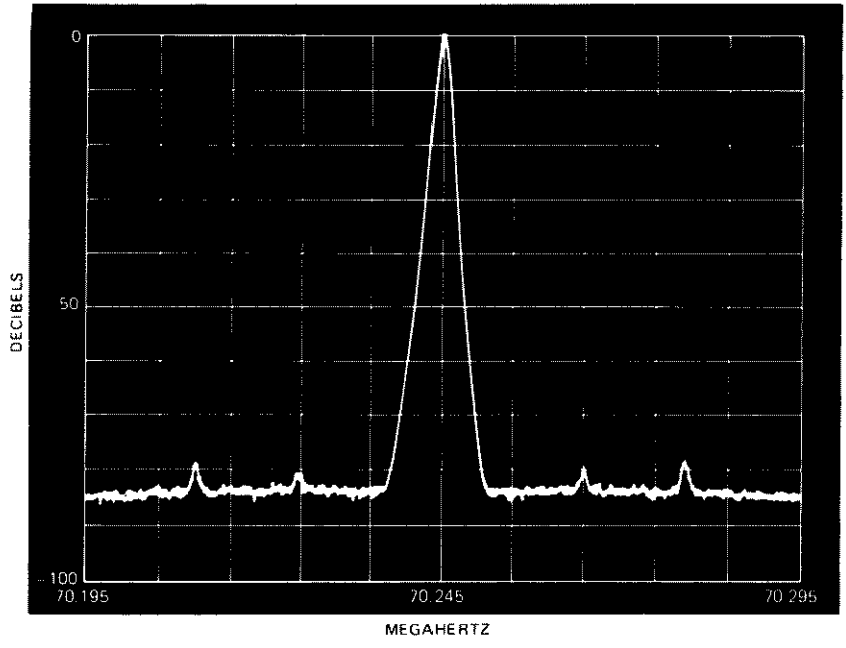

Fig. 11—Test tone with spurious modulation.

shipped for field application. The results of these tests were interpreted by subtracting out frequency characteristics attributable to other transmitter components. Such analysis shows that the average transmission characteristic for 100 amplifiers (with samples at every channel) has a bow of approximately 0.1 dB across the 30-MHz channel. (Note that any residual slope of the transmitter is equalized.) This is approximately what one would expect, considering the gain variation shown in Fig. 4.

Also, a test was made to check for a spurious modulation caused by very low ripple voltages at frequencies that are multiples of the 30- and 20-kHz switching rates of the power supply. A test tone was applied to the amplifier and sidetones were measured. The sidetones were required to be at least 77 dB below the level of the test tone. A graph extracted from a spectrum analyzer photograph shows a typical result (Fig. 11).

## X. ACKNOWLEDGMENTS

J. R. Meszar and C. A. Waldron were highly instrumental in the development of the power supply and TWT, respectively.

# Predistortion for the Traveling-Wave-Tube Amplifier

By R. P. HECKEN,* R. C. HEIDT,* and D. E. SANFORD*

(Manuscript received February 7, 1983)

To satisfy the single-sideband amplitude-modulated system noise requirements, the transmitter must be very linear. Predistortion reduces intermodulation distortion of the transmitter to acceptable levels. This paper deals with the design considerations, the model of the transmitter used to analyze third-order intermodulation products, and the methods applied to align the predistorter-transmitter combination for effective intermodulation reduction.

## I. INTRODUCTION

The frequency stability required for single-sideband amplitude-modulated (SSB-AM)† system operation results in the potential for in-phase addition of intermodulation noise from repeater to repeater. Traveling-Wave Tubes (TWTs) offer the best linearity (and, consequently, the lowest intermodulation distortion) available for currently existing 6-GHz power amplifiers. However, linearity must be improved to satisfy system noise requirements.

The concept of predistortion to reduce intermodulation distortion

had originally been explored extensively at 4 GHz[1] and was found considerably less complex than feedforward.[2] In particular, predistortion at intermediate frequencies appeared attractive because of its simplicity and economy. Operating at intermediate frequency (IF), the predistorter is placed ahead of the up converter and is, therefore, able to cancel intermodulation products generated in the converter and the traveling-wave tube. Clearly, the latter is the major contributor to nonlinear distortions and will be treated accordingly.

Extensive measurements have shown that TWTs, if operated at low radio frequency (RF) power levels, i.e., in a domain of weak nonlinearity, behave essentially as first- and third-order devices and produce odd-order intermodulation products within the narrow frequency band of interest. In the AR6A* System the predistorter is designed to cancel distortions in this power region, and it is important to distinguish this mode of operation from other methods where predistortion is analyzed in a region of strong nonlinearity.[3,4]

In the following section we will proceed with a simple analysis of nonlinearities of the transmitter, which is based on a model that proved to be very accurate within the useful power range of the AR6A System. Section III will deal with practical design considerations, and in Section IV we will conclude with the results.

## II. NARROWBAND DISTORTION ANALYSIS

### *2.1 Nonlinear model of the traveling-wave tube*

Measurements on a large number of traveling-wave tubes having a saturated power-handling capability from 5 to 20W showed that even at very low RF power levels (<1W), the simple memory-free polynomial model describing gain nonlinearity of the TWT is inadequate. Two additional effects must be included in the analysis to achieve substantial intermodulation reduction of 20 dB or more: the amplitude and phase distortions due to reactive circuit elements and the amplitude modulated to phase modulated (AM-PM) conversion effect. A model of the TWT that was found very useful is shown in Fig. 1. This model characterizes a special class of nonlinear systems in which a memory-free, nonlinear two-port network is embedded between two linear passive two-port networks having the impulse responses $h_A(t)$ and $h_B(t)$, respectively. For narrowband systems the nonlinear two-port is well modeled by a finite odd-order power series in two variables with constant coefficients[5,6]

$$w = b_1' u + b_3' u^3 + b_5' u^5 + \cdots + b_1'' \dot{u} + b_3'' \dot{u}^3 + b_5'' \dot{u}^5 + \cdots, \quad (1)$$

*Amplitude Modulation Radio at 6 GHz for the initial (A) version.

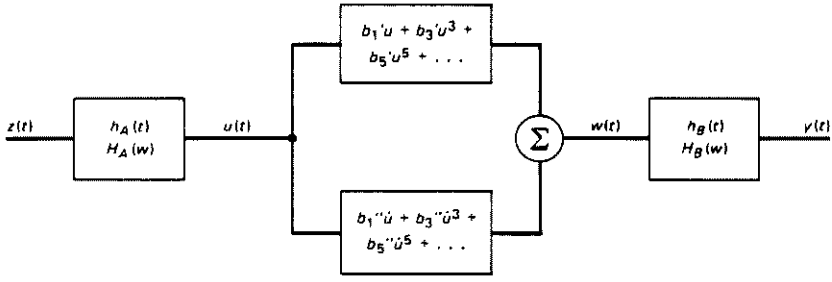

Fig. 1—Approximate model of a traveling-wave-tube amplifier with weak nonlinearities.

where $\dot{u} = du/dt$. The partial series in powers of $\dot{u}$ accounts for AM-PM conversion. An important aspect of this TWT model is the fact that the two interfaces between the three two-ports are, in general, not accessible.

For our analysis, we will limit the power series to first- and third-order terms. Applying the Fourier transformation to eq. (1), we obtain the complex nonlinear input-output relation

$$W = B_1 U + B_3 U^{3*} + \cdots, \tag{2}$$

with the notation $U^{3*}$ indicating the repeated convolution $U*U*U$. The complex coefficients are given by

$$B_1 = b_1' + j\omega_c b_1'', \tag{3a}$$

and

$$B_3 = b_3' - j\omega_c^3 b_3''. \tag{3b}$$

The narrowband assumption manifests itself in eq. (3), in that the frequency variable, $\omega$, has been replaced by the constant channel frequency, $\omega_c$, while performing the convolutions. With the input-output relations for the nonlinear portion of the TWT established, we can write the overall transfer function for the TWT model. Let $Z$ and $Y$ be the Fourier transforms of the input and output signals; then

$$Y = H_B B_1 H_Z Z + H_B B_3 (H_A Z)^{3*} + \cdots, \tag{4}$$

where $H_A$ and $H_B$ are the transfer functions of the input and output networks, respectively. Before we proceed with the distortion analysis of the transmitter, we need first to discuss some properties of the up converter.

### *2.2 The Schottky modulator*

Comparative measurements on Varactor Diode Converters (VDC) and Schottky Diode Converters (SDC) have shown the superiority of

the latter when considering its nonlinear distortion characteristics versus RF output power. These measurements revealed that the SDC, when pumped with high local oscillator power, behaves like a third-order device over a wide range of RF signal levels. This property is indeed useful because it allows the predistorter, tailored to compensate for third-order distortions, to improve the converter distortions as well. Moreover, because of its conversion loss, in contrast to the conversion gain of a VDC, a higher level of distortions can be tolerated in an SDC. This is so because, for a given performance, the TWT essentially limits the RF output power. To illustrate this, we compute the power of a three-tone, third-order product generated in the converter as it appears at the output of the TWT. If we refer to Fig. 2 this power is

$$P_{A+B-C} = M_{A+B-C} + 3P_A + G \qquad \text{(dBm)}, \tag{5}$$

where $M_{A+B-C}$ is the particular intermodulation coefficient[7] in decibels of the converter, $P_A$ is the power in dBm of each of the equal-level, three-tones at the output of the converter, and $G$ is the overall gain of the bandpass filter (BPF) and TWT. Since the single-tone power at the tube output is

$$P_{AO} = P_A + G \qquad \text{(dBm)}, \tag{6}$$

we find that

$$P_{A+B-C} = M_{A+B-C} - 2G + 3P_{AO} \qquad \text{(dBm)}. \tag{7}$$

Thus, for a specified performance ($P_{AO}$ fixed) the device distortion $M_{A+B-C}$ can be reduced by 2 dB for each decibel increase in TWT gain. Since the difference in conversion loss and gain can be as high as 12 dB, the Schottky diode converter may have an $M_{A+B-C}$ that could be 24 dB worse than that of a varactor diode converter, yet may still yield the same distortion performance. Typically, the SDC has an $M_{A+B-C}$ of about −25 dB compared to −40 dB of the VDC, which clearly shows the disadvantage of the varactor diode converter.

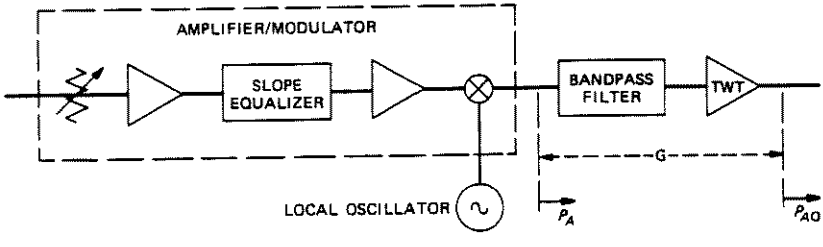

Fig. 2—Simplified block diagram of the AR6A amplifier/modulator with bandpass filter and traveling-wave tube.

It is useful to compare the distortion power generated by the converter to that of the TWT. At a total signal output power of +27 dBm for three equal-level tones, the single-tone power $P_{AO}$ is approximately +22 dBm. With $G = 45$ dB and $M_{A+B-C} = -25$ dB from eq. (7), $P_{A+B-C} = -49$ dBm. A TWT having an $M_{A+B-C} = -91$ dB generates intermodulation power of the same product at a level of −25 dBm. Obviously, one can ordinarily neglect the contribution of the converter since it increases the total intermodulation power by only 0.53 dB. However, if the predistorter can reduce distortions by more than 20 dB, the converter will contribute significantly to the resulting intermodulation noise unless the predistorter also reduces its nonlinearities. In spite of this, to keep our discussion simple we will not include the converter-generated distortions in our analysis.

### *2.3 Generalized nonlinear transmitter model*

The mathematical treatment of the nonlinearities of the complete transmitter is complicated, even when we neglect the converter nonlinearities, because of the operation in two frequency domains. As is shown in the appendix, the frequency translation from IF to RF requires each sideband to be considered separately. We will point out the differences where appropriate and develop the analysis for the upper sideband only. To arrive at a tractable model of the complete transmitter, we actually include the converter, bandpass filter, etc., in the TWT model as described in the appendix. Frequency characteristics at RF are then referred to the IF band, allowing the predistorter to be directly connected to this TWT model. The cascade of predistorter with IF amplifiers and the converter with bandpass filter, TWT, etc., is depicted in Fig. 3, where we used a nonlinear model of the predistorter that is similar to that of the TWT. Thus, we assume that the predistorter has the transfer function

$$Z = G_B A_1 G_A X + G_B A_3 (G_A X)^{3^*}, \tag{8}$$

which leads to the following overall transfer function for the upper sideband (USB):

$$Y_{\text{USB}} = H_B B_1 H_A G_B A_1 G_A X + H_B B_1 H_A G_B A_3 (G_A X)^{3^*} + H_B B_3 (H_A G_B A_1 G_A X)^{3^*} + \cdots. \tag{9}$$

In eq. (9) all terms requiring higher than third-order convolutions have been neglected. Two observations can be made immediately: the distortion terms depend directly or indirectly on the product $G_A X$ as part of the convolution process. Thus, the frequency characteristic of the input network of the predistorter will have no effect on the minimization of these terms. Also, $H_B$ is a factor in both distortion

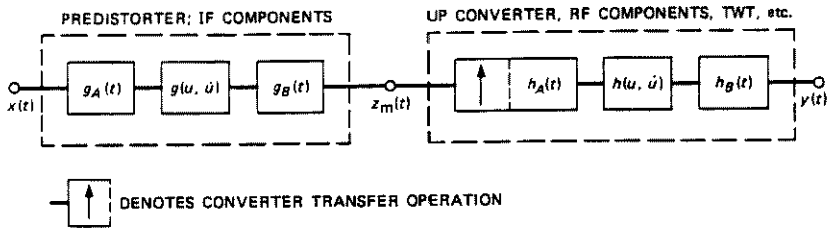

Fig. 3—A generalized model of the AR6A transmitter.

terms, indicating that the frequency characteristic of the TWT output network also has no effect on the intermodulation cancellation. For the purpose of this analysis we can, therefore, set $G_A = 1$ and $H_B = 1$. With these simplifications the third-order distortion term becomes, in the case of the upper sideband,

$$D_3 = B_1 H_A G_B A_3 (X)^{3^*} + B_3 (H_A G_B A_1 X)^{3^*} \qquad \text{(USB)}. \tag{10}$$

It can be shown that in order for $D_3$ to at least vanish over the frequency band where $X$ exists, it is necessary for the product $H_A G_B A_1$ to have constant magnitude and constant delay as function of frequency within that band, i.e., the condition must be met

$$H_A G_B A_1 = C e^{-j\omega\tau}, \tag{11}$$

where

$$C = |H_A G_B A_1| \qquad \text{and} \qquad \omega\tau = \sphericalangle(H_A G_B A_1).$$

This yields for $D_3$

$$D_3 = \left( B_1 \cdot \frac{A_3}{A_1} C e^{-j\omega\tau} + B_3 C^3 e^{-j\omega\tau} \right) X^{3^*}.$$

Hence, frequency-independent cancellation of the third-order distortions at the upper sideband is possible if, in addition to eq. (11), the following condition is fulfilled:

$$\frac{A_3}{A_1} = -\frac{B_3}{B_1} \cdot |H_A G_B A_1|^2 \qquad \text{(USB)}. \tag{12a}$$

The corresponding condition for the lower sideband (LSB) is

$$\frac{A_3}{A_1} = -\frac{\check{B}_3}{\check{B}_1} \cdot |H_A G_B A_1|^2 \qquad \text{(LSB)}, \tag{12b}$$

where $\check{B}$ is the complex conjugate of $B$. Thus, the required complex ratios $A_3/A_1$ for the LSB and USB are conjugate to each other. The

fundamental relationships for wideband distortion cancellation are described in eqs. (11) and (12). Therefore, design as well as alignment procedures are essentially based on these criteria. Obviously, eq. (11) requires amplitude and delay equalization for all components in the signal path between the nonlinear element of the predistorter and the nonlinear region of the TWT, unless these components have inherently flat response and constant delay. In the AR6A transmitter, however, a certain amount of slope equalization was required to achieve intermodulation improvement by more than 30 dB. This equalizer is integrated into the modulator/amplifier unit.

From eqs. (12a) and (12b) we derive the required magnitude and phase of the distortions to be generated in the predistorter. The magnitude is practically independent of the sideband used since the TWT generates approximately the same intermodulation level at both frequencies. Therefore,

$$|A_3| = \left| \frac{B_3}{B_1} \right| \cdot |A_1|^3 \cdot |H_A G_B|^2. \tag{13}$$

It is obvious that for stable operation of the predistorted transmitter, the magnitude of the transfer coefficients, $|A_1|$ of the predistorter and $|H_A G_B|$ of the interconnecting networks (which includes the up converter), must be very well controlled and remain stable over time and temperature. The same is true for the gain of the TWT, represented by $|B_1|$ in eq. (13).

The phase condition for the upper sideband is

$$(\sphericalangle A_3 - \sphericalangle A_1) = \pi + (\sphericalangle B_3 - \sphericalangle B_1) \qquad \text{(USB)}, \tag{14a}$$

and for the lower sideband is

$$(\sphericalangle A_3 - \sphericalangle A_1) = \pi - (\sphericalangle B_3 - \sphericalangle B_1) \qquad \text{(LSB)}. \tag{14b}$$

Thus, means have to be provided in the predistorter to achieve both phases since either the USB or LSB may be deployed, depending on the channel, in the AR6A System.

### *2.4 Interaction distortions*

In the derivation of the overall nonlinear transfer function for the transmitter, terms involving convolutions of higher than third order have been neglected. It is worthwhile, however, to discuss the next higher-order term, which is found to be

$$D_5 = 3B_3(H_A G_B A_1 X)^{2^*} * (H_A G_B A_3)(X)^{3^*}. \tag{15}$$

Assuming that the transmitter is aligned properly, such that conditions in eqs. (11) and (12) are fulfilled, the magnitude of $D_5$ becomes

$$|D_5| = 3|H_A G_B A_1|^5 \cdot \left| \frac{B_3^2}{B_1} \right| \cdot |X^{5^*}|. \tag{16}$$

We see from the above expressions that this fifth-order distortion is strictly due to interaction between the third-order terms of the predistorter and TWT and that the magnitude is very sensitive to the first- and third-order coefficients of the TWT. For $|D_5|$ to remain small, $|B_1|$ (i.e., TWT gain) should be large and $|B_3|$ of the device must be small at the outset.

### *2.5 Residual third-order distortions*

In practice it is not possible to fulfill the conditions given by eqs. (11) and (12) at all frequencies. It becomes necessary, therefore, to estimate the amount of residual distortions after imperfect predistortion. In particular, the effect of deviations from the ideal condition in eq. (11) is important because of the strong sensitivity of $D_3$, defined in eq. (10), to the transfer function $T = H_A G_B A_1$. We will, therefore, attempt to analyze $|D_3|$ as a function of small deviations $\delta_c$ and $\delta_\alpha$ of $|T|$ and $\alpha = \measuredangle T$, respectively. Thus, we express $T$ as

$$T = (C + \delta_c) \cdot e^{-j(\omega\tau + \delta_\alpha)}, \tag{17a}$$

which is approximately equal to

$$T \simeq Ce^{-j\omega\tau} + (\delta_c/C - j\delta_\alpha)Ce^{-j\omega\tau}$$

or

$$T \simeq T_o + E \cdot T_o. \tag{17b}$$

Obviously, $T_o = C \cdot e^{-j\omega\tau}$ represents the ideal transfer function, which we will assume to fulfill the condition in eq. (11). The error term $E \cdot T_o$ is proportional to the complex quantity

$$E = \frac{\delta_c}{C} - j\delta_\alpha, \tag{18}$$

and is a function of frequency. Introducing eq. (17b) into eq. (10) we obtain

$$D_3 = B_1 \frac{A_3}{A_1} (T_o + ET_o)(X)^{3^*} + B_3(T_o X + ET_o X)^{3^*}. \tag{19}$$

Performing the convolutions on the last term, eq. (19) can be expressed as

$$D_3 = B_1 \frac{A_3}{A_1} T_o(X)^{3^*} + B_3 C^2 T_o(X)^{3^*} + D_{3R}. \tag{20}$$

With the predistorter active and conditions in eqs. (11) and (12)

being met, the first two terms cancel. The residual distortions are then approximately given by

$$D_{3R} = B_1 \frac{A_3}{A_1} ET_oX^{3^*} + 3B_3(T_oX)^{2^*} * (ET_oX) + \cdots, \qquad (21)$$

where terms of higher order in $(ET_oX)$ have been neglected. By introducing eq. (12) and using the identity $(T_oX)^{2^*} = CT_o(X)^{2^*}$ we obtain

$$D_{3R} = -B_3C^2T_o[EX^{3^*} - 3X^{2^*} * (Ee^{-j\omega\tau}X)]. \qquad (22)$$

The power spectrum of $D_{3R}$ for given deviations $E$ can be computed using eq. (22). Unfortunately, this involves, in general, complex numerical calculations and results do not easily provide further insight. Instead, we have used eq. (22) to arrive at an upper bound for the magnitude of $D_{3R}$. By using the inequality

$$|D_{3R}| \leq |B_3| \cdot C^3[|E| \cdot |X^{3^*}| + 3|X^{2^*}| * |E \cdot X|] \qquad (23)$$

we have examined each term within the brackets individually for two typical, yet simplified, error functions $E$.

### *2.5.1 Case 1—Out-of-band residual distortions*

If we assume that $|E|$ and $|X|$ are as illustrated in Fig. 4, it becomes obvious that only the first term in eq. (23) contributes to residual distortions, because the product $E \cdot X$ vanishes everywhere. Typically, the bandpass filter between converter and TWT produces this type of residual out-of-band third-order distortion. In the AR6A System, their

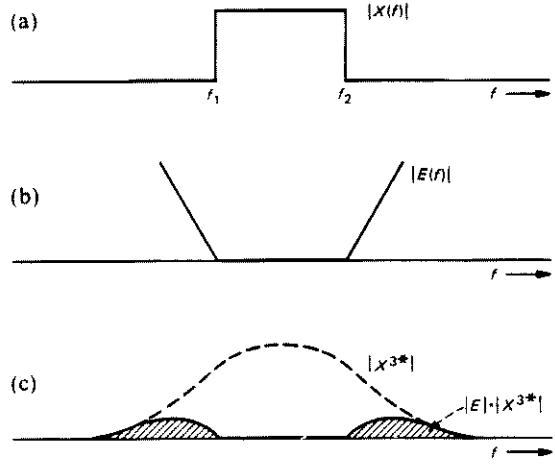

Fig. 4—Out-of-band distortions with perfect in-band predistortion: (a) input spectrum; (b) deviation from flatness; (c) distortion spectrum.

level is sufficiently small to cause no interference with other radio channels.

### 2.5.2 *Case 2—In-band residual third-order distortions*

This important case deals with parabolic in-band deviations $E$, as illustrated in Fig. 5. Satisfactory, but imperfect, tuning of the RF bandpass filter or insufficient flatness of the IF driver amplifier in the converter are primary causes for parabolic-type residual deviations. For simplicity, we approximate these by a triangular distribution, which causes the in-band residual distortions as shown shaded in Figs. 5c and 5d. It is important to recognize that the level of distortions due to the second term of eq. (23) varies in direct proportion to the fractional bandwidth $\Delta f$ over which $|E|$ assumes a substantial magnitude. This is in contrast to the contribution stemming from the first term, the maximum level of which is only proportional to the magnitude of $E$. As a rule of thumb, the first term dominates if

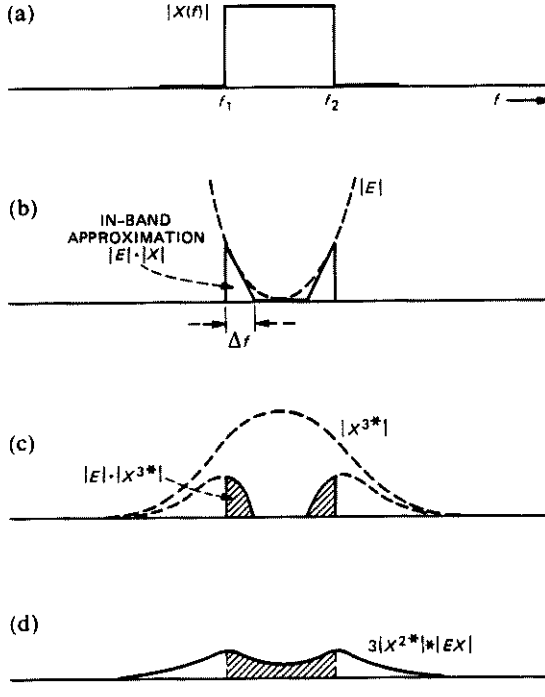

Fig. 5—Residual in-band third-order distortion spectrum: (a) input spectrum; (b) deviation from flatness; (c) residual distortion spectrum, first term, eq. (23); (d) residual distortion spectrum, second term, eq. (23).

$$3\Delta f < \tfrac{1}{4} \cdot BW,$$

where $BW$ is the bandwidth of the input spectrum, i.e., $BW = f_2 - f_1$. In the AR6A System a special slope equalizer has been incorporated into the driver amplifier of the up converter to ensure that essentially only parabolic residual deviations remain at the very edges of the signal band, thus, keeping $\Delta f$ as small as practicable.

The maximum tolerable amount of these deviations has been derived from eq. (23) by requiring that the ratio $|D_{3R}/D_{3o}|$ is below a specified level, where $|D_{3o}| = |B_3|C^3|X^{3^*}|$ represents the unpredistorted intermodulation spectrum within the message band. Thus, this ratio is a direct measure of distortion reduction. The predistortion improvement (PDI) in decibels is given by

$$PDI = -20 \log|D_{3R}/D_{3o}| \qquad \text{(dB)}. \tag{24}$$

If only the first term in eq. (23) contributes to residual distortions, the predistortion improvement becomes

$$PDI = -10 \log\left[\left(\frac{\delta_c}{C}\right)^2 + \delta_x^2\right] \qquad \text{(dB)}.$$

Figure 6 shows plots of constant PDI values as a function of phase deviation (in degrees) and flatness, defined as $20 \log(1 \pm \delta_c/C)$. We see that to achieve a PDI $\geq 40$ dB, the flatness must be better than $\pm 0.06$ dB and phase linearity is required to be within $\pm 0.4$ degree, provided both deviations contribute equal amounts.

Deviations in other coefficients describing the transmitter model, in particular $A_1$, $A_3$ and $B_1$, $B_3$, have been treated similarly. Except for $A_1$, their effect is less complicated because they are not convolved. It can be shown that as long as the residual distortions are caused only by nonconvoluted terms, the total amount of residual distortions is bound by the inequality

$$\left|\frac{D_{3R}}{D_{3o}}\right| \leq \sqrt{\left(\sum_{i=1}^{N} |m_i|\right)^2 + \left(\sum_{i=1}^{N} |\Delta\psi_i|\right)^2}, \tag{25}$$

where $m_i$ represents the deviation from flat magnitude and $\Delta\psi_i$ the deviation from phase linearity of the $i$th contributing coefficient. This upper bound estimate given by eq. (25) is very conservative because it is based on the assumption that at any frequency all deviations of the different component parts are causing in-phase addition. This is, in general, not true and a more useful estimate based on statistical addition is

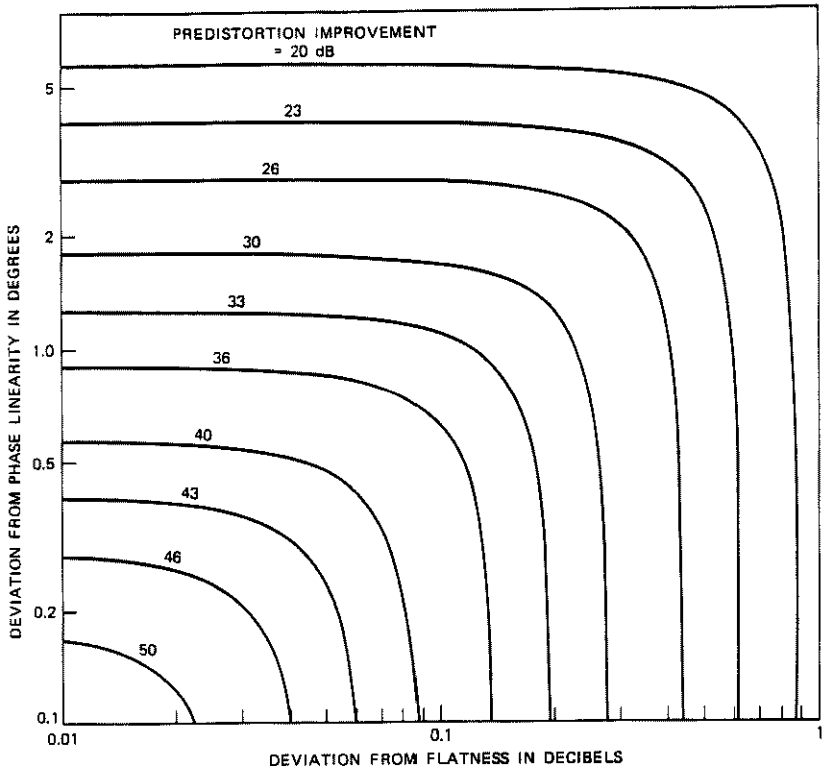

Fig. 6—Contours of constant predistortion improvement.

$$\left| \frac{D_{3R}}{D_{3o}} \right| \equiv \sqrt{\sum_{i=1}^{N} |m_i|^2 + \sum_{i=1}^{N} |\Delta\psi_i|^2}. \tag{26}$$

For the AR6A transmitter, under nominal testing conditions, the objective was to achieve a PDI of at least 30 dB over the full 30-MHz band. Allowing an additional margin of 3 dB and allocating equal deviations to each of the five possible contributors in the transmitter model (namely, $A_1$, $A_3$, $B_1$, $B_3$, and the product $H_A G_B$) results in a flatness requirement within ±0.06 dB and phase linearity requirement within ±0.4 degree. (Using the conservative upper bound would yield ±0.03 dB and ±0.18 degree as requirements on the model coefficients.) Since the coefficients $A_1$ and $A_3$ are only representative of the various components in the predistorter, its actual circuit requirements have been set at nominally ±0.02 dB for flatness. The corresponding requirements for phase linearity are then automatically met because of the minimum phase property of the circuits used.

## III. PRACTICAL DESIGN CONSIDERATIONS

### *3.1 Components*

The predistorter comprises components operating over the 30-MHz bandwidth centered at 74.1 MHz. The predistorter is described in the block diagram shown in Fig. 7. The key component is the nonlinear generator referred to as the cuber.[8] It consists of four back diodes arranged in a bridge configuration so that signals incident at the input of the network are attenuated by approximately 60 dB at the output. The amplitude of each third-order complementary distortion term at the cuber output is related to the amplitudes of the input signals at frequencies A, B, and C by

$$P_{A+B-C} = 46.6 + P_A + P_B + P_C \quad \text{(dBm)}. \tag{27}$$

The driver amplifier at the input to the predistorter provides gain so that the input signal to the cuber is at the optimum level. The optimum is dictated by choosing the drive such that the cuber does not generate fifth-order distortion terms that would exceed the level assumed in eq. (9). The distortion amplifier provides gain so that the complementary distortion terms generated by the cuber have the required amplitude. The gain in the distortion amplifier must be limited because of the addition of thermal noise back into the main path. The distortion adjustment potentiometer in the output coupler is used to fine tune the amplitude to provide the exact value of $|A_3|$ required for each individual transmitter.

The phase of the third-order complementary distortion terms generated in the cuber is established by the phase resolver network.[9] This network is designed to provide a constant-phase linear-phase difference between the two output ports and has the adjustment capability to cover the range of phase angles required. The output ports of the

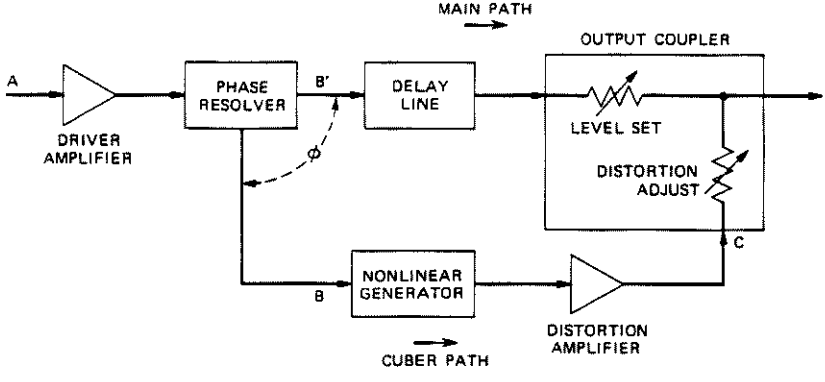

Fig. 7—Predistorter block diagram.

resolver network are arranged so that the connections to these ports can be interchanged. By doing so, the predistorter is adaptable for either USB or LSB operation.

The delay line in the main path is added to match the delay of the cuber path. To account for tolerances of the components, a delay adjustment is required during the manufacturing procedure so that the delays of the two paths are matched as closely as possible.

Because of the large amount of delay required, mismatches at the ends of the delay line result in shape over the 30-MHz channel that is difficult to equalize. Thus, the return loss of the appropriate ports of the delay line, phase resolver, and output coupler is carefully controlled.

### *3.2 Equalization*

Transmission deviations from a flat shape in either the main or cuber path result in residual third-order distortion. Two slope equalizers in the predistorter are employed to control the linear portion of the deviations.

The first slope equalizer adjusts the path from point $A$ to point $B$, as shown in Fig. 7. This slope equalizer is part of the driver amplifier. The end points over the 30-MHz channel are equalized within ±0.02 dB. This procedure imposes strict shape requirements on the resolver network so that

$$|H_{AB}| \cong |H_{AB}'|. \tag{28}$$

The second slope equalizer adjusts the path from point $B$ to point $C$. This slope equalizer is part of the distortion amplifier. The equalization process is accomplished by first disabling the bridge network in the cuber, then equalizing the end points over the 30-MHz channel to within ±0.02 dB.

### *3.3 Alignment of transmitter*

Since each predistorter is equalized during the manufacturing process as previously discussed, the rest of the transmitter must be equalized after all the parts are assembled. From eq. (11) these separate equalizations are equivalent to requiring that $H_A$ be aligned in the transmitter configuration while $G_B A_1$ is aligned separately.

From Figs. 2 and 3, we see that $H_A$ includes the amplifier/modulator, bandpass filter, and the input network of the TWT. A slope equalizer is incorporated in the amplifier/modulator. It is clear that the interface of this portion of the transmitter is somewhere within the active portion of the TWT and is, therefore, not accessible using standard methods. A special scanning intermodulation (IM) test set[10] was designed to permit this measurement to be made. The scanning

capability of the test set permits the transmission path to be slope equalized over the 30-MHz channel.

The overall result of the equalization process is measurable using the scanning IM test set to measure the predistortion improvement across the band. The results of a number of such measurements are summarized in Fig. 8. Two types of TWTs have been used in the AR6A transmitter. For the transmitters using the WE 473A TWT, the average PDI for 24 TWTs indicates a minimum value of 33 dB. To obtain this result, the deviation from flatness must be approximately 0.1 dB. For the transmitters using the KS-22469 TWT, the average PDI for 27 TWTs indicates a minimum value of 35 dB with the corresponding deviation from flatness being approximately 0.07 dB.

Final measurements are made using the scanning IM test set on each transmitter. At this time approximately 3000 units have been produced. The results still show an average minimum PDI of approximately 35 dB.

## IV. PERFORMANCE

### *4.1 Variation with time*

Predistortion of the traveling-wave tube has been demonstrated in the laboratory and manufacturing environment. Transmitter perform-

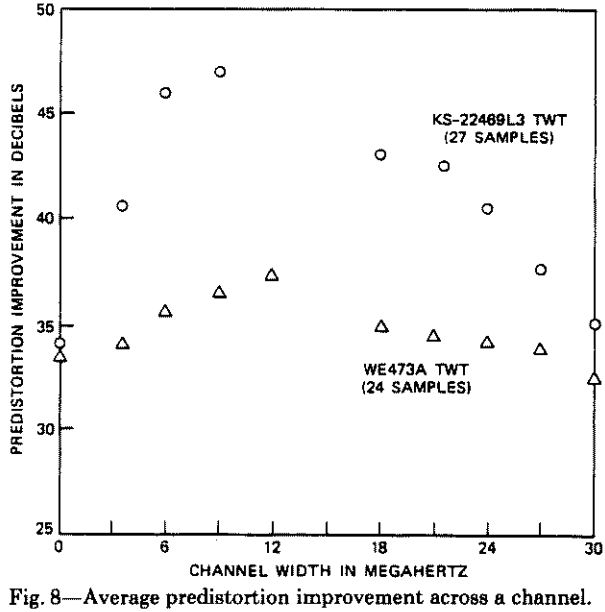

Fig. 8—Average predistortion improvement across a channel.

ance in the field with time and temperature is being tracked by observing the AR6A System in its operating environment.

Data accumulated over a period of several years for 25 TWT amplifiers indicate that the performance with time largely depends upon the stability of the TWT and power supply. The change of gain of the TWT amplifier has been, in general, less than 0.35 dB per year (corresponding to a PDI of 22 dB). Exceptions exist; some amplifiers have demonstrated very large (>2 dB) gain changes. Although no regular monitoring plan has been established, occasional evaluation of selected channels has corroborated the stability estimates.

### *4.2 Variation with temperature*

Temperature changes also cause transmitter gain variation and, therefore, cause the PDI to vary. The AR6A transmitter was tested over an ambient temperature range from 40 to 120°F. These tests revealed that the variation of the PDI was due to transmitter gain changes. The largest contributor to the gain change is the TWT amplifier. Separate tests of five amplifiers established an average change of 0.35 dB over the temperature range. For a transmitter aligned at 80°F, this type of gain variation results in a worst-case PDI of 27 dB.

### *4.3 Summary*

In some cases, gain variations with time and temperature significantly exceed the typical value expected. The AR6A System design compensates for these extreme cases by allowing sufficient margin. The overall intermodulation level in a switch section is monitored. When limits are exceeded, the monitoring system can identify the transmitter or transmitters that require adjustment. In a typical switch section, the random aging and temperature conditions result in an overall switch section performance that satisfies objectives.

## APPENDIX

### *On the Transfer Function for the Up Converter With a Traveling-Wave Tube*

The conversion characteristic of a Schottky diode converter is, for our purposes, most conveniently approximated by the ideal multiplier function

$$z(t) = \mathrm{K} \cdot s(t) \cdot z_{\mathrm{m}}(t), \tag{29}$$

where K is a frequency-independent constant, $s(t)$ the local oscillator (pump) signal, and $z_{\mathrm{m}}(t)$ the modulating (IF) signal. With $s(t) = \cos \omega_o t$, one can see that eq. (29) represents a double-sideband signal with suppressed carrier. Since the bandpass filter following the converter in the actual transmitter suppresses the unwanted sideband, as well as any residual carrier, the use of eq. (29) is indeed justified. Applying a single-tone modulating signal $z_{\mathrm{m}}(t) = A_{\mathrm{m}} \cos(\omega_{\mathrm{m}} t + \phi_{\mathrm{m}})$, one obtains from eq. (29) the lower single-sideband (SSB) signal

$$z(t) = \frac{A_{\mathrm{m}}}{2} \mathrm{K}\ Re\{e^{j(\omega_o - \omega_{\mathrm{m}})t} \cdot e^{-j\phi_{\mathrm{m}}}\}, \tag{30a}$$

and the upper SSB signal

$$z(t) = \frac{A_{\mathrm{m}}}{2} \mathrm{K}\ Re\{e^{j(\omega_o + \omega_{\mathrm{m}})t} \cdot e^{+j\phi_{\mathrm{m}}}\}. \tag{30b}$$

The converter, thus, not only translates the modulating frequency to the desired RF band, but also causes the conjugation of the modulating signal phase. One may, therefore, define two ideal converter transfer operations linking the two frequency domains as follows:

$$Z_{\mathrm{LSB}} = Z(\omega_o - \omega_{\mathrm{m}}) = \mathrm{K_c} \cdot \check{Z}_{\mathrm{m}}(\omega_{\mathrm{m}}) \qquad \text{(LSB)} \tag{31a}$$

and

$$Z_{\mathrm{USB}} = Z(\omega_o + \omega_{\mathrm{m}}) = \mathrm{K_c} \cdot Z_{\mathrm{m}}(\omega_{\mathrm{m}}) \qquad \text{(USB)}, \tag{31b}$$

where $\check{Z}$ is the complex conjugate of $Z$, and $\mathrm{K_c}$ a frequency-independent constant. Note that these operations describe the combined functions

of up converter and bandpass filter. Introducing eq. (31a) into the nonlinear transfer function, eq. (4) of the main text, yields (with some simplifications)

$$Y_{\mathrm{LSB}} = H_B(B_1 H_A \check{Z}_{\mathrm{m}} + B_3(H_A \check{Z}_{\mathrm{m}})^{3^*}) \tag{32a}$$

and

$$Y_{\mathrm{USB}} = H_B(B_1 H_A Z_{\mathrm{m}} + B_3(H_A Z_{\mathrm{m}})^{3^*}). \tag{32b}$$

With these expressions we have derived nonlinear transfer functions for the cascade of up converter, bandpass filter, and TWT. Note that for the LSB and the USB case, the modulating signal is $Z_{\mathrm{m}}$ and it is the converter that performs the conjugation. It also must be mentioned that for the intentions of this model, the converter constant $K_c$ and the transfer function of the bandpass filter have tacitly been absorbed in $H_A$.

(Manuscript received February 14, 1983)

The paper describes some of the key networks needed for the AR6A System for the predistorter, Intermediate Frequency (IF) filtering, and terminal multiplex. The design of a passive broadband adjustable phase splitter for the predistorter is described. Network designs using inductors, capacitors, and, in some cases, crystals for IF filtering, equalization, and multimastergroup connection are also described.

## I. INTRODUCTION

A large number of filters and equalizers, and an adjustable phase splitter are needed in AR6A for pilot insertion and removal, band limiting, amplitude correction, and predistortion circuitry in repeaters and in multiplex equipment. Technology developed for TD and TH radio[1,2] and L4 and L5 coaxial-carrier transmission systems[3–5] was enhanced to meet the specific and demanding needs of the AR6A† System filters and equalizers; however, a special approach was required for the design of an adjustable phase resolver (phase splitter) for the predistorter. The phase resolver is an adjustable Inductor Capacitor (LC)‡ network that allows matching the phase of the predistortion

signal to the opposite of the phase of the distortion component of the main signal. The filters provide wider bandwidths and higher discrimination than their FM radio counterparts, and amplitude equalization, rather than delay equalization, is required. Extensive use was made of computer aids for design and analysis. A high-speed, precision interactive mini Computer-Operated Transmission Measurement Set (COTMS) proved necessary for laboratory development of networks. More than 700 models of about 140 network designs were needed for development and final design of the AR6A System.

The theory and design of the phase resolver for the AR6A predistorter is described in some detail. Descriptions of the Intermediate Frequency (IF) filter and equalizer, the upper and lower IF bandpass filters, and the multimastergroup connector filters follow.

## II. PHASE RESOLVER

### *2.1 Function*

The phase resolver is a passive three-port network used in the AR6A predistorter.[6] It splits the predistorter input signal into two equal-amplitude signals that have a constant phase difference in the IF band between 59 and 89 MHz. The phase difference is manually adjustable. This provides adjustment of the phase predistortion component to cancel the distortion products generated in the traveling-wave tube.

### *2.2 Theory*

The phase-resolver network consists of a quadrature hybrid network, two attenuators, and a combining hybrid transformer connected as shown in Fig. 1. The outputs can be shown to be

$$E_B = 0.5\ E_A(G_1 + jG_2), \qquad (1)$$

$$E_C = 0.5\ E_A(-G_1 + jG_2).$$

Thus, the magnitude of either output is

$$|E_{B,C}| = 0.5\ |E_A|\ \sqrt{G_1^2 + G_2^2}, \qquad (2)$$

and the phase difference is

$$\Theta_B - \Theta_C = 2\ \tan^{-1}(G_2/G_1). \qquad (3)$$

A key element of this network is the broadband quadrature hybrid network.

To achieve a wideband quadrature hybrid network, a Cauer configuration[7] was chosen. This is a four-port network consisting of two hybrid transformers connected to two lossless LC networks, $N$ and $N'$, as shown in Fig. 2. With port A driven, ports B and C will have quadrature phase, and port D will be isolated if $N$ and $N'$ are

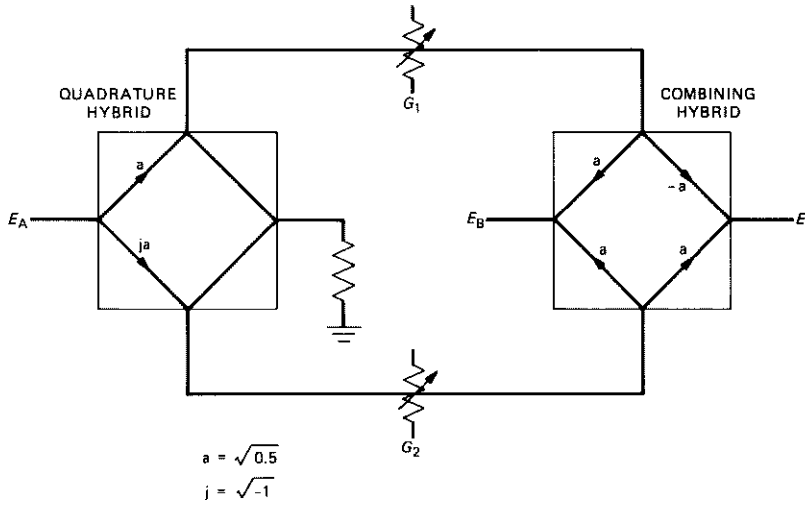

Fig. 1—Phase-resolver block diagram.

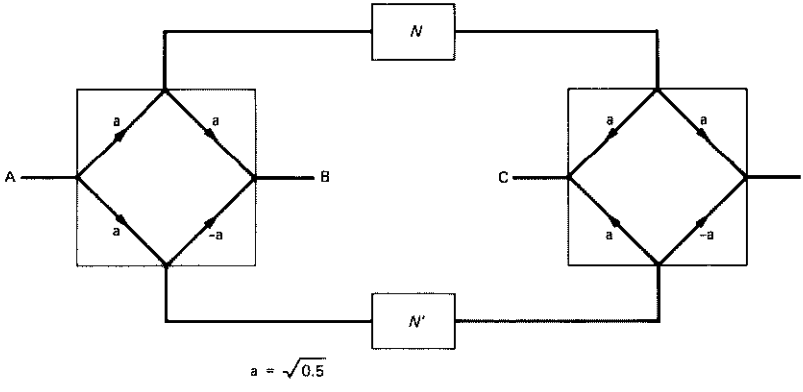

Fig. 2—Cauer network.

dual symmetric networks. This can be determined if the scattering parameters for the complete network are derived in terms of the scattering parameters of $N$ and $N'$.

$$s_{AA} = (s_{11} + s'_{11})/2$$
$$s_{BA} = (s_{11} - s'_{11})/2$$
$$s_{CA} = (s_{21} + s'_{21})/2$$
$$s_{DA} = (s_{21} - s'_{21})/2. \quad (4)$$

If $N$ and $N'$ are dual networks, then

$$s_{11} = -s'_{11}, \quad (5)$$

and

$$s_{21} = s'_{21}.$$

Then,

$$\begin{aligned} s_{AA} &= 0, \\ s_{BA} &= s_{11}, \\ s_{CA} &= s_{21}, \\ s_{DA} &= 0. \end{aligned} \tag{6}$$

The other twelve scattering parameters for the four-port network have a corresponding form. These relations describe a hybrid network with port A isolated from port D, and port B isolated from port C. It is a quadrature network if $N$ and $N'$ are not only dual but also symmetric lossless LC networks. This can be shown as follows.

It is convenient to define a split ratio, $\Gamma$, as

$$\Gamma = \frac{s_{BA}}{s_{CA}} = \frac{s_{11}}{s_{21}}. \tag{7}$$

For a quadrature network, $\Gamma$ must have the following form:

$$\Gamma(s) = s\,\frac{P_{11}(s^2)}{P_{21}(s^2)} \quad \text{or} \quad \frac{P_{11}(s^2)}{sP_{21}(s^2)}. \tag{8}$$

Here, $P_{11}$ and $P_{21}$ are polynomials. With $s = j\omega$, phase quadrature can be observed. To avoid right-half plane transmission zeros requiring right-half plane zeros, $\Gamma$ is restricted to the following form:

$$\Gamma(s) = \frac{P_n(s^2)}{s^{2m+1}}. \tag{9}$$

Here, $P_n$ is an $n$th-order polynomial and $m$ is an integer. Then the networks, $N$ and $N'$, are simple ladder networks.

The design of a quadrature Cauer network consists of first finding a suitable polynomial, $P_n(-\omega^2)$, such that $|\Gamma|$ approximates unity over the frequency band of interest. A corresponding symmetric ladder network and its dual are then synthesized to realize $N$ and $N'$. The synthesis procedure can be simplified by taking advantage of the fact that the networks are symmetric.

### *2.3 Realization*

Extensive use was made of computer aids and computer-operated transmission measuring sets during the design and development. The hybrid transformers were characterized on COTMS.[8] With this characterization used in a circuit analysis program, an optimization routine

could be used to modify $N$ and $N'$ to compensate for parasitics. For model characterization and laboratory correction of parasitics, a high-accuracy, high-speed computer-operated transmission measurement set proved necessary. This set, "Mini COTMS," has a measurement speed fast enough for computer-corrected simultaneous real-time display of loss, phase or delay, and input and output return loss.

Figure 3 is a photograph of the phase resolver.

## III. IF FILTER/EQUALIZER

### *3.1 Function*

This circuit provides the 74.13-MHz center frequency IF filtering and amplitude equalization. Figure 4 shows that four networks are used. The bandpass filter limits adjacent channel interference and image interference in the Multimastergroup Translator for Radio (MMGT-R). One basic equalizer and two mop-up equalizers provide static amplitude equalization. The basic equalizer corrects for systematic amplitude variations in the overall Transmitter-Receiver (TR) bay transmission characteristic. Two mop-up equalizers correct for unit-to-unit amplitude deviations.

### *3.2 Design*

Design was facilitated by two interactive computer programs. One does the rational function approximation and insertion loss synthesis; the other performs Norton transformations to optimize filter topology and element values. A general-purpose linear network analysis program allowed simulation of parasitic effects in any of the designs.

An 11th-order filter was synthesized to meet the objectives. Two

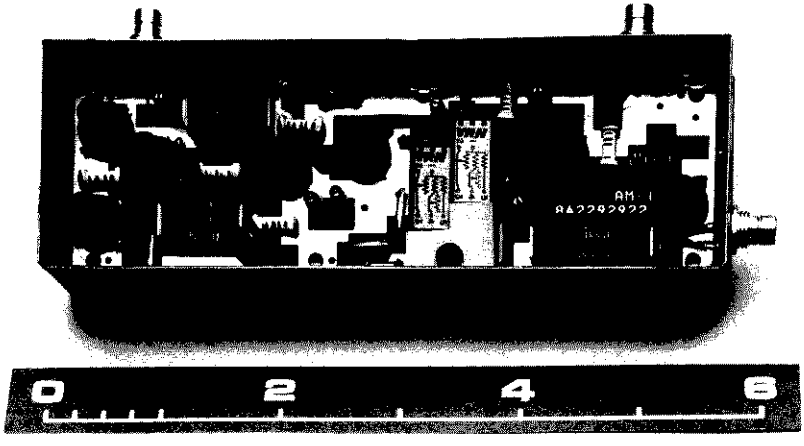

Fig. 3—Photograph of phase resolver.

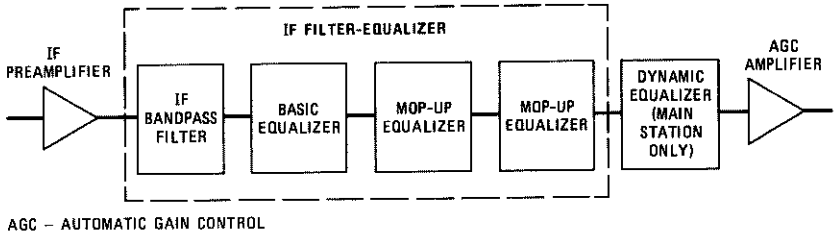

Fig. 4—IF filter-equalizer block diagram.

bridged-T sections are needed to compensate for amplitude variations caused by the finite $Q$ of the filter inductors. The filter is assembled on a printed wiring board that is attached to a cast-aluminum housing as shown in Fig. 5. Electrostatic shields are contained within the housing. Field tests have confirmed that the filter meets system requirements.

Four mop-up equalizer designs achieve positive-slope, negative-slope, positive-quadratic-shape, and negative-quadratic-shape amplitude response. Bridged-T sections are used to realize each of the required shapes. Frequency response measurements of the AR6A switch section involved are used to choose the shapes used. When a mop-up equalizer is not needed, a 3.5-dB pad is used.

## IV. LOWER AND UPPER IF BANDPASS FILTERS

### *4.1 Function*

The transmitting-output and the receiving-input spectrum of the MMGT-R each cover the 59.844- to 88.460-MHz band and contain ten mastergroups. This frequency spectrum is split into two bands of five mastergroups each. The Lower-band Intermediate Frequency (LIF) is from 59.844 to 73.116 MHz, and the Upper-band Intermediate Frequency (UIF) is from 75.188 to 88.460 MHz.

Two bandpass filters (BPFs), the LIF and the UIF filters, are used in the MMGT-R to select each of these bands in the modulator and in the demodulator. The filters reject the carrier frequency, the upper sideband, and second and third harmonics of the carrier. Lower sideband loss keeps crosstalk and tone interference into adjacent radio channels, due to undesired modulator products, at acceptable levels.

### *4.2 Design*

The designs of the two filters are similar, so only the LIF BPF will be covered. The stopbands cover a wide frequency range and very high losses are required. To achieve reasonable element values, to reduce the effect of parasitics for this wideband, and to ease tuning, a low-pass filter and a high-pass filter in tandem are used rather than a

Fig. 5—Photograph of IF filter.

bandpass design. Computer-aided insertion loss methods (Section 3.2) were used to synthesize a 13th-order Cauer elliptic high-pass filter and a ninth-order equal ripple passband with arbitrary stopband low-pass filter. Norton and pi-delta transformations were applied to achieve equal termination resistances and desirable element values. Two bridged-T constant resistance sections are required to compensate for amplitude variations in the passband caused by the finite $Q$ of the inductors.

The filter is assembled on two printed wiring boards and housed in a drawn steel enclosure (see Fig. 6). One board contains the equalizer, pad, and high-pass sections; the other board contains the low-pass section. Each filter inductor is shielded, and there is a shield between the printed wiring boards to reduce magnetic coupling between inductors.

## V. MULTIMASTERGROUP CONNECTOR FILTERS

### *5.1 Function*

The AR6A multimastergroup (MMG) connector is a precision passive network which allows a direct connection from the MMGT-R receiver to the MMGT-R transmitter when separation of the various components of the MMG signal is not required for routing or other purposes. In this application, the type-B Mastergroup Translators (MGTB) and other multiplexing equipment are not required. The key elements of the MMG connector are a highly selective bandpass filter and a crystal band-elimination filter. Figure 7 is a photograph of the two filters. The bandpass filter selects the 8.628- to 21.9-MHz MMG

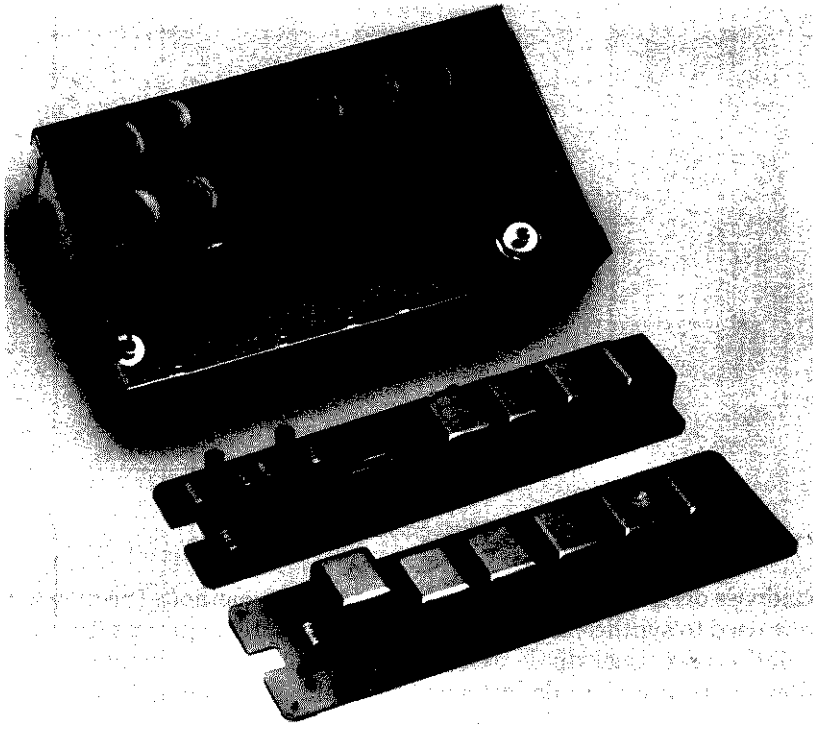

Fig. 6—Photograph of LIF BPF.

spectrum and rejects other frequencies to avoid crosstalk between radio channels. It also suppresses two pilot tones. The Band-Elimination Filter (BEF) suppresses four additional pilot tones.

The filters must have minimum effect on the message spectrum in spite of the high selectivity required. Wide skirts on the pilot suppression characteristic are needed to reduce noise near the pilots. The skirts increase the complexity of the crystal BEF significantly.

### *5.2 Design*

The electrical design of the bandpass filter was achieved with the help of two interactive computer programs (Section 3.2). The inductor values were chosen to match a family of precision high-$Q$ adjustable inductors originally designed for MGTB.[5] A complex arm bridged-T equalizer section was added to compensate for loss variations due to finite $Q$ effects. The result is a 22nd-order loss-equalized bandpass filter. It was also possible to suppress two of the pilots by placing six crystal units at each frequency in shunt arms of the filter.

Four filters in tandem are used to suppress the remaining four pilots. For each frequency, a low-pass filter is designed to pass the desired

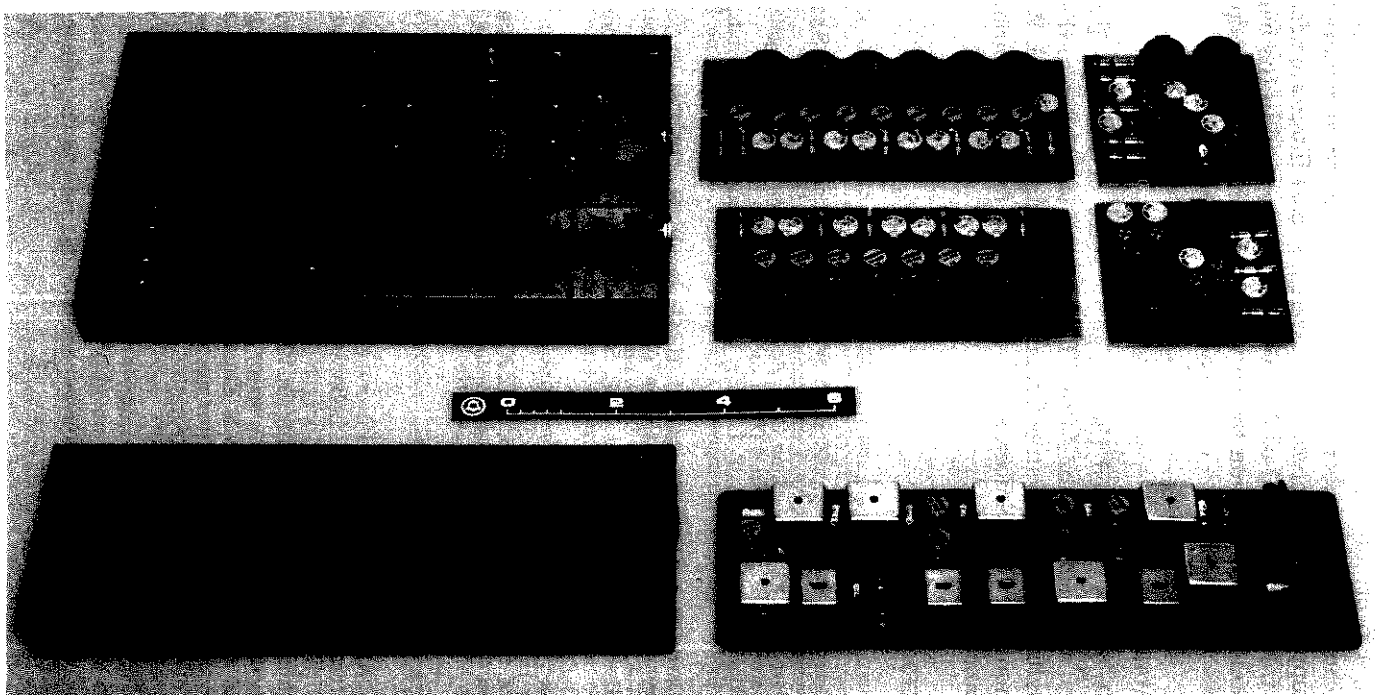

Fig. 7—Photograph of MMG connector filters with bandpass filter at top and crysal band-elimination filter at bottom.

spectrum, and crystal units are placed in shunt arms to reject the pilot. Because of the number of crystal units required to achieve the desired suppression characteristic, separate low-pass filters are needed for each frequency. A total of 28 crystal units are used in the band-elimination filter in addition to the 12 crystal units in the bandpass filter.

## VI. SUMMARY

The paper has described the design of some of the key filters, equalizers, and networks for AR6A. The authors would like to thank S. Darlington for his innovative Cauer coupler designs, and F. J. Witt, T. H. Simmonds, R. P. Snicer, and J. L. Garrison for their inspiration and guidance.

## *The AR6A Single-Sideband Microwave Radio System:*

# Special Test Equipment

By R. I. FELSBERG* and M. E. SANDS*

(Manuscript received January 22, 1983)

This paper describes two specialized test sets designed specifically for AR6A transmit-receive radio equipment alignment. The scanning intermodulation (IM) test set can adjust the transmitter for proper gain shape and optimum predistorter performance. It can also confirm that the transmitter is meeting its IM requirements. The pilot selection test set is used to test the radio intermediate frequency receiver units for proper operation during changing received signal conditions. This test set provides signals to simulate either flat or selective fades and can be used to check the pilot resupply function or space-diversity switch transition levels.

## I. INTRODUCTION

It was realized early in the development of the AR6A† Radio System that special test equipment would be needed to ensure that performance objectives of this new single-sideband (SSB)‡ system were met. Two specialized test sets have been designed for this purpose: (1) the scanning intermodulation (IM) test set, and (2) the pilot selection test set. Both sets are self-contained in carrying cases with handles and

are provided with the necessary cables and other accessories for use in the field.

The scanning IM test set has been developed to adjust the transmitters in the AR6A Radio System to meet the critical linearity requirements necessary for a multihop radio route. Swept wideband measurement of IM single-sideband amplitude-modulated (SSBAM) radio is required for predistorter and up-converter alignment and to verify that the high degree of linearity necessary for this type of transmission has been obtained. The transmitter alignment is accomplished by one single-tone level measurement/adjustment and three separate three-tone, third-order IM measurement/adjustments made with the test set. An auxiliary oscilloscope (the display section of the radio transmission test set) is used to display the resulting transmitter intermodulation characteristics over the frequency band of interest.

The AR6A receiver conditions the received signal prior to retransmission to the next station. The circuits that perform this function require special test signals to verify the correct functioning of this portion of the AR6A System. The pilot selection test set was developed to supply the required signals in a convenient manner.

## II. SCANNING INTERMODULATION TEST SET

### *2.1 General*

The single-sideband amplitude-modulated transmitters in AR6A are required to be extremely linear so that the third-order IM noise that accumulates over a long route is held to an acceptable level. Transmission with very low IM noise is accomplished by using a traveling-wave tube (TWT) operated well below its maximum power output capability and by the use of predistortion. Use of the predistorter requires flat transmitter third-order IM characteristics and precise alignment to obtain maximum third-order IM reduction. Predistortion operates by generating third-order IM noise that is equal in amplitude and opposite in phase to the third-order IM noise generated by the nonlinearities in the transmitter. These nonlinearities result in cancellation (nulling) of the IM noise. To obtain wideband predistortion, the overall third-order IM from the transmitter must have a flat IM frequency characteristic. The IM test set is used to adjust the up converter and predistorter in the transmitter for the required third-order IM flatness and third-order IM distortion cancellation. In addition to the linearity requirement, the transmitter output power level is required to be held within certain limits. The alignment of the transmitter requiring IM slope adjustment and predistorter IM null adjustment interacts with the transmitter gain. As a result, the output power must be monitored as adjustments are made to maintain the required power level.

A portable scanning IM test set has been developed to provide easy and rapid alignment of transmitters in the field where the three-tone, third-order IM distortion product from the transmitter can be rapidly scanned and displayed over the entire frequency band of interest. The set is divided into two modules (Figs. 1 and 2) to reduce the weight

Fig. 1—Test module of scanning IM test set.

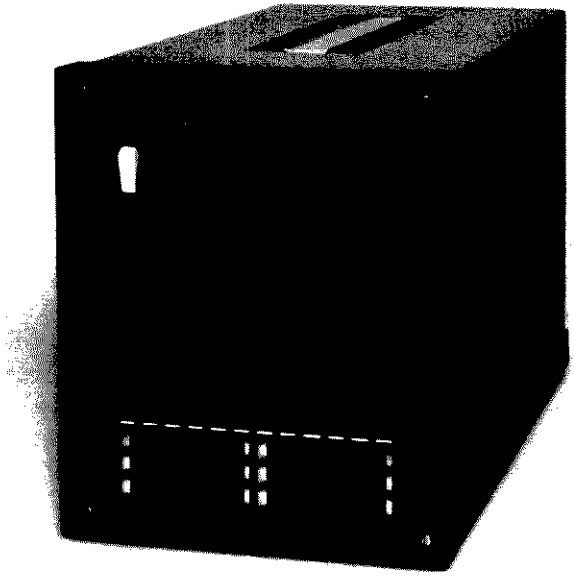

Fig. 2—Power module of scanning IM test set.

and size to acceptable values. The units are housed in metallic cases with retractable carrying handles. Separate lightweight soft-pack and hard-pack shipping cases are available to protect the modules during transportation. Space has been provided in the power module soft-pack and hard-pack to store the ten cables required for operation of the test set. An auxiliary oscilloscope is required for use with the test set to display the IM characteristics as a function of frequency. An auxiliary power meter is also required to monitor the output power during alignment.

### *2.2 Principle of operation*

The test set can be divided into two basic sections consisting of a tone-generating section and a receiving- or signal-processing section. Referring to the simplified block diagram of Fig. 3, the three-tone generating section is located on the upper left. A manually swept, voltage-controlled oscillator (VCO) tone is split and applied to two mixers. Also applied to the two mixers are tones from crystal oscillators with frequencies that differ by 1 MHz. The two down-converted tones fall within, and can be manually swept over, the required 30-MHz intermediate frequency (IF) band. In addition, a third tone fixed in level and frequency near the center of the IF band is combined with the two manually swept tones. The three tones are sampled at the output coupler and applied to the automatic gain control (AGC) unit and then to the variolosser to maintain the level of the swept tones constant across the 30-MHz band. The three-leveled tones are applied to the device under test (DUT), i.e., the transmitter. The three-tone, third-order IM distortion product $P_{a-b+c}$ resulting from nonlinearity in the transmitter is fixed in frequency since the difference in frequency between tone (a) and tone (b) remains fixed (1 MHz apart) although the tones are swept in frequency and the third tone (c) is also fixed in frequency. As a result, the IM product, although fixed in frequency, reflects any change in IM distortion versus frequency as a change in its amplitude when the two tones are swept over the frequency band. The tones and the resulting IM products from transmitter nonlinearities are coherently down converted from 6 GHz to IF in the signaling processing circuits shown on the right of Fig. 3. The IF signals are down converted again to 315,920 Hz so that only the single IM distortion product $P_{a-b+c}$ from the transmitter falls within the very narrow passband (50 Hz) of the monolithic crystal filters employed in the test set. As a result, all other tones and IM products are excluded, thus preventing any spurious three-tone IM from being generated in the gain stages following the filter. In addition, a signal-to-noise advantage is gained by use of the filters. This is important, since the IM product signal level at the input to the filter is very low and therefore requires high amplification. Very stable crystal oscilla-

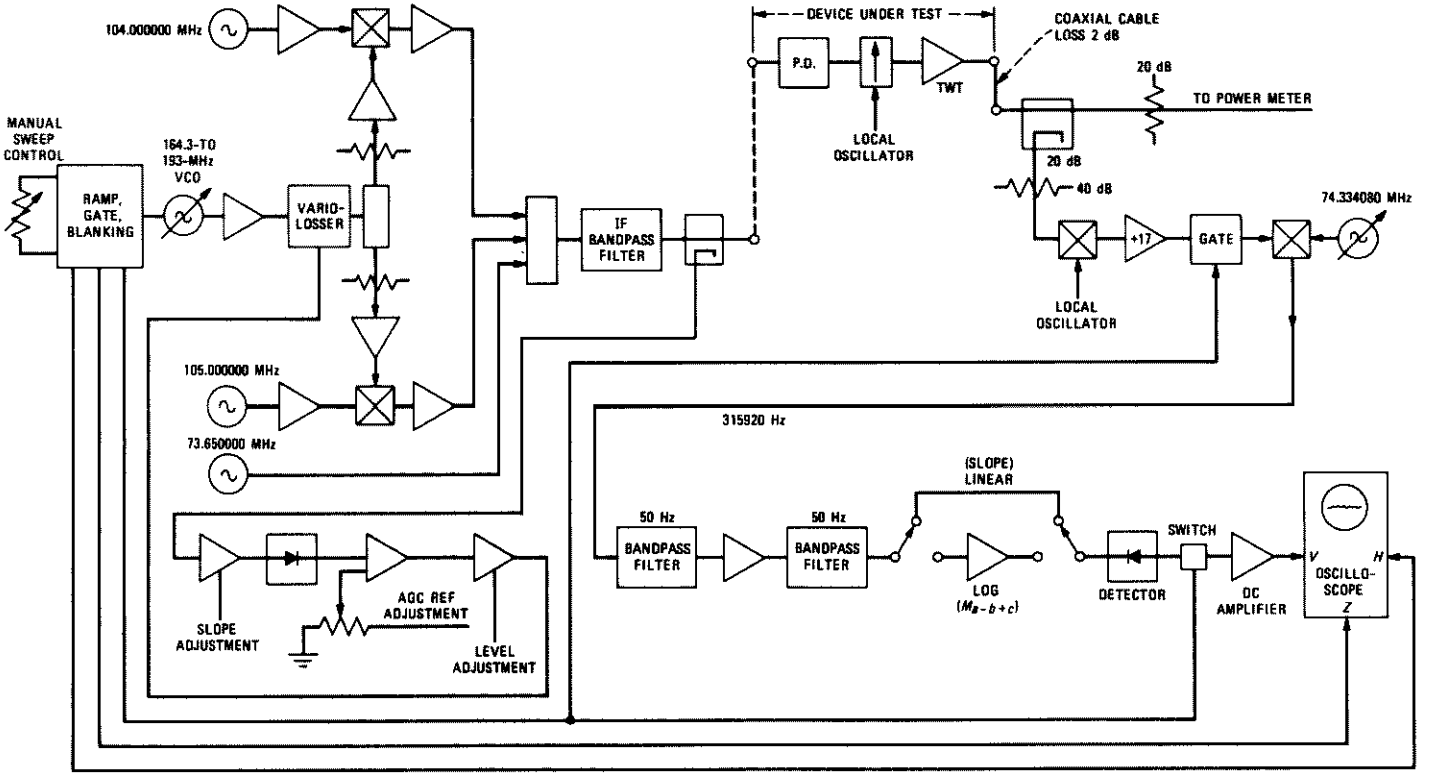

Fig. 3—Simplified block diagram of a scanning IM test set.

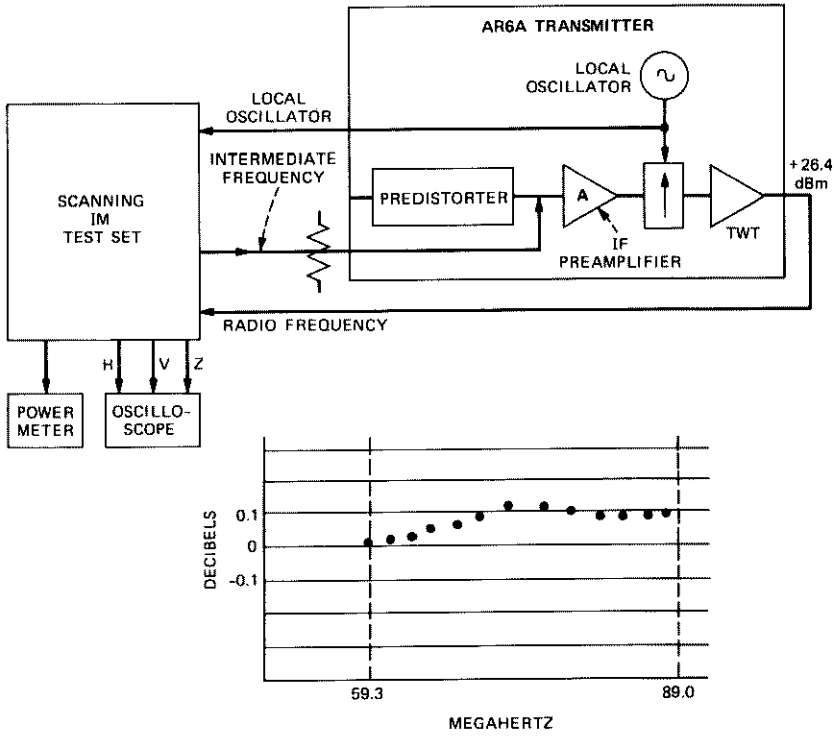
tors are employed to ensure that the IM product remains within the very narrow passband of the filters. Four oven-stabilized crystal oscillators are used for this purpose and have a stability of better than one part in $10^7$ per day. One oscillator, employed by the signal processing section, is made adjustable by means of a knob on the front panel of the test set to center the IM product in the filter passband when necessary to compensate for crystal oscillator drift.

### *2.3 Tests performed*

The first test (LEVEL) provides a calibrated tone to the input of the transmitter so that the power output may be set to the required level. The remaining three tests are three-tone, third-order IM distortion tests. The test set supplies three IF tones, two manually swept and one fixed in frequency, to the input of the transmitter for this purpose. In the second test (SLOPE) shown in Fig. 4, a three-tone,



SCOPE DISPLAY OF TYPICAL ADJUSTED THREE-TONE IM TRANSMITTER SLOPE OBTAINED OVER THE FREQUENCY BAND IN SLOPE TEST MODE.

Fig. 4—Transmitter slope adjustment.

third-order IM distortion product, resulting from distortion in the transmitter, is adjusted for flatness over the 30-MHz band by means of a slope adjustment control located in the up-converter preamplifier (A) in the transmitter. In the third test (NULL) shown in Fig. 5, the predistorter in the transmitter is now included in the transmitter circuit and is switched on and three tones are held fixed in frequency. The IM distortion product is minimized (nulled as shown diagrammatically in the figure as a spot moving downward) by adjustment of the phase and amplitude controls on the predistorter in the transmitter. The fourth test (IM) also shown in Fig. 5 displays typical reduction of manually swept three-tone IM distortion versus frequency obtained by predistortion. It can then be determined on the calibrated display if the IM distortion reduction meets or exceeds requirements over the entire frequency band and, if so, this indicates that the preceding tests and alignments have been satisfactorily completed.

### 2.4 Requirements for the scanning IM test set

#### 2.4.1 Tone requirements

The test set is required to supply a single IF tone of a specified power level for the LEVEL test mode, and three tones, one fixed and two that can be manually swept in frequency, of specified power levels for the other three IM test modes. The single-tone level has been specified to have a power level equal to the full-load signal level and is used to adjust the transmitter gain to the required level. The total power of the three tones has been specified to be the same as that for the single tone. Intermodulation testing is required over the entire frequency range of each transmitter to ensure linear operation over the entire frequency band of each channel. The test set is required to produce tones that can be manually swept over the 30-MHz IF band (59.3 to 89.0 MHz). A worst-case maximum intermodulation condition has been found to exist when the three tones are held fixed in proximity to each other. The test set is designed with the three tones held fixed in frequency near the center of the band in the NULL mode so that the predistorter is nulled under worst-case conditions.

#### 2.4.2 Spurious tone requirement

All spurious tones from the test set are required to be at least 40 dB below the power levels of the three tones. Any spurious tones that coincide with the fundamental tones as they are swept should be at least 50 dB below the power levels of the three tones so that they will add less than 0.025 dB to any of the fundamental tones. This will ensure that spurious signals will be held low enough that they will have negligible effect on the IM product. However, with swept measurements, this effect is almost unnoticeable since the spurious signals move at two or more times the rate of the fundamental tones and pass rapidly through them unnoticed, allowing the 50-dB criteria to be relaxed by 10 dB to the 40-dB requirement.

#### 2.4.3 Tone flatness requirement

The tones from the test set are required to be flat with frequency to within 0.03 dB as they are swept over the 30-MHz frequency band. This requirement ensures that the tone levels and consequently the IM derived from these tones in the transmitter will reflect mainly the IM characteristics of the transmitter with minimum contribution of IM from the test set. The tones are set to be flat (0-dB variation) at the band edges with the maximum allowed variation of 0.03 dB at midband. The maximum variation of each of the two swept tones contributes 0.06-dB error to the CRT display of transmitter slope at midband. This small error is of little consequence, particularly since the slope can be adjusted using only the extreme frequency points.

### *2.4.4 Test set IM requirements*

The three-tone, third-order IM generated by the test set is required to be at least 50 dB below that of the transmitter without predistortion. This requirement ensures that any three-tone, third-order IM originating in the test set is much less than the IM originating in the transmitter (with predistorter on) that is being measured. Therefore, the IM contributed by the test set to the measurement (less than 1 dB) would be barely discernible on a cathode ray tube (CRT) display of a 25-dB PDI (predistorter IM improvement in dB). Test set tone flatness and thermal noise from the transmitter and test set limit the amount of PDI that can be measured with reasonable accuracy to about 40 dB.

## III. PILOT SELECTION TEST SET

### *3.1 General*

The IF shelf of the AR6A Radio System contains a number of circuits to condition the received signal prior to retransmission. It was necessary to provide a way to check these circuits for proper operation when they were connected together in the system. A test set was designed that would condition test signals fed to the AR6A IF shelf to be representative of the type that would be experienced during normal system operation.

### *3.2 Principle of operation*

The required test signal is composed of three pilot tones at frequencies of 62.448, 75.122, and 85.856 MHz. These three tones are varied in amplitude in certain prescribed ways to exercise the IF shelf signal correction circuits. This signal simulation technique checks for the proper functioning of the shelf, resupply switch, pilot detector, receiver control, AGC amplifier, and the dynamic equalizer.

### *3.3 Description of test set*

The pilot selection test set (PSTS) is a portable unit that can be easily transported for field testing of the AR6A System. The unit is completely passive and requires no source of power. The PSTS must be used in conjunction with a suitable power meter.

The PSTS is made up of narrowband filters, shape networks, continuously variable attenuators, and a precision step attenuator. These components are interconnected in various ways by means of patch connectors on the front panel of the test set. All attenuators, shape networks, and filters can be used as individual items by access from the front panel jacks (see Fig. 6).

The PSTS does not contain the oscillators that supply the three required pilot tones (see Fig. 7). Each AR6A support bay contains a

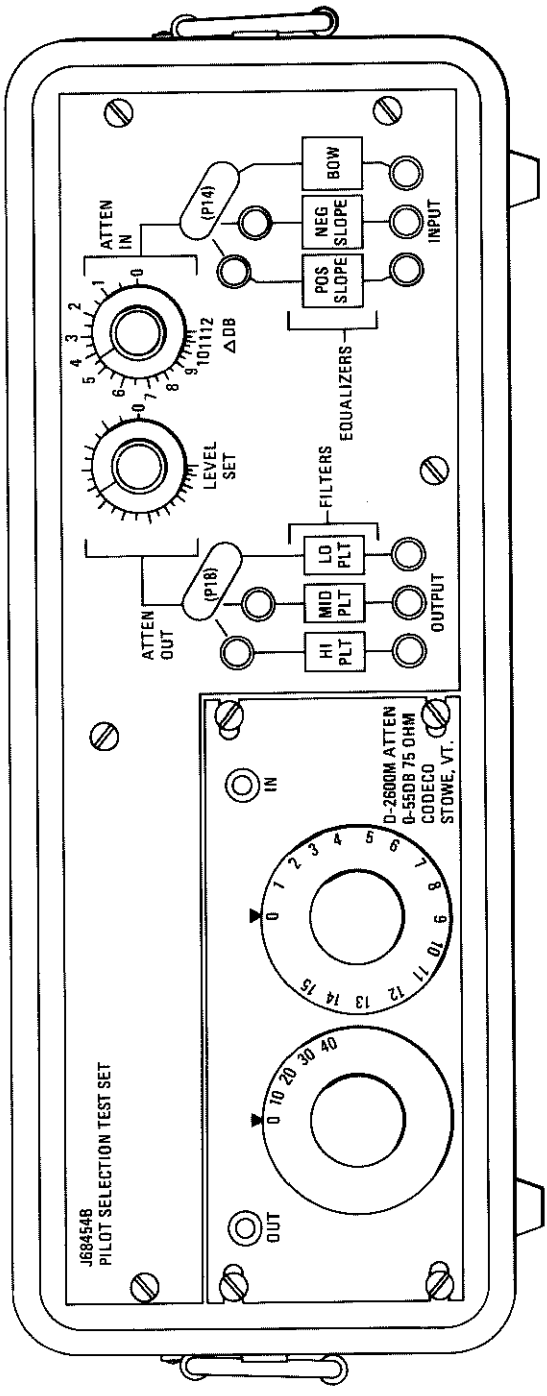

Fig. 6—Pilot selection test set.

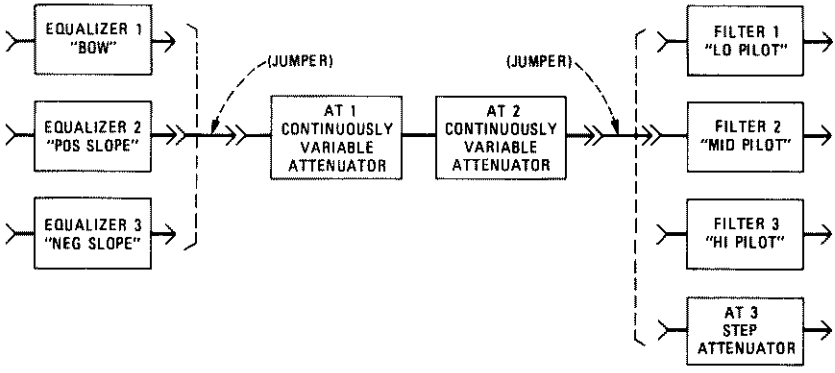

Fig. 7—Block diagram of the pilot selection test set.

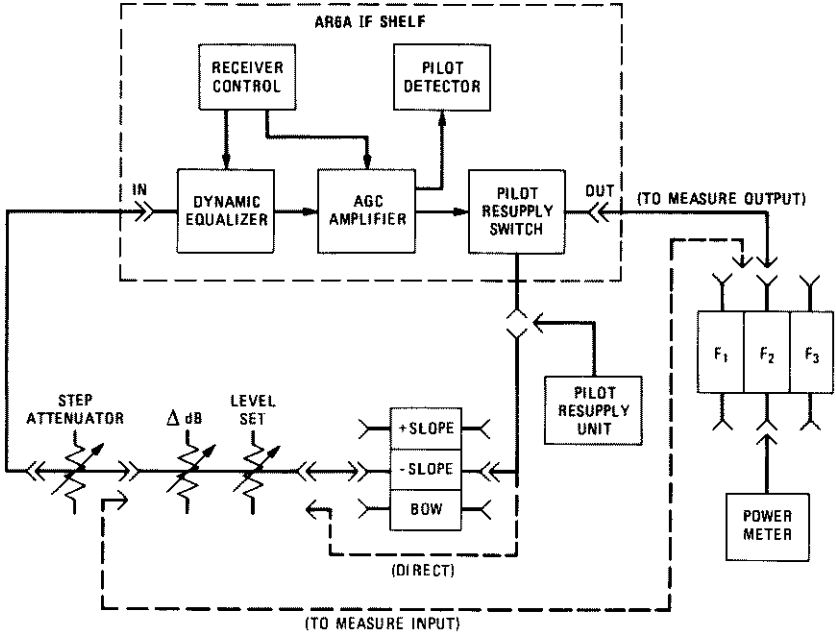

Fig. 8—Shelf-test functional diagram.

pilot source that is used for the pilot resupply mode of operation of the TR bay. The pilot resupply unit supplies the fixed amplitude pilot tones and the PSTS then modifies their amplitudes as required to test the AR6A bay (see Fig. 8).

The output from the pilot resupply unit contains all three pilot tones mixed together. The PSTS contains a narrowband monolithic crystal filter for each of the tones. These filters, when used in conjunction with a power meter, allow each tone to be measured individ-

ually. This arrangement is used to set the pilot reference power levels initially and then to observe the pilot levels after being acted upon by the AR6A receiver under test.

The PSTS checks the performance of the AR6A dynamic equalizer by first establishing equal pilot signal levels and then introducing known level differences in the pilots by the use of shape networks. Signal correction by the dynamic equalizer can then be observed.

The three shape networks are a positive slope, a negative slope, and a bow shape. All three shape networks attenuate the center frequency pilot 10 dB. The positive slope network attenuates the low-frequency pilot 18 dB and the high-frequency pilot 2 dB. The negative slope network attenuates the low-frequency pilot 2 dB and the high-frequency pilot 18 dB. Thus, the two networks can exercise the end pilots relative to the center pilot by ±8 dB. The bow network attenuates the center pilot frequency 10 dB and both the upper and lower pilot frequencies 2 dB. The resulting signal transmission through the network will be a bow with the end pilots 8 dB higher than the center pilot.

The PSTS checks the performance of the AR6A AGC amplifier by varying the amplitude of all three pilots together with a step attenuator while monitoring the AGC function. A precision step attenuator is provided to adjust signal levels over a 55-dB range in 1-dB steps. This step attenuator can also be used with the linearity test set if desired. The pilot resupply and space-diversity threshold levels are checked by varying the amplitude of all three pilots together with a continuously variable attenuator while watching for trip levels to occur.

Two continuously variable attenuators are provided. One is used to set the input power level accurately while the other is used to determine trip levels. The use of two variable attenuators allows the input power level adjustment to remain undisturbed while the second attenuator searches for trip levels. The original test set input power level can then easily be restored by turning the second attenuator back to zero. The use of continuously variable attenuators eliminates the transient effects on trip levels associated with step attenuators.

For convenience, hairpin patch plugs simplify the interconnection of the shape networks to the variable attenuator input. Also, a second hairpin plug interconnects the variable attenuator output to the pilot filters.

## IV. CONCLUSION

The scanning IM test set has proven to be essential in the field for the initial transmitter predistorter linearity alignment and for the continued confirmation and maintenance of the high degree of linearity required by the AR6A Radio System.

The pilot selection test set is essential in the field to verify the correct functioning of the IF receiver circuits and to provide simulated fading for checking trip levels of the pilot resupply and space-diversity circuits.
